Obviously, online personal profiles can help people connect with others of similar backgrounds and provide valuable resources for businesses, especially for personnel resource managers to find talents (Yang et al., 2011a; Guy et al., 2010). In the profiles, the personal skill information is the most important aspect to reflect the expertise of a person. However, few social platforms allow users to manually attach such personal skill information into their personal profiles. For example, in our collected dataset, 91.8% skills appear less than 10 times. Even the distribution of the top 10 frequently occurring skills is asymmetric, and only 43.1% people attach skills on their profiles. For this regard, it is highly desirable to develop reliable methods to automatically infer personal skills for personal profiles.

Although it is straightforward to recast skill inference as a standard text classification problem, i.e., predicting the skills with the profile text alone, personal profiles usually are poorly organized, even with critical information missing. Thus, it is challenging to infer skills given the limited information from the profile texts. We propose two assumptions to address above challenges by incorporating additional connection information between persons and skills:

- People are always connected to others with similar academic and business backgrounds (e.g. co-major, co-corporation). For example if there is co-major, co-university, or co-corporation relationship between two persons, it is very likely that they may share similar skills. Therefore, it is reasonable to resort to personal connection information to improve the performance of skill inference.

*corresponding author

Proceedings of COLING 2014, the 25th International Conference on Computational Linguistics: Technical Papers, pages 520–529, Dublin, Ireland, August 23-29 2014.

- One person tends to have some related skills. For example, it is very likely that C++, C, and Python programming languages may co-occur in the one's profile, i.e., if a person has skill C++, it is highly possible that he would have the skills such as C or Python. Thus, it is useful to integrate skill connection information when inferring personal skills.

Based on these assumptions, we propose a Joint Prediction Factor Graph (JPFG) model, which collectively predicts personal skills with help of both personal and skill connections. In particular, the JPFG model provides a general framework to integrate three kinds of knowledge, i.e. local textual attribute functions of an individual person, personal connection factors between persons, and skill connection factors between skills, in collectively inferring personal skills. Specially, we extract personal connections with similar academic and business background (e.g. co-major, co-corporation). We then extract skill connections between skills from same person. Evaluation on a large-scale data set from LinkedIn.com indicates that our JPFG model can significantly improve the performance of personal skill inference.

The remainder of this paper is structured as follows. We review the related work in Section 2. In Section 3, we introduce the data collection. In Section 4, we give the problem definition and some analysis on the task of personal skill reference. In Section 5, we propose the JPFG model and corresponding algorithms for parameter estimation and prediction. In Section 6, we present our experimental results. In Section 7, we summarize our work and discuss future directions.

2 Related Works

In this section, we briefly review related studies in expert finding, social tag suggestion and factor graph model.

2.1 Expert Finding

Expert finding aims to find right persons with appropriate skills or knowledge, i.e. "Who are the experts on topic X?" TREC-2005 and TREC-2006 have provided a common platform for researchers to empirically evaluate methods and techniques on expert finding (Soboroff et al, 2006; Zhang et al., 2007a).

In the literature, expert finding tends to consider each skill individually and seeks the most authority experts for each skill. Thus, expert finding is always considered as a ranking process, i.e., ranking the experts from the candidates who are most suitable for the skill (Balog and Rijke, 2007). For example, Campbell et al. (2003) investigated the issue of expert finding in an email network. They utilized the link between email authors and receivers to improve the expert finding performance.

Besides that link structure-based algorithms, such as PageRank and HITS, are employed to analyze the relationship of the link-relationship graph, social networks are utilized to improve the performance of expert finding. Zhang et al. (2007a) proposed a unified propagation-based approach to address the issue of expert finding in a social network, considering both personal local and network information (e.g. the relationship between persons).

Expert finding is in nature different from skill inference. Our study predicts various skills attachable to a person collectively with both personal and skill connections among people. One distinguishing characteristics of our study is that several skills from a person are simultaneously modeled and the relationship among these skills is fully leveraged in the inference.

2.2 Social Tag Suggestion

Social tag suggestion aims to extract proper tags from social media and can thus help people organize their information in an unconstrained manner (Ohkura et al., 2006; Si et al., 2010). Ohkura et al. (2006) created a multi-tagger to determine whether a particular tag from a candidate tag list should be attached to a weblog. Lappas et al. (2011) proposed a social endorsement-based approach to generate social tags from Twitter.com and Flickr.com where various kinds of information in recommendations and comments are used. Liu et al. (2012) propose a probabilistic model to connect the semantic relations between words and tags of microblog, and takes the social network structure as regularization. Li et al., (2012) propose to model context-aware relations of tags for suggestion by regarding resource content as context of tags.

Different from above researches, our study is forced on skill inference instead of traditional tag suggestion. Basically, the social connections in skill inference are much different from those in social tagging. In our study, we use co-major, co-title and other academic and business relationships to build the social connections. Meanwhile, there are also few researches concern to propose a joint model to leverage both personal and skill connections.

2.3 Factor Graph Model

Among various approaches investigated in social networks in the last several years (Leskovec et al., 2010; Lu et al., 2010; Lampos et al., 2013; Guo et al., 2013), Factor Graph Model (FGM) becomes an effective way to represent and optimize the relationship in social networks (Dong et al., 2012; Yang et al., 2012b) via a graph structure. Tang et al. (2011a) and Zhuang et al. (2012) formalized the problem of social relationship learning as a semi-supervised framework, and proposed Partially-labeled Pairwise Factor Graph Model (PLP-FGM) for inferring the types of social ties. Tang et al. (2013) further proposed a factor graph based distributed learning method to construct a conformity influence model and formalize the effects of social conformity in a probabilistic way.

Different from previous studies, this paper proposes a pairwise factor graph model to collectively infer personal skills with both social connection factor and skill connection factor.

3 Data Construction

We collect our data set from LinkedIn.com. It contains a large number of personal profiles generated by users, containing various kinds of information, such as personal Summary, Experience, Education, and Skills & Expertise. We do not collect personal names in public profiles to protect people's privacy.

The dataset contains 7,381 personal profiles, among which only 3,182 profiles (43.1% of all the profiles) show the Skills & Expertise field. In this study, we adopt only these profiles in all our experiments. As a result, we get 6,863 skills in total, among which 6,299 skills (91.8% of them) appear less than 10 times. Among the remaining 564 skills, we select top 10 frequently occurring skills as the candidate personal skills in this study (Since the remaining 554 skills only appear less than 250 times in total, it is difficult to build an effective classifier for them). Table 1 illustrates the statistics.

Skill	Number	Ratio
Semiconductors	948	0.298
IC	369	0.116
Thin Films	328	0.103
Characterization	326	0.102
CMOS	311	0.098
Matlab	287	0.090
Microsoft Office	283	0.089
Manufacturing	278	0.087
Design of Experiments	262	0.082
Semiconductor Industry	250	0.079

Table 1: The distribution of the candidate personal skills

From Table 1, we can see that the skill distribution in the personal profiles is asymmetric. For example, the Semiconductor skill occurs about 1,000 times, taking 29.8%, while the Semiconductor Industry skill occurs 250 times only, taking 7.9%.

4 Problem Definition and Analysis

Before presenting our approach for skill inference, we first give the definition of the problem, and convey a series of discoveries we observed from the data.

4.1 Problem Definition

We first introduce some necessary definitions and then formulate of the problem.

Definition 1: *Skill inference*. In principle, we cast skill inference as a skill prediction problem. Since one person might have several skills, we build several vectors for a person and each vector is designed to determine whether the corresponding skill is appropriate for the person or not ("Positive" means that the person has the target skill, whereas "Negative" stands for the opposite). Note that the number of vectors for a person is equal to the number of candidate skills. For example, suppose we have m persons and n candidate skills in the dataset, we totally build vectors to represent if these skills are attached in these persons' profiles.

Definition 2: *Textual information*. We use texts of Summary and Experience as the textual information for our research. Texts of Summary and Experience are unstructured information, while texts of Skills & Expertise are structured information. However, some skills in the Skill & Expertise fields may not be mentioned in the Summary and Experience fields.

Definition 3: *Personal connections*. We can explicitly extract four kinds of personal relationships between two persons from the Education and Experience fields, as follows:

- *co_major*, which denotes that two persons have the same major at school
- *co_univ*, which denotes that two persons graduated from the same university
- *co_title*, which denotes that two persons have the same title in a corporation.
- *co_corp*, which denotes that two persons work in the same corporation.

Definition 4: *Skill connections*. We extract skill connections from same person. That is, if two vectors are from the same person with different skills, we consider these two vectors share skill connections (e.g. John has IC and Thin Films skills).

Learn task: Given the textual information of each profile, the personal connections between profiles, and skill connections of skill from same persons, the goal is to infer the skill through the above information.

To learn the skill inference model, there are several requirements. First, the skills of persons are related to multiple factors, e.g., network structure, personal connections, and skill connections, it is important to find a unified model which is able to incorporate all the information together. Second, the algorithm to learn the inference model should be efficient. In practice, the scale of the social network might be very large.

4.2 Statistics and Observations

In the following, we give some statistics and observations on personal and skill connections.

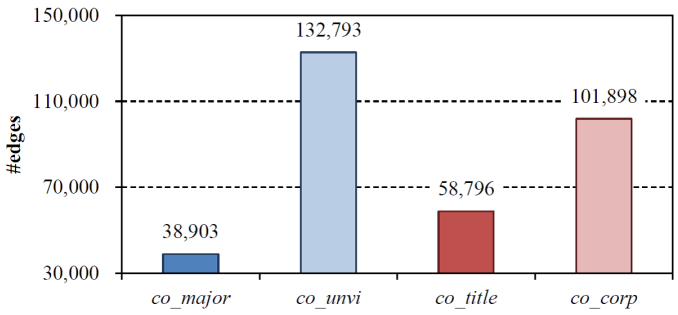

Figure 1: The statistic of personal connection edges in our dataset

Statistics of personal connections: Figure 1 gives the statistics of personal connection edges. It shows that with 3,182 profiles, there exist 332,390 personal connection edges. Besides, among all the

four relations, co_major, co_unvi, co_title, and co_corp occupy 11.7%, 40.0%, 17.7% and 30.6% respectively.

Observations of skills connections: To validate the tendency of a person sharing similar skills, we use PMI (Point-wise Mutual Information) to measure the co-occurrence between two skills. As a popular way to measure the co-occurrence between a pair (Turney, 2002), PMI is calculated as follows:

$$PMI(i,j) = \log\left(N\frac{P(i\&j)}{P(i)P(j)}\right) \tag{1}$$

N is the number of profiles, $P(i\&j)$ denotes the probability of the skills (i.e., i and j) co-occurrence in a person's profile, while $P(i)$ denotes the probability of the skill i appearing in a person's profile.

Skill i	**Skill** j	**PMI**
C	COMS	1.711
Thin Films	Characterization	1.624
Thin Films	Design of Experiments	1.543
Semiconductor Industry	IC	1.345
Semiconductor Industry	Design of Experiments	1.345
IC	Microsoft Office	-2.390
CMOS	Microsoft Office	-2.627
Semiconductor Industry	Matlab	-3.112
Average PMI score		0.190

Table 2: The top-5 and bottom-3 co-occurred skill pairs with their PMI scores

Table 2 lists the top-5 and bottom-3 co-occurred skill pairs with their PMI scores, together with the average PMI score. From this table, we can see that if two skills are related, e.g., "IC" and "CMOS", these two skills tend to co-occur in one person's profile, vice versa.

5 Joint Prediction Factor Graph Model

In this section, we propose a Joint Prediction Factor Graph (JPFG) model for learning and predicting the skills with personal and skill connection information besides local textual information.

5.1 Model

We formalize the problem of skill prediction using a pairwise factor graph model, and our basic idea of defining the correlations is to use different types of factor functions (i.e., personal connection factor, and skill connection factor). Here, the objective function $P_\theta(Y|X,G)$ is defined based on the joint probability of the factor functions, and the problem of collective skill inference model learning is cast as learning model parameters θ that maximizes the joint probability of skills based on the input continuous dynamic network.

Since directly maximizing the conditional probability $P_\theta(Y|X,G)$ is often intractable, we factorize the "global" probability as a product of "local" factor functions, each of which depends on a subset of the variables in the graph (Tang et al., 2013). In particular, we use three kinds of functions to represent the local textual information of the vector (local textual attribute function), personal connection information between vectors (personal connection factor) and skill connection information between skills (skill connection factor), respectively. We now briefly introduce the ways to define the above three functions.

Local textual attribute functions $f(x_{ij},y_i)_j$ **:** It denotes the attribute value associated with each person i. Here, we define the local textual attribute as a feature (Lafferty et al., 2001) and accumulate all the attribute functions to obtain local entropy for a person:

$$\frac{1}{Z_1}\exp\left(\sum_i\sum_k \alpha_k f_k(x_{ik},y_i)\right) \tag{2}$$

Where α_k is the function weight, representing the influence degree of the attribute k. For simplicity, we use word unigrams of a text as the basic textual attributes.

Personal connection factor function $g(y_i, y_j)$ **:** For the personal correlation factor function, we define it through the pairwise network structure. That is, if a person i and another person j have a personal relationship, we define a personal connection factor function as follows:

$$g(y_i, y_j) = \exp\left\{\beta_{ij}(y_i - y_j)^2\right\} \tag{3}$$

The personal connections are defined Section 4, i.e., co_major, co_univ, co_title, and co_corp. We define that if two persons have at least one personal connection edge, they have a personal relationship. In addition, β_{ij} is the weight of the function, representing the influence degree of i on j.

Skill connection factor function $h(y_i, y_j)$**:** For the skill connection factor function, we define it through the pairwise network structure. That is, if vector i and vector j are from the same person with different skills, we define their skill connection influence factor function as follows:

$$h(y_i, y_j) = \exp\left\{\gamma_{ij}(y_i - y_j)^2\right\} \tag{4}$$

Where γ_{ij} is the function weight, representing the influence degree of i on j.

By the above defined correlations, we can construct the graphical structure in the factor model. According to the Hammersley-Clifford theorem (Hammersley and Clifford, 1971), we integrate all the factor functions and obtain the following log-likelihood objective function:

$$\begin{aligned} L(\theta) &= \log_\theta P(Y|X,G) \\ &= \frac{1}{Z_1}\sum_i\sum_k \alpha_k f_k(x_{ik}, y_i) \\ &+ \frac{1}{Z_2}\sum_i \sum_{j\in NB(i)} \exp\left\{\beta_{ij}(y_i - y_j)^2\right\} \\ &+ \frac{1}{Z_3}\sum_i \sum_{k\in SAME(i)} \exp\left\{\gamma_{ik}(y_i - y_k)^2\right\} - \log Z \end{aligned} \tag{5}$$

Where (i, j) is a pair derived from the input network, $Z = Z_1 Z_2 Z_3$ is a normalization factor and $\theta = (\{\alpha\}, \{\beta\}, \{\gamma\})$ indicates a parameter configuration, $NB(i)$ denotes the set of social relationship neighbors nodes of i (personal connection), and $SAME(i)$ denotes the set of the node with the same person of i (skill connection).

5.2 Learning and Prediction

Model Learning: Learning of the factor model is to find the best configuration for free parameters $\theta = (\{\alpha\}, \{\beta\}, \{\gamma\})$ that maximizes the log likelihood objective function $L(\theta)$.

$$\theta^* = \arg\max L(\theta) \tag{6}$$

As the network structure in a social network can be arbitrary (e.g. possible of containing cycles), we use the Loopy Belief Propagation (LBP) algorithm (Tang et al., 2011a) to approximate the marginal distribution. To explain how we learn the parameters, we can get the gradient of each β_k with regard to the objective function (Eq. 5), taking β (the weight of the personal connection factor function $g(y_i, y_j)$) as an example:

$$\frac{L(\theta)}{\beta_k} = E[g(i,j)] + E_{\beta_k P(Y|X,G)}[g(i,j)] \tag{7}$$

Where $E[g(i,j)]$ is the expectation of factor function $g(i,j)$ given the data distribution in the input network and $E_{\beta_k P(Y|X,G)}[g(i,j)]$ represents the expectation under the distribution learned by the model, i.e., $P(y_i|X,G)$.

With the marginal probabilities, the gradient is obtained by summing up all triads (similar gradients can be derived for parameter α_k and γ_{ij}). It is worth noting that we need to perform the LBP process

twice in each iteration. The first run to estimate the marginal distribution of unknown variables $y_i =?$ and the second one is to estimate the marginal distribution over all pairs. Finally, with the obtained gradient, we update each parameter with a learning rate η.

Skill Prediction: We can see that in the learning process, additional loopy belief propagation is used to infer the label of unknown relationships. After learning, all unknown skills are assigned with labels that maximize the marginal probabilities (Tang et al., 2011b), i.e.,

$$Y^* = \arg\max L(Y|X, G, \theta) \tag{8}$$

6 Experimentation

In this section, we first introduce the experimental setting, and then evaluate the performance of our proposed JPFG model with both personal and skill connection information.

6.1 Experimental Setting

As described in Section 3, the experimental data are collected from LinkedIn.com. With top 10 frequently used skills as candidate skills in all our experiments, we randomly select 2,000 profiles as training data and 1,000 profiles as testing data.

Though positive and negative samples of each skill are imbalanced (In this paper, the number of the negative samples is much larger than that of the positive samples), we select balanced testing and training samples for each skill. Following models are implemented and compared.

- *Keyword*, for each profile, we consider the profile attached with the skill, only if the text of the skill appears on the profile article with textual information.

- *MaxEnt*, which first uses local textual information as features to train a maximum entropy (ME) classification model, and then employs the classification model to predict the skills in the testing data set. The ME algorithm is implemented with the mallet toolkit [1].

- *JPFG*, exactly our proposed model, which jointly predicts personal skills with local textual information, personal connection and skill connection.

For performance evaluation, we adopt Precision (P.), Recall (R.) and F1-Measure (F1.).

6.2 Comparison with Baselines

Our first group of experiments is to investigate whether the JPFG model is able to improve skill inference and whether the personal and skill connections are useful. The experimental results are shown in Table 3. From the table we can find that as some skills may not be mentioned on the Summary and Experience fields directly, the performance of the Keyword approach is far from satisfaction. As incorporating personal and skill connections, the JPFG model yields a much higher F1-measure, which improves the performance with about 6.8% gain than the MaxEnt model.

6.3 Performance of JPFG with Different Training Data Sizes

After we evaluate the effective of the JPFG model with the large-scale training data, we carry out experiments to test the effect of the JPFG model with different training data sizes. Experiment results are shown in Figure 3. It shows that the JPFG model with both personal and skill connections always outperform the two baseline models. Impressively, our JPFG model using 20% training data outperforms MaxEnt using 100% training data.

[1] http://mallet.cs.umass.edu/

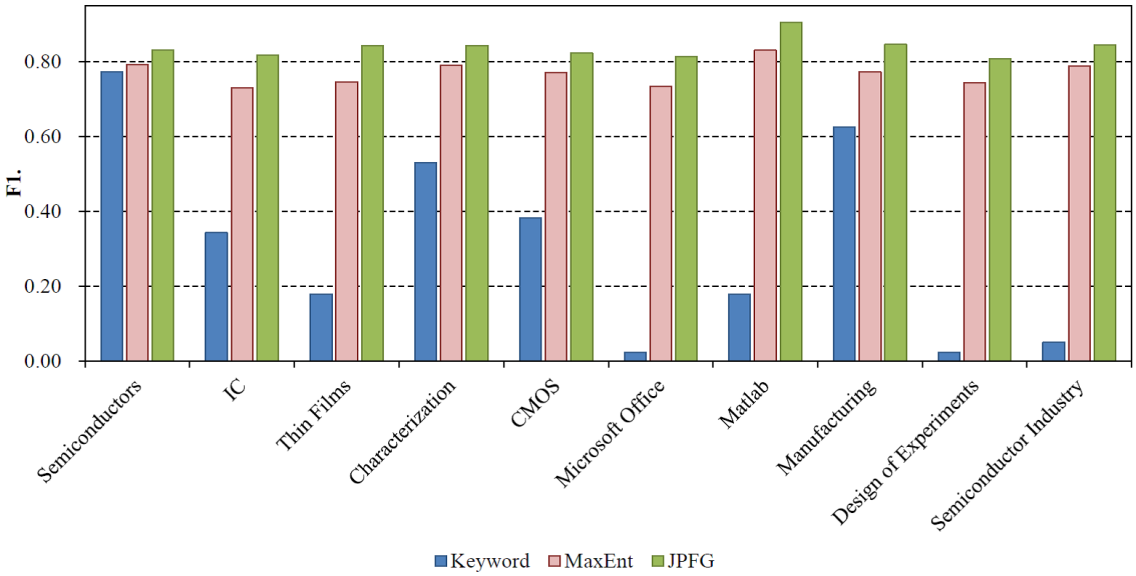

Figure 2: The performance of different methods for skill inference

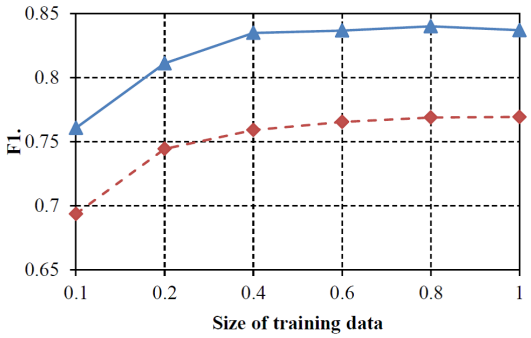

Figure 3: The performance of JPFG with different training data sizes

6.4 Connections Contribution Analysis

Personal connections and skill connections can be also used to build the factor graph models to infer the skills. We therefore want to compare our JPFG model with the factor graph model with only consider the personal connections or skill connections, and analysis the contribution of each kinds of connection. Specifically, MaxEnt-Personal employs the personal connections as additional features incorporated with textual features to build the maximum entropy classification. FGM-Personal is a simplified version of the JPFG model, which only employs textual attribute functions and personal connection factor functions to build the factor graph model. Likewise, FGM-Skill only employs textual attribute functions and skill connection factor functions to build the factor graph model. Table 3 shows the experiment results.

System	P.	R.	F1.
MaxEnt	0.744	0.797	0.769
MaxEnt-Personal	0.758	0.812	0.783
FGM-Personal	0.765	0.817	0.790
FGM-Skill	0.704	**0.967**	0.815
JPFG	**0.780**	0.905	**0.837**

Table 3: The contribution of connections

From Table 3, we can observe that, 1) Both FGM-Personal and FGM-Skill outperform the baseline

MaxEnt approach. It shows that both personal connections and skill connections are helpful for skill inference; 2) MaxEnt-Personal and FGM-Personal outperform the baseline MaxEnt approach, it show that personal connections are helpful for inferring skills, and as considering the global optimization, FGM-Personal is more effective; 3) FGM-Skill built on the skill connections is more effective than MaxEnt-Personal and FGM-Personal, it show that skill connections are more useful than personal connections; 4) JPFG model outperforms both FGM-Personal and FGM-Skill, it suggests that we should incorporate both personal and skill connections to the factor graph model when we infer the skills from profile.

7 Conclusion

In this study, we propose a novel task named personal skill inference, which aims to determine whether a person takes a specific skill or not. To address this task, we propose a joint prediction factor graph model with help of both personal and skill connections besides local textual information. Evaluation on a large-scale dataset shows that our joint model performs much better than several baselines. In particular, it shows that the performance on personal skill inference can be greatly improved by incorporating skill connection information.

The general idea of exploring personal and skill connections to help predict people's skills represents an interesting research direction in social networking, which has many potential applications. Besides, as skill information of a person is normally incomplete and fuzzy, how to better infer personal skills with weakly labeled information is challenging.

Abstract

For languages such as English, several constituent-to-dependency conversion schemes are proposed to construct corpora for dependency parsing. It is hard to determine which scheme is better because they reflect different views of dependency analysis. We usually obtain dependency parsers of different schemes by training with the specific corpus separately. It neglects the correlations between these schemes, which can potentially benefit the parsers. In this paper, we study how these correlations influence final dependency parsing performances, by proposing a joint model which can make full use of the correlations between heterogeneous dependencies, and finally we can answer the following question: parsing heterogeneous dependencies jointly or separately, which is better? We conduct experiments with two different schemes on the Penn Treebank and the Chinese Penn Treebank respectively, arriving at the same conclusion that jointly parsing heterogeneous dependencies can give improved performances for both schemes over the individual models.

1 Introduction

Dependency parsing has been intensively studied in recent years (McDonald et al., 2005; Nivre, 2008; Zhang and Clark, 2008; Huang et al., 2009; Koo and Collins, 2010; Zhang and Nivre, 2011; Sartorio et al., 2013; Choi and McCallum, 2013; Martins et al., 2013). Widely-used corpus for training a dependency parser is usually constructed according to a specific constituent-to-dependency conversion scheme. Several conversion schemes for certain languages have been available. For example, the English language has at least four schemes based on the Penn Treebank (PTB), including the `Yamada` scheme (Yamada and Matsumoto, 2003), the `CoNLL 2007` scheme (Nilsson et al., 2007), the `Stanford` scheme (de Marneffe and Manning, 2008) and the `LTH` scheme (Johansson and Nugues, 2007). There are different conversion schemes for the Chinese Penn Treebank (CTB) as well, including the `Zhang` scheme (Zhang and Clark, 2008) and the `Stanford` scheme (de Marneffe and Manning, 2008). It is hard to judge which scheme is more superior, because each scheme reflects a specific view of dependency analysis, and also there is another fact that different natural language processing (NLP) applications can prefer different conversion schemes (Elming et al., 2013).

Traditionally, we get dependency parsers of different schemes by training with the specific corpus separately. The method neglects the correlations between these schemes, which can potentially help different dependency parsers. On the one hand, there are many consistent dependencies across heterogeneous dependency trees. Some dependency structures remain constant in different conversion schemes. Taking the `Yamada` and the `Stanford` schemes as an example, overall 70.27% of the dependencies are identical (ignoring the dependency labels), according to our experimental analysis. We show a concrete example for the two heterogeneous dependency trees in Figure 1, where six of the twelve dependencies are consistent in the two dependency trees (shown by the solid arcs).

On the other hand, differences between heterogeneous dependencies can possibly boost the evidences of the consistent dependencies. For example in Figure 1, the dependencies "do$\overset{\text{VC}}{\frown}$think"

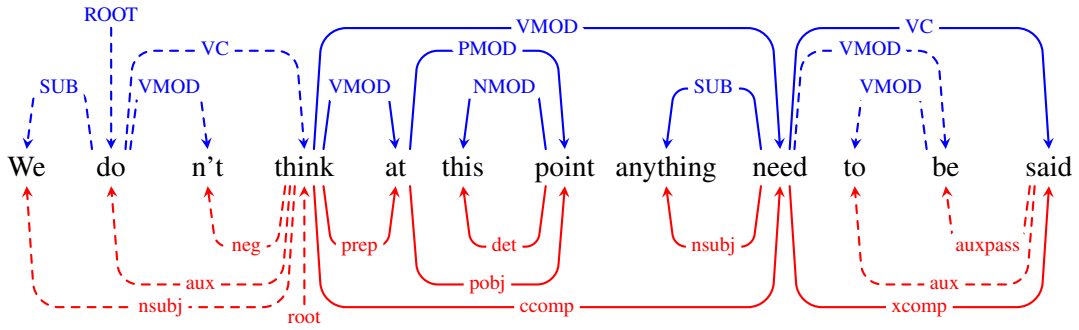

Figure 1: An example to show the differences and similarities of two dependency schemes. The above dependency tree is based on the `Yamada` scheme, while the below dependency tree is based on the `Stanford` scheme. The solid arcs show the consistent dependencies between the two dependency trees, while the dashed arcs show the differences between the two trees.

and "We$\overset{\text{nsubj}}{\curvearrowright}$think" from the two trees can both be potential evidences to support the dependency "think$\curvearrowright$at". Another example, the label "PMOD" from the `Yamada` scheme and the label "pobj" from the `Stanford` scheme on a same dependency "at$\curvearrowright$point" can make it more reliable than one alone.

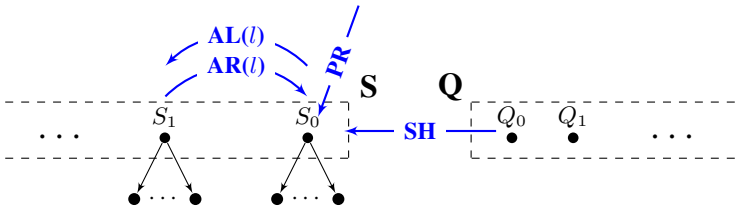
In this paper, we investigate the influences of the correlations between different dependency schemes on parsing performances. We propose a joint model to parse heterogeneous dependencies from two schemes simultaneously, so that the correlations can be fully used by their interactions in a single model. Joint models have been widely studied to enhance multiple tasks in NLP community, including joint word segmentation and POS-tagging (Jiang et al., 2008; Kruengkrai et al., 2009; Zhang and Clark, 2010), joint POS-tagging and dependency parsing (Li et al., 2011; Hatori et al., 2011), and the joint word segmentation, POS-tagging and dependency parsing (Hatori et al., 2012). These models are proposed over pipelined tasks. We apply the joint model into parallel tasks, and parse heterogeneous dependencies together. To our knowledge, we are the first work to investigate joint models on parallel tasks.

We exploit a transition-based framework with global learning and beam-search decoding to implement the joint model (Zhang and Clark, 2011). The joint model is extended from a state-of-the-art transition-based dependency parsing model. We conduct experiments on PTB with the `Yamada` and the `Stanford` schemes, and also on CTB 5.1 with the `Zhang` and the `Stanford` schemes. The results show that our joint model gives improved performances over the individual baseline models for both schemes on both English and Chinese languages, demonstrating positive effects of the correlations between the two schemes. We make the source code freely available at `http://sourceforge.net/projects/zpar/,version0.7`.

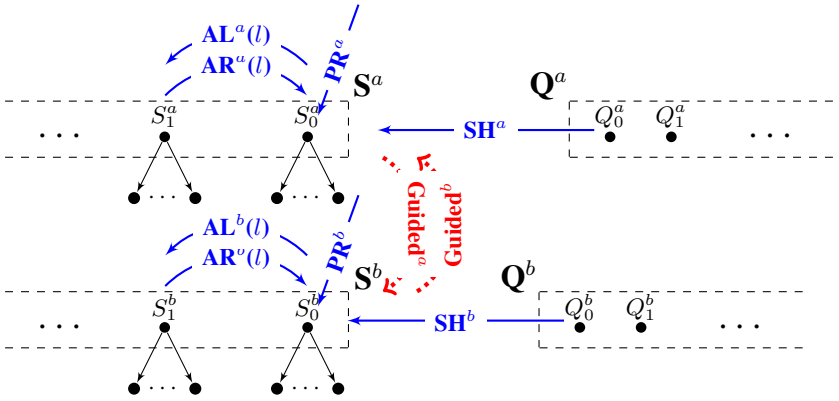
2 Baseline

Traditionally, the dependency parsers of different schemes are trained with their corpus separately, using a state-of-the-art dependency parsing algorithm (Zhang and Clark, 2008; Huang et al., 2009; Koo and Collins, 2010; Zhang and McDonald, 2012; Choi and McCallum, 2013). In this work, we exploit a transition-based arc-standard dependency parsing model combined with global learning and beam-search decoding as the baseline. which is initially proposed by Huang et al. (2009). In the following, we give a detailed description of the model.

In a typical transition-based system for dependency parsing, we define a transition state, which consists of a stack to save partial-parsed trees and a queue to save unprocessed words. The parsing is performed incrementally via a set of transition actions. The transition actions are used to change contents of the stack and the queue in a transition state. Initially, a start state has an empty stack and all words of a sentence in its queue. Then transition actions are applied to the start state, and change states step by step. Finally, we arrive at an end state with only one parsed tree on the stack and no words in the queue. We score each state by its features generated from the historical actions.



(a) Arc-standard dependency parsing model for a single dependency tree



(b) The joint model based on arc-standard dependency parsing for two dependency trees

Figure 2: Illustrations for the baseline dependency parsing model and our proposed joint model.

In the baseline arc-standard transition system, we define four kinds of actions, as shown in Figure 2(a). They are *shift* (SH), *arc-left with dependency label* l (AL(l)), *arc-right with dependency label* l (AR(l)) and *pop-root* (PR), respectively. The *shift* action shifts the first element Q_0 of the queue onto the stack; the action *arc-left with dependency label* l builds a left arc between the top element S_0 and the second top element S_1 on the stack, with the dependency label being specified by l; the action *arc-right with dependency label* l builds a right arc between the top element S_0 and the second top element S_1 on the stack, with the dependency label being specified by l; and the *pop-root* action defines the root node of a dependency tree when there is only one element on the stack and no element in the queue.

During decoding, each state may have several actions. We employ a fixed beam to reduce the search space. The low-score states are pruned from the beam when it is full. The feature templates in our baseline are shown by Table 1, referring to *baseline feature templates*. We learn the feature weights by the averaged percepron algorithm with early-update (Collins and Roark, 2004; Zhang and Clark, 2011).

3 The Proposed Joint Model

The aforementioned baseline model can only handle a single dependency tree. In order to parse multiple dependency trees for a sentence, we usually use individual dependency parsers. This method is not able to exploit the correlations across different dependency schemes. The joint model to parse multiple dependency trees with a single model is an elegant way to exploit these correlations fully. Inspired by this, we make a novel extension to the baseline arc-standard transition system, arriving at a joint model to parse two heterogeneous dependency trees for a sentence simultaneously.

In the new transition system, we double the original transition state of one stack and one queue into two stacks and two queues, as shown by Figure 2(b). We use stacks S^a and S^b and queues Q^a and Q^b to save partial-parsed dependency trees and unprocessed words for two schemes a and b, respectively. Similarly, the transition actions are doubled as well. We have eight transition actions, where four of them are aimed for scheme a, and the other four are aimed for scheme b. The concrete action definitions are similar to the original actions, except an additional constraint that actions should be operated over the corresponding stack and queue of scheme a or b.

We assume that the actions to build a specific tree of scheme a are $A_1^a A_2^a \cdots A_n^a$, and the actions to

Table 1: Feature templates for the baseline and joint models, where w denotes the word; t denotes the POS tag; v_l and v_r denote the left and right valencies; l denotes the dependency label; s_l and s_r denotes the label sets of the left and right children; the subscripts l and r denote the left-most and the right-most children, respectively; the subscripts $l2$ and $r2$ denote the second left-most and the second right-most children, respectively; h_{guide} denotes the head direction of the top two elements on the processing stack in the other tree; l_{guide} denotes the label of the same word in the other tree.

build a specific tree of scheme b for the same sentence are $A_1^bA_2^b\cdots A_n^b$. We use $\mathrm{ST}_0^a\mathrm{ST}_1^a\cdots\mathrm{ST}_n^a$ and $\mathrm{ST}_0^b\mathrm{ST}_1^b\cdots\mathrm{ST}_n^b$ to denote the historical states for the two action sequences, respectively. A sequence of actions should consist of $A_1^aA_2^a\cdots A_n^a$ and $A_1^bA_2^b\cdots A_n^b$ in a joint model. However, one question that needs to be answered is that, for a joint state $(\mathrm{ST}_i^a, \mathrm{ST}_j^b)$, which action should be chosen as the next step to merge the two action sequences into one sequence, A_{i+1}^a or A_{j+1}^b? To resolve the problem, we employ a parameter t to limit the next action in the joint model. When t is above zero, an action for scheme b can be applied only if the last action of scheme a is t steps in advance. For example, the action sequence is $A_1^aA_1^bA_2^aA_2^b\cdots A_n^aA_n^b$ when $t=1$. t can be negative as well, denoting the reverse constraints.

In the joint model, we extract features separately for the two dependency schemes. When the next action is aimed for scheme a, we will extract features from S^a and Q^a, according to *baseline feature templates* in Table 1. In order to make use of the correlations between the two dependency parsing trees, we introduce several new feature templates, shown in Table 1 referring to *proposed new feature templates for the joint model*. The new features are based on two kinds of atomic features: the guided head h_{guide} and the guided dependency label l_{guide}. Assuming that the currently processing scheme is a, when the top two elements (S_0^a and S_1^a) have both found their heads in Guided^b (the partial-parsed trees of scheme b), we can fire the atomic feature h_{guide}, which denotes the arc direction between S_0 and S_1 in Guide^b ($S_0^{\curvearrowleft}S_1$, $S_0^{\curvearrowright}S_1$ or other). When S_0^a or S_1^a has its dependency label in Guided^b, we can fire the atomic feature l_{guide}, which denotes the dependency label of S_0^a or S_1^a in Guided^b. Similarly we can extract the h_{guide} and l_{guide} from Guide^a when we are processing scheme b. When t is infinite, we always have

the two atomic features, because the other tree is already parsed. Thus the proposed new features can be the most effective when $t = \infty$ and $t = -\infty$. In other conditions, the other tree may not be ready for the new feature extracting. Similar to the baseline model, we use the beam-search decoding strategy to reduce the search space, and use the averaged perceptron with early-update to learn the feature weights.

We are especially interested in two cases of the joint models when t is infinite ($t = \infty$ and $t = -\infty$), where the tree of one specified scheme is always processed after the other tree is finished, because the new features can be most effectively exploited according to the above analysis. We assume that the first and second processing schemes are s_1 and s_2 respectively, to facilitate the below descriptions. We can see that the joint model behaves similarly to a pipeline reranking model, in optimizing scheme s_1's parsing performances. First we get K-best (K equals the beam size of the joint model) candidates for scheme s_1, and then employ additional evidences from scheme s_2's result, to rerank the K-best candidates, obtaining a better result. The joint model also behaves similarly to a pipeline feature-based stacking model (Li et al., 2012), in optimizing scheme s_2's parsing performances. After acquiring the best result of scheme s_1, we can use it to generate guided features to parse dependencies of scheme s_2. Thus additional information from scheme s_1 can be imported into the parsing model of scheme s_2. Different with the pipeline reranking and the feature-based stacking models, we employ a single model to achieve the two goals, making the interactions between the two schemes be better performed.

4 Experiments

4.1 Experimental Settings

In order to evaluate the baseline and joint models, we conduct experiments on English and Chinese data. For English, we obtain heterogeneous dependencies by the `Yamada` and the `Stanford` schemes, respectively. We transform the bracket constituent trees of English sentences into the `Yamada` dependencies with the Penn2Malt tool,[1] and into the `Stanford` dependencies with the Stanford parser version 3.3.1.[2] Following the standard splitting of PTB, we use sections 2-21 as the training data set, section 22 as the development data set, and section 23 as the final test data set. For Chinese, we obtain heterogeneous dependencies by the `Zhang` and the `Stanford` schemes, respectively. The `Zhang` dependencies are obtained by the Penn2Malt tool using the head rules from Zhang and Clark (2008), while the `Stanford` dependencies are obtained by the Stanford parser version 3.3.1 similar to English.

We use predicted POS tags in all the experiments. We utilize a linear-CRF POS tagger to obtain automatic POS tags for English and Chinese datasets.[3] We use a beam size of 64 to train dependency parsing models. We train the joint models with the `Yamada` or `Zhang` dependencies being handled on stack S^a and queue Q^a, and the `Stanford` dependencies being handled on stack S^b and queue Q^b, referring to Section 3. We follow the standard measures of dependency parsing to evaluate the baseline and joint models, including unlabeled attachment score (UAS), labeled attachment score (LAS) and complete match (CM). We ignore the punctuation words for all these measures.

4.2 Development Results

4.2.1 Baseline

Table 2 at the subtable "Baseline" shows the baseline results on the development data set. The performances of the `Yamada` scheme are better than those of the `Stanford` scheme. The UAS and LAS of the `Yamada` scheme are 92.83 and 91.73 respectively, while they are 92.85 and 90.49 for the `Stanford` scheme respectively. The results demonstrate that parsing the `Stanford` dependencies is more difficult than parsing the `Yamada` dependencies because of the lower performances of the `Stanford` scheme.

[1] `http://stp.lingfil.uu.se/~nivre/research/Penn2Malt.html`.

[2] The tool is available on `http://nlp.stanford.edu/software/lex-parser.shtml`. We use three options to perform the conversion: "-basic" and "-keepPunct", respectively.

[3] The tagging accuracies are 97.30% on the English test dataset and 93.68% on the Chinese test dataset. We thank Hao Zhang for sharing the data used in Martins et al. (2013) and Zhang et al. (2013a).

Table 2: The main results on the development data set of the baseline and proposed joint models.

4.2.2 Parameter Tuning

The proposed joint model has one parameter t to adjust. The parameter t is used to control the decoding in a joint model, determining which kind of dependencies should be processed at the next step. In our joint model, if t is larger than zero, scheme a (the Yamada scheme) should be handled t steps in advance, while when t is smaller than zero, scheme b (the Stanford scheme) should be handled in advance. When the value of t is infinite, the dependency tree of one scheme is handled until the dependency tree of the other scheme is finished for a sentence.

As shown by Table 2, we have two major findings. First, the joint models are slightly better when t is above zero, by decoding with the Yamada scheme in advance. The phenomenon demonstrates that the decoding sequence is important in the joint parsing models. Second, no matter when t is above or below zero, the performances arrive at the peak when t is infinite. One benefit of the joint models is that we can use the correlations between different dependency trees, through the new features proposed by us. The new features can be the most effective when t is infinite according to the analysis Section 3. Thus this finding indicates that the new features are crucial in the joint models, since the ineffective utilization would decrease the model performances a lot. Actually, when the absolute value of t is small, the features can sometimes be fired and in some other times are not able to be fired, making the training insufficient and also inconsistent for certain word-pair dependencies when their distances can differ (when $t = 1$ for example, the joint model can fire the new features only if the dependency distance equals 1). This would make the final model deficient, and can even hurt performances of the Yamada scheme.

According to the results on the development data set, we use the $t = \infty$ for the final joint model, which first finishes the Yamada tree and then the Stanford tree for each sentence. Our final model achieves increases of 0.21 on UAS and 0.28 on LAS for the Yamada scheme, and increases 0.67 on UAS and 0.66 on LAS for the Stanford scheme.

4.2.3 Feature Ablation

In order to test the effectiveness of the proposed new features, we conduct a feature ablation experiment. Table 3 shows the results, where the mark "/wo" denotes the model without the new features proposed by us. For the Yamada scheme, losses of 0.15 on UAS and 0.21 on LAS are shown without the new features. While for Stanford scheme, larger decreases are shown by 0.57 on UAS and 0.58 on LAS, respectively. The results demonstrate the new features are effective in the joint model.

Table 4: The final results on the test data set, where the results with mark ‡ demonstrates that the p-value is below 10^{-3} using t-test. Our Stanford dependencies are slightly different with previous works, where the results with mark * show the numbers for the Stanford dependencies from Stanford parser version 2.0.5 and the results with mark ** show the numbers for the Stanford dependencies from Stanford parser version 3.3.0.

4.3 Final Results

Table 4 shows our final results on the English test dataset. The final joint model achieves better performances than the baseline models for both the `Yamada` and the `Stanford` schemes, by increases of 0.18 on UAS and 0.19 on LAS for the `Yamada` scheme, and increases of 0.58 on UAS and 0.58 on LAS for the `Stanford` scheme. The results demonstrate that the interactions between the two dependency schemes are useful, and the joint model is superior to separately trained models in handling heterogeneous dependencies.

We compare our results with some representative previous work of dependency parsing as well. Zhang and Nivre (2011) is a feature-rich transition-based dependency parser using the arc-eager transition system. Rush and Petrov (2012), Zhang et al. (2013a) and Zhang and McDonald (2014) are state-of-the-art graph-based dependency parsers. Martins et al. (2013) and Kong and Smith (2014) report their results with the full TurboParser. TurboParser is also a graph-based dependency parser but its decoding algorithm has major differences with the general MST-style decoding.

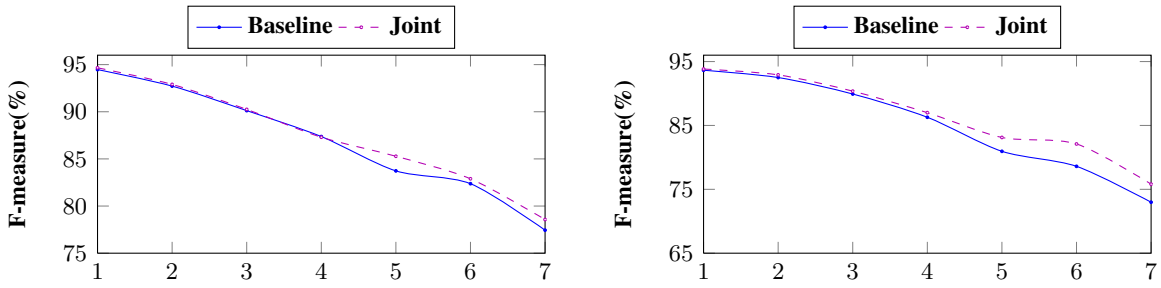
4.4 Analysis

To better understand the joint model, we conduct analysis work on the Chinese development dataset. First, we make a comparison to see whether the consistent dependencies give larger increases by the joint model. As mentioned before, the consistent dependencies can be supported by different evidences from heterogeneous dependencies. We compute the proportion of the consistent dependencies (ignoring the dependency labels) between the `Yamada` and the `Stanford` dependencies, finding that 70.27% of the overall dependencies are consistent. Table 5 shows the comparison results. The joint model shows improvements for the consistent dependencies. However, it does not always show positive effectiveness for the inconsistent dependencies. The results support our initial motivation that consistent dependencies can benefit much in joint models .

We also make a comparison between the baseline and joint models with respect to dependency distance. We use the F-measure value to evaluate the performances. The dependency distances are normal-

	Yamada				Stanford			
	Consistent		Inconsistent		Consistent		Inconsistent	
	UAS	LAS	UAS	LAS	UAS	LAS	UAS	LAS
Baseline	93.43	92.39	91.44	90.17	93.74	91.35	90.75	88.47
Our joint model	93.81	92.85	91.21	90.02	94.58	92.15	91.01	88.78
Δ	**+0.38**	**+0.46**	-0.23	-0.15	**+0.84**	**+0.80**	+0.36	+0.31

Table 5: Performances of the baseline and joint models by whether the dependencies are consistent across the Yamada and the Stanford schemes, where the bold numbers denote the larger increases by comparisons of consistent and inconsistent dependencies for each scheme.



(a) Yamada (b) Stanford

Figure 3: F-measures of the two heterogeneous dependencies with respect to dependency distance.

ized to a max value of 7. Figure 3 shows the comparison results. We find that the joint model can achieve consistent better performances for the dependencies of different dependency distance, demonstrating the robustness of the joint model in improving parsing performances. The joint model performs slightly better for long-distance dependencies, which is more obvious for the Stanford scheme.

4.5 Parsing Heterogeneous Chinese Dependencies

Table 6 shows our final results on the Chinese test data set. For Chinese, the joint model achieves better performances with Stanford dependencies being parsed first. The final joint model achieves better performances than the baseline models for both the Zhang and the Stanford schemes, by increases of 1.13 on UAS and 0.99 on LAS for the Zhang scheme, and increases of 0.30 on UAS and 0.36 on LAS for the Stanford scheme. The results also demonstrate similar conclusions with the experiments on English dataset.

5 Related Work

Our work is mainly inspired by the work of joint models. There are a number of successful studies on joint modeling pipelined tasks where one task is a prerequisite step of another task, for example, the joint model of word segmentation and POS-tagging (Jiang et al., 2008; Kruengkrai et al., 2009; Zhang and Clark, 2010), the joint model of POS-tagging and parsing (Li et al., 2011; Hatori et al., 2011; Bohnet and Nivre, 2012), the joint model of word segmentation, POS-tagging and parsing (Hatori et

al., 2012; Zhang et al., 2013b; Zhang et al., 2014), and the joint model of morphological and syntactic analysis tasks (Bohnet et al., 2013). In our work, we propose a joint model on parallel tasks, to parse two heterogeneous dependency trees simultaneously.

There has been a line of work on exploiting multiple treebanks with heterogeneous dependencies to enhance dependency parsing. Li et al. (2012) proposed a feature-based stacking model to enhance a specific target dependency parser with the help of another treebank. Zhou and Zhao (2013) presented a joint inference framework to combine the parsing results based on two different treebanks. All these work are case studies of annotation adaptation from different sources, which have been done for Chinese word segmentation and POS-tagging as well (Jiang et al., 2009; Sun and Wan, 2012). In contrast to their work, we study the heterogeneous annotations derived from the same source. We use a unified model to parsing heterogeneous dependencies together.

Our joint parsing model exploits a transition-based framework with global learning and beam-search decoding (Zhang and Clark, 2011), extended from a arc-standard transition-based parsing model (Huang et al., 2009). The transition-based framework is easily adapted to a number of joint models, including joint word segmentation and POS-tagging (Zhang and Clark, 2010), the joint POS-tagging and parsing (Hatori et al., 2012; Bohnet and Nivre, 2012), and also joint word segmentation, POS-tagging and parsing (Hatori et al., 2012; Zhang et al., 2013b; Zhang et al., 2014).

6 Conclusions

We studied the effectiveness of the correlations between different constituent-to-dependency schemes for dependency parsing, by exploiting these information with a joint model to parse two heterogeneous dependency trees simultaneously. We make a novel extension to a transition-based arc-standard dependency parsing algorithm for the joint model. We evaluate our baseline and joint models on both English and Chinese datasets, based on the `Yamada/Zhang` and the `Stanford` dependency schemes. Final results demonstrate that the joint model which handles two heterogeneous dependencies can give improved performances for dependencies of both schemes. The source code for the joint model is publicly available at `http://sourceforge.net/projects/zpar/,version0.7`.

An LR-inspired generalized lexicalized phrase structure parser

benoit.crabbe@univ-paris-diderot.fr

Abstract

The paper introduces an LR-based algorithm for efficient phrase structure parsing of morphologically rich languages. The algorithm generalizes lexicalized parsing (Collins, 2003) by allowing a structured representation of the lexical items. Together with a discriminative weighting component (Collins, 2002), we show that this representation allows us to achieve state of the art accurracy results on a morphologically rich language such as French while achieving more efficient parsing times than the state of the art parsers on the French data set. A comparison with English, a lexically poor language, is also provided.

1 Introduction

The paper provides a phrase structure parsing algorithm inspired by LR (Knuth, 1965), GLR (Tomita, 1988) and the recent developments of (Huang and Sagae, 2010) for dependency grammar. The parsing algorithm comes with a discriminative weighting framework inspired by (Collins, 2002). Although discriminative phrase structure parsing has been shown to be challenging when it comes to efficiency issues (Turian and Melamed, 2006; Finkel et al., 2008), we use here several approximations that make the framework not only tractable but also efficient and accurate on a lexically rich language such as French.

Despite the successes of dependency grammar, we are interested in phrase structure grammar since it naturally allows to support compositional semantic representations as recently highlighted by (Socher et al., 2012). It remains that most phrase structure parsers have been designed in priority for modelling lexically poor languages such as English or Chinese (Collins, 2003; Charniak, 2000; Zhu et al., 2013). Although highly accurate multilingual parsers exist (Petrov et al., 2006), they remain relatively both slow for wide coverage purposes and their inner formal structure is not designed to handle naturally morphological information.

We assume that parsing lexically rich languages benefits from taking into account the structured morphological information that can be extracted from lexical forms. Using French as a case study we show that we can reach both parsing efficiency with an approximative inference method and we can get a state of the art accurracy by generalizing lexicalized parsing to handle feature structure-based word representations. Our proposal also differs theoretically from related ones (Sagae and Lavie, 2006; Zhang and Clark, 2011; Zhu et al., 2013) by explicitly using an LR automaton. The explicit introduction of the LR automaton allows us to establish a formal difference between shift reduce phrase structure parsing and shift reduce dependency parsing. It further provides some insights on the nature of the grammar underlying many contemporary parsers.

The paper is organized as follows. First, section 2, we set up a formal framework for describing weighted phrase structure parsing as a 2-LCFG (Nederhof and Satta, 2010). Observing that the tree structures are actually constrained in practice we formulate in section 3 an LR automaton construction method for treebank grammars suitable for encoding these constraints. We then provide in section 4 a description of the algorithm and its components. Section 5 give an extension to 2-LCFG suitable for parsing morphologically rich languages and meeting common practical requirements. The whole

Proceedings of COLING 2014, the 25th International Conference on Computational Linguistics: Technical Papers, pages 541–552, Dublin, Ireland, August 23-29 2014.

framework is then evaluated in section 6 on French and English allowing to better identify its properties with respects to the state of the art.

2 Grammatical representation

The first step we consider is the grammar actually used for parsing and how it is generated. We suppose here a bilexical context free grammar or 2-LCFG (Nederhof and Satta, 2010). A 2-LCFG is a CFG whose rules are of the form given in Figure 1 (left). Symbols of the form x and h denote terminal symbols while symbols of the form $A[h]$ or $A[x]$ denote lexicalized non terminals. A, B, C are non lexicalized non terminals and h denotes a head. A 2-LCFG rule is typically of the form $NP[cat] \rightarrow D[a]\, N[cat]$.

For practical robust parsing, 2-LCFG are grammars with a very large number of rules generated dynamically at runtime (Section 4). Most of the static grammatical preprocessing involved for the generation of an LR automaton only applies to the underlying delexicalized 2-CFG by ignoring lexical annotation symbols.

$$
\begin{aligned}
A[h] &\rightarrow B[h]\, C[x] \\
A[h] &\rightarrow B[x]\, C[h] \\
A[h] &\rightarrow h
\end{aligned}
$$

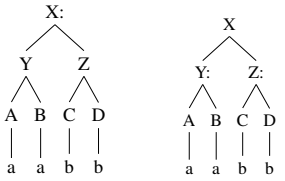

Figure 1: 2-LCFG rule patterns and invalid 2-CFG trees

The first step towards robust parsing thus requires to generate a grammar suitable for this purpose. In our case, the grammar is a treebank grammar and since most treebanks do encode trees with variable branching arities we must transform it to match the 2-LCFG required pattern. The first step amounts to apply an order 0 head markovization (Collins, 2003) which is followed by a reduction of unary rules. Both transformations guarantee that the trees do follow strictly a Chomsky Normal Form (CNF). Trees in CNF have two properties of interest. First, one can show by induction that they can be generated with a constant number of derivation steps η for a sentence of length $n : \eta = 2n-1$. This property is in principle critical for the comparison of weighted parsing hypotheses (Section 5) and explains why we use 2-LCFG as a grammatical representation in the first place. Second, the binarization (markovization) procedure also introduces temporary symbols we consider to be different from other non terminal symbols. These temporary symbols are further constraining the tree structure. Using ':' to denote a temporary symbol in Figure 1 (right), we observe for instance that the root of a tree cannot be temporary and two siblings cannot be temporaries either. By contrast, arc standard dependency parsers such as the one of (Huang and Sagae, 2010) do verify the first property while the second property is irrelevant in that case.

3 LR automaton construction

We use an LR automaton to enforce the parser to generate parse trees satisfying the above mentioned structural constraints. Although, other proposals such as (Sagae and Lavie, 2006) apparently returns a failure when the parser generates invalid trees and (Zhu et al., 2013) apparently handles the problem with local constraints preventing the parser to generate invalid configurations, we use here an $LR(0)$ automaton to ensure that the parser globally enforces these constraints. This seemed to us theoretically justified, easier to generalize (Section 6) and easier to implement.

As such, a traditional $LR(0)$ parser (Knuth, 1965) is not suited for parsing natural language: it aims to statically eliminate ambiguity from the grammar. Here, following (Tomita, 1985) the LR tables are built without trying to resolve conflicts. Instead the conflicts are kept and determinism is brought by a weighting component. The use of $LR(0)$ tables aims to ensure that the parser actually generates valid parse derivations. In this case, the generation of the derivations requires to constrain the underlying 2-CFG grammar with respects to temporary symbols. This being said, building an $LR(0)$ automaton for robust treebank grammars raise two issues. The first is inductive, a grammar read off from a treebank is not guaranteed to be robust and to generalize to other text, since a treebank remains a finite sample of language. The second is practical : traditional $LR(0)$ compilation methods involve the determinisation of

the LR NFA which is exponential in the number n of states of this NFA. In case of very large ambiguous treebank grammars n is very large and the compilation becomes intractable (Briscoe and Carroll, 1993).

These two observations lead us to design this automata by the following construction. First, let Σ be the set of non terminal symbols read off from the treebank, T be the set of temporaries introduced by binarization and N the set of non temporary symbols such that $\Sigma = N \cup T$ and $N \cap T = \emptyset$. Second we note W the set of terminal symbols extracted from the treebank and $A \in N$ the unique axiom of this grammar. We then partition Σ with the following set of equivalence classes: $[a] = \{A\}, [t] = T$ and $[n] = \Sigma - (T \cup A)$. For convenience we also note $[w] = W$. Given these equivalence classes, we define the matrix grammar $G_m = \langle \Sigma_m, [w], [a], R_m \rangle$ (where $\Sigma_m = \{[a], [n], [t]\}$). The rules R_m of G_m are then designed to enforce the above mentioned tree well formedness constraints. Some possible such rules are given in Table 1 using ID/LP notation (Gazdar et al., 1985).In other words, an immediate dominance rule of the form $a \rightarrow b\,,\, c$ is expanded as two rules $a \rightarrow b\,c$ and $a \rightarrow c\,b$. Such a grammar allows

$[a] \rightarrow [n]\,,\, [t]$	$[n] \rightarrow [n]\,,\, [t]$	$[t] \rightarrow [n]\,,\, [t]$
$[a] \rightarrow [n]\,,\, [n]$	$[n] \rightarrow [n]\,,\, [n]$	$[t] \rightarrow [n]\,,\, [n]$
$[a] \rightarrow [w]$	$[n] \rightarrow [w]$	

Table 1: Example of Immediate Dominance rules for G_m

to enforce the above-mentioned constraints, it is also small and it is robust : $L(G_m) = [w]+$. We can then very easily build a deterministic $LR(0)$ automaton $A_m = \langle \Sigma_m \cup \{[w]\}, Q, i, F, E_m \rangle$ with classical methods (Aho et al., 2006). From this automaton we can then efficiently generate an expanded automaton $A_{exp} = \langle \{\Sigma \cup W\}, Q, i, F, E \rangle$ where $E = \{(q, a, q') \mid (q, [x], q') \in E_m, \forall a \in [x]\}$. In order to read off the $LR(0)$ table from A_{exp}, we consider the set of actions $\mathcal{A} \stackrel{def}{=} \{RL(X)|X \in \Sigma\} \cup \{RR(X)|X \in \Sigma\} \cup \{RU(X)|X \in \Sigma\} \cup \{S\}$ first introduced by (Sagae and Lavie, 2006). In short S denotes the shift action, $RU(X)$ denotes an unary reduction by terminal X, $RL(X)$ denotes a binary reduction by terminal X with left symbol marked as head, and $RR(X)$ denotes a binary reduction by terminal X with right symbol marked as head. By contrast with a classical LR action set, we extract the actions $RL(X)$ and $RR(X)$ from a state $q \in Q$ if we have an LR item of the form $\langle X \rightarrow A\,B\bullet \rangle$ without requiring that $\langle X \rightarrow B\,A\bullet \rangle \in q$. This simplification, mirrorring that of (Sagae and Lavie, 2006), reduces the number of actions, eases learning and makes parsing more efficient. This being said, the matrix grammar G_m given in Table 1 is not the only one possible (see also section 6). A valid rule set must enforce tree well formedness constraints by building upon a partition of Σ in equivalence classes. On the other hand the action set $\mathcal{A}$ defined here implies that for every rule $R \in R_m$ of the form $[x] \rightarrow [y]\,[z]$ there is a rule $R' \in R_m$ of the form $[x] \rightarrow [z]\,[y]$. That is why we formulate the rules R_m with ID/LP notation and this also means that we cannot express any word ordering constraint with this grammar. This last property is actually shared by many robust parsers.

4 Discriminative LR-based parsing

The LR tables being built by preserving conflicts, determinism is achieved by a weighting component derived from the global perceptron described by (Collins, 2002). We start by describing the weighted parsing procedure before turning our attention to the weight estimation problem.

We assume that an $LR(0)$ table has been built. The GOTO function of this table GOTO: $(\Sigma \cup W) \times \mathbb{N} \mapsto \mathbb{N}$ sends a couple of symbol and LR state to a new LR state. The ACTION: $(\mathbb{N} \times W) \mapsto 2^{\mathcal{A}}$ function of this table returns a set $\mathbf{a}$ of possible actions given a state and a terminal symbol. The initial LR state of the table is σ_i while σ_e denotes a final state.

The algorithm relies on two data structures: a stack $\mathbf{S}$ and a queue. The stack $\mathbf{S} = \ldots|s_2|s_1|s_0$ has s_0 for topmost element. A node $s_i = \langle \sigma, \tau \rangle$ in the stack is a couple where σ is an LR state number and $\tau = (s_i.c_t[s_i.w_t] \quad s_i.c_l[s_i.w_l] \quad s_i.c_r[s_i.w_r])$ encodes a local tree of depth 1. $s_i.c_t, s_i.c_l, s_i.c_r$ denote the root left child and right child categories of tree and $s_i.w_t, s_i.w_l, s_i.w_r$ denote the root, the left child and right child terminals of this tree such that a node $s_i.c.[s_i.w.]$ denotes a non terminal 2-LCFG symbol at node s_i in the stack. The queue is static and initially filled up with the sequence of tokens to be parsed:

$$\textsc{Item} \quad \langle j, \mathbf{S} \rangle : w$$
$$\textsc{Init} \quad \langle 1, \langle \sigma_i, \epsilon \rangle \rangle : 0$$
$$\textsc{Goal} \quad \langle n+1, \langle \sigma_e, \tau \rangle \rangle : w$$

$$\textsc{Shift} \quad \frac{\langle j, \mathbf{S}_\ominus \mid s_0 = \langle \sigma, \_ \rangle \rangle : w}{\langle j+1, \mathbf{S}_\ominus \mid s_0 \mid \langle \textsc{Goto}(t_j, \sigma), (t_j[t_j] \_\_) \rangle : w + F(S, \langle j, \mathbf{S} \rangle)}$$

$$\text{RL(X)} \quad \frac{\langle j, \mathbf{S}_\ominus \mid s_2 = \langle \sigma_2, \_ \rangle : w_2 \mid s_1 = \langle \sigma_1, (s_1.c_t[s_1.w_t] \_\_) \rangle : w_1 \mid s_0 = \langle \sigma_0, (s_0.c_t[s_0.w_t] \_\_) \rangle \rangle : w_0}{\langle j, \mathbf{S}_\ominus \mid s_2 \mid \langle \textsc{Goto}(X, \sigma_2), (X[s_1.w_t]\ s_1.c_t[s_1.w_t]\ s_0.c_t[s_0.w_t]) \rangle : w_0 + F(RL(X), \langle j, \mathbf{S} \rangle)}$$

$$\text{RR(X)} \quad \frac{\langle j, \mathbf{S}_\ominus \mid s_2 = \langle \sigma_2, \_ \rangle : w_2 \mid s_1 = \langle \sigma_1, (s_1.c_t[s_1.w_t] \_\_) \rangle : w_1 \mid s_0 = \langle \sigma_0, (s_0.c_t[s_0.w_t] \_\_) \rangle \rangle : w_0}{\langle j, \mathbf{S}_\ominus \mid s_2 \mid \langle \textsc{Goto}(X, \sigma_2), (X[s_0.w_t]\ s_1.c_t[s_1.w_t]\ s_0.c_t[s_0.w_t]) \rangle : w_0 + F(RR(X), \langle j, \mathbf{S} \rangle)}$$

$$\text{RU(X)} \quad \frac{\langle j, \mathbf{S}_\ominus \mid s_1 = \langle \sigma_1, (s_1.c_t[s_1.w_t] \_\_) \rangle \mid s_0 = \langle \sigma_0, (s_0.c_t[s_0.w_t] \_\_) \rangle \rangle : w_0}{\langle j, \mathbf{S}_\ominus \mid s_1 \mid \langle \textsc{Goto}(X, \sigma_1), (X[s_0.w_t]\ s_0.c_t[s_0.w_t]) \rangle : w_0 + F(RU(X), \langle j, \mathbf{S} \rangle)}$$

$$\text{GR} \quad \frac{\langle j, \mathbf{S}_\ominus \mid s_1 = \langle \sigma_1, (s_1.c_t[s_1.w_t] \_\_) \rangle \mid s_0 = \langle \sigma_0, (s_0.c_t[s_0.w_t] \_\_) \rangle \rangle : w_0}{\langle j, \mathbf{S}_\ominus \mid s_1 \mid \langle \textsc{Goto}(GR, \sigma_1), (s_0.c_t[s_0.w_t] \_\_) \rangle : w_0 + F(GR, \langle j, \mathbf{S} \rangle)} \qquad \text{(Rule introduced in section 5)}$$

Figure 2: Actions as inference rules in extended deductive notation

$\mathcal{T} = t_1 \dots t_n$. Parsing is performed by generating sequentially configurations $C_i = \langle j, \mathbf{S} \rangle$ where $\mathbf{S}$ is a stack and j the index of the first element of the queue. Given an initial configuration $C_0 = \langle 1, \langle \sigma_i, \epsilon \rangle \rangle$, a derivation step $C_{i-1} \overset{a_{i-1}}{\Rightarrow} C_i$ generates a new configuration $C_i = \langle j', \mathbf{S}' \rangle$ provided a configuration $C_{i-1} = \langle j, \mathbf{S}_\ominus | \langle \sigma, \tau \rangle \rangle$ by applying the action $a_{i-1} \in \textsc{Action}(\sigma, t_j)$. A $k-$step derivation sequence $C_{0 \Rightarrow k}$ is a sequence of derivation steps such that $C_0 \overset{a_0}{\Rightarrow} \dots \overset{a_{k-1}}{\Rightarrow} C_k$. A derivation sequence is finished when the configuration $C_{3n-1} = \langle n+1, \langle \sigma, \tau \rangle \rangle$ is generated[1]. If $\sigma = \sigma_e$ then the derivation is a success, otherwise it is a failure. A derivation is also finished when $\textsc{Action}(\sigma, t_j) = \emptyset$ for a configuration $C_k = \langle \sigma, t_j \rangle$ which is another case of failure. The actions detailed in Figure 2 using extended deductive notation are responsible for modifying the stack and updating LR states. The shift action, SHIFT, thus pushes onto the stack a local tree rooted by the category of the next token in the queue. The reduce left $RL(X)$ and the reduce right $RR(X)$ actions pop the top two elements from the stack and push a new element of category $X[w]$ on top of it. The two actions differ only by the way the head w is assigned: $RL(X)$ chooses w to be X's left child head word while $RR(X)$ sets w to be X's right child head word. $RU(X)$ is an unary reduction action that pops the stack top and pushes a new top element with category X whose head is its unique child head. By design of the automaton we ensure that $RU(X)$ can only be applied after a shift reduction took place.

In order to achieve disambiguation, a derivation sequence $C_{0 \Rightarrow k} = C_0 \overset{a_0}{\Rightarrow} \dots \overset{a_{k-1}}{\Rightarrow} C_k$ is also weighted by a function of the form:

$$W(C_{0 \Rightarrow k}) = \mathbf{w} \cdot \mathbf{\Phi}_g(C_{0 \Rightarrow k}) = \sum_{i=0}^{k-1} \mathbf{w} \cdot \mathbf{\Phi}(a_i, C_i)$$

that is the weight of a derivation sequence is given by an inner product that the parser approximates as a sum of inner products local to each derivation step. $\mathbf{w} \in \mathbb{R}^d$ is a d-dimensional vector of weights and each $\mathbf{\Phi}(a_i, C_i) \in \{0, 1\}^d$ is a d-dimensional vector of feature functions in which every ϕ_i has signature $\phi_i(a, \boldsymbol{\kappa}, j)$. The values a and j denote an action and the current index of the head of the queue in $\mathcal{T}$ while $\boldsymbol{\kappa}$ is a kernel vector similar to the one defined by (Huang and Sagae, 2010). It summarizes information accessible from the stack for the purpose of feature function evaluation. Figure 3 illustrates the actual kernel vector used in this paper: together with j, the index of the first element in the queue, the kernel

[1]For shift reduce parsing with a 2-CFG grammar, the number of steps is the number of reduction steps plus n shifts: $\eta = 2n - 1 + n = 3n - 1$.

vector $\boldsymbol{\kappa}$ is the set of values accessible to feature functions $\phi_i(a, \boldsymbol{\kappa}, j)$ in the stack. As can be seen the stack stores local trees with instanciated 2-LCFG nodes labelled with the notation introduced in section 4. Since the score of a derivation is a sum of independent terms, the (prefix) weight $w = W(C_{0\Rightarrow k})$ of a derivation sequence can be computed at each derivation step. This allows to store the (prefix) weight of this sequence on configurations such that a configuration has the extended form $C_k = \langle j, \mathbf{S}\rangle : w$ in the weighted case. We make explicit the actual prefix weight computation in Figure 2 by using the following abbreviation: $F(a_i, C_i) = \mathbf{w} \cdot \boldsymbol{\Phi}(a_i, C_i)$.

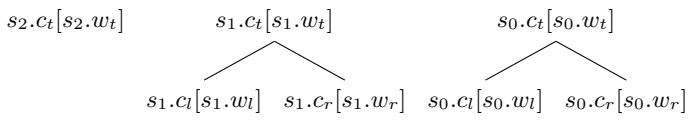

Figure 3: Representation of the kernel vector $\boldsymbol{\kappa}$

For a given input sequence $\mathcal{T}$, the parser is naturally non deterministic. Non determinism is introduced by the ACTION function which returns a set $\mathbf{a} \in 2^{\mathcal{A}}$ of possible actions given the current configuration. In the nondeterministic case, we thus derive from a given derivation sequence $C_{0\Rightarrow k-1}$ a set $\delta(C_{0\Rightarrow k-1})$ of $k-$steps derivation sequences. If we let $\text{GEN}_{k-1}(\mathcal{T})$ be the set of derivation sequences at step $k-1$, the set of derivation sequences at step k is $\text{GEN}_k(\mathcal{T}) = \bigcup_{C_{0\Rightarrow k-1}\in\text{GEN}_{k-1}(\mathcal{T})} \delta(C_{0\Rightarrow k-1})$. In this context, achieving deterministic parsing amounts to solve the following optimization problem:

$$\hat{\mathcal{C}} = \underset{C_{0\Rightarrow 3n-1}\in\text{GEN}_{3n-1}(\mathcal{T})}{\text{argmax}} W(C_{0\Rightarrow 3n-1}) \tag{1}$$

Since in the worst case, the size of $\text{GEN}_k(\mathcal{T})$ is $|\mathcal{A}|^k$, the search space has exponential size. Like (Zhu et al., 2013), we use in this paper a beam search approximation. A beam $\text{GEN}^K_k(\mathcal{T})$ is a subset of size K of $\text{GEN}_k(\mathcal{T})$. Provided a beam $\text{GEN}^K_{k-1}(\mathcal{T})$ we build $\text{GEN}^K_k(\mathcal{T})$ with the following recurrence: $\text{GEN}^K_k(\mathcal{T}) = \text{K-argmax}_{C_{0\Rightarrow k}\in\Delta(\text{GEN}^K_{k-1}(\mathcal{T}))} W(C_{0\Rightarrow k})$ where $\Delta(\text{GEN}^K_{k-1}(\mathcal{T})) = \bigcup_{C_{0\Rightarrow k-1}\in\text{GEN}^K_{k-1}(\mathcal{T})} \delta(C_{0\Rightarrow k-1})$, Using a beam aims to reduce complexity to $\mathcal{O}(K|\mathcal{A}|(3n-1)) \approx \mathcal{O}(n)$ and makes inference computationally tractable in practice. On the other hand it makes inference incomplete (the parser may fail to find a solution even if it exists) and does not guarantee the solution to be optimal. In other words, Equation 1 is replaced by an approximation:

$$\tilde{\mathcal{C}} = \underset{C_{0\Rightarrow 3n-1}\in\text{GEN}^K_{3n-1}(\mathcal{T})}{\text{argmax}} W(C_{0\Rightarrow 3n-1}) \tag{2}$$

The weight estimation procedure is performed by the averaged percetron algorithm (Collins, 2002). As pointed out by (Huang et al., 2012) using a beam introduces an approximation that can also harm the convergence of the learning procedure since we provide at each training iteration the approximative solution given by equation 2 instead of the exact solution to equation 1 expected in theory by the perceptron algorithm. To overcome the problem we perform updates on subderivation sequences. Let $C^{(r)}_{0\Rightarrow k}$ be a subderivation sequence at step k and let $C^{(0)}_{0\Rightarrow k} = \text{argmax}_{C_{0\Rightarrow k}\in\text{GEN}^K_k(\mathcal{T})} W(C_{0\Rightarrow k})$ be the best subderivation in the beam at step k. In this context the perceptron update has the form: $\mathbf{w} \leftarrow \mathbf{w} + \boldsymbol{\Phi}_g(C^{(r)}_{0\Rightarrow k}) - \boldsymbol{\Phi}_g(C^{(0)}_{0\Rightarrow k})$. We tested two methods for choosing k satisfying the weaker convergence criterions established by (Huang et al., 2012) : $C^{(0)}_{0\Rightarrow k} \neq C^{(r)}_{0\Rightarrow k}$ and $W(C^{(0)}_{0\Rightarrow k}) > W(C^{(r)}_{0\Rightarrow k})$. If we let $V = \{k \,|\, C^{(0)}_{0\Rightarrow k} \neq C^{(r)}_{0\Rightarrow k}, W(C^{(0)}_{0\Rightarrow k}) > W(C^{(r)}_{0\Rightarrow k})\}$, then the *early update* method amounts to choose $k = \min_{k\in V} k$ and the *max violation update* method amounts to choose $k = \text{argmax}_{k\in V} W(C^{(0)}_{0\Rightarrow k}) - W(C^{(r)}_{0\Rightarrow k})$.

5 Generalisations

This section introduces two extensions to the algorithm meeting practical motivations: grammar relaxation and extended word representations.

In practical cases, it may be convenient to interface the parser with a morphological tagger. In this case terminal symbols $t_1 \dots t_n$ are part of speech tags. Since grammar transformations introduced in section 2 can potentially modify the tagset and since enforcing a strict Chomsky normal form in this case makes little sense, we allow the trees to have structures such as the one given in Figure 4.

This kind of structure licences the following new patterns of 2-CFG rules: $A \rightarrow B\,t$ and $A \rightarrow t\,B$ where t denotes a terminal symbol (in this case a tag). These new rule patterns modify a property of 2-LCFG on which we relied so far, η is now variable : $n-1 \leq \eta \leq 2n-1$. We observe that longer derivation sequences tend to have an higher weight. Indeed weights increase linearly with the length of the derivation sequence as illustrated in Figure 5 where the weights are averaged out of measurements made over the parses on the French development set described in Section 6.

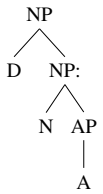

Figure 4: Relaxed tree structure

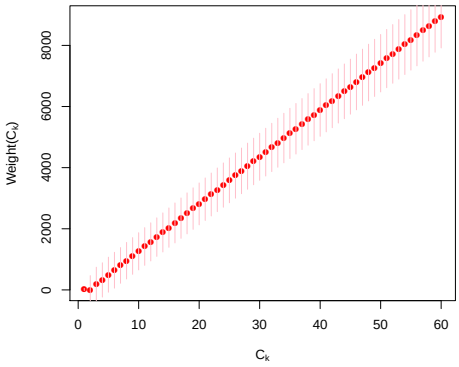

Figure 5: Average derivation weight as a function of the derivation length

Although weights can in principle be positive or negative, this apparently counter-intuitive behaviour is caused by the beam which keeps for further steps only the highest weighted configurations. To further study the behaviour of variable length sequences, we define two variants of the parser: first the 'naive' variant modifies the termination condition. Let $\mathcal{S} = \{C_{0\Rightarrow k} | C_k = \langle n+1, \langle \sigma_e, \tau \rangle \rangle, 2n-1 \leq k \leq 3n-1\}$. In this context, equation 2 is reframed as: $\tilde{\mathcal{C}} = \text{argmax}_{C_{0\Rightarrow k} \in \mathcal{S}}\ W(C_{0\Rightarrow k})$. A second version, called the 'synchronized version' introduces an additional inference rule called the Ghost Reduction and referred as GR in Figure 2. A slight modification of the LR automaton construction, designed to trigger either an unary reduction action or a Ghost reduction after a shift allow us to enforce the property that $\eta = 3n-1$ in this case too. The ghost reduction is designed to both make the parser 'wait' one step during derivation in case it chooses not to perform an unary reduction after shift and also to avoid modifying the content of the stack.

The second extension allows terminals to be not only lexical tokens or part-of-speech tags but arbitrary tuples ω. This allows to encode words with an arbitrary set of additional structured features such as their lemmas, gender, number, case, semantic representation. The exact nature of these additional features depends on the capacity of a parsing preprocessor to actually supply them. In this context the non terminal symbols of the 2-LCFG have thus the form $A[\omega]$. The fields of the tuples are then made accessible to feature functions. This extension is motivated by the hypothesis that parsing morphologically rich languages will benefit significantly from structured word representations, for instance allowing the parser to take advantage of morphology.

We are now in position to describe the feature templates used by the parser (Figure 6). Before the dot s_i and q_i denote respectively the address in the stack and in the queue of the adressed node. t, l, r denote the top, left and right nodes of the local trees in the stack. After the dot w_c, w_f denote a category and a word form, while c is a constituent category. w_m denote the mood of a verb and w_X an refined category dubbed `subcat` in the French Treebank (Abeillé et al., 2003): these subcategories refine crude tags by encoding information such as the definiteness of a determiner, subtypes of adjectives etc. gen, num, agr

denote the gender, the number and their interaction. The notation $e(\cdot, \cdot)$ is an equality function returning true if the values of both its argument are equal.

6 Experiments

The following experiments aim to identify the contribution of the components of the parser both to parsing accurracy and to parsing speed. Experiments are carried mainly on French. A final set of tests is also carried out on English in order to highlight the generality of the framework and to ease comparisons with other proposals.

6.1 Protocol

The experiments use the French SPMRL dataset (Seddah et al., 2013) which is newer and larger than datasets previously used for parsing French (Crabbé and Candito, 2008). It instanciates the full French Treebank described in (Abeillé et al., 2003) and will surely become the new standard data set for parsing French in the next few years. We use this data set as is, with two scenarios: one with gold standard tags and the second with tags predicted by a 97.35% accurate tagger (Seddah et al., 2013). The French data is head annotated with head rules provided by (Arun and Keller, 2005). Additionally, compound word structures are systematically left headed. For English, we use the Penn Treebank with standard split: section 02-21 for training, section 22 for development and section 23 for test. The predicted scenario uses the MELT tagger (Denis and Sagot, 2012) with an accurracy of 97.1%. The head annotations have been inferred by aligning the phrase structure treebank with its dependency conversion described by (de Marneffe et al., 2006).

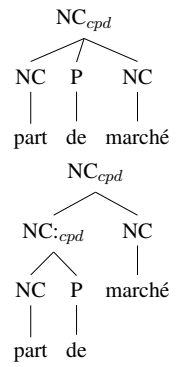
We use a C++ implementation of the algorithm described above for running the experiments. Scores reported for the Berkeley parser (Petrov et al., 2006) use the runs described by (Seddah et al., 2013). F-score is measured with the classical `evalb` and times are measured on the same machine (MacOSX 2.4Ghz) and do not take into account input/output times for both parsers.

Each experiment modifies a single experimental variable by contrast with a default parser configuration. The default parser configuration sets the beam size to $K = 4$ and uses the naive synchronisation procedure (Section 5). The LR automaton uses the grammar $G_m^{(base)}$ (Figure 7) and the update method is *early update* (Section 4). The set of templates is given in Figure 6 except for English where agreement, mood and subcat are ignored since there is no morphology directly available.

Experiment 1 This first experiment tests the impact of the beam size by running the parser with different sizes: $K = 2, K = 4, K = 8, K = 16$.

Experiment 2 The second experiment contrasts the naive synchronisation (*naive*) with the ghost reduction synchronisation (*sync*) described in section 5.

Experiment 3 This third experiment contrasts two different matrix grammars (Figure 7). This experiment aims to test whether we can take advantage of the LR automaton to better account for compound words encoded in the French data. To this end we designed two matrix grammars generating two different automata. In Figure 7, the top left tree is an example of the representation of compound words in the French data set. The corresponding binary structure is given on bottom left. The general grammar $G_m^{(base)}$ encodes a matrix grammar that does not specifically handle compound words and for which equivalence classes are $[a]$ the axiom symbol, $[n]$ non terminal symbols and $[w]$ terminal symbols. Each temporary non terminal $t \in T$ yields its own equivalence class. The grammar $G_m^{(cpd)}$ adds further equivalence classes: $[n]_{cpd}$ gathers non terminals marked as compounds (cpd) and is disjoint from $[n]$, the non compound non terminals. $T_{(cpd)}$ gathers temporary symbols marked as compounds and is disjoint from T. From these two matrix grammar we generate two different LR automata with one of them encoding a specific subgrammar for compounds (*cpd*) while the other is a generic grammar (*base*).



Immediate dominance rules for G_m^{base}		
$[a] \rightarrow [n]\,[n]$	$[n] \rightarrow [n]\,,\,[n]$	$t \rightarrow [n]\,,\,[n] \quad (\forall t \in T)$
$[a] \rightarrow [n]\,,\,[w]$	$[n] \rightarrow [n]\,,\,[w]$	$t \rightarrow [n]\,,\,[w] \quad (\forall t \in T)$
$[a] \rightarrow [w]\,[w]$	$[n] \rightarrow [w]\,,\,[w]$	$t \rightarrow [w]\,,\,[w] \quad (\forall t \in T)$
$[a] \rightarrow [w]$	$[n] \rightarrow [w]$	$t \rightarrow [n]\,,\,t \quad (\forall t \in T)$
$[a] \rightarrow [n]\,,\,t \quad (\forall t \in T)$	$[n] \rightarrow [n]\,,\,t \quad (\forall t \in T)$	$t \rightarrow [w]\,,\,t \quad (\forall t \in T)$
$[a] \rightarrow [w]\,,\,t \quad (\forall t \in T)$	$[n] \rightarrow [w]\,,\,t \quad (\forall t \in T)$	
Additional immediate dominance rules for G_m^{cpd}		
$[a] \rightarrow [n]_{cpd}\,,\,[n]$	$[n] \rightarrow [n]_{cpd}\,,\,[n]$	$t \rightarrow [n]_{cpd}\,,\,[n] \quad (\forall t \in T)$
$[a] \rightarrow [n]_{cpd}\,,\,[n]_{cpd}$	$[n] \rightarrow [n]_{cpd}\,,\,[n]_{cpd}$	$t \rightarrow [n]_{cpd}\,,\,[n]_{cpd} \quad (\forall t \in T)$
$[a] \rightarrow [n]_{cpd}\,,\,[w]$	$[n] \rightarrow [n]_{cpd}\,,\,[w]$	$t \rightarrow [n]_{cpd}\,,\,[w] \quad (\forall t \in T)$
$[a] \rightarrow [n]_{cpd}\,,\,t \quad (\forall t \in T)$	$[n] \rightarrow [n]_{cpd}\,,\,t \quad (\forall t \in T)$	$t \rightarrow [n]_{cpd}\,,\,t \quad (\forall t \in T)$
$[n]_{cpd} \rightarrow [w]\,,\,[w]$	$[n]_{cpd} \rightarrow t_{cpd}\,,\,[w] \quad (\forall t_{cpd} \in T_{cpd})$	$t_{cpd} \rightarrow t_{cpd}\,,\,[w] \quad (\forall t_{cpd} \in T_{cpd})$
$[n]_{cpd} \rightarrow [w]$	$t_{cpd} \rightarrow [w]\,,\,[w] \quad (\forall t_{cpd} \in T_{cpd})$	$t_{cpd} \rightarrow [w] \quad (\forall t_{cpd} \in T_{cpd})$

Figure 7: Structured representation of compound words (French data set) and related matrix grammars.

Experiment 4 This experiment contrasts *early update* with *max violation update*. Max violation update is trained over 12 epochs, while early update is trained over 25 epochs

Experiment 5 This last experiment contrasts the use of morphology. We remove (*no-morph*) the templates under mood, agreement and subcategories in Figure 6 in order to assess their impact.

6.2 Results

Results with respect to accurracy are given in table 2. Experiments are carried out on the development set with gold part of speech tags (Table 2, left) and predicted part of speech tags (Table 2, right).

Experiment 1 The parser achieves its best result with a beam of size 8 ($K = 8$). Quite surprisingly it achieves already a very correct score with a beam of size 4. We observe that increasing the size of the beam does not proide significant improvements. Using beams of size 16 (or even 32) only bring marginal accurracy improvements, if any, at the expense of more important parsing times.

Experiment 2 This second experiment is apparently more disappointing: synchronisation does not seem to play a significant role on accurracy, or a detrimental one if any. This effect seems caused by a property of the dataset. A more careful analysis of the parser error patterns shows that the parsing model naturally misses many unary reductions. Since the *naive* automaton is biased towards predicting longer sequences with higher weights, it somehow helps to favor longer derivations containing more unary reductions, hence improving the accurracy.

Table 2: Experimental results (development)

Experiment 3 This experiment highlights the problems related to further constraining a parser with approximative search: we observe that parsing coverage is reduced. This can be explained by the fact that further constraining the grammar creates less success states in the automaton and that the parser sometimes has to perform less local decisions without all the necessary information available. This suggests for further work that a more constrained matrix grammar should be used with a more robust search strategy than simple beam search.

Experiment 4 In experiment 4, we observe that max violation update converges twice as fast as early update but we experienced more overfitting problems explaining the lower scores. It is however harder to achieve fair comparisons since the number of iterations is significantly different.

Experiment 5 This last experiment is probably the most significative. We observe that morphology is the variable that allows the parser to improve significantly on French (dev F=81.79). This result thus confirms those observed by (Hohensee and Bender, 2012) on several languages for dependency parsing, yet we had to isolate agreement, refined subcategories and verbal mood to get significant improvements (Figure 6).

Final tests In order to compare this proposal with current state of the art parsers, we provide comparative measures of speed and accurracy with the Berkeley parser (Petrov et al., 2006), known to be representative of the state of the art in accurracy and in speed on French and in accurracy on English (Table 3).

French Test (gold tags)	F$\leq$ 40	F	Cov

Table 3: Experimental results (test)

Interestingly parsing the English dataset with templates designed on French data is almost state of the art on English (dev F=89.3, test F=89.1). This suggests that feature engineering is a less important issue than often thought and it also suggests that the parser is likely to be easy to adapt to other languages by generalizing the method used to parse English.

Although the differences are modest, the parser is state of the art on French (F=81.43) if we compare with the Berkeley parser (F=80.73) known to be indicative of the state of the art on French (Seddah et al., 2013) and if we ignore ensemble and semi-supervised parsers.

The most important difference is related to speed. (Petrov et al., 2006) is reported to be the fastest phrase structure parser for English by (Huang and Sagae, 2010) where the authors compare with (Charniak, 2000). Yet (Petrov et al., 2006) is a polynomial time parser, while this one has linear time behaviour. We compared the speed of both parsers on the same hardware (ignoring input/output times) and we find (Petrov et al., 2006) has an average parse time of $t_\mu = 0.28$s with maximum $t_{max} = 10.27$s while our linear time algorithm has mean time $t_\mu = 0.06$s and maximum $t_{max} = 0.1$s with beam 4 and $t_\mu = 0.1s, t_{max} = 0.5s$ with beam 8 (Figure 8). Further constraining the automaton shows to be useful for speed, since for experiment 3, $t_\mu = 0.04s$ with $K = 4$ which is clearly faster.

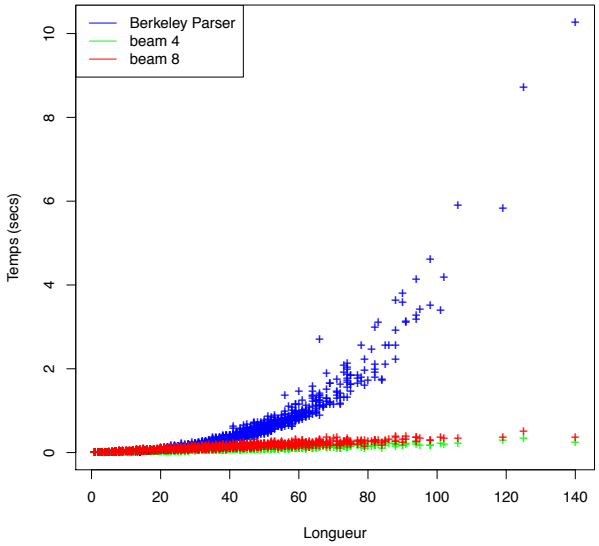

Figure 8: Parsing times

We finally observe on English that the LR strategy performs reasonably accurately and faster than the implementation of (Petrov et al., 2006) whereas optimisations of PCFG-LA described by (Bodenstab et al., 2011) are significantly less accurate and not significantly faster. Although it is currently hard to to compare directly on French with the most similar proposal, the Chinese/English parser described by (Zhu et al., 2013), since it does not handle morphology. With respects to speed, their impressive result on English suggests that there is still room for speed improvements without loss of accurracy.

7 Conclusion

To our knowledge, this is the first formulation of a discriminative LR-automaton driven parser for natural language. This LR inspired algorithm shares many properties with shift reduce parsers for phrase structure grammar described by (Sagae and Lavie, 2006) and (Zhu et al., 2013). (Sagae and Lavie, 2006) describe a first version of this kind of algorithm using a weighting system based on a local maximum entropy classifier. It thus enables them to use a best first search strategy that allows in principle to achieve near-optimal parsing. By contrast, like (Zhu et al., 2013), we use here a global perceptron algorithm together with a beam based breadth first search to which we add an explicit LR component. The LR automaton allows us to guarantee that the parser generates a viable prefix. We believe the LR framework can also shed light on theoretical, practical and experimental issues related to phrase structure parsing by comparison with dependency parsing. However using the LR automaton to constrain the parsing model

for multi-word expressions turns out to be disappointing since it forces the parser to take less local decisions for which the beam approximation is not well suited. This suggests for future work to explore search methods aiming to achieve optimality (Zhao et al., 2013).

Mirroring a common practice in dependency parsing, the parser also provides a first support for phrase structure parsing of morphologically rich languages thanks to structured word representations. The richer lexical structure makes morphological information available during the parsing process. For the case of French it enables, among others, to integrate agreement in the parsing model. This simple integration of morphology then allows the parser to achieve state of the art accurracy on French. Since in principle nothing in the algorithm is specific to French, we expect to generalize and experiment with the model on other morphologically rich languages. Further work for such languages is expected to involve a refinement of the interface with morphology along the lines of (Hatori et al., 2012; Bohnet et al., 2013).

Abstract

Most text classification approaches model text at the lexical and syntactic level only, lacking domain robustness and explainability. In tasks like sentiment analysis, such approaches can result in limited effectiveness if the texts to be classified consist of a series of arguments. In this paper, we claim that even a shallow model of the argumentation of a text allows for an effective and more robust classification, while providing intuitive explanations of the classification results. Here, we apply this idea to the supervised prediction of sentiment scores for reviews. We combine existing approaches from sentiment analysis with novel features that compare the overall argumentation structure of the given review text to a learned set of common *sentiment flow patterns*. Our evaluation in two domains demonstrates the benefit of modeling argumentation for text classification in terms of effectiveness and robustness.

1 Introduction

Text classification is a key technique in natural language processing and information retrieval that is applied for several tasks. Standard classification approaches map a text to a vector of lexical and shallow syntactic surface-level features, from which class information is inferred using supervised learning (Manning et al., 2008). Even though the results of such approaches can hardly be explained, they have proven effective for narrow-domain texts with explicit class information (Joachims, 2001; Pang et al., 2002).

However, surface-level features often do not help to classify out-of-domain texts correctly, because they tend to model the domain of the texts and not the classes to be inferred, as we observe in (Wachsmuth and Bujna, 2011) among others. Moreover, they are likely to fail on texts where the class information is implicitly represented by the argumentation of the writer. Such texts are in the focus of popular tasks like authorship attribution, automatic essay grading, and, above all, sentiment analysis. As an example, consider the short hotel review at the top and bottom of Figure 1. It contains more positive than negative statements. Hence, a surface-level analysis would probably classify the review to have a positive overall sentiment polarity. In fact, the argumentation of the review text reveals a clear negative sentiment.

The analysis of argumentation is recently getting more attention (cf. Section 2 for details). With respect to sentiment, related approaches analyze discourse relations (Mukherjee and Bhattacharyya, 2012), identify the different aspects mentioned in a text (Lazaridou et al., 2013), or the like. While these approaches can infer implicit class information from argumentative texts like reviews, they do not address the domain dependency problem of sentiment analysis (Wu et al., 2010). In addition, they still lack explainability, which limits end user acceptance in case of wrong results (Lim and Dey, 2009).

In this paper, we consider the question of how to capture the argumentation of reviews for a domain-robust and explainable text classification. As Figure 1 illustrates, we rely on a shallow model of review argumentation, which represents a text as a sequence of statements that express local sentiment on domain concepts and that are connected by discourse relations. We claim that, by focusing on features that model the abstract argumentation structure of a text, a more robust sentiment analysis can be achieved. At the same time, such an analysis can explain its results based on the underlying model.

Proceedings of COLING 2014, the 25th International Conference on Computational Linguistics: Technical Papers, pages 553–564, Dublin, Ireland, August 23-29 2014.

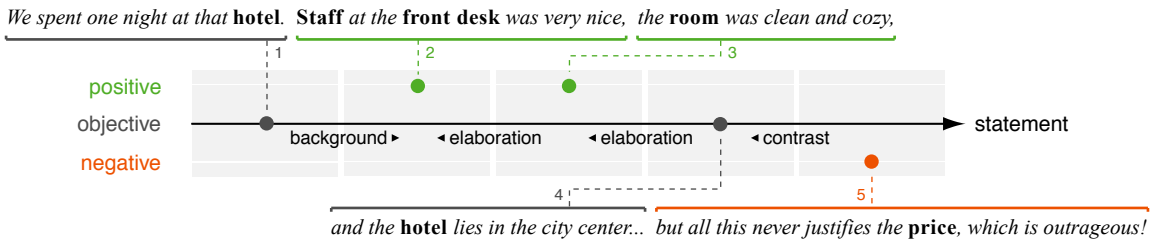

Figure 1: Illustration of our shallow model of review argumentation for a sample review text from the hotel domain. Domain concepts, such as "front desk", are marked in bold. Each circle denotes a statement with local sentiment. The statements are connected by directed discourse relations like "elaboration".

Concretely, here we address the supervised prediction of sentiment scores. To this end, we combine a number of existing argumentation-related features with a novel approach that learns common patterns in sequences of local sentiment through a cluster analysis in order to capture a review's overall argumentation structure. Inspired by explicit semantic analysis (Gabrilovich and Markovitch, 2007), we then compute the similarity of a given review text to each of these *sentiment flow patterns* and we use these similarities as features for sentiment scoring. To explain a predicted score and, hence, to increase user acceptance, both the underlying model and the sentiment flow patterns can be visualized.

We evaluate our approach on reviews of the hotel domain and the movie domain. In comparison to standard baselines, we demonstrate the effectiveness and robustness of modeling argumentation. Our results suggest that especially the sentiment flow patterns learned in one domain generalize well to other domains. Altogether, the contributions of this paper are:

1. A shallow model of review argumentation for text classification that enables a more domain-robust and explainable sentiment analysis (Section 3).
2. A novel feature type named *sentiment flow patterns* that, for the first time, captures the abstract overall argumentation structure of review texts, irrespective of their domain (Section 4).
3. Experimental evidence for the existence of common patterns in the argumentation structure of review texts across domains (Section 5).

2 Related Work

Argumentation plays a key role in human communication and cognition. Its purpose is to provide persuasive information for or against a decision or claim. This involves the identification of facts and warrants justified by a backing or countered by a rebuttal (Toulmin, 1958). Argumentation is studied in various disciplines, such as logic, philosophy, and artificial intelligence. We consider the linguistics perspective, where it is pragmatically viewed as a regulated sequence of speech or text (Walton and Godden, 2006).

In particular, we analyze *monological argumentations* in written text as opposed to dialogical argumentations where participants persuade each other with arguments (Cabrio and Villata, 2012). In terms of text, one of the most obvious forms of monological argumentation can be found in reviews. A review comprises a *positional argumentation*, where an author collates and structures a choice of facts, pros, and cons in order to inform intended recipients about his or her beliefs (Besnard and Hunter, 2008).

According to Mochales and Moens (2011), an *argumentation analysis* targets at "the content of serial arguments, their linguistic structure, the relationship between the preceding and following arguments, recognizing the underlying conceptual beliefs, and understanding within the comprehensive coherence of the specific topic." The authors work on *argumentation mining*, i.e., the detection of different arguments for justifying a conclusion as well as their interactions. Our model of argumentation matches the quoted definition. Similar to the distinction between shallow and deep parsing (Jurafsky and Martin, 2009), our approach can be seen as a *shallow argumentation analysis* in that we consider only the sequence of arguments. This abstraction appears very promising to address text classification.

Unlike *argumentative zoning* (Teufel et al., 2009), which classifies segments of scientific articles according to argumentative functions, we predict the sentiment scores of reviews from a sequence of classified segments. Sentiment scoring is tackled in both computational linguistics (Pang and Lee, 2005) and

information retrieval (Wang et al., 2010). Such kind of sentiment analysis benefits from modeling argumentative discourse (Villalba and Saint-Dizier, 2012). Related works already employ discourse features to detect sentiment polarity. Some rely on complex discourse parsing (Heerschop et al., 2011), whereas others argue that a lightweight approach is more robust for noisy texts (Mukherjee and Bhattacharyya, 2012). We rather follow the latter, but we see discourse only as one part of review argumentation.

In accordance with Lazaridou et al. (2013) who address *aspect-based sentiment analysis*, we additionally analyze the connection of local sentiment to domain concepts and discourse relations. Even more important for us is the *local sentiment flow* in a text. This term was introduced by Mao and Lebanon (2007), who infer a text's global sentiment from its sequence of local (sentence) sentiments, classified with conditional random fields. Their approach converts each sentiment in the sequence to a single feature and learns a mapping from the features to global sentiment. By that, it actually disregards the ordering of local sentiment. In contrast, our sentiment flow patterns measure the similarity between complete sequences of local sentiment. This resembles *explicit semantic analysis* (Gabrilovich and Markovitch, 2007), which classifies texts based on their relatedness to concepts modeled by complete texts.

In (Wachsmuth et al., 2014), we reveal correlations between a review's sentiment score and its local sentiment flow. Similar to Socher et al. (2013), we therefore argue that global sentiment emanates from the composition of local sentiment. The authors model the semantic compositionality of words in given sentences, thus capturing the language of a given domain. Conversely, our sentiment flow patterns focus on the structure of complete texts in order to reduce domain dependency, which is a general problem in text classification (Wu et al., 2010). Among others, existing strategies to tackle this problem align features of the source and the target domain, as we do in (Prettenhofer and Stein, 2010).

Given a vector of features, text classification approaches typically output only a class label (Manning et al., 2008). This renders the understanding and debugging of classification results hard (Kulesza et al., 2011). Instead, our approach explains results by making the argumentation of texts visible. Thereby, we increase intelligibility and, thus, support user acceptance (Lim and Dey, 2009).

3 A Shallow Model of Review Argumentation

This section first sketches our general hypothesis. Then, we present our model of review argumentation.

3.1 Hypothesis behind Modeling Argumentation for Text Classification

Several text classification tasks relate to the argumentation of a text. As an obvious example, *automated essay scoring* explicitly rates argumentative texts, mostly targeting at structural aspects (Dikli, 2006). In *genre identification*, a central concept is the form of texts. Some genre-related tasks address argumentation, e.g. by classifying texts according to their function (Wachsmuth and Bujna, 2011). Criteria in *text quality assessment* often measure structure (Anderka et al., 2012), while *readability* is connected to discourse (Pitler and Nenkova, 2008). *Authorship attribution* profits from argumentation clues like unconsciously used function words (Stamatatos, 2009), and *plagiarism detection*, in the end, aims to check if the argumentation in a fragment of a text refers to the author of the text (Potthast et al., 2013).

We hypothesize that in these and further tasks the class of a text is often decided by the structure of its argumentation rather than by its content, while the content adapts the argumentation to the domain at hand. Following Besnard and Hunter (2008), an argumentation consists of a composition of arguments used to justify a decision or claim. Each argument can be seen as a statement with some evidence. Under our hypothesis, an explicit model of statements and their composition hence supports the identification of domain-independent patterns. Together with the content, the statements enable a fine-grained analysis, while serving as the basis for an explanation. Since the relevant types of statements vary among tasks, we argue that such a model should be task-specific. Below, we investigate reviews on products and services from a sentiment analysis perspective. Because of its positional nature (cf. Section 2), review argumentation makes its arguments explicit, i.e., facts and opinions on different product features and aspects.

3.2 Modeling Review Argumentation for Sentiment Analysis

We consider reviews that comprise a text about some product or service as well as a numerical overall rating. Any other metadata that might be given for reviews is ignored in the following. Our assumption

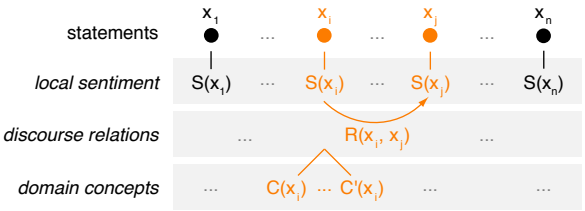

Figure 2: Our shallow model of review argumentation defined by a segmentation into statements and by three functions based on the statements.

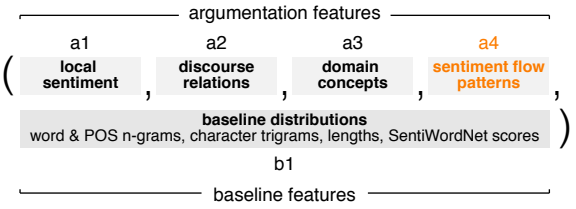

Figure 3: A vector with all five considered feature types including the novel sentiment flow patterns. Each found pattern becomes a single feature in a4.

is that the overall rating denotes a *sentiment score* y from a metric sentiment scale that quantifies the possibly implicit conclusion of the review text in terms of its global sentiment.

Statements To capture a review's argumentation, we model the review's text as a sequence of $n > 0$ statements $x_1, \ldots, x_n$. Here, we define a *statement* x syntactically to be a main clause together with all its subordinate clauses. The notion behind is that, in our experience, such a text segment is usually meaningful on its own while bearing at most one sentiment. Many sentences in reviews comprise series of statements. For instance, the following excerpt from Figure 1 consists of two statements, x_4 and x_5:

x_4: and the hotel lies in the city center... x_5: but all this never justifies the price, which is outrageous!

Based on the set of all statements $\mathbf{X}$, we capture the structure and content of review texts as follows:

Local Sentiment We assume each statement to represent either an objective fact obj, a positive opinion pos, or a negative opinion neg (for a wide applicability, we ignore sentiment intensity). So, there is an unknown function that maps each statement to a local sentiment, e.g. x_4 to obj and x_5 to neg:

$$\textit{local sentiment}: \quad \mathbf{X} \rightarrow \{S(x) \mid S \in \{pos, neg, obj\}\}$$

Discourse Relations As for x_4 and x_5, the composition of statements in a text is, in general, not coincidental. Rather, it implies a structure made up of an ordered choice of statements as well as of a number of directed discourse relations. We define a discourse relation to have some type R of a set of relation types $\mathbf{R}$ and to relate two (typically neighboring) statements, e.g. *contrast(x_5, x_4)* in the example above. The following function hence can be understood as a shallow version of the *rhetorical structure theory* (Mann and Thompson, 1988):

$$\textit{discourse relations}: \quad \mathbf{X} \rightarrow \{R(x_i, x_j) \mid 1 \leq i, j \leq n \; ; \; R \in \mathbf{R}\}$$

Domain Concepts The argumentation structure of a text is bound to the domain at hand through the text's content. In particular, a review text discusses a subset of the *domain concepts* $\mathbf{C}$ that are associated to a product or service, each being referred to in one or more statements. For instance, x_5 discusses the price of the hotel, i.e., *price(x_5)*. We capture the domain concepts in statements as follows:

$$\textit{domain concepts}: \quad \mathbf{X} \rightarrow \{C(x_i) \mid 1 \leq i \leq n \; ; \; C \in \mathbf{C}\}$$

Altogether, our model represents a review text as a sequence of interrelated statements of certain types and content. Figure 2 illustrates the defined functions. An instance of the model is visualized in Figure 1. The model is an abstraction of argumentation, covering some information only implicitly if at all (e.g. lexical or syntactic clues). However, it can be extended by further information, as we do below.

4 Features for Robust Sentiment Analysis and Explanation

We now present different types of features for supervised learning that capture both distributional and structural aspects of review argumentation based on our shallow model. Here, we assume that all information represented in the model is given, but Section 5 analyzes the effects of inferring the information from a text. Figure 3 gives an overview of the vector with all feature types that we consider, including a common set of baseline features (b1). The goal of all argumentation features (a1–a4) is twofold: (1) To enable an effective and robust sentiment analysis. (2) To provide means to explain analysis results.

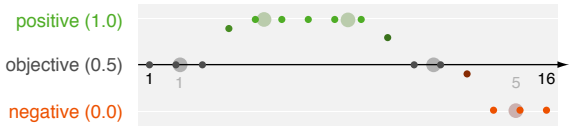

Figure 4: Illustration of a length-normalized version (small circles) of the sample local sentiment flow from Figure 1 (big circles) for length 16.

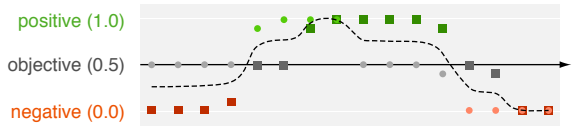

Figure 5: Sketch of the construction of a sentiment flow pattern (dashed curve), here from two sample local sentiment flows (circles and squares).

4.1 Quantification of Distributional Argumentation Aspects

In terms of the distributional aspects of the three functions introduced in Section 3, we combine a selection of ideas from existing sentiment analysis approaches that are related to review argumentation. Some features of the types described in the following are selected only if they occur frequently in a given set of training texts. Thus, the concrete numbers of features vary, as we see in the evaluation in Section 5.

Local Sentiment (a1) In (Wachsmuth et al., 2014), we stress the impact of the distribution of local sentiment. Accordingly, here we determine the frequencies of all types of local sentiment in the given text as well as of series of statements with the same type and of changes from one type to another. Also, we have features that denote the local sentiment at specific positions like the first and last two statements, and we compute the average local sentiment. For the latter, we map pos to 1.0, obj to 0.5, and neg to 0.0.

In addition, we follow Mao and Lebanon (2007) in that we capture the local sentiment flow based on the defined mapping. To preserve the original flows as far as possible, we length-normalize the sequence of values using non-linear interpolation with subsequent sampling. Figure 4 shows an example.

Discourse Relations (a2) We count the occurrences of different discourse relation types from (Mann and Thompson, 1988), e.g. *contrast* or *elaboration* (in Section 5, we distinguish a subset of ten types). To model connections between sentiment and discourse, we do the same for all frequently occurring combinations of discourse relation types and local sentiment of the related statements, e.g. *contrast(*pos*,* neg*)* or *contrast(*neg*,* pos*)*. By that, we imitate Lazaridou et al. (2013) to some extent.

Domain Concepts (a3) With the same intention, we determine the most frequent domain concepts in the given training set and we compute how often each concept cooccurs with each type of local sentiment. Examples from the sample text in Figure 1 are *hotel(*obj*)* or *price(*neg*)*. Moreover, we count the number of different domain concepts as well as the instances of all possibly distinguished types of domain concepts, which would be *product* (like "hotel") and *product feature* (like "price") in the given case.

Types a1–a3 refer to important characteristics of review argumentation. However, none of them captures a review's overall argumentation structure. Even the local sentiment flow in a1 rather measures the impact of local sentiment at different positions. The reason behind is that the flow positions are represented by individual features. Hence, common learning approaches like regression will naturally tend to assign positive weights to all positions, not considering the sentiment flow as a whole.

4.2 Learning of Structural Argumentation Aspects

To capture the impact of the structure of an argumentation, we introduce a novel feature type based on the local sentiment flows of texts only. The idea behind resembles *explicit semantic analysis* (Gabrilovich and Markovitch, 2007) in that every single feature represents the similarity to a complete flow:

Sentiment Flow Patterns (a4) We first construct a set of common *sentiment flow patterns* from a set of known training review texts, where each pattern denotes the average of a set of similar local sentiment flows of normalized length. Given an unknown review text, we then measure the similarity of its normalized local sentiment flow to each constructed pattern. The set of these similarities forms a4.

Figure 5 exemplifies the pattern construction. Our hypothesis behind sentiment flow patterns is that similar local sentiment flows entail similar sentiment scores. Accordingly, flows that construct a pattern should be as similar as possible and flows of different patterns as dissimilar as possible. Therefore, we apply *clustering* (Manning et al., 2008) to partition the flows of all texts from the given training set based on some flow similarity function (in Section 5, we use the manhattan distance). The centroid of each ob-

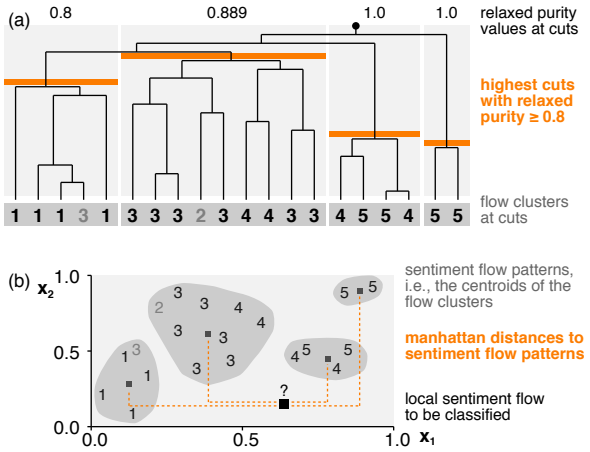

Figure 6: (a) A purity threshold of 0.8 derives four clusters from a hierarchical clustering of 20 local sentiment flows represented by their scores from 1 to 5. (b) 2D plot of computing distances to the sentiment flow patterns, i.e., the clusters' centroids.

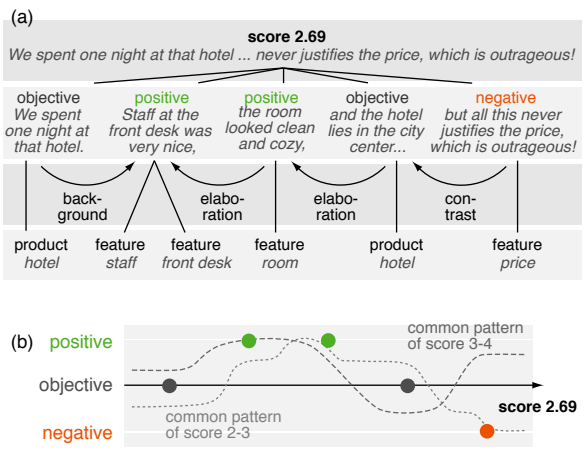

Figure 7: Two possible explanations of scoring the sample text from Figure 1: (a) Graph visualization of our model of review argumentation. (b) Comparison of the local sentiment flow of the text with the two most similar sentiment flow patterns.

tained cluster ω then becomes a sentiment flow pattern. Since we know the sentiment scores associated to the flows in the training set, we can measure the *purity* of a cluster ω, which here denotes the fraction of those flows ω_{y^*} in ω whose score equals the majority score y^* in ω (Manning et al., 2008). The original purity definition, however, assumes exactly one correct score for each flow. Here, this would mean that a flow alone decides a score. Instead, for larger sentiment scales, we propose to relax the purity measure by assuming also the dominant neighbor of the majority score as correct:

$$relaxed\ purity(\omega) \;=\; \left(|\omega_{y^*}| + \max(|\omega_{y^*-1}|,|\omega_{y^*+1}|)\right) / \,|\omega|$$

We seek for clusters with a high purity, because such clusters support that similarities between flows and patterns indicate specific sentiment scores. At the same time, the number of clusters should be small in order to achieve a high average cluster size and, thus, a high commonness of the patterns. For this purpose, we rely on *hierarchical clustering*, where we can easily find a flat clustering with a certain number of clusters through cuts at appropriate nodes in the binary tree of the associated hierarchy. Pattern construction profits from compact clusters, suggesting to compute distances between clusters from their *group-average links* (Manning et al., 2008). To minimize the number of clusters, we search for all nodes closest to the tree's root that represent clusters with a purity above some threshold, e.g. 0.8 in the example in Figure 6(a). The centroids of these clusters become sentiment flow patterns, if they are made up of some minimum number of flows.

At the end of the clustering process, we remain with one feature for each constructed sentiment flow pattern. Given a review text to be classified, we then compute its normalized local sentiment flow and we measure the flow's distance to all patterns. Each distance represents one similarity in the feature type a4. Figure 6(b) sketches the computation of the distances, mapped into two dimensions.

4.3 Comparison with Baseline Approaches

In the evaluation below, we compare the feature types a1 to a4 with the well-known sentiment scoring approach of Pang and Lee (2005) in terms of effectiveness. Our focus, however, is the robustness of modeling argumentation structure in contrast to standard text classification features employed in many other approaches, such as n-grams or variations of them (Qu et al., 2010). To this end, we also integrate the following baseline features, most of which model a text at the lexical and syntactic level:

Baseline Distributions (b1) We compute the distributions of all word and part-of-speech unigrams, bigrams, and trigrams as well as of all character trigrams that frequently occur in a given training set. In addition, we determine the length of the given text in different units and some average *SentiWordNet* scores with respect to both the first and the average senses of its words (Baccianella et al., 2010).

4.4 Explanation of Sentiment Scores

We propose a shallow statistical argumentation analysis that learns to predict sentiment scores on a training set of review texts. After prediction, we can directly exploit the information captured in our model as well as the values of the feature types a1–a4 in order to explain the predicted score. Two possible explanations are visualized in Figure 7, while a combination of them is exemplified in Figure 1. We believe that such explanations can increase a user's confidence in statistical analysis results and, hence, the acceptance of corresponding applications. To demonstrate the analysis and explanation of review argumentation, we provide a free-to-use tool and webservice at http://www.arguana.com.

5 Evaluation of Modeling Argumentation for Sentiment Scoring

In this section, we evaluate the effectiveness and domain robustness of modeling argumentation for sentiment scoring with a focus on the sentiment flow patterns. The source code of the evaluation can be found at http://www.arguana.com. Our experiments are based on two English text corpora with reviews from the hotel domain and the movie domain, respectively. In both cases, we leave out the review titles for generality, because our approach targets at arbitrary reviews including those without a title.

Text Corpora On the one hand, we process the *ArguAna TripAdvisor corpus* that we have introduced in (Wachsmuth et al., 2014). This corpus compiles a collection of 2,100 reviews of hotels from seven locations, balanced with respect to their sentiment scores between 1 and 5. All of the reviews' texts are segmented into statements with an average of 14.8 statements per text. Each statement is annotated as an objective fact, a positive, or a negative opinion. Moreover, all mentions of domain concepts are marked as such. The corpus is also available at http://www.arguana.com, free for scientific use. In the experiments, we rely on the provided corpus split with 900 reviews from three hotel locations in the training set, and 600 reviews from two locations in the validation set and test set each.

On the other hand, we use the *Sentiment Scale dataset* (Pang and Lee, 2005) consisting of 5,006 movie reviews that are split into four text corpora according to their authors (*Author a*, *b*, *c*, and *d*). From these, we have discarded eight reviews due to encoding problems. We choose the provided sentiment scale from 0 to 2, so we can logically map the scale of the hotel reviews (1–5) to it for a domain transfer. In particular, scores 1–2 are mapped to 0, 3 to 1, and 4–5 to 2. On average, the movie reviews are much longer with 36.1 statements per text. Since no local sentiment annotations are given, we also process the *subjectivity dataset* (Pang and Lee, 2004) and the *sentence polarity dataset* (Pang and Lee, 2005) in order to develop classifiers for sentence sentiment. Accordingly, we assume each movie review sentence to denote one statement. To directly compare our results to those of Pang and Lee (2005), we perform 10-fold cross-validation separately on the dataset of each single author, averaged over five runs.

Preprocessing For feature computations, we preprocess all texts with a tokenizer, a sentence splitter, and the part-of-speech tagger from (Schmid, 1995). We employ lexicon-based extractors for discourse relations and domain concepts, which aim at a high precision while not being able to recognize unseen instances. The former resembles the lightweight approach of Mukherjee and Bhattacharyya (2012). Primarily, it looks for conjunctions that indicate certain discourse relations, such as "but" or "because". The latter detects exactly those domain concepts that are annotated largely consistently in the training set of the ArguAna TripAdvisor corpus. Thus, it helps only on the hotel reviews. These reviews are segmented into statements with a respective algorithm that comes with the corpus.

For both domains, we have trained linear support vector machines (SVMs) from Chang and Lin (2011) that classify the subjectivity of each statement (opinion or fact) and the polarity of each opinion (positive or negative). They use 1k to 2k features of different types: word and part-of-speech unigrams, character trigrams, SentiWordNet scores (Baccianella et al., 2010), and some special features like the first word of a statement or its position in the text. On the test set of the hotel domain, the classifiers have an accuracy of 78.1% for subjectivity and of 80.4% for polarity. In the movie domain, we achieve a subjectivity accuracy of 91.1%, but a polarity accuracy of only 73.8% (measured through 10-fold cross-validation).

Feature Computation We determine one distinct feature set for each evaluated text corpus made up of the feature types presented in Section 4. Where necessary, we divide the computed feature values by

the length of the text (in tokens or statements, as appropriate), in order to ensure that all feature values always lie between 0 and 1.

Local sentiment flows are normalized to length 30 in case of the hotel reviews and to length 60 in case of the movie reviews, which allows us to represent most of the original flows without loss. Altogether, feature type a1 sums up to 50 and 80 features, respectively. For a2, a3, and b1, we consider only those features whose frequency in the training texts exceeds some specified threshold. For instance, a word unigram is taken into account within b1 only if it occurs in at least 5% of the hotel reviews or 10% of the movie reviews, respectively. As a result, the number of evaluated features varies depending on the processed text corpus. Concretely, we obtain 64 to 78 features for discourse relations (a2), 78 to 114 for domain concepts (a3), and 1026 to 2071 baseline features (b1). More details are given in the instruction and configuration files that come with the provided source code.

To construct sentiment flow patterns (a4), we have developed an agglomerative hierarchical clusterer that implements the approach from Section 4.2. After some tests with different settings, we decided to measure flow and cluster similarity using group-average link clustering based on the manhattan distance between the length-normalized local sentiment flows. For the hierarchy tree cuts, we use a purity threshold of 0.8, where we take the relaxed purity for the sentiment scale 1–5 of the hotel reviews, but the original purity for the movie reviews (because of the limited scale from 0 to 2). All centroids of clusters with at least three flows become a sentiment flow pattern, resulting in 16 to 86 features in a4.

Sentiment Scoring On the hotel reviews, we compute the root mean squared error of linear sentiment score regression trained using stochastic gradient descent (SGD) from *Weka 3.7.5* (Hall et al., 2009). Both the regularization parameter and the learning rate of SGD are set to 10^{-5}, whereas we determine the epochs parameter of SGD on the validation set. Then, we measure the error on the test set.

For the comparison to (Pang and Lee, 2005), we predict the scores of the movie reviews using classification, which additionally stresses the domain change. In particular, we measure the accuracy of a linear 1-vs.-1 multi-class SVM with probability estimates and normalization. While we optimize the cost parameter of the SVMs in the in-domain task, we rely on the default value (1.0) for the domain transfer.

5.1 Effectiveness of Modeling Argumentation

First, we measure the theoretically possible scoring effectiveness of all feature types within one domain. To this end, we compare the feature types based on the ground-truth annotations of the ArguAna TripAdvisor corpus. The column *Corpus* of Table 1 lists the resulting root mean squared errors. As can be seen, all argumentation feature types clearly outperform the baseline distributions (b1) and improve strongly over random guessing. The distributional local sentiment (a1) does best with an error of 0.77, whereas the domain concepts perform worst among a1 to a4. Still, they result in an 0.12 lower root mean squared error than the baseline distributions (b1). Overall, the lowest observed error is 0.75, achieved by the SVM with all features as well as by two subsets of the argumentation features alone.

In practice, no ground-truth annotations are given, so we need to create annotations in the review texts ourselves using the preprocessing described above. This in turn changes the feature set and the respective values of the argumentation features. The third column of Table 1 (*Self*) shows that such a resort to self-created annotations leads to a root mean squared error increase of 0.14 to 0.22 for the types a1 to a4. Nevertheless, the argumentation features succeed over the baseline distributions with 0.94 as opposed to 1.11, which demonstrates the effectiveness of modeling the argumentation of hotel reviews.

5.2 Robustness of Modeling Argumentation Structure

We hypothesize that the developed structure-based argumentation features are robust against domain transfer to a wide extent. To investigate this, we classify sentiment scores using SVMs based either on all or on one single feature type (except for a3, for lack of movie domain concept extractors) in two tasks on the four movie datasets: (1) with training in the movie domain (through 10-fold cross-validation), and (2) with training out-of-domain on the hotel review training set.

Figure 8 contrasts the accuracy results for the two tasks and compares them to the best SVM approach of Pang and Lee (2005), i.e., *ova* (open squares). In the in-domain task, our SVM based on all feature types (black squares) is significantly better than *ova* on one dataset (*Author a*) and a little worse on

Feature type		Corpus	Self
none	Random guessing	1.41	1.41
a1	Local sentiment	0.77	0.99
a2	Discourse relations	0.84	1.01
a3	Domain concepts	0.99	1.13
a4	Sentiment flow patterns	0.86	1.07
b1	Baseline distributions	1.11	1.11
a1–a4	Argumentation features	0.76	0.94
a2, a3, a4	w/o local sentiment	0.79	0.99
a1, a3, a4	w/o discourse relations	0.76	0.97
a1, a2, a4	w/o domain concepts	**0.75**	0.95
a1, a2, a3	w/o sentiment flow patterns	**0.75**	0.95
all	All features	**0.75**	**0.93**

Table 1: Root mean squared error of sentiment score regression on the hotel review test set for all evaluated features types and for different combinations of these types. Features are computed based on ground-truth annotations (*Corpus*) or based on self-created annotations (*Self*).

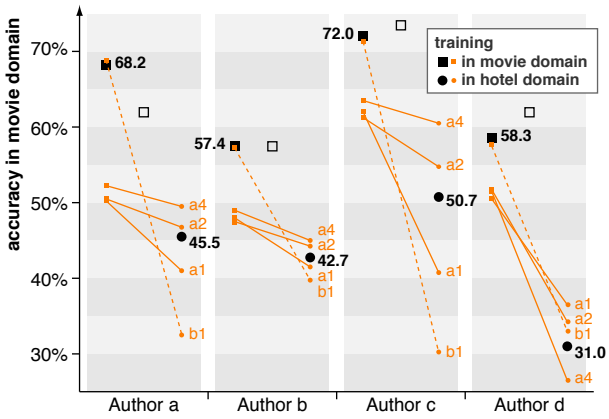

Figure 8: Sentiment scoring accuracy of the SVM based on feature type a1, a2, a4, and b1 (black icons) and of each SVM based on one of these types (orange icons) on the four movie datasets, when trained on movie reviews (squares) or on hotel reviews (circles). Open squares: *ova* from (Pang and Lee, 2005).

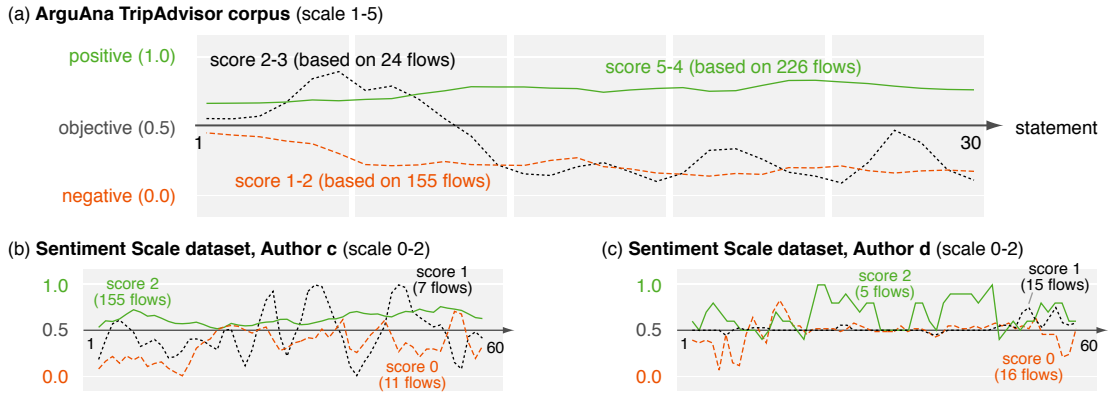

Figure 9: (a) The three most common sentiment flow patterns in the training set of the ArguAna TripAdvisor corpus, labeled with their associated sentiment scores. (b–c) The according sentiment flow pattern for each possible score of the texts of *Author c* and *Author d* in the Sentiment Scale dataset, respectively.

two other datasets (*Author c* and *Author d*). On all four datasets, a4 classifies sentiment scores more accurately than both a1 and a2, but none of the argumentation feature types can compete with the baseline distributions (b1). We suppose that the reason behind mainly lies in the limited effectiveness of our opinion polarity classifier, which reduces the impact of all features that rely on statement sentiment.

Conversely, b1 fails completely in the out-of-domain task (from squares to circles) with accuracy drops of up to 41% (on *Author c*). This indicates a large *covariate shift* (Shimodaira, 2000) in the distribution of the baseline features. In contrast, a1, a2, and a4 suffer much less from the domain transfer. Especially the accuracy of the sentiment flow patterns (a4) remains stable on three of the four datasets and, hence, provides strong support for our hypothesis. In case of *Author c*, the SVM based on a4 alone even achieves a significantly higher accuracy than the SVM based on all features (60.5% as opposed to 50.7%), thus offering evidence for the decisiveness of the structure of an argumentation. Only on *Author d*, all four evaluated feature types similarly fail when trained on hotel reviews with a4 being the worst. Apparently, the argumentation structure in the texts of *Author d* differs from the others, which is reflected by the found sentiment flow patterns and which we therefore finally analyze.

5.3 Insights into Sentiment Flow Patterns

In Figure 9, we plot the three most common sentiment flow patterns in the training set of the ArguAna TripAdvisor corpus (with self-created annotations) as well as the respective patterns in the movie reviews

of *Author c* and *Author d* for each possible sentiment score. In total, we found 38 sentiment flow patterns in the hotel reviews, meaning that a4 consists of 38 features in this case. As depicted in Figure 9(a), they are constructed from the local sentiment flows of up to 226 texts. One of the 75 patterns of *Author c* results from 155 flows, whereas each of the 41 patterns of *Author d* represents at most 16 flows.

With respect to the depicted sentiment flow patterns, the movie reviews show less clear sentiment but more changes of local sentiment than the hotel reviews. While there appears to be a certain similarity in the overall argumentation structure between the hotel reviews and the movie reviews of *Author c*, two of the three patterns of *Author d* contain only little clear sentiment at all, especially in the middle parts. The disparity of the *Author d* dataset is additionally emphasized by the different proportions of opinions in the evaluated text corpora. In particular, 79.7% of all statements in the ArguAna TripAdvisor corpus are opinions, but only 36.5% of the sentences of *Author d* are classified as subjective. The proportions of the three other movie datasets at least range between 58.4% and 66.5%. These numbers also serve as a general explanation for the limited accuracy of a1, a2, and a4 in the movie domain.

A solution to achieve higher accuracy and to further improve the domain robustness of the structure-based argumentation features might be to construct flow patterns from the subjective statements or from the changes of local sentiments only, which we leave for future work. Here, we conclude that our novel feature type a4 does not yet solve the domain dependency problem, but it still defines a promising step towards a more domain-robust sentiment analysis.

6 Conclusion

Text classification tasks like sentiment analysis are domain-dependent and tend to be hard on texts that comprise an involved argumentation, such as reviews. To classify the sentiment scores of reviews, we model a review's text as a composition of local sentiment, discourse relations, and domain concepts. Based on this shallow model of argumentation, we combine existing sentiment analysis approaches with novel features that capture the abstract overall argumentation structure of reviews irrespective of their domain and their linguistic style. In particular, we learn common sequences of local sentiment in reviews through clustering in order to then compare a given review to each of these learned *sentiment flow patterns*. Our evaluation on hotel and movie reviews suggests that the sentiment flow patterns generalize well across domains and it indicates the effectiveness of modeling argumentation. In addition, both the patterns and our model help to explain sentiment scoring results, as exemplified.

Due to errors in the preprocessing of texts, some obtained effectiveness gains are rather small, though. In the future, we seek to develop features that are less affected from preprocessing. A promising variation in this respect is e.g. to learn patterns based on the changes of local sentiment only. Also, we plan to analyze common sequences of discourse relations in order to capture the argumentation structure of a text in an even more domain- and language-independent manner. By that, we contribute to the general research on robust and explainable text classification. As outlined in Section 3, many text classification tasks can profit from modeling argumentation. For this purpose, other types of statements, relations, and domain concepts will be needed as well as, in some cases, a deeper argumentation analysis.

Abstract

Genre classification has been found to improve performance in many applications of statistical NLP, including language modeling for spoken language, domain adaptation of statistical parsers, and machine translation. It has also been found to benefit retrieval of spoken or written documents. At its base, however, classification assumes separability. This paper revisits an assumption that genre variation is continuous along multiple dimensions, and an early use of principal component analysis to find these dimensions. Results on a very heterogeneous corpus of post-1990s American English reveal four major dimensions, three of which echo those found in prior work and the fourth depending on features not used in the earlier study. The resulting model can provide a basis for more detailed analysis of sub-genres and the relation between genre and situations of language use, as well as a means to predict distributional properties of new genres.

1 Introduction

Although a precise definition of the term "genre" has traditionally proven to be elusive, it cannot be disputed that a genre represents a set of *shared regularities* among written or spoken documents that enables readers, writers, listeners and speakers to signal discourse function, and that conditions their expectations of linguistic form. Genre distinctions are therefore an important aspect of language use and understanding. They clearly have a role to play in statistical language processing, which relies on regularities of form as well as content. Indeed, with the advent of the Web, statistical methods for genre differentiation have been applied to information retrieval to limit search criteria and organize results (Karlgren and Cutting, 1994; Kessler et al., 1997; Mehler et al., 2010; Ward and Werner, 2013), and the study of genres on the web has become a sub-field in its own right (see for example (Mehler et al., 2010)). More recently, the development of genre-dependent models for a variety of natural language processing (NLP) tasks such as parsing (Ravi et al., 2008; McClosky et al., 2010; Roux et al., 2012), speech recognition (Iyer and Ostendorf, 1999), word sense disambiguation (Martinez and Agirre, 2000), and machine translation (Wang et al., 2012) has been found to significantly improve performance. The ability to match documents by genre has also become important for collecting data to train language models for spoken language understanding, given the difficulty of creating large repositories of transcribed spoken language corpora (Bulyko and Ostendorf, 2003; Sarikaya et al., 2005).

Proceedings of COLING 2014, the 25th International Conference on Computational Linguistics: Technical Papers, pages 565–576, Dublin, Ireland, August 23-29 2014.

While the utility of document characterization by genre for empirical language analysis is widely acknowledged, there is relatively little agreement on methodology. In part, this stems from the difficulty of providing a comprehensive list of genres or even an operational definition of what constitutes a distinct genre, much less a definitive set of features to characterize genre differences. The earliest large-scale statistical study of genre is that of Biber (Biber, 1988), who applied principal component analysis (PCA) to a one-million word corpus consisting of heterogeneous varieties of spoken and written discourse in order to identify multiple dimensions of variation in language. Biber argued that linguistic variation was continuous along six dimensions: involved vs. informational, narrative vs. non-narrative, explicit vs. situation-dependent reference, overt expression of persuasion, abstract vs. non-abstract information, and on-line information elaboration; he identified features associated with each dimension, and characterized kinds of discourse by joint assessment of similarities and differences across these dimensions. Interestingly, since Biber's study, there has been comparatively little investigation of how genres vary using multivariate distributional methods (see, for example, the discussion in (Kilgarriff, 2001)).

Biber's work, which was completed in the mid-1980's, relied on a large number of features extracted using somewhat *ad hoc* methods and reported no reliability measures. Given the renewed interest in genre classification and the increasing interest in automatic techniques to adapt NLP tools across different kinds of corpora, we feel it is worth subjecting Biber's thesis to a new test, utilizing state-of-the-art methods for extracting features from a high quality, very heterogeneous corpus. In addition to replicating Biber's basic approach with more reliable features, we include newer genres (e.g., email, blogs, tweets) in an attempt to verify that these methods can generalize over different kinds of data. We use a smaller feature set that overlaps with Biber's for the most part, but which also includes features unavailable in the earlier work. In our set, each feature was identified using freely available NLP tools and was manually validated. In our use of different features, our experiment constitutes a strong test of Biber's claim that the dimensions of variation he identified arise from underlying constraints on usage. We find three components similar to his, and a new one he did not find, based on our use of Named Entity features. We find that genres that are separable on one component are often co-extensive on another. To quantify the distinctiveness of each of the genres relative to the others, we use a metric that has previously been used to measure separability of classes.

2 Related work and motivation

Our work builds on Biber's 1988 study, but differs in the corpus and features used. Biber's corpus and MASC (Ide et al., 2010), the corpus used in our study, differ in source language (British English versus American English), time coverage (skewed towards a single year versus three decades), and the situations of use. Biber's corpus was drawn from the Lancaster-Oslo-Bergen (LOB) Corpus of British English, consisting of works published in 1961, the London-Lund corpus of spoken English, consisting of 87 texts of British English from private conversation, public interviews and panel discussions, telephone conversations, radio broadcasts, spontaneous speeches and prepared speeches produced in the 1970s. To these Biber added a collection of his own professional and personal letters. MASC represents a larger time slice (1990s to present) and is more heterogeneous, including a wider range of traditional genres as well as new social media (email, blogs, twitter) and collectively generated fiction (ficlets). We take advantage of MASC's rich set of validated annotations to include features that would not have been (easily) available at the time of Biber's study, and reconsider the use of some features used in his work.

Some work on genre classification contrasts with Biber's approach, which assumes that documents fall discretely into distinct classes or clusters. Genre classification has been treated as a standalone task (Karlgren and Cutting, 1994; Kessler et al., 1997; Feldman et al., 2009; Stamatatos et al., 2000a; Santini, 2004), or combined with topic classification (Rauber and Müller-Kögler, 2001; Lee and Myaeng, 2002). All of these studies assume that documents fall discretely into distinct classes or clusters. These studies vary in their approach to determining the genre of text, either by using corpora with pre-defined classes (Karlgren and Cutting, 1994), manually refining pre-existing classes (Kessler et al., 1997), creating genre classes using annotators, or locating *a priori* classifications (e.g., web product reviews). The feature sets in genre studies have remained rather stable over the past three decades, mostly utilizing word-based

features similar to many of Biber's such as individual lexical items and/or their orthographic characteristics (e.g., contractions), part-of-speech (POS), punctuation (Kessler et al., 1997; Stamatatos et al., 2000b), derivative statistics (e.g., average word/sentence length, ratios among lexical or POS classes), and POS-ngrams (Santini, 2004; Feldman et al., 2009).

Karlgren and Cutting (1994) apply discriminant analysis to pre-defined classes from the Brown corpus using easily identifiable information such as POS counts, type/token ratios, and sentence length. They achieve relatively low accuracy of 52%. Kessler et al. (1997) also use the Brown corpus and classify documents into three facets: brow, narrative, and genre. They extract 55 features, avoiding features at the syntactic level that are computationally expensive to identify, and characterize them as lexical, character-level, and derivative (log ratios and their sums). They achieve nearly 80% accuracy on their six *genre* classes (reportage, editorial, scitech, legal, non-fiction, fiction). Feldman et al. (2009) create a corpus of eight genres of speech and web text and test an approach to factor documents by genre, formality and number of speakers. They achieve accuracy of 55% using quadratic discriminant analysis on a representation consisting of features based on POS tags, words, and punctuation, reduced using PCA. Santini (2004) applies high-dimensional POS trigram vectors to ten BBC genres (four spoken, six written) with Naïve Bayes classification. A document representation using a length-835 vector achieves 82.6% accuracy for 10-fold cross-validation on all 10 genres, and a Kappa agreement of 0.80.

Rauber and Müller-Kögler (2001) apply self-organizing maps (Kohonen, 1995) for both topic and genre clustering, using features typical of readability measures (e.g., sentence and word lengths, punctuation frequency). Lee and Myaeng (2002) address classification of web text and also do simultaneous genre and subject (topic) classification, using a Naive Bayes learner. Tests on seven genres for both English and Korean achieve 0.80 micro-averaged f-measure or 0.87 cosine similarity.

More recent work finds good performance from the use of ngram features for words, characters and part-of-speech (Gries et al., 2009; Kanaris and Stamatatos, 2009; Sharoff et al., 2010). Gries et al. (2009) relies only on word ngrams of various lengths to produce clusters with high maximum average silhouette width, where higher widths represent more homogeneous clusters that are more distinct from one another. They find that trigrams do best. Kanaris and Stamatatos (2009) uses frequently occurring character ngrams without regard to their discriminatory power, and Sharoff et al. (2010) find that character ngrams outperform word and pos ngrams. On benchmark corpora with from 4 to 8 genres, the latter two works achieve accuracies of up to 96-97% on some corpora. They assume that genres can be taken as a given, although Sharoff et al. (2010) note that chance-corrected human agreement on the gold standard is only moderate.

Another strand of investigation addresses genre variation as a requirement for achieving better performance in new domains, as in language modeling for speech applications (Bulyko and Ostendorf, 2003; Sarikaya et al., 2005) or statistical parsers applied to text (Ravi et al., 2008; McClosky et al., 2010; Roux et al., 2012), where downstream applications can include assignment of semantic argument structure. Bulyko and Ostendorf (2003) select web text for class-based n-gram language modeling. They locate relevant documents using queries representative of conversational speech, rather than characterizing the documents as a whole in terms of statistical features, but demonstrate a significant reduction in Word Error Rate (WER) for their enhanced language models. Sarikaya et al. (2005) achieve even higher improvements using a similar query methodology, then use BLEU scores, a machine translation similarity method (Papineni et al., 2002), to find sentences that are closest to a domain sample. Ravi et al. (2008) propose a method to predict parser accuracy based on properties of the new domain of interest and properties of the domain on which the parser was trained. Lexical features for words other than the 500 most frequent were found to generalize less well than features such as POS and sentence length. Subsequent work models corpus differences using regression models to predict parser accuracy McClosky et al. (2010), or incorporates explicit genre classifiers Roux et al. (2012).

In our initial exploration of genre variation in MASC, we exploited a set of features that subsume most of those discussed in the works reviewed above. We applied a variety of methods, including k-means clustering, discriminative classifiers such as Naïve Bayes, and PCA. Through comparison of results, we discovered that classification had variable performance, and that PCA provided an explanation: docu-

ments from distinct classes often fell within an identifiable region on one or more dimensions discovered by PCA, but these regions overlapped one another along other dimensions. We concluded that whether or not a set of documents can be categorized into relatively distinct classes by their linguistic forms rather than content depends on how the documents are selected, how the classes are defined, and what features are used. Our goal here is to refine a method to learn key dimensions of variation relevant for the same types of applications referenced in work on genre identification, as discussed in Section 7.

3 Corpus and data preparation

MASC is a 500,000 word corpus of post 1990s American English comprised of texts from nineteen genres of spoken and written language data in roughly equal amounts, shown in Figure 1a). Roughly 15% of the corpus consists of spoken transcripts, both formal (court and debate) and informal (face-to-face, telephone conversation, etc.); the remaining 85% covers a wide range of written genres, including social media (tweets, blogs). The annotation types and coverage in MASC are given in Figure 1b); all MASC annotations are hand-validated or manually produced. The corpus is fully open and freely available.[1]

To prepare the data, we developed a framework in Groovy[2] (a dialect of Java) to extract linguistic features, using version 1.2.0 of the GrAF API[3] to access the MASC data and annotations. Most texts in MASC comprise complete discourse units, e.g. full conversations, letters, chapters from a book, etc., with the exception of tweets, jokes, and (to some extent) ficlets.[4] As shown in Figure 1a), although each MASC genre contains roughly 25,000 tokens, the number of texts in any given genre varies widely, from as few as two to over 100. To standardize the number of data points per genre, the texts in each genre were concatenated and then divided into samples of even length, rounded to the nearest sentence boundary. Portions of the texts containing email headers, bibliographic references, and computer code, which contain an excess of certain punctuation and other special characters, were eliminated prior to creating the samples.

Initially, we created sample sets consisting of 1,000 tokens per sample,[5] motivated by Biber's observation that even rare linguistic features are relatively stable across samples of this size (Biber, 1993). Our

[1] MASC is downloadable from http://www.anc.org/data/masc and available from the Linguistic Data Consortium (LDC).

[4] Ficlets are story fragments to which "prequels" or "sequels" are added by online participants.

[5] We use tokens as the unit of analysis rather than blank-separated words (strings), which, given the MASC tokenization strategy, means that hyphenated words such as "able-bodied" and possessive markers (*'s*) are treated as individual tokens.

(b) Boxplots of the 37 features: the box shows the range of the 25th to 75th percentiles with the median value identified by the vertical red bar. The black whiskers show the extreme values not considered outliers, and the red are the outliers. The most extreme outliers of feature 21 were dropped to save space.

Figure 2: Feature names and boxplots

experiments showed, however, that for the features used here, results were comparable using 500-token chunks, which enabled us to work with a set of data points of the same size as Biber's. Our process generated 965 500-token chunks, with roughly 50 chunks per genre.

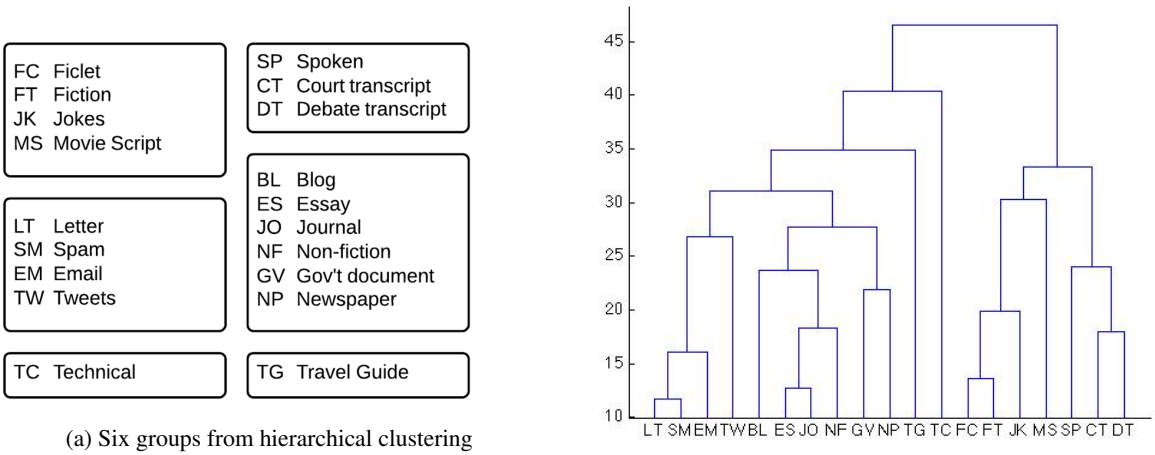
4 Features and feature analysis

Biber used sixty-seven features consisting primarily of lexical items and groups, parts of speech, and quasi-syntactic features such as coordination, negation, relative pronoun deletion, *that*-clauses, and so on. Many of the features in our set overlap with Biber's, but we also exploit annotations in MASC to provide additional features. All the MASC annotations have been manually validated, including those produced by automated tools such as POS-taggers, NE recognizers, and shallow parsers.

PCA is appropriate for data with normally distributed values and can be used to reduce the number of features to include only those that are the least correlated. It highlights features with the greatest variation. Figure 2b) shows boxplots of thirty-seven features we began with. These are mainly frequencies normalized by the total token count in the document samples we created. They also include the average characters per word, and average tokens per sentence, noun chunk, and verb chunk. Figure 2a) lists the features by number. Features 21, 23, 28 and 36, which are foreign words, interjections, suasive verbs and exclamations, have median values (red line within the box) near the 25th percentile, so are highly skewed. We therefore dropped these and carried out the PCA with the remaining thirty-three.[6]

Hierarchical clustering of the dataset by MASC genre yields the dendogram in Figure 3. We used the city block metric (also known as taxicab distance), which is similar to Euclidean distance but less sensitive to outliers. The legend identifies six major clusters for the 19 genres, with two singletons (Travel guides and Technical documents), a cluster with three spoken genres (Court and Debate transcripts, and transcripts of face-to-face and telephone conversations), two four-genre clusters, and one six-genre

[6]To insure comparability of feature influence, all our features were re-scaled in [-1,1] with mean 0.



(a) Six groups from hierarchical clustering

(b) Hierarchical clustering

Figure 3: Hierarchical clustering of 19 MASC genres

cluster. These larger clusters consist of "story-telling" genres (ficlets, fiction, jokes and movie scripts), offline-interactive genres (letters, spam, email and tweets), and discursive text (blog, essay, journal, non-fiction, government documents, and news). Thus the distribution of our features across the data predict groupings that correspond well with our intuitions about the genres defined in MASC, providing some justification for both our feature selection and the genre assignments in the corpus. The groupings also reflect several of Biber's dimensions of variation, as discussed in Section 7.

Here, we describe PCA in general terms to present four principal components identified in our analysis. We focus on features associated with the components, and on the six MASC document clusters.

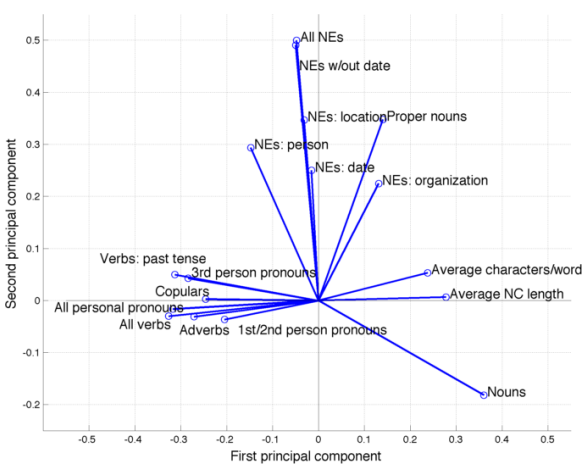
PCA starts with a covariance matrix of all features: a square matrix where each cell value is the covariance of feature x_i with feature x_j for $i, j \in M$. Covariance of x_i, x_j is analogous to variance: for all datapoints $n \in [1 : N]$, you subtract x_{i_n} from $\overline{x_i}$, x_{j_n} from $\overline{x_j}$, sum the products of these differences, and normalize by n-1.[7] A common explanatory visualization will show a scatterplot of hypothetical data values in a sausage shape at a diagonal to the x-axis. A line along the maximum width of the sausage represents the dimension of greatest variation. A second axis can be placed orthogonal to this first component; it will account for less of the variance in the data, and in a different direction. PCA consists of computation of these axes (eigenvectors) from a covariance matrix.

5 PCA results

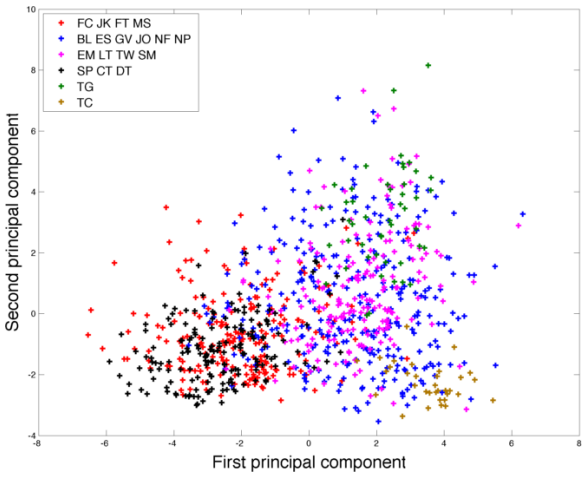
Figure 4a) shows a plot of our first principal component by the second component and the features that contribute most to each, based on the features' loadings (weights) on the new components. The components are rotated to become the new x,y axes and centered at zero. Projection of the individual features onto the rotated axes shows which features contribute most directly to each dimension. Figure 5a) shows a similar plot for the third and fourth components. Twenty-seven features have loadings of at least 0.2 on any component. Many have similar loadings (e.g., commas and prepositions on the fourth component), indicating the data could be represented with fewer, uncorrelated features.

Past tense verbs, copula verbs, personal pronouns, and adverbs load heavily on one pole of the first principal component, while characters per word, noun chunk length and nouns load higher on the opposite pole. This component corresponds rather well to Biber's first component, which had similar loadings for personal pronouns, adverbs, nouns and word length, and which he interpreted as *involved versus informational*–i.e., interactive, unplanned, primarily spoken data vs. polished written documents conveying (sometimes dense) information about a given topic.

[7] See any text on covariance for an explanation of why n-1 is a better normalization term than n.

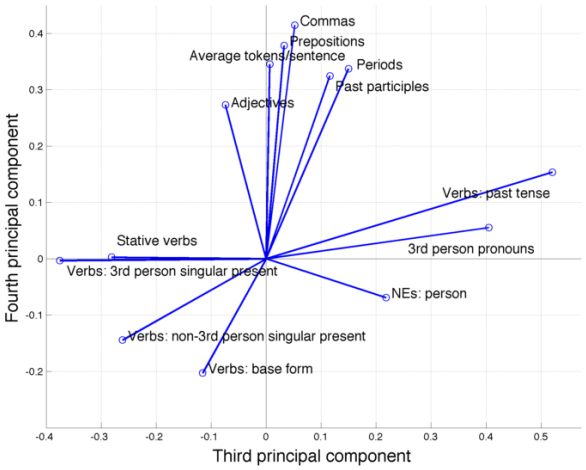


(a) First and second principal components

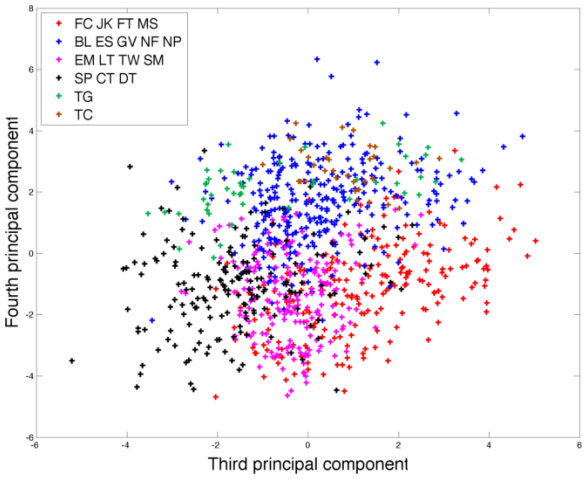


(b) Document regions for components one and two

Figure 4: First and Second Principal Components



(a) Third and fourth principal components



(b) Document regions for components three and four

Figure 5: Third and Fourth Principal Components

Our second principal component is defined almost entirely by the contrast between NEs and common nouns. It corresponds to none of Biber's components; he had no NE features. Our third component has loadings from 3rd person present tense verbs (and other verb forms) at one end, and past tense verbs, third person pronouns, and person NEs at the other. It corresponds to Biber's second component, which had similar loadings for past tense verbs and third person pronouns, and somewhat less for present tense verbs. He interpreted this dimension as representing the variation from non-narrative to narrative.

Our fourth component corresponds to Biber's fifth, which he characterized as abstract versus non-abstract. At one extreme we have commas, prepositions, sentence length (in tokens) and past participles, with base verbs loading to some degree on the other extreme. The features loaded on Biber's fifth component were conjuncts, which might correlate with longer sentence length, past participles, and agentless passives. In the corresponding scatterplots (Figures 4b and 5b), each datapoint (document chunk) has been color-coded according to the six clusters found in the preceding section. There are clearly distinct regions along the first component for spoken interactions (black), story telling (red), offline interaction (pink) and discursive (blue), but with a great deal of overlap. Travel guides (green) and technical (gold) are at the blue extreme, but at different locations along the second dimension. Moving from left to right in Figure 4b), each next color has greater dispersion along the second component, apart from green and gold, which have clearly separate locations from each other, at the top and bottom,

	Story telling	Discursive	Offline Interaction	Spoken Interaction	Travel Guide	Technical
Story Telling	0.00	0.23	0.13	<u>0.06</u>	0.63	0.91
Discursive	0.23	0.00	0.21	0.24	0.15	0.35
Offline Interaction	0.13	0.21	0.00	0.07	0.57	**1.07**
Spoken Interaction	<u>0.06</u>	0.24	0.07	0.00	0.68	0.88
Travel Guide	0.63	0.15	0.57	0.68	0.00	0.78
Technical	0.91	0.35	**1.07**	0.88	0.78	0.00

Table 1: Mean Bhattacharyya Distance of all Genre Pairs using PCA Scores

respectively. In Figure 5b), the overall dispersion is more even across both dimensions, with separate centers for each of the four major colors (black, pink, red and blue), but again without sharp separation.

6 Genre Distance Measurement

A metric that summarizes how separable a pair of genres are in the defined PCA space would be more convenient than the visualizations in Figures 4b and 5b. Bhattacharyya distance, which measures the similarity of two discrete or continuous probability distributions, has been used in image segmentation and signal selection, to minimize the probability of misclustering for segmentations (Coleman and Andrews, 1979), or the probability of misclassifying different signals (Kailath, 1967). Here we illustrate its use in summarizing the separability of a pair of genres across the four principal components.

In statistics, the Bhattacharyya distance measures the similarity of two discrete or continuous probability distributions. It is closely related to the Bhattacharyya coefficient, which measures the amount of overlap between two statistical samples or populations.

The Bhattacharyya coefficient for two continuous probability distributions $p(x)$ and $q(x)$ is:

$$\text{Bhattacharyya coefficient} = \rho = \int_C \sqrt{q(x)p(x)}dx$$

Where C is the domain of probability density $p(x)$ and $q(x)$. The Bhattacharyya coefficient takes on values in [0,1]. Bhattacharyya distance maps the Bhattacharyya coefficient to [0,∞]:

$$\text{Bhattacharyya distance} = B = -\ln \rho$$

We take the mean Bhattacharyya Distance of a pair of genres across all four components as a summary measure of seprability. As an illustration, consider the two clusters of offline interaction (pink) and discursive text (blue) from Figures 4b) and 5b). Their Bhattacharyya Distances on the first through fourth components, using the PCA scores, are: 0.05, 0.01, 0.14, 0.63. They have the largest distance on the fourth component, the axis of abstract vs non-abstract, which is consistent with the visualizations. The summary statistic is then the mean of the four individual distances: 0.21.

Table 1 gives the mean Bhattacharyya Distance of each pair of genres for the four components. The pair of genres that is the closest on all four components is story telling and spoken interaction (0.06; underlined). The pair that is the most distant on all four components is technical and offline interaction (1.07; in bold). Bhattacharyya Distance can also be computed for each pair of genres using the original normalized feature values. In three cases the Bhattacharyya Distance in the PCA space is the same as in the original feature space, but in all other cases the Bhattacharyya Distance is much greater.

7 Discussion

Strong patterns of similarity in dimensions of variation across many genres of English emerge from our comparison with Biber's study, despite differences in the features used, the contrast between American and British English, and the use of new media types. The results support the view that relatively stable dimensions of variation arise from properties of the situations of use across varieties of English. This applies as well to genres that did not exist in Biber's time (email, twitter, spam), which group with the interactive genre included in Biber's corpus (letters) and are similar to other offline discourse despite representing an interactive form–albeit an "offline interactive" form–of discourse.

A significant departure from Biber's results concerns the component defined primarily by Named Entities (NEs), which emerges as the second strongest dimension of variation in our study. This demonstrates that additional features–in particular, features beyond those based on orthographic and morpho-syntactic properties that have figured in most genre studies to date–can dramatically impact Biber's original model and extend the range of properties that can characterize particular text types. It also suggests that higher-level linguistic properties and other more complex features can contribute substantially to genre characterization and discrimination, a topic we plan to pursue in the future.

In what follows, we discuss similarities and differences in the two PCA analyses, the conclusions this leads to regarding the feasibility of genre classification, and ways in which the analysis can support retrieval, language modeling, and domain adaptation.

Our first principal component is very similar to Biber's first factor, which he interpreted as differentiating situations of use with more of an informational focus from those with an interactive or affective function. In addition, he noted a contrast between *online* and *offline* production–i.e., spoken vs. written production modes. The heavily loaded features the two analyses have in common are consistent with the interpretation: 1st/2nd person pronouns, many verb features, and adverbs are at one pole, with word length and nouns at the other. He claimed that this distinction *is obviously a very powerful factor . . . not an artifact of the factor extraction technique*, meaning that it arises from differences between the demands of face-to-face, online interaction and those of offline, expository discourse. Having found a very similar dimension using different (correlated) features, we agree with this claim. Figure 4b) shows that the spoken interaction documents in MASC fall on the "involved" side of this dimension, while expository texts fall on the "informational" side.

Interestingly, the genres that did not exist in Biber's time (email, twitter, spam) group with the interactive genre included in Biber's corpus (letters), and they are similar to other offline discourse despite representing an interactive form–albeit an "offline interactive" form–of discourse. This provides a strong argument for the validity of the first component and its link to underlying situational factors of language use. In Figure 4b), the hypothetical centroid of the pink (offline interactive) region seems somewhat less to the right on the x-axis than a corresponding centroid for the blue (expository) set, but the pink and blue are relatively co-extensive, and in particular, are clearly separated from both the black (face-to-face online interaction) and red (storytelling) genres. This makes intuitive sense, as storytelling genres often depict face-to-face interaction ("so the elephant says to the camel"), and therefore mimic its immediacy.

Our second principal component is defined primarily by Named Entities (NEs), which has no correlate in Biber's study; his features included proper nouns but not NEs. Person NEs load with past tense verbs and third person pronouns on our third component, which resembles Biber's narrative dimension. Most of the MASC genres seem to be dispersed all along our second dimension, suggesting that NE frequency varies across texts in these genres; the exception is travel guides, which consistently include larger numbers of NEs. The explanation here is less on production constraints than on function, as travel guides survey geographical points of interest, historical monuments and persons, hotels and restaurants, and so on.

As noted in Section 5, our third component is very similar to Biber's second (narrative versus non-narrative), and our fourth is somewhat similar to Biber's fifth (abstract versus non-abstract). Note that the fourth dimension shows a greater separation of expository (blue) and offline-interactive (pink) genres, which substantially overlap on the first dimension. This provides a good example of how the 4-dimensional visualization provided by the scatterplots reveals potentially very different relations among genres across the components, which in turn explains why fixed definitions of genre are difficult, if not impossible, and why genre classification can be hard to achieve. We observe that the genre classes can be more or less separable on one dimension but not another. As another example, travel guides and technical documents are at distinct locations on the second component, but span the same locations on the first.

This lack of separability on one or more dimensions is true for nearly all pairs of our six genre classes, as well as for any pair of dimensions. This suggests that an application that requires genre classification could use PCA to find dimensions of variation that lead to the best separation, and summarize the separability using the mean Bhattacharyya distance. As the number of genres one needs to classify increases,

it could be that the number of orthogonal dimensions required to lead to the best separation might also increase. In Table 1, for example, with the exception of the row for Discursive Text, all rows have at least one cell with a value close to or above 0.80, indicating that each of the six genres can be clearly separated from at least one other genre. We would predict that Discursive Text would be the most difficult to classify using genre features alone.

The strong similarities among the major components in Biber's study and ours support the view that genre variation is continuous along multiple dimensions due to contextual properties such as cognitive constraints, interactivity, and function. As such, we view the dimensions as arising from observable properties of discourse situations. Given a new genre, it should be possible to predict where it would be located in the PCA space defined here. We would predict that chats, for example, would pattern more closely with face-to-face interaction than with offline interactive genres. The same methodology could be applied to a sub-genre, such as the discursive texts, to discover more specific dimensions to differentiate among them.

Because language use changes over time, and new genres arise, we do not view the 4-dimensions as a definitive representation of genre space. We do, however, envision a concrete application of this particular representation, namely to measure corpus similarity in a multivariate fashion. Because our PCA analysis makes it possible to locate new documents in the defined space, it would be possible to identify which MASC documents a new set of documents is most similar to. PCA scores could be computed on the four dimensions for corresponding features in the new documents. This approach could be used in any application where it is desirable to find similar documents, such as retrieval, language modeling, or domain adaptation. For example, in recent work on domain adaptation of parsers, McClosky et al. (2010) present a confusion matrix with six corpora to demonstrate how performance of a Charniak parser (Charniak, 2000) varies depending on which corpus it is trained on. They assume that a new target domain will be a mixture of their six source domains and build a simple regression (three features) to predict which of the six parsers will perform best on a new corpus. They subsequently state that an alternative approach could use a high-dimensional vector space to compare corpora. Inspired by this suggestion, we are currently developing a web service that will allow researchers to locate their corpora in the 4-dimensional space identified in this study, and to compute the values of their PCA scores. This would make it possible to use Bhattacharrya distance as described in Section 6 to measure the similarity of corpora in genre space, which could be quite relevant for adapting parsers or other NLP tools. This contrasts with the similarity measures used in Ravi and Knight (Ravi et al., 2008) and McClosky (McClosky et al., 2010), which are based on lexical features.

8 Conclusion

Using a relatively small set of under three dozen features to represent the linguistic forms in discourse, PCA reveals four principal components of variation in a very heterogeneous corpus of post 1990s American English that are comparable to those identified in Biber's work, as well as additional dimensions based on features not included in that earlier study. Six genres derived from the MASC corpus using hierarchical clustering are separable on some but not all components. These differences in separability potentially explain the variations in performance across different works that do genre classification. The resulting 4-dimensional genre space provides a basis for more detailed analysis of sub-genres, for a better understanding of the relation between genre and situations of language use, and for predicting the distributional properties of new genres. In future work, we plan to build on this basis to develop an increasingly detailed and, at the same time, generalizable characterization of genre.

Our results depict a *big picture* for how discourse in English varies with respect to style or form, and how different genres are conditioned by aspects of the situations of language use. We believe that exploration of genre in these terms can provide a more viable approach to measuring distinctions among texts than the approach used in most recent work, and can provide a more informed basis to incorporate genre distinctions in information retrieval, language modeling, and domain adaptation for statistical NLP.

Abstract

We present a cross-lingual discourse relation analysis based on a parallel corpus with discourse information available only for one language. First, we conduct a corpus study to explore differences in discourse organization between Chinese and English, including differences in information packaging, implicit/explicit discourse expression divergence, and discourse connective ambiguities. Second, we introduce a novel approach to learning to recognize discourse relations, using the parallel corpus instead of discourse annotation in the language of interest. Our resulting semi-supervised system reaches state-of-art performance on the task of discourse relation detection, and outperforms a supervised system on discourse relation classification.

1 Introduction

The analysis of the way spans of text semantically connect with each other to create a coherent text has a rich theoretical and empirical tradition (Mann and Thompson, 1988; Marcu, 1997; Di Eugenio et al., 1997; Allbritton and Moore, 1999; Schilder, 2002). Because of the difficulty in annotation, however, labelled datasets were rare and rather small.

The release of the Penn Discourse Treebank (PDTB) (Prasad et al., 2008) brought about a new sense of maturity in discourse analysis, finally providing a high-quality large-scale resource for training discourse parsers for English. Based on the PDTB, a number of studies have provided insightful analysis of the use of discourse connectives in English news text and have developed methods for the identification of discourse relations and their arguments (Wellner and Pustejovsky, 2007; Pitler et al., 2008; Pitler and Nenkova, 2009; Pitler et al., 2009; Lin et al., 2009; Prasad et al., 2010; Park and Cardie, 2012; Lin et al., 2014). Some have applied the insights and classifiers to standard natural language processing tasks such as assessing text coherence and text quality (Pitler and Nenkova, 2008; Lin et al., 2011), detecting causal dependencies of events (Do et al., 2011), and machine translation (Meyer and Popescu-Belis, 2012).

A resource like the PDTB is extremely valuable, and it would be desirable to have a similar resource in other languages as well. Following the release of the PDTB, smaller corpora annotated with discourse relations have been developed for Hindi (Oza et al., 2009), Turkish (Zeyrek and Webber, 2008), Arabic (Al-Saif and Markert, 2010), and the effort is on-going with Chinese (Zhou and Xue, 2012).

On the other hand, for the vast majority of languages, such well-annotated resource for discourse relations is not available. In our work we carry the valuable annotations in the PDTB over to another language—Chinese—using parallel corpora. Projecting information available in one language onto another has been explored in areas such as part-of-speech tagging (Yarowsky et al., 2001; Das and Petrov, 2011), grammar induction (Hwa et al., 2005; Ganchev et al., 2009) and semantic role labeling (Pado and Lapata, 2005; Johansson and Nugues, 2006; van der Plas et al., 2011). For discourse relations, prior work has shown that a parallel corpus is helpful for disambiguating certain explicit discourse connectives (Meyer et al., 2011). To the best of our knowledge, the work we present here is the first study that directly infers discourse relations using resources only available in another language.

Proceedings of COLING 2014, the 25th International Conference on Computational Linguistics: Technical Papers, pages 577–587, Dublin, Ireland, August 23-29 2014.

The goal of our work is not only to measure the accuracy with which discourse relations can be identified in another language without annotations beyond the PDTB, but also to catalog the differences in discourse relation realization across different languages, Chinese and English in our case. We show that the two languages vastly differ in how information is packaged into a sentence, which also leads to differences in the implicit/explicit expression of discourse relations and the ambiguities in discourse connectives. These differences challenge the currently accepted distinctions between syntax and discourse between the two languages for applications such as machine translation. Then we present our semi-supervised learning algorithm to recognize explicit discourse relations in Chinese, relying solely on discourse information available in English. For multiway classification, our system outperforms a supervised system trained on the existing pilot dataset of discourse relations in Chinese (Zhou and Xue, 2012). In the task of binary classification for identifying specific discourse relations, the performance of our system is within 4% accuracy of that of the supervised system for all but one relations.

2 Data

As our parallel corpus, we use the newswire portion of the GALE Chinese-English Word Alignment and Tagging Training corpus (parts 1 and 2). The corpus contains 2,175 newswire articles, corresponding to 6,255 translation segments with 248,999 Chinese characters. These articles were translated into English by human translators. Gold standard word alignments are available for this corpus. A *minimal match* alignment approach (Li et al., 2010) was adopted for creating the gold standard, namely, alignments are between an English word and only the necessary Chinese *characters*. We repurpose this resource created for machine translation research for our cross-lingual discourse analysis. The availability of manual alignments between Chinese discourse connectives and their English translation makes it possible to conduct a reliable analysis by focusing on actual cross-lingual divergences, without noise introduced by potential errors from automatic aligners. [1]

We use a highly accurate supervised classifier for English explicit discourse relations (Pitler and Nenkova, 2009)[2] to automatically annotate the English portion of the GALE parallel corpus. The classifier was trained on the PDTB to identify discourse relations explicitly signaled by a set of 100 discourse connectives such as *however, because, while* or *for example*. For each instance of the 100 words or expressions, the classifier predicts if the expression is used as a discourse connective or if the instance is a non-discourse connective sense of the phrase or word. For each instance predicted to be a discourse connective, the classifier identifies the discourse relation signaled by the connective: TEMPORAL, COMPARISON, CONTINGENCY or EXPANSION. In our work we predict the same five categories for Chinese expressions which can serve as discourse connectives.

For evaluation and the study of discourse connective ambiguities, we use a development set from the Chinese Discourse Treebank (CDTB) (Zhou and Xue, 2012) consisting of 170 documents[3]. In the CDTB, an annotation style similar to the PDTB is applied on the texts from the Chinese Treebank corpus (Xue et al., 2005). For a discourse connective, one of eight discourse relation senses is annotated. All of these classes are subsumed by the four top-level relations in the PDTB. We map them to the PDTB relation senses according to their definitions:

Alternative → Expansion; Causation → Contingency; Conditional → Contingency; Conjunction → Expansion; Contrast → Comparison; Expansion → Expansion; Purpose → Contingency; Temporal → Temporal.

3 Information packaging characteristics

The notion of sentence in Chinese is very different from that in English. Punctuation marks were introduced in the early 20^{th} century; sentences resemble more a collection of related information than structurally well-defined syntactic units as in English. In fact, commas are often ambiguous, signaling

[1] While cross-lingual projection could be directly applied to automatic word alignments, discourse relation analysis raises some specific challenges because the main target of analysis (discourse connectives) are function words, which do not have as much of an impact on the final analysis in applications focusing on content words. As a result, we exclusively use manual alignment links in this study, and will address issues raised by automatic alignments in future work.

[2] The classifier is available at http://www.cis.upenn.edu/∼epitler/discourse.html

[3] This is an on-going annotation project. We are grateful to the authors for providing us with their valuable development set.

	% data	avg-length	std-length
1-many	18.83	61.42	28.85
1-1	81.17	35.73	25.34

Table 1: Percentage, length and standard deviation of sentences for which one Chinese source sentence is translated into one (1-1) or multiple (1-many) English sentences. Length is calculated based on the number of Chinese characters.

either clausal subordination, coordination or end-of-sentence (as construed from an English-centric point of view). Automatic systems have been developed to disambiguate the function of commas (Jin et al., 2004; Xue and Yang, 2011). This is a rather interesting phenomenon for discourse processing, as the English equivalents of Chinese sentences are in fact multi-sentential discourses in English.

The GALE corpus allows us to examine how often this mismatch of discourse organization occurs. Here we look for Chinese source sentences that were translated into multiple English sentences by the human translators. Consider the following example in which the corresponding clauses on both sides are numbered and marked in square brackets:

source [近年来“救灾外交”、“救灾援助”等新名词不断出现]$_1$，[各国围绕救灾问题展开了暗中的竞争与较量]$_2$，[一些国家谋求以救灾为名成立各种国际联盟]$_3$。

ref [In recent years, new phrases such as “disaster relief diplomacy” and “disaster relief aid” have appeared constantly]$_1$. [In relation to the issue of disaster relief, all countries have been silently competing with one another and comparing offerings]$_2$. [Some countries are trying to establish various kinds of international alliance in the name of disaster relief]$_3$.

In this example, the Chinese sentence packed the following related content into a single sentence: the occurrence of the new phrases about disaster relief, the competition among the countries related to disaster relief, and alliances in the name of disaster relief. The phrases expressing this information are separated by the commas in the source Chinese sentence because they are about a single concept “disaster relief”. However, this information needs to be partitioned into three different sentences, each with different subjects, when translated to English.

In the GALE corpus, we identified 1,178 (out of total 6,255) source sentences with reference translations containing more than one sentence. In other words, sentence/discourse mismatch between Chinese and English occurs for 18.83% of the data. Table 1 shows the portion of data involved in such mismatch, with percentage, mean and standard deviation of source sentence length. Not surprisingly, Chinese sentences that require multiple sentences in their English translation are much longer. These long sentences are fairly common, which suggests that the difference in information packaging is highly prevalent and could potentially affect key applications such as machine translation, where systems are trained on a sentence to sentence basis.

We will return to the discussion of this mismatch later, when we discuss how English and Chinese also appear to differ in the way discourse relations are signaled. Briefly, the issue is that relations that are explicit in one language may become implicit in the other, easily inferred by the reader but not marked by a discourse connective. Also, there is an increase in the sense ambiguity of discourse connectives related to EXPANSION relations in Chinese.

4 Implicit and explicit relations

In this section, we present two other differences between the two languages related to discourse organization. One is the need for a discourse relation expressed implicitly in one language to be expressed explicitly in another. The other is the difference of the ambiguity of discourse connectives across the two languages. Before the discussion of these interesting asymmetries, we first present the method for direct projection of discourse relations using the GALE gold standard alignments, which we use to gather a set of explicit discourse connectives in Chinese.

4.1 Direct projection

Thus far we have available a parallel Chinese/English corpus, discourse connectives automatically tagged with their senses on the English side and manual alignments of atomic units between English and Chi-

	Comparison	Contingency	Expansion	Temporal
CH/EN mismatch	63	109	360	195
all	551	469	1198	885
% data	11.43	23.24	30.05	22.03

Table 2: Numbers and percentages of Chinese/English implicit/explicit mismatches.

nese. So for each discourse connective in an English sentence, it is straightforward to identify the corresponding expressions in the Chinese sentence following the gold standard alignments. Then the aligned Chinese expression can be assigned a discourse tag—non-discourse use or one of the four main discourse relation types—which is the same as in the English translation. We call the resulting annotation on the Chinese sentences *discourse projection*.

Further we discard potential expressions of Chinese connectives if they occurred with the same part of speech only once in the entire corpus. The result is a list of a total of 118 Chinese discourse connectives harvested using direct projection.

4.2 Implicit or Explicit?

A discourse relation can be expressed either with an explicit connective (e.g. *however, since*), or implicitly without a connective, in which case the relation would have to be inferred by the reader. Languages may differ in how they express discourse relations.

We investigate such implicit/explicit mismatch using direct projection. Specifically, we study the cases in which an English discourse connective is not aligned to any part of its corresponding Chinese sentence. In this case, the human translator explicitly expressed a discourse relation that was implicitly conveyed in the corresponding Chinese sentence.

The following four examples illustrate a Chinese/English implicit/explicit mismatch for each of the TEMPORAL, COMPARISON, CONTINGENCY and EXPANSION relation, respectively. On the Chinese side we also mark the position of the inserted English connective.

source [当地时间4月27日]$_1$，[阿富汗首都喀布尔举行的抗击苏联入侵胜利阅兵式遭到袭击]$_2$，when$_{\text{TEMPORAL}}$ [阿富汗总统卡尔扎伊和其他政要慌忙撤离现场]$_3$。
ref [On april 27 local time]$_1$, [Afghan president Karzai and other important officials were forced to flee the scene]$_3$ [when$_{\text{TEMPORAL}}$ a military parade in Kabul, Afghanistan commemorating victory in the fight against the soviet invasion was attacked]$_2$.

source [但在目前普遍使用的十种语言中]$_1$，[阿拉伯语仅名列第四位]$_2$，while$_{\text{COMPARISON}}$[英语名列第一]$_3$。
ref [However, of the ten commonly-used languages today]$_1$, [Arabic only ranks fourth]$_2$, [while$_{\text{COMPARISON}}$ English ranks first]$_3$.

source ["中华航空"上海代表处首席代表董大伟告诉记者]$_1$："[现在的两岸包机还不是真正意义上的'直航']$_2$，since$_{\text{CONTINGENCY}}$[还需要经过香港飞行情报区]$_3$。"
ref [Tung Ta-Wei, head representative for China Airlines in Shanghai, told reporters]$_1$, "[presently, the cross-strait charter flights are still not 'direct flights' in the true sense of the term]$_2$, [since$_{\text{CONTINGENCY}}$ they still have to pass through the hong kong flight information region]$_3$. "

source [柳斌杰说]$_1$，[中国出版业下一个发展的重点将是参与国际竞争]$_2$，and$_{\text{EXPANSION}}$[今后双方可就此加大合作力度]$_3$。
ref [Liu Binjie said]$_1$, [a key area of development for the Chinese publishing industry will be participating in international competition]$_2$, [and$_{\text{EXPANSION}}$ in the future the two sides can strengthen their cooperation in this area]$_3$.

The first example is particularly interesting from a discourse point of view as it combines information ordering considerations along with the implicit/explicit expression of discourse relations: not only is the connective *when* missing in Chinese but the two arguments of the connective appeared in reverse order in the English translation of the sentence, with the comma omitted.

In Table 2, we show the numbers and percentages of Chinese/English implicit/explicit mismatches for each relation. We also list the ten connectives that are most frequently associated with the mismatch (i.e., were added to the reference translation), in the format of *connective (# mismatches)* below:

and (341), when (120), while (45), if (37), so that (29), but (23), after (22), so (22), as (21), then (18)

This analysis reveals that the EXPANSION relation is more likely to be implicitly expressed in Chinese, although in other relations this phenomenon is also present.

Connective	Senses	Connective	Senses
而	COMPARISON (7) EXPANSION (2)	又	CONTINGENCY (1) EXPANSION (1)
则	COMPARISON (1) EXPANSION (2)	在...同时	TEMPORAL (3) EXPANSION (2)
如	CONTINGENCY (1) EXPANSION (3)	同时	TEMPORAL (1) EXPANSION (1)

Table 3: Ambiguous Chinese connectives, according to manual annotations in the development CDTB.

A similar mismatch also happens when an English discourse connective is aligned to a punctuation mark in Chinese, illustrated in the following example, where the comma underlined in the source sentence was translated to *and*, thus to an explicit EXPANSION in English:

source [这个总队所属驻边境线中队]$_1$，[大都驻地偏远]$_2$，[自然条件艰苦]$_3$，[信息化建设比较滞后]$_4$。
ref [Most of the contingent's squadrons garrisoned along the border]$_1$ [are stationed in remote areas]$_2$ [where the natural conditions are rough]$_3$ [and$_{\text{EXPANSION}}$ the construction of informatization relatively lags behind]$_4$.

The insertion of the explicit discourse connective *and* makes the use of punctuation between "rough conditions" and "informatization" unnecessary in English. Through our direct projection we found 136 such implicit to explicit transformations with commas and 5 with semicolons. All of them are of the relation EXPANSION, further highlighting the differences in information packaging between the two languages.

4.3 Ambiguity of connectives

Although most of the English discourse connectives identified in the PDTB are not ambiguous, some of the most frequently used ones are (Pitler et al., 2008; Miltsakaki et al., 2008). For example, *while* can signal both TEMPORAL and COMPARISON relations; *since, as* can signal both TEMPORAL and CONTINGENCY relations. Discourse connectives in different languages have different ambiguities; prior work has shown that it is easier to disambiguate the sense of an ambiguous connective when parallel corpora are available (Meyer et al., 2011). The two languages analyzed in Meyer et al. (2011), English and French, are closely related European languages; here we investigate such differences in ambiguities between English and Chinese connectives.

Specifically, using the connectives collected from direct projection, we inspect the relations annotated for these connectives in the Chinese Discourse Treebank development set, and extract connectives such that the majority sense they signal constitutes less than 90% of their total occurrences. Unlike in English where the vast majority of ambiguities are between TEMPORAL and some other sense, we find that all such connectives in Chinese are ambiguous between some relation and EXPANSION. An example of ambiguity between TEMPORAL and EXPANSION is shown below:

source 这样杜伊才能在拿足所有合同内工资的同时$_{\text{TEMPORAL}}$，又乐得清闲，冷眼旁观。
ref Only in this way can Dujkovic sit back and do nothing and look on others disinterestedly when$_{\text{TEMPORAL}}$ getting his full salary per contract.

source 在减少开车出行的同时$_{\text{EXPANSION}}$，还往汽油里掺上从餐馆回收来的食油。
ref While$_{\text{EXPANSION}}$ reducing driving time, they are also mixing gasoline with cooking oil recycled from restaurants.

In the first case, there is a synchrony relation between Dujkovic's "sitting back and doing nothing", and "getting his full salary". In the second case, "reducing driving time" and "mixing gasoline with cooking oil" are a list of methods for saving gasoline.

In Table 3 we list these ambiguous Chinese connectives, their senses and the frequency with which they were annotated. The ambiguities we see here are very different from those in English where the TEMPORAL—CONTINGENCY and COMPARISON—CONTINGENCY ambiguities are most prominent.

5 Predicting discourse relation sense in Chinese

Our analysis so far has revealed considerable differences in the expression of discourse relations in Chinese and English. We now show that projected annotations can be used to disambiguate Chinese discourse connectives despite these differences.

5.1 Learning with unlabeled data

The main idea of learning by projection across parallel corpora is to use a classifier to annotate the English portion of the data, then project the discourse relation sense labels onto the corresponding Chinese sentences. Then a classifier can be trained using features gathered on the Chinese portion of the data.

However, labels gathered from direct projections are not suitable for learning systems without extra processing. If an English connective is aligned to one of the Chinese connectives, we can transfer its label from English to the Chinese connective. However, it is highly likely that a Chinese connective appears in the source sentence but the reference translation used an alternative expression or paraphrase rather than the 100 identified connectives in the PDTB. It is difficult to distinguish through direct projection if an explicit discourse connective in Chinese was expressed implicitly in English or if the Chinese expression was used in a non-discourse sense.

The possibilities described above imply that in our work, we cannot assume that through direct projection we have a fully labeled dataset for discourse connective senses in Chinese. Instead we have a mixture of data with labeled positive examples (when an explicit English connective was aligned to the phrase) and unlabeled examples (where there was no explicit discourse connective in English, so the Chinese expression is either used in a non-discourse sense or is expressed implicitly or using alternative expressions in English, and thus the label is unknown).

Luckily, learning from positive and unlabeled examples, especially for binary classification, is a fairly well studied problem in machine learning (Lee and Liu, 2003; Liu et al., 2003; Elkan and Noto, 2008). We adopt such methods as part of our semi-supervised learning system.

In this work, we propose the following components for relation classification:

(Noisy) data labeling Classify each instance of a possible connective on the English side of the corpus into either *non-discourse use*, or one of TEMPORAL, CONTINGENCY, COMPARISON or EXPANSION. If the English connective signals one of the four relations, transfer the labels to the connectives expressed in the corresponding Chinese sentences through alignments, as described in Section 4.1.

Train sense classifier This classifier is trained only on the Chinese expressions labeled as one of the four main classes of discourse relation. We can train either a binary classifier to predict if a connective expresses a particular relation, or a 4-way classifier which assigns the most probable sense to each connective. The potentially problematic labels for the *non-discourse* class are not used in this stage.

Train discourse use classifier This classifier has to use the potentially problematic data, where we cannot distinguish negative examples from untagged positive examples. The problem is solved as a cascade of classifiers, an approach developed in Elkan and Noto (2008). The idea is to train a noisy classifier that produces a soft score for the data—a probability of being in the class rather than a strict class assignment.

Let y be the *true* discourse use class to be predicted: $y = 1$ for examples of discourse use, and $y = 0$ for examples of non-discourse use. Let l indicate whether the example is *labeled* as discourse use ($l = 1$), or *unlabeled* ($l = 0$, unknown or non-discourse use). First, we use a logistic regression classifier LR to estimate $P(l = 1|y = 1)$. Let's call this estimate e. Using LR, e can be estimated as $\sum_{x \in P} LR(x)/|P|$, where P is the set of the original positively labeled examples, $LR(x)$ is the probability of expression x to be labeled positively. We then use the estimator e to calculate the estimated value of $P(y = 1|l = 0)$, the probability of an expression being discourse use from the original *unlabeled* examples:

$$w = \frac{LR(x)}{e} / \frac{1 - LR(x)}{1 - e}$$

In the second stage, each of the *unlabeled* examples are duplicated, once as a positive example with weight w and once as a negative example with weight $1 - w$. Our second stage classifier—linear-kernel SVM with weights for each example—is trained on the combined set of positive examples (discourse use) and the duplicated version of the unlabeled examples (unknown and non-discourse use class). When w is close to 0.5, the example is practically noise (with labels 0.5 and -0.5) and does not affect the learning of parameters much. Weights closer to 1 practically reassign the originally non-discourse use example to

the discourse use class (labels 1 and 0); a weight close to 0 leaves the example as one of the non-discourse use instances (with labels 0 and -1).

Test phase In testing, first the second-stage SVM model for discourse vs. non-discourse use is applied. For only the expression predicted to be discourse connectives (discourse use), we run the sense classifier to do binary or multiway relation classification. Binary classification labels whether a connective signals a particular relation; multiway classification labels one of the five possible classes: *non-discourse use*, TEMPORAL, COMPARISON, CONTINGENCY and EXPANSION. This series of classifiers results in a system that can assign the same labels as the classifiers trained for English.

To complete our presentation of the approach, we now turn to describe the features used to represent instances of potential discourse connectives.

5.2 Features

The following set of features for each expression we need to classify are extracted solely from the Chinese part of the corpus[4]. The syntactic parse trees were obtained automatically (Levy and Manning, 2003).

Connective The connective expressions themselves. The vast majority of connectives (at least in English) are unambiguous, so using the identity of the connective is a hard-to-beat baseline for sense prediction (Pitler et al., 2008).

Categories The syntactic category of the expression itself, as well as that of its parents, and its left and right siblings (if any). These features are adapted from Pitler and Nenkova (2009).

Depth Depth of the expressions's syntactic category in the parse tree for the sentence.

POS bigram Bigram of part-of-speech tags of the entire sentence.

Production pairs Parent-child node category pairs, gathered from subtrees of two ancestors starting from the parent of the expression's self-category. For example, a subtree IP→NP VP would yield the features (IP NP) and (IP VP). Production rules have shown to be effective for implicit discourse relation classification (Lin et al., 2009; Park and Cardie, 2012). This is a less sparse adaptation of such features.

Punctuation This class corresponds to two features. The first feature takes one of the three possible values: if the expression starts a sentence, if there is a punctuation to the immediate left of the expression, or none of above. The second feature has two values corresponding to whether there is a punctuation to the expression's immediate right.

Sequence pairs Left-to-right sequence pairs of node categories, gathered from subtrees of two ancestors starting from the parent of the expression's self-category. For example, a subtree IP→NP VP PU would yield the features (NP VP) and (VP PU).

Size of ancestor nodes The number of children a node has, calculated with three ancestors starting from the parent of the expression's self-category.

 # characters The number of Chinese characters in the connective expression.

5.3 Classification results

In this section, we demonstrate the effectiveness of learning discourse relations through parallel data projection and semi-supervised learning. We use the GALE corpus for training and the Chinese Discourse Treebank development set (CDTB-dev) for testing. There are 5,136 training instances and 490 testing instances. In addition, we compare performance with 10-fold cross validation results over CDTB-dev. We obtain predictions for each fold and evaluate on the combined data from all folds, instead of averaging performance for each fold. In this way the results from 10-fold validation and those from the semi-supervised classifier trained on projected data are directly comparable. The LIBLINEAR package (Fan et al., 2008) was used for binary classification (including the discourse use classifier[5]), and SVM-Multiclass (Tsochantaridis et al., 2004) with linear kernel was used for multiway classification.

[4] As a reminder, the list of possible connectives was derived from direct projection after pruning items that occurred only once with a particular part-of-speech. There is a total of 118 such expressions for Chinese.

	5-way Baseline	Projection	5-way Supervised
connective (C)	0.6332	0.6434	0.6114
C+tree depth	0.5959	0.6367	0.6384
C+punctuation	0.6224	0.6776	0.6425
C+size of ancestor	0.5939	0.6469	0.6073
C+categories	0.5837	0.6633	0.6359
C+POS bigram	0.6469	0.6980	0.6714
above, combined	0.6245	**0.7020**	0.6355

Table 5: Multiway discourse relation classification accuracies, for top and the combined features.

Discourse vs. non-discourse To demonstrate the cascade learning component in our system, we first show results from the intermediate stage of the discourse vs. non-discourse prediction task. We compare three systems: our cascade approach for handling noisy labels for non-discourse use, a baseline trained only on the original noisy non-discourse labels (this corresponds to the hard-label performance of the first stage classifier in our approach) and a supervised system trained on CDTB-dev (where predictions are obtained in 10-fold cross validation fashion).

In Table 4 we show the accuracy, precision/recall and F measure for each system, using connective expressions themselves and the five features that gave the best performance on the test set.

Cascade learning achieved a strong boost over the baseline with significant improvements on recall, although it does not perform as well as the fully supervised system. The features most useful for this task are POS bigrams and punctuations; syntactic category features are very useful for the supervised system, but not as useful for the cascade system.

Multiway classification Now we show how our system performs for the complete task of multiway classification of discourse relations for Chinese, recognizing each expression either as *non-discourse use* or one of the four discourse relation senses. We compare our semi-supervised multiway classification system against: *(i)* a baseline system that performs 5-way classification with the noisy labels from direct projection in the GALE data (again corresponding to the hard-label performance of the first stage classifier in our approach); *(ii)* a supervised system for 5-way classification trained on CDTB-dev (where predictions are obtained in 10-fold cross-validation fashion).

Table 5 records the accuracies for the connective expression and the five features performed best for this task. The top features for multiway relation classification, in addition to connectives, are part-of-speech bigrams, punctuations, and syntactic categories.

Notably, without any annotated data on the Chinese side, the projected semi-supervised system outperforms the 5-way supervised system for all but one of the features, and is significantly better when the top features are combined (70.2% vs. 63.55%). This finding justifies the idea and feasibility of using parallel corpora for discourse relation classification.

Binary classification Finally, we present results and the most informative features for binary classification of each relation sense individually. The semi-supervised projection system is compared against a fully supervised binary classification system over 10-fold CDTB-dev, with accuracies and F scores

	Projection		Supervised		Feature set
	A	F	A	F	
COMPARISON	94.49	59.70	96.33	57.14	Connective, categories, size of ancestor, # characters, POS bigram
CONTINGENCY	92.65	41.94	96.33	70.97	Connective, production pairs
EXPANSION	85.10	69.20	87.96	77.20	Connective, categories, production pairs, sequence pairs, POS bigram
TEMPORAL	88.37	48.65	94.08	60.47	Connective, categories, production pairs, sequence pairs

Table 6: Accuracy and F measure for binary classification for each relation, including features that significantly improves performance beyond the identity of the connective itself.

shown in Table 6. The feature sets included are the ones that significantly improve the F measure of a relation compared to that when using the connective expressions alone.

For accuracies, the semi-supervised system is only slightly (1.8-3.7%) below that of the supervised system for three of the four relations. On the other hand, F measures of the semi-supervised system are not as good as the supervised system except for the COMPARISON relation. The feature categories indicate that for Chinese discourse connectives, different feature sets are appropriate for different relations.

6 Conclusion

We investigated the tasks of discourse analysis and recognition without manual annotation. Instead, we used parallel corpora to project automatic annotations available on one side (English) to the other (Chinese). First, we conducted a corpus study which demonstrates the differences in information packaging and discourse organization between English and Chinese. We highlighted the existence of long sentences in Chinese that correspond to multiple sentences in English, mismatches between discourse expressions that are implicit vs. explicit in the two languages, and differences in the ambiguity of discourse connectives. Second, we presented a semi-supervised system that learns to predict discourse relations from the noisy annotations derived from parallel corpora. On the multiway discourse relation classification task, our system outperforms a fully supervised system trained using clean gold-standard annotation in the targeted language.

Abstract

This paper addresses the problem of building concise, diverse and relevant lists of documents, which can be recommended to the participants of a conversation to fulfill their information needs without distracting them. These lists are retrieved periodically by submitting multiple implicit queries derived from the pronounced words. Each query is related to one of the topics identified in the conversation fragment preceding the recommendation, and is submitted to a search engine over the English Wikipedia. We propose in this paper an algorithm for diverse merging of these lists, using a submodular reward function that rewards the topical similarity of documents to the conversation words as well as their diversity. We evaluate the proposed method through crowdsourcing. The results show the superiority of the diverse merging technique over several others which not enforce the diversity of topics.

1 Introduction

We present a diverse retrieval technique for ranking documents that are spontaneously retrieved and recommended to people during a conversation. These documents represent potentially useful information for the conversation participants. The information needs of the participants are represented by implicit queries which are built in the background based on their current speech, specifically from keywords obtained from the conversation transcripts. Since people usually mention several topics even during a short conversation span, such keyword sets are made of content words related to different topics. When juxtaposed in an implicit query, these topics may have noisy effects on the retrieval results (Bhogal et al., 2007; Carpineto and Romano, 2012).

The purpose of this paper is to present a method for merging lists of documents retrieved through multiple implicit queries prepared for short conversations spans. Several topically-separated queries are constructed from keywords, and generate several lists of documents. The goal of the method proposed here is to generate a unique and concise list of documents that can be recommended in real time to the conversation participants. The list should cover the maximum number of implicit queries and therefore topics. To merge the lists of documents according to these criteria, we use inspiration from extractive text summarization (Lin and Bilmes, 2011; Li et al., 2012) and from our own previous work on diverse keyword extraction (Habibi and Popescu-Belis, 2013). The method proposed here rewards at the same time topic similarity – to select the most relevant documents to the conversation fragment – and topic diversity – to cover the maximum number of implicit queries and therefore topics in a concise and relevant list of recommendations, if more than one topic is discussed in the conversation fragment.

Several studies have been previously carried out on merging lists of results in information retrieval. Despite the superficial similarity, the problem here is in fact different from distributed information retrieval, where several lists of results from *different* search engines for the *same* query must be merged. Moreover, many studies addressed the topic diversification approach for re-ranking the retrieved results of a single query. However, these approaches are not directly applicable to multiple queries.

Proceedings of COLING 2014, the 25th International Conference on Computational Linguistics: Technical Papers, pages 588–599, Dublin, Ireland, August 23-29 2014.

The paper is organized as follows. In Section 2 we review existing techniques for merging and re-ranking lists of search results which are applicable here. We then explain the general framework of our document recommender system in Section 3. In Section 4 we describe the proposed algorithm for diverse merging of lists of recommendations. Section 5 presents the data, the parameters setting, and evaluation tasks for comparing document lists. In Section 6 we first demonstrate empirically the benefits, for just-in-time document recommendation, of separating users' information needs into multiple topically-separated queries rather than using a unique query. Then, we compare the proposed diverse merging technique with several alternative ones, showing that it outperforms them according to human judgments of relevance, and also exemplify the results on one conversation fragment given in the Appendix A.

2 Related Work

Just-in-time document retrieval systems have been designed to recommend to their users documents which are potentially relevant to their activities, e.g. individual users authoring documents or browsing various repositories, or small groups holding business or private meetings (Hart and Graham, 1997; Rhodes and Maes, 2000; Popescu-Belis et al., 2008). When using a document recommender system, people are generally unwilling to examine a large number of recommended documents, mainly because this would distract them from their main activity. Several solutions to this problem have been proposed.

For instance, the Watson document recommender system (Budzik and Hammond, 2000), designed for reading or writing activities, clustered the document results and selected from each cluster the best representative to generate a list of recommendations. Clustering results is not suitable for our application where the mixture of topics in a single query will degrade the document results aimed to be clustered (Bhogal et al., 2007; Carpineto and Romano, 2012), and consequently may have a damaging effect on the clusters' representatives. The second part of the method, which selected the best representative of the clusters in the final document list can be helpful; however, its effectiveness relies on having clusters with the same level of importance (Wu and McClean, 2007).

Many studies in information retrieval addressed the problem of diverse ranking, which can be stated as a tradeoff between finding relevant versus diverse information (Robertson, 1997). The existing diverse ranking proposals differ in their diversifying policies and definitions, which can be categorized into implicit methods (Carbonell and Goldstein, 1998; Zhai et al., 2003; Radlinski and Dumais, 2006; Wang and Zhu, 2009) or explicit ones (Agrawal et al., 2009; Carterette and Chandar, 2009; Santos et al., 2010; Vargas et al., 2012). The implicit approaches assume that similar documents will cover similar aspects of a query, and have to be demoted in the ranking to promote relative novelty and reduce overall redundancy. In one of the earliest approaches, Carbonell and Goldstein (1998) introduced Maximal Marginal Relevance (MMR) to re-rank documents based on a tradeoff between the relevance of document results and relative novelty as a measure of diversity. MMR was also used by Radlinski and Dumais (2006) to re-rank results from a query set which is generated for a user query and represents a variety of potential user intents.

Instead of implicitly accounting for the aspects covered by each document, another option is to explicitly model these aspects within the diversification approach. Agrawal et al. (2009) introduced a submodular objective function to minimize the probability of average user dissatisfaction by assuming a taxonomy of information and modeling user query aspects at the topical level of this taxonomy. Alternatively, Santos et al. (2010) proposed another submodular objective function to maximize coverage and minimize redundancy with respect to query aspects modeled in a keyword-based representation form instead of a predefined taxonomy.

In our case, the recommender system for conversational environments requires diversity in the results of multiple topically-separated queries, rather than of a single ambiguous query. Therefore, a new approach will be proposed, and will be compared in particular to a version of the explicit diversification approach (Santos et al., 2010) adapted to our problem.

3 Framework of our Document Recommender System

We have designed the Automatic Content Linking Device (ACLD), a speech-based just-in-time document recommender system for business meetings (Popescu-Belis et al., 2008; Popescu-Belis et al., 2011).

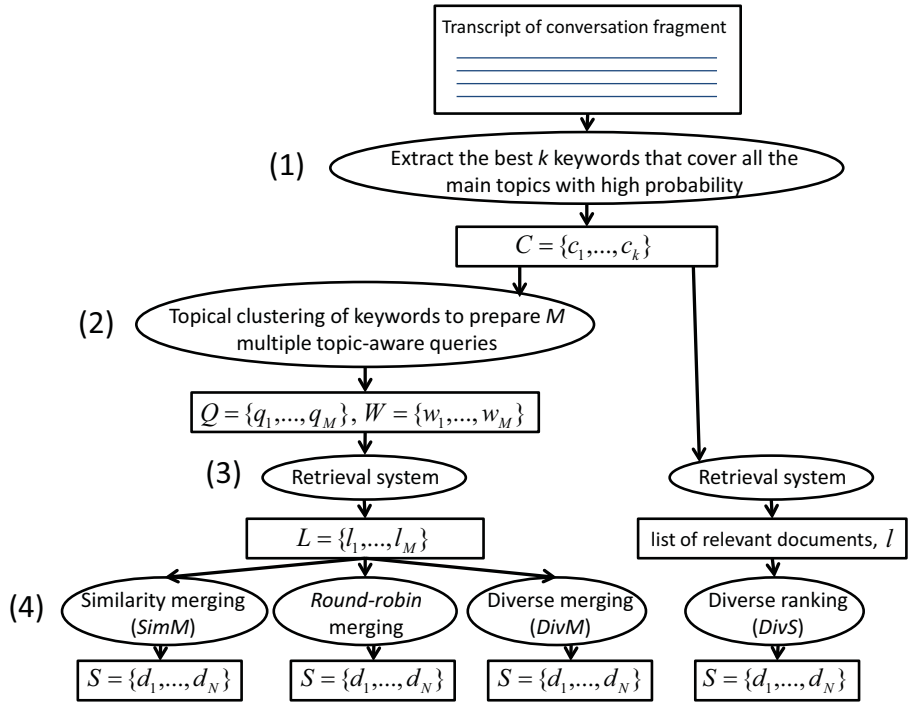

Figure 1: The four stages of our document recommendation approach (shown vertically: 1–4) and the four options considered in this paper (bottom line: *SimM*, *Round-robin*, *DivM*, and *DivS*).

The ACLD monitors the ongoing conversation, and formulates queries based on the words detected by a real-time automatic speech recognition (ASR) system (Garner et al., 2009). The queries are fired periodically to retrieve documents which are then recommended to users by displaying their titles along with relevant excerpts. As these queries are built and triggered in the background, they are referred to as 'implicit queries', as opposed to 'explicit' ones that could be formulated by users. Just-in-time document recommendation in the ACLD system proceeds according to the steps shown in Figure 1, which displays at step 4 the various options for merging lists of results that are the focus of this paper.

Prior to the first processing step outlined in Figure 1, the ACLD must decide when to make a recommendation, and what portion of the conversation prior to that moment should be used. This question is beyond the scope of this paper, and remains to be fully investigated, using verbal and non-verbal criteria. Here, for the reasons explained in Section 5.2, the ACLD recommends documents every two minutes, segmenting the conversation at the end of the nearest utterance and using the entire conversation fragment since the previous recommendation. Although in practice the results of the current recommendation process are merged with the previous ones (using a weighted mechanism that embodies the idea of "persistence" of documents over time), in this paper we will consider the recommendation for each fragment independently of the previous one.

The recommendation process represented in Figure 1 starts by extracting a set of keywords, C, from the words recognized by the ASR system from the users' conversations. The keywords are extracted using the diverse keyword extraction technique that we proposed (Habibi and Popescu-Belis, 2013), which maximizes the coverage of the topics of a text by the extracted keyword set, as we also target in this paper. Then, implicit queries which express the users' information needs are formulated using the keyword set, following two alternative approaches depicted in step 2 of Figure 1. In a baseline model (right side of the figure), a single query is built for the conversation fragment using the entire keyword list as an implicit query. In the approach we are advocating, multiple topically-separated queries are produced for the conversation fragment (step 2, left side of the figure). This is described in a separate document (Habibi and Popescu-Belis, submitted), but can be outlined as follows. The implicit queries are obtained by clustering the above-mentioned keyword set into several topically-separated subsets, each one corresponding to an abstract topic obtained using topic modeling techniques (similarly to the model

presented in Subsection 4.1). Each subset is an implicit query, and is weighted based on the importance of the topic to which it is associated.

In step 3, we separately submit each implicit query to the Apache Lucene search engine over the English Wikipedia and obtain several lists of relevant articles. Finally, we merge and re-rank these lists before recommendation (step 4). One baseline alternative is the explicit diverse ranking technique proposed by Santos et al. (2010) for diversifying the primary search results retrieved for a single query, shown on the right side of the figure. To compare the methods, we adapted this latter method to make it applicable to our system when a single implicit query is built for a conversation fragment, by defining query aspects using the abstract topics employed for query and document representation. The method is noted *DivS* as it *diversifies* documents from a *single* list.

Our proposal lies at step 4. As represented on the left side of Figure 1, in our system, we merge the lists of documents retrieved for multiple implicit queries. We thus propose a new method noted *DivM* and we compare it with two other merging techniques. The first one, noted *SimM*, ignores the diversity of topics in the list of results and ranks documents only by considering their topic similarity to the conversation fragment. The second one is the merging technique used by the above-mentioned Watson system (Budzik and Hammond, 2000), which uses Round robin merging, hence it is noted *Round-robin*. In contrast, our proposed method, *DivM*, is a *diverse merging* technique which we now proceed to define formally.

4 Diverse Merging of the Results of Multiple Queries

The diverse merging of retrieved document lists is the process of creating a short, diverse and relevant list of recommended documents which covers the maximum number of topics of each conversation fragment. The merging algorithm rewards diversity by decreasing the gain of selecting documents from a list as the number of its previously selected documents increases. The method proceeds in two steps. First, we represent queries and the corresponding list of candidate documents from the Apache Lucene search engine using topic modeling techniques, and then we rank documents by using topical similarity and rewarding the coverage of different lists.

4.1 Document and Query Representation

A topic model represents the abstract topics which occur in a collection of documents – here, preferably, a collection that is representative of the domain of the conversations. Once trained, topic models such as Probabilistic Latent Semantic Analysis (PLSA) or Latent Dirichlet Allocation (LDA) can be used to determine the distribution of abstract topics in each set of words composing either a conversation fragment, or a query, or a document. LDA implemented in the Mallet toolkit (McCallum, 2002) is used here to train topic models because it does not suffer from the over-fitting of PLSA (Blei et al., 2003).

We first learn a probability model for observing a word v in a document d through the set of abstract topics $T = \{t_1, ..., t_z, ..., t_Z\}$, where Z is the number of topics, using the Mallet toolkit:

$$p(v|d) = \sum_{z=1}^{Z} p(v|t_z) \cdot p(t_z|d) \quad (1)$$

The topic-word distribution $p(v|t_z)$ and the document-topic distribution $p(t_z|d)$, which are obtained using topic modeling, respectively show the contribution of the word v in the construction of the topic t_z, and the distribution of topic t_z in the document d with respect to the other topics.

We represent each new text or fragment A (e.g. from a conversation or document) by a set of probability distributions over all abstract topics T noted as $P(A) = \{p(t_1|A), ..., p(t_z|A), ..., p(t_Z|A)\}$ where $p(t_z|A)$ is inferred using the Gibbs sampling implemented by the Mallet toolkit given the topic models previously learned. We associate to each new document d_i and query q_j a set of topic probabilities according to the above definition noted respectively as $P(d_i) = \{p(t_1|d_i), ..., p(t_z|d_i), ..., p(t_Z|d_i)\}$ and $P(q_j) = \{p(t_1|q_j), ..., p(t_z|q_j), ..., p(t_Z|q_j)\}$.

4.2 Diverse Merging Problem

As stated above, our goal is to recommend a short ranked list of documents answering the users' information needs hypothesized in a conversation fragment, which are modeled by multiple topic-aware implicit

queries as described in Section 3. We build the final list of recommended documents by merging the document lists, one from each implicit query, with the objective of the maximum coverage of the topics of the conversation fragment. Since each document list contains documents found by a search engine given an implicit query, which was prepared for one of the main topics of the conversation fragment, we merge the lists by selecting documents from the maximum number of lists in addition to maximizing their topical similarity to the conversation fragment.

The problem of diverse merging of lists thus amounts to finding a ranked subset of documents $S \subset \cup_{i=1}^{M} l_i$, which are the most representative of all the result lists l_i, and potentially the most informative with respect to the conversation fragment and the information needs that are implicitly stated. This problem is an instance of the maximum coverage problem, which is known to be NP-hard. Our formulation and solution proceed as follows.

Let us consider a set of implicit queries $Q = \{q_1, ..., q_M\}$, and the corresponding set of document lists $L = \{l_1, ..., l_M\}$ resulting from each query. M is the number of implicit queries of the fragment, and each l_i is a list of documents $\{d_1, ..., d_{N_i}\}$ which are retrieved for query q_i. We define the weight w_i of each query q_i as the importance within the conversation fragment of the topics represented in the query q_i, and compute it as the topical similarity of q_i to the fragment, as shown in Equation 2. In this equation, q is the query made from the whole keyword set, which we call a *collective query*, and includes keywords for all the main topics of the conversation fragment in one query. In turn, we associate to q a set of probabilities over abstract topics, $P(q) = \{p(t_1|q), ..., p(t_Z|q)\}$, similar to the representation of implicit queries explained in Subsection 4.1.

$$w_i = \sum_{z=1}^{Z} p(t_z|q_i) \cdot p(t_z|q) \tag{2}$$

4.3 Defining a Diverse Reward Function

Although the maximum coverage problem is NP-hard, it has been shown that a greedy algorithm can find an approximate solution guaranteed to be within a factor of $(1 - 1/e) \simeq 0.63$ of the optimal one if the coverage function is submodular and monotone non-decreasing[1] (Nemhauser et al., 1978). Several monotone submodular functions have been proposed in various domains for a similar underlying problem, such as explicit diverse re-ranking of retrieval results (Agrawal et al., 2009; Santos et al., 2010; Vargas et al., 2012), extractive summarization of a text (Lin and Bilmes, 2011; Li et al., 2012), or our own model of diverse keyword extraction from a text (Habibi and Popescu-Belis, 2013).

We define a monotone submodular function for diverse merging of document lists inspired by the latter two applications, who proposed a power function with a scaling exponent between 0 and 1 for diverse selection of sentences (or keywords) covering the maximum number of topics of a given document with a fixed number of items. To adapt these techniques to the problem of diverse merging, from the perspective of capturing users' information needs in the set of recommended documents, we define here a reward function enforcing the diverse merging of the lists of document results.

We first estimate the topical similarity of the document subset $S_i = S \cap l_i$ to the collective query q (see Subsection 4.2) as r_{S_i}:

$$r_{S_i} = \sum_{d \in S_i} \sum_{z=1}^{Z} p(t_z|d) \cdot p(t_z|q) \tag{3}$$

We then propose the following reward function f for each S_i containing relevant documents selected from l_i (results of implicit query q_i), where w_i is the topical similarity of q_i to the conversation fragment (see Equation 2), and λ is an exponent parameter between 0 and 1. This reward function is submodular because it has the diminishing returns property when r_{S_i} increases.

$$f : r_{S_i} \rightarrow w_i \cdot r_{S_i}^{\lambda} \tag{4}$$

[1] A function F is *submodular* if $\forall A \subseteq B \subseteq T \setminus t$, $F(A + t) - F(A) \geq F(B + t) - F(B)$ (diminishing returns) and is *monotone non-decreasing* if $\forall A \subseteq B$, $F(A) \leq F(B)$.

The set S is ultimately ranked by maximizing the cumulative reward function $R(S)$ over all the lists, written as follows:

$$R(S) = \sum_{i=1}^{M} w_i \cdot r_{S_i}^{\lambda} \tag{5}$$

The probability of selecting documents from the list of results for q_i thus depends on w_i, the topical similarity of the query to the conversation fragment. This is in contrast to choosing the best representative document from the list of documents relevant to each query, like in the Watson system, which does not select more documents for queries with higher weight before considering lower weight ones. Our model rewards diversity to increase the chance of choosing documents from all the lists of results retrieved for implicit queries.

4.4 Finding the Optimal Document List

Since $R(S)$ is a monotone submodular function, we propose a greedy algorithm (Alg. 1) to maximize $R(S)$. If $\lambda = 1$, the reward function ignores the diversity constraint, because it does not penalize multiple selections from the same list l_i and ranks documents only depending on their similarity to the collective query and on the weights of implicit queries. However, when $0<\lambda<1$, as soon as a document is selected from the list of results of an implicit query, other documents from the same list start having diminishing returns as competitors for selection. Decreasing the value of λ increases the impact of the diversity constraint on ranking documents, which augments the chance of recommending documents from other document lists.

Input : query set Q of size M with probabilities, set of weights W, set of lists of document results L with probabilities, number of recommended documents k
Output: set of recommended documents S
$S \leftarrow \emptyset$;
for $i = 1$ ***to*** M ***step*** 1 **do**
  $S_i \leftarrow \emptyset$;
end
while $|S| \leq k$ **do**
  $S \leftarrow S \cup argmax_{d \in ((\cup_{i=1}^{M} l_i) \setminus S)}(g(d))$ where $g(d) = \sum_{i=1}^{M} w_i \cdot [r_{\{d\} \cap l_i} + r_{S_i}]^{\lambda}$;
  for $i = 1$ ***to*** M ***step*** 1 **do**
    $S_i = l_i \cap S$;
  end
end
return S;

Algorithm 1: Diverse merging of document results for recommendation.

5 Data, Settings and Evaluation Method

The experiments were performed on conversational data from the ELEA Corpus (Emergent LEader Analysis, Sanchez-Cortes et al. (2012)). Implicit queries were formulated as presented above in Figure 1 using keywords extracted from each conversation fragment, defined as below (Subsection 5.1). Each subset of keywords obtained by topical clustering of the keyword set resulted in an implicit query. The lists of document results for each implicit query were obtained by submitting the query to the Apache Lucene search engine[2] over the English Wikipedia[3]. These initial lists of results were ultimately merged into final recommendation lists of documents using the four alternative methods from Figure 1, including the one we proposed. This section presents the data, system parameters, and evaluation methods used in our experiments.

[2]Available from `http://lucene.apache.org`.
[3]A local copy was downloaded from `http://dumps.wikimedia.org`.

5.1 Conversational Corpus

The ELEA Corpus comprises nearly ten hours of recorded meetings in English and French. Each meeting consists in a role play game in which participants play survivors of an airplane crash in a mountainous region. They must rank a list of 12 items with respect to their utility for surviving until they are rescued. We used from the ELEA corpus four English conversations of around fifteen minutes each, which have been manually transcribed and segmented at the speaker turn level.

One of the most important issues for a just-in-time document recommender system is to determine the appropriate timing of the recommendations, and the size of the context to use for computing them. Here, awaiting future investigations[4], we decided to make recommendations approximately every two minutes, at the end of an ongoing speaker turn, and consider as input the words uttered since the previous recommendation. A segment size of two minutes enables us to collect an appropriate number of words (neither too small nor too large) in order to extract keywords, model the topics, and formulate implicit queries. Based on our experience with the ACLD, it also corresponds to an acceptable frequency for receiving suggestions.

Therefore, our test data comprises 26 two-minute segments, each of them ending at a speaker change. On average, segments contain 278 words (including stop words). Once topic modeling is applied, the average number of topics per fragment is 5, with an observed minimum of 3 and a maximum of 9.

5.2 Parameter Settings for Experimentation

As document search is performed over the English Wikipedia, we trained our topic models on this corpus as well. We used only a subset of it for tractability reasons, i.e. about 125,000 articles as in other studies (Hoffman et al., 2010). The subset is randomly selected from the entire English Wikipedia. As in previous studies, we fixed the number of topics at 100 (Boyd-Graber et al., 2009; Hoffman et al., 2010).

The exponent of the submodular function was set to $\lambda = 0.75$, as in our diverse keyword extraction study (Habibi and Popescu-Belis, 2013). This was found to be the best value for diverse merging of lists of results, as it leads to a reasonable balance between relevance and diversity in the aggregated list of documents. Of course, if sufficient training data were available, this could be used to optimize λ.

The number of recommended documents was fixed at five in our experiments. This value was selected again based on user preferences observed with the ACLD. Moreover, this is also the value of the average number of topics in a conversation fragment, which allows the system to cover on average one result per topic. Experiments with other values were not carried out due to the cost of evaluation.

5.3 Evaluation Protocol and Metrics

We designed a task that measures the relevance of recommended document lists for each of the test conversation fragment. Based on validation experiments in our previous work (Habibi and Popescu-Belis, 2012), the task requires subjects to compare two lists obtained by two different methods. Using a web browser, the subjects had to read the conversation transcript, answer several control questions about its content, and then decide which of the two lists provides more relevant documents, with the following options: the first list is better than the second one; the second is better than the first; both are equally relevant; or both are equally irrelevant. The position of each system (first or second) was randomized across the tasks.

The 26 comparison tasks (one for each ELEA fragment) were crowdsourced via Amazon's Mechanical Turk as "human intelligence tasks" (HITs). For each HIT we recruited ten workers, only accepting those with greater than 95% approval rate and more than 1000 previously approved HITs (qualification control). We only kept answers from the workers who answered correctly our control questions about each HIT. Each worker could answer the entire set of 26 HITs, or part of it. We observed that the average time spent per HIT was around 90 seconds.

[4]For instance, they could combine an analysis of non-verbal information to detect "interruptibility" and of verbal information to detect topic changes and perform online segmentation (Mohri et al., 2010). Topic changes, however, are not appropriate moments to make recommendations because it would be useless to recommend documents about a topic that the users no longer discuss (Jones and Brown, 2004).

To consolidate the comparative judgments over a large number of subjects and conversation fragments, and compute an aggregated score, we applied a qualification control factor to the human judgments (to reduce the effect of judgments which disagree with the majority vote) and another one to the HITs (to reduce the impact of undecided HITs on the global scores). This was done by using the PCC-H metric, defined and validated in our previous work (Habibi and Popescu-Belis, 2012), which provides two scores, one for each document list, summing up to 100%; a higher value indicates a better list. In addition to PCC-H, we also provide below (Table 1) the raw preference scores for each comparison, i.e. the number of times a system was preferred over another one, although PCC-H was shown to be a more reliable indicator of quality.

6 Experimental Results

We merged and re-ranked the document lists intended to be recommended during a conversation by the four methods presented above in Section 3 and Figure 1. Three methods merge lists of results from topically-separated queries: *SimM* only considers their similarity with the fragment; *Round-robin* picks the best document in each list; and our proposal, *DivM*, considers the diversity and importance of topics. A fourth method, *DivS*, uses one query made of all keywords extracted from the conversation fragment, and ranks the documents using the diverse re-ranking technique proposed by Santos et al. (2010).

Binary comparisons were performed between pairs of techniques, using crowdsourcing over 26 conversation fragments of the ELEA Corpus, and aiming to minimize the number of binary comparisons while still ordering completely the methods according to their perceived quality.

6.1 Diverse Re-ranking vs. Similarity Merging

We first performed a comparison between the top five documents generated by two recommendation strategies, *DivS* and *SimM*, over 26 conversation fragments of the ELEA Corpus. The consolidated relevance score (PCC-H) is 75% for *SimM* vs. 25% for *DivS*, as shown in Table 1. These scores indicate the superiority of *SimM* over *DivS*. In other words, separating the mixture of topics of a fragment into multiple topically-separated queries mitigates the negative effect of the mixture of topics on the suggestions.

6.2 Comparison across Merging Techniques

Binary comparisons were then performed between pairs of merging techniques (*SimM*, *Round-robin*, and *DivM*), using the same experimental settings. The PCC-H scores are 62% for *DivM* vs. 38% for *Round-robin*, 59% for *DivM* vs. 41% for *SimM*, and 56% for *Round-robin* vs. 44% for *SimM*, as shown in Table 1. The scores show that the diverse merging of lists of documents improves recommendations, and indicate the following high to low ranking: *DivM* $>$ *Round-robin* $>$ *SimM*.

SimM ranks lowest in this ordering, likely because of the ignorance of diversity in the list of results. *Round-robin* is second, likely because it disregards the major differences of importance among implicit queries in a conversation fragment. The results of the comparisons confirm that the *DivM* technique, which merges lists of documents by considering the diversity of topics in the list of recommendations, in proportion to their importance in the conversation, is the most satisfying to the majority of human subjects.

6.3 Impact of the Topical Diversity of Fragments

To further examine the benefits of our method, we studied its sensitivity to the number of topics in the conversation fragments. For this purpose, we divided the set of test fragments into two subsets. The first one (noted 'A' in Table 1) gathers the fragments for which fewer than or exactly five main topics (and therefore implicit queries) have been computed. The other fragments, with more than five main topics, form the second subset (noted 'B'). The value of five corresponds to the average number of main topics per fragment as well as to the number of recommended documents in our experiments.

As shown in Table 1, although there is an improvement in the comparison scores of *DivS* over *SimM* when the number of conveyed topics in the fragments is higher than the number of recommended documents (subset B), the comparison scores indicate the superiority of *SimM* over *DivS* in both cases, and

Compared methods (m_1 vs. m_2)	PCC-H relevance score (%)						Raw preferences (%)	
	A		B		A ∪ B		A ∪ B	
	m_1	m_2	m_1	m_2	m_1	m_2	m_1	m_2
SimM* vs. *DivS	**80**	20	**70**	30	**75**	25	**70**	30
Round-robin* vs. *SimM	33	**67**	**68**	32	**56**	44	**52**	48
DivM* vs. *Round-robin	**64**	36	**60**	40	**62**	38	**58**	42
DivM* vs. *SimM	**54**	46	**60**	40	**59**	41	**58**	42

Table 1: Comparative scores of the recommended document lists from four methods: *DivS*, *SimM*, *Round-robin*, and *DivM*, evaluated by human judges over the ELEA Corpus. Subset A gathers fragments with fewer than or exactly five topics, while subset B gathers all the other fragments. The results imply the following ranking: *DivM* > *Round-robin* > *SimM* > *DivS*.

confirm the benefit of the diverse merging techniques. When comparing *Round-robin* versus *SimM*, the scores show the superiority of the former method when the number of conveyed topics in fragments is higher than the number of recommended documents, because it provides a diverse lists of documents in which documents relevant to less important topics are not displayed. However, when the number of topics is smaller than the number of recommendations, *SimM* provides better results. The reason of the decrease in the scores of *Round-robin* is likely the ignorance of the actual importance of the main topics when ranking documents. Overall, as shown in Table 1, regardless of the number of topics conveyed in the fragments, *DivM* always outperforms *Round-robin* and *SimM*.

6.4 Example of Document Results

To illustrate how *DivM* surpasses the other techniques, we consider an example from one of the conversation fragments of the ELEA Corpus. The manual transcript of this conversation fragment is given in the Appendix A. As described in Section 5, the conversation participants had to select a list of 12 items vital to survive in winter while waiting to be rescued. The keywords extracted from the manual transcript of this fragment by our method (Habibi and Popescu-Belis, 2013) are: *fire, lighter, cloth, shoe, cold, die, igloo, walking*. As our keyword extraction method was shown to be robust to ASR noise, we only use here the reference transcripts (Habibi and Popescu-Belis, submitted).

We display the topically-aware implicit queries prepared by our method from this keyword list along with their weights in Table 2. Then, in Table 3 we show the retrieval results (five highest-ranked Wikipedia pages) obtained by the four methods using the reference transcript of this fragment.

As shown in Table 2, each implicit query corresponds to one of the main topics of the fragment with a specific weight. In this example, the main topics spoken in the fragment are about making an igloo, lightening a fire, having warm clothes, and suitable shoes for walking.

As shown in Table 3, *DivS* provides two irrelevant documents likely because the single (collective) query does not separate the mixture of topics in the conversation fragment, and leads to some poor results (Wikipedia pages) such as "Cold Fire (Koontz novel)". *SimM* slightly improves the results by separating the discussed topics of the conversation fragment into multiple queries. However, it does not cover all the

Implicit queries	Weights
q_1 = {fire, cold, igloo, lighter}	w_1 = 0.110
q_2 = {shoe, lighter, walking}	w_2 = 0.097
q_3 = {cloth}	w_3 = 0.058
q_4 = {die}	w_4 = 0.040
q_5 = {igloo}	w_5 = 0.026

Table 2: Example of implicit queries built from the keyword list extracted from a sample fragment of the ELEA Corpus. Each query covers one of the main topics of the fragment and has a different weight.

DivS	***SimM***	***Round-robin***	***DivM***
Flint spark lighter	Igloo	Igloo	Igloo
Extended Cold Weather Clothing System	Flint spark lighter	Shoe	Shoe
Cold Fire (Koontz novel)	Lighter	Jersey (clothing)	Flint spark lighter
Igloo	Lighter (barge)	Die Hard	Jersey (clothing)
Walking	Worcester Cold Storage Warehouse fire	Flint spark lighter	Lighter

Table 3: Example of retrieved Wikipedia pages from the four different methods tested in this paper. Results of diverse merging (*DivM*) appear to cover more topics relevant to the conversation fragment than other methods. The average ranking (*DivM* > *Round-robin* > *SimM* > *DivS*) is also observed in this example.

topics mentioned in the fragment due to mostly focusing on the single topic represented by q_1. *Round-robin* further enhances the results by adding diversity, but as it gives the same level of importance to all topics, it provides a poor result like "Die Hard" from a topic of the conversation fragment with a small weight. The results of *DivM* appear to be the most useful ones, as they include other articles relevant to q_1, q_2, and q_3 before showing results relevant to the low weight queries q_4 and q_5. Therefore, in this example, *DivM* provides better ranking of documents by covering the largest number of main topics mentioned in the fragment.

7 Conclusion

We proposed a diverse merging technique for combining lists of documents from multiple topically-separated implicit queries, prepared using keyword lists obtained from the transcripts of conversation fragments. Our *diverse merging* method *DivM* provides a short, diverse, and relevant list of recommendations, which avoids distracting participants that would consider it during the conversation. We also compared *DivM* to existing merging techniques, in terms of comprehensiveness and relevance of the final recommended list of documents to the conversation fragment. The human judgments collected via Amazon Mechanical Turk showed that *DivM* outperforms all other methods.

Moreover, these results emphasized the benefit of splitting the keyword set into multiple topically-separated queries: the suggested lists of documents from *DivS* (which accounts for the diversity of results by re-ranking the documents of a single list) were indeed found less relevant than those from *SimM* and the other two methods, which merged results from multiple queries.

In the future, the diverse merging method *DivM* will be integrated in the ACLD just-in-time retrieval system for conversational environments, with implicit queries that are prepared from the ASR transcript of users' conversation. User-oriented evaluation experiments will be conducted. We will also enable the system to answer explicit queries asked by users, considering contextual factors to improve the relevance of the answers, which will complement the recommendation functionality based on implicit queries.

Appendix A. Transcript of a Conversation Fragment from the ELEA Corpus

The following transcript of a conversation fragment (speakers noted A through C) was submitted to the document recommender system and is exemplified in Section 6.4. The corresponding implicit queries and recommendations are respectively shown in Tables 2 and 3.

```
  A: okay I start.
  B: how  how do you want to proceed?
  A: I guess -
  C: yes what is the most important?
  A: I guess fire light.
  B: fire lighter?
  A: fire, yes.  I would say if we had something we can fire with -- I guess that
the lighter is useful in getting some sparks.
  B: hopefully.
  A: so we can use either newspaper or -- something like that.
  C: but again - first it is more important to have enough err clothes.
  A: and for me, more important to know where to go.  I would say that the compass.
  C: I mean -- if you don't have enough clothes so -- at one point you can --
  B: you can die.
  C: yes you can -- you will die.  so first issue, try to keep yourself alive and
then you can --
  A: but -- but you already have some --
  B: basics.  you everything.  you have enormous which is and so is no shoes here.
  C: okay that we have shoes so -- okay.
  B: because seventy kilometers will take you how many days?  err in the snow --
what do you think?
  A: two or three.
  B: it can be two or three days?
  C: yes, but okay you cannot always have fire with you -- but you need always
have clothes with you.  I mean it is the only thing that protects you when you are
walking.
  B: oh yes.  and erm you can make an igloo during the evening.  not that cold.
only about five degrees.  so lighting a fire is not so important.
  C: I guess fire is an extra.  I mean it is important but err for me first it is
important that when you keep walking you should be protected.

Abstract

Infographics, such as bar charts and line graphs, occur often in popular media and are a rich knowledge source that should be accessible to users. Unfortunately, information retrieval research has focused on the retrieval of text documents and images, with almost no attention specifically directed toward the retrieval of information graphics. Our work is the first to directly tackle the retrieval of infographics and to design a system that takes into account their unique characteristics. Learning-to-rank algorithms are applied on a large set of features to develop several models for infographics retrieval. Evaluation of the models shows that features pertaining to the structure and the content of graphics should be taken into account when retrieving graphics and that doing so results in a model with better performance than a baseline model that relies on matching query words with words in the graphic.

1 Introduction

Infographics are non-pictorial graphics such as bar charts and line graphs. When such graphics appear in popular media, they generally have a high-level message that they are intended to convey. For example, the graphic in Figure 1 ostensibly conveys the message that Toyota has the highest profit among the automobile companies listed. Thus infographics are a form of language since, according to Clark (Clark and Curran, 2007), language is any deliberate signal that is intended to convey a message.

Although much research has addressed the retrieval of documents, very little attention has been given to the retrieval of infographics. Yet research has shown that the content of an infographic is often not included in the article's text (Carberry et al., 2006). Thus infographics are an important knowledge source that should be accessible to users of a digital library.

Techniques that have been effective for document or image retrieval are inadequate for the retrieval of infographics. Current search engines employ strategies similar to those used in document retrieval, relying primarily on the text surrounding a graphic and web link structures. But the text in the surrounding document generally does not refer explicitly to the infographic or even describe its content (Carberry et al., 2006). An obvious extension to using the article text would be to collect all the words in an infographic and use it as a bag of words. However, infographics have structure and often a high-level message, and bag of words approaches ignore this structure and message content.

This paper explores the features that should be taken into account when ranking graphics for retrieval in response to a user query. Using a learning-to-rank algorithm on a wide range of features (including structural and content features), we produce a model that performs significantly better than a model that ignores graph structure and content. Analysis of the model shows that features based on the structure and content of graphs are very important and should not be ignored. To our knowledge, our research is the first to take graph structure and content into account when retrieving infographics.

2 Related Work

Information retrieval research has focused on the retrieval of text documents and images. Two popular approaches to text retrieval are the vector space method and probabilistic methods. The vector space method (Dubin, 2004) represents the document and the query each as a vector of weighted words and then uses a similarity function to measure the similarity of each document to the query. Most weighting mechanisms reward words that occur frequently in both the document and query but infrequently in the overall collection of documents. Probabilistic retrieval models instead estimate the probability that a document is relevant to a user query. In recent years, the language modeling approach has shown promise as a retrieval strategy with sound statistical underpinnings (Lv and Zhai, 2009; Manning et al., 2008). In all of the above approaches, query expansion techniques have been used to expand the query with synonyms and related words before ranking documents for retrieval. Work on short document and query expansion have shown improvements in retrieval performance (Arguello et al., 2008; Escalante et al., 2008; Metzler and Cai, 2011).

Work in Content Based Image Retrieval (CBIR) (Datta et al., 2008) has progressed from systems that retrieved images based solely on visual similarity, relying on low-level features such as color, texture and shape ((Flickner et al., 1995; Swain and Ballard, 1991; Smith and Chang, 1997; Gupta and Jain, 1997), among others), to systems which attempt to classify and reason about the semantics of the images being processed (Bradshaw, 2000; Smeulders et al., 2000; Datta et al., 2008). However, images are free-form with relatively little inherent structure; thus it is extremely difficult to determine what is conveyed by an image, other than to list the image's constituent pieces. Most systems that retrieve infographics, such as SpringerImages (http://www.springerimages.com) and Zanran (http://www.zanran.com), are based on textual annotations of the graphics as in image retrieval (Gao et al., 2011) or on matching the user's query against the text surrounding the graphic. However, the structure and content of the graph are not taken into consideration.

In this paper, we focus on natural language queries given that such queries allow users to express their specific information need more clearly than keywords (Phan et al., 2007; Bendersky and Croft, 2009). Previous work on verbose and natural language queries (Bendersky and Croft, 2008; Liu et al., 2013) used probabilistic models and natural language processing techniques to identify the key contents in such queries. Our query processing method not only extracts key entities but also further classifies the extracted key entities into different components using a learned decision tree model.

3 Problem Formulation

Our research is currently limited to two kinds of infographics: simple bar charts and single line graphs. We assume that our digital library contains an XML representation of each graphic that includes 1) the graphic's image, 2) its structural components: the set of independent axis (x-axis) labels[1], the entity being measured on the dependent axis (y-axis), and the text that appears in the graphic's caption, referred to as G_x, G_y, and G_c respectively, and 3) the graphic's intended message G_m and any entities G_f that the

[1]We will refer to the independent axis as the x-axis and the dependent axis as the y-axis throughout this paper.

message focuses on. This paper is not concerned with the computer vision problem of recognizing the bars, labels, colors, etc. in a graphic; other research efforts, such as the work in (Chester and Elzer, 2005; Futrelle and Nikolakis, 1995) are addressing the parsing of electronic images such as bar charts and line graphs.

Prior research on our project has addressed issues that arise in recognizing G_y, G_m, and G_f. The dependent axis of an infographic often does not explicitly label what is being measured, such as *net profit* in Figure 1, and these must be inferred from other text in the graphic. Our prior work (Demir et al., 2007) identified a hierarchy of graphic components in which pieces of the entity being measured might appear; a set of heuristics were constructed that extracted these pieces and melded them together to form what we refer to as a *measurement axis descriptor* and which is G_y. The project's prior work also identified a set of 17 categories of intended message, such as *Rank*, *Relative-difference*, *Maximum*, and *Rising-trend*, that might be conveyed by simple bar charts and line graphs; a Bayesian system (Elzer et al., 2011; Wu et al., 2010) was developed that utilizes communicative signals in a graphic (such as the coloring of one bar differently from the other bars) in order to recognize a graphic's intended message, including both the message category and the parameters of the message such as any focused entity. For example, the intended message of the bar chart in Figure 1 is ostensibly that Toyota has the highest net profit of any of the automobile manufacturers listed; thus its message falls into the *Maximum* message category and its focused entity is *Toyota*.

Our vision is that since graphics have structure and content, the users whose particular information needs could be satisfied by an infographic will formulate their queries to indicate the requisite structure of the desired graphics. Thus we assume the use of full-sentence queries so that the semantics of the query can be analyzed to identify characteristics of relevant graphics. For example, consider the following two queries that contain similar keywords but represent different information needs:

Q_1: *Which countries have the highest occurrence of rare diseases?*
Q_2: *Which rare diseases occur in the most countries?*

These two queries contain almost identical words but are asking for completely different graphics. Query Q_1 is asking for a comparison of countries (independent axis) according to their occurrence of rare diseases (dependent axis) while query Q_2 is asking for a comparison of different rare diseases (independent axis) according to the number of countries in which they occur (dependent axis). In addition, both queries are asking for a graphic with a *Rank* message that ranks countries (query Q_1) or rare diseases (query Q_2) as opposed to a graphic that shows the trend in rare diseases throughout the world.

4 Methodology

To retrieve relevant graphics in response to a user query, the query will first be analyzed to identify requisite characteristics of relevant infographics. We have developed learned decision trees (Li et al., 2013a; Li et al., 2013b) for analyzing a query and identifying the requisite structure of relevant infographics (the content of the independent axis or x-axis and dependent axis or y-axis, referred to as Q_x and Q_y), and the category of intended message and focused entity, if any, (referred to as Q_m and Q_f) that will best satisfy the user's information need.

Given a new user query, it is parsed and noun phrases are extracted. Each query-phrase pair, consisting of a query and an extracted noun phrase, is processed by a decision tree that determines whether the noun phrase represents x-axis content, y-axis content, or neither. Attributes used by this decision tree include whether the main verb of the query is a comparison verb (such as "differ" and "compare") or a trend verb (such as "change" and "decrease"), whether the noun phrase is preceded by a quantity phrase such as "the number of" suggesting that the noun phrase specifies y-axis content of relevant infographics, and whether the noun phrase describes a period of time.

Similarly, another decision tree is constructed to identify the category of graph intended message (such as *Trend* or *Rank*) that the query desires, using a subset of the attributes from the axes decision tree combined with the classification results of the axes decision tree. An example of the reused attributes is the class of the main verb in the user query; for example, a comparison main verb suggests that relevant infographics will convey a comparison-based intended message, such as a *Relative-difference* or *Rank*

intended message. Other attributes include the presence of a superlative or comparative in the query and attributes depending on the identified content of the x and y axes by the axes decision tree, such as the number of x-axis entities, their plurality, and whether an x-axis entity describes a time interval. A third decision tree is constructed for identifying whether a noun phrase describes a specific focused x-axis entity. Then the infographics in the digital library must be rank-ordered according to how well they satisfy the requirements of the user query.

This paper is concerned with identifying the most important features in a metric for rank-ordering the graphics in response to a user query. We experiment with two learning-to-rank algorithms and 56 features that include both general features such as bag of words comparisons and structural and content features. Our hypothesis is that structural and content-based features play an important role in graph retrieval and cannot be ignored. Section 5 discusses the features used in our experiments, Section 6 discusses the learning algorithms, Section 6.1 compares the resultant models with a baseline that uses just general features treating query and graphic each as one bag of words, and Section 6.2 discusses the features that appear most influential in the models.

5 Features

We consider three kinds of features: 1) general features that compare words in the query with words in the graphic, 2) structural features that compare the requisite structure hypothesized from the query with the structure of candidate infographics, and 3) content-based features that compare the requisite message hypothesized from the user query with the intended message of candidate graphics.

Query expansion is a commonly used strategy in information retrieval to bridge the vocabulary gap between terms in a query and those in documents. The basic idea is to expand the original query with terms that are semantically similar to the ones in the query. This addresses the problem encountered when the query uses the word *car* but the document uses the term *automobile*. But retrieval of information graphics presents an additional problem. Consider a query such as *"Which car manufacturer has the highest net profit?"* A graphic such as the one in Figure 1 displays a set of car manufacturers on the x-axis (Toyota, Nissan, etc.) but nowhere in the graphic does the word *car* or a synonym appear. Identifying the ontological category, such as *car* or *automobile*, of these labels is crucial since the user's query often generalizes the entities on the independent axis of relevant graphs rather than listing them.

To expand a given text string s, we use Wikimantic (Boston et al., 2013), a term expansion method that uses Wikipedia articles as topic concepts. A topic concept is a unigram distribution built from words in the Wikipedia article for that topic. A string *s* is interpreted by Wikimantic into a mixture concept that is a weighted vector of topic concepts that capture the semantic meaning of the words in s. Each topic concept is weighted by the likelihood that the concept (Wikipedia article) generates the text string s. The weighted concepts are then used to produce a unigram distribution of words that serve as the expansion of the terms in the string s. One issue in graph retrieval is correlating the requisite x-axis content specified in the user query with the x-axis labels in graphs. A query such as "Which car manufacturer has ... ?" is requesting a graph where "car manufacturers" are listed on the x-axis. Thus we need to recognize individual x-axis words which are often proper nouns (e.g., "Ford", "Nissan", "Honda") as instances of car manufacturers. In the case of labels on the independent axis (such as *Toyota*, *Nissan*, *Honda*, etc.), words such as *car* or *automobile* are part of the produced unigram distribution — that is, as a side effect, the ontological category of the individual entities becomes part of the term expansion.

We use Wikimantic to interpret and expand each of the graph components G_x, G_y, G_f, and G_c. The expansion of the graph components (as opposed to the typical expansion of the query) accomplishes two objectives: 1) it addresses the problem of sparse graphic text by adding semantically similar words and 2) it addresses the problem of terms in the query capturing general classes (such as *car* or *automobile*) when the graphic instead contains an enumeration of members of the general class. Expansion of the words in the graphics, unlike query expansion, has the added advantage that it is completed in advance and off-line.

5.1 General Features

Our general feature set includes 17 general features capturing a variety of different kinds of relevance scorings between two bags of words consisting respectively of words from the user query and words from the candidate infographic:

- GF_1: A modified version of Okapi-BM25 (Fang et al., 2004) calculated as:

$$\text{Okapi-BM25 Score} = \sum_{w \in Q} \log \frac{|D|+1}{df_w+1} \cdot \frac{tf_w \cdot (1+k_1)}{tf_w+k_1}$$

  where Q is a query, $|D|$ is the number of graphs in the digital library, w is a query word in Q, df_w is the frequency of graphs containing word w in the digital library, tf_w is the frequency of word w in the text expansion of the given graphic, and k_1 is a parameter that is typically set to 1.2. Okapi-BM25 is a bag-of-words ranking function used in many information retrieval systems. Our modified version of Okapi-BM25 addresses the problem of negative values that can occur with the original Okapi formula. In addition, our formula does not take text length or query term frequency into account since graphics have relatively similar amounts of text and most terms in a query occur only once.

- GF_2: The term frequency-inverse document frequency (tf-idf) value of query words that appear in the expanded graphic.

- GF_3: The maximum, minimum, and arithmetic mean of the term frequency (tf) of query words that appear in the expanded graphic.

- GF_4: The maximum, minimum, and arithmetic mean of inverse document (graphic) frequency (idf) of query words that appear in the expanded graphic.

5.2 Structural Features

Our structural feature set includes 35 features: 17 that address how well a graphic's x-axis (independent axis) relates to the requisite x-axis content hypothesized from the user's query and 18 that address how well a graphic's y-axis (dependent axis) content captures the requisite dependent axis content hypothesized from the query. The following are a few of the x-axis features:

- SFX_1: The Okapi-BM25 value using the same modified formula as for general features, given the query x-axis words and the text expansion of the x-axis labels in the graphic.

- SFX_2: The tf-idf of x-axis words hypothesized from the query that appear in the expansion of the x-axis labels in the graphic.

- SFX_3: The maximum, minimum, and arithmetic mean of tf of x-axis words hypothesized from the query that appear in the expansion of the x-axis labels in the graphic.

- SFX_4: The maximum, minimum, and arithmetic mean of idf of x-axis words hypothesized from the query that appear in the expansion of the x-axis labels in the graphic.

The y-axis features (SFY_1, SFY_2, SFY_3, and SFY_4) include the same relevance measurements as used for the x-axis features; for example, feature SFY_1 captures the Okapi-BM25 score for the y-axis content hypothesized from the query and the text expansion of the graphic y-axis words, and feature SFY_2 is the tf-idf score for the y-axis content hypothesized from the query and the expansion of the graphic y-axis words. One additional feature that is specific to the y-axis is:

- SFY_5: The posterior probability of the Wikimantic (Boston et al., 2013) mixture concept[2] for the y-axis words hypothesized from the query, given the Wikimantic mixture concept representing the y-axis words in the graph, referred to as $p(Q_y|G_y)$. Both query y-axis words and the graphic y-axis

[2] A Wikimantic mixture concept is a set of weighted concepts (Boston et al., 2013).

descriptor are each interpreted by Wikimantic into a mixture concept, M_{qy} and M_{gy} respectively. Recall from the introduction to Section 5 that a mixture concept is a weighted vector of topic concepts that defines the semantic meaning of a term or set of terms. For example, the mixture concept for the country China is represented by a vector of topic concepts such as *"China"*, *"People's Republic of China"*, *"Mainland China"*, and so on. Wikimantic estimates the probability of a concept given another concept by the amount of overlapping words between the two concepts. For example, the topic concept for the country *"United States"* is likely to contain similar words to the concept for *"China"*, such as the words *"country"*, *"nation"*, *"region"*, *"capital"*, *"GDP"*, etc. Therefore the probability of *United States* given *China* is likely to be higher than that of *United States* given the topic *"rugby"*.

5.3 Content Features

Our content feature set contains four features that address how well the intended message of a graphic captures the requisite message content hypothesized from the user's query. Ideally, a relevant graphic's intended message G_m will match the message category Q_m hypothesized from the user's query. When the two do not match exactly, we use a hierarchy of message categories and the concept of *relaxation* as the paradigm for estimating how much perceptual effort would be required to extract the message specified by the query from the graphic. For example, suppose that the query requests a *Rank* message; graphics with *Rank* messages will convey the rank of a specific entity by arranging the entities in order of value and highlighting in some way the entity whose rank is being conveyed. Graphics with a *Rank-all* intended message will convey the rank of a set of entities without highlighting any specific entity; the *Rank-all* message category appears as a parent of *Rank* in the message hierarchy since it is less specific than *Rank*. Although one can identify the rank of a specific entity from a graphic whose intended message is a *Rank-all* message, it is perceptually more difficult since one must search through the graph for the entity whose rank is desired. By moving up or down the message hierarchy from Q_m to G_m, Q_m is relaxed to match different G_m. The greater the degree of relaxation involved, the less message-relevant the infographic is to the user query. The four content-based features are:

- CF_1: Whether the message category Q_m hypothesized from the user's query matches exactly the intended message category G_m of the graphic.
- CF_2: The amount of relaxation needed to relax the message category Q_m hypothesized from the user's query so that it matches the intended message category G_m of the graphic.
- CF_3: The Okapi-BM25 value given the intended message focused entity Q_f (if any) hypothesized from the user's query and the focused entity G_f in the graphic, if any.
- CF_4: The Okapi-BM25 value given the intended message focused entity Q_f(if any) hypothesized from the user's query and the non-focused x-axis entities G_{nf} in the graphic.

6 Constructing a Ranking Model for Graph Retrieval

Learning-to-rank algorithms (Liu, 2009) construct a learned model that ranks objects based on partially ordered training data. Tree-based ensemble methods have been shown to be very effective (Chapelle and Chang, 2011). We experimented with two state-of-the-art tree-based learning-to-rank algorithms as implemented in the RankLib library (http://people.cs.umass.edu/vdang/ranklib.html): Multiple Additive Regression Trees abbreviated as MART (Friedman, 2001) and Random Forest (Breiman, 2001).

A human subject experiment was performed to collect a set of 152 full sentence user queries from five topics. The queries were collected from 5 different tasks and covered a variety of topics involving companies. Two sample queries are "What credit card company made the most money in 2008?" and "How does Avis rank compared to other car rental companies in revenue?". We used the collected queries to search on popular commercial image search engines to get more infographics from the same topics. These commercial search engines include Google Image, Microsoft Bing Image Search, and Picsearch. This produced a set of 257 infographics that are in the topics of the collected queries. Each

query-infographic pair was assigned a relevance score on a scale of 0-3 by an undergraduate researcher. A query-infographic pair was assigned 3 points if the infographic was considered highly relevant to the query and 0 points if it was irrelevant. Query-infographic pairs where the graphic was somewhat relevant to the query were assigned 1 or 2 points, depending on the judged degree of relevance of the graphic to the query. This produced a corpus for training and testing.

Using MART and Random Forest, we developed four models from all 56 features, including the structural and content features. Two of the models were built using our learned decision trees (Li et al., 2013b; Li et al., 2013a) to analyze the queries and hypothesize the requisite x-axis content, y-axis content, message category, and focused entity (if any); see the second row of Table 1. Since the learned decision trees are not perfect, the other two models were built from hand-labelled data; see the last row of Table 1. In addition, two baseline models were constructed using only the general features and omitting the structural and content-based features.

6.1 Evaluating the Models

Normalized Discounted Cumulative Gain (NDCG) (Järvelin and Kekäläinen, 2002) is used to evaluate the retrieval result. Table 1 displays the NDCG@10 results. In each case, we averaged together the NDCG results of 10 runs using the Bootstrapping Method (Tan et al., 2006) in which the query data set is sampled with replacement to select 152 queries; these 152 queries, and for each query the relevance judgements assigned to each of the graphics, comprised the training set, with the unselected queries and their relevance judgements comprising the testing set. The Bootstrapping method is a widely used evaluation method for small datasets. Typically, approximately 63% of the dataset is selected for the training set (with some items appearing more than once in the training set) and 37% for the testing set. The second row of Table 1 provides results when each query is processed by our learned decision trees to extract the structural content and message category that the query specifies. However, the decision trees are imperfect. To determine whether our system could do even better if the decision trees were improved, the third row of Table 1 reports results when each query was hand-labelled with the correctly extracted structural and message content.

The models using all 56 features produced significantly better results than the baseline model that used just the general features, indicating that structural and content-based features are very important and must be taken into account in graph retrieval. In addition, the models built from the hand-labelled data produced better results than the models where the structural and content features were automatically extracted from the queries using the learned decision trees; this suggests that improving the decision trees that process the queries would improve the accuracy of the learned graph retrieval models. In some cases, the Random Forest learned model performed better than the MART model, but the improvement was not significant. The experimental results show that both MART and Random Forest using all 56 features, either using the hand-labelled query data or decision tree query data, provide significantly better results than the baseline approach ($p<0.0005$).

Algorithm	MART	Random Forest
Baseline	0.4943	0.4935
Decision Tree Query Data	0.6239	0.6258
Hand-labelled Query Data	0.6723	0.6758

Table 1: NDCG@10 Results

Figure 2 displays the NDCG@k results for different values of k. The bottom solid line and the line composed of triangles depict the baseline results, the middle dashed line and the line composed of circles depict the results using the decision tree query data, and the top solid line and the line composed of triangles depict the results using the hand-labelled data. All of the models improve as k increases. Most important, both our MART and Random Forest models constructed from all 56 features perform much better than the baseline models for all values of k. Thus we conclude that the use of structural and content features helps in selecting the most relevant graphic as well as the most relevant sets of graphics.

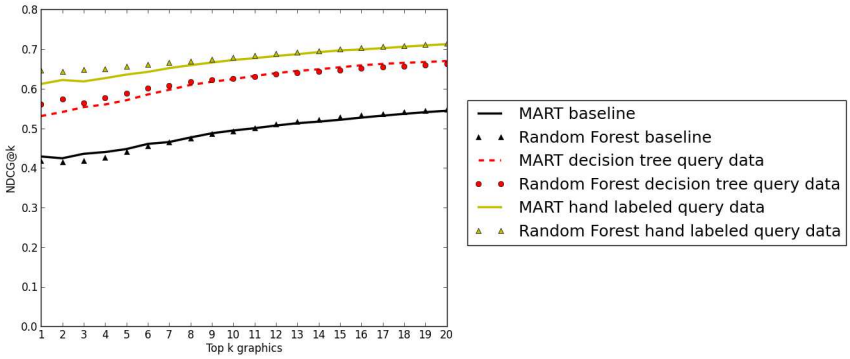

Figure 2: NDCG@k for Various Values of n

6.2 Analysis of Influential Features

In both MART and Random Forest, features that are used at the top levels of each tree are more important in ranking a graphic than features that appear lower in the tree. We analyzed the importance of each of the 56 features based on the level in each tree where the feature is first used. 70% of the top ten most important features in the trees produced by both MART and Random Forest were structural or content features. The most influential two features in trees produced by MART were SFY_5 which captures $p(Q_y \mid G_y)$ and SFX_2 which captures the tf-idf of x-axis words hypothesized from the query that appear in the expansion of the x-axis labels in the graphic. Although these two features were not the two most influential features in the trees produced by Random Forest, they did appear among the top 5 features. Two content-based features appeared among the top ten most important features: CF_3 which captures the relevance of the focused entity Q_f (if any) hypothesized from the query to the focused entity G_f (if any) in the graphic and CF_4 which captures the relevance of the focused entity Q_f (if any) hypothesized from the query to the non-focused entities G_{fx} in the graphic. The content features CF_1 and CF_2 that measure relevance of the message category hypothesized from the query to the intended message category in a candidate graphic appeared among the top 20 features but not among the top 10 features. Further inspection of the trees and analysis of the queries and graphics leads us to believe that message category relevance is influential in refining the ranking of graphics once graphics with appropriate structural content have been identified. Our future work will examine these two features more closely and determine whether modifications of them, or changes in how they are used, will improve results.

Based on these results, we conclude that structural and content-based features are important when ranking infographics for retrieval and must be taken into account in an effective graph retrieval system.

7 Conclusion and Future Work

To our knowledge, no other research effort has considered the use of structural and content-based features when ranking graphics for retrieval from a digital library. We developed learned models that take into account how well the structure and content of an infographic matches the requisite structure and content hypothesized from the user query, and showed that these models perform significantly better than baseline models that ignore graph structure and message content. In addition, an analysis of the learned models showed which structural and content features were most influential. In our future work, we will improve our methods for hypothesizing requisite features of relevant graphics and will analyze our relaxation metric to determine whether an improved metric will play a more influential role in ranking graphics for retrieval.

Inducing Discourse Connectives from Parallel Texts

Majid Laali and Leila Kosseim
Department of Computer Science and Software Engineering,
Concordia University, Montreal, Quebec, Canada
{m_laali, kosseim}@cse.concordia.ca

Abstract

Discourse connectives (e.g. *however, because*) are terms that explicitly express discourse relations in a coherent text. While a list of discourse connectives is useful for both theoretical and empirical research on discourse relations, few languages currently possess such a resource. In this article, we propose a new method that exploits parallel corpora and collocation extraction techniques to automatically induce discourse connectives. Our approach is based on identifying candidates and ranking them using Log-Likelihood Ratio. Then, it relies on several filters to filter the list of candidates, namely: Word-Alignment, POS patterns, and Syntax. Our experiment to induce French discourse connectives from an English-French parallel text shows that Syntactic filter achieves a much higher MAP value (0.39) than the other filters, when compared with LEXCONN resource.

1 Introduction

Discourse relations are often categorized as being *implicit* or *explicit* depending on how they are marked linguistically (Prasad et al., 2008). *Implicit* relations between two text spans are inferred by the reader even if they are not explicitly connected through lexical cues. On the other hand, *explicit* relations are explicitly identified with syntactically well-defined terms, so called *discourse markers* or *discourse connectives* (DCs). A list of DCs is a valuable resource to help the automatic detection of discourse relations in a text. Discourse parsers (e.g. (Lin et al., 2010)) often use DCs as a powerful distinguishing feature to tag discourse relations (Pitler and Nenkova, 2009). A list of DCs is also instrumental in generating annotated training data which, in turn, is critical for training data-driven parsers (Prasad et al., 2010).

In this article, we propose an automatic method to induce a list of DCs for one language from a parallel corpus. We present an experiment in inducing a French DC list from an English-French parallel text. Our approach is based on the hypothesis that discourse relations are retained during the translation process. Therefore, if a reliable discourse tagger exists in a language, we can produce a corpus with discourse annotation labels in any language that has a parallel text with that language. Fortunately, according to (Versley, 2011), in English, the discourse usage of DCs can be automatically identified and labeled with their relation with 84% precision; a result that is close to the reported inter-annotator agreement. Moreover, with the advancement of statistical machine translation, today English parallel corpora for several languages are publicly available.

Although we can expect little variability in the usage of discourse relations in parallel texts, this is not the case for DCs. In other words, translated texts may not always reproduce DCs of the source texts. Since discourse relations can be conveyed either explicitly with a DC or implicitly, a translator may choose to remove explicit DCs in the source text and express the relation in the translated text implicitly. In fact, Meyer and Webber (2013) has shown that DCs drop out up to 18% of the times in human reference translations.

Proceedings of COLING 2014, the 25th International Conference on Computational Linguistics: Technical Papers, pages 610–619, Dublin, Ireland, August 23-29 2014.

To alleviate noisy data (i.e. sentences whose DCs are dropped during the translation), we have been inspired by work in collocation extraction (e.g. (Seretan, 2010)). As such, our approach consists of two main steps: candidate identification and candidate ranking and filtering. We have used several types of information to filter out incorrect DC candidates and used Log-Likelihood ratio to rank them. These filters include Part-of-speech tags, syntactic tree and word-alignment. Our results show that syntactic information outperforms the other filtering methods for the DC identification task.

This paper is organized as follow. Section 2 reviews related work. Section 3 describes our approach to extract DCs from a parallel text. Section 4 reports detailed experimental results, and finally Section 5 presents our conclusion and future work.

2 Related Work

Currently, publicly available lists of DCs already exist for English (Knott, 1996), Spanish (Alonso Alemany et al., 2002), German (Stede and Umbach, 1998), and French (Roze et al., 2012). Typically, these lists have been manually constructed by applying systematic linguistic tests to a list of potential DCs. For example, (Roze et al., 2012) gathered a potential list of DCs (about 600 expressions) from English DC translations and various lists of subordinate conjunctions and prepositions. Then, they applied syntactic, semantic, and discourse tests to filter this initial list and identify DCs and their associated relations.

A list of DCs can also be created automatically by analyzing lexically-grounded discourse annotated corpora. The Penn Discourse Tree Bank (PDTB) (Prasad et al., 2008) is the largest resource to date that provides a discourse annotated corpus in English. In this corpus, discourse relations between two text spans are labeled with a DC. If a discourse relation is expressed without any explicit DC, an inferred DC which conveys the same discourse relation has been inserted between the text spans. This approach has been widely adopted to create discourse tree banks in several other languages such as Turkish (Zeyrek et al., 2010), Chinese (Zhou and Xue, 2012), Arabic (Al-Saif and Markert, 2010), Czech (Mladová et al., 2008), and Hindi (Oza et al., 2009).

Several work have already investigated the use of discourse relations in machine translation (e.g. (Meyer and Webber, 2013; Meyer, 2011)). Others have attempted to generate discourse annotated corpora from parallel corpora (e.g. (Cartoni, 2013; Meyer, 2011; Popescu-Belis et al., 2012; Versley, 2010; Zhou et al., 2012)). Among these, the most similar approach to ours is Versley (2010) who has projected English DCs to their counterparts in German in a parallel corpus. Doing this, he produced a corpus where discourse vs. non-discourse usage of German DCs were annotated and built a discourse parser from the corpus. Although Versley (2010) used a list of DCs in generating the dataset, he also tried to automatically induce the DCs from his corpus. However, Versley (2010) did not explicitly evaluate his list of DCs, but rather focused on his parser. The main difference between our work and Versley (2010) is that he has solely employed word alignment to find DCs, which as mentioned in his paper, is not sufficient to align discourse connectives. In contrast, we have used and compared three approaches for inducing a DC list: word-alignment, POS patterns and syntactic information.

3 Method

Our approach to the extraction of DCs consists of two steps. The first step is the preparation of the parallel corpus with discourse annotations; the next step is the mining of the parallel corpus to identify DCs.

3.1 Preparing the Parallel Corpus

Our experiment has focused on building a French list of DCs from English. In order to build the English-French parallel corpus with discourse annotations, we used the Europarl corpus (Koehn, 2005). The Europarl corpus contains sentence-aligned texts in 21 European languages that have been extracted from the proceeding of the European parliament. For our study, we have only considered the English-French part of this corpus.

To label discourse relations in the parallel text, we have automatically parsed the English side of the parallel text and assumed that the same relation existed in the French translation. Although this

assumption is not directly addressed in previous work, it has been implicitly used by many (e.g. (Cartoni, 2013; Meyer et al., 2011; Popescu-Belis et al., 2012; Versley, 2010; Prasad et al., 2010)). In particular, Prasad et al. (2010) have suggested to the use of the back-translation technique (translating a text from language A to language B, then back translate the same text from language B to language A again) to discover new DCs. In this work, the authors have implicitly assumed that the discourse relations of the initial text are maintained in the back-translation. We argue that since discourse relations are semantic and rhetorical in nature, they usually transfer from source language to target language. We have used the PDTB-style End-To-End Discourse parser (Lin et al., 2010) to parse the English text. This parser has been trained on Section 02-22 of the PDTB corpus (Prasad et al., 2008) and can identify and label a DC with its relation with 81.19% precision when tested on Section 23 of the PDTB.

After tagging the English text, we have only kept parallel sentences whose English translation had exactly one discourse relation. This was done to ensure that no ambiguity would exist in the discourse relation of the French sentences, once we transfer the discourse relation from English to French. In other words, we can label each French sentence with a single discourse relation, that of its English translation. In addition, we have also removed sentences whose discourse relations were expressed implicitly. Although the (Lin et al., 2010) parser is able to identify both implicit and explicit discourse relations, we have only considered relations expressed with a DC. This has been done, since not only the precision of the parser in detecting discourse relation in the absence of DC is very low (24.54%), but also we would not expect implicit relations to help us to identify DCs in French. In other words, a translator only occasionally inserts DCs in a translation and therefore we would not expect that too many DCs would exist in the translation of sentences with an implicit discourse relation.

Table 1 provides statistics on the original English-French Parallel Corpus and the corpus extracted with exactly one explicit discourse relation per sentence. Initially, the Europarl corpus contained 2,054K sentences (57 million and 63 million words in the English and the French sides respectively). However, after removing the sentences with more than one discourse relation, the corpus was reduced to 543K sentences automatically annotated with discourse relations. The English part of these sentences contains 14 million words, while the French part contains 15 million words.

	# Parallel Sentences	**# English Words**	**# French Words**
Original Europarl Corpus	2,054K	57M	63M
Extracted Corpus	543K	14M	15M

Table 1: Statistics on the Parallel Corpora

Although this new annotated corpus represents only 26% of the original French Europarl, the corpus still represents a large annotated corpus with respect to existing discourse-annotated corpora. For example, the corpus is almost 30 times bigger than PDTB. Therefore, due to the large size of the corpus, it can be expected that eventual errors in the corpus (e.g. sentences whose discourse relations have been changed during the translation) should not affect the results significantly.

3.2 Mining the Parallel Corpus

Once the aligned corpus has been built, we have mined the French side to identify DCs. To do this, we have produced an initial list of DC candidates from the corpus; then we have ranked the list based on the Log-Likelihood Ratio (LLR). Finally, we have applied several filters to refine the final list.

To produce the initial DC candidates, we have extracted n-grams (unigrams, bigrams, ..., and six-grams) from all French sentences as a potential candidate for a DC. Then, we have stored each potential candidate with its discourse relation as a pair. For example, in sentence (1) below, the English sentence contains an ALTERNATIVE relation signaled with the "*So*" English DC. We have therefore produced the pairs "{ALTERNATIVE, *Donc*}", "{ALTERNATIVE, *Donc d*}", "{ALTERNATIVE, *Done d un*}", etc. from its corresponding French sentence.

(1) So, judicially, something needs to be done./ALTERNATIVE
Donc, d'un point de vue judiciaire, il convient de prendre des mesures.

Once the initial list of DC candidates has been extracted, we have used the LLR to rank the DCs[1]. LLR evaluates association strength between a pair of events based on their frequency. This measure, for example, has been largely used in collocation extraction (e.g. (Seretan, 2010)). According to Evert (2004), LLR is equivalent to the average mutual information that one event conveys about the other. For the sake of completeness, Figure 1 shows the formula used to calculate LLR for two binary random variables X and Y. Note that in Figure 1, O refers to the observed frequencies, E refers to the expected frequencies and N refers to the total number of observations.

$$LLR(X,Y) = 2 \times \sum_{i=1}^{2} \sum_{j=1}^{2} O_{ij} \times log(\frac{O_{ij}}{E_{ij}})$$

$$E_{ij} = \frac{\sum_{k=1}^{2} O_{ik} \times \sum_{k=1}^{2} O_{kj}}{N}, \; N = \sum_{i=1}^{2} \sum_{j=1}^{2} O_{ij}$$

	$Y = v$	$Y = \neg v$
$X = u$	O_{11}	O_{12}
$X = \neg u$	O_{21}	O_{22}

Figure 1: The formula used to calculate LLR.

In our configuration, our pairs of events consist of the observation of a discourse relation and a DC candidate. We have computed contingency tables of frequencies of these pairs from the French corpus and then used the NSP package (Pedersen et al., 2011) to calculate the LLR for each candidate to rank them. Once the initial list of DCs has been ranked, we have experimented with several types of filters to refine it.

Frequency Filter: This simple filter tries to account for the fact that low frequent events may affect the reliability of the LLR measure. Therefore, as a simple baseline filter, we have removed DC candidates that appear less than a certain number of times in the French corpus.

Word-Alignment Filter: This filter removes any DC candidate that does not align with any part of an English DC. In other words, this filter keeps any consecutive words in the French text if at least one of its composing words aligns to at least one word of an English DC when using a word-alignment model. A word-alignment model maps each word in the target text to its translation in the source text (creating an n-to-one mapping). Therefore, two word-alignment models can be produced (i.e. when the target text is French (En2Fr) or when the target text is English (Fr2En)). In addition, Och and Ney (2003) have also presented another word-alignment model called Intersect word-alignment that uses a heuristic to combine En2Fr and Fr2En word alignments. Figure 2 presents the later alignment for two parallel sentences. An alignment between two words is shown by a line connecting them. For example, in these sentences, the connective "*therefore*" is aligned to the three French words "*raison pour laquelle*". We have used MGIZA++ (Gao and Vogel, 2008) to generate En2Fr and Fr2En word-alignments; then used Moses (Koehn et al., 2007) to compute the Intersect word alignment. In this article, we only consider Intersect word-alignment, as it is able to map n-to-m mapping[2].

Syntactic Filters: DCs are defined as syntactically well-defined terms (Prasad et al., 2008). The syntactic filters exploit this property and remove any constituent that is not categorized as a DC. In other words, these filters keep only Prepositional Phrases (PP), Coordinate Phrases (CP) or Adverbial Phrases (ADVP). We have implemented two types of Syntactic Filters. The first one (called **POS Filter**) uses predefined POS patterns to filter out incorrect candidates. We have manually defined POS patterns based on an analysis of the French DCs in the LEXCONN resource (Roze et al., 2012). Table 2 shows the POS patterns we have used along with an example. The second approach (called **Syntax Tree Filter**) makes use of Syntax Trees to filter unlikely syntactic combinations. Therefore, after parsing all the

[1]We have also used other association measures, such as PMI, t-score test, and Chi-square test, but LLR achieved the best results in terms of mean average precision.

[2]We have also experimented with other word-alignments but their performances were not better. The Intersect model outperformed the Fr2En word-alignment model and acheived similar results as the En2Fr word-alignment model.

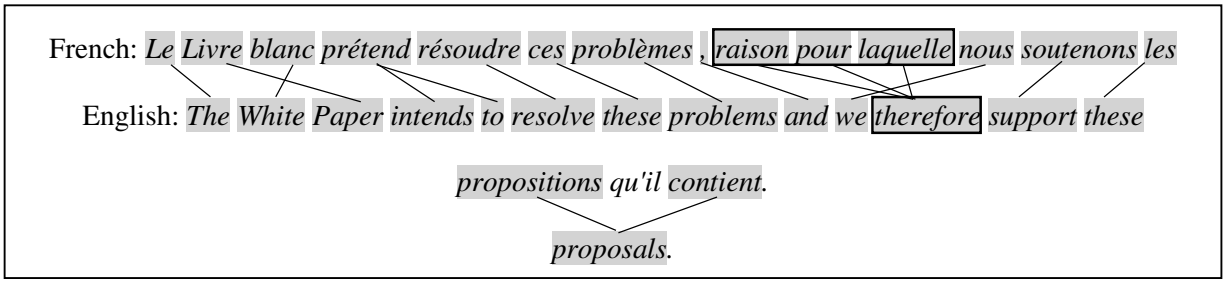

Figure 2: Example of Word-Alignments between English and French Texts.[3]

French sentences, the Syntax Tree Filter only kept PPs, CPs and ADVPs. We have used the Stanford POS Tagger (Toutanova et al., 2003) and the Stanford PCFG Parser (Green et al., 2011) for POS tagging and parsing the French text, respectively.

POS Pattern	Example	POS Pattern	Example
ADV	alors	P ADV	après tout
C	et	P N	par exemple
P	comme	P P	avant de
ADV C	encore que	V C	considérant que
ADV P	en outre	N D P	de ce fait
C C	parce que	P N P	de manière à
N P	histoire de	P D N	dans ce cas

Table 2: POS Patterns Used in the POS Filter.

3.3 Gold Dataset

To evaluate our final ranked list of French DCs candidates and compare the four filters, we have used the LEXCONN dataset (Roze et al., 2012). This manually constructed dataset includes 467 French discourse connectives with their syntactic categories and the discourse relations that they express[4]. Table 3 provides some statistics about LEXCONN. We also provide statistics about the DCs in PDTB for comparative purposes. Each row of Table 3 indicates the number of DCs and the average number of relations per DC in parenthesis. For example, in LEXCONN, 70 DCs are unigrams and on average they indicate 1.66 different discourse relations. Table 3 also shows statistics on the length of DCs (in number of words). It is interesting to note that French tends to have longer DCs than English. Indeed LEXCONN contains 69 DCs that contain four words (e.g."*au même titre que*", "*dans l'espoir de*", etc.) while there are only 4 four-gram DCs in English (e.g. "*as it turns out*" or "*on the other hand''*).

Although there are fewer relations in PDTB, English DCs tend to be more ambiguous. As Table 3 shows, each English DC conveys 3.05 relations on average, while this number is 1.29 for French DCs. We also notice that the longer the DC, the less ambiguous it is in terms of discourse relations it can convey. For example, unigram DCs in French convey on average 1.66 relations, however the number of relations decreases when the length of the DC increases, so that for a trigram DC, on average, there are 1.22 relations.

3.4 Evaluation Metric

Since our task is very similar to a collocation extraction task, we have used a similar evaluation methodology to evaluate our results. We have modeled the task of inducing DCs as a binary classification and tried to evaluate it using precision and recall. In other words, by choosing a threshold for LLR, we can

[3]The examples in this figure are taken from the Europarl corpus.

[4]LEXCONN has 431 DCs, however if we consider different spelling of each DC (e.g. "*alors que''* and "*alors qu'*"), the number increases to 467.

[5]As the parser labels relations at the second level of the PDTB hierarchy, we here report only the number of second level relations.

	LEXCONN (French)	PDTB DCs (English)
# Discourse relation	29	16[5]
# Total number of DCs	467 (1.29)	133 (3.05)
# Unigram DCs	70 (1.66)	76 (3.50)
# Bigram DCs	169 (1.25)	33 (2.70)
# Trigram DCs	139 (1.22)	18 (2.11)
# Four-gram DCs	69 (1.17)	4 (2.50)
# Five-gram DCs	14 (1.07)	1 (1.00)
# Six-gram DCs	5 (1.20)	0 (-)
# Seven-gram DCs	1 (2.00)	1 (1.00)

Table 3: Statistics on Discourse Connectives in LEXCONN and PDTB v.2.

label each potential DC candidate as "*DC*" if its LLR is above the threshold or "*non-DC*" otherwise. However, choosing the LLR threshold depends on the application and there is no principled way to determine an ideal value for the threshold. Therefore, we measured the performance of the ranked list of DCs with 11-point interpolated average precision curve (Manning et al., 2008). This curve shows highest precision at the 11 recall levels of 0.0, 0.1, 0.2, ..., 1.0. Using this methodology, we can evaluate the ranked list without considering any threshold.

In addition to the 11-point interpolated average precision, we also used Mean Average Precision (MAP) (Manning et al., 2008). As Pecina (2010) noted for the evaluation of collocation extraction, since the precision is not reliable at low recall levels and changes frequently at high recall levels, we only consider average precision in the interval of $<0.1, 0.9>$when we are calculating MAP.

Another consideration when evaluating our final ranked lists is how to evaluate DC fragments. For example, when evaluating the candidate "*à ce point*", we have to label it as a wrong DC because it is not repertoried in LEXCONN. However, it is a segment of the French DC "*à ce point que*" and only one word is missing in the expression. This issue has been also addressed in the field of collocation extraction; in particular, Kilgarriff et al. (2010) suggested to consider a partial collocation as a true positive, since it signals the presence of the longer collocation. However, this "was not a decision that human evaluators were comfortable with" (Kilgarriff et al., 2010). In our evaluation, we have used two approaches to evaluate fragment DCs. In the first approach, the Exact Match approach, we have considered fragment DCs as an incorrect DC. In the other approach, the Exclude-From-The-List approach, we have removed them from our list, so that when we analyzed the find list, they do not appear as an incorrect DC.

4 Results

To evaluate the DC extraction approach, we first analyzed the candidate generation step without any filtering. Table 4 provides the frequency distribution of LEXCONN's DCs in the annotated corpus. This table shows that the longer the DCs, the less frequent they are in our corpus. For example, all one-word DCs of LEXCONN appear in the corpus, while 21% of LEXCONN's five-gram and 60% of LEXCONN's six-gram DCs never occur in the corpus. Overall, 14% of all LEXCONN DCs do not appear in the corpus.

Recall that the Frequency filter removes DCs that do not appear enough times in order to use LLR to rank candidates. In our experiment, we used a minimum threshold of 10 for this filter. Therefore, the filter removed additional 20% DCs, so that overall only 66% of LEXCONN's DCs are considered in the corpus. Most of these removed DCs are not common or rather formal expressions in French such as "*conséquemment*", "*hormis que*", "*tout bien considéré*". However, several more informal DCs commonly used in French were also removed, especially in the trigram and more groups of DCs (e.g. "*à part ça*").

Once we calculated the number of available DCs in the corpus, we evaluated the ranked list of DCs after applying each filter. Table 5 shows the MAP values of each filter using both the Exact Match

	freq > 10	**$10 \geq$ freq > 0**	**freq $= 0$**
# Unigram DCs	93%	7%	0%
# Bigram DCs	76%	16%	8%
# Trigram DCs	60%	24%	16%
# Four-gram DCs	36%	31%	33%
# Five-gram DCs	50%	29%	21%
# Six-gram DCs	20%	20%	60%
Overall	66%	20%	14%

Table 4: Distribution of LEXCONN DCs in the Extracted Corpus.

Filter	**MAP with Exact Match**	**MAP with Exclude-From-The-List**
LLR only	0.06	0.07
LLR + Word-Alignment Filter	0.10	0.12
LLR + POS Pattern Filter	0.12	0.14
LLR + Syntax Tree Filter	0.39	0.44

Table 5: MAP of Each Filter.

and Exclude-From-The-List approaches to judge fragment DCs[6] (see Section 3.4). With all four filters, we first used the Frequency Filter and then ranked the candidates using LLR. Our results show that using the POS Pattern Filters outperforms the Word-Alignment filter. For example, if we consider the Exact Match metric, the MAP value of the Word-Alignment is 0.10 while it is 0.12 for the POS-Pattern Filter. As Table 5 shows, the best MAP values are achieved using the Syntax Tree Filter. For the rest of document, we only consider the Exclude-From-The-List approach to judge fragment DCs, since we would like to focus on other sources of errors in the ranked list of DCs in addition to the fragment DCs.

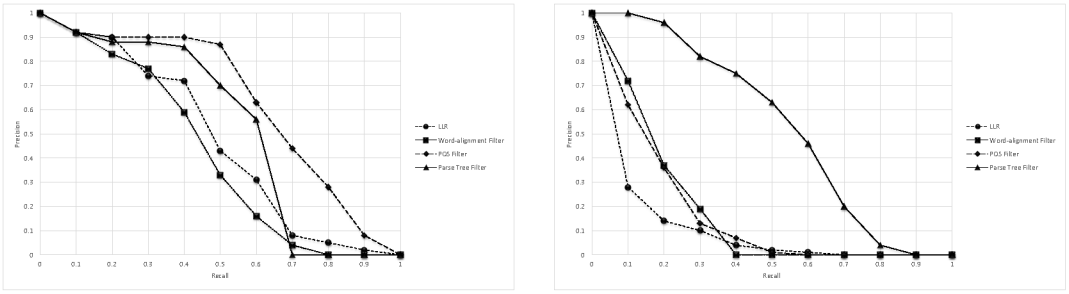
After analyzing the list of DCs generated by all approaches, we noted that the size of a DC affects the performance of our approach. Figure 3 shows the performance of each filter in detecting unigram (Figure 3a) and bigram (Figure 3b) DCs. These figures shows that except for the Syntax Tree filter, the performance of the identification of bigram DCs drops rapidly when compared with the identification of unigram DCs. To better understand why longer DCs are more difficult to identify, we manually analyzed the errors of each filters. The most significant proportion of errors with bigram DCs is generated from a unigram DC and a noisy word. For example, "*mais je*" is composed of the French DC "*mais*" and a noisy word "*je*". As these errors usually do not create a syntactic well-defined constituent, they can only be filtered out by the Syntax Tree Filter.

The POS pattern filter cannot detect noisy syntactic components since detecting such components needs contextual syntactic information. When we analyzed negative examples of this filter, we noticed that most of bigram errors are comprised of two words that belong to two different chunks. For example, in sentence (2) below, the POS pattern "ADV C" extracts "*donc que*", but these two words belong to two different syntactic constituents (i.e *ADV* and *Ssub*).

(2) VN [Je demande] ADV [donc] Ssub[que l'on soutienne l'Irlande dans ce cas particulier].

It is interesting to note that the ranked list created with the Syntax Tree Filter includes several DCs that do not appear in the LEXCONN lexicon but are nevertheless correct DCs in French. Among the top 100 candidates labeled as an incorrect DC, we have found 31 correct DCs which are not listed in LEXCONN, such as"*toutefois*", "*certes*" and "*au lieu de cela*". The work of (Roze et al., 2012) (or any manually curated list of DCs) constitutes an invaluable resource. However, as Prasad et al. (2010) mentioned, DCs are open-class terms. Therefore, our approach to induce DCs from parallel texts can be

[6]When calculating recall points, we only considered the available DCs in the dataset after applying the Frequency Filter (i.e. 66% of DCs).



(a) Unigram DCs (b) Bigram DCs

Figure 3: 11-Point Interpolated Average Precision Curve for the Extraction of Unigram and Bigram DCs

used to improve the coverage of such a list.

The results of the Word-alignment show that the intersect word-alignment model cannot align DCs in English to French. Indeed, our analysis shows that only 176 LEXCONN DCs (38%) were aligned to English DCs. We believe that since a discourse relation can be conveyed with different DCs and human translators can choose between them during the translation, aligning DCs is much harder for alignment models. Moreover, DCs can be also placed at the beginning or at the end of discourse units, therefore the word-alignment needs to tolerate long-distance alignment to align them.

Finally, since LEXCONN uses a different set of relations than PDTB's relations, we cannot evaluate relations that are assigned to French DCs in the ranked list of candidates. However, a preliminary analysis of 20 randomly selected pairs of <DC, relation>among the top 100 pairs in the ranked list of the Syntax Tree Filter showed that it achieves 75% precision in labeling DCs.

5 Conclusion and Future Work

In this paper, we have presented an approach to induce discourse connectives from a parallel text. In our approach, we have extracted a list of DC candidates and ranked them with the Log-Likelihood Ratio. We have also used several filters to prune the final list of DCs: Word-Alignment, POS Patterns and Syntax Tree Filter. We have achieved the best result in term of MAP with the Syntax Tree Filter. Our analysis shows that the size of discourse connectives affects the quality of the filters. We also found that some candidates that labeled as wrong discourse connective, are indeed correct discourse connectives, yet are not covered in the LEXCONN lexicon.

There are several ways in which this work can be extended. Firstly, although we used the French language to do our experiment, the same methodology can be applied to other languages. It is worth mentioning that French has pervasive multi-word expressions and our approach suffers from such components since they are usually long expressions. We believe that our approach would achieve a better result in languages with shorter discourse connectives. However, for languages that mark discourse relations through other means such as morphology (e.g. Arabic), the approach would certainly have to be reviewed. Secondly, we have produced a huge number of sentences and automatically tagged them with their discourse relation, however, the discourse relations have not been evaluated. As a future work, we would like to evaluate the discourse relations in these sentences and use the same corpus to implement a French discourse connective classifier that labels discourse connectives with their relations.

Acknowledgement

The authors would like to thank the anonymous referees for their insightful comments on an earlier version of the paper. Many thanks also to Laurence Danlos and Félix-Hervé Bachand for fruitful discussions on this work. This work was financially supported by an NSERC grant.

Abstract

We present a novel approach for analysing and classifying lyrics, experimenting both with n-gram models and more sophisticated features that model different dimensions of a song text, such as *vocabulary*, *style*, *semantics*, *orientation towards the world*, and *song structure*. We show that these can be combined with n-gram features to obtain performance gains on three different classification tasks: genre detection, distinguishing the best and the worst songs, and determining the approximate publication time of a song.

1 Introduction

The ever growing amount of music available on the internet calls for intelligent tools for browsing and searching music databases. Music recommendation and retrieval systems can aid users in finding music that is relevant to them. This typically requires automatic music analysis, e.g., classification according to genre, content or artist and song similarity. In addition, automatic music (and lyrics) analysis also offers potential benefits for musicology research, for instance, in the field of Sociomusicology where lyrics analysis is used to place a piece of music in its sociocultural context (Frith, 1988).

In principle, both the audio signal and the lyrics (if any exist) can be used to analyse a music piece (as well as additional data such as album reviews (Baumann et al., 2004)). In this paper, we focus on the contribution of the lyrics. Songwriters deploy unique stylistic devices to build their lyrics. Some of those can be measured automatically and we hypothesise that these are distinctive enough to identify song classes such as genre, song quality and publication time. There is, in fact, strong empirical evidence that it is worthwhile to look deeper into lyrical properties when analysing and classifying music. For example, it has been shown that classifiers that incorporate textual features outperform audio-only classifiers on most classification tasks (Mayer et al., 2008a; Mayer and Rauber, 2011; Li and Ogihara, 2004). Lyrics are also often easier to obtain and process than audio data, and non-musicians, in particular, often rely strongly on lyrics when interacting with a music retrieval system (Baumann and Klüter, 2002; Bainbridge et al., 2003). Moreover, lyrics do not only add semantic content, they can serve as an (easily observable) proxy for the melodic, structural and rhythmic properties of the audio signal. Melody and rhythm, for example, can often be traced in the stress pattern of the text (Nichols et al., 2009), while a song's overall structure is reflected in the order of textual elements such as chorus, verse and bridge. Psychological research also provides evidence the audio and textual content are indeed processed independently in the brain and hence are complementary for our appreciation of a song (Besson et al., 1998).

We extend previous research on lyrics-based song classification in two important ways: First, while earlier approaches mostly used fairly shallow textual features, such as bags-of-words, we designed features that model semantic and stylistic properties of lyrics at a much deeper level and show that these features can indeed be beneficial. Second, we address two novel classification tasks beyond genre detection, namely distinguishing 'best' and 'worst' songs[1] and determining the approximate publication time, and show that these can also be tackled by lyrics analysis.

[1]There is a growing body of work on automatic hit prediction but we would argue that this is a different task as hits are not necessarily qualitatively good songs and vice versa.

Proceedings of COLING 2014, the 25th International Conference on Computational Linguistics: Technical Papers, pages 620–631, Dublin, Ireland, August 23-29 2014.

2 Related Work

This study draws on earlier work on text classification, including genre detection (Lustrek, 2007) and authorship attribution (Stamatatos, 2009; Holmes, 1994), but also more specifically on poetry analysis (Simonton, 1990) and, in particular, lyrics-based music classification. Generally, shallow features, such as average word and sentence length, part-of-speech and function word distribution tend to work well for authorship and genre classification, while content word distribution is more indicative of the topic. Recent work on text classification has also employed deeper features, such as distributions of syntactic constructions (see e.g., Kim et al. (2010)). However, not all features that work well for prose carry over to song lyrics. Syntax, for example, is strongly constrained by meter. On the other hand, additional features like meter and rhyme properties might be useful. So far, most studies on lyrics classification have used rather simple features, for example (tf-idf weighted) bags-of-words (Neumayer and Rauber, 2007; Mahedero et al., 2005; Logan et al., 2004), sometimes enriched by synonymy and hypernymy information (Scott and Matwin, 1998). Mayer et al. (2008a; 2008b) also include POS tag distributions, simple text statistics (avg. word length, proportion of hapax legomena per document/line, distribution of punctuation marks and digits, words per minute) and simple (end-of-line) rhyme features. Li and Ogihara (2004) use a similar feature set but also include function word distributions. Finally, Hirjee and Brown (2010) analyse Rap lyrics and focus exclusively on rhyme features, providing a sophisticated statistical rhyme detector which can also identify in-line and slant rhymes. We build on this work but extend the feature space with more explicit modelling of abstract stylistic and linguistic dimensions such as vocabulary, style, semantics, orientation of the song content with respect to the world and overall song structure.

3 Material

Since no large lyrics dataset was publicly available (cf. Mayer and Rauber (2011)), we had to collect our own.[2] Song lyrics are widely available across the internet in the form of user-generated content. We chose *Lyricsmode*[3] because of its large coverage and subjectively high consistency. Even so, a certain amount of inconsistency and noise remains. We employed heuristics to clean the data, e.g., to remove duplicate song texts and normalise the notation style of different users.[4] Only English lyrics were included; songs in other languages were filtered out using language detection.[5] Furthermore, to minimise data sparseness, songs were only included if more than 20 song texts were available for the corresponding artist. The final corpus consists of roughly 400k English song texts of 7.2k artists.[6] For the experiments, the lyrics were POS tagged[7] and chunked.[8]

In addition to the lyrics themselves, we need three types of metadata for our experiments: genre information, quality ratings, and publication time. In all experiments, we classify songs rather than artists or albums. However, to avoid artist effects on our results, we control for the artist, i.e., we make sure that the test set does not contain (songs of) an artist if the training set already contains (songs of) the same artist; test and training set are completely disjunct with respect to artists.[9] Because of this, we need to ensure a sufficient number of artists for each output class in the three experiments.

[2]The Million Song Database (Bertin-Mahieux et al., 2011), a large publicly available data set for music classification, does not contain lyrics and the only available data set that does contain lyrics, SLAC (McKay et al., 2010), only contains lyrics for 160 songs, which is too small to train and test on.

[3]`http://www.lyricsmode.com`

[4]See Fell (2014) for more details on the heuristics used in the present study and Knees et al. (2005) for an overview of the types of noise typically encountered and general methods for cleaning.

[5]A freely available Java library for language detection (Shuyo, 2010) was used.

[6]Note that there is no guarantee that the artist also wrote the lyrics. The corpus might contain covers and lyrics/songs that were written 'on request'. However, performers do not choose their songs randomly but try to stick to songs that fit in with their preferred genre and style.

[7]`http://nlp.stanford.edu/software/tagger.shtml`

[8]`https://opennlp.apache.org`

[9]Most previous studies did not explicitly control for this. However, we noticed in a preliminary experiment that the results can be notably inflated if training and test set overlap in artists. For genre classification, we saw an increase in F-Score of up to 7%, while for publication time classification, the F-Score increased by up to 12% (Fell, 2014). This indicates that lyrics may provide a stronger signal for the artist than for other classes such as genre or publication time.

Genre information was obtained from *Allmusic*,[10] which classifies artists and bands according to 21 coarse-grained genres and numerous subgenres. We excluded artists who experimented with several genres like Peter Gabriel (Pop/Rock, International) or Prince (R&B, Pop/Rock, Electronic) because in that case it is not clear which genre a particular song belongs to. As most genres occur only sparsely in our corpus, we focused on the nine most common genres,[11] resulting in a data set of 4,712 artists from the nine major genres with the following numbers of artists per genre: Pop/Rock: 2602, Metal: 1140, Rap: 390, Country: 225, R&B: 153, Religious: 118, Reggae: 38, Blues: 26, Folk: 20.

Besides genre, we retrieved album ratings and publication years from *Rateyourmusic*.[12] Album ratings range from 0 stars (worst) to 5 stars (best) and are typically averaged over hundreds to thousands user ratings. To exclude "one-hit-wonders", only artists with at least two rated albums were considered. Theoretically, it would be possible to assign all songs a rating by transferring an album rating to all songs in the album. However, in practice this is difficult to do robustly because album ratings and lyrics come from different sites and are not trivial to align. Song listings for an album are sometimes incomplete and song titles noisy, making it difficult to map album ratings directly to songs. As a way around this we map album ratings to artists (which are much more robustly identifiable from the metadata) and then compute an overall artist rating as the median over all album ratings for the artist. Each song by the artist is then assigned this rating. Basically, we hypothesise that a good artist consistently writes good songs, which is, obviously, a simplifying assumption.

4 Features

We designed 13 feature classes, consisting of one or more related features each, and grouped them into five abstract sets, reflecting different stylistic and linguistic dimensions (see Table 1).[13]

Model	Dimension	Feature Classes
topK	vocabulary:	output class specific top 100 n-grams ($n \leq 3$)
extended	vocabulary:	type-token ratio, non-standard words
	style:	POS/chunk tags, length, echoisms, rhyme features
	semantics:	imagery
	orientation:	pronouns, past tense
	song structure:	chorus, title, repetitive structures

Table 1: Overview of features

As a baseline (*topK*), we implemented an n-gram model, which captures words and collocations that are most specific to an output class. This model can be considered 'uninformed' in that it does not attempt to represent abstract stylistic or structural properties. We rank n-grams according to the tf-idf for the class (i.e., the genres are considered 'documents' and the frequency of an n-gram is incremented by 1 for each song in which it occurs). To reduce the impact of vocabulary preferences of individual artists, we then re-rank by discounting n-grams which are too artist-specific. The top 100 n-grams (for $n \leq 3$) are represented in the feature vector.[14]

The remaining features (*extended*) attempt to model the following five dimensions of the lyrics:

VOCABULARY: These features estimate the vocabulary richness (**type-token ratio** for n-grams up to $n = 3$) and the use of **non-standard words**, i.e., uncommon and slang words. Uncommon words are defined as words not found in Wiktionary.[15] Slang words are defined as words contained in the Urban Dictionary,[16] but not in Wiktionary. We encode the (normalised) logarithmic frequency of slang words and the ratio of uncommon words to all words.

[10] `http://www.allmusic.com`

[11] We excluded the, also fairly frequent, genre Electronic as it is mainly musically defined (Logan et al., 2004).

[12] `http://www.rateyourmusic.com`

[13] Note that features are normalised by the length of the lyrics where necessary.

[14] The total number of encoded n-gram features is maximally 300 per output class but can be less, since n-grams common to multiple classes are encoded only once.

[15] `http://en.wiktionary.org`

[16] `http://www.urbandictionary.com`

STYLE: We employed the **POS and chunk tag** distributions as proxies for syntactic structure. To reduce data sparseness, all tags are mapped to supertags such as V, N, ADV. We also implemented various **length** features (lines per song, tokens per song, tokens per line). **Rhyme** structure is modelled by encoding the output of the rhyme detection tool by Hirjee and Brown (2010), which detects perfect and imperfect in-line and line final rhymes. Repetitions of letters ("riiiiise") or words ("money, money") are common in lyrics and often caused by a mismatch between number of syllables and line meter but they can also be employed as a means for emphasis and indicating emotion. We collectively dub such repetitions **echoisms**. We also group in-line (slant) rhymes ("burning turning", "where were we") under 'echoisms'. Echoisms are computed by looking for words with letter repetitions or word sequences with a relatively high similarity (according to an edit distance measure). Frequencies per type (letter reduplication, word repetition) and sequence length (less or more than 3 words) are encoded.

SEMANTICS: Lyrics can vary widely with respect to the topics they mention and the images they evoke. Instead of using a linguistic model of semantic fields, we opted to build on work in psychology and use the Regressive Imagery Dictionary (RID) (Martindale, 1975; Martindale, 1990) to identify predominant concepts ("imageries") in a text. RID classifies words as belonging to the separate fields "conceptual thought" (abstract, logical, reality-oriented), "primordial thought" (associative, concrete, fantasy), and "emotion". For example, the imagery 'Moral' (conceptual) contains words such as "should", "right", and "virtue". Whereas the imagery 'sensation' (primordial) contains "delicious", "perceive", and "glamour". We chose this resource because, intuitively, it is not only important *what* is said but also *how* it is said and the RID seemed to capture both aspects well. We computed the dominant imageries for each text and encoded this information in the feature vector.

ORIENTATION: This dimension models how the song narrative (entities, events) is oriented with respect to the world. We encode a temporal dimension, i.e., whether the song mainly recounts past experiences or present/future ones, by representing the fraction of **past tense verb forms** to all verb forms as a feature. We also model how "egocentric" a song is. We compute **pronoun** frequencies for 1st, 2nd, 3rd singular and plural person. As derived features, we also encode the proportion of self-referencing pronouns (first person singular/plural) to non-self-referencing ones and the ratio of first person singular pronouns to second person. The former feature measures the degree of talking about oneself as opposed to talking about other people, the latter measures whether the "I" or the "you" carries more weight in an interpersonal relationship.

SONG STRUCTURE: Structural repetitions are characteristic of song texts. We search for **repetitive structures**, i.e., identical or similar multi-line blocks that re-occur, typically but not always representing the chorus. We use heuristics to align such structures, allowing for fuzzy matches. An example of a song text[17] with a repeated structure is provided in Figure 1, where lines 56-60 are aligned to lines 61-65. It can be seen that corresponding lines are not lexically identical but only structurally and lexically similar. To be able to recognise such cases, we compute the overall similarity between two lines as a weighted sum of their lexical and structural similarities which are modelled in terms of word and POS tag bigram overlaps, respectively. Using this information and a set of heuristics, it is then determined whether a song contains a **chorus** and whether the **title** appears in the song text.

[56] 'Cause now I see right through you	**[61]** But I see right through you
[57] Look into my eyes	**[62]** I look into your eyes
[58] Tell me what you see	**[63]** Tell you what I see
[59] I see a man who thought you loved me	**[64]** I see a girl who ran game on me
[60] You played me like a fool	**[65]** You thought you had me fooled

Figure 1: Alignment of two blocks in the same song text

[17] *See right through you* by 'NSync.

	genre	best vs. worst			approx. publication time
training set	2,520	1,008 (Rap)	1,680 (Metal)	3,360 (Pop/Rock)	315 (Pop/Rock)
test set	840	294 (Rap)	546 (Metal)	1,092 (Pop/Rock)	105 (Pop/Rock)

Table 2: Average data set sizes (number of songs) for each experiment

5 Experiments

We carried out three experiments: classifying songs by (i) their genre, (ii) their quality (best vs. worst), and (iii) their approximate publication time. There is empirical evidence that lyrics may indeed play a crucial role in all three classification tasks. Musical genre is often defined as a cultural category, rather than a purely musical one (Fabbri, 1981). What topics artists sing about and how they sing about them clearly belongs to this cultural dimension. Lyrics also contribute to whether a song is viewed as 'good' or 'bad'. A study by Cunningham et al. (2005) also indicates that the lyrics are an important factor for *disliking* a song and Salley (2011) provides examples of how (text-)stylistic devices such as alliteration can make a song more engaging and therefore more successful. Finally, Hirjee and Brown (2010) show, for Rap, that the dominant style of song texts can change over time.

In all experiments, we compared our baseline feature set (*topK*) against the extended set (*extended*) and a combined set (*combined*). As the class distribution in our data is severely skewed, we performed random undersampling to create balanced sets for all experiments and thus avoid problems commonly associated with learning from imbalanced data (He and Garcia, 2009). The sampled data sets were split into 75% for training and 25% for testing. The exact numbers depend on the experiment (see Table 2). We repeated the sampling, training and testing procedure between 100 and 1000 times (depending on the experiment) and report the average. The Weka (Hall et al., 2009) implementation of SVMs with the default setting was used for classification.

5.1 Experiment 1: Genre Classification

We focused on the following eight genres: Blues, Rap, Metal, Folk, R&B, Reggae, Country, and Religious. Pop/Rock was excluded because it is the most heterogeneous genre and comprises many subgenres. Table 3 shows the results per genre and averaged over all genres, as well as the standard deviations. The n-gram model (*topK*) outperforms the *extended* model on all genres except Country but a combination of both models consistently yields even better results with an overall average F-Score of 52.5%. All F-Score differences between the three models are statistically significant at $p < 0.01$.[18] The fact that the combined model performs best indicates that the two basic models are at least partially complementary. The n-gram model hones in on the topic of a text, while the extended model captures more abstract structural and stylistic properties. However, both perform similarly on individual genres, i.e., they both in themselves capture important aspects of 'genre'. Looking at the individual genres, Rap seems to be most easily detectable on the basis of the lyrics alone (77.6% F-Score, *combined*). This is not surprising, since Rap lyrics have properties that are quite unique, such as complex rhyme structures, long lyrics and a fairly distinctive vocabulary. Folk seems to be the most difficult genre (29.6% F-Score, *combined*). A look at the confusion matrix revealed that Folk was frequently confused with Blues or Country. All share similar topics (e.g., love, traveling) and are also structurally and stylistically similar. They are mainly distinguished by musical properties (instrumentation, rhythm etc.). Lyrical similarities and differences are also revealed by looking at the top 100 unigrams for each genre (Figures 3 to 10). It can be seen that some genres stand out lexically, for example Rap (dominant slang use), Reggae (Jamaican slang, Rastafarian terms), Religious (religious terms) and Metal (death, violence). Some genres, however, are lexically quite similar such as Folk, Blues and Country.

Figure 2 shows the contributions of different feature groups to the overall performance of the combined model.[19] It can be seen that *length* contributes most, followed by *slang use*, *type-toke ratio*, *POS/Chunk*

[18] We performed a non-exhaustive permutation test by sampling 10^7 permutations and computed the Wilson-Score Interval for the estimated p-value with probability 99.9999%.

[19] The feature contribution is measured by correlating the features with the output class labels by computing the Symmetric

F-score [%]	Blues	Rap	Metal	Folk	R&B	Reggae	Country	Religious	Average
topK	51.2	76.0	49.0	28.3	48.7	44.4	41.3	53.3	49.0 ($\pm$ 2.5)
extended	46.6	75.1	47.3	24.5	47.7	35.8	53.8	37.3	46.0 ($\pm$ 2.4)
combined	**54.1**	**77.6**	**52.0**	**29.6**	**52.6**	**45.4**	**54.6**	**53.8**	**52.5** ($\pm$ 2.7)
human optimistic	40.9	66.7	42.4	18.2	34.8	12.1	28.8	53.0	37.1 ($\pm$ 8.4)
human pessimistic	37.6	53.8	38.3	18.6	29.4	15.3	27.7	47.8	33.6 ($\pm$ 7.5)

Table 3: F-Scores[%] for genre classification (1000 runs, averages)

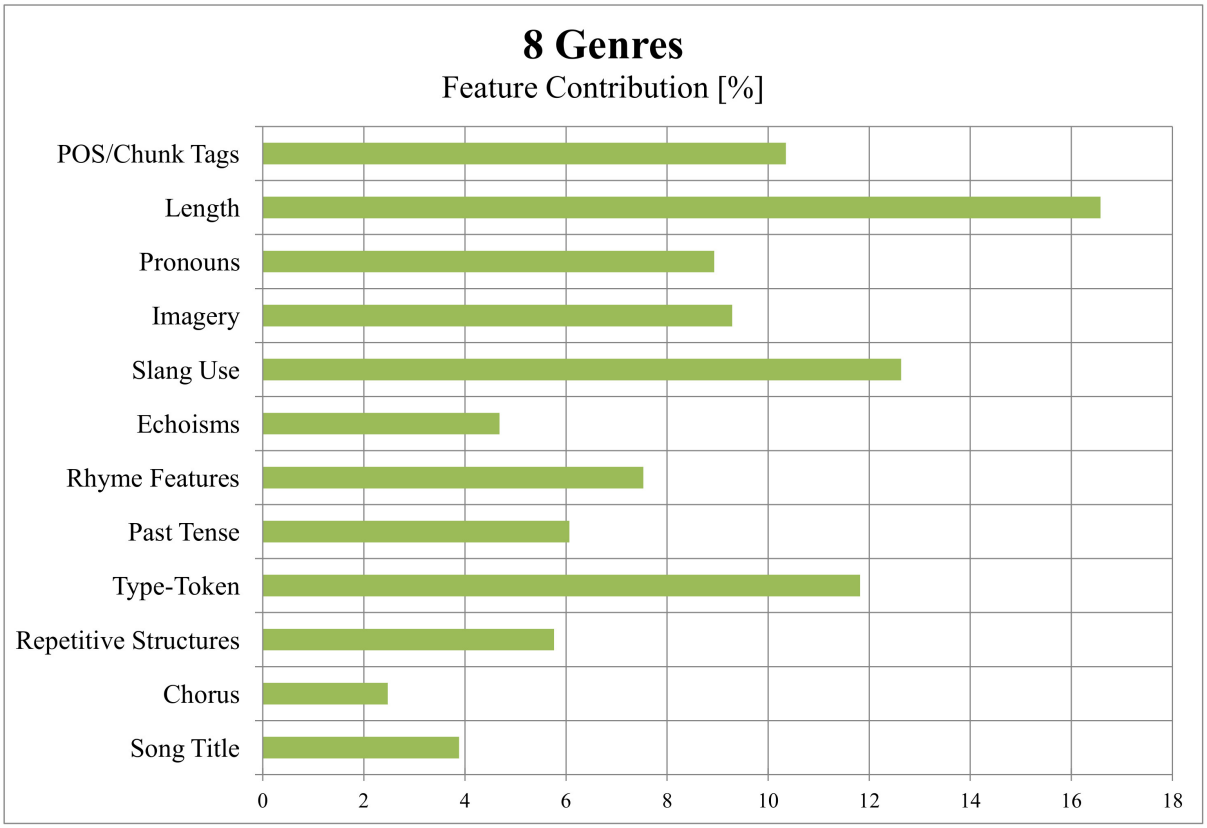

Figure 2: Feature Contributions for Experiment 1 (combined model)

tags and the more semantic features *imagery* and *pronouns*. Rap, which tends to have long lyrics with many slang words, is the genre that is identified most reliably by the classifiers and it is therefore not surprising that the two most contributing feature groups are particularly well suited for distinguishing Rap from the remaining genres.

While the performance of the combined model is promising,[20] there is still room for improvement. In order to determine whether this is a limitation inherent to the model or whether lyrics alone simply do not provide a strong enough signal for music genre classification, we performed a human annotation experiment. Participants ($n = 11$) had to classify randomly selected song texts into the 8 genres. They were allowed to assign up to two genres to each song. We report two performance measures (see Table 3): *human optimistic* counts an instance as correct if the correct genre was in the set of genres assigned, *human pessimistic* only counts unique genre assignments which correspond to the gold standard as correct. It can be seen that the human performance is actually worse than the automatic classification.[21]

Uncertainty (SU) (Witten and Frank, 2005) for each feature and class label. By accumulating the SUs for all features in a feature group we estimate to which proportion on average a group of features helps in identifying the correct class.

[20]The random baseline for this experiment is 12.5% F-Score.

[21]While this is unusual, the same observation has been made for some other stylometric tasks, in particular translation detection (Baroni and Bernardini, 2006).

Apparently, humans had difficulty picking up on subtle stylistic properties, especially since they were not 'trained' in any way, i.e., they had to rely on their own conception of what is typical for a genre. Hence, they (self-reportedly) relied mostly on the topic of a text.[22] Comparing results on individual genres, however, humans behave similar to the automatic classifier: Folk is the most difficult genre, Rap the easiest. An exception is Reggae which was more difficult for our participants than for the models. We performed a more detailed (statistical) comparison of the confusion matrices for humans and classifiers, which indicated that genres are indeed similarly confused by both. This could suggest that some genres are inherently more difficult to detect than others (based on lyrics alone).

Figure 9: Country top 100 words

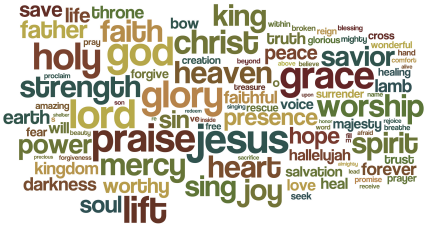

Figure 10: Religious top 100 words

5.2 Experiment 2: Best vs. Worst Music

In our second experiment, we tested whether the 'best' songs can be distinguished from the 'worst' solely on the basis of their lyrics. Having obtained average artist ratings (see Section 3), we defined the best (worst) artists as top (bottom) percentiles of all ratings. We also made sure that the distance between best and worst ratings was at least 1 point to ensure there was still a large enough gap. We assume that the quality of a song is genre-dependent, i.e., properties that make a good rap song are not necessarily desirable for a good blues song. Hence, our classifiers were trained and tested within genres. Only three of the original genres had enough material to satisfy the constraints: Pop/Rock, Metal, and Rap. For Pop/Rock and Metal, where more material was available, the 'best' ('worst') was defined as the top (bottom) 5% of artists, while for Rap the top (bottom) 10% percentiles were considered.

[22] The standard deviation is quite high for humans. This may be due to the relatively small number of participants or due to the fact that some participants had more previous exposure to different genres.

Model	Pop/Rock			Metal			Rap		
	Best	Worst	Average	Best	Worst	Average	Best	Worst	Average
topK	69.4	72.0	70.8 ($\pm$ 2.2)	71.3	72.0	71.7 ($\pm$ 3.7)	85.9	85.1	85.6 ($\pm$ 4.1)
extended	72.6	73.9	73.3 ($\pm$ 2.0)	76.5	76.2	76.4 ($\pm$ 4.0)	81.1	82.4	81.8 ($\pm$ 4.2)
combined	**74.7**	**76.2**	**75.5** ($\pm$ 2.3)	**76.7**	**76.2**	**76.5** ($\pm$ 4.3)	**86.4**	**86.3**	**86.4** ($\pm$ 4.1)

Table 4: F-Score[%] for Best vs. Worst (100 runs, averages)

Table 4 shows the results, which are encouragingly high, ranging from 75.5% to 86.4% F-Score (compared to a random baseline of 50% F-Score). It seems that the quality of a song does indeed at least partially depend on the quality of its lyrics and that the latter can to some extend be determined automatically. As in the previous experiment the *combined* model outperforms the other two models. However, unlike in the previous experiment, the *extended* model now outperforms the *topK* on two genres (Pop/Rock and Metal). This suggests that, at least for these two genres, the simple word n-grams are not sufficient to distinguish good and not so good songs; other features, contribute as well. Rap is the odd-one-out here: For this genre, the quality of a song seems to lie largely in the words and phrases used. All differences in F-Scores between the three models are significant with $p < 0.01$, except for the difference *extended* vs. *combined* for Metal, which is not significant ($p > 0.3$).

Figure 11 shows the feature contributions in the combined model. It can be seen that Rap behaves differently than the other two genres. For Rap the features *length* and *slang* contribute most, followed by *type-token ratio*, *POS/Chunk tags*, *pronouns* and *rhyme features*. The latter are noticeably more important for Rap than for the other two genres. For Pop/Rock and Metal, *type-token ratio* is by far the most important, closely followed by *length*. Orientation features (*pronouns*, *past tense*), song structure (*repetitive structures*, *chorus*) and *POS/Chunk tags* also contribute quite a lot. Generally, it seems to hold for all three genres that the best songs are characterised by a higher type-token ratio, fewer interjections and nonsense words ("lalala"), and lower ratio of first person pronouns.

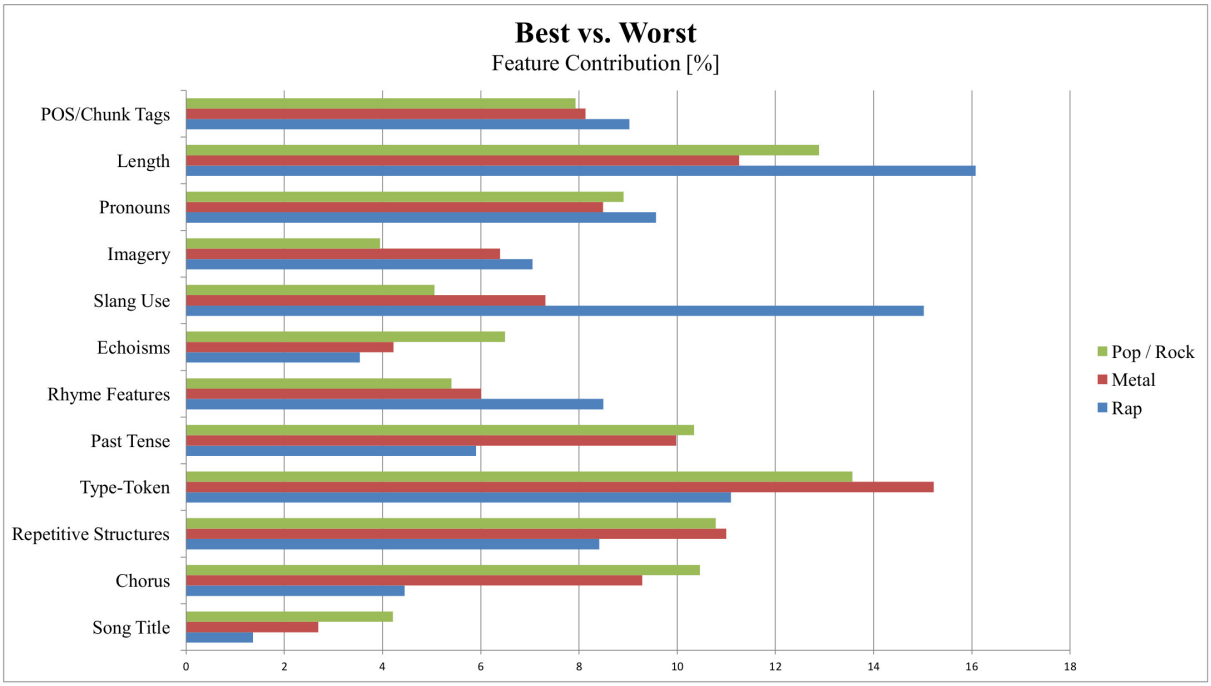

Figure 11: Feature Contributions for Experiment 2 (combined model)

We also look at n-grams distinguishing good from bad songs. Generally, it can be said that the best songs are much less concerned with sex and violence and more with story-telling. For example, the best Rap songs deal with the cosmic battle of man, good vs. evil, and rapping - while the worst Rap seems to be more about sex, violence, and money (see Figures 12 and 13).

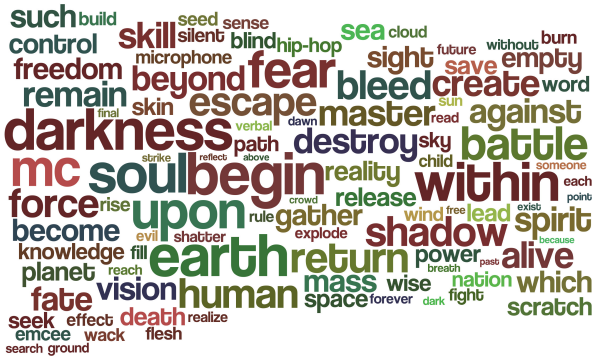

Figure 12: Best Rap top 100 words

Figure 13: Worst Rap top 100 words

5.3 Experiment 3: Approximate Publication Time

In the final experiment, we investigate whether one can automatically predict the approximate publication time of a song given its lyrics. We controlled both for genre and musical quality and trained classifiers to separate the song texts according to their age. We chose Pop/Rock since we have the most material for this genre and defined three time groups in such a way that we have sufficient data for each of them: *New* contains songs published since 2008, *mid-age* songs published between 1998 and 2001, and *old* songs published before 1988. We intentionally left gaps between the three classes since the boundaries are somewhat arbitrary and we assume that a song published in, say, 2008 will not *per se* differ substantially from one published in 2007.

Table 5 shows the results. Regarding the performance of the different models, we see a similar trend as in the previous experiments: the combined model performs best, the n-gram model performs slightly better than the extended model but there is not much between them. The differences in F-Scores between the models are statistically significant with $p < 0.01$. Overall, while all models beat the random baseline (33% F-Score), the results are still relatively low. By inspecting the confusion tables, we discovered that *old* and *new* are separated well from each other, with *new* being classified as *old* in only 23% of the cases and the opposite happening in 17% of the cases. On the other hand, *mid-age* shows the lowest F-Score and is misclassified in an almost symmetrical way (*new*: 27%, *mid-age*: 41%, *old*: 32%). It seems that, while the publication date of a song can at least partially be determined on the basis of the lyrics, only songs which are published 20 years and more apart can be distinguished relatively well. In a way this is not so surprising; we would expect the musical style to change over shorter times spans reflecting for example changes in taste regarding instrumentation and recording technology (live drums vs. drum computers, use of auto-tune effects etc.), properties of the lyrics, however, tend to change over much longer time periods.

Model	New	Mid-Age	Old	Avg.
topK	47.2	39.2	48.7	45.0 ($\pm$ 4.4)
extended	44.1	39.1	43.2	42.2 ($\pm$ 4.9)
combined	48.9	41 .0	50.5	46.8 ($\pm$ 5.4)

Table 5: F-Scores [%] for Old vs. Mid-Age vs. New Pop/Rock (100 runs, averages)

Nonetheless, our models learnt some interesting properties that distinguish old and new songs. Predictably, it was found that newer song texts tend to be longer. This is in line with the fact that the duration of songs increased over time. Older songs also contain more repetitive structures, more exact matches between text blocks and have a higher chance of containing a chorus. With respect to overall song structure it thus seems that the songwriters deviated more and more from traditional structure templates over time. Interestingly (and more surprisingly), newer songs also contain less possessive pronouns and more terms referring to food and drink. Figure 14 shows the feature contributions, confirming the importance of length and repetitive structures. Figures 15 to 17 show the word clouds.

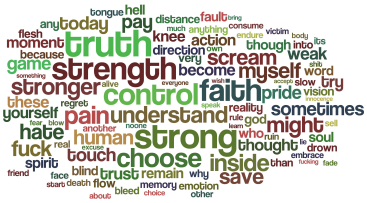

Figure 16: Pop/Rock *mid-age*, top 100 words

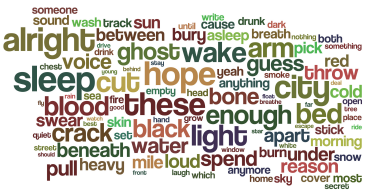

Figure 17: Pop/Rock *new*, top 100 words

6 Conclusion

We showed that lyrics-based statistical models can be employed to perform different music classification tasks: genre detection, distinguishing the best from the worst songs, and predicting the approximate publication time. The latter two are novel, as far as we know. Our study was partly exploratory and we experimented with different feature types, comparing simple n-gram models to more sophisticated approaches. The latter modelled vocabulary, style, semantics, how the writers positions themselves and the story told with respect to the outside world, and overall song structure. Both models were tested in isolation and combined on all three tasks. We found that an n-gram model is often a good first approximation for all of the tasks, however extending the feature space with more sophisticated features nearly always significantly improves the results. We believe that lyrics-based song classification has potential benefits not only for applications such as music retrieval and recommendation but also for basic musicology research by enabling researchers to mine lyrics corpora for interesting trends. Lyrics-based music mining is still in its infancy and would benefit from the development of more sophisticated methods for cleaning, processing and analysing song texts. This applies both to the adaptation of standard NLP tools to this domain and to the further development of stylometric techniques dedicated to analysing lyrics.

Abstract

This paper addresses the specific features of Chinese discourse connectives, including types (word-pair and single-word), linking directions (forward and backward linking), positions and ambiguous degrees, and discusses how they affect the discourse relation recognition. A semi-supervised learning method is proposed to learn the probability distributions of discourse functions of connectives from a small labeled dataset and a big unlabeled dataset. The statistics learned from the dataset demonstrates some interesting linguistic phenomena such as connective synonyms sharing similar distributions, multiple discourse functions of connectives, and couple-linking elements providing strong clues for discourse relation resolution.

1 Introduction

Discourse relation labeling determines how two discourse units cohere to each other. A discourse unit may be a clause, a sentence, or a group of sentences. The labeled relation has many potential applications. Coherence is considered as a metric to evaluate the essay writing by essay scorer (Lin et al., 2011). Discourse relations are used to order sentences in an event in a summarization system (Derczynski and Gaizauskas, 2013). Sentiment transition of two clausal arguments is identified based on their discourse relation in sentiment analysis (Hutchinson, 2004; Zhou et al., 2011; Wang et al., 2012; Huang et al., 2013).

The pioneer research of discourse has been established by Hobbs (1985), Polanyi (1988), Hovy and Maier (1992), and Asher and Lascarides (1995). Various discourse relation types have been defined in the frameworks such as Sanders et al. (1992), Hovy and Maier (1992), RST-DT (Carlson et al., 2002), Wolf and Gibson (2005), and PDTB (Prasad et al., 2008). *Temporal*, *Contingency*, *Comparison*, and *Expansion*, the four classes on the top level of PDTB sense hierarchy, are common used in the discourse relation labeling tasks. When two arguments are temporally related, they form a *Temporal* relation. The *Contingency* relation talks about the situation that the event in one argument casually affects the event in the other argument. *Comparison* is used to show the difference between two arguments. The last one relation, *Expansion*, is the most common. An *Expansion* relation either expands the information for one argument in the other one or continues the narrative flow.

In the recent years, discourse relation recognition has been studied for different languages (Afantenos et al., 2012, Cartoni et al., 2013). In explicit English discourse relation labeling tasks, the accuracy of the approach using just the connectives is already quite high, 93.67%, and incorporating the syntactic features raises performance to 94.15% (Pitler and Nenkova, 2009). In our previous work, we investigate Chinese intra-sentential relation detection and show an accuracy of 81.63% and an F-score of 71.11% in the two-way classification (*Contingency* vs. *Comparison* relations) when connectives are

Proceedings of COLING 2014, the 25th International Conference on Computational Linguistics: Technical Papers, pages 632–643, Dublin, Ireland, August 23-29 2014.

introduced as features (Huang and Chen, 2012a). We also report an accuracy of 27.10% and an F-score of 24.27% in the four-way inter-sentential relation classification when only connectives are used (Huang and Chen, 2011). Sporleder and Lascarides (2008) point out some English connectives are often ambiguous between multiple discourse relations or between discourse and non-discourse usage, and Roze et al. (2010) report the ambiguity of French connectives. This issue also occurs in Chinese. Zhou et al. (2012) propose a framework to identify the ambiguous Chinese discourse connectives, and report an F-score of 74.81% in the four-way classification at the intra-sentential level.

The above discourse relation labeling tasks are done on the datasets of different size for different languages at the intra-/inter-sentential levels, thus the results cannot be compared directly. However, these works show a tendency: discourse connectives are useful clues for explicit discourse relation recognition, and the uses of Chinese connectives in discourse relation labeling are more challenging than those of English connectives. In comparison with English, the connectives in Chinese are more and their parts of speech are diverse. There are 100 English explicit connectives annotated in the PDTB 2.0. In Chinese, the linguists report a list of 808 discourse connectives (Cheng and Tian, 1989; Cheng, 2006). In addition, the Chinese discourse connectives have a variety of parts-of-speech. For example, 假設 (jiǎ shè, suppose) is a verb and listed as a discourse connective of the *Contingency* relation.

The following examples address some specific features of Chinese discourse connectives. On the one hand, the two words, "雖然" (suī rán, although) and "但是" (dàn shì, but), which form a word-pair connective, appear in the two discourse units shown in (S1), respectively. These two units demonstrate a *Comparison* relation. On the other hand, "雖然" (suī rán, although) and "但是" (dàn shì, but) can appear individually as single-word connectives shown in (S2)-(S6). The two discourse units have different discourse relations when the single-word connectives appear at different positions, i.e., (S2): *Comparison*, (S3): *Comparison*, (S4): *Expansion*, (S5): *Comparison*, and (S6): *Expansion*. Furthermore, the short word "而" (ér) can be an individual connective, which is interpreted as "而且" (and), "然而" (but), or "因而" (thus), and serves as functions of *Expansion*, *Comparison*, and *Contingency*, respectively. In addition, it can be linked with "雖然" (suī rán, although) and "因為" (yīn wèi, because) to be word-pair connectives, which are interpreted as *Comparison* and *Contingency* functions in (S7) and (S8), respectively. These examples demonstrate word-pair connectives composed of a same word and other words may have different discourse functions, so does the same single-word connective at different positions.

(S1) 雖然湯姆很聰明，但是他並不用功。(Although Tom is smart, he doesn't study hard.)
(S2) 雖然湯姆很聰明，他並不用功。(Although Tom is smart, he doesn't study hard.)
(S3) 他流很多汗，雖然才走幾哩路。(He sweated a lot, although he went only a few miles.)
(S4) 我會好好閱讀，雖然我真的覺得蜘蛛好可怕。(I'll read, even if I really feel spider terrible.)
(S5) 湯姆很聰明，但是他並不用功。(Tom is smart, but he doesn't study hard.)
(S6) 但是在巴黎，他放棄了學醫。(But in Paris, he gave up studying medicine.)
(S7) 雖然你不說，而我一聞就知道。(Although you did not say, I knew that smell.)
(S8) 他因為晚回家，而被媽媽罵了。(Because he came home late, he was scolded by his mother.)

In this paper, we investigate special features of Chinese discourse connectives and apply the results to discourse relation labeling. A semi-supervised learning algorithm is proposed to estimate the probability distribution of the discourse functions of each connective. We address the issue of ambiguity between multiple discourse relations of Chinese connectives. The ambiguity between discourse and non-discourse usages is not our focus in this paper. This paper is organized as follows. Section 2 analyses the types of Chinese connectives and their forward/backward linking properties. Section 3 presents a semi-supervised method to deal with the probability distributions of discourse functions of Chinese connectives and discourse relation labeling. The experimental results are shown and discussed. In Section 4, we further introduce the discourse relation labeler to annotate 302,293 unlabeled sentences and analyze the linguistic phenomena of discourse connectives. We conclude this work in Section 5.

2 Types of Discourse Connectives

From the surface form, there are three kinds of linking elements in Chinese (Li and Thompson, 1981): forward-linking elements, backward-linking elements, and couple-linking elements. Discourse connectives are such kinds of linking elements. A discourse unit containing a forward-linking (backward-linking) element is linked with its next (previous) discourse unit. A couple-linking element is a pair of words that exist in two discourse units (Chen, 1994).

Figure 1 shows connectives and their linking direction. The word-pair connective "雖然...但是" (suī rán…dàn shì, although…but) in (S1) is a couple-linking element. A single-word connective may function as a forward-linking element and/or a backward-linking element. It may be a word appearing in a word-pair connective, e.g., "雖然" (suī rán, although), or a word existing individually, e.g., "以及" (yǐ jí, and). A single-word connective which is the first (the second) word of a word-pair connective may function as a forward-linking (backward-linking) element. The single-word connective "雖然" (suī rán, although) in (S2) is a typical example. It keeps the major discourse function, i.e., *Comparison*, of the word-pair connective that it belongs when it appears in the first discourse unit. In contrast, it may become ambiguous when its position is reversed from the first to the second (i.e., S3 and S4). It may link to the previous or the next discourse units. S5 and S6 have the similar behaviors. The single-word "但是" (dàn shì, but) in (S5) shows a backward-linking. In (S6), it is shifted to the first position and becomes ambiguous. It may be linked to the previous, or to the next discourse units. The correct interpretation depends on the context. These phenomena show a single-word connective may have different senses when it is not at its original position.

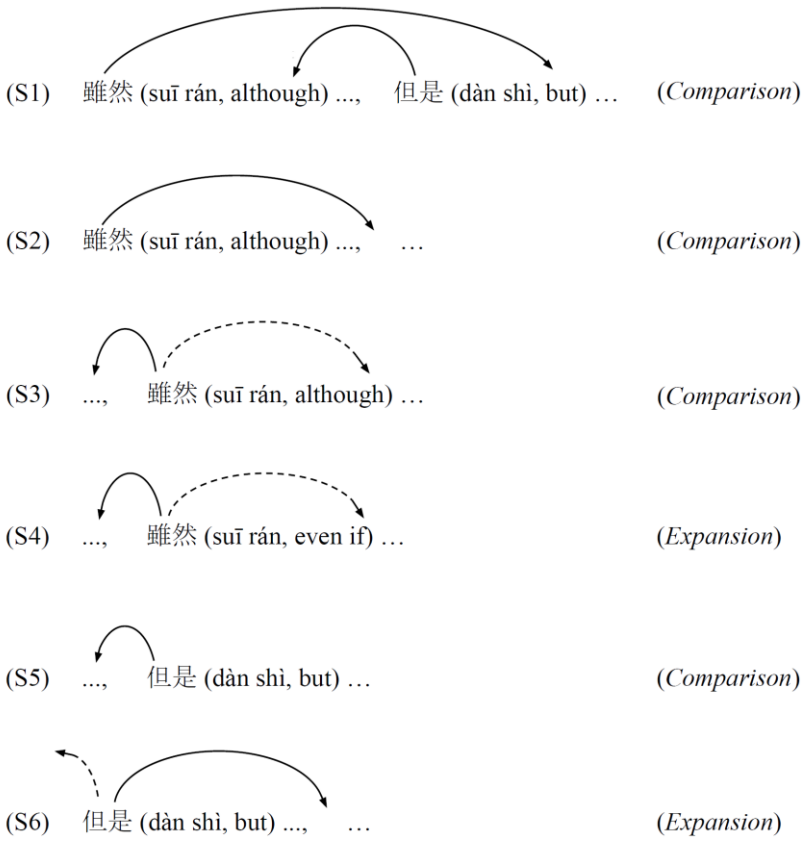

Figure 1: Examples for forward linkging and backward linking.

In this study, we collect 808 discourse connectives based on Cheng and Tian (1989), Cheng (2006), and Lu (2007). The discourse connective lexicon contains 319 single-word and 489 word-pair connectives. Initially, each connective is associated with only one discourse function manually by linguists.

For example, the word-pair connective, "雖然...但是" (suī rán…dàn shì, although…but), is assigned a *Comparison* function. The assignment is one-to-one mapping, thus it cannot capture the complete discourse functions of Chinese connectives. Table 1 shows an overview of the discourse connective lexicon. In this lexicon, *Expansion* is the majority, and *Comparison* is the minority. The percentages of *Contingency* and *Expansion* are close. *Temporal* is the third largest discourse function. Intuitively, the discourse connective lexicon cannot cover all their senses. To learn the probability distribution of the discourse functions of a connective needs a large-scale discourse corpus. Compared with RST-DT (Carlson et al., 2002) and PDTB (Prasad et al., 2008), Chinese discourse corpora are not publicly available (Zhou and Xue, 2012; Huang and Chen, 2012b).

Discourse Function	Number of Connectives	Examples of Single-Word and Word-Pair Discourse Connectives
Temporal	151 (18.69%)	接著 (jiē zhe, then), 最初...現在 (zuì chū…xiàn zài, first...now)
Contingency	261 (32.30%)	因為 (yīn wèi, because), 如...則 (rú…zé, if ... then)
Comparison	87 (10.77%)	即使 (jí shǐ, even if), 儘管…但 (jǐn guǎn…dàn, although…but)
Expansion	309 (38.24%)	另外 (lìng wài, besides), 不僅…而且 (bù jǐn…ér qiě, not only…but also)

Table 1: A Chinese discourse connective lexicon.

3 Learning Discourse Functions of Connectives

This section proposes a semi-supervised learning method to learn the interpretation of discourse connectives from an incomplete and sparse dataset.

3.1 A Semi-Supervised Learning Algorithm

Given a pair of discourse units ds_1 and ds_2 containing an explicit connective *c*, a discourse relation classifier *drc* aims at selecting a relation *r* from the set {*Temporal*, *Contingency*, *Comparison*, *Expansion*} to illustrate how ds_1 and ds_2 cohere to each other. The connective *c* may be a word-pair $c_1 \ldots c_2$, where c_1 and c_2 appear in ds_1 and ds_2, respectively. It may be a single word appearing in ds_1 or ds_2. Each discourse unit is mapped into a representation. Various features from different linguistic levels have been explored in the related work (Huang and Chen, 2011; Huang and Chen, 2012a; Zhou et al, 2011; Zhou et al., 2012). We adopt some of their features shown as follows. Here we focus in particular on the probability distributions of the discourse functions and the positions of connectives.

Length. This feature includes the word counts of ds_1 and ds_2.

Punctuation. The punctuation at the end of ds_2 is regarded as a feature. The possible punctuation includes a full stop, a question mark, or an exclamation mark. The punctuation at the end of ds_1 is dropped from the features because it is always a comma.

Words. The bags of words in ds_1 and ds_2 are considered.

Hypernym. The bags of hypernyms of the words in ds_1 and ds_2 are considered. A Chinese thesaurus, Tongyici Cilin[1], is consulted. The categorization scheme at the fourth level is adopted.

Shared Word. The number of words shared in ds_1 and ds_2 is considered as a feature.

Collocated Word. Collocated words are word pairs mined from the training set. The first and the second words of a pair come from ds_1 and ds_2, respectively.

POS. The bags of parts of speech in ds_1 and ds_2 are considered.

Polarity. Polarity and discourse relation may be related (Huang et al., 2013; Zhou, et al., 2011). For example, a *Comparison* relation implies its two discourse units are contrasting, and some contrasts are presented with different polarities. We estimate the polarity of ds_1 and ds_2 by a lexicon-based approach. The polarity score and the existence of negation are taken as features.

Discourse Connective. A discourse connective *c* is represented as a probability distribution of discourse functions denoted by a quadruple ($P_{(c,temporal)}$, $P_{(c,contingency)}$, $P_{(c,comparison)}$, $P_{(c,expansion)}$), where $P_{(c,temporal)}$, $P_{(c,contingency)}$, $P_{(c,comparison)}$, and $P_{(c,expansion)}$ indicate the probabilities of the four discourse functions of *c*, such that $P_{(c,temporal)}+P_{(c,contingency)}+P_{(c,comparison)}+P_{(c,expansion)}=1$. Section 3.3 shows how we assign the probabilities to each connective in different experimental settings.

Position. The linguistic phenomena discussed in Section 2 show a single-word connective at different position may play different discourse function. Thus, the position of *c* is considered as a feature.

[1] http://ir.hit.edu.cn/

Because the number of Chinese connectives is large (e.g., 808 Chinese connectives in our lexicon) and the large-scale labeled Chinese discourse corpus is not available, how to learn the probability distribution is a challenging issue. This paper proposes a semi-supervised learning method as follows. Its pseudo code is shown in Algorithm 1.

(1) Train a 4-way discourse relation classifier *drc* with the training set and LIBSVM (Chang and Lin, 2011).
(2) Initialize probability distributions of unknown connectives in the test set (see experiments).
(3) Use *drc* to label all the instances in the test set.
(4) Compute the new probability distribution of discourse functions of each connective based on the labeled results in the current run. Maximum likelihood estimation is adopted.
(5) Repeat (3) and (4) until the number of label changes between two successive runs is below 1%.

Algorithm 1. Probability Estimation for the Discourse Functions of Connectives

Input:

D={*Temporal*, *Contingency*, *Comparison*, *Expansion*}: a set of discourse relations and discourse functions for argument pairs and discourse connectives,

$C=\{c_1, c_2, \ldots, c_n\}$: a set of n discourse connectives,

$S=\{s_1, s_2, \ldots, s_p\}$: a set of p labeled argument-pairs $[sa_1, sa_2]$ containing connective $c \in CS \subseteq C$, each with a label $d \in D$, where CS is a set of connectives appearing in S,

$T=\{t_1, t_2, \ldots, t_q\}$: a set of q unlabeled argument-pairs $[ta_1, ta_2]$ containing connective $c \in CT \subseteq C$, where CT is a set of connectives appearing in T.

Output:

$Q=\{q_1, q_2, \ldots, q_n\}$: a probability distribution q_i for connective $c_i \in C$.

Method:

1. Initialization
   1) Train a classifier *drc* using S.
   2) Initialize the probability distribution with equal weight, (0.25, 0.25, 0.25, 0.25), for connective $c \in CT\text{-}CS$, and build $Q^{(0)}$.
   3) $i \leftarrow 0$

2. Relation labeling
   For each $t \in T$, estimate the probabilities of four discourse relations, $P_{(t,temporal)}$, $P_{(t,contingency)}$, $P_{(t.comparison)}$, and $P_{(t.expansion)}$, using the classifier *drc* with $Q^{(i)}$.

3. Updating the probability distribution
   1) For each $c \in C$, compute the average probability of each discourse relation among the argument-pairs containing c in T:
      $P_{(c,tempora)l} \leftarrow$ Average of $P_{(t,temporal)}$ for all t containing c in T.
      $P_{(c,contingency)} \leftarrow$ Average of $P_{(t,contingency)}$ for all t containing c in T.
      $P_{(c,comparison)} \leftarrow$ Average of $P_{(t,comparison)}$ for all t containing c in T.
      $P_{(c,expansion)} \leftarrow$ Average of $P_{(t,expansion)}$ for all t containing c in T.
   2) Form a new $Q^{(i+1)}$
   3) $i \leftarrow i+1$

4. Repeat steps 2-3 until the ratio of the number of label changes by previous and current runs is less than 1%.

5. $Q \leftarrow Q^{(i)}$

3.2 Experimental Setup

For the corpus study of discourse connectives and discourse relations, we refer to a public available Chinese Web POS tagged corpus (Yu et al., 2012). This Chinese POS-tagged corpus is developed based on the ClueWeb09 dataset (CMU, 2009), where Chinese material is the second largest. To capture the discourse functions of individual connectives more accurately, the following three criteria are used to sample sentences:

1. A sentence should contain only two clauses.
2. A sentence should contain exact one discourse connective.

3. The lengths of both clauses in a sentence are no more than 20 Chinese characters.

Total 7,601 sentences composed of two discourse units linked by a connective are sampled from a public available Chinese Web POS tagged corpus (Yu et al., 2012). Each sentence is annotated with a most likely discourse relation selected from {*Comparison*, *Contingency*, *Comparison*, *Expansion*} by three annotators guided by an instruction manual. The majority is taken as the ground truth. A mentor is involved to make a final decision for the tie conditions. The inter-agreement among the annotators is 0.41 in Fleiss' Kappa values, which is a moderate agreement. The discourse category with the lowest inter-annotation agreement is *Temporal*, which annotators usually confuse with *Expansion*. It shows the difficulty to distinguish *Temporal* and *Expansion* even by human. Table 2 shows the statistics of the corpus. More than 50% of pairs are annotated with *Expansion* relation. The second largest group is *Contingency* relation. The percentages of *Temporal* and *Comparison* relations are near. Only 359 connectives appear in the corpus. That reflects the incompleteness issue.

Discourse Relation	# Instances	Percentage
Temporal	846	11.13%
Contingency	1,594	20.97%
Comparison	926	12.18%
Expansion	4,235	55.72%

Table 2: Statistics of the experimental discourse corpus.

This Chinese discourse corpus is used for training and testing. We set up the experiments to simulate the scenario of estimating the probability distributions of discourse functions of the unknown connectives based on the information in the training set. We evaluate the experimental results by 5-fold cross-validation. To ensure the discourse connectives appearing in the test set are mutual exclusive of those connectives in the training set, we split the discourse connectives into 5 mutual exclusive sets and split all the 7,601 sentences into 5 folds according to the 5 sets of discourse connectives.

The kernel of our SVM classifier is the radial basis function. The two parameters, cost *c* and gamma *g*, are optimized by the grid-search algorithm within the range $c \in \{2^{-5}, 2^{-3}, 2^{-1}, \ldots, 2^{15}\}$ and $g \in \{2^{-15}, 2^{-13}, 2^{-11}, \ldots, 2^{3}\}$.

3.3 Results and Discussions

To demonstrate the performance of our proposed semi-supervised learning methods, the following five models are experimented and compared.

M0: Label the relation between two discourse units linked by a connective *c* based on the *c*'s discourse function defined in the connective lexicon. M0 is considered as a baseline model.

M1: Train a 4-way discourse relation classifier *drc* with the training set, then initialize the function probability distributions of the unknown connectives to (0.25, 0.25, 0.25, 0.25), and finally label all the pairs of discourse units by the classifier *drc*. M1 is a supervised-learning method.

M2: M2 model is similar to M1 model except that the probability distribution ($p_{(c,temporal)}$, $p_{(c,contingency)}$, $p_{(c,comparison)}$, $p_{(c,expansion)}$) of an unknown connective is initialized based on its setting in the connective lexicon. The probability of the unique function is set to 1, and the others are set to 0.

M3: M3 is a semi-supervised learning method. In testing, the function probability distributions of the unknown connectives are initialized to (0.25, 0.25, 0.25, 0.25). Discourse relation labeling and probability distribution updating are done iteratively. Finally, all the test instances are labeled, and probability distributions of discourse functions are learned for all test connectives.

M4: M4 is similar to M3 except that the initial probability distributions are set based on the connective lexicon.

Table 3 compares the performances of these five models. The average tendency is M4>M3>M2>M1>M0. It shows the proposed two semi-supervised learning methods are significantly better than the baseline model M0 and the two supervised-learning methods M1 and M2 at p=0.001. The best model is M4, but the performance differences between M3 and M4 are not significant. It demonstrates that both the two initial assignments, i.e., equal-weight assignment and lexicon-based

assignment, are effective. If a connective is not listed in the lexicon due to its coverage, we can still derive its probability distribution starting from the equal-weight approach.

We further examine the individual performance of each discourse relation. Comparing M1 and M3, the semi-supervised classifier (M3) outperforms the supervised classifier (M1) in all three metrics in all the four relations except recall and F-score in the *Temporal* relation. Because more than one half of the pairs of discourse units annotated with *Temporal* relation whose discourse connectives have *Expansion* function in the connective lexicon, some discourse-units of *Temporal* relation are misclassified as *Expansion* relation. That is why the recall is dropped by 8.22% in M3. The precisions of all the four relations are increased. In particular, the precisions of *Temporal*, *Contingency*, and *Comparison* gain more than 10%. The overall F-score is increased 6.61%.

Moreover, M4 is better than M2 in F-score for all the relations. In particular, the precisions of *Temporal*, *Contingency*, and *Comparison* recognition by M4 are greatly increased. In other words, the boosting algorithm tends to correct those instances that are originally misclassified into the *Expansion* relation. The t-test also confirms M4 has a significant improvement over M2 at p=0.001.

The semi-supervised algorithm learns the probability distributions of discourse functions of the unknown connectives from the test instances, so that their size may affect the performance. Figure 2 analyzes how the number of test instances of a connective affects the performance. Each point (x, y) in this figure denote a connective, where x is its total occurrences in the test set, and y is its F-score in Figure 2(a) and its precision/recall in Figure 2(b). We can find (1) many connectives have good performance, (2) connectives containing more test instances demonstrate better performance, and (3) connectives containing fewer instances are sensitive to the evaluation. We treat the probability distribution of discourse functions of each connective as a vector of four real numbers and compute the cosine similarity among the distributions of connectives derived by the connective lexicon, human annotators, and our best model M4. When the 114 connectives containing more than 10 instances are counted, the average cosine similarity between our model and human is 0.940, and the average cosine similarity between the connective lexicon and human is 0.767.

Metric	Model	Temporal	Contingency	Comparison	Expansion	Average
Precision	M0	0.3933	0.7124	0.5092	0.7364	0.6656
	M1	0.5618	0.6005	0.5982	0.7147	0.6595
	M2	0.5024	0.7038	0.5332	0.7529	0.6879
	M3	0.6682	0.7652	0.7749	0.7254	0.7334
	M4	**0.6708**	**0.7773**	**0.7869**	**0.7373**	**0.7344**
Recall	M0	0.3757	**0.6014**	**0.6588**	0.7389	0.6600
	M1	**0.5371**	0.5098	0.4154	0.8114	0.6694
	M2	0.4808	0.5808	0.6207	0.7578	0.6731
	M3	0.4549	0.5387	0.5065	**0.9015**	0.7276
	M4	0.4480	0.5803	0.5821	0.8985	**0.7299**
F-score	M0	0.3843	0.6522	0.5744	0.7376	0.6606
	M1	**0.5492**	0.5515	0.4903	0.7600	0.6644
	M2	0.4913	0.6364	0.5736	0.7553	0.6805
	M3	0.5413	0.6323	0.6126	0.8039	0.7305
	M4	0.5372	**0.6645**	**0.6691**	**0.8099**	**0.7322**

4 Further Analyses on a Big Dataset

We further apply the best model (M4) to predict the probability distributions of discourse functions of connectives on a big dataset. For each discourse connective *c*, up to 500 sentences composed of two discourse units linked by *c* are randomly selected from the Chinese Web POS tagged corpus (Yu et al., 2012). The limitation of 500 is set to reduce the imbalance among the discourse connectives. Some connectives appear quite often in the dataset, e.g., the connective "也" (yě, also). Some connectives appear less than 500 times, e.g., "千萬…不然" (qiān wàn…bù rán, must...otherwise) occurs only 212 times. Finally, total 302,293 sentences are extracted and predicted. Because the dataset is very large, it is not easy to evaluate each pair of discourse units. We examine the linguistic phenomena instead. A lexicon of the probability distributions of connectives estimated by M4 is available at http://nlg.csie.ntu.edu.tw/ntu-discourse/.

We sort the discourse connectives by the ratios of their largest relations. In this way, the top connectives in this order almost contain one relation. They can be considered to be less ambiguous. The top ten connectives which appear 500 times are shown in Table 4. Note the bracket notation [ds_1, ds_2] denotes the discourse units where connectives appear. The discourse function defined in the discourse connective lexicon specified in Section 2 is marked in bold. The probabilities of the major discourse function of these connectives are larger than 0.89. The distribution is consistent with the human assignment except the last connective "除非...不然" (chú fēi...bù rán, unless...otherwise), which is assigned to *Contingency* in the lexicon. This connective denotes a negated cause-effect relation between *ds1* and *ds2* in which *ds2* is the effect when *ds1* is not satisfied. In such a case, *ds1* and *ds2* show clear contrast, so that it is reasonable to label this connective with a higher probability of the *Comparison* relation. There are two groups of synonyms in the list: (1) "雖然...不過" (suī rán…bú guò, although…but) and "雖然...可是" (suī rán…kě shì, although…but), and (2) "簡言之" (jiǎn yán zhī, in short) and "簡而言之" (jiǎn ér yán zhī, in short). Table 4 shows that synonyms share similar distributions. The cosine similarities of their probability distributions are 0.99996 and 0.99952, respectively.

The probability of each discourse function of each connective *c* is the average of the probabilities estimated by the classifier, thus the distributions reported by our model is not completely identical to the empirical distribution. For example, all the instances containing the connective "雖然...不過" (suī rán…bú guò, although…but) are labeled with the major discourse function *Expansion*, but the estimated probability of *Expansion* of this connective is 93.47%.

We also sort the discourse connectives by the ratio of their second largest relations. In this manner, the top connectives in this order may have two major discourse functions. In other words, they are ambiguous. Table 5 shows the top ten estimated ambiguous discourse connectives. It is interesting that *Expansion* is one of the two major discourse functions, and the other one shown in bold is the discourse function defined in the connective lexicon. The discourse connectives "緊接著" (jǐn jiē zhe, then), "現在" (xiàn zài, now), "未來" (wèi lái, in the future), and "終於" (zhōng yú, finally), which are defined to have *Temporal* function in the lexicon, frequently occur in the discourse units with *Expansion* relation. The estimated distribution of the connective "而" (ér, and; but; thus) is consistent with the human interpretation, i.e., it has multiple discourse functions.

Chinese single-word connectives are usually put together with other words to form word-pair connectives. Tables 6 and 7 show examples for "雖然" (suī rán, although) and "所以" (suǒ yǐ, so),

Discourse Connectives [ds1, ds2]	Temporal (%)	Contingency (%)	Comparison (%)	Expansion (%)
[簡言之, …] ([in short, …])	2.78	2.08	1.67	**93.47**
[雖然, 不過] ([although, but])	0.77	1.80	**92.70**	4.74

[…, 而] ([…, and; but; thus])	3.72	6.13	**42.78**	47.37
[…, 終於] ([…, finally])	**42.39**	6.13	2.99	48.49

Table 5: Some ambiguous connectives estimated by using a big dataset.

respectively. The former is often connected with a word in the second discourse unit to form a couple-linking, while the latter is connected with a word in the first one. We can find word-pair connectives are less ambiguous than single-word connectives in different probabilities. The former ("雖然", suī rán, although) tends to have *Comparison* function. When the word-pair connectives are shorten to single-word connectives, the probability to have *Comparison* function becomes lower. The connective "雖然" (suī rán, although) in the first argument still has probability 0.7639 to have *Comparison* function. When "雖然" (suī rán, although) is moved to the second argument, the probability to serve as *Comparison* function is decreased to 0.4417, which is even lower than that of *Expansion* function. It shows that couple-linking elements provide strong clue to determine discourse relation. Besides, a single-word connective has some tendency to function as either forward linking or backward linking. For example, "雖然" (suī rán, although) is a forward-linking element. Normally, it will link the first discourse unit containing it with the second one. When it appears in the second discourse unit, it becomes ambiguous. The connectives containing "所以" (suǒ yǐ, so) have the similar effects. It tends to be a backward linking element, so its companion appears in the first discourse unit. Its probability to have *Contingency* function decreases from a word-pair connective to a single-word connective. When it appears in the first discourse unit, it may link to the previous sentence at the inter-sentential level.

Some Chinese short words like "而" (ér) is often a part of word-pair connectives. Table 8 shows 10 words which are often connected with "而" (ér) to form word-pair connectives. The word-pair connectives tend to have one major function. When the word-pair connective is "abbreviated" to a single-

Discourse Connectives [ds1, ds2]	Temporal (%)	Contingency (%)	Comparison (%)	Expansion (%)

Table 7: Effects of single-word and word-pair connectives containing "所以" (so).

word connective, it becomes ambiguous. The discourse function depends on which word-pair connective it is mapped. The determination relies on contextual information.

Table 9 further shows the effects of positions of single-word connectives. The major discourse function of the first 7 sets of connectives is changed when the connectives are shifted from the first discourse unit to the second one. In contrast, the last 3 sets of connectives keep their major discourse function no matter whether they are placed in the first or the second discourse unit. The only difference is the probability to serve as the major discourse function is changed. For example, the probability of the connective "只不過" (zhǐ bú guò, only; just; merely) to have *Comparison* function is increased from 0.6920 to 0.8501 when it is shifted from the first discourse unit to the second one.

5 Conclusion

In this paper, we address the issue of the ambiguous discourse functions of Chinese connectives in discourse relation labeling and propose a semi-supervised learning method to estimate the probability distribution of discourse functions of connectives. We examine the constructions of Chinese connectives and their effects on the discourse relation recognition. The proposed approach learns the probability distributions of discourse functions of Chinese connectives from a small labeled dataset and a big unlabeled dataset. The results reflect many interesting linguistic phenomena. We compare the ambiguity degrees of single-word and word-pair connectives, and show the effects of the positions of single-word connectives on the discourse functions. The discourse relation recognizer integrating the

probability distributions and contextual information significantly outperforms the approaches without the knowledge.

This methodology can be extended to estimate the probability distribution of discourse functions of connectives on much finer relation categories. In the current experiments, we focus on explicit discourse relation recognition. The 302,293 labeled sentences in Section 4 can be regarded as a training corpus for implicit discourse relation recognition. Those labeled sentences composed of unambiguous connectives will be sampled from the reference corpus for training an implicit discourse relation recognition system. Furthermore, how to employ the learned probability distributions to deal with discourse units containing multiple connectives will be investigated. In the future, we will tell out the discourse connective and non-discourse connective uses of words and explore their interpretations on the discourse relation recognition. Besides, we will make use of the probability distributions to the relation labeling on more than two clauses and further extend the methodology to experiments at the inter-sentence level.

Abstract

In this paper we present a novel method for unsupervised coreference resolution. We introduce a precision-oriented inference method that scores a candidate entity of a mention based on the most informative mention pair relation between the given mention entity pair. We introduce an informativeness score for determining the most precise relation of a mention entity pair regarding the coreference decisions. The informativeness score is learned robustly during few iterations of the expectation maximization algorithm. The proposed unsupervised system outperforms existing unsupervised methods on all benchmark data sets.

1 Introduction

Due to the advent of the internet, the world wide web, social media, the electronic distribution of information and new means of communication, the amount of text available in many different languages is rising. Natural language processing (NLP) is in charge of automatic processing this growing data. NLP research has mainly focused on English and very few other languages. Therefore there is a rich set of annotated corpora for linguistic analysis tasks for these languages. However, there are no such corpora for thousands of other languages. Since unsupervised methods do not require annotated data for learning a model, employing unsupervised methods has become a popular and important area of research in NLP.

In this paper, we propose a new precision oriented method for unsupervised coreference resolution. Our method evaluates the candidate entities of mentions based on the most precise relation of each mention and its candidate entity. Though we develop and evaluate our method for the English language, we intend to apply it to low resource languages in the future.

Common coreference resolution approaches rely on a combination of different features for each decision (for an overview over such approaches, see Ng (2010)). However, a few approaches break down this combination having precision in mind (Baldwin, 1997; Zhou and Su, 2004; Haghighi and Klein, 2009; Lee et al., 2013). The idea of starting with high precision knowledge is used in various NLP tasks including parsing (Borghesi and Favareto, 1982), word alignment (Brown et al., 1993), and named entity classification (Collins and Singer, 1999) with different names like "islands of reliability", "stepping stones", and "cautiousness". Lee et al. (2013) is a successful recent work that implements this idea as "sieve architecture". Lee et al. (2013) first decide on the basis of more precise features, and then they extend these decisions by using less precise features in later sieves. In this system less precise knowledge is used for extending the decisions made by high precision knowledge.

Our proposed inference method goes in the same direction but in a different way. The probability of each coreference decision is computed based on a single relation of a mention-entity. This single relation is the most precise relation that exist between the mention-entity. In contrast to Lee et al. (2013), our inference method will never take into account less precise relations if more precise ones are present. The relative precision of relations can be determined based on our linguistic intuition. If we would rely on linguistic intuition, our system would look much like Lee et al.'s (2013)'s system, except that it processes

Proceedings of COLING 2014, the 25th International Conference on Computational Linguistics: Technical Papers, pages 644–655, Dublin, Ireland, August 23-29 2014.

all mentions in a single sieve, instead of iterating over all mentions for each input relation. However, it is not a trivial task to determine the relative importance of relations for each new relation, new domain, or new language. In this regard, we propose an informativeness score for automatically determining the relative precision of relations.

The informativeness score is computed based on the distinguishing power of relations among coreferring and non-coreferring mentions. We learn the informativeness score in an unsupervised way via few iterations of the Expectation Maximization (EM) algorithm. Overall, our inference method first finds the most precise relation that a mention has with its candidate entity based on the computed informativeness scores. It then computes the probability of joining the mention to the entity based on this best relation and its distribution among all candidate entities.

We empirically validate our approach on the OntoNotes and ACE data sets, showing that despite being entirely unsupervised, our system performs well on all benchmark data sets.

2 Related Work

Early coreference resolution systems were mainly rule-based systems (Lappin and Leass, 1994; Baldwin, 1997). The success of statistical approaches in different NLP tasks together with the availability of coreference annotated corpora (like MUC-6 (Chinchor and Sundheim, 2003) and MUC-7 (Chinchor, 2001)) facilitated a shift from deploying rule-based methods to machine learning approaches in coreference research in the 1990s.

The increasing importance of multilingual processing, brought the deployment of semi-supervised and unsupervised methods into attention for automatic processing of limited resource languages. There are several works which treat coreference resolution as an unsupervised problem (Cardie and Wagstaff, 1999; Angheluta et al., 2004; Haghighi and Klein, 2007; Ng, 2008; Poon and Domingos, 2008; Haghighi and Klein, 2009; Haghighi and Klein, 2010; Kobdani et al., 2011). We compare our results with the unsupervised systems of Haghighi and Klein (2007), Poon and Domingos (2008), Haghighi and Klein (2009), and Kobdani et al. (2011). The Haghighi and Klein (2010) approach is an almost unsupervised approach, and we do not include this system in our comparisons.

We use the expectation maximization algorithm for unsupervised learning. EM has been previously used for coreference resolution (Cherry and Bergsma, 2005; Ng, 2008; Charniak and Elsner, 2009). Cherry and Bergsma (2005) and Charniak and Elsner (2009) use EM for pronoun resolution, and Ng (2008) models coreference resolution as EM clustering. The model parameters of Ng (2008) are of the form $P(f_1, \ldots, f_k|C_{ij})$, where f_i is a feature, and C_{ij} corresponds to the coreference decision of two mentions m_i and m_j. These parameters along with the entity set, are two sets of unknown variables in Ng (2008). He computes the posterior probabilities of entities in the E-step, and determines the parameters from the N-best clustering (i.e. estimated entities) in the M-step. Ng (2008) starts from an initial guess about the entities and determines the parameters based on this initial guess (M-step). In order to compute the N-best clustering, Ng (2008) uses the Bell tree approach of Luo et al. (2004).

The informativeness scores of mention pair relations (Section 3.2.1) are our unknown parameters. Our inference method only requires the ranking of the informativeness scores (and not their exact values). Therefore, it is much easier to estimate the ranking of these parameters than parameters like $P(f_1, \ldots, f_k|C_{ij})$, and our search space for finding an optimized ranking of the informativeness scores is very small. Since it is easier to have an initial guess about the ranking of informativeness scores (rather than guessing an initial entity set), we start from an E-step with a random ranking.

In our experiments, EM converges very fast regardless of the initial state. Indeed, in the M-step, we use our new inference method for computing an estimation of entities. The use of the EM algorithm in our approach is discussed in more detail in Section 3.3.

3 Method Description

Our coreference resolution method is a mention-entity approach which works at mention-mention granularity for processing candidate entities. It estimates entities incrementally while processing the mentions.

For resolving each mention, our inference method scores all candidate entities. For scoring each candidate entity, it first finds the most informative mention-mention relation that exists between the mention and the candidate entity. It then computes the probability of joining the mention to the entity (i.e. the score of the candidate entity) based on the distribution of this relation among all candidate entities of the mention.

In order to find the best mention-mention relation of a mention and an entity, we introduce an informativeness score that scores mention pair relations based on their association with coreference links. This measure is a global measure, and it is computed based on the association analysis of the mention pair relations and coreference links on a whole entity set of all input documents.

We learn the informativeness score in an unsupervised way by using the EM algorithm. Inference is performed at each E-step of the EM iterations. At each E-step, the whole set of entities is constructed from scratch. The informativeness score of the input relations is computed in the M-step based on the estimated entities of the E-step.

3.1 Notations

Assume that M is a mention set of the input document, and each document consists of a set of entities E in which each entity contains one or more mentions of M. $R = \{r_1, \ldots, r_K\}$ is a set of input relations with the following property:

$$\forall r \in R: \; r(m,n) \in \{0,1\} \tag{1}$$

where m and n are two mentions and r can be any arbitrary relation between two mentions like having a specific feature-value (in which the feature can be a combinational feature), or a linguistic rule.

In order to capture the natural left-to-right ordering of mentions, $r(m,n)$ is zero when n is positioned after m in the input document.

3.2 Inference Method

The inference method processes mentions in the text from the beginning of a document to its end. Initially, each mention is in its own entity. For each mention $m \in M$, all partial entities that have been estimated so far (i.e. entities constructed while processing mentions which are positioned before m) are considered as candidate entities of m (i.e. E_m).

For each candidate entity u, the inference method first determines the best relation among all existing mention pair relations between m and u that can indicate a coreference link based on the informativeness score. We call this relation r_u:

$$r_u = \underset{r \in R}{\operatorname{argmax}} \; (IS(r) \times \max_{n \in u} r(m,n)) \tag{2}$$

where $IS(r)$ is the informativeness score of the r relation.

Apparently, when $IS(r) \times \max_{n \in u} r(m,n)$ is equal to zero, u will be removed from E_m.

After finding the most informative relation that exists between m and u (i.e. r_u), we compute the probability of joining m to u based on r_u as follows:

$$Pr[m \rightarrow u] = \frac{\sum_{n \in u} r_u(m,n)}{\sum_{v \in E_m} \sum_{x \in v} r_u(m,x)} \tag{3}$$

Equation 3 computes the local distribution of r_u among all entities belonging to E_m. After computing the probability of Equation 3 for all candidate entities, m will be joined to the $\hat{u}$ that has the highest probability:

$$\hat{u} = \underset{u \in E_m}{\operatorname{argmax}} \, Pr[m \rightarrow u] \tag{4}$$

In case of a tie condition ($\forall_{u,v \in E_m} \; Pr[m \rightarrow u] = Pr[m \rightarrow v]$), $\hat{u}$ will be the entity whose most informative relation is more precise than the most informative relation of the other candidates:

$$\hat{u} = \underset{u \in E}{\operatorname{argmax}} \, [\max_{r \in R} (IS(r) \times \max_{n \in u} r(n,m))] \tag{5}$$

After finding the best candidate entity of m, the method proceeds to find the best entity of the next mention, based on the new updated E.

A mention m will be left in its own entity in two cases: 1) when E_m is empty, and 2) when the value of $Pr[m \rightarrow \hat{u}]$ is below a predefined threshold. We consider this threshold equal to 0.5 in our experiments. This threshold indicates situations in which less than half of the occurrences of $r_{\hat{u}}$ exist between m and $\hat{u}$, and the others are spread among other entities. This entity can be extended while processing later mentions or it may remain as a singleton.

Please note that the inference method does not care about the exact values of $\{IS(r)\}$, and it only needs to have a ranking of the informativeness scores for the given relations in order to select the most informative one.

3.2.1 Informativeness Score

We want to score a set of given relations based on their discriminative power in making coreference decisions. From a statistical point of view, this can be expressed as to determine whether the existence of a relation indicates a coreference link or is due to chance. In this regard, we can examine the following two hypotheses:

$$\textbf{Hypothesis 0: } P(C = 1|r = 1) = p = P(C = 1|r = 0) \tag{6}$$

$$\textbf{Hypothesis 1: } P(C = 1|r = 1) = p_1 \neq p_2 = P(C = 1|r = 0) \tag{7}$$

where $C \in \{0, 1\}$ is a random variable for coreference decisions.

Hypothesis 0 (null hypothesis) formalizes independence (the coreference decisions are independent of relation r). Hypothesis 1 formalizes dependence, which in case $p_1 \gg p_2$ indicates a strong positive association between r and C. This is the pattern that we are interested in.

We use the G^2 log-likelihood ratio statistics for testing these hypotheses. The statistics was introduced to the NLP community by Dunning (1993), and is defined as follows:

$$-2 \log \lambda = 2 \cdot \log \frac{L(H1)}{L(H0)} \tag{8}$$

where $L(H)$ is the likelihood of a hypothesis based on observed data assuming a binomial probability distribution for the existence of r between coreferring mentions. Asymptotically, $-2 \log \lambda$ is χ^2 distributed with one degree of freedom.

Assuming that we have the whole set of entities of input documents, we can use the maximum likelihood estimator to compute p_1, p_2, and p as follows:

$$\begin{aligned}
p_1 &= \frac{\sum_{u \in E} \sum_{m \in u} \sum_{\substack{n \in u \\ n \neq m}} r(m, n)}{\sum_{x \in M} \sum_{\substack{y \in M \\ y \neq x}} r(x, y)} \\
p_2 &= \frac{\sum_{u \in E} \sum_{m \in u} \sum_{\substack{n \in u \\ n \neq m}} (1 - r(m, n))}{\sum_{x \in M} \sum_{\substack{y \in M \\ y \neq x}} (1 - r(x, y))} \\
p &= \frac{\sum_{u \in E} \sum_{m \in u} \sum_{\substack{n \in u \\ n \neq m}} 1}{\sum_{x \in M} \sum_{\substack{y \in M \\ y \neq x}} 1}
\end{aligned} \tag{9}$$

The log-likelihood ratio statistics can be used both for filtering out non-informative relations and for scoring the remaining relations. The filtering is done by comparing the value of $-2 \log \lambda$ to the desired threshold value obtained from the χ^2 table (15.0 in our experiments) and removing the relations that are not significant at the desired level.

Similar to Dunning (1993), the test statistics can be used as a measure for scoring. In our formulation, the test statistics scores given mention pair relations based on their association with coreference links in a way that more precise relations (relations that indicate a coreference link more strongly) will get a

higher score, and less precise relations (relations that are randomly spread among coreferring and non-coreferring mentions) will get a lower score.

The formulation of the log-likelihood ratio in Dunning (1993) is a two-tailed statistical test that if p_1 and p_2 significantly diverge from each other, the $-2\log\lambda$ would get a high value. However, as mentioned above, we are just interested in the cases that p_1 is much higher than p_2, because, otherwise, coreference links among the mentions which have the relation r in common are less frequent than expected.

Therefore, we use the one-sidedness condition as discussed by Kiss and Strunk (2006) for the log-likelihood test. In this case, a relation r is selected as an informative relation for coreference resolution when the $-2\log\lambda$ is larger than the desired threshold, and also $p_1 > p_2$:

$$IS(r) = \begin{cases} -2\log\lambda & \text{if } p_1 > p_2 \\ 0 & \text{otherwise} \end{cases} \tag{10}$$

We compute the values of $\{IS(r)\}$ based on entities of the whole set of input documents in order to have a global estimation of the associations in the input data. In order to have a domain- or genre-specific model, one should learn different $\{IS(r)\}$ for each different domain/genre. The domain/genre adaptation is discussed in more detail in the discussion part.

3.3 Learning Method

From what we have discussed so far, $\{IS(r)\}$ values and document entities (E) are two unknown sets of variables that we want to find. When $\{IS(r)\}$ is known, we can estimate entities by using the inference method described in Section 3.2. When the entities are known, we can compute the $\{IS(r)\}$ as described in Section 3.2.1. We can see that these two steps (i.e. determining entities and the informativeness scores), correspond to the E- and M-steps of the expectation maximization algorithm, respectively.

Expectation maximization is an iterative procedure for computing the maximum likelihood estimator of a parameter set when only a subset of data is available. The EM model involves some hidden variables (Z), observed data (X) and a set of unknown parameters (θ). In our modeling, the informativeness scores are the unknown parameters, the observed data is a set of relations corresponding to R, and entities are hidden variables.

In the M-step, the model estimates $\{IS(r)\}$ by using the association analysis of mention pair relations and coreference links over the entire entity set of the input documents. In the E-step, the algorithm performs the inference method of Section 3.2 and reconstructs the whole set of entities based on the given $\{IS(r)\}$ values. As mentioned before, the inference method only needs the ranking of the informativeness scores, and therefore different values of $\{IS(r)\}$ with similar ordering will lead to the same result. Our model starts from an initial E-step, in which the values of $\{IS(r)\}$ are ranked randomly. The iteration between the E- and M-steps continues until $\{IS(r)\}$ converges to steady values. The convergence and the initial state of the EM algorithm are discussed in more detail in the discussion part.

4 Experiments

4.1 Mention Pair Relations

Here is the list of pairwise relations that we use for common and proper nouns:

- *String match:* Two mentions have the same string after removing their post-modifiers.
- *Compatible head match:* Two mentions have the same head, and the pre-modifiers of the anaphor are a subset of the pre-modifiers of the antecedent.
- *Proper head match:* Two proper names have the same head, and they do not contain numeric or location pre-modifiers.
- *Substring:* All words of the anaphor appear in the antecedent (possibly in different order).
- *Acronym:* One mention is an acronym of the other.

For the ACE data, we use additionally the following relations:

- *Apposition:* Two mentions are in an apposition structure.
- *Demonym:* One mention is a name for a resident of a place that derives from the name of the place, and the other mention is the place name itself.
- *Predicate nominative:* The anaphor follows a linking verb and renames or describes the subject mention.
- *Role apposition:* The antecedent (with a noun head) is a modifier of a noun phrase whose head is the anaphor.

For the OntoNotes data sets, *Same speaker* (Lee et al., 2013) is the only feature for resolving pronouns. For the ACE data *Relative pronoun* (i.e. the anaphor is a relative pronoun that modifies the head of the antecedent) is also used. Pronouns, for which we do not have any feature, are linked to the nearest antecedent (based on the Hobbs distance) that currently belongs to a partial entity which is compatible with the pronoun. The compatibility is measured in terms of number, gender, person, animacy, and named entity label. This approach corresponds to the pronoun resolution strategy of the Stanford system.

The differences between the relations of the OntoNotes and ACE corpora is due to the fact that these two corpora have different annotation schemes. Some of the relations mentioned (e.g. *Apposition*) are considered as coreference relations only in the ACE data.

4.2 Data

We evaluate our method on the following data sets:

- **OntoNotes-Dev**: Development set of the OntoNotes data provided by the CoNLL2012 shared task (Pradhan et al., 2012). This data set consists of 303 documents.
- **OntoNotes-Test**: Test set of the OntoNotes data provided by the CoNLL2012 shared task (Pradhan et al., 2012). This data set consists of 322 documents.
- **ACE2004-nwire**: Newswire subset of the ACE 2004 data set consisting of 128 documents. This split of ACE2004 has been utilized in previous work (Poon and Domingos, 2008; Finkel and Manning, 2008; Haghighi and Klein, 2009; Lee et al., 2013).
- **ACE2004-Culotta-Test**: One of the test splits of the ACE 2004 data set that has been used in previous work (Culotta et al., 2007; Bengtson and Roth, 2008; Haghighi and Klein, 2009; Lee et al., 2013). This data set consists of 107 documents.
- **ACE2003-BNEWS**: BNEWS subset of the ACE 2003 data set utilized in Ng (2008) and Kobdani et al. (2011) consisting of 51 documents.
- **ACE2003-NWIRE**: NWIRE subset of the ACE 2003 data set utilized in Ng (2008) and Kobdani et al. (2011) consisting of 29 documents.

4.3 Preprocessing

The mention detection of the Stanford coreference system (Lee et al., 2013) is used for the OntoNotes data sets. We use the predicted information in the OntoNotes data sets for named entity labels, and syntactic roles. For experiments on the ACE data sets, gold mentions are used, so that comparison with previous work is possible. For preprocessing, the Stanford parser (Klein and Manning, 2003) and named entity recognizer (Finkel et al., 2005) are deployed.

We also use the singleton detection of the Stanford system (Recasens et al., 2013) for the OntoNotes data sets. When both mentions are detected as a singleton by the singleton detection module, the value of all their corresponding relations will be set to zero. In other words, $r(m, n)$ is set to zero when both n and m have been detected as a singleton. For examining the effect of the singleton detection module

4.4 Results

We evaluate our proposed model with the most commonly used metrics for coreference resolution: for the OntoNotes data sets MUC (Vilain et al., 1995), B^3 (Bagga and Baldwin, 1998), CEAF (Luo, 2005) and their average F1 as used in the CoNLL 2011 and 2012 shared tasks; for the ACE data sets MUC and B^3. The experimental results for the OntoNotes and ACE data sets are presented in Tables 1 and 2, respectively.

On the OntoNotes test set, we compare our method with the three best publicly available coreference systems including the Berkeley system (Durrett and Klein, 2013), the IMS system (Björkelund and Farkas, 2012), and the Stanford system (Lee et al., 2013; Recasens et al., 2013). The Berkeley and IMS systems are both supervised approaches with a rich set of lexical features. At the other hand, the Stanford system is a deterministic system with a set of entity-level features that needs to go through all mentions for incorporating each of the input features. The Stanford system is the winner of the CoNLL2011 shared

task. The IMS system is the 3rd best system on the CoNLL2012 shared task. The Berkeley system is a state-of-the-art supervised coreference system that outperforms both the Stanford and IMS systems. Despite being totally unsupervised and using pairwise features, the results of our system are on par with those of the Stanford system (according to the approximate randomization test, there is no significant difference). The comparison with this state-of-the-art rule based system (Lee et al., 2013), indicates the effectiveness of our coreference resolution approach, as it uses the same preprocessing modules and a simpler and smaller set of features. All results in the Table 1 are reported using the scorer-v7[1] of the CoNLL-2012 shared task (Pradhan et al., 2014).

On the ACE data sets, we compare our performance to those of the unsupervised systems mentioned in Section 2. As Table 2 shows, our method considerably outperforms other unsupervised systems on all data sets (except only for the MUC measure on the ACE2004-Culotta-Test data set).

5 Discussion

5.1 Informativeness Score

As discussed in Section 3.2.1, we determine the discriminative power of mention pair relations in coreference decisions based on the informativeness score (Equation 10), in which the statistical test is computed on the unsupervised estimated set of entities. The resulting ranking of the informativeness score for our input relations is presented in Table 3 on both OntoNotes and ACE data sets.

Another point that needs to be mentioned here is that we are currently using a set of simple and precise input relations. While using these input relations, the informativeness score cannot be efficiently used. The effectiveness of our informativeness score can be usefully assessed with complex relations (i.e. combinatorial features). However, learning of the informativeness scores for complex relations is not possible in a totally unsupervised configuration and one should at least use an informative initial state to guide the learning. We address this issue in our future work.

5.2 Domain/Genre Adaptation

The OntoNotes data set has seven genres regarding the type of text's sources: newswire (NW), broadcast news (BN), broadcast conversation (BC), magazine (MZ), telephone conversation (TC), web data (WB), pivot text (PT). Domain or genre adaptation is one of the current obstacles in language processing. In order to test the effect of genre adaptation in our approach, we try a variant of our approach in which the informativeness scores of the input relations (i.e. $\{IS(r)\}$) are learned separately for each genre. The results of this evaluation are presented in Table 1 by the name "& Genre".

As can be seen in Table 1, the genre-specific variant of our system is performing as well as the base version. This experiment indicates the robustness of our approach regarding the genre/domain adaptation. It can learn an appropriate approximation of the informativeness scores from a small amount of data (i.e. the data provided for a single genre instead of the data from all genres). The learned orderings of the informativeness scores for all genres are presented in Table 4.

When evaluated on each genre separately, the system has the best performance on PT, and the worst performance on the WB genre. The total ordering of genres based on the performance of our system is

as follow: PT, MZ, TC, BN, NW, BC, WB.

5.3 EM Initial State and Convergence

For the initial state of our EM algorithm, we need a ranking of the informativeness scores of the input relations. We try different initial states for the EM algorithm, from an informative ranking based on linguistic intuition about the precision of input relations to a misleading ranking (the informative order reversed). However, in all cases, the EM algorithm leads to the same ranking (as listed in Table 3). This indicates the robustness of our modeling.

It is more likely that a more precise relation will also get a higher value for its corresponding join probability of Equation 3, because it is unlikely that a precise relation connects a mention to several candidate entities. However, relations with low precision may connect a mention to several different entities, because they are spread over more different entities than relations with higher precision.

In our experiments, for all tested initial states, the model converges in 4 iterations on the OntoNotes data sets and 5 iterations on the ACE data sets.

5.4 Promising Alternative for the Stanford System

Our coreference resolution method is a self- contained approach, that does not need any external linguistic knowledge regarding the coreference relations. However, we can also consider a simple variant of this system in which a predefined ordering of features (based on linguistic intuition) is given, like the Stanford system. In this case, the EM algorithm will be no longer needed, and therefore, the algorithm resolves all mentions in a single iteration.

Therefore, this variant of our system can be considered as an efficient alternative to the Stanford system, that uses a simpler (pairwise instead of entity-based) and smaller (5 instead of 7 string matches) set of relations, and more importantly processes all mentions in a single iteration (instead of iterating over all mentions for each relation), and it still performs as well as its entity-based multi-sieve variant.

6 Conclusions

In this paper, we presented a new unsupervised coreference resolution method. We deploy a new precision-oriented inference method that decides about joining a mention to a candidate entity based on only the most informative mention pair relation that exists between the given mention entity pair. In order to determine the most informative relation of a mention and its candidate entity, we introduce an informativeness score for scoring mention-mention relations based on their global association with

coreference links. A relation whose existence strongly indicates a coreference link will get a high score, and a relation which is randomly spread among coreferring and non-coreferring mentions will get a low score. The informativeness score is robustly learned during a very few iterations of the EM algorithm.

Our proposed method performs well on all benchmark data sets. In the future we intend to apply this robust and efficient approach to new genres, domains, and also new languages.

Abstract

Community Question Answering (CQA) websites such as Quora are widely used for users to get high quality answers. Users are the most important resource for CQA services, and the awareness of user expertise at early stage is critical to improve user experience and reduce churn rate. However, due to the lack of engagement, it is difficult to infer the expertise levels of newcomers. Despite that newcomers expose little expertise evidence in CQA services, they might have left footprints on external social media websites. Social login is a technical mechanism to unify multiple social identities on different sites corresponding to a single person entity. We utilize the social login as a bridge and leverage social media knowledge for improving user performance prediction in CQA services. In this paper, we construct a dataset of 20,742 users who have been linked across Zhihu (similar to Quora) and Sina Weibo. We perform extensive experiments including hypothesis test and real task evaluation. The results of hypothesis test indicate that both prestige and relevance knowledge on Weibo are correlated with user performance in Zhihu. The evaluation results suggest that the social media knowledge largely improves the performance when the available training data is not sufficient.

1 Introduction

One of the main challenges for social startup websites is how to gain a considerable number of users quickly. A growing number of social startups outsource sign-up process to existing social networking services. They allow users to log in to the services using their existing social media accounts. For example, Quora allows users to log in with their Google, Twitter or Facebook accounts based on the OpenID technology. Lots of startup web services benefit from the huge number of users and rich relationships accumulated by social network sites. Social login helps the newborn web services to collect crowds of users in a short time. Moreover, startup web services can gain reliable profiles through social login. It also offers a convenient mechanism for users to surf the web using a unified social identity (e.g., Twitter account). For example, by the end of 2013, there are about 600,000 web services including mobile applications using social login offered by Sina Weibo.

When we go beyond simple import of profiles and consider the general problem of leveraging knowledge from social media, many subtasks arise. One of them is how to incorporate data from social media and startup web service to better predict user performance. In this paper, we take the largest social based question answering service Zhihu in China, which closely resembles Quora, as the testbed. Different from traditional CQA sites such as Baidu Zhidao, Zhihu have more prominent social features, which supports login with Sina Weibo accounts. Although Zhihu grows quickly and attracts more and more users, about 85% of the users answer fewer than 10 questions and 60% of the users answer fewer than 4 questions in our dataset, which is a large sample of Zhihu.

Previously, many studies have been proposed to improve expertise ranking on CQA services. Link analysis based approaches (Jurczyk and Agichtein, 2007; Zhang et al., 2007) exploit the question-answering relationships to construct a graph and run PageRank or HITS on the graph. Jeon et al. (2006)

Proceedings of COLING 2014, the 25th International Conference on Computational Linguistics: Technical Papers, pages 656–666, Dublin, Ireland, August 23-29 2014.

propose a method based on the non-textual behaviors. Moreover, co-training model (Bian et al., 2009) jointly infers answer quality and user expertise. Liu et al. (2011) formalize expertise ranking as a competition game with the insight that the best answerer beats other answerers in the same question thread. However, the above studies highly rely on the history data, which might not work well for newcomers or users with few answering records. For startup services, many users may not accumulate sufficient data to support the reliable estimation for their expertise levels. Indeed, the importance of newcomers has been noted in related studies, and it has been shown that the effective evaluation of users' performance at an early stage significantly affects the overall development of QA services (Nam et al., 2009; Sung et al., 2013).

In this paper, we propose a method that incorporates social media and social startup data to predict newcomers' performance. This problem is technically challenging due to the heterogeneous characteristics across websites. Given a user, we hypothesize that her capability of contributing high quality answers is dependent on her prestige and relevance. The more contents a user publishes on an area and the higher prestige a user has on social media sites, the higher likelihood that user can offer high quality answers. Thus, the first goal is to precisely measure the relevance between question and a user's tweets. Owing to the short question length and noisy tweet content, this problem brings technical challenges. We make use of user-annotated tags and adopt a translation based model to improve relevance estimation. For prestige, a straightforward way is to use the standard graph based ranking algorithm, however, Zhihu users have very sparse links on Weibo and the standard PageRank algorithm does not work well on sparse graphs. To address it, we add virtual links to alleviate the sparsity problem by finding available paths on a large Weibo graph. Furthermore, we propose a performance biased random walk algorithm and naturally incorporates Zhihu performance history as the supervised information.

We carefully construct a dataset of 20,742 users who have been linked across Zhihu and Weibo, which represent the social startup and the social media site respectively. We first conduct Spearman correlation test for these two hypotheses. Our results have shown that prestige in Weibo has a strong correlation with overall performance in Zhihu. For the performance in question level, we have found that the relevance of Weibo contents is also significantly correlated with answer quality in Zhihu. Based on these findings, we further incorporate the extracted prestige and relevance knowledge into the existing framework for user performance prediction. To simulate the process of history data accumulation, we also conduct experiments with the varying observed number of answers. The experiment results suggest that the borrowed social media knowledge, i.e., prestige and relevance information in Weibo, largely improves the performance when the available training data is not sufficient. Interestingly, we have found that even individual prestige feature can achieve very competitive results.

Although our approach is tested on a joint combination of Weibo and Zhihu, it is equally applicable to other knowledge sharing startup web services. The flexibility of our approach lies in that we identify two important and general types of knowledge that are easy to leverage from external social media sites.

The rest of this paper is organized as follows. The construction of the dataset collection and the problem formulation are given in Section 2 and 3 respectively. Section 4 presents the detailed feature engineering and is followed by the experiment part in Section 5. Finally, the related work and conclusions are given in Section 6 and 7 respectively.

2 Construction of the Dataset Collection

We focus on a popular social question answering website, Zhihu as the studied service. We select Sina Weibo, the largest Chinese microblogging service as the external website to help improve user expertise estimation task in Zhihu. We exploit the social login mechanism to identify the same user across these two platforms: if a user logs in Zhihu with her Weibo account, her Zhihu profile will contain the corresponding Weibo account link. This approach accurately links users across websites.

Zhihu dataset. Zhihu[1] is a social based question answering site in China, which is similar to Quora in terms of overall design and service. Zhihu has three major components: users, questions, and topics. Users on Zhihu can ask and answer questions, furthermore, they can comment on or vote for answers.

[1] http://www.zhihu.com

Each question is usually assigned with a small set of topic tags by the asker and opens a discussion thread consisting of candidate answers. Topics are represented as tags and organized in a directed acyclic graph where a child topic can have multiple parent topics.

Zhihu was founded in January 2011, and we obtain the data between January 2011 and November 2013 via a Web crawler. The dataset contains 266,672 users, 819,125 questions and 2,730,013 answers. These questions are associated with 44,333 topic tags. Since the aim is to examine whether knowledge extracted from Weibo is helpful to improve tasks in Zhihu, we only keep the users who explicitly use social login and get 136,002 cross-site users, which roughly covers 50% of the users in our dataset. For a robust evaluation, we further remove users who have answered fewer than ten questions. Finally, we obtain a total of 20,742 users and summarize the data statistics in Table 1.

#users	#topics	#questions	#answers
20,742	44,333	335,145	883,373

Table 1: Basic statistics of Zhihu dataset for linked users.

Weibo Dataset. Sina Weibo is the largest Chinese microblogging service which has about 500 million registered users by the end of 2012. We have crawled all the detailed information of these 20,742 linked users, including tweets, followers, and following links. These users are indeed active on Weibo and have posted 21,121,955 tweets in total. In later sections, we will adopt the PageRank algorithm to estimate the prestige scores of these linked users, thus we need a dense following graph for reliable estimation. By using these linked users as seeds, we further crawl their followings and followers as well as the following links between all the crawled users. Finally, we obtain 253,361,449 edges between 1,322,425 users. Note that we only use these 20,742 linked users for further study, and the rest are only used to help compute more accurate PageRank scores.

In what follows, we refer to a user who has both a Weibo account and a Zhihu account in our dataset as a *linked user*.

3 Problem Formulation

Users are the most valuable resource in community question answering (CQA) services. Discovering users' expertise at an early stage is important to improve the service quality. A typical task on CQA services is to predict users' performance or expertise: given a question, it aims to estimate the user expertise level and identify experts who can provide good answers to this question.

Borrowing the ideas from information retrieval, we solve the performance prediction task via the learning to rank framework (Liu, 2009). Formally, we assume that there are a set of m questions (i.e., queries) $\mathcal{Q} = \{q^{(1)}, q^{(2)}, q^{(3)}, ...q^{(m)}\}$. A question is associated with a set of $n^{(i)}$ answers $\{a_1^{(i)}, ..., a_{n^{(i)}}^{(i)}\}$ provided by $n^{(i)}$ users $\{u_1^{(i)}, ..., u_{n^{(i)}}^{(i)}\}$ respectively. For each user, let $y_j^{(i)}$ denote the performance score of user $u_j^{(i)}$ with respect to query $q^{(i)}$. A higher value of $y_j^{(i)}$ indicates better performance for query $q^{(i)}$. In our work, we instantiate the performance score by *the number of votes* that a user receives on a question. A feature vector $\boldsymbol{x}_j^{(i)}$ is constructed based on a pair of question and user $(q^{(i)}, u_j^{(i)})$. The aim of the learning task is to derive a ranking function f such that, for each feature vector $\boldsymbol{x}_j^{(i)}$, it outputs a prediction score $f(\boldsymbol{x}_j^{(i)})$ for the performance of user $u_j^{(i)}$ on the question $q^{(i)}$. With this function, when a new question comes, we can predict who will be competent at it.

For prediction tasks, the answer information $\{a_1^{(i)}, ..., a_{n^{(i)}}^{(i)}\}$ is not available during training. Besides users' accumulated history data on Zhihu, external knowledge from Weibo is available to help construct the query-user feature vector. We assume that the studied Zhihu users have already been linked to the corresponding Weibo accounts, and we can obtain their Weibo information, including tweets and followings/followers. The key of the learning to rank framework is how to derive effective features. In our task, we consider two types of features, i.e., Zhihu features and Weibo features. Our focus in this paper is how to leverage microblogging information for improving CQA service, i.e., how to incorporate knowledge from Weibo as features into the learning to rank framework.

4 Feature Engineering

In this section, we discuss how to derive effective features from both Zhihu and Weibo. In particular, we mainly study how to leverage Weibo knowledge for the current task.

4.1 Weibo features

In our work, we focus on two types of Weibo features: prestige and relevance. For prestige, it aims to capture the social status of a user. In our setting, it refers to the status or authority level of a user on online social networks (Anderson et al., 2012). We hypothesize that a user is likely to have similar status levels across multiple online communities, thus the prestige scores of Zhihu users can be roughly estimated based on the rich link information of Weibo. The second type of knowledge we consider is relevance. A user is more likely to be an expert on an area that she is interested in, and Weibo provides a good platform to identify users' interests. Since Weibo and Zhihu are text based websites, we hypothesize that a user will show similar interests on these two medias.

Prestige. Prestige features aim to capture the status of one user. Status characteristic theory posits that one with higher status characteristic is expected to perform better in the group task (Oldmeadow et al., 2003). Prestige estimation has been a classical problem in both web graph analysis and social networking analysis (Easley and Kleinberg, 2012). We are motivated by previous study on authority ranking in Twitter (Kwak et al., 2010), which utilizes the following relations as the evidence of authority. A straightforward way is to run standard PageRank algorithm on the Weibo subgraph consisting of these 20,742 linked users. However, the subgraph of these linked users is very sparse, each linked user has only about 5 out-links to other linked users on average. Such a sparse graph will not produce meaningful ranking results.

Our solution is to add virtual links between linked users. Let N ($N = 20,742$) denote the number of linked users and $\mathbf{M}_{N\times N}$ denote the transition matrix based on the graph of these linked users. Given two users u_i and u_j, we check whether there is a directed path between them on our large Weibo graph. Recall that we have 253,361,449 edges between 1,322,425 users in Weibo dataset. We run the breadth-first search algorithm to find the shortest path between two linked users. If there exists a directed path between two linked users, we add a virtual link between them and set the weight to *the reciprocal of the shortest path length*, i.e., $I(i,j) = \frac{1}{\text{len}(u_i \rightarrow u_j)}$, where $\text{len}(u_i \rightarrow u_j)$ denotes the length of the shortest path between u_i and u_j. In this way, we have $M_{ij} = \frac{I(i,j)}{\sum_k I(i,k)}$. By adding virtual links, we obtain a more dense graph of these linked users. Formally, the standard PageRank algorithm (Brin and Page, 1998) can be formulated as:

$$\boldsymbol{r}^{(n+1)} = \mu \cdot \mathbf{M}^{\mathbf{T}} \cdot \boldsymbol{r}^{(n)} + (1-\mu) \cdot \boldsymbol{y} \tag{1}$$

where μ is the damping factor usually set to 0.85 and $\boldsymbol{y}$ is the restart probability vector usually set to be uniform (Yan et al., 2012). When the algorithm converges, we can obtain the stationary distribution of users (i.e., $\boldsymbol{r}$) as the prestige scores.

The above method assumes that users have same restart probability, which may not be true in reality. Since we are considering improving Zhihu service quality, we incorporate users' history data from Zhihu as supervised information. The main idea is that instead of using a uniform restart distribution $\boldsymbol{y}$, we use a performance biased restart distribution in Eq. 1. We set the restart probability of a user to her average vote ratio based on the questions she has answered. Formally, we set $y_u = \text{Average}(\sum_q \frac{\#vote(q,u)}{\sum_v \#vote(q,v)})$, where $\#vote(q,u)$ denotes the number of votes user u receives on question q and $\sum_v \#vote(q,v)$ denotes the total number of votes that all users receive on question q. We do not use other measures such as best answer ratio because we assume that the history window is very limited and our proposed method provides more robust estimation. Let us further explain the idea. At the beginning of each iteration, each user is assigned to her performance score estimated based on Zhihu data: the more competent she is, the larger score she has. During the iteration, each user begins to collect authority evidence from her incoming neighbors on the Weibo graph. The final score is indeed a trade-off between her own performance on Zhihu and her authority on Weibo.

There are also other measures to consider, e.g., the follower number and the times of being retweeted. In our experiments, we have tried these variants and found that no one is more effective than the above method.

Relevance. Intuitively, a user is more likely to be an expert on an area that she is interested in. In the setting of Zhihu, a user tends to perform better on the topics that are more relevant to her interests. Status characteristic theory also conveys that task relevance is an important factor which affects one's performance (Oldmeadow et al., 2003). Weibo provides a good platform to infer users' interests, which is helpful to derive relevance scores.

We formulate relevance estimation as an information retrieval task. Let $\mathcal{V}$ denote a term vocabulary and w denote a word in $\mathcal{V}$. Note that we take the union of the Weibo vocabulary and Zhihu vocabulary. The interest of a user u is modeled as a multinomial distribution over the terms in $\mathcal{V}$, i.e., $\theta^u = \{\theta^u_w\}_{w\in\mathcal{V}}$. Given a question q, we also model it as a multinomial distribution over the terms in $\mathcal{V}$, i.e., $\theta^q = \{\theta^q_w\}_{w\in\mathcal{V}}$. Following (Zhai, 2008), the relevance score between question q and user u can be estimated by the negative Kullback-Leibler divergence between θ^q and θ^u:

$$\text{Rel}(q,u) = -KL(\theta^q,\theta^u) = -\sum_{w\in\mathcal{V}} p(w|\theta^q)\log\frac{p(w|\theta^q)}{p(w|\theta^u)} \tag{2}$$

We first estimate θ^q. The straightforward way is to estimate θ^q based on the question text. However, the question text is usually short and noisy, which does not yield good results in our experiments. Recall a question is associated with a small set of user-annotated topic tags, and tags are good semantic indicators of the question. A topic tag usually indexes a considerable amount of questions, and we can use tags to leverage semantics from the indexed questions. Formally, we adopt the translation based model (Zhai, 2008) to estimate the question model:

$$\theta^q_w \propto \sum_{t\in q} p(w,t|q) = \sum_{t\in q} p(w|t)p(t|q) \tag{3}$$

where $p(w|t)$ is the translation probability from a tag to a term, and $p(t|q)$ is the empirical distribution of tag t in question q. Here we make an independent assumption: given a tag, the question is independent of a word, i.e., $p(w|t,q) = p(w|t)$. The procedure can be interpreted as follows: sample a tag from the question and then compute the probability of translating the tag into a specific word. We estimate the tag-term translation probability as $p(w|t) = \frac{\#(w,t)+1}{\sum_{w'\in\mathcal{V}}\#(w',t)+|\mathcal{V}|}$, where $\#(w,t)$ denotes the term frequency of w in the question text that tag t indexes. We use the additive-one smoothing.

We also try to incorporate the question text into the above estimation formula. However, it does not result in any improvement. The main reason is that the question words may be too specific, as a comparison, tags provide a general level of semantics, which is more effective to identify expertise areas.

Next, we estimate user interest model θ^u. We consider aggregating all the tweets of a user as a "document", and then estimate the document-term probability as $\theta^u_w = \frac{\#(w,u)+1}{\sum_{w'\in\mathcal{V}}\#(w',u)+|\mathcal{V}|}$, where $\#(w,u)$ denotes the term frequency of w in the aggregated document of user u.

4.2 Zhihu features

Now we describe the features extracted from Zhihu, and we refer to them as *baseline features* since we take the performance of them as a base reference. We summarize these features in Table 2.

These features have been extensively tested to be very effective by previous related studies (Song et al., 2010; Liu et al., 2011), which represent the state-of-art of the current task.

Summary. We have considered two general types of knowledge in social media which are potential to improve user expertise estimation in Zhihu. It is easy to see that our approach can be equally applicable to other third-party websites which is text based and contain manually annotated tags.

Features	Abbr	Formulas
Number of Best Answers	NBA	—
Number of Answers	NA	—
Number of Received Votes	NV	—
Average Number of Votes	AVA	—
Smoothed Average number of Votes	SAVA	$\text{SAVA}(u) = \frac{\sum_q \sigma(v(q,u))}{\text{NA}(u)}, \sigma(x) = \frac{1}{1+e^{(-x)}}$
Best Answer Ratio	BAR	$\text{BAR}(u) = \frac{\text{NBA}(u)}{\text{NA}(u)}$
Smoothed Best Answer Ratio	SBAR	$\text{SBAR}(u) = \frac{\text{BAR}(u)*\text{NA}(u)+\text{BAR}_{\text{avg}}*\text{NA}_{\text{avg}}}{\text{NA}_{\text{avg}}+\text{NA}(u)}$
Average Answer Length	AAL	—

Table 2: List of baseline features with corresponding abbreviations and formulas. Here u denotes a Zhihu user.

5 Experiment

Questions with fewer than five answerers do not receive much attention, and we only keep questions which involve at least six users. In this way, we have obtained a total of 25,262 questions. The number of votes is used as the measure of answer quality. The question threads are sorted by the post time, and we can simulate the cold-start phenomenon to examine the performance of different methods. We split the dataset into a training set and a test set by question threads with the ratio of 3:1. The "history" data of a user is put into the training set and the rest is treated as test data. We further vary the size of "history data" that can be used for performance prediction in three levels, i.e., at most 3, 5, and 10 "historical" question threads have been observed for a given user.

5.1 Hypothesis Testing

In this part, we first examine the fundamental hypotheses of our work: whether Weibo knowledge is potentially effective to improve the performance of tasks in Zhihu. We conduct significance test to examine the correlation between user features extracted from Weibo and user performance in Zhihu. We adopt the Spearman's rank correlation coefficient as the test measure. For a sample of size n, the n raw scores X_i, Y_i are converted to ranks x_i, y_i, and the Spearman correlation coefficient ρ is computed as $\rho = 1 - \frac{6\sum_i d_i^2}{n(n^2-1)}$, where $d_i = x_i - y_i$. The Spearman's coefficient ρ lies in the interval $[-1, 1]$, and a value of "+1" or "-1" indicates a perfect, positive or negative Spearman correlation.

Test of prestige. In our test, the overall performance of a user is estimated by the average vote counts she receives per answer, and the prestige level of a user is estimated by her PageRank score on the original Weibo following graph with a uniform restart probability. With these two measures, it is straightforward to generate two rankings of users, either by user prestige level or by user performance. However, it is noted that ρ is usually very sensitive when the sample size is too large, and it is difficult to obtain robust correlation values in this case. To better capture the overall correlation patterns, we group users according to their prestige levels and examine the correlation degree in the group level. We sort users according to their PageRank scores in a descending order, and split users equally into 100 buckets. The correlation value between performance and PageRank is $\rho = 0.5617$ at the significance level of $9.879e^{-10}$, which indicates there is a strong correlation between performance and prestige.

Test of relevance. Different from prestige, relevance is defined to be question specific, so we cannot perform global correlation analysis. We perform the correlation analysis in the question level. For each question, we have two rankings of involved users: the relevance ranking and the question-specific performance ranking. Let ρ denote the correlation coefficient between the relevance ranking and the performance ranking for a given question. Formally, given a question, we have the null hypothesis H_0 being "ρ is zero", whereas H_1 being "ρ is not zero". If H_0 is rejected, we can conclude that prestige in Weibo is correlated with users' performance on Zhihu for the given question. Our experiments have shown that 14.48% of the questions rejected the H_0 hypothesis at the confidence level of 0.9.

5.2 Evaluation metrics

In the above, we have shown that prestige and relevance knowledge extracted from Weibo are correlated with user performance in Zhihu. Next we are going a step further to examine the feasibility of using these external features to improve user performance ranking in CQA service. In this paper, we consider studying this problem in two aspects: in the first case, we only focus on the user who provides the *best answer*; while in the second case, we focus on the *overall ranking* of all engaged answerers in a given question thread. By following previous studies (Song et al., 2010; Deng et al., 2012), we adopt traditional evaluation metrics in information retrieval for evaluating user performance prediction in CQA services.

Best answer prediction. Our first task is to predict which user will provide the best answer given a question. The user who has received the maximum vote counts in a question thread will be labeled as relevant and the rest will be treated as non-relevant. Then we can adopt the widely used relevance metrics Precision at rank n (P@n) and Mean Reciprocal Rank (MRR).

Top expert recommendation. Unlike best answer prediction, top expert recommendation aims to provide a short list of candidate experts given a question. By following the study (Liu et al., 2011), we use nDCG (normalized Discounted Cumulative Gain) as the evaluation metrics. Let $vote(i)$ denote the vote counts of the answer ranked at i in a system output. To reduce the effects of large outliers, we set the gain value for an answer with the vote counts v to be $\log(v+1)$. The metrics are formally defined as follows:

$$DCG@n = \sum_{i=1}^{n} \frac{\log(vote(i)+1)}{\log(i+1)} \tag{4}$$

$$maxDCG@n = \sum_{i=1}^{n} \frac{\log(vote^*(i)+1)}{\log(i+1)} \tag{5}$$

$$nDCG@n = \frac{DCG@n}{maxDCG@n} \tag{6}$$

where $vote^*$ denotes the vote counts list of the ideal ranking system, i.e., the answer list is sorted by vote counts in the descending order.

Similar to query-specific information retrieval tasks, all our experiments are question specific. For a system, we evaluate its performance of each question and then average all the results as the final performance.

5.3 Results

As studied in Section 3, the above two tasks can be formulated as the learning to rank problem. Following previous work (Song et al., 2010), we adopt SVMRank as the ranking model and implement SVMRank using the tool package SVMLight[2]. We use the linear kernel for SVMRank, and report the results in Table 3 and Table 4.

We refer to the system with all Zhihu features as *Baseline*. We use two ways to compute prestige features: *P+UniformG* denotes the system which implements the standard PageRank algorithm with uniform restart probability, while *P+HisG* denotes the system which implements the biased PageRank algorithm with users' history performance on Zhihu as the restart probability. *Rel* denotes the system with only relevance features and *Baseline+Weibo* denotes the system with all the features.

Analysis of baseline results. The baseline system is built with all Zhihu features, which are estimated using history data, and it is natural to see that the performance of the baseline system improves with the increasing of the history data. Recall that all the question threads in our dataset contain more than six answers, indeed, 36.3% of them contain more than ten answers. A random algorithm to guess the best answer can only achieve a poor P@1 value of 11.07%. Results in Table 3 and Table 4 show that our baseline is competitive even on long question threads. In our experiments, the system performance begins to stay stable when the history window is set to ten question threads since quite a few users have engaged in fewer than ten question threads.

History Window Size	Systems	NDCG@1	NDCG@3	NDCG@5
NULL	P+UniformG	0.510	0.555	0.621
	Rel.	0.360	0.434	0.519
$\leq$3 question threads	(B)aseline	0.508	0.582	0.656
	P+HisG	0.550	0.596	0.658
	B.+Weibo	0.580	0.617	0.676
	vs. B.	+14.17%**	+6.01%***	+3.05%***
$\leq$5 question threads	(B)aseline	0.509	0.578	0.658
	P+HisG	0.556	0.603	0.668
	B.+Weibo	0.589	0.625	0.687
	vs. B.	+15.72%***	+8.13%***	+4.41%***
$\leq$10 question threads	(B)aseline	0.534	0.602	0.671
	P+HisG	0.568	0.616	0.679
	B.+Weibo	0.595	0.637	0.696
	vs. B.	+11.42%	+5.81%	+3.73%*

Table 3: Overall ranking performance with varying history window sizes. "*", "**", "***" indicate the improvement is significant at the level of 0.1, 0.05 and 0.01 respectively.

Analysis of the effect of Weibo features. We now incorporate Weibo features and check whether they can help improve the system performance. In Table 3 and Table 4, we present the improvement ratios over baselines with the incorporation of Weibo features. We can see that Weibo features yield a large improvement over the baseline system, especially when the size of history window is small, i.e., $\leq$3 question threads. This indicates the effectiveness of Weibo features on alleviating the cold-start problem in Zhihu. When we have more history data, i.e., $\leq$10 question threads, the improvement becomes smaller.

It is noteworthy that the single prestige feature (i.e., *P+UniformG* and *P+HisG*) achieves good performance. Especially, *P+HisG* obtains very competitive results compared with the baseline system. *P+HisG* naturally combines history data on Zhihu and prestige information on Weibo, which largely improves the standard prestige estimation method *P+UniformG*. As a comparison, the relevance feature is not that effective but still improves the overall performance a bit. These findings indicate that the incorporation of social media data can be a very promising way to improve the tasks of startup services.

6 Related Work

Our task is built on community question and answering site and researchers have studied CQA from many perspectives. One perspective focuses on user expertise estimation. Generally, there are two principle methods for expertise ranking, interaction graph analysis and interest modeling. Interaction graph based methods (Jurczyk and Agichtein, 2007; Zhang et al., 2007) construct a graph using interaction(e.g., asking and answering) behavior, and rank users using some generalization of PageRank (Brin and Page, 1998) or HITS (Kleinberg, 1999). Interest modeling methods characterize users' interests using question category (Guo et al., 2008) or latent topic modeling (Liu et al., 2005). There are also methods that combine both interest modeling and graph structure (Zhou et al., 2012; Yang et al., 2013) to rank users. Another research perspective on question answering service is quality prediction including answer quality prediction (Harper et al., 2008; Shah and Pomerantz, 2010; Severyn and Moschitti, 2012; Severyn et al., 2013) and question quality prediction (Anderson et al., 2012). However, since the methods mentioned above are based on the history data, the system will experience the cold start problem. Our work explore to what extent can external features help relieve the problem.

This work is also concerned with mining across heterogeneous social networks. Recently, many researches focus on mapping accounts from different sites to one single identity (Zafarani and Liu, 2013; Liu et al., 2013; Kong et al., 2013). By utilizing these recent studies on linking users across communities, our work can be extended to larger scale datasets. From another perspective, cross-domain recommendation has also been widely studied. Zhang et al. (Zhang and Pennacchiotti, 2013a; Zhang and Pennacchiotti, 2013b) explore how Facebook profiles can help boost product recommendation on e-commerce site. Previous work (Zhang et al., 2014) analyze user novelty seeking traits on social network and e-commerce site, which can be used to personalized recommendation and targeted advertisement. Different from simply borrowing user's profiles or psychological traits, our work integrates user footprints from heterogenous social networks and captures performance related characteristics more precisely.

7 Conclusion

In this paper, we take the initiative attempt to leverage social media knowledge for improving the social startup service. We carefully construct a dataset of 20,742 users who have been linked across Zhihu and Weibo, which are social startup and external social media websites respectively. We hypothesize that a user with higher prestige and more relevant Weibo contents to a question is more likely to have better performance.

We first carefully construct testing experiments for these two hypotheses. Our results indicate that prestige in Weibo has strong correlation with overall performance in Zhihu. For question specific performance, we have found that relevance between questions and a user's tweets also correlates with user performance on Zhihu. Based on these findings, we further add prestige and relevance knowledge into existing user performance prediction framework. The experiment results show that prestige and relevance information in Weibo largely improve the performance when the available training data is not sufficient. Moreover, individual prestige feature achieves very competitive results. Our approach is equally applicable to other knowledge sharing web services with appropriate external social media information.

Abstract

Topic modelling has been popularly used to discover latent topics from text documents. Most existing models work on individual words. That is, they treat each topic as a distribution over words. However, using only individual words has several shortcomings. First, it increases the co-occurrences of words which may be incorrect because a phrase with two words is not equivalent to two separate words. These extra and often incorrect co-occurrences result in poorer output topics. A multi-word phrase should be treated as one term by itself. Second, individual words are often difficult to use in practice because the meaning of a word in a phrase and the meaning of a word in isolation can be quite different. Third, topics as a list of individual words are also difficult to understand by users who are not domain experts and do not have any knowledge of topic models. In this paper, we aim to solve these problems by considering phrases in their natural form. One simple way to include phrases in topic modelling is to treat each phrase as a single term. However, this method is not ideal because the meaning of a phrase is often related to its composite words. That information is lost. This paper proposes to use the generalized Pólya Urn (GPU) model to solve the problem, which gives superior results. GPU enables the connection of a phrase with its content words naturally. Our experimental results using 32 review datasets show that the proposed approach is highly effective.

1 Introduction

Topic models such as LDA (Blei et al., 2003) and pSLA (Hofmann 1999) and their extensions have been popularly used to find topics in text documents. These models are mostly governed by the phenomenon called "higher-order co-occurrence" (Heinrich 2009), i.e., how often terms co-occur in different contexts. Word w_1 co-occurring with word w_2 which in turn co-occurs with word w_3 denotes a second-order co-occurrence between w_1 and w_3. Almost all these models regard each topic as a distribution over words. The words under each topic are often sorted according to their associated probabilities. Those top ranked words are used to represent the topic. However, this representation of topics as a list of individual words has some [1]major shortcomings:

- Topics are often difficult to understand or interpret by users unless they are domain experts and also knowledgeable about topic models. In most real-life situations, these are not the case. In some of our applications, we show users several good topics, but they have no idea what they are because many domain phrases cannot be split to individual words. For example, "battery" and "life" are put under the same topic, which is not bad. But the users wondered why "battery" and "life" are the same because they thought words under a topic should somehow have similar meanings. We had to explain that it is due to "battery life." As another example, sentences such as "This hotel has a very nice sandy beach" may cause a topic model to put "hotel" and "sandy" in a topic, which is not wrong but again it is hard to understand by a user who may not be able to connect the two words. Thus in order to interpret topics well, the user must know the phrases (they are split into individual words) that may

Proceedings of COLING 2014, the 25th International Conference on Computational Linguistics: Technical Papers, pages 667–676, Dublin, Ireland, August 23-29 2014.

be used in a domain and how words may be associated with each other. To make the matters worse, in most cases, the topics generated from a topic model are not perfect. There are some wrong words under a topic, which make the interpretation even harder.

- Individual words are difficult to use in practice because in some cases a word under a topic may not have its intended meaning for the topic in a particular sentence context. This can cause many mistakes. For example, in sentiment analysis of product reviews, a topic is often regarded as a set of words indicating a product feature or attribute. This is not true in many cases. For example, if "battery" and "life" are put in one topic, when the system sees "life," it assumes it is related to "battery." But in the sentence "The life expectancy of the machine is about 2 years," this "life" has nothing to do with battery or battery life. This causes an error. If the system can directly use phrases, "battery life" and "life expectancy," the error will not occur.
- Splitting phrases into multiple individual words causes extra co-occurrences that may result in poor or wrong topics involving other words. For example, due to sentences like "Beach staffs are rude" and "The hotel has a nice sandy beach," a topic model may put "staff" and "sandy" under a topic for staff and/or put "beach" and "rude" together under the topic of beach views.

Based on our experiences in opinion mining and social media mining, these are major issues with topic models. We believe that they must be dealt with before wide spread adaptation of topic models in real-life applications. In this paper, we make an attempt to solve this problem. We will use *term* to represent both word and phrase, and use *word* or *phrase* when we want to distinguish them.

One obvious way to consider phrases is to use a natural language parser to find all phrases and then treat each phrase as one term, e.g., "battery life," "sandy beach" and "beach staff." However, the problem with this approach is that it may lose the connection of many related words or phrases in a topic. For example, under the topic for beach, we may not find "sandy beach" because there is no co-occurrence of "sandy beach" and "beach" if we treat "sandy beach" as a single term. This is clearly not a good solution as it may miss a lot of topical terms (words or phrases) for a topic. It can also result in poor topics due to the loss of co-occurrences.

Another obvious solution is to use individual words as they are, but add an extra term representing the phrase. For example, we can turn the sentence "This hotel has a nice sandy beach" to "This hotel has a nice sandy beach <sandy beach>." This solution helps deal with the problem of losing co-occurrences to some extent, but because the words are still treated individually, the three problems discussed above still exist, although the phrase "sandy beach" now can show up in some topics. However, due to the fact that phrases are obviously less frequent than individual words, they may be ranked very low, which make little difference to solving the three problems.

In this paper, we propose a novel approach to solve the problem, which is based on the generalized Pólya urn (GPU) model (Mahmoud 2008). GPU was first introduced into LDA in (Mimno et al., 2011) to concentrate words with high co-document frequency. However, Mimno et al. (2011) and other researchers Chen et al., (2013) still use them in the framework of individual words. In the GPU model, we can deal with the problems above by treating phrases as individual terms and allowing their component words to have some connections or co-occurrences with them. Furthermore, we can push phrases up in a topic as phrases are important for understanding but are usually less frequent than individual words and ranked low in a topic. The intuition here is that when we see a phrase, we also see a small fraction of their component words; and when we see each individual word, we also see a small fraction of its related phrases. Further, in a phrase not all words are equally important. For example, in "hotel staff", "staff" is more important as it is the head noun, which represents the semantic category of the phrase.

Our experiments are conducted using online review collections from 32 domains. We will see that the proposed method produces significantly better results both quantitatively based on the statistical measure of topic coherence and qualitatively based on human labeling of topics and topical terms.

In summary, this paper makes the following contributions:

1. It proposes to consider phrases in topic models, which as we have explained above, is important for accurate topic generation, the use of the resulting topics and human interpretation. As we will see in Section 2, although some prior works exist, they are based on n-grams (Mukherjee and Liu, 2013). They are different from our approach. N-grams can generate many non-understandable phrases. Furthermore, due to infrequency of n-grams (much less frequent than individual words),

typically a huge amount of data is needed in order to produce reasonable topics, which many applications simply do not have.
2. It proposes to use the generalized Pólya Urn (GPU) model to deal with the problems arising in considering phrases. To the best of our knowledge, the GPU model has not been used in the context of phrases. This model not only generates better topics, but also rank phrases relatively high in their topics, which greatly helps understanding of the generated topics.
3. Comprehensive experiments conducted using product and service review collections from 32 domains demonstrate the effectiveness of the proposed model.

2 Related Work

GPU was first introduced to topic modelling in (Mimno et al., 2011), in which GPU is used to concentrate words with high co-document frequency based on corpus-specific co-occurrence statistics. Chen et al. (2013) applied GPU to deal with the adverse effect of using prior domain knowledge in topic modeling by increasing the counts of rare words in the knowledge sets. However, these works still use only individual words.

Topics in most topic models like LDA are unigram distributions over words and assume words to be exchangeable at the word level. However, there exists some work that tries to take word order into consideration by including n-gram language models. Wallach (2006) proposed the Bigram Topic Model (BTM) which integrates bigram statistics with topic-based approaches to document modeling. Wang et al. (2007) proposed the Topical N-gram Model (TNG), which is a generalization of the BTM. It generates words in their textual order by first sampling a topic, then sampling its status as a unigram or bigram, and then sampling the word from a topic-specific unigram or bigram distribution. Although the "bag-of-words" assumption does not always hold in real-life applications, it offers a great computational advantage over more complex models taking word order into account for discovering significant n-grams. Our approach is different from these works in two ways. First, we still follow the "bag-of-words" or rather "bag-of-terms" assumption. Second, we find actual phrases rather than just n-grams. Most n-grams are still hard to understand because they are not natural phrases.

Blei and Lafferty (2009), Liu et al. (2010) and Zhao et al. (2011) also try to extract keyphrases from texts. Their methods, however, are very different because they identify multi-word phrases using relevance and likelihood scores in the post-processing step based on the discovered topical unigrams.

Mukherjee and Liu (2013) and Mukherjee et al. (2013) all try to include n-grams to enhance the expressiveness of their models while preserving the advantages of "bag-of-words" assumption, which has a similar idea as our paper. However, as we point out in the introduction, this way of including phrases/n-grams suffers from several shortcomings. Solving these problems is the goal of our paper.

Finally, since we use product reviews as our datasets, our work is also related to opinion mining using topic models, e.g. (Mei et al., 2007; Lu and Zhai, 2008; Titov and McDonald, 2008; Zhao et al., 2010; Li et al., 2010; Sauper and Barzilay, 2013; Lin and He, 2009; Jo and Oh, 2011). However, none of these models uses phrases.

3 Proposed Model

We start by briefly reviewing the Latent Dirichlet Allocation (LDA) model (Blei et al., 2003). Then we describe the simple Pólya urn (SPU) model, which is embedded in LDA. After that, we present the generalized Pólya urn (GPU) model and discuss how it can be applied to our context. The proposed model uses GPU for its inference. It shares the same graphical model as LDA. However, the GPU inference mechanism is very different from that of LDA, which cannot be reflected in the graphical model or the generative process as it only helps to infer more desirable posterior distributions of topic models.

3.1 Latent Dirichlet Allocation

LDA is a generative probabilistic model for a document collection. It assumes that documents are represented as a mixture of latent topics, and each latent topic is characterized by a distribution over terms. In order to generate a term $w_n^{(d)}$ in document d, where n is its position, we first draw a discrete topic assignment $z_n^{(d)}$ from a document-specific distribution over T topics θ_d, which is drawn from a prior Dirichlet distribution with hyperparameter α. Then we draw a term from the topic-specific distribution

over the vocabulary $\phi_{z_n^{(d)}}$, which is drawn from a prior Dirichlet distribution with hyperparameter β.

For inference, instead of directly estimating θ and ϕ, Gibbs sampling is used to approximate them based on the posterior estimates of latent topic assignment $\boldsymbol{z}$. The Gibbs sampling procedure considers each term in the documents in turn, and estimates the probability of assigning the current term to each topic, conditioned on the topic assignments to all other terms. Griffiths and Steyvers (2004) showed this could be calculated by:

$$p\left(z_n^{(d)} = t \middle| \boldsymbol{z}_{-d,n}, W, \alpha, \beta\right) \propto \frac{C_{t|d} + \alpha}{C_d + T\alpha} \times \frac{N_{w_n^{(d)}|t} + \beta}{N_t + V\beta} \quad (1)$$

where $z_n^{(d)} = t$ represents the topic assignment of term $w_n^{(d)}$ to topic t, and $\boldsymbol{z}_{-d,n}$ refers to the topic assignments of all other terms. W denotes all terms in the document collection, V denotes the size of vocabulary of the collection, T is the number of topics in the corpus, $N_{w|t}$ is the count of term w under topic t, $N_t = \sum_{w'} N_{w'|t}$, and $C_{t|d}$ refers the count of topic t being assigned to some terms in document d, $C_d = \sum_{t'} C_{t'|d}$. All these counts exclude the current term.

3.2 Simple Pólya Urn Model

Traditionally, the *Pólya urn* model is designed in the context of colored balls and urns. In the context of topic models, a term can be seen as a ball of a certain color and the urn contains a mixture of balls with various colors. The classic topic-word (or topic-term) distribution can be reflected by the color proportion of balls in the urn. LDA follows the *simple Pólya urn* (SPU) model, which works as follows: when a ball of a particular color is drawn from an urn, that ball is put back to the urn along with another ball of the same color. This process corresponds to assigning a topic to a term in the Gibbs sampler of LDA. Based on the topic-specific "collapsed" probability of a term w given topic t, $\frac{N_{w|t}+\beta}{N_t+V\beta}$, which is essentially the second ratio in (1), drawing a term w will only increase the probability of seeing w in the future sampling process. This self-reinforcing property is known as "the rich get richer". In the next subsection, we will introduce the *generalized Pólya urn* (GPU) model, which increases the probability of seeing certain other terms when we sample a term.

3.3 Generalized Pólya Urn Model

The *generalized Pólya urn* (GPU) model differs from SPU in that, when a ball of a certain color is drawn, two balls of that color is put back along with a certain number of balls of some other colors. Unlike SPU, GPU sampling not only allows us to see a ball of the same color again with higher probability, but also increases the probability of seeing balls with certain other colors. These additional balls of certain other colors added to the urn increase their proportions in the urn. We call this the *promotion* of these colored balls. Applying the idea, there are two directions of promotion in our application (Note that in each sentence, we need to identify each phrase, but do not need to add any extra information):

1. Word to phrase: When an individual word is assigned to a topic (analogous to drawing a ball of a certain color), each phrase containing the word will be promoted, meaning that the phrase will be added to the same topic with a small count. That is, a fraction of the phrase will be assigned to the topic. This is justified because it is reasonable to assume that the phrase is related to the word to some extent in meaning.
2. Phrase to word: When a phrase is assigned to a topic, each component word in it is also promoted with a certain small count. That is, each word is also assigned the topic by a certain amount. In most cases, the head nouns are more important. Thus, we promote the head nouns more. For example, in "hotel staff", "staff" is the head noun that determines the category of the noun phrase. The rationale of this promotion is similar to that above.

Let $w_n^{(d)}$ be a word and p_w be the word itself or a phrase containing the word $w_n^{(d)}$. v represents a term, and p_v indicates all the related terms of v. The new GPU sampling is as follows:

$$p\left(z_n^{(d)} = t \middle| \boldsymbol{z}_{-d,n}, W, \alpha, \beta, A\right) \propto \frac{C_{t|d} + \alpha}{C_d + T\alpha} \times \frac{\sum_{p\_w} N_{p\_w|t} A_{p\_w, w_n^{(d)}} + \beta}{\sum_v \sum_{p\_v} N_{p\_v|t} A_{p\_v,v} + V\beta} \quad (2)$$

where A is a $V \times V$ real-value matrix, each cell of which contains a real value *virtualcount*, indicating the amount of promotion of a term under a topic when assigning this topic to another term. V is size of all terms. The new model retains the document-topic component of standard LDA, which is the first ratio in (1), but replaces the usual Pólya urn topic-word (topic-term) component, the second ratio in (1), with a generalized Pólya urn framework (Mahmoud 2008; Mimno et al., 2011). The simple Pólya urn model is a simplified version of GPU in which matrix A is an identity matrix. In this paper, A is an asymmetric matrix because the main goal of using GPU is to promote the less frequent phrases in the documents.

4 EXPERIMENTS

In this section, we evaluate the proposed method of considering phrases in topic discovery, and compare it with three baselines. The first baseline discovers topics using LDA in a traditional way without considering phrases, i.e., using only individual words. We refer to this baseline as *LDA*(*w*). The second baseline considers phrases by treating each whole phrase as a separate term in the corpus. We refer to this baseline as *LDA*(*p*). The third baseline considers phrases by keeping individual component words in the phrases as they are, but also adding phrases as extra terms. We refer to this baseline as *LDA*(*w_p*). We refer to our proposed method as *LDA*(*p_GPU*). Note that for those words that are not in any phrases, they are treated as individual words (or unigrams).

Data Set: We use product reviews from 30 sub-categories (types of product) in the electronics domain from Amazon.com. The sub-categories are "Camera", "Mouse", "Cellphone," etc (see the whole list below Figure 1). Each domain contains 1,000 reviews. Besides, we also use a collection of hotel reviews and a collection of restaurant reviews from TripAdvisor.com and Yelp.com. The hotel review data contains 101,234 reviews, and the restaurant review data contains 25,459 reviews. We thus have a total of 32 domains. We ran the Stanford Parser to perform sentence detection, lemmatization and POS tagging. Punctuations, stopwords, numbers and words appearing less than 5 times in each dataset are removed. Domain names are also removed, e.g., word "camera" for the domain Camera, since it co-occurs with most words in the dataset, leading to high similarity among topics/aspects.

Sentences as Documents: As noted in (Titov and McDonald, 2008), when standard topic models are applied to reviews as documents, they tend to produce topics that correspond to global properties of products (e.g., product brand name), but cannot separate different product aspects or features well. The reason is that all reviews of the same product type basically evaluate the same aspects of the product type. Only the brand names and product names are different. Thus, using individual reviews for modelling is ineffective for finding product aspects or features, which are our topics. Although there are approaches which model sentences (Jo and Oh, 2011; Zhao et al., 2010; Titov and McDonald, 2008), we take the approach in (Brody and Elhadad, 2010; Chen et al., 2013), dividing each review into sentences and treating each sentence as an independent document.

Noun Phrase Detection: Although there are different types of phrases, in this first work we focus only on noun phrases as they are more representative of topics in online reviews. We will deal with other types of phrases in the future. Our first step is thus to obtain all noun phrases from each domain. Due to the efficiency issue of full natural language parser with a huge number of reviews, instead of applying the Stanford Parser to recognize noun phrases, we design a rule-based approach to recognize noun phrases as consecutive nouns based on POS tags of sentences. Although the Stanford Parser may give us better noun phrases, our simple method serves the purpose and gives us very good results. In fact, based on our initial experiments, the Stanford Parser also gives many wrong phrases.

Parameter Settings: In all our experiments, the posterior inference was drawn after 2000 Gibbs sampling iterations with a burn-in of 400 iterations. Following (Griffiths and Steyvers, 2004), we fix the Dirichlet priors as follows: for all document-topic distributions, we set α=50/K, where K is the number of topics. And for all topic-term distributions, we set β=0.1. We also experimented with other settings of these priors and did not notice much difference.

Setting the number of topics/aspects in topic models is often tricky as it is difficult to know the exact number of topics that a corpus has. While non-parametric Bayesian approaches (Teh et al., 2005) do exist for estimating the number of topics, it's not the focus of this paper. We empirically set the number of topics to 15. Although 15 may not be optimum, since all models use the same number, there is no bias against any model.

In Section 3.3, we introduced the *promotion* concept for the GPU model. When we sample a topic for a word, we add *virtualcount* of topic assignment to all its related phrases. However, not all words in a phrase are equally important. For example, in phrase "hotel staff", "staff" is more important, and we call such words the head nouns. In this work, we apply a simple method used in (Wang et al., 2007), which is to always assume that the last word in a noun phrase is the head noun. Although we are aware of the potential harm to our model when we promote a wrong word, we will leave it as our future work. Again, because we want to connect phrases with their component words and promote the rank of phrases in their topics, we add less virtual counts to individual words. Thus, we add 0.5 * *virtualcount* to the last word in a phrase and add 0.25 * *virtualcount* to all other words. We set *virtualcount* = 0.1 in our experiments empirically.

Based on the discovered topics, we conduct statistical evaluation using topic coherence, human evaluation and also a case study to quantitatively and qualitatively show the superiority of the proposed method in terms of both interpretability and topic wellness.

4.1 Statistical Evaluation

Perplexity and KL-divergence are often used to evaluate topic models statistically. However, researchers have found that perplexity on held-out documents is not always a good predictor of human judgments of topics (Chang et al., 2009). In our application, we are not concerned with the test on future data using the hold-out set. KL-divergence measures the difference of distributions, and thus can be used to measure the distinctiveness of topics. However, distinctiveness of topics does not necessarily mean human agreeable topics. Recently, Mimno et al. (2011) proposed a new measure called topic coherence, which has been shown to correlate with human judgments of topic quality quite well. Higher topic coherence score indicates higher quality of topics, i.e., better topic coherence. Topic coherence is computed as below.

$$TC\left(t; V^{(t)}\right) = \sum_{m=2}^{M} \sum_{l=1}^{m-1} log \frac{D\left(v_m^{(t)}, v_l^{(t)}\right) + 1}{D\left(v_l^{(t)}\right)} \tag{3}$$

in which $D(v)$ is the document frequency of term v (i.e., the number of documents with at least one term v) and $D(v, v')$ is the co-document frequency of term v and term v' (i.e., the number of documents containing both term v and term v'). Also, $V^{(t)} = \left(v_1^{(t)}, \ldots, v_M^{(t)}\right)$ is the list of M most probable terms in topic t. 1 is added as a smoothing count to avoid taking the logarithm of zero.

We thus use this measure to score all four experiments. Figure 1 and Figure 2 show the topic coherence using top 15 terms and top 30 terms respectively on the 32 different domains. Notice the topic coherence is a negative value, and a smaller absolute value is better than a larger one. Firstly, we can see from both charts that our proposed model *LDA*(*p_GPU*) is better than all other three baselines by a large margin. Secondly, the performance of the other three baselines are quite similar. In general, *LDA*(*p*) is slightly worse than the other two baselines. It is because replacing many words with phrases decreases the number of co-occurrences in the corpus. In contrast, *LDA*(*w_p*) is slightly better than the other two baselines on most domains because some frequent phrases add more reliable co-occurrences in the corpus. However, as we point out in the introduction, some problems still exist. Firstly, it does not solve the problem of phrases and their component words having different meanings, and thus artificially creating such wrong co-occurrences may damage the overall performance. Secondly, even if the number of co-occurrences increases, most of the phrases are still too infrequent to be ranked high in their associated topics to be useful in helping users understand the topic.

In order to test the significance of the improvement, we conduct paired *t*-tests on the topic coherence results. Using both 15 top terms and 30 top terms, statistical tests show that our proposed method, *LDA*(*p_GPU*), outperforms all three baselines significantly ($p < 0.01$). However, there's no significant improvement between any pair of the three baselines.

4.2 Manual Evaluation

Although several statistical measures, such as perplexity, KL-divergence and topic coherence, have been used to statistically evaluate topic models, since topic models are mostly (including ours) unsupervised,

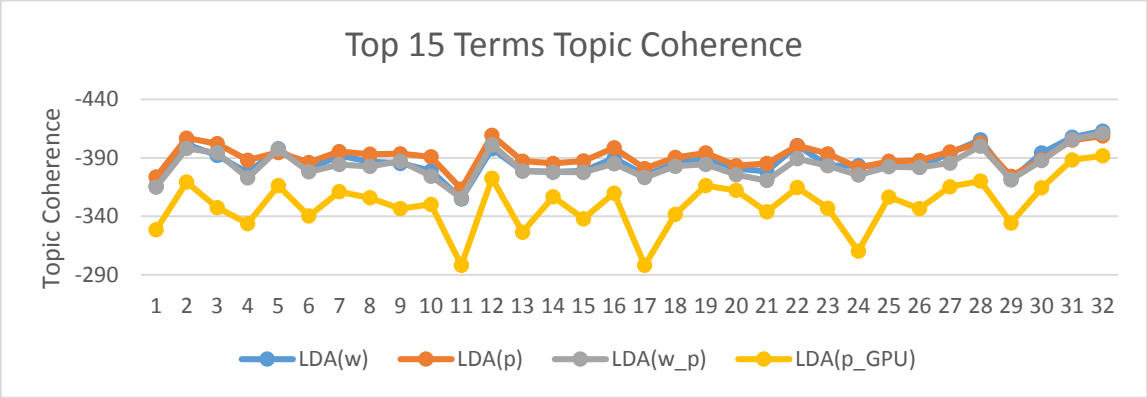

Figure 1: Topic coherence of the top 15 terms of each model on each of the 32 datasets. Notice that since topic coherence is a negative value, a smaller absolute value is better than a larger one.

Domain/dataset names are listed as follows (1:Amplifier; 2:BluRayPlayer; 3:Camera; 4:CellPhone; 5:Computer; 6:DVDPlayer; 7:GPS; 8:HardDrive; 9:Headphone; 10:Keyboard; 11:Kindle; 12:MediaPlayer; 13:Microphone; 14:Monitor; 15:Mouse; 16:MP3Player; 17:NetworkAdapter; 18:Printer; 19:Projector; 20:RadarDetector; 21:RemoteControl; 22:Scanner; 23:Speaker; 24:Subwoofer; 25:Tablet; 26:TV; 27:VideoPlayer; 28:VideoRecorder; 29:Watch; 30:WirelessRouter; 31:Hotel; 32:Restaurant).

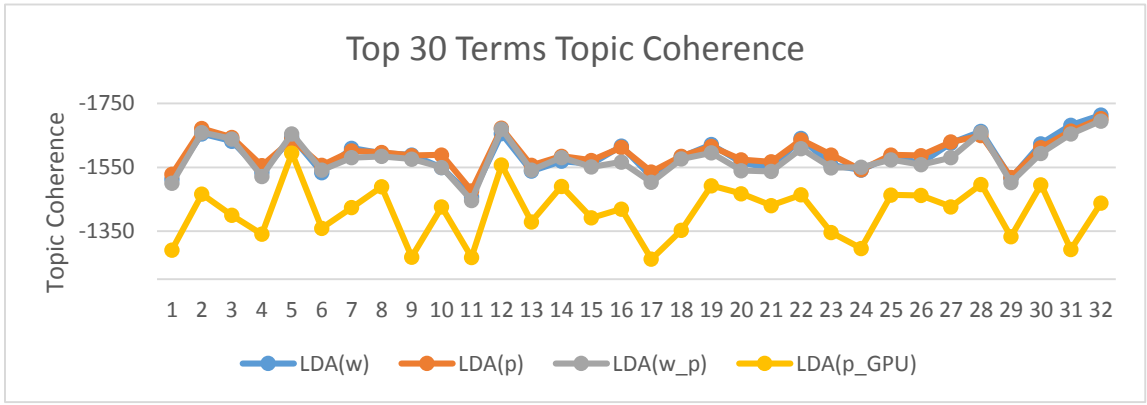

Figure 2: Topic coherence of the top 30 terms of each model on each dataset. Notice again that since topic coherence is a negative value, a smaller absolute value is better than a larger one. X-axis indicates the domain id numbers, whose names are listed below Figure 1.

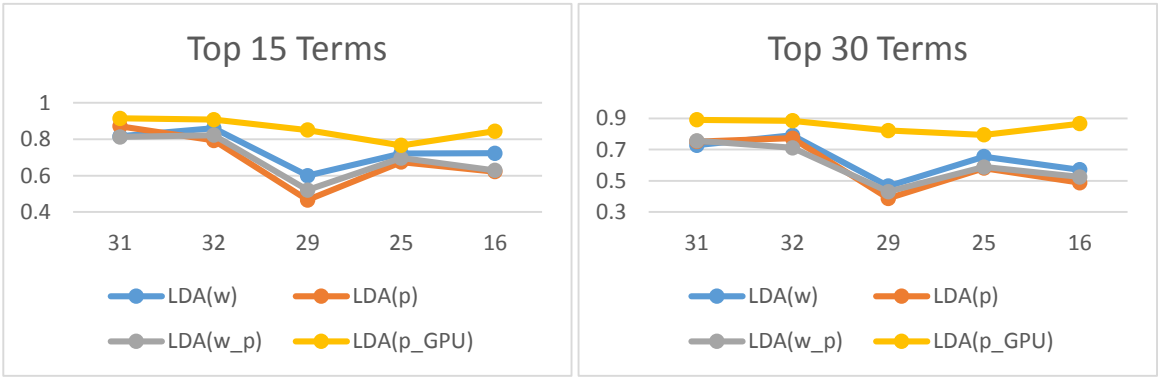

Figure 3: Human evaluation on five domains using top 15 and top 30 terms. X-axis indicates the domain id numbers, whose corresponding domain names are listed below Figure 1. Y-axis indicates the ratio of correct topic terms.

statistical measures may not always correlate with human interpretations or judgments. Thus, in this sub-section, we perform a manual evaluation through manual labeling of topics and topical terms.

Manual labeling was done by two annotators, who are familiar with reviews and topic models. The labeling was carried out in two stages sequentially: (1) labeling of topics and (2) labeling of topical terms in each topic. After the first stage, an annotator agreement is computed and then the two annotators discuss about the disagreed topics to reach a consensus. Then, they move on to the next stage to label the top ranked topical terms in each topic (based on their probabilities in the topic). For the annotator

Table 1: Example topics discovered by LDA(w) and LDA(p_GPU)

Hotel		**Restaurant**		**Watch**	
LDA(w)	LDA(p_GPU)	LDA(w)	LDA(p_GPU)	LDA(w)	LDA(p_GPU)
bed	clean	service	service	hand	big
comfortable	comfortable	star	friendly	minute	hand

agreement, we compute Kappa scores. The Kappa score for topic labeling is 0.838, and the Kappa score for topical terms labeling is 0.846. Both scores indicate strong agreement in the labeling.

Evaluation measure. A commonly used evaluation measure in human evaluation is *precision@n* (or *P@n* for short), which is the precision at a particular rank position *n* in a topic. For example, *Precision*@5 means the precision of the top ranked 5 terms for a topic. To be consistent with the automatic evaluation, we use *Precision*@15 and 30. Top 15 terms is usually sufficient to represent the topic. However, since we include phrases in our experiments which may lead to some other terms ranked lower than using only words, we labeled up to top 30 terms. The *Precision*@n measure is also used in (Zhao et al., 2010) and some others, e.g., (Chen et al., 2013).

In our experiments, we labeled four results for each domain, i.e., those of *LDA*(*w*), *LDA*(*p*), *LDA*(*w_p*) and *LDA*(*p_GPU*). Due to the large amount of human labeling effort, we only labeled 5 domains. We find that it is sometimes hard to figure out what some of the topics are about and whether some terms are related to a topic or not, so we give the results to our human evaluators together with the phrases in each domain extracted by our rules in order to let them be familiar with the domain vocabulary. The human evaluation results are shown in Figure 3.

Results and Discussions. Again, we conduct paired *t*-tests on the human evaluation results of top 15 and 30 terms. Statistical tests show that our proposed method, *LDA*(*p_GPU*), outperforms all other three methods significantly ($p < 0.05$) using both top 15 and top 30 terms. However, there's no significant improvement between any pair of the three baselines.

4.3 Case Study

In order to illustrate the importance of phrases in enhancing human readability, we conduct case study using one topic from each of the five manually labeled domains. Due to space limitations, we only compare the results of our model *LDA*(*p_GPU*) with *LDA*(*w*).

In the above table, we notice that with phrases, the topics are much more interpretable than only reading individual words given by *LDA*(*w*). For example, "hand" in "Watch" domain given by *LDA*(*w*) is quite confusing at first, but in *LDA*(*p_GPU*), "hour hand" makes it more understandable. Another example is "aaa" in "MP3Player" domain. It is quite confusing at first, but "aaa battery" should make it more interpretable by an application user who is not familiar with topic models or does not have extensive domain knowledge. Also, due to wrong co-occurrences created by individual words in a phrase, the *LDA*(*w*) results contain much more noise than those of *LDA*(*p_GPU*).

5 CONCLUSION

This paper proposed a new method to consider phrases in discovering topics using topic models. The method is based on the generalized Pólya urn (GPU) model, which allows us to connect phrases with their component words during the inference and rank phrases higher in their related topics. Our method preserves the advantages of "bag-of-words" assumption while preventing the side effects that traditional methods have when considering phrases. We tested our method against three baselines across 32 different domains, and demonstrated the superiority of our method in improving the topic quality and human interpretability both quantitatively and qualitatively.

Abstract

Detecting opinion relation is a crucial step for fine-gained opinion summarization. A valid opinion relation has three requirements: a correct opinion word, a correct opinion target and the linking relation between them. Previous works prone to only verifying two of these requirements for opinion extraction, while leave the other requirement unverified. This could inevitably introduce noise terms. To tackle this problem, this paper proposes a joint approach, where all three requirements are simultaneously verified by a deep neural network in a classification scenario. Some seeds are provided as positive labeled data for the classifier. However, negative labeled data are hard to acquire for this task. We consequently introduce one-class classification problem and develop a One-Class Deep Neural Network. Experimental results show that the proposed joint approach significantly outperforms state-of-the-art weakly supervised methods.

1 Introduction

Opinion summarization aims to extract and summarize customers' opinions from reviews on products or services (Hu and Liu, 2004; Cardie et al., 2004). With the rapid expansion of e-commerce, the number of online reviews is growing at a high speed, which makes it impractical for customers to read throughout large amounts of reviews to choose better products. Therefore, it is imperative to automatically generate opinion summarization to help customers make more informed purchase decisions, where detecting opinion relation is a crucial step for opinion summarization.

Before going further, we first introduce some notions. An *opinion relation*, is a triple $o = (s, t, r)$, where three factors are involved: s is an *opinion word* which refers to those words indicating sentiment polarities; t is an *opinion target*, which can be any entity or aspect of an entity about which an opinion has been expressed; r refers to the linking relation between s and t. As in Example 1, s=$\{$*clear*$\}$, t=$\{$*sceen*$\}$, and there is a linking relation between the two words because *clear* is used to modify *screen*.

Example 1. *This mp3 has a clear screen.*

For a valid opinion relation, there are three requirements corresponding to the three factors: (i) the opinion word indicates sentiment polarity; (ii) the opinion target is related to current domain; (iii) the opinion word modifies the opinion target. Previous weakly supervised methods often expand a seed set and identify opinion relation either by co-occurrence statistics (Hu and Liu, 2004; Hai et al., 2012) or syntactic dependencies (Popescu and Etzioni, 2005; Qiu et al., 2009) following the assumption below.

Assumption 1. Terms that are likely to have linking relation with the seed terms are believed to be opinion words or opinion targets.

For example, if one has an opinion word seed *clear* (which satisfies requirement i), and one finds that it modifies the word *screen* in Example 1 (which satisfies requirement iii). Then one infers that *screen* is an opinion target according to Assumption 1 (whether *screen* is correct is not checked). However, in Example 2(a), we can see that *good* is an opinion word and it modifies *thing*, but *thing* is not related to

Proceedings of COLING 2014, the 25th International Conference on Computational Linguistics: Technical Papers, pages 677–687, Dublin, Ireland, August 23-29 2014.

mp3 domain. If one follows Assumption 1, *thing* will be mistaken as an opinion target. Similarly, in Example 2(b), if one uses *mp3* to extract *another* as an opinion word, he may get an objective word.

Example 2. (a) *This mp3 has many good things.* (b) *Just another mp3 I bought.*

The reason for the errors above is that Assumption 1 only verifies two requirements for an opinion relation. Unfortunately, this issue occurs frequently in online reviews. As a result, previous methods often suffer from these noise terms. To produce more precise opinion summary, it is argued that we shall follow a more restricted assumption as follows.

Assumption 2. The three requirements: the opinion word, the opinion target and the linking relation between them, shall be all verified during opinion relation detection.

To make accordance with Assumption 2, this paper proposes a novel joint opinion relation detection method, where opinion words, opinion targets and linking relations are simultaneously considered in a classification scenario. Following previous works, we provide a small set of seeds (i.e. opinion words or targets) for supervision, which are regarded as positive labeled examples for classification. However, negative labeled examples (i.e. noise terms) are hard to acquire, because we do not know which term is not an opinion word or target. This leads to One-Class Classification (OCC) problem (Moya et al., 1993). The key to OCC is semantic similarity measuring between terms, and Deep Neural Network (DNN) with word embeddings is a powerful tool for handling this problem. We consequently integrate DNN into a OCC classifier and develop a *One-Class Deep Neural Network* (OCDNN). Concretely, opinion words/targets/relations are first represented by embedding vectors and then *jointly* classified. Experimental results show that the proposed joint method which follows Assumption 2 significantly outperforms state-of-the-art weakly supervised methods which are based on Assumption 1.

2 Related Work

In opinion relation detection task, previous works often used co-occurrence statistics or syntax information to identify opinion relations. For co-occurrence statistical methods, Hu and Liu (2004) proposed a pioneer research for opinion summarization based on association rules. Popescu and Etzioni (2005) defined some syntactic patterns and used Pointwise Mutual Information (PMI) to extract product features. Hai et al. (2012) proposed an opinion feature mining method which employed Likelihood Ratio Tests (LRT) (Dunning, 1993) as the co-occurrence statistical measure. For syntax-based approaches, Riloff and Wiebe (2003) performed syntactic pattern learning while extracting subjective expressions. Zhuang et al. (2006) used various syntactic templates from an annotated movie corpus and applied them to supervised movie feature extraction. Kobayashi et al. (2007) identified opinion relations by searching for useful syntactic contextual clues. Qiu et al. (2009) proposed a bootstrapping framework called *Double Propagation* which introduced eight heuristic syntactic rules to detect opinion relations.

However, none of the above methods could verify opinion words/targets/relations simultaneously during opinion relation detection. To perform joint extraction, various models had been proposed, most of which employed classification or sequence labeling models, such as HMM (Jin and Ho, 2009), SVM (Wu et al., 2009) and CRFs (Breck et al., 2007; Jakob and Gurevych, 2010; Li et al., 2010). Besides, optimal models such as Integer Linear Programming (ILP) were also employed to perform joint inference for opinion extraction (Choi et al., 2006; Yang and Cardie, 2013).

Joint methods had been shown to achieve better performance than pipeline approaches. Nevertheless, most existing joint models rely on full supervision, which have the difficulty of obtaining annotated training data in practical applications. Also, supervised models that are trained on one domain often fail to give satisfactory results when shifted to another domain. Our method does not require annotated data.

3 The Proposed Method

To detect opinion relations, previous methods often leverage some seed terms, such as opinion word seeds (Hu and Liu, 2004; Baccianella et al., 2010) and opinion target seeds (Jijkoun et al., 2010; Hai et al., 2012). These seeds can be used as positive labeled examples to train a classifier. However, it is hard to get negative labeled examples for this task. Because opinion words or targets are often domain

dependent and words that do not bear any sentiment polarity in one domain may be used to express opinion in another domain. It is also very hard to specify in what case there is no linking relation between two words.

To deal with this problem, we employ one-class classification, and develop a One-Class Deep Neural Network (OCDNN) for opinion relation detection. The architecture of OCDNN is shown in Figure 1, which consists of two levels. The lower level learns feature representations unsupervisedly for opinion words/targets/relations, where the left component uses word embedding learning to represent opinion words/targets, and the right component maps linking relations to embedding vectors by a recursive autoencoder. Then the upper level uses the learnt features to perform one-class classification.

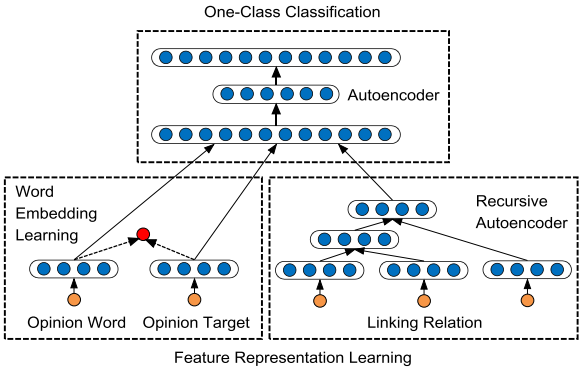

Figure 1: The architecture of OCDNN.

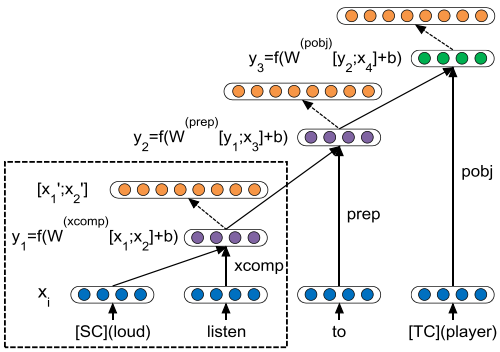

Figure 2: An example of recursive autoencoder.

3.1 Opinion Seed Generation

To obtain training data for OCDNN, we shall first get some seed terms as follows.

Opinion Word Seeds. We manually pick 186 domain independent opinion words from SentiWordNet (Baccianella et al., 2010) as the opinion word seed set SS.

Opinion Target Seeds. Likelihood Ratio Tests (LRT) (Dunning, 1993) used in (Hai et al., 2012) is employed to generate opinion target seeds. LRT aims to measure how greatly two terms T_i and T_j are associated with each other by sentence-level corpus statistics which is defined as follows,

$$LRT = 2[\log L(p_1, k_1, n_1) + \log L(p_2, k_2, n_2) - \log L(p, k_1, n_1) - \log L(p, k_2, n_2)] \quad (1)$$

where $k_1 = tf(T_i, T_j), k_2 = tf(T_i, \bar{T}_j), k_3 = tf(\bar{T}_i, T_j), k_4 = tf(\bar{T}_i, \bar{T}_j), tf(\cdot)$ denotes term frequency; $L(p, k, n) = p^k(1-p)^{n-k}$, $n_1 = k_1 + k_3$, $n_2 = k_2 + k_4$, $p_1 = k_1/n_1$, $p_2 = k_2/n_2$ and $p = (k_1 + k_2)/(n_1 + n_2)$. We measure LRT between a domain name (e.g. *mp3*, *hotel*, etc.) and all opinion target candidates. Then N terms with highest LRT scores are added into the opinion target seed set TS.

Linking Relation Seeds. Linking relation can be naturally captured by syntactic dependency, because it directly models the modification relation between opinion word and opinion target. We employ an automatic syntactic opinion pattern learning method called *Sentiment Graph Walking* (Xu et al., 2013) and get 12 opinion patterns with highest confidence as the linking relation seed set RS.

After seed generation, every opinion relation $s_o = (s_s, s_t, s_r)$ in review corpus that satisfies $s_s \in SS$, $s_t \in TS$ and $s_r \in RS$ is taken as a positive labeled training instance.

3.2 Opinion Relation Candidate Generation

The opinion term candidate set is denoted by $C = \{SC, TC\}$, where SC/TC represents opinion word/target candidate. Following previous works (Hu and Liu, 2004; Popescu and Etzioni, 2005; Qiu et al., 2009), we take adjectives or verbs as opinion word candidates, and take nouns or noun phrases as opinion target candidates. A statistic-based method in Zhu et al. (2009) is used to detect noun phrases.

An opinion relation candidate is denoted by $c_o = (c_s, c_t, c_r)$, where $c_s \in SC$, $c_t \in TC$, and c_r is a potential linking relation. To get c_r, we first get dependency tree of a sentence using Stanford Parser (de

Marneffe et al., 2006). Then, the shortest dependency path between a c_s and a c_t is taken as a c_r. To avoid introducing too many noise candidates, we constrain that there are at most four terms in a c_r.

3.3 Word Representation by Word Embedding Learning

Word embedding, a.k.a *word representation*, is a mathematical object associated with each word, which is often used in a vector form, where each dimension's value corresponds to a feature and might even have a semantic or grammatical interpretation (Turian et al., 2010). By word embedding learning, words are embedded into a hyperspace, where two words that are more semantically similar to each other are located closer. This characteristic is precisely what we want, because the key to one-class classification is semantic similarity measuring (illustrated in Section 3.5).

For word representation, we use a matrix $LT \in \mathbb{R}^{n \times |V_w|}$, where *i*-th column represents the embedding vector for term t_i, n is the size of embedding vector and V_w is the vocabulary of LT. Therefore, we can denote t_i by a binary vector $b_i \in \mathbb{R}^{|V_w|}$ and get its embedding vector by $x_i = LTb_i$. The training criterion for word embeddings is,

$$\hat{\theta} = \underset{\theta}{\operatorname{argmin}} \sum_{c \in C} \sum_{v \in V_w} max\{0, 1 - s_\theta(c) + s_\theta(v)\} \tag{2}$$

where θ is the parameters of neural network used for training. See Collobert et al. (2011) for the detailed implementation.

3.4 Linking Relation Representation by Using Recursive Autoencoder

The goal of this section is to represent the linking relation between an opinion word and an opinion target by a *n*-element vector as we do during word representation. Specifically, we combine embedding vectors of words in a linking relation by a recursive autoencoder (Socher et al., 2011) according to syntactic dependency structure. In this way, linking relations are no longer limited to the initial seeds during classification, because linking relations that are similar to the seed relations will have similar vector representations.

Figure 2 shows a linking relation representation process by an example: *too loud to listen to the player*. First, we get its dependency path between the opinion word c_s*:loud* and the opinion target c_t*:player*. Then c_s and c_t are replaced by wildcards *[SC]* and *[TC]* because they are not concerned in the linking relation. The dash line box in Figure 2 shows a standard autoencoder, which is a three-layer neural network, where the number of nodes in input layer is equal to that of output layer. It takes two *n*-element vectors as input and compresses semantics of the two vectors into one *n*-element vector in hidden layer by,

$$y = f(W^{(dep)}[x_1; x_2] + b),\ W^{(dep)} = \frac{1}{2}[I_1; I_2; I_b] + \epsilon \tag{3}$$

where $[x_1; x_2]$ is the concatenation of the two input vectors and f is the sigmoid function; $W^{(dep)}$ is a parameter matrix that is chosen according to the dependency relation between x_1 and x_2 (In the case of y_1, $W^{(dep)} = W^{(xcomp)}$), which is initialized by I_i, where I_i is a $n \times n$ unit matrix, I_b is a n-element null vector, and ϵ is sampled from a uniform distribution $U[-0.001, 0.001]$ (Socher et al., 2013). Then $W^{(dep)}$ are updated during training. The training criterion of autoencoder is to minimize Euclidean distance between the original input and its output,

$$E_{rae} = ||[x_1; x_2] - [x_1'; x_2']||^2 \tag{4}$$

where $[x_1'; x_2'] = W^{(out)}y$ and $W^{(out)}$ is initialized by ${W^{(dep)}}^T$.

We always start the combination process from *[SC]* and it is repeated along the dependency path. For example, the result vector y_1 of the first combination is used as the input vector when computing y_2. Finally, the linking relation is represented by a n-element vector (the green vector in Figure 2).

3.5 One-Class Classification for Opinion Relation Detection

We represent an opinion relation candidate $c_o = (c_s, c_t, c_r)$ by a vector $v_o = [v_s; v_t; v_r]$, which is a concatenation of the opinion word embedding v_s, the opinion target embedding v_t and the linking relation embedding v_r. Then v_o is feed to the upper level autoencoder in Figure 1.

To perform one-class classification, the number of nodes in the hidden layer of the upper level autoencoder is constrained to be smaller than that of the input layer. By using such a "bottleneck" network structure, characteristics of the input are first compressed into the hidden layer and then reconstructed by the output layer (Japkowicz et al., 1995). Concretely, characteristics of positive labeled opinion relations are first compressed into the hidden layer, and then the autoencoder should be able to adequately reconstruct positive instances in the output layer, but should fail to reconstruct negative instances which present different characteristics from positive instances. Therefore, the detection of opinion relation is equivalent to assessing how well a candidate is reconstructed by the autoencoder. As the input vector v_o consists of representations for opinion words/targets/relations, characteristics of the three factors are *jointly* compressed by one hidden layer. Either false opinion word/target/relation will lead to failure of reconstruction. Consequently, our approach follows Assumption 2.

For opinion relation detection, candidates with reconstruction error scores that are smaller than a threshold ϑ are classified as positive. Determining the exact value of ϑ is very difficult. Inspired by other one-class approaches (Liu et al., 2002; Manevitz and Yousef, 2007), we introduce some negative opinion terms to help to estimate ϑ.[1] Although negative instances are hard to acquire, Xu et al. (2013) show that a set of general nouns (such as *thing*, *one*, etc., we denote them by GN) seldom appear to be opinion targets. One the other hand, we create a 50-opinion-word validation set SV from SentiWordNet.

To estimate ϑ, we first introduce a *positive proportion* (pp) score,

$$pp(t) = tf^{+}(t)/tf(t),\ t \in PE,\ PE = \{c_o | E_r(c_o) < \vartheta\} \tag{5}$$

where PE denotes the opinion relations that are classified as positive, $E_r(\cdot)$ is the reconstruction error of OCDNN and $tf^{+}(\cdot)$ is the frequency of term in PE. Then an error function E_ϑ is minimized, which balances between the proportion of non-target terms (GN) in PE (which shall be as small as possible) and the proportion of opinion words in validation set (SV) in PE (which shall be as large as possible).

$$E_\vartheta = \sum_{t \in GN \cap PE} [pp(t) - 0]^2 + \sum_{s \in SV \cap PE} [pp(s) - 1]^2 \tag{6}$$

3.6 Opinion Target Expansion

We apply bootstrapping to iteratively expand opinion target seeds. It is because the vocabulary of seed set is limited, which cannot fully represent the distribution of opinion targets. So we expand opinion target seeds in a self-training manner to alleviate this issue. After training OCDNN, all opinion relation candidates are classified, and opinion targets are ranked in descent order by,

$$s(t) = \log tf(t) \times pp(t). \tag{7}$$

Then, top M candidates are added into the target seed set TS for the next training iteration.

4 Experiments

4.1 Datasets and Evaluation Metrics

Datasets. Three real world datasets are selected for evaluation. The first one is called *Customer Review Dataset (CRD)* [2] which contains reviews on five products (denoted by D1 to D5). The second is a benchmark dataset (Wang et al., 2011) on *MP3* and *Hotel*[3]. The last one is crawled from www.amazon.com, which involves *Mattress* and *Phone*. Two annotating criteria are applied.

[1] This is not in contradiction with OCC problem, because these negative examples are NOT used during training.

[2] http://www.cs.uic.edu/ liub/FBS/sentiment-analysis.html

[3] http://timan.cs.uiuc.edu/downloads.html

Annotation 1 is used to evaluate opinion words/targets extraction. Firstly, 10,000 sentences are randomly selected from reviews and all possible terms are extracted along with their contexts. Then, annotators are required to judge whether each term is an opinion word or an opinion target.

Annotation 2 is used to evaluate intra-sentence opinion relation detection. Annotators are required to carefully read through each sentence and find out every opinion relation, which consists of an opinion word, an opinion target, as well as the linking relation between them. The annotation is very labor-intensive, so only 5,000 sentences are annotated for *MP3* and *Hotel*.

Two annotators were required to annotate following the criteria above. When conflicts happened, a third annotator would make the final judgment. Note that Annotation 1 and Annotation 2 were annotated by two different groups. Detailed information of the annotated datasets are shown in Table 1. Furthermore, the kappa values between Annotation 1 and Annotation 2 are 0.88 for opinion words and 0.84 for opinion targets, showing highly substantial agreement.

Domain	#OW	#OT	Kappa_OW	Kappa_OT
Hotel	434	1,015	0.72	0.67
MP3	559	1,158	0.69	0.65
Mattress	366	523	0.67	0.62
Phone	391	862	0.68	0.64

(a) Annotation 1

Domain	#LR	#OW	#OT	Kappa_LR
Hotel	2,196	317	735	0.62
MP3	2,328	342	791	0.61

(b) Annotation 2

Table 1: The detailed information of Annotations. OW/OT/LR stands for opinion words/opinion targets/linking relations. The Kappa-values are calculated by using *exact* matching metric for Annotation 1 and *overlap* matching metric for Annotation 2.

Evaluation Metrics. We perform evaluation in terms of Precision(P), Recall(R) and F-measure(F) according to *exact* and *overlap* matching metrics (Wiebe et al., 2005). The *exact* metric is used to evaluate opinion word/target extraction, which requires exact string match. And the *overlap* metric is used to evaluate opinion relation detection, where an extracted opinion relation is regarded as correct when both the opinion word and the opinion target in it overlap with the gold standard.[4]

Evaluation Settings. Four state-of-the-art weakly supervised approaches are selected as competitors. Two are co-occurrence statistical methods and two are syntax-based methods, all of which follow Assumption 1.

AdjRule extracts opinion words/targets by using adjacency rules (Hu and Liu, 2004).

LRTBOOT is a bootstrapping algorithm which employs *Likelihood Ratio Tests* (Dunning, 1993) as the co-occurrence statistical measure (Hai et al., 2012).

DP denotes the *Double Propagation* algorithm (Qiu et al., 2009).

DP-HITS is an enhanced version of *DP* proposed by Zhang et al. (2010), which ranks terms by

$$s(t) = \log tf(t) \times importance(t) \tag{8}$$

where $importance(t)$ is estimated by the HITS algorithm (Kleinberg, 1999).

OCDNN is the proposed method. The target seed size $N = 40$, the opinion targets expanded in each iteration $M = 20$, and the max bootstrapping iteration number is $X = 10$. The representation learning in lower level of OCDNN is trained on the whole corpus, while the test data are the same for all settings. All results of OCDNN are taken by average performance over five runs with randomized parameters.

4.2 OCDNN vs. the State-of-the-art

We compare *OCDNN* with state-of-the-art methods for opinion words/targets extraction. In *OCDNN*, Eq. 7 is used to rank opinion words/targets. The results on *CRD* and the four domains are shown in Table 2 and Table 3. *DP-HITS* does not extract opinion words so their results for opinion words are not taken into account.

[4]Determining the exact boundaries of opinion terms is hard even for human (Wiebe et al., 2005), so we use this relaxation.

Table 3: Results of opinion terms extraction on the four domains.

From Table 2, we can see that our method outperforms co-occurrence-based methods *AdjRule* and *LRTBOOT*, but achieves comparable or a little worse results than syntax-based methods *DP* and *DP-HITS*. This is because *CRD* is quite small, which only contains several hundred sentences for each product review set. In this case, methods based on careful-designed syntax rules have superiority over those based on statistics (Liu et al., 2013). For results on larger datasets shown in Table 3, our method outperforms all of the competitors. Comparing *OCDNN* with *DP-HITS*, the two approaches use similar term ranking metrics (Eq. 7 and Eq. 8), but *OCDNN* significantly outperforms *DP-HITS*. Therefore, the *positive proportion* score estimated by *OCDNN* is more effective than the *importance* score in *DP-HITS*. Comparing *OCDNN* with *LRTBOOT*, we find that *LRTBOOT* achieves better recall but lower precision. This is because *LRTBOOT* follows Assumption 1 during bootstrapping, which suffers a lot from error propagation, while our joint classification approach effectively alleviates this issue. We will discuss the impact of error propagation in detail later.

4.3 Assumption 1 vs. Assumption 2

This section evaluates intra-sentence opinion relation detection, which is more useful for practical applications. It also reflects the impacts of Assumption 1 and Assumption 2. The results are shown in Table 4 and Table 5, where *OCDNN* significantly outperforms all competitors. The average improvement of F-measure over the best competitor is 6% on *CRD* and 9% on *Hotel* and *MP3*.

As Assumption 1 only verifies two of the requirements in an opinion relation, it would inevitably introduce noise terms during extraction. For syntax-based method *DP*, it extracts many false opinion relations such as *good thing* and *nice one* (where *thing* and *one* are false opinion targets) or objective expressions like *another mp3* and *every mp3* (which contain false opinion words *another* and *every*). For co-occurrence statistical methods *AdjRule* and *LRTBOOT*, it is very hard to deal with ambiguous linking relations. For example, in phrase *this mp3 is very good except the size*, co-occurrence statistical methods could hardly tell which opinion target does *good* modify (*mp3* or *size*). Our method follows Assumption

Table 5: Results of opinion relation detection on the two domains.

2, which verifies all three requirements for opinion word/target/relation in an opinion relation, so the above errors are greatly reduced. Therefore, Assumption 2 is more reasonable than Assumption 1.

4.4 The Effect of Joint Classification

We evaluate the three bootstrapping methods (*DP*, *LRTBOOT* and *OCDNN*) for opinion target expansion. The precision of each iteration is shown in Figure 3. We can see that *DP* and *LRTBOOT* gradually suffer from error propagation and the precision drops quickly along with the number of iteration increases. For *OCDNN*, although error propagation is inevitable, the precision curve retains at a high level. Therefore, the joint approach produces more precise results.

For more detailed analysis, we give a variation of the proposed method named ***3NN***, which uses 3 individual autoencoders to classify opinion words/targets/relations separately. An opinion relation candidate is classified as positive only when the three factors are all classified as positive. Then opinion relations are ranked by the sum of reconstruction scores of the three factors. In the results of opinion relation detection, when the recall is fixed at 0.6, the precisions of *3NN* are 0.67 for *MP3* and 0.65 for *Hotel*, while the precisions of *OCDNN* are 0.73 for *MP3* and 0.70 for *Hotel*. Therefore, *OCDNN* achieves much better performance than *3NN*.

An example may explain the reason of why *3NN* gets worse performance. In our experiment on *Hotel*, a false opinion relation *happy day* is misclassified as positive by *3NN*. It is because the word *day* has a small reconstruction score in *3NN*. At the same time, *happy* is a correct opinion word, so the whole expression *happy day* also has a small reconstruction score and then be misclassified. In contrast, the reconstruction score of *happy day* from *OCDNN* is quite large so the phrase is dropped. The reason is that the joint approach captures the semantic of a whole phrase rather than its single components. Therefore, it is more reasonable.

5 Conclusion and Future Work

This paper proposes One-Class Deep Neural Network for joint opinion relation detection in one-class classification scenario, where opinion words/targets/relations are simultaneously verified during classification. Experimental results show the proposed method significantly outperforms state-of-the-art weakly supervised methods that only verify two factors in an opinion relation.

In future work, we plan to adapt our method and make it be capable of capturing implicit opinion relations.

Abstract

Microblogging services have attracted hundreds of millions of users to publish their status, ideas and thoughts, everyday. These microblog posts have also become one of the most attractive and valuable resources for applications in different areas. The task of identifying the main targets of microblogs is an important and essential step for these applications. In this paper, to achieve this task, we propose a novel method which converts the target company identification problem to the translation process from content to targets. We introduce a topic-specific generative method to model the translation process. Topic specific trigger words are used to bridge the vocabulary gap between the words in microblogs and targets. We examine the effectiveness of our approach via datasets gathered from real world microblogs. Experimental results demonstrate a 20.2% improvement in terms of F1-score over the state-of-the-art discriminative method.

1 Introduction

With the rapid growth of social media, about 72% of adult internet users are also members of a social networking site[1]. Over the past few years, microblogging has become one of the most popular services. Meanwhile, microblogs have also been widely used as sources for analyzing public opinions (Bermingham and Smeaton, 2010; Jiang et al., 2011), prediction (Asur and Huberman, 2010; Bollen et al., 2011), reputation management (Pang and Lee, 2008; Otsuka et al., 2012), and many other applications (Bian et al., 2008; Sakaki et al., 2010; Becker et al., 2010; Guy et al., 2010; Lee and Croft, 2013; Guy et al., 2013). For most of these applications, identifying the microblogs that are relevant to the targets of interest is one of the basic steps (Lin and He, 2009; Amigó et al., 2010; Qiu et al., 2011; Liu et al., 2013). Let us firstly consider the following example:

Example 1: *11" MacBook Air can run for up to five hours on a single charge.*

"*MacBook Air*" can be considered to be the target being discussed on the microblog, and we can also infer from the microblog that it is related to Apple Inc. The ability to discriminate which company is being referred to in a microblog is required by many applications.

Previous studies on fine-grained sentiment analysis and aspect-based opinion mining proposed supervised (Popescu and Etzioni, 2005; Liu et al., 2012a; Liu et al., 2013) and unsupervised methods (Hu and Liu, 2004; Wu et al., 2009; Zhang et al., 2010) to extract targets of opinion expressions. Based on the associations between opinion targets and opinion words, some methods were also introduced to simultaneously solve the opinion expression and target extraction problems (Qiu et al., 2011; Liu et al., 2012a). However, most of the existing methods in this area only focus on extracting items about which opinions are expressed in a given domain. The implicated information of targets is rarely considered. Moreover, domain adaptation is another big challenge for these fine-grained methods in processing different domains.

[1]It is reported by the Pew Research Center's Internet & American Life Project in Aug 5, 2013.

Proceedings of COLING 2014, the 25th International Conference on Computational Linguistics: Technical Papers, pages 688–697, Dublin, Ireland, August 23-29 2014.

The WePS-3[2] (Amigó et al., 2010) and RepLab 2013[3] (Amigó et al., 2013) evaluation campaigns also addressed the problem from the perspective of the disambiguation of company names in microblogs. Microblogs that contain company names at a lexical level are classified based on whether it refers to the company or not. Various approaches have been proposed to address the task with different methods (Pedersen et al., 2006; Yerva et al., 2010; Zhang et al., 2012; Spina et al., 2012; Spina et al., 2013). However, the microblogs that do not contain company names cannot be correctly processed using these methods. From analyzing the data, we observe that a variety of microblog posts belong to this type. They only contain products names, slang terms, and other related company content.

To achieve this task, in this paper, we propose the use of a translation based model to identify the targets of microblogs. We assume that the microblog posts and targets describe the same topic using different languages. Hence, the target identification problem can be regarded as a translation process from the content of the microblogs to the targets. We integrate latent topical information into the translation model to facilitate the translation process. Because product names, series, and other related information are important indicators for this task, we also incorporate this background knowledge into the model. To evaluate the proposed method, we collect a large number of microblogs and manually annotate a subset of these as golden standards. We compare the proposed method with state-of-the-art methods using the constructed dataset. Experimental results demonstrate that the proposed approach can achieve better performance than the other approaches.

2 The Proposed Method

2.1 The Generation Process

Given a corpus $D = \{d_i, 1 \leq i \leq |D|\}$, which contains a list of microblogs $\{d_i\}$. A microblog is a sequence of N_d words denoted by $w_d = \{w_{d1}, w_{d2}, ..., w_{dN_d}\}$. Each microblog contains a set of targets denoted by $c_d = \{c_{d1}, c_{d2}, ..., c_{dM_d}\}$. A word is defined as an item from a vocabulary with V distinct words indexed by $w = \{w_1, w_2, ..., w_V\}$. The nth word in the dth microblog is associated with not only one topic z_{dn}, but also an indicator variable l_{dn} which indicates whether w_{dn} belongs to the ontology ($l_{dn} = 1$), which contains company names, product names, series, and other related information, or is a common word ($l_{dn} = 0$). Each target is from the vocabulary with C distinct company names indexed by $c = \{c_1, c_2, ..., c_C\}$. The mth target in the dth microblog is associated with a topic z_{dm}. The notations used in this paper are summarized in Table 1. Fig. 1 shows the graphical representation of the generation process. The generative story for each microblog is as follows:

1. Sample word distribution $\phi^{t,l}$ from $Dir(\beta^l)$ for each topic $t = 1, 2, ..., T$ and each label $l = 1, ..., L$.
2. For each microblog d=1,2,...,$|D|$
   a. Sample topic distribution θ_d from $Dir(\alpha)$
   b. For each word $n = 1, 2, ..., N_d$
      i. Sample a topic $z_{dn} = t$ from $Multinomial(\theta_d)$
      ii. Sample a label $l_{dn} = l$ from the distribution over labels, $v^{d,n}$
      iii. Sample a word w according to multinomial distribution $P(w_{dn} = w|z_{dn} = t, l_{dn} = l, \phi^{t,l})$
   c. For each target $m = 1, 2, ..., M_d$
      i. Sample a topic $z_{dm} = t$ from $Multinomial(\theta_d)$
      ii. Sample a target $c_{dm} = c$ according to probability $P(c_{dm} = c|w_d, l_d, z_{dm} = t, B)$

As described above, we use l_{dn} to incorporate the ontology information into the model. In this work, we construct an ontology which contains 4,926 company names, 7,632 abbreviations, and 26,732 product names. These companies names are collected based on the top search queries in different categories [4]. We propose to use the distribution $v^{d,n}$ to indicate the probability of variable l_{dn}. We set $v^{d,n}$ by applying

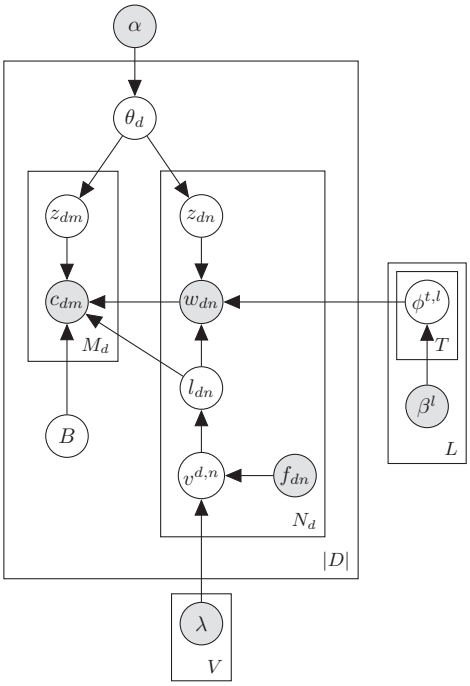

Figure 1: The graphical representation of the proposed model. Shaded circles are observations or constants. Unshaded ones are hidden variables.

various sources of ontology (presented by λ) and the context features of the word w_{dn} (presented by f_{dn}). In this work, we only consider the word itself as its context feature. This information is encoded into the hyperparameters $\{\lambda^w | w \in \{w_1, w_2, ..., w_V\}\}$, where λ^w is hyperparameter for the word w, and $\lambda_0^w + \lambda_1^w = 1$. For each word w in the ontology, we set λ_1^w to a value 0.9, λ_0^w to a value 0.1. For each word w not contained by ontology, we set λ_1^w to a value 0 and λ_0^w to a value 1. Based on the ontology, $v^{d,n}$ could be set as follows:

$$P(l_{dn} = l | w_{dn} = w) = v_l^{d,n} = \frac{\lambda_l^w}{\lambda_1^w + \lambda_0^w}, l \in \{0, 1\} \tag{1}$$

2.2 Model Inference

We use collapsed Gibbs sampling (Griffiths and Steyvers, 2004) to obtain samples of hidden variable assignment and to estimate the model parameters from these samples.

On the microblog content side, the conditional probability of a latent topic and label for the nth word in the dth microblog is:

$$Pr(z_{dn} = t, l_{dn} = l | w_{dn} = w, \mathbf{w}^{\neg n}, \mathbf{z}^{\neg n}, \mathbf{l}^{\neg n}) \propto \frac{\lambda_l^w}{\lambda_1^w + \lambda_0^w} \times \frac{N_{t,l}^{w,\neg n} + \beta^l}{N_{t,l}^{\neg n} + V\beta^l} \times \frac{N_d^{t,\neg n} + \alpha}{N_d^{\neg n} + T\alpha}, \tag{2}$$

where $N_{t,l}^{w,\neg n}$ is the number of the word w that are assigned to topic t under the label l; $N_{t,l}^{\neg n}$ is the number of all the words that are assigned to topic t under the label l; $N_d^{t,\neg n}$ is the number of topic t in the microblog d; $N_d^{\neg n}$ is the number of all the topics in the document d; $\neg n$ indicates taking no account of the current position n.

Given the conditional probability of $z_{dn} = t, l_{dn} = l$, we formalize the marginal probability of $z_{dn} = t$ as follows:

$$Pr(z_{dn} = t | w_{dn} = w, \mathbf{w}^{\neg n}, \mathbf{z}^{\neg n}, \mathbf{l}^{\neg n}) \propto \sum_{l=0}^{L-1} \frac{\lambda_l^w}{\lambda_1^w + \lambda_0^w} \times \frac{N_{t,l}^{w,\neg n} + \beta^l}{N_{t,l}^{\neg n} + V\beta^l} \times \frac{N_d^{t,\neg n} + \alpha}{N_d^{\neg n} + T\alpha} \tag{3}$$

Table 1: The notation used in the proposed model.

$\|D\|$	The number of microblogs in the data set
V	The number of unique words in the vocabulary
C	The number of companies
T	The number of topics
L	The number of labels
N_d	The number of words in the dth microblog
M_d	The number of companies in the dth microblog
w_d	All the words in the dth microblog
c_d	All the targets in the dth microblog
z_d	The topic of the words in the dth microblog
l_d	The label of the words in the dth microblog
B	The topic-specific word alignment table between a word and a target
$\phi^{t,l}$	Distribution of words for each topic t and each label l
θ_d	Distribution of topics in microblog d
$v^{d,n}$	Distribution of labels for word w_{dn}
$N_{t,l}^{w,\neg n}$	The number of the word w that is assigned to topic t under the label l except the position n
$N_{t,l}^{\neg n}$	The number of all the words that are assigned to topic t under the label l. except the position n
$N_d^{t,\neg n}$	The number of topic t in the microblog d except the position n
$N_d^{\neg n}$	The number of all the topics in the microblog d except the position n
$N_{t,l}^{c,w}$	The number of the target c that co-occurs with the word w labeled as l under topic t

After re-assigning the topic $z_{dn} = t$ for the current word, the conditional probability of ontology label for the nth word in the dth microblog is:

$$Pr(l_{dn} = l | w_{dn} = w, z_{dn} = t, \mathbf{w}^{\neg n}, \mathbf{z}^{\neg n}, \mathbf{l}^{\neg n}) \propto \frac{\lambda_l^w}{\lambda_1^w + \lambda_0^w} \times \frac{N_{t,l}^{w,\neg n} + \beta^l}{N_{t,l}^{\neg n} + V\beta^l} \tag{4}$$

On the target side, we perform topic assignments for each target as follows:

$$Pr(z_{dm} = t | c_{dm} = c, \mathbf{c}^{\neg m}, \mathbf{w}, \mathbf{l}, \mathbf{z}^{\neg m}) \propto \sum_{n=1}^{N_d} \delta^{l_{dn}} \frac{N_{t,l_{dn}}^{c,w_{dn},\neg m}}{N_{t,l_{dn}}^{w_{dn}} + \gamma C} \times \frac{N_d^{t,\neg m} + \alpha}{N_d^{\neg m} + T\alpha}, \tag{5}$$

where $\delta^{l_{dn}}$ is the weight for the label ($\delta^1 > 1, \delta^0 = 1$); $N_{t,l_{dn}}^{c,w_{dn},\neg m}$ is the number of the company c that co-occurs with the word w_{dn} labeled as l_{dn} under topic t; γC is a smoothing part; $N_{t,l_{dn}}^{w_{dn}}$ is the number of the word w_{dn} labeled as l_{dn} under topic t; $N_d^{t,\neg m}$ is the number of occurrences of topic t in the document d; $N_d^{\neg m}$ is the number of occurrences of all the topics in the document d; $\neg m$ indicates taking no account of the current position m.

Based on the above equations, after enough sampling iterations, we can estimate word alignment table B, $B_{c,w,t,l} = \delta^l \frac{N_{t,l}^{c,w}}{N_{t,l}^w + \gamma C}$. Some companies just occur few times, and most of the words co-occur with them also alignment with other companies, for this case, we use γC to smooth, where C represent the number of company c. And also we can estimate topic distribution θ for each document, and word distribution ϕ for each topic and each label, as follows:

$$\theta_d^t = \frac{N_d^t + \alpha}{N_d + T\alpha}, \quad \phi_w^{t,l} = \frac{N_{t,l}^w + \beta^l}{N_{t,l} + V\beta^l}$$

The possibility table $B_{c,w,t,l}$ has a potential size of $V \cdot C \cdot T \cdot L$. The data sparsity may pose a problem in estimating $B_{c,w,t,l}$. To reduce the data sparsity problem, we introduce the remedy in our model. We

employ a linear interpolation with topic-free word alignment probability to avoid data sparsity problem:

$$B^*_{c,w,t,l} = \sigma B_{c,w,t,l} + (1-\sigma)P(c|w), \tag{6}$$

where $P(c|w)$ is topic-free word alignment probability between the word w and the company c. σ is trade-off of two probabilities ranging from 0.0 to 1.0.

2.3 Target Company Extraction

Just like standard LDA, the proposed method itself finds a set of topics but does not directly extract targets. Suppose we have a dataset which contains microblogs without targets, we can use the collapsed Gibbs sampling to estimate the topic and label for the words in each microblog. The process is the same as described in Section 3.2.

After the hidden topics and label of the words in each microblog become stable, we can estimate the distribution of topics for the dth microblog by: $P(t|w_d) = \theta^t_d = \frac{N^t_d + \alpha}{N_d + T\alpha}$. With the word alignment table B^*, we can rank companies for the dth microblog in unlabeled data by computing the scores:

$$Pr(c_{dm}|w_d) \propto \sum_{t=1}^{T}\sum_{n=1}^{N_d} P(c_{dm}|t, w_{dn}, l_{dn}, B^*) \cdot P(t|w_d)P(w_{dn}|w_d), \tag{7}$$

where $P(w_{dn}|w_d)$ is the weight of the word w_{dn} in the microblog content w_d. In this paper, we use inverse document frequency (IDF) score to estimate it. Based on the ranking scores calculated by Eq.(7), we can extract the top-ranked targets for each microblog to users.

3 Experiments

In this section, we will introduce the experimental results and datasets we constructed for training and evaluation. We will firstly describe the how we construct the datasets and their statistics. Then we will introduce the experiment configurations and baseline methods. Finally, the evaluation results and analysis will be given.

3.1 Datasets

We started by using Sina Weibo's API[5] to collect public microblogs from randomly selected users. The dataset contains 282.2M microblogs published by 1.1M users. We use *RAW-Weibo* to represent it in the following sections. Based on the collected raw microblogs, we constructed three datasets for evaluation and training.

3.1.1 Training data

Since social media users post thoughts, ideas, or status on various topics in social medias, there are a huge number of related companies. Manually constructing training data is a time consuming and cost process. In this work, we propose a weakly manual method based on ontology and hashtag. A hashtag is a string of characters preceded by the symbol #. In most cases, hashtags can be viewed as an indication to the context of the tweet or as the core idea expressed in the tweet. Hence, we can use hashtag as the targets.

We extract the microblogs whose hashtags contain ontology items as training data and the corresponding ontology items as targets. Obviously, the training data constructed based on this method is not perfect. However, since this method can effectively generate a great quantity of data, we think that general characteristics can be modeled with the generated training data. To evaluate the corpus, we randomly selected 100 microblogs from the training data and manually labeled their targets. The accuracy of the sampled dataset is 91%. It indicates that the proposed training data generation method is effective. From the *RAW-Weibo* dataset, we extracted a total of 1.79M microblogs whose hashtags contain more than one target. Training instances for 2,574 target companies are included in the training data.

[5]http://open.weibo.com/

3.1.2 Test data

For evaluation, we manually constructed a dataset *RAN-Weibo*, which contains 2,000 microblogs selected from *RAW-Weibo*. Three annotators were asked to label the target companies for each microblog. To evaluate the quality of annotated dataset, we validate the agreements of human annotations using Cohen's kappa coefficient. The average κ among all annotators is 0.626. It indicates that the annotations are reliable.

Since some targets are ambiguous, inspired by the evaluation campaigns WePS-3 and RepLab 2013, we also constructed a dataset *AMB-Weibo*, where microblogs include 10 popular company names which may cause ambiguity. For each target, we randomly selected and annotated 200 microblogs as golden standards. Three annotators were also asked to label whether the microblog is related the given target or not. The agreements of human annotations were also validated through Cohen's kappa coefficient. The average κ among all annotators is 0.692.

3.2 Experiment Configurations

We use precision (P), recall (R), and F1-score (F_1) to evaluate the performance. We ran our model with 500 iterations of Gibbs sampling. We use 5-fold cross-validation in the training data to optimize hyperparameters. The number of topics is set to 30. The other settings of hyperparameters are as follows: $\alpha = 50/T$, $\beta = 0.1$, $\delta = 20$, $\gamma = 0.5$. The smoothing parameter σ is set to 0.8.

For baselines, we compare the proposed model with the following baseline methods.

- **Naive Bayes (NB)**: The target identification task can be easily formalized as a classification task, where each target is considered as a classification label. Hence, we applied Naive Bayes to model the posterior probability of each target given a microblog.
- **Support Vector Machine (SVM)**: The content of microblogs are represented as vectors and SVM is used to model the classification problem.
- **IBM1**: Translation model (IBM model-1) is applied to obtain the alignment probability between words and targets.
- **TTM**: Topical translation model (TTM) was proposed by Ding et al. (2013) to achieve microblog hashtag suggestion task. We adopted it to estimate the alignment probability between words and targets.

3.3 Experimental Results

We evaluate the proposed method from the following perspectives: 1) comparing the proposed method with the state-of-the-art methods on the two evaluation datasets; 2) identifying the impacts of parameters.

Table 2 shows the comparisons of the proposed method with the state-of-the-arts discriminative and generative methods on the evaluation dataset *RAN-Weibo*. "*Our*" denotes the method proposed in previous sections. "*Our w/o BG*" represents the proposed method without background knowledge. From the results, we can observe that the proposed method is better than other methods. Discriminative methods achieve worse results than generative methods. We think that the large number of targets is one of the main reasons of the low performances. The results of the proposed models with and without ontology information also show that background knowledge can benefit both the precision and recall. TTM achieves better performance than IBM1. It indicates that topical information is useful for this task. The performances of our method are significantly better than TTM. It illustrates that our smoothing method and incorporation of background knowledge are effective.

From the description of the proposed model, we can know that there are several hyperparameters in the proposed model. To evaluate the impacts of them, we evaluate two crucial ones among all of them, the number of topics T and the smoothing factor σ. Table 3 shows the influence of the number of topics. From the table, we can observe that the proposed model obtains the best performance when T is set to 30. And performance decreases with more number of topics. We think that data sparsity may be one of the main reasons. With much more topic number, the data sparsity problem will be more serious when

Table 2: Evaluation results of NB, SVM, IBM1, TTM, and our method on the evaluation dataset *RAN-Weibo*.

Methods	Precision	Recall	F_1
NB	0.168	0.154	0.161
SVM	0.312	0,286	0.298
IBM1	0.236	0.214	0.220
TTM	0.356	0.327	0.341
Our w/o BG	0.488	0.448	0.467
Our	**0.522**	**0.479**	**0.500**

Table 3: The influence of the number of topics T of the proposed method.

T	Precision	Recall	F_1
10	0.516	0.473	0.493
30	**0.522**	**0.479**	**0.500**
50	0.508	0.466	0.486
70	0.489	0.449	0.468
100	0.488	0.448	0.467

estimating topic-specific translation probability. Table 4 shows the influence of the translation probability smoothing parameter σ. When σ is set to 0.0, it means that the topical information is omitted. Comparing the results of $\sigma = 0.0$ and other values, we can observe that the topical information can benefit this task. When σ is set to 1.0, it represents the method without smoothing. The results indicate that it is necessary to address the sparsity problem through smoothing.

Figure 2 shows the results of different methods on the dataset *AMB-Weibo*. All the models are trained with same dataset as the above experiments. From the results, we can observe that the F1-scores vary from less than 0.40 up to almost 0.60. The performances' variations of other methods are also huge. We think that training data size and difficulty level are two main reasons. The size of training data of different targets vary greatly in the dataset. However, comparing with other method, the proposed method is the most stable one. Comparing with other methods, the proposed method achieves better performance than other methods for all targets.

4 Related Work

Organization name disambiguation task is fundamental problems in many NLP applications. The task aims to distinguish the real world relevant of a given name with the same surface in context. WePS-3[6] (Amigó et al., 2010) and RepLab 2013[7] (Amigó et al., 2013) evaluation campaigns have also addressed the problem from the perspective of disambiguation organization names in microblogs. Pedersen et al. (2006) proposed an unsupervised method for name discrimination. Yerva et al. (2010) used support vector machines (SVM) classifier with various external resources, such as WordNet, metadata profile, category profile, Google set, and so on. Kozareva and Ravi (2011) proposed to use latent dirichlet allocation to incorporate topical information. Zhang et al. (2012) proposed to use adaptive method for this task. However, most of these methods focused on the text with predefined surface words. The documents which do not contain organization names or person names can not be well processed by these methods.

To bridge the vocabulary gap between content and hashtags, Liu et al. (2012b) proposed to use translation model to handle it. They modeled the tag suggestion task as a translation process from

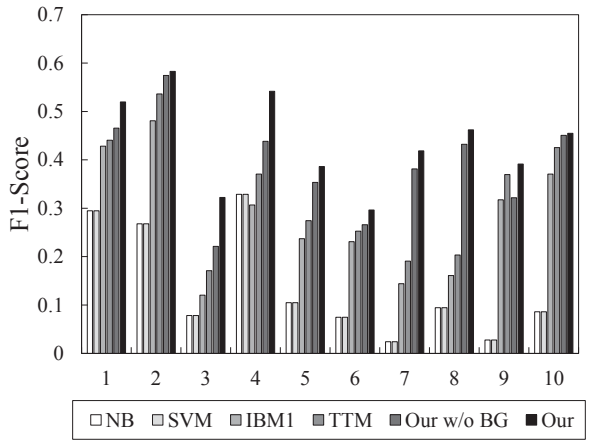

Figure 2: Evaluation results of NB, SVM, IBM1, TTM, and our method on the different companies in the test dataset *AMB-Weibo*.

document content to tags. Ding et al. (2013) extended the translation based method and introduced a topic-specific translation model to process the multiple meanings of words in different topics. Motivated by these methods, we also propose to use topic-specific translation model to handle vocabulary problem. Based on the model, in this work, we incorporate the background knowledge information into the model.

5 Conclusions

To identify target companies of microblogs, in this paper, we propose a novel topical translation model to achieve the task. The main assumption is that the microblog posts and targets describe the same thing with different languages. We convert the target identification problem to a translation process from content of microblogs to targets. We integrate latent topical information into translation model to hand the themes of microblogs in facilitating the translation process. We also incorporate background knowledge (such as product names, series, et al.) into the generation model. Experimental results on a large corpus constructed from a real microblog service and a number of manually labeled golden standards of easily ambiguous entities demonstrate that the proposed method can achieve better performance than other approaches.

Inducing Latent Semantic Relations for Structured Distributional Semantics

Abstract

Structured distributional semantic models aim to improve upon simple vector space models of semantics by hypothesizing that the meaning of a word is captured more effectively through its relational — rather than its raw distributional — signature. In accordance, they extend the vector space paradigm by structuring elements with relational information that decompose distributional signatures over discrete relation dimensions. However, the number and nature of these relations remains an open research question, with most previous work in the literature employing syntactic dependencies as surrogates for truly semantic relations. In this paper we propose a novel structured distributional semantic model with latent relation dimensions, and instantiate it using latent relational analysis. Evaluation of our model yields results that significantly outperform several other distributional approaches on two semantic tasks and performs competitively on a third relation classification task.

1 Introduction

The distributional hypothesis, articulated by Firth (1957) in the popular dictum "You shall know the word by the company it keeps", has established itself as one of the most popular models of modern computational semantics. With the rise of massive and easily-accessible digital corpora, computation of co-occurrence statistics has enabled researchers in NLP to build distributional semantic models (DSMs) that have found relevance in many application areas. These include information retrieval (Manning et al., 2008), question answering (Tellex et al., 2003), word-sense disambiguation (McCarthy et al., 2004) and selectional preference modelling (Erk, 2007), to name only a few.

The standard DSM framework, which models the semantics of a word by co-occurrence statistics computed over its neighbouring words, has several known short-comings. One severe short-coming derives from the fundamental nature of the vector space model, which characterizes the semantics of a word by a single vector in a high dimensional space (or some lower dimensional embedding thereof).

Such a modelling paradigm goes against the grain of the intuition that the semantics of a word is neither unique nor constant. Rather, it is composed of many facets of meaning, and similarity (or dissimilarity) to other words is an outcome of the aggregate harmony (or dissonance) between the individual facets under consideration. For example, a shirt may be similar along one facet to a balloon in that they are both coloured blue, at the same time being similar to a shoe along another facet for both being articles of clothing, while being dissimilar along yet another facet to a t-shirt because one is stitched from linen while the other is made from polyester.

Structured distributional semantic models (SDSMs) aim to remedy this fault with DSMs by decomposing distributional signatures over discrete relation dimensions, or facets. This leads to a representation that characterizes the semantics of a word by a distributional tensor, rather than a vector. Previous attempts in the literature include the work of Padó and Lapata (2007), Baroni and Lenci (2010) and Goyal et al. (2013). However, all these approaches assume a simplified representation in which truly semantic relations are substituted by syntactic relations obtained from a dependency parser.

Proceedings of COLING 2014, the 25th International Conference on Computational Linguistics: Technical Papers, pages 698–708, Dublin, Ireland, August 23-29 2014.

We believe that there are limiting factors to this approximation. Most importantly, the set of syntactic relations, while relatively uncontroversial, is unable to capture the full extent of semantic nuance encountered in natural language text. Often, syntax is ambiguous and leads to multiple semantic interpretations. Conversely, passivization and dative shift are common examples of semantic invariance in which multiple syntactic realizations are manifested. Additionally, syntax falls utterly short in explaining more complex phenomena – such as the description of buying and selling – in which implicit semantics are tacit from complex interactions between multiple participants.

While it is useful to consider relations that draw their origins from semantic roles such as Agent, Patient and Recipient, it remains unclear what this set of semantic roles should be. This problem is one that has long troubled linguists (Fillmore, 1967; Sowa, 1991), and has been previously noted by researchers in NLP as well (Màrquez et al., 2008). Proposed solutions range from a small set of generic Agent-like or Patient-like roles in Propbank (Kingsbury and Palmer, 2002) to an effectively open-ended set of highly specific and fine-grained roles in Framenet (Baker et al., 1998). In addition to the theoretic uncertainty of the set of semantic relations there is the very real problem of the lack of high-performance, robust semantic parsers to annotate corpora. These issues effectively render the use of pre-defined, linguistically ordained semantic relations intractable for use in SDSM.

In this paper we propose a novel approach to structuring distributional semantic models with *latent* relations that are automatically discovered from corpora. This approach effectively solves the conceptual dilemma of selecting the most expressive set of semantic relations. To the best of our knowledge this is the first paper to propose latent relation dimensions for SDSMs. The intuition for generating these latent relation dimensions leads to a generic framework, which — in this paper — is instantiated with embeddings obtained from latent relational analysis (Turney, 2005).

We conduct experiments on three different semantic tasks to evaluate our model. On a similarity scoring task and another synonym ranking task the model significantly outperforms other distributional semantic models, including a standard window-based model, a syntactic SDSM based on previous approaches proposed in the literature, and a state-of-the-art semantic model trained using recursive neural networks. On a relation classification task, our model performs competitively, outperforming all but one of the models it is compared against.

2 Related Work

Since the distributional hypothesis was first proposed by Firth (1957), a number of different research initiatives have attempted to extend and improve the standard distributional vector space model of semantics. Insensitivity to the multi-faceted nature of semantics has been one of the focal points of several papers. Earlier work in this regard is a paper by Turney (2012), who proposes that the semantics of a word is not obtained along a single distributional axis but simultaneously in two different spaces. He proposes a DSM in which co-occurrence statistics are computed for neighbouring nouns and verbs separately to yield independent domain and function spaces of semantics.

This intuition is taken further by a stance which proposes that a word's semantics is distributionally decomposed over *many* independent spaces – each of which is a unique relation dimension. Authors who have endorsed this perspective are Erk and Padó (2008), Goyal et al. (2013), Reisinger and Mooney (2010) and Baroni and Lenci (2010). Our work relates to these papers in that we subscribe to the multiple space semantics view. However, we crucially differ from them by structuring our semantic space with information obtained from latent semantic relations rather than from a syntactic parser. In this paper the instantiation of the SDSM with latent relation dimensions is obtained using LRA (Turney, 2005), which is an extension of LSA (Deerwester et al., 1990) to induce relational embeddings for pairs of words.

From a modelling perspective, SDSMs characterize the semantics of a word by a distributional tensor. Other notable papers on tensor based semantics or semantics of compositional structures are the simple additive and multiplicative models of Mitchell and Lapata (2009), the matrix-vector neural network approach of Socher et al. (2012), the physics inspired quantum view of semantic composition of Grefenstette and Sadrzadeh (2011) and the tensor-factorization model of Van de Cruys et al. (2013).

A different, partially overlapping strain of research attempts to induce word embeddings using meth-

ods from deep learning, yielding state-of-the-art results on a number of different tasks. Notable research papers on this topic are the ones by Collobert et al. (2011), Turian et al. (2010) and Socher et al. (2010).

Other related work to note is the body of research concerned with semantic relation classification, which is one of our evaluation tasks. Research community wide efforts in the SemEval-2007 task 4 (Girju et al., 2007), the SemEval-2010 task 8 (Hendrickx et al., 2009) and the SemEval-2012 task 2 (Jurgens et al., 2012) are notable examples. However, different from our work, most previous attempts at semantic relation classification operate on the basis of feature engineering and contextual cues (Bethard and Martin, 2007).

3 Structured Distributional Semantics and Latent Semantic Relation Induction

In this section we formalize the notion of SDSM as an extension of DSM and present a novel SDSM with latent relation dimensions.

A DSM is a vector space V that contains $|\Sigma|$ elements in $\mathbb{R}^n$, where $\Sigma = \{w_1, w_2, ..., w_k\}$ is a vocabulary of k distinct words. Every vocabulary word w_i has an associated semantic vector $\vec{v_i}$ representing its distributional signature. Each of the n elements of $\vec{v_i}$ is associated with a single dimension of its distribution. This dimension may correspond to another word — that may or may not belong to Σ — or a latent dimension as might be obtained from an SVD projection or an embedding learned via a deep neural network. Additionally, each element in $\vec{v_i}$ is typically a normalized co-occurrence frequency count, a PMI score, or a number obtained from an SVD or RNN transformation. The semantic similarity between two words w_i and w_j in a DSM is the vector distance defined by $cos(\vec{v_i}, \vec{v_j})$ on their associated distributional vectors.

An SDSM is an extension of DSM. Formally, it is a space U that contains $|\Sigma|$ elements in $\mathbb{R}^{d \times n}$, where $\Sigma = \{w_1, w_2, ..., w_k\}$ is a vocabulary of k distinct words. Every vocabulary word w_i has an associated semantic tensor $\vec{\vec{u_i}}$, which is itself composed of d vectors $\vec{u_{i1}}, \vec{u_{i2}}, ..., \vec{u_{id}}$ each having n dimensions. Every vector $\vec{u_{il}} \in \vec{\vec{u_i}}$ represents the distributional signature of the word w_i in a relation (or along a facet) r_l. The d relations of the SDSM may be syntactic, semantic, or latent (as in this paper). The n dimensional relational vector $\vec{u_{il}}$ is configurationally the same as a vector $\vec{v_i}$ of a DSM. This definition of an SDSM closely relates to an alternate view of Distributional Memories (DMs) (Baroni and Lenci, 2010) where the semantic space is a third-order tensor, whose modes are Word $\times$ Link $\times$ Word.

The semantic similarity between two words w_i and w_j in an SDSM is the similarity function defined by $sim(\vec{\vec{u_i}}, \vec{\vec{u_j}})$ on their associated semantic tensors. We use the following decomposition of the similarity function:

$$sim(\vec{\vec{u_i}}, \vec{\vec{u_j}}) = \frac{1}{d} \sum_{l=1}^{d} cos(\vec{u_{il}}, \vec{u_{jl}}) \tag{1}$$

Mathematically, this corresponds to the ratio of the normalized Frobenius product of the two matrices representing $\vec{\vec{u_i}}$ and $\vec{\vec{u_j}}$ to the number of rows in both matrices. Intuitively it is simply the average relation-wise similarity between the two words w_i and w_j.

3.1 Latent Relation Induction for SDSM

The intuition behind our approach for inducing latent relation dimensions revolves around the simple observation that SDSMs, while representing semantics as distributional signatures over relation dimensions, also effectively encode relational vectors between pairs of words. Our method thus works backwards from this observation — beginning with a relational embedding for pairs of words, that are subsequently transformed to yield an SDSM.

Concretely, given a vocabulary $\Gamma = \{w_1, w_2, ..., w_k\}$ and a list of word pairs of interest from the vocabulary $\Sigma_V \subseteq \Gamma \times \Gamma$, we assume that we have some method for inducing a DSM V' that has a vector representation $\vec{v'_{ij}}$ of length d for every word pair $w_i, w_j \in \Sigma_V$, which intuitively embeds the distributional signature of the relation binding the two words in d latent dimensions. We then construct an SDSM U where $\Sigma_U = \Gamma$. For every word $w_i \in \Gamma$ a tensor $\vec{\vec{u_i}} \in \mathbb{R}^{d \times k}$ is generated. The tensor $\vec{\vec{u_i}}$

has d unique k dimensional vectors $\vec{u_{i1}}, \vec{u_{i2}}, ..., \vec{u_{id}}$. For a given relational vector $\vec{u_{il}}$, the value of the jth element is taken from the lth element of the vector $\vec{v_{ij}}$ belonging to the DSM V'. If the vector $\vec{v_{ij}}$ does not exist in V' – as is the case where the pair $w_i, w_j \notin \Sigma_V$ – the value of the jth element of $\vec{u_{il}}$ is set to 0. By applying this mapping to generate semantic tensors for every word in Γ, we are left with an SDSM U that effectively embeds latent relation dimensions. From the perspective of DMs we matricize the third-order tensor and perform truncated SVD, before restoring the resulting matrix to a third-order tensor.

3.1.1 Latent Relational Analysis

In what follows, we present our instantiation of this model with an implementation that is based on Latent Relational Analysis (LRA) (Turney, 2005) to generate the DSM V'. While other methods (such as RNNs) are equally applicable in this scenario, we use LRA for its operational simplicity as well as proven efficacy on semantic tasks such as analogy detection. The parameter values we chose in our experiments are not fine-tuned and are guided by recommended values from Turney (2005), or scaled suitably to accommodate the size of Σ_V.

The input to LRA is a vocabulary $\Gamma = \{w_1, w_2, ..., w_k\}$ and a list of word pairs of interest from the vocabulary $\Sigma_V \subseteq \Gamma \times \Gamma$. While one might theoretically consider a large vocabulary with all possible pairs, for computational reasons we restrict our vocabulary to approximately 4500 frequent English words and only consider about 2.5% word pairs with high PMI (as computed on the whole of English Wikipedia) in $\Gamma \times \Gamma$. For each of the word pairs $w_i, w_j \in \Sigma_V$ we extract a list of contexts by querying a search engine indexed over the combined texts of the whole of English Wikipedia and Gigaword corpora (approximately 5.8×10^9 tokens). Suitable query expansion is performed by taking the top 4 synonyms of w_i and w_j using Lin's thesaurus (Lin, 1998). Each of these contexts must contain both w_i, w_j (or appropriate synonyms) and optionally some intervening words, and some words to either side.

Given such contexts, patterns for every word pair are generated by replacing the two target words w_i and w_j with placeholder characters X and Y, and replacing none, some or all of the other words by their associated part-of-speech tag or a wildcard symbol. For example, if w_i and w_j are "eat" and "pasta" respectively, and the queried context is "I eat a bowl of pasta with a fork", one would generate patterns such as "* X * NN * Y IN a *", "* X DT bowl IN Y with DT *", etc. For every word pair, only the 5000 most frequent patterns are stored.

Once the set of all relevant patterns $P = p_1, p_2, ..., p_n$ have been computed a DSM V is constructed. In particular, the DSM constitutes a Σ_V based on the list of word pairs of interest, and every word pair w_i, w_j of interest has an associated vector $\vec{v_{ij}}$. Each element m of the vector $\vec{v_{ij}}$ is a count pertaining to the number of times that the pattern p_m was generated by the word pair w_i, w_j.

3.1.2 SVD Transformation

The resulting DSM V is noisy and very sparse. Two transformations are thus applied to V. Firstly all co-occurrence counts between word pairs and patterns are transformed to PPMI scores (Bullinaria and Levy, 2007). Then given the matrix representation of V — where rows correspond to word pairs and columns correspond to patterns — SVD is applied to yield $V = M\Delta N$. Here M and N are matrices that have unit-length orthogonal columns and Δ is a matrix of singular values. By selecting the d top singular values, we approximate V with a lower dimension projection matrix that reduces noise and compensates for sparseness: $V' = M_d\Delta_d$. This DSM V' in d latent dimensions is precisely the one we then use to construct an SDSM, using the transformation described above.

Since the large number of patterns renders it effectively impossible to store the entire matrix V in memory we use a memory friendly implementation[1] of a multi-pass stochastic algorithm to directly approximate the projection matrix (Halko et al., 2011; Rehurek, 2010). A detailed analysis to see how change in the parameter d effects the quality of the model is presented in section 4.

The optimal SDSM embeddings we trained and used in the experiments detailed below are available for download at `http://www.cs.cmu.edu/~sjauhar/Software_files/LR-SDSM.tar.`

gz. This SDSM contains a vocabulary of 4546 frequent English words with 130 latent relation dimensions.

4 Evaluation

Section 3 has described a method for embedding latent relation dimensions in SDSMs. We now turn to the problem of evaluating these relations within the scope of the distributional paradigm in order to address two research questions: 1) Are latent relation dimensions a viable and empirically competitive solution for SDSM? 2) Does structuring lead to a semantically more expressive model than a non-structured DSM? In order to answer these questions we evaluate our model on two generic semantic tasks and present comparative results against other structured and non-structured distributional models. We show that we outperform all of them significantly, thus answering both research questions affirmatively.

While other research efforts have produced better results on these tasks (Jarmasz and Szpakowicz, 2003; Gabrilovich and Markovitch, 2007; Hassan and Mihalcea, 2011), they are either lexicon or knowledge based, or are driven by corpus statistics that tie into auxiliary resources such as multi-lingual information and structured ontologies like Wikipedia. Hence they are not relevant to our experimental validation, and are consequently ignored in our comparative evaluation.

4.1 Word-Pair Similarity Scoring Task

The first task consists in using a semantic model to assign similarity scores to pairs of words. The dataset used in this evaluation setting is the WS-353 dataset from Finkelstein et al. (2002). It consists of 353 pairs of words along with an averaged similarity score on a scale of 1.0 to 10.0 obtained from 13–16 human judges. Word pairs are presented as-is, without any context. For example, an item in this dataset might be "book, paper $\rightarrow$ 7.46".

System scores are obtained by using the standard cosine similarity measure between distributional vectors in a non-structured DSM. In the case of a variant of SDSM, these scores can be found by using the cosine-based similarity functions in Equation 1 of the previous section. System generated output scores are evaluated against the gold standard using Spearman's rank correlation coefficient.

4.2 Synonym Selection Task

In the second task, the same set of semantic space representations is used to select the semantically closest word to a target from a list of candidates. The ESL dataset from Turney (2002) is used for this task, and was selected over the slightly larger TOEFL dataset (Landauer and Dumais, 1997). The reason for this choice was because the latter contained more complex vocabulary words — several of which were not present in our simple vocabulary model. The ESL dataset consists of 50 target words that appear with 4 candidate lexical substitutes each. While disambiguating context is also given in this dataset, we discard it in our experiments. An example item in this dataset might be "rug $\rightarrow$ sofa, ottoman, carpet, hallway", with "carpet" being the most synonym-like candidate to the target.

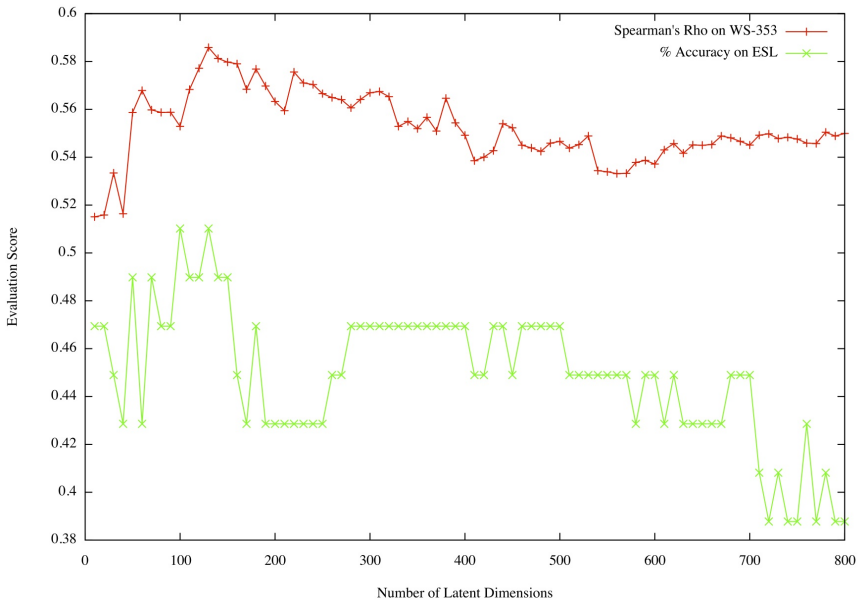

Figure 1: Evaluation results on WS-353 and ESL with varying number of latent dimensions. Generally high scores are obtained in the range of 100-150 latent dimensions, with optimal results on both datasets at 130 latent dimensions.

Similarity scores — which are obtained in the same manner as for the previous evaluation task — are extracted between the target and each of the candidates in turn. These scores are then sorted in descending order, with the top-ranking score yielding the semantically closest candidate to the target. Systems are evaluated on the basis of their accuracy at discriminating the top-ranked candidate.

4.3 Results

We compare our model (LR-SDSM) to several other distributional models in these experiments. These include a standard distributional vector space model (DSM) trained on the combined text of English Wikipedia and Gigaword with a window-size of 3 words to either side of a target, a syntax-based SDSM (Goyal et al., 2013; Baroni and Lenci, 2010) (synSDSM) trained on the same corpus parsed with a dependency parser (Tratz and Hovy, 2011) and the state-of-the-art neural network embeddings from Collobert et al. (2011) (SENNA). We also give the expected evaluation scores from a random baseline, for comparison.

An important factor to consider when constructing an SDSM using LRA is the number of latent dimensions selected in the SVD projection. In Figure 1 we investigate the effects of selecting different number of latent relation dimensions on both semantic evaluation tasks, starting with 10 dimensions up to a maximum of 800 (which was the maximum that was computationally feasible), in increments of 10. We note that optimal results on both datasets are obtained at 130 latent dimensions. In addition to the SDSM obtained in this setting we also give results for an SDSM with 300 latent dimensions (which has been a recommended value for SVD projections in the literature (Landauer and Dumais, 1997)) in our comparisons against other models. Comparative results on the Finkelstein WS-353 similarity scoring task are given in Table 1, while those on the ESL synonym selection task are given in Table 2.

4.4 Discussion

The results in Tables 1 and 2 show that LR-SDSM outperforms the other distributional models by a considerable and statistically significant margin (p-value < 0.05) on both types of semantic evaluation tasks. It should be noted that we do not tune to the test sets. While the 130 latent dimension SDSM yields the best results, 300 latent dimensions also gives comparable performance and moreover outperforms all the other baselines. In fact, it is worth noting that the evaluation results in figure 1 are almost all better

	Random	SENNA-Mik	DSM		SENNA		**LR-SDSM**
			AVC	MVC	AVC	MVC

Table 3: Results on Relation Classification Task. LR-SDSM scores competitively, outperforming all but the SENNA-AVC model.

than the results of the other models on either datasets.

We conclude that structuring of a semantic model with latent relational information in fact leads to performance gains over non-structured variants. Also, the latent relation dimensions we propose offer a viable and empirically competitive alternative to syntactic relations for SDSMs.

Figure 1 shows the evaluation results on both semantic tasks as a function of the number of latent dimensions. The general trend of both curves on the figure indicate that the expressive power of the model quickly increases with the number of dimensions until it peaks in the range of 100–150, and then decreases or evens out after that. Interestingly, this falls roughly in the range of the 166 frequent (those that appear 50 times or more) frame elements, or fine-grained relations, from FrameNet that O'Hara and Wiebe (2009) find in their taxonomization and mapping of a number of lexical resources that contain semantic relations.

5 Semantic Relation Classification and Analysis of the Latent Structure of Dimensions

In this section we conduct experiments on the task of semantic relation classification. We also perform a more detailed analysis of the induced latent relation dimensions in order to gain insight into our model's perception of semantic relations.

5.1 Semantic Relation Classification

In this task, a relational embedding is used as a feature vector to train a classifier for predicting the semantic relation between previously unseen word pairs. The dataset used in this experiment is from the SemEval-2012 task 2 on measuring the degree of relational similarity (Jurgens et al., 2012), since it characterizes a number of very distinct and interesting semantic relations. In particular it consists of an aggregated set of 3464 word pairs evidencing 10 kinds of semantic relations. We prune this set to discard pairs that don't contain words in the vocabularies of the models we consider in our experiments. This leaves us with a dataset containing 933 word pairs in 9 classes (1 class was discarded altogether because it contained too few instances). The 9 semantic relation classes are: "Class Inclusion", "Part-Whole", "Similar", "Contrast", "Attribute", "Non-Attribute", "Case Relation", "Cause-Purpose" and "Space-Time". For example, an instance of a word pair that exemplifies the "Part-Whole" relationship is "engine:car". Note that, as with previous experiments, word pairs are given without any context.

5.2 Results

We compare LR-SDSM on the semantic relation classification task to several different models. These include the additive vector composition (AVC) and multiplicative vector composition methods (MVC) proposed by Mitchell and Lapata (2009); we present both DSM and SENNA based variants of these models. We also compare against the vector difference method of Mikolov et al. (2013) (SENNA-Mik) which sees semantic relations as a meaning preserving vector translation in an RNN embedded vector space. Finally, we note the performance of random classification as a baseline, for reference. We attempted to produce results of a syntactic SDSM on the task; however, the hard constraint imposed by syntactic adjacency meant that effectively all the word pairs in the dataset yielded zero feature vectors.

To avoid overfitting on all 130 original dimensions in our optimal SDSM, and also to render results comparable, we reduce the number of latent relation dimensions of LR-SDSM to 50. We similarly reduce

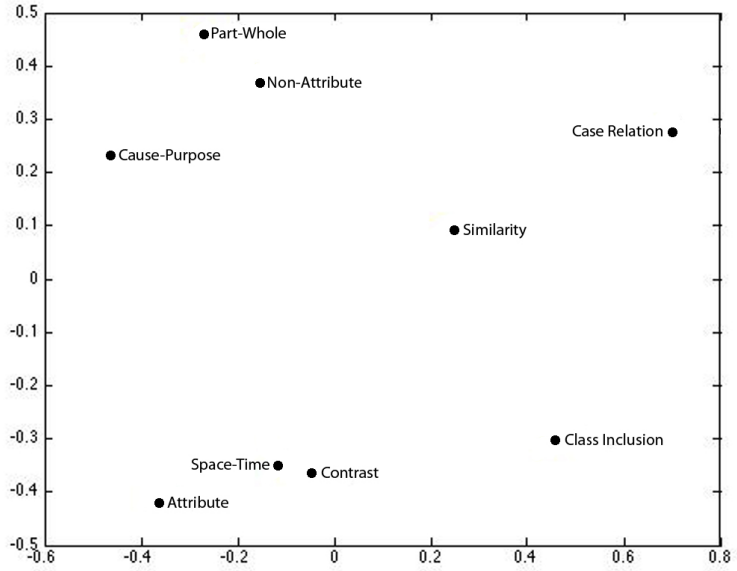

Figure 2: Correlation distances between semantic relations' classifier weights. The plot shows how our latent relations seem to perceive humanly interpretable semantic relations. Most points are fairly well spaced out, with opposites such as "Attribute" and "Non-Attribute" as well as "Similar" and "Contrast" being relatively further apart.

the feature vector dimension of DSM-AVC and DSM-MVC to 50 by feature selection. The dimensions of SENNA-AVC, SENNA-MVC and SENNA-Mik are already 50, and are not reduced further.

For each of the methods we train a logistic regression classifier. We don't perform any tuning of parameters and set a constant ridge regression value of 0.2, which seemed to yield roughly the best results for all models. The performance on the semantic relation classification task in terms of averaged precision, recall, F-measure and percentage accuracy using 10-fold cross-validation is given in Table 3.

Additionally, to gain further insight into the LR-SDSM's understanding of semantic relations, we conduct a secondary analysis. We begin by training 9 one-vs-all logistic regression classifiers for each of the 9 semantic relations under consideration. Then pairwise correlation distances are measured between all pairs of weight vectors of the 9 models. Finally, the distance adjacency matrix is projected into 2-d space using multidimensional scaling. The result of this analysis is presented in Figure 2.

5.3 Discussion

Table 3 shows that LR-SDSM performs competitively on the relation classification task and outperforms all but one of the other models. The performance differences are statistically significant with a p-value < 0.5. We believe that some of the expressive power of the model is lost by compressing to 50 latent relation dimensions, and that a greater number of dimensions might improve performance. However, testing a model with a 130-length dense feature vector on a dataset containing 933 instances would likely lead to overfitting and also not be comparable to the SENNA-based models that operate on 50-length feature vectors.

Other points to note from Table 3 are that the AVC variants of the the DSM and SENNA composition models tend to perform better than their MVC counterparts. Also, SENNA-Mik performs surprisingly poorly. It is worth noting, however, that Mikolov et al. (2013) report results on fairly simple lexico-syntactic relations between words – such as plural forms, possessives and gender – while the semantic relations under consideration in the SemEval-2012 dataset are relatively more complex.

In the analysis of the latent structure of dimensions presented in Figure 2, there are few interesting points to note. To begin with, all the points (with the exception of one pair) are fairly well spaced out. At

the weight vector level, this implies that different latent dimensions need to fire in different combinations to characterize distinct semantic relations, thus resulting in low correlation between their corresponding weight vectors. This indicates the fact that the latent relation dimensions seem to capture the intuition that each of the classes encodes a distinctly different semantic relation. The notable exception is "Space-Time", which is very close to "Contrast". This is probably due to the fact that distributional models are ineffective at capturing spatio-temporal semantics. Moreover, it is interesting to note that "Attribute" and "Non-Attribute" as well as "Similar" and "Contrast", which are intuitively semantic inverses of each other are also (relatively) distant from each other in the plot.

These general findings indicate an interesting avenue for future research, which involves mapping the empirically learnt latent relations to hand-built semantic lexicons or frameworks. This could help to validate the empirical models at various levels of linguistic granularity, as well as establish correspondences between different views of semantic representation.

6 Conclusion and Future Work

In this paper we have proposed a novel paradigm for SDSMs, that allows for structuring via latent relational information. We have introduced a generic operational framework that allows for building such SDSMs and outlined an instantiation of the model with LRA. Experimental results of the model support our claim that the resulting SDSM captures the semantics of words more effectively than a number of other semantic models, and presents a viable — and empirically competitive — alternative to syntactic SDSMs. Additionally we have conducted experiments on a relation classification task and shown promising results, as well as performed analyses to investigate the structure of, and interactions between, the latent relation dimensions.

These findings motivate a number of future directions of research. Since our framework is fairly general we hope to explore techniques other than LRA (such as RNNs) to generate relational embeddings for word pairs. A desiderata for future techniques is scalability so that we can characterize vocabularies that are larger than the one in our current experiments. We also hope to explore mappings between our empirically learnt latent relations, and semantic lexicons and frameworks that catalog semantic relations. Finally, we hope to test our model on more realistic application task such as event coreference, recognizing textual entailment, and semantic parsing in future work.

Acknowledgments

The authors would like to thank the anonymous reviewers for their valuable comments and suggestions to improve the quality of the paper. This work was supported in part by the following grants: NSF grant IIS-1143703, NSF award IIS-1147810, DARPA grant FA87501220342.

Abstract

In this paper, we address the issue of building and improving a distributional thesaurus. We first show that existing tools from the information retrieval domain can be directly used in order to build a thesaurus with state-of-the-art performance. Secondly, we focus more specifically on improving the obtained thesaurus, seen as a graph of k-nearest neighbors. By exploiting information about the neighborhood contained in this graph, we propose several contributions. 1) We show how the lists of neighbors can be globally improved by examining the reciprocity of the neighboring relation, that is, the fact that a word can be close of another and vice-versa. 2) We also propose a method to associate a confidence score to any lists of nearest neighbors (i.e. any entry of the thesaurus). 3) Last, we demonstrate how these confidence scores can be used to reorder the closest neighbors of a word. These different contributions are validated through experiments and offer significant improvement over the state-of-the-art.

1 Introduction

Distributional thesauri are useful for many NLP tasks and their construction is an issue widely discussed for several years (Grefenstette, 1994). However this is still a very active research field, maintained by the increasingly large number of available corpus and by many applications. These thesauri associate each of their entry with a list of words that are desired semantically close to the entry. This notion of proximity varies (synonymy, other paradigmatic relations, syntagmatic relations (Budanitsky and Hirst, 2006; Adam et al., 2013, for a discussion)), but the methods used for the automatic construction of thesauri are often shared. For the most part, these methods rely on the distributional hypothesis of (Firth, 1957): each word is characterized by the set of contexts in which it appears, and the semantic proximity of two words can be inferred from the proximity of their contexts. This hypothesis has been implemented in different ways, and several propositions to improve the results have been explored (see next section for a state of the art).

The work presented in this article are part of this framework. We propose several contributions on the creation of these distributional thesauri and their improvement. We first show that models from information retrieval (IR) can provide information on semantic relationships, and are thus adapted to the task of creating these thesauri. In addition, they offer very competitive results compared to the state of the art, while enjoying existing tools (Section 3).

The most important part of our work then focuses on the exploitation of such semantic neighborhood relations. The IR models indeed provide lists ordering all words by decreasing similarity, that form a graph of nearest neighbors. We propose to take advantage of some of the neighborhood information contained in this graph and we derive three contributions.
1) We globally improve neighbor lists by taking into account the reciprocity of the neighborhood relationship, that is to say the fact that a word is a close neighbor of another and vice versa (Section 4).
2) We also propose a method that associates each neighbor list (i.e. each entry of the thesaurus built) with a confidence score (Section 5). This method uses the nearest neighbor graph to estimate the probabilities that a given word is the i-th neighbor of another word.

Proceedings of COLING 2014, the 25th International Conference on Computational Linguistics: Technical Papers, pages 709–720, Dublin, Ireland, August 23-29 2014.

3) Finally, on the basis of this work, we show how to use this confidence score and these probabilities to reorder the list of nearest neighbors (Section 6). To achieve this goal, we model the reranking as an optimization problem of assignments, solved by the Hungarian algorithm (Kuhn and Yaw, 1955).

2 Related work

The notion of distributional thesaurus, as it was initially defined by Grefenstette (1994), followed by Lin (1998a) and Curran and Moens (2002), is not often considered specifically, probably because of its strong link with the notion of semantic similarity. As a consequence, the improvement of distributional thesauri has been first a side effect of the improvement of the distributional similarity measures used for their building and more precisely, of the distributional data they rely on. Both the nature of the constituents of distributional contexts and their weighting have been considered in this regard. Concerning their weighting, Broda et al. (2009) proposed to turn the weights of context constituents into ranks to make them less dependent on a specific weighting function while Zhitomirsky-Geffet and Dagan (2009), extended by Yamamoto and Asakura (2010), defined a bootstrapping method for modifying the weights of constituents in the distributional context of a word according to the similarity with its semantic neighbors.

The nature of distributional contexts has been first considered through the distinction between window-based and syntactic co-occurrents (Grefenstette, 1994; Curran and Moens, 2002). However, most of the work related to this issue has focused on the fact that the "traditional" representation of distributional contexts is very sparse and redundant, as illustrated by Hagiwara et al. (2006). Hence, several methods for dimension reduction were tested in this context: from Latent Semantic Analysis (Landauer and Dumais, 1997), extended for syntactic co-occurrents (Padó and Lapata, 2007), to Random Indexing (Sahlgren, 2001), Non-negative Matrix Factorization (Van de Cruys, 2010) and more recently, lexical representations learnt by neural networks (Huang et al., 2012; Mikolov et al., 2013).

The work we present in this article follows a different perspective as our objective is to improve an existing distributional thesaurus by relying on its structure through a reranking of its neighbors. Such approach was adopted to some extent by Zhitomirsky-Geffet and Dagan (2009) as it exploited the neighbors of an entry in an initial thesaurus for reweighting its distributional representation and finally, reranking its neighbors. Ferret (2013) proposed a more indirect method in which the reranking is based on the downgrading of the neighbors that are detected as not similar to their entry through a pseudo word sense disambiguation task: such detection occurs if a certain proportion of the occurrences of a neighbor are not tagged as the entry. Finally, the closest work to ours is (Ferret, 2012), which selects in an unsupervised way a set of examples of semantically similar words from an initial thesaurus for training a classifier whose decision function is used for reranking the neighbors of each entry. Its unsupervised selection of examples is more precisely based on the symmetry of semantic similarity relations.

As Ferret (2012), our work exploits a certain kind of symmetry in the relation of distributional neighborhood between words but extends it to a larger scale by considering the initial thesaurus as a k-nearest neighbor graph and using the relations in this graph for reranking the neighbors of each entry, similarly to Pedronette et al. (2014) in the context of image retrieval.

3 IR models for building distributional thesauri

3.1 Principles

As mentioned in the state of the art, distributional approaches aim to calculate similarities between textual representations of word contexts. Methods to calculate similarities from IR seem then relevant for this problem. For a given word, the set of contexts of all its occurrences is considered as a document. The proximity between two words is then measured on their contexts by a similarity function from IR. This idea has many links with the work from the state of the art, but seems relatively unexplored, with the exeption of (Vechtomova and Robertson, 2012) in the specific context of similar named entities. It offers the advantage of being easily implementable because of the numerous IR tools available. Some adaptations are of course required. In contrast to IR, the stop words are kept as well as their positions relative to the considered occurrence. Lemmatization instead of stemming is performed. For example, in the excerpt: "... all forms of restrictions on freedom of expression, threats ...", the indexing terms restriction-2,

on-1, of+1, expression+2 are added to the context of freedom noted $\mathcal{C}(\text{freedom})$. The whole set of collected contexts for a word is used as a query in order to find its distributional neighbors. According to an IR similarity measure, the nearest words of this query (those whose contexts are closest) are returned.

We tested some of the most classical similarity measures used in IR: Hellinger (Escoffier, 1978; Domengès and Volle, 1979), TF-IDF/cosinus, and Okapi-BM-25 (Robertson et al., 1998). The last model can be seen as a variation of TF-IDF that better takes into account the difference between document sizes. This point is of importance since in our case the documents (namely the set of contexts of a word) are actually of very variable sizes, due to the very variable number of occurrences of each word. The Okapi-BM25 similarity between a word w_i ($\mathcal{C}(w_i)$ being the query), and w_j ($\mathcal{C}(w_j)$ being a document), is given in Eqn 1.

$$\text{similarity}(w_i, w_j) = \sum_{t \in \mathcal{C}(w_i)} \frac{(k_3+1)*qtf}{k_3+qtf} * \frac{tf*(k_1+1)}{tf+k_1*(1-b+b*\frac{dl(\mathcal{C}(w_j))}{dl_{avg}})} * \log \frac{n-df(t)+0.5}{df(t)+0.5} \quad (1)$$

qtf is the number of occurrences of the word t in the query ($\mathcal{C}(w_i)$), dl is the size of $\mathcal{C}(w_j)$), dl_{avg} the average size of all contexts, n is the number of documents (that means in our case the number of considered words/thesaurus entries). $df(t)$ is the number of contexts ($\mathcal{C}(\cdot)$) containing t. Finally, k_1, k_3 and b are some constants, with default values $k_1 = 2$, $k_3 = 1000$ and $b = 0.75$. Details of these classical IR models are not given here but can be found in (Manning et al., 2008).

In the following experiments, the context of an occurrence is defined by the two words before and after the occurrence, and we also use an adjusted version of Okapi-BM25 similarity that enhances the influence of the document size and gives more importance to the most discriminating context words by setting $b = 1$ and putting the IDF squared to give more importance to the most discriminating context words.

3.2 Experimental setup

For the sake of comparison, we use in our experiments the data and baselines provided by Ferret (2013). The corpus used to build the distributional thesaurus is AQUAINT-2. It is a collection of articles from press containing about 380 million words. The thesaurus entries are all the nouns in the corpus with a frequency > 10. That represents 25,000 entries (i.e. unique nouns), denoted by n in the remaining. The corpus is labeled in parts of speech by TreeTagger (Schmid, 1994). In this way, we can identify the names that form the thesaurus entries and thus compare to existing work. However this information is not used to build the thesaurus, ensuring the portability of the method to other languages, similarly to (Freitag et al., 2005).

To evaluate the built thesauri, WordNet 3.0 synonyms (Miller, 1990) and Moby (Ward, 1996) are used as references, either separately, or jointly. These two resources exhibit quite different and complementary characteristics: on the one hand, WordNet indicates strong paradigmatic links between words (synonyms or quasi-synonyms). On the other hand, Moby groups words sharing more extended syntagmatic and paradigmatic relations, including synonymy, hyper/hypo-nymy, meronymy, but also many more complex types such as the composition of co-hyponymy and hyponymy (*abolition – annulment*, *cataclysm – debacle*) or hypernymy and co-hyponymy (*abyss – rift*, *algorithm – routine*). As a result, WordNet provides lists of 3 neighbors on average for the 10,473 names of the corpus it covers, while Moby provides lists of 50 neighbors on average for 9,216 names. When combined, the two resources provide a reference of 38 neighbors on average for 12,243 names. It is this combination of WordNet and Moby that will be used as the main reference in all evaluations of this article. Some results restricted to WordNet or Moby only as reference are also given in some cases to illustrate the impact of our methods on semantic simlarity versus semantic relatedness relations.

Through this intrinsic evaluation framework, the semantic neighbors of about half of the entries of our thesauri are evaluated, which can be considered as a very large evaluation set compared to classical benchmarks such as WordSim 353 for instance (Gabrilovich and Markovitch, 2007). This kind of intrinsic evaluation is of course limited by the relations that are present in the resources used as gold standards, often restricted to "classical" relation types such as synonymy or hypernymy. In our case, this limitation

Table 1: Performance of IR models for distributional thesaurus building with the references WordNet, Moby and WordNet+Moby

holds true for WordNet's synonyms but can be considered as far less restrictive for the related words of Moby, due to the diversity of their underlying relation types.

3.3 Results

For a given name, our approach by IR models returns a list of names ordered by decreasing similarity. This list is compared to the reference one by computing several classical measures (expressed in % in the following): the precision after k first names, denoted P@k, the Mean Average Precision (MAP) which is the mean of the average precision scores for each query after a reference synonym is found, and the R-precision (precision at R-th position in the ranking of results, where R is the number of relevant names for the query).

Table 1 indicates the performance of different models of IR similarities. For purposes of comparison, we show the results obtained under the same conditions by Ferret (2013), with both a state of the art approach based on using cosine similarity over pointwise mutual information between contexts (referred as *base* in the table), and an improved version by learning as described in section 2 (referred as *best rerank*). We also give the results on the same corpus on an approach based on syntactic co-occurrents (Ferret, 2014 in press), extracted with the Minipar syntactic parser as in (Lin, 1998b).

In these early results, it is worth noting that some IR similarities are quite inefficient, including the TF alone or Hellinger similarity. This is hardly surprising since these similarities use very basic weights that do not enhance the discriminative contexts of words. The similarities that include a notion of IDF get better results in this. Okapi BM25-based similarities offer good results. The standard Okapi version yields performance similar to the state of the art, and the adjusted version even widely outperforms the two systems from Ferret (2013), in particular in terms of overall quality (measured by the MAP). Moreover, the results of this adjusted version are comparable to those obtained with syntactic co-occurrents while it only exploits window-based co-occurents, known to give usually worst results than syntactic co-occurrents, without even lemmatization. This latest version of the system serves as reference for the rest of this article.

4 Reciprocity in the graph of k-NN

Computing all the similarities between all pairs of words produces a weighted graph of neighbors: Each word is connected with certain strength to the n other words. The results above do not reflect this structure. The following sections aim to examine how take advantage of the neighborhood relations embedded in this graph. It must be first noted that some of the IR similarity measures we used are not symmetric, including Okapi-BM25. The similarity between a word w_i, used as query, and another word w_j does not give the same value as the similarity between the query w_j and w_i. Apart from that, even if

the similarity measure it-self is symmetric, nearest neighbor relationships are not.

It seems then reasonable to assume that the reciprocity between two adjacent words (each belonging to the k nearest neighbors of the other) is a sign of confidence on the proximity between these words. Using this information to improve the previous results is discussed in this section. In the following, $\tau_{w_i}(w_j)$ denotes the rank of the word w_j in the list of neighbors of w_i. $\tau_{w_i}(w_j)$ thus varies from 1 to n.

4.1 Distributional neighborhood graph

Reciprocal relationship in distributional neighborhood has already been discussed and used in some work (Ferret, 2013) on distributional semantic, or more generally, on nearest neighbors graphs (Pedronette et al., 2014). In these papers, the reciprocity was considered for giving a new similarity score in a simple way. For a word w_i and its neighbor w_j, the maximal or the minimal rank between $\tau_{w_i}(w_j)$ and $\tau_{w_j}(w_i)$ is taken as the new rank. These two operators have too severe effects as only one rank is taken into consideration to decide the final score. This leads to highly degraded performance as shown later. Many other aggregation operators have however been proposed in other contexts with a behavior may be more appropriate to the task, including fuzzy logic (Detyniecki, 2000). These operators carry some semantic that allow to comprehend their behavior, such as T-norms (fuzzy logic AND) and S-norms (or T-conorms, fuzzy OR).

In this section, we test some of these operators without claiming to be exhaustive. These are defined on $[0, 1]^2$, 1 being the certainty. They are used to generate a new similarity score according to:

$$\text{score}_{w_i}(w_j) = \text{Aggreg}(1 - \tau_{w_i}(w_j)/n, 1 - \tau_{w_j}(w_i)/n) \quad (2)$$

where Aggreg is an aggregation operator. The new scores are then used to produce a new list of nearest neighbors of w_i (the higher the score, the greater proximity is proven). We thus perceive the semantic associated with these operators. For example, if the aggregation function is $\max$, we get the expected behavior of the fuzzy OR associated with this S-norm: w_j will be ranked very close to w_i in the new list if w_j was close to w_i *or* if w_i was close to w_j. For the T-norm $\min$, this happens if w_j is close to w_i *and* w_i is close to w_j.

4.2 Results

Besides the $\min$ and $\max$ aggregation operators, Figure 1 reports the results obtained with the following T-norms (or T-norm families dependent on a parameter γ) used as aggregation function Aggreg:

$\text{T}_{\text{Prob}}(x, y) = x * y$

$\text{T}_{\text{Lukasiewicz}}(x, y) = \max(x + y - 1, 0)$

$\text{T}_{\text{Hamacher}}(x, y) = \frac{x*y}{\gamma+(1-\gamma)*(x+y-x*y)}$; $\gamma \geq 0$

$\text{T}_{\text{Yager}}(x, y) = \max(0, 1 - \sqrt[\gamma]{(1-x)^\gamma + (1-y)^\gamma})$; $\gamma > 0$

We also tested the standard related S-norms, obtained by generalization of the De Morgan's law: $S(x, y) = 1 - T(1 - x, 1 - y)$. For the T-norm families dependent on a parameter, we varied this parameter value in a systematic way. The results reported correspond to the parameter values that maximize the MAP.

All these operators get very different results. Some operators, such as min, max, Lukasiewicz, and others for some γ, induce a threshold effect which degrades the performance: they return a default value generating too much ex aequo among the neighbors, for some values of $\tau_{w_i}(w_j)$ and $\tau_{w_j}(w_i)$. T-norms, focusing on pairs of words symmetrically close to each other, are too restrictive. This is consistent with the conclusions of the work cited: if the reciprocity condition is applied too strictly, it does not improve the nearest neighbor lists over all the words. In contrast, S-norms seem better able to take advantage of the ranking. The improvements are modest in terms of overall quality (MAP), but important at some ranks (e.g. P@10).

Finally, it is important to note that these results depend heavily on the resource used as reference. We tested the aggregation rank with $\text{S}_{\text{Hamacher}}$, $\gamma = 0.95$, on Moby and WordNet references separately. Results are given in Table 2. Because Wordnet is based on a synonymy relationship strong enough (and therefore reciprocal), the performance gains on WordNet are much higher than on Moby.

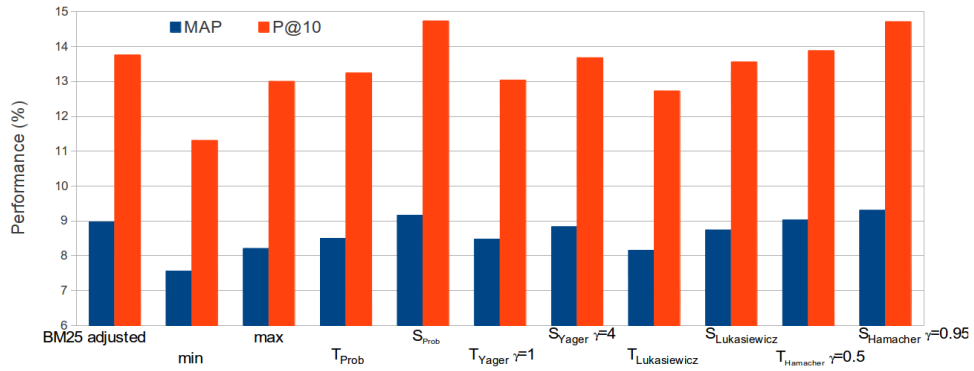

Figure 1: Performance of reciprocal rank aggregation, on the reference WordNet+Moby

Reference	MAP	R-Prec	P@1	P@5	P@10	P@50	P@100

5 Confidence estimation for a distributional neighborhood list

In the previous section, the rank of w_i in the list of neighbors of w_j is used to improve the ranking of w_j in the list of neighbors of w_i. We can also be interested in a more general way to the relative positions of w_i and w_j in all neighbor lists of all the words. Thereby, we expect to derive a more complete information. As a first step, we define a confidence criterion associated with each list of nearest neighbors, only based on the neighborhood graph.

5.1 Principle

We make the following assumption: the nearest neighbor list of a word w is probably of good quality if the distance (in terms of rank) between w and each of its neighbors w_i, denoted $\delta(w, w_i)$, is consistent with the distance observed between these same words (w, w_i) in other lists. The intuition here is that words supposed to be close should also be found close to the same other words. If k nearest neighbors of w have this property, then we attribute a high confidence to the neighbor list of w.

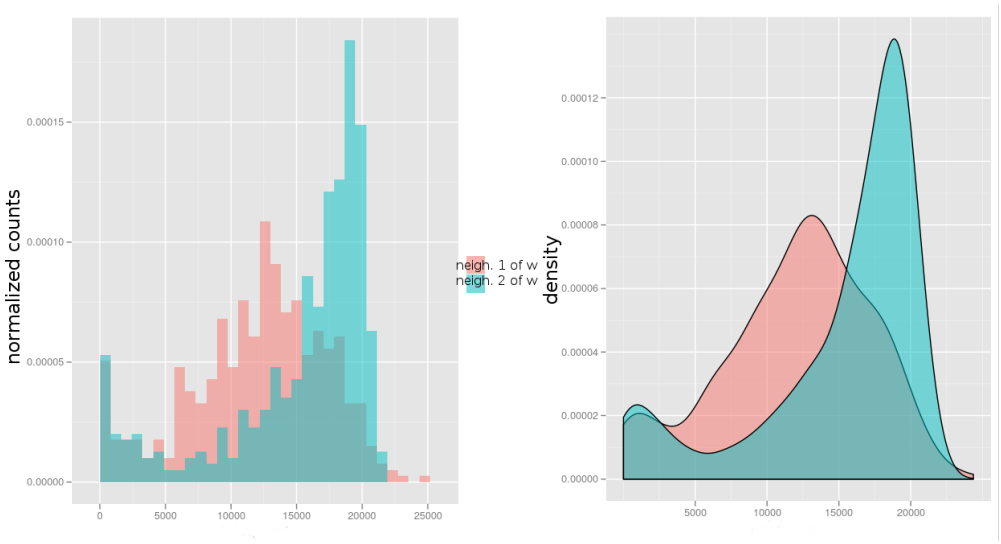
Formally, we define the confidence of the k-nearest neighbor list of w by:

$$Q(w) = \prod_{\{w_i | \tau_w(w_i) \leq k\}} p(\delta(w, w_i) = \tau_w(w_i)) \tag{3}$$

where $p(\delta(w, w_i) = \tau_w(w_i))$ is the probability that w_i is the $\tau_w(w_i)$-th neighbor of w. The problem is then to estimate the probability distribution $p(\delta(w, w_i))$ for each pair of words (w, w_i). To achieve this goal, we use the Parzen windows which is a method for nonparametric density estimation. We describe below how this classic method (Parzen, 1962; Wasserman, 2005) is applied in our context.

5.2 Parzen-window density estimation

Let $x_{ab} = \delta(w_a, w_b)$ be the distance (in terms of ranks) between two words w_a and w_b in a list of neighbors of any given word. Considering the n words of the thesaurus, we have a sample of n realizations assumed *iid*: (x^1_{ab}, x^2_{ab}, ... , x^n_{ab}), which are the observed distances between w_a et w_b in each (complete) neighbor list of each word. These counts can be represented by an histogram as illustrated in Figure 2 (a). Using the Parzen window technique, we can then estimate the probability density of x_{ab} with a kernel



(a) (b)

Figure 2: (a) Example of two distributions of distances x_{ab} and x_{ac} between a word w_a and two of its neighbors w_b and w_c, represented as histograms (blue and red) (b) Same distributions represented by densities estimated with the Parzen-windows method.

density estimator with Eqn 4 where h is a smoothing parameter called the bandwidth, and $K(\dot{)}$ is a kernel that we choose Gaussian. The resulting density is illustrated in Figure 2 (b).

$$\widehat{p_h}(x_{ab}) = \frac{1}{n\,h}\sum_{i=1}^{n} K\left(\frac{x_{ab} - x_{ab}^i}{h}\right) \quad \text{with} \quad K(u) = \frac{1}{\sqrt{2\pi}} e^{\frac{-u^2}{2}} \tag{4}$$

Thus, the resulting probability is a mixture of Gaussians centered on each x_{ab}^i. These methods are known to be sensitive to the bandwidth h, which controls the regularity of the estimation. The problem of choosing h is crucial in density estimation and was widely discussed in the literature. We use Silverman's rule of thumb (Silverman, 1986, page 48, eqn (3.31)) to set its value. Under the assumption of normality of the underlying distribution, this rule provides a simple way to calculate the optimal parameter h when Gaussian functions are used to approximate univariate data (Eqn 5 where $\hat{\sigma}$ is the standard deviation of the samples, and $q_3 - q_1$ is the interquartile range).

$$\hat{h} = 0.9\ \min(\hat{\sigma}, \frac{q_3 - q_1}{1.34})\ n^{-\frac{1}{5}} \tag{5}$$

Once these probabilities have been estimated on each of the k-nearest neighbors of w, we can calculate the confidence score $Q(w)$. The complexity of this estimation for all neighbor lists is $\mathcal{O}(k * n^2)$.

5.3 Using the confidence score

The expected benefit of using the confidence score is to have an a priori indication on the quality of a neighbor list for a given word. Such a score may thus be useful for many applications using thesauri produced by our approach (e.g. for expanding queries in information retrieval tasks). An evaluation of the confidence score through such applications would certainly be the most suitable, but beyond the scope of this article. We use default direct assessment towards the MAP: we measure the correlation between MAP and the confidence score, the idea being that an entry with a neighbor list of low quality matches an entry with low MAP. We use Spearman's correlation ρ and the Kendall's rank correlation coefficient τ, which do not make any assumption about linearity and compare only the order of words classified according to their MAP with the order according to their confidence score. The results of these coefficients are given in Table 3, along with p-value of the associated test of significance. A coefficient

Correlation coefficient	value	statistical significance
Kendall τ	0.37	$p < 10^{-64}$
Spearman ρ	0.51	$p < 10^{-64}$

Table 3: Correlation coefficient values between the MAP and the confidence score, and their statistical significance (p-value).

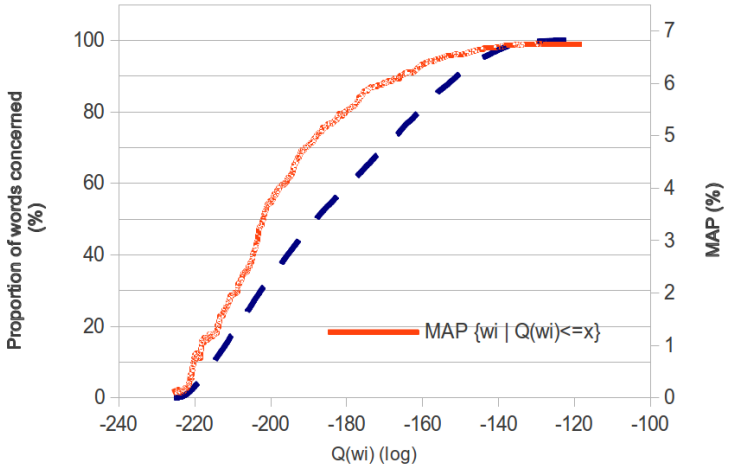


Figure 3: Average MAP computed on words with a confidence score lower than a threshold q (x-axis, log-scale), and cumulative proportion of concerned words.

value of 1 indicates a perfect correlation, 0 no correlation and -1 an inverse correlation. A low p-value, for example < 0.05, indicates a statistically significant result. The confidence scores are obtained with $k = 20$. Other experiments, not reported here, show that this parameter k has little influence on the correlation, for values between 5 and 100.

These measures attest to some statistically significant correlation between our confidence score and the MAP, however this correlation is imperfect and non-linear. We compute the average MAP on neighbor lists with a confidence score lower than a threshold q. Figure 3 represents the average MAP (y-axis) in function of the threshold q (x-axis). It shows that the confidence score is still a good indicator of quality, as the MAP decreases with the confidence score.

The confidence score can be used to improve the performance of aggregation techniques presented in Section 4 by integrating it in the final score:

$$\text{score}_{w_i}(w_j) = Q(w_j) * \text{Aggreg}(1 - \tau_{w_i}(w_j)/n, 1 - \tau_{w_j}(w_i)/n) \quad (6)$$

As shown in Table 4, using this information allows even greater gains than those reported in the previous section (a Wilcoxon test ($p < 0.05$) (Hull, 1993) is performed to ensure that the differences are statistically significant; non-significant ones are shown in italics). In the next section, we propose another use of the confidence scores to improve results more specifically on the head of the lists, that is to say on the neighbors judged closest.

Method	MAP	R-Prec	P@1	P@5	P@10	P@50	P@100
S_{Hamacher} $\gamma = 0.95$	9.61 (+7.20)	11.59 (+5.85)	*30.86 (-0.53)*	19.52 (+5.83)	14.76 (+7.24)	7.03 (+8.88)	4.93 (+8.67)

Table 4: Performance gains (%) by reciprocal rank aggregation using the confidence score, on WordNet+Moby reference.

Target	MAP	R-Prec	P@1	P@5	P@10
all words	9.16 (+2.17)	11.24 (+2.76)	*30.73 (-1.02)*	19.30 (+4.64)	14.37 (+4.44)
the third of words with the lowest $Q(w)$	9.55 (+6.44)	11.81 (+7.99)	31.85 (+2.56)	20.43 (+10.81)	15.46 (+12.37)

Table 5: Performance gains (%) of reranking with the Hungarian algorithm.

6 Local reranking

The previous method gives an overall score to the list, but one can also make use of the individual ranking probabilities $p(\delta(w_i, w_j))$, estimated according to the method of Parzen windows. For a given word w, we have for each of its neighbors w_j the probability of his current rank: $p(\delta(w, w_j)) = \tau_w(w_j)$. For a given neighbor w_j, we can also calculate the probability of any other rank τ: $p(\delta(w, w_j)) = \tau$ with $\tau = 1, 2, ...$ In this section, we propose to rely on these more local information to improve the performance by reranking the k-nearest neighbors.

6.1 Reranking by the Hungarian algorithm

A simple approach would be to reorder the list based on this criterion, from the most probable neighbors to the least ones. But ranking probability estimation for each word is imperfect, and such a reranking strongly degrades the results. We therefore propose instead a method to rerank the k-nearest neighbors on a more local and controlled manner: a word that was not originally in the k-nearest neighbors can not become a k-nearest neighbor, and a word can not be reranked too far from its original rank.

Our problem is expressed by the following matrix $\mathcal{M}_{\text{profit}}$. The rows correspond to words in their original ranks (denoted w_1 to w_k), the columns to new ranks τ at which these words can be assigned, and matrix values are the probabilities of each word w_j to appear at rank τ. Given these probabilities, the goal is to find the most likely permutation of the k-nearest neighbors.

$$\mathcal{M}_{\text{profit}} = \begin{pmatrix} p(\delta(w, w_1) = 1) & \cdots & p(\delta(w, w_1) = k) \\ \vdots & \ddots & \vdots \\ p(\delta(w, w_k) = 1) & \cdots & p(\delta(w, w_k) = k) \end{pmatrix}$$

As pointed out, we want to avoid that an initially very close neighbor was moved far away and vice versa. This constraint is added by multiplying the matrix $\mathcal{M}_{\text{profit}}$ by a penalty matrix $\mathcal{M}_{\text{penalty}}$ (see below) with the Hadamard product (element by element matrix product, denoted $\circ$).

$$\mathcal{M}_{\text{penalty}} = \begin{pmatrix} 1 & \frac{k-1}{k} & \cdots & 0 \\ \frac{k-1}{k} & 1 & \cdots & \frac{1}{k} \\ \vdots & \ddots & \vdots & \\ 0 & \frac{1}{k} & \cdots & 1 \end{pmatrix}$$

We then face a combinatorial optimization problem which can be solved in polynomial time by the Hungarian method (Kuhn and Yaw, 1955, for a description of the algorithm) on the matrix of assignment costs $\mathcal{M}_{\text{profit}} \circ \mathcal{M}_{\text{penalty}}$. This algorithm was originally proposed to optimize the assignment of workers (in our case, the neighbors) on tasks (in our case, ranks), according to the profit generated by each worker for each task (in our case, the probability that a neighbor stands at a given rank). The result of this algorithm therefore indicates a new rank for each word. The algorithm converges to an optimal solution with a complexity $\mathcal{O}(k^3)$ (for reranking the k-nearest neighbors).

6.2 Results

Table 5 presents the performance achieved by our local reranking method compared to the adjusted Okapi-BM25 reference using the same experimental conditions as above. As before, the considered neighborhood is set to $k = 20$. Precisions beyond this threshold are unchanged and thus not reported. We test the effectiveness of the local reranking on all neighbor lists and on a third of lists with the lowest quality scores.

It appears that the reranking on the whole lists does not provide a real gain. However, the gain is substantial on the lists with low confidence score. Moreover, unlike the experiments of section 4, these

gains apply by construction to the heads of lists, which are most likely to be used in practice. This difference between results on the whole set of words and on those with the lowest confidence scores can be explained in two ways. First, the lists with the highest confidence scores correspond largely to the lists with the best MAP, as expected and illustrated in Figure 3. This therefore suggests a priori little room for improvement. Second, regardless of MAP, we can also assume that these lists already have an optimum arrangement of individual probabilities that explains the high confidence score. The reranking thus concerns only few neighbors.

7 Conclusion and future work

The different contributions proposed in this article do not place themselves all at the same level. The thesaurus construction using tools from the IR is not a major conceptual innovation, but this approach seems curiously unexplored although it provides very competitive results while requiring minimum implementations through existing tools from IR.

The various propositions exploiting the neighborhood graph to improve the thesaurus are part of a more original approach where the whole thesaurus is considered. We have specifically examined the aspects of reciprocity and distance, in terms of rank, between two words to offer several contributions. The improvements obtained by aggregation over all neighbors or by the local reranking from confidence scores validate our approach. It should be noted that the gains are small in absolute terms, but, compared to those observed in the field, correspond to significant improvements.

The various aspects of this work open up many prospects of research. For example, many other aggregate functions in addition to those tested in section 4 exist in the literature. Some may even offer the possibility of integrating the confidence score associated with each neighbor, as Choquet's or Sugeno's integrals (Detyniecki, 2000). More generally, it would be interesting to iteratively use improvements of neighbor lists to update the confidence scores, etc., in the spirit for example of what is proposed by Pedronette et al. (2014). A detailled analysis of the impact of these techniques according to the type of semantic relation is still to be performed. Beyond the distributional thesauri construction, the proposed methods to compute confidence scores or reorder lists of neighbors can be applied to other problems where the k-nearest neighbor graphs of are built. Also note that we have only considered a small part of the information carried by the neighborhood graph. We focused on the aspects of reciprocity, but taking into account other aspects of the graph (in particular the transitivity, or more generally its topology), could lead to further improvements.

Abstract

Compositional Distributional Semantics Models (CDSMs) are traditionally seen as an entire different world with respect to Tree Kernels (TKs). In this paper, we show that under a suitable regime these two approaches can be regarded as the same and, thus, structural information and distributional semantics can successfully cooperate in CSDMs for NLP tasks. Leveraging on distributed trees, we present a novel class of CDSMs that encode both structure and distributional meaning: the distributed smoothed trees (DSTs). By using DSTs to compute the similarity among sentences, we implicitly define the distributed smoothed tree kernels (DSTKs). Experiment with our DSTs show that DSTKs approximate the corresponding smoothed tree kernels (STKs). Thus, DSTs encode both structural and distributional semantics of text fragments as STKs do. Experiments on RTE and STS show that distributional semantics encoded in DSTKs increase performance over structure-only kernels.

1 Introduction

Compositional distributional semantics is a flourishing research area that leverages distributional semantics (see Turney and Pantel (2010), Baroni and Lenci (2010)) to produce meaning of simple phrases and full sentences (hereafter called *text fragments*). The aim is to scale up the success of word-level relatedness detection to longer fragments of text. Determining similarity or relatedness among sentences is useful for many applications, such as multi-document summarization, recognizing textual entailment (Dagan et al., 2013), and semantic textual similarity detection (Agirre et al., 2013).

Compositional distributional semantics models (CDSMs) are functions mapping text fragments to vectors (or higher-order tensors). Functions for simple phrases directly map distributional vectors of words to distributional vectors for the phrases (Mitchell and Lapata, 2008; Baroni and Zamparelli, 2010; Clark et al., 2008; Grefenstette and Sadrzadeh, 2011; Zanzotto et al., 2010). Functions for full sentences are generally defined as recursive functions over the ones for phrases (Socher et al., 2011; Socher et al., 2012; Kalchbrenner and Blunsom, 2013). Distributional vectors for text fragments are then used as inner layers in neural networks, or to compute similarity among text fragments via dot product.

CDSMs generally exploit structured representations t^x of text fragments x to derive their meaning $f(t^x)$, but the structural information, although extremely important, is obfuscated in the final vectors. Structure and meaning can interact in unexpected ways when computing cosine similarity (or dot product) between vectors of two text fragments, as shown for full additive models in (Ferrone and Zanzotto, 2013). Smoothed tree kernels (STK) (Mehdad et al., 2010; Croce et al., 2011) instead realize a clearer interaction between structural information and distributional meaning. STKs are specific realizations of convolution kernels (Haussler, 1999) where the similarity function is recursively (and, thus, compositionally) computed. Distributional vectors are used to represent word meaning in computing the similarity among nodes. STKs, however, are not considered part of the CDSMs family. As usual in kernel machines

Proceedings of COLING 2014, the 25th International Conference on Computational Linguistics: Technical Papers, pages 721–730, Dublin, Ireland, August 23-29 2014.

(Cristianini and Shawe-Taylor, 2000), STKs directly compute the similarity between two text fragments x and y over their tree representations t^x and t^y, that is, $STK(t^x, t^y)$. The function f that maps trees into vectors is only implicitly used, and, thus, $STK(t^x, t^y)$ is not explicitly expressed as the dot product or the cosine between $f(t^x)$ and $f(t^y)$. Such a function f, which is the underlying reproducing function of the kernel (Aronszajn, 1950), is a CDSM since it maps trees to vectors by using distributional meaning. However, the huge dimensionality of $\mathbb{R}^n$ (since it has to represent the set of all possible subtrees) prevents to actually compute the function $f(t)$, which thus can only remain *implicit*.

Distributed tree kernels (DTK) (Zanzotto and Dell'Arciprete, 2012) partially solve the last problem. DTKs approximate standard tree kernels (such as (Collins and Duffy, 2002)) by defining an *explicit* function DT that maps trees to vectors in $\mathbb{R}^m$ where $m \ll n$ and $\mathbb{R}^n$ is the explicit space for tree kernels. DTKs approximate standard tree kernels (TK), that is, $\langle DT(t^x), DT(t^y)\rangle \approx TK(t^x, t^y)$, by approximating the corresponding reproducing function (Aronszajn, 1950). Thus, these distributed trees are small vectors that encode structural information. In DTKs tree nodes u and v (and then also words) are represented by nearly orthonormal vectors, that is, vectors $\vec{u}$ and $\vec{v}$ such that $\langle \vec{u}, \vec{v}\rangle \approx \delta(\vec{u}, \vec{v})$ where δ is the Kroneker's delta. This is in contrast with distributional semantics vectors where $\langle \vec{u}, \vec{v}\rangle$ is allowed to be any value in $[0, 1]$ according to the similarity between the words v and u. Thus, early attempts to include distributional vectors in the DTs failed (Zanzotto and Dell'Arciprete, 2011).

In this paper, leveraging on distributed trees, we present a novel class of CDSMs that encode both structure and distributional meaning: the distributed smoothed trees (DST). DSTs carry structure and distributional meaning on a 2-dimensional tensor (a matrix): one dimension encodes the structure and one dimension encodes the meaning. By using DSTs to compute the similarity among sentences with a generalized dot product (or cosine), we implicitly define the distributed smoothed tree kernels (DSTK) which approximate the corresponding STKs. We present two DSTs along with the two smoothed tree kernels (STKs) that they approximate. We experiment with our DSTs to show that their generalized dot products approximate STKs by directly comparing the produced similarities and by comparing their performances on two tasks: recognizing textual entailment (RTE) and semantic similarity detection (STS). Both experiments show that the dot product on DSTs approximates STKs and, thus, DSTs encode both structural and distributional semantics of text fragments in tractable 2-dimensional tensors. Experiments on STS and RTE show that distributional semantics encoded in DSTs increases performance over structure-only kernels. DSTs are the first positive way of taking into account both structure and distributional meaning in CDSMs.

The rest of the paper is organized as follows. Section 2 introduces the basic notation used in the paper. Section 3 describe our distributed smoothed trees as compositional distributional semantic models that can represent both structural and semantic information. Section 4 reports on the experiments. Finally, Section 5 draws some conclusions.

2 Notation

Before describing the *distributed smoothed trees* (DST) we introduce a formal way to denote constituency-based *lexicalized parse trees*, as DSTs exploit this kind of data structures.

Lexicalized trees are denoted with the letter t and $N(t)$ denotes the set of non terminal nodes of tree t. Each non-terminal node $n \in N(t)$ has a label l_n composed of two parts $l_n = (s_n, w_n)$: s_n is the syntactic label, while w_n is the semantic headword of the tree headed by n, along with its part-of-speech tag. For example, the root node of the tree in Fig.1 has the label S:*booked::v* where S is the syntactic information and *booked::v* is the semantic head of the whole tree. Terminal nodes of trees are treated differently, these nodes represent only words w_n without any additional information, and their labels thus only consist of the word itself (see Fig. 1). The structure of a tree is represented as follows: Given a tree t, $\mathsf{h}(t)$ is its root node and $\mathsf{s}(t)$ is the tree formed from t but considering only the syntactic structure (that is, only the s_n part of the labels), $c_i(n)$ denotes i-th child of a node n. As usual for constituency-based parse trees, pre-terminal nodes are nodes that have a single terminal node as child. Finally, $\vec{s_n} \in \mathbb{R}^m$ and $\vec{w_n} \in \mathbb{R}^k$ represent respectively *distributed* vectors for node labels s_n and *distributional* vectors for words w_n, whereas $\mathbf{T}$ represents the matrix of a tree t encoding structure and distributional meaning. The difference between distributed and distributional vectors is described in the next section.

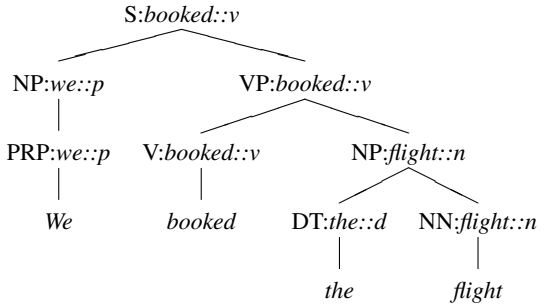

Figure 1: A lexicalized trees

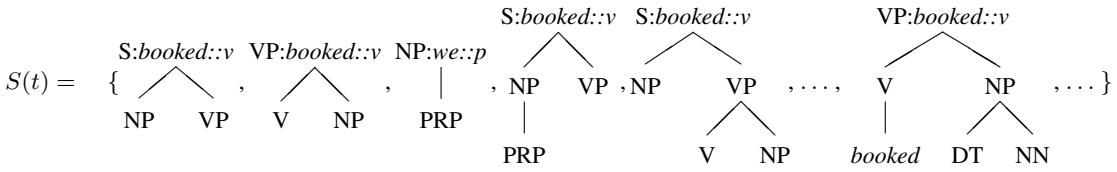

Figure 2: Subtrees of the tree t in Figure 1 (a non-exhaustive list)

3 Distributed Smoothed Trees as Compositional Distributional Semantic Models

We define Distributed Smoothed Trees as recursive functions DST mapping lexicalized trees t to $\mathbb{R}^{m \times k}$ where matrices $\mathbf{T} = DST(t)$ encode both syntactic structures and distributional vectors. DSTs are thus compositional distributional models, as they map lexicalized trees to matrices, and they are defined recursively on distributed vectors for syntactic node labels and distributional vectors for words. In the following we introduce DSTs: Section 3.1 gives a rough idea of the method, Section 3.2 describes how to recursively encode structures in vectors by means of distributed trees (Zanzotto and Dell'Arciprete, 2012), and finally Section 3.3 merges distributed trees and distributional semantic vectors in matrices.

3.1 The method in a glance

We describe here the approach in a few sentences. In line with tree kernels over structures (Collins and Duffy, 2002), we introduce the set $S(t)$ of the subtrees t_i of a given lexicalized tree t. A subtree t_i is in the set $S(t)$ if $\mathsf{s}(t_i)$ is a subtree of $\mathsf{s}(t)$ and, if n is a node in t_i, all the siblings of n in t are in t_i. For each node of t_i we only consider its syntactic label s_n, except for the head $\mathsf{h}(t_i)$ for which we also consider its semantic component w_n. Figure 2 reports a sample for the subtrees of the tree in Fig. 1 The recursive functions DSTs we define compute the following:

$$\mathbf{T} = \sum_{t_i \in S(t)} \mathbf{T}_i$$

where $\mathbf{T}_i$ is the matrix associated to each subtree t_i. The similarity between two text fragments a and b represented as lexicalized trees t^a and t^b can be computed using the Frobenius product between the two matrices $\mathbf{T}^a$ and $\mathbf{T}^b$, that is:

$$\langle \mathbf{T}^a, \mathbf{T}^b \rangle_F = \sum_{\substack{t_i^a \in S(t^a) \\ t_j^b \in S(t^b)}} \langle \mathbf{T}_i^a, \mathbf{T}_j^b \rangle_F \quad (1)$$

We want to obtain that the product $\langle \mathbf{T}_i^a, \mathbf{T}_j^b \rangle_F$ approximates the dot product between the distributional vectors of the head words ($\langle \mathbf{T}_i^a, \mathbf{T}_j^b \rangle_F \approx \langle \mathsf{h}(\overrightarrow{t_i^a}), \mathsf{h}(\overrightarrow{t_j^b}) \rangle$) whenever the syntactic structure of the subtrees is the same (that is $\mathsf{s}(t_i^a) = \mathsf{s}(t_j^b)$), and $\langle \mathbf{T}_i^a, \mathbf{T}_j^b \rangle_F \approx 0$ otherwise. This property is expressed as:

$$\langle \mathbf{T}_i^a, \mathbf{T}_j^b \rangle_F \approx \delta(\mathsf{s}(t_i^a), \mathsf{s}(t_j^b)) \cdot \langle \mathsf{h}(\overrightarrow{t_i^a}), \mathsf{h}(\overrightarrow{t_j^b}) \rangle \quad (2)$$

3.2 Representing Syntactic Structures with Distributed Trees

Distributed trees (Zanzotto and Dell'Arciprete, 2012) recursively encode syntactic trees t in small vectors by means of a recursive function DT. These DTs preserve structural information as the dot product between the DTs of two trees approximates the classical tree kernels TK as defined by Collins and Duffy (2002), that is, $TK(t^a, t^b) \approx \langle DT(t^a), DT(t^b) \rangle$. To obtain this result, distributed trees $DT(t)$ are defined as follows:

$$DT(t) = \sum_{t_i \in S(t)} \sqrt{\lambda^{|N(t_i)|}} \; \vec{\mathsf{s}}(t_i) \tag{3}$$

where $S(t)$ is again the set of the subtrees of t, $\vec{\mathsf{s}}(t_i)$ are vectors in $\mathbb{R}^m$ corresponding to tree fragment t_i and $\sqrt{\lambda^{|N(t_i)|}}$ is the weight of subtree t_i in the final feature space, with λ being the traditional parameter used to penalize large subtrees and $|N(t_i)|$ being the number of nodes in t_i. The approximation of tree kernels is then given by the fact that $\langle \vec{\mathsf{s}}(t_i), \vec{\mathsf{s}}(t_j) \rangle \approx \delta(\mathsf{s}(t_i), \mathsf{s}(t_j))$. Vectors with this property are called *distributed vectors*. A key feature of the distributed vectors of subtrees $\vec{\mathsf{s}}(t_i)$ is that these vectors are built compositionally from a set $\mathcal{N}$ of *nearly orthonormal random vectors* $\vec{s_n}$, that are associated to each node label. Given a subtree $\mathsf{s}(t_i)$, the related vector is obtained as:

$$\vec{\mathsf{s}}(t_i) = \vec{s_{n_1}} \odot \vec{s_{n_2}} \odot \ldots \odot \vec{s_{n_k}} = \bigodot_{(s_n, w_n) \in N(t_i)} \vec{s_n}$$

where node vectors $\vec{s_{n_i}}$ are ordered according to a depth-first visit of subtree t_i and $\odot$ is a vector composition operation, specifically the *shuffled circular convolution*[1]. This function guarantees that two different subtrees have nearly orthonormal vectors (see (Zanzotto and Dell'Arciprete, 2012) for more details). For example, the fifth tree t_5 of set $S(t)$ in Figure 2 is $\vec{\mathsf{s}}(t_5) = \vec{S} \odot (\vec{NP} \odot (\vec{VP} \odot (\vec{V} \odot \vec{NP})))$. Thus, DTs in Equation 3 can be recursively defined as:

$$DT(t) = \sum_{n \in N(t)} \sigma(n) \tag{4}$$

where $\sigma(n)$ is recursively defined as follows:

$$\sigma(n) = \begin{cases} \sqrt{\lambda}\,(\vec{s_n} \odot \vec{w}) & \text{if } n \text{ is a pre-terminal node} \\ \sqrt{\lambda}\,\vec{s_n} \odot (\bigodot_i (\vec{s_{c_i(n)}} + \sigma(c_i(n)))) & \text{if } n \text{ is an internal node} \end{cases} \tag{5}$$

The vector $\sigma(n)$ encodes all the subtrees that have root in n along with their penalizing weight $\sqrt{\lambda^{|N(t_i)|}}$, that is:

$$\sigma(n) = \sum_{t_i \in S(t) \wedge \mathsf{h}(t_i) = n} \sqrt{\lambda^{|N(t_i)|}} \; \vec{\mathsf{s}}(t_i)$$

This is what we need in order to define our *distributed smoothed trees*.

3.3 Representing distributional meaning and distributed structure with matrices

We now move from distributed trees (encoded as small vectors) to distributed smoothed trees (DST) represented as matrices. DST is a function that maps trees t to matrices $\mathbf{T}$. In analogy with Equation 4, DST is defined as:

$$DST(t) = \sum_{n \in N(t)} S(n)$$

where $S(n)$ is now defined as:

$$S(n) = \sigma(n) \vec{w_n}^{\top}$$

[1] The *shuffled circular convolution* $\odot$ is defined as $\vec{a} \odot \vec{b} = s_1(\vec{a}) * s_2(\vec{b})$ where $*$ is the circular convolution and s_1 and s_2 are two different (but fixed) random permutations of vector elements.

where $\sigma(n)$ is the one defined in Equation 5 and $(\cdot)^\top$ is vector transposition. By combining the two equations, $DST(t)$ is the sum of the matrices described in Equation 1:

$$DST(t) = \sum_{n \in N(t)} \sum_{t_i \in S(t) \wedge \mathsf{h}(t_i)=n} \sqrt{\lambda^{|N(t_i)|}}\ \vec{\mathsf{s}(t_i)} \vec{w_n}^\top = \sum_{t_i \in S(t)} \vec{\mathsf{s}(t_i)} \vec{w_n}^\top$$

where n is $\mathsf{h}(t_i)$ and $\mathbf{T}_i = \vec{\mathsf{s}(t_i)} \vec{w_{\mathsf{h}(t_i)}}^\top$ is the outer product between the distributed vector $\vec{\mathsf{s}(t_i)}$ and the distributional vector $\vec{w_{\mathsf{h}(t_i)}}$. There is an important property of the outer product that applies to the Frobenius product: $\langle \vec{a}\vec{w}^\top, \vec{b}\vec{v}^\top \rangle_F = \langle \vec{a}, \vec{b} \rangle \cdot \langle \vec{w}, \vec{v} \rangle$. Using this property, we have that Equation 2 is satisfied as:

$$\langle \mathbf{T}_i, \mathbf{T}_j \rangle_F = \langle \vec{\mathsf{s}(t_i)}, \vec{\mathsf{s}(t_j)} \rangle \cdot \langle \vec{w_{h(t_i)}}, \vec{w_{h(t_j)}} \rangle \approx \delta(\mathsf{s}(t_i), \mathsf{s}(t_j)) \cdot \langle \vec{w_{h(t_i)}}, \vec{w_{h(t_j)}} \rangle$$

We refer to the Frobenius product of two distributed smoothed trees as *distributed smoothed tree kernel* (DSTK). These DSTKs are approximating the smoothed tree kernels described in the next section. We propose two versions of our DSTKs according to how we produce distributional vectors for words. We have a plain version $DSTK_0$ when we use distributional vectors $\vec{w_n}$ as they are, and a slightly modified version $DSTK_{+1}$ when we use as distributional vectors $\vec{w_n}' = \begin{pmatrix} 1 & \vec{w_n} \end{pmatrix}$.

3.4 The Approximated Smoothed Tree Kernels

The two CDSMs we proposed, that is, the two distributed smoothed tree kernels $DSTK_0$ and $DSTK_{+1}$, are approximating two specific tree kernels belonging to the smoothed tree kernels class (e.g., (Mehdad et al., 2010; Croce et al., 2011)). These two specific smoothed tree kernels recursively compute (but, the recursive formulation is not given here) the following general equation:

$$STK(t^a, t^b) = \sum_{\substack{t_i \in S(t^a) \\ t_j \in S(t^b)}} \omega(t_i, t_j)$$

where $\omega(t_i, t_j)$ is the similarity weight between two subtrees t_i and t_j. $DTSK_0$ and $DSTK_{+1}$ approximate respectively STK_0 and STK_{+1} where the weights are defined as follows:

$$\omega_0(t_i, t_j) = \langle \vec{w_{\mathsf{h}(t_i)}}, \vec{w_{\mathsf{h}(t_j)}} \rangle \cdot \delta(\mathsf{s}(t_i), \mathsf{s}(t_j)) \cdot \sqrt{\lambda^{|N(t_i)|+|N(t_j)|}}$$

$$\omega_{+1}(t_i, t_j) = (\langle \vec{w_{\mathsf{h}(t_i)}}, \vec{w_{\mathsf{h}(t_j)}} \rangle + 1) \cdot \delta(\mathsf{s}(t_i), \mathsf{s}(t_j)) \cdot \sqrt{\lambda^{|N(t_i)|+|N(t_j)|}}$$

STK_{+1} is actually computing a sum between STK_0 and the tree kernel (Collins and Duffy, 2002).

4 Experimental investigation

4.1 Experimental set-up

Generic settings We experimented with two datasets: the Recognizing Textual Entailment datasets (RTE) (Dagan et al., 2006) and the the Semantic Textual Similarity 2013 datasets (STS) (Agirre et al., 2013). The STS task consists of determining the degree of similarity (ranging from 0 to 5) between two sentences. We used the data for core task of the 2013 challenge data. The STS datasets contains 5 datasets: headlines, OnWN, FNWN, SMT and MSRpar, which contains respectively 750, 561, 189, 750 and 1500 pairs. The first four datasets were used for testing, while all the training has been done on the fifth. RTE is instead the task of deciding whether a long text T entails a shorter text, typically a single sentence, called hypothesis H. It has been often seen as a classification task (see (Dagan et al., 2013)). We used four datasets: RTE1, RTE2, RTE3, and RTE5, with the standard split between training and testing. The dev/test distribution for RTE1-3, and RTE5 is respectively 567/800, 800/800, 800/800, and 600/600 T-H pairs. Distributional vectors are derived with DISSECT (Dinu et al., 2013) from a corpus obtained by the concatenation of ukWaC (wacky.sslmit.unibo.it), a mid-2009 dump of

		RTE1	RTE2	RTE3	RTE5	headl	FNWN	OnWN	SMT
STK_0 vs $DSTK_0$	1024	0.86	0.84	0.90	0.84	0.87	0.65	0.95	0.77
	2048	0.87	0.84	0.91	0.84	0.90	0.65	0.96	0.77
STK_{+1} vs $DSTK_{+1}$	1024	0.81	0.77	0.83	0.72	0.88	0.53	0.93	0.66
	2048	0.82	0.78	0.84	0.74	0.91	0.56	0.94	0.67

Table 1: Spearman's correlation between Distributed Smoothed Tree Kernels and Smoothed Tree Kernels

the English Wikipedia (en.wikipedia.org) and the British National Corpus (www.natcorp.ox.ac.uk), for a total of about 2.8 billion words. We collected a 35K-by-35K matrix by counting co-occurrence of the 30K most frequent content lemmas in the corpus (nouns, adjectives and verbs) and all the content lemmas occurring in the datasets within a 3 word window. The raw count vectors were transformed into positive Pointwise Mutual Information scores and reduced to 300 dimensions by Singular Value Decomposition. This setup was picked without tuning, as we found it effective in previous, unrelated experiments. To build our DTSKs and for the two baseline kernels TK and DTK, we used the implementation of the distributed tree kernels[2]. We used: 1024 and 2048 as the dimension of the distributed vectors, the weight λ is set to 0.4 as it is a value generally considered optimal for many applications (see also (Zanzotto and Dell'Arciprete, 2012)). The statistical significance, where reported, is computed according to the sign test.

Direct correlation settings For the *direct correlation* experiments, we used the RTE data sets and the testing sets of the STS dataset (that is, *headlines*, *OnWN*, *FNWN*, *SMT*). We computed the Spearman's correlation between values produced by our $DSTK_0$ and $DSTK_{+1}$ and produced by the standard versions of the smoothed tree kernel, that is, respectively, STK_0 and STK_{+1}. We obtained text fragment pairs by randomly sampling two text fragments in the selected set. For each set, we produced exactly the number of examples in the set, e.g., we produced 567 pairs for RTE1 dev, etc..

Task-based settings For the *task-based* experiments, we compared systems using the standard evaluation measure and the standard split in the respective challenges. As usual in RTE challenges the measure used is the accuracy, as testing sets have the same number of entailment and non-entailment pairs. For STS, we used MSRpar as training, and we used the 4 test sets as testing. We compared systems using the Pearson's correlation as the standard evaluation measure for the challenge[3]. Thus, results can be compared with the results of the challenge.

As classifier and regression learner, we used the java version of LIBSVM (Chang and Lin, 2011). In the two tasks we used in a different way our DSTs (and the related STKs) within the learners. In the following, we refer to instances in RTE or STS as pairs $p = (t^a, t^b)$ where t^a and t^b are the two parse trees for the two sentences a and b for STS and for the text a and the hypothesis b in RTE.

We will indicate with $K(p_1, p_2)$ the final kernel used in the learning algorithm, which takes as input two training instances, while we will use κ to denote either any of our DSTK (that is, $\kappa(x, y) = \langle DST(x), DST(y)\rangle$) or any of the standard smoothed tree kernels (that is, $\kappa(x, y) = STK(x, y)$).

In STS, we encoded only similarity feature between the two sentences. Thus, we used two classes of kernels: (1) the syntactic/semantic class (SS) with the final kernel defined as $K(p_1, p_2) = (\kappa(t^a_1, t^b_1) \cdot \kappa(t^a_2, t^b_2) + 1)^2$; and, (2) the SS class along with token-based similarity (SSTS) where the final kernel is $K(p_1, p_2) = (\kappa(t^a_1, t^b_1) \cdot \kappa(t^a_2, t^b_2) + TS(a_1, b_1) \cdot TS(a_2, b_2) + 1)^2$ where $TS(a, b)$ counts the percent of the common content tokens in a and b.

In RTE, we followed standard approaches (Dagan et al., 2013; Zanzotto et al., 2009), that is, we exploited two models: a model with only a rewrite rule feature space (RR) and a model with the previous space along with a token-level similarity feature (RRTWS). The two models use our DSTs and the standard STKs in the following way as kernel functions: (1) $RR(p_1, p_2) = \kappa(t^a_1, t^a_2) + \kappa(t^b_1, t^b_2)$; (2) $RRTS(p_1, p_2) = \kappa(t^a_1, t^a_2) + \kappa(t^b_1, t^b_2) + (TWS(a_1, b_1) \cdot TS(a_2, b_2) + 1)^2$ where TWS is a weighted token similarity as in Corley and Mihalcea (2005).

Table 2: Task-based analysis: Correlation on Semantic Textual Similarity († is different from DTK, TK, $DSTK_{+1}$, and STK_{+1} with a stat.sig. of $p > 0.1$; $*$ the difference between the kernel and its distributed version is not stat.sig.)

We also used two standard and simple CDSMs to compare with: the Additive model (Add) and the Multiplicative model (Mult) as firstly discussed in Mitchell and Lapata (2008). The Additive Model performs a sum of all the distributional vectors of the content words in the text fragment and the Multiplicative model performs an element-wise product among all the content vectors. These are used in the above models as $\kappa(a, b)$.

Finally, to investigate whether our DSTKs behave better than purely structural models, we experimented with the classical tree kernel (TK) (Collins and Duffy, 2002) and the distributed tree kernel (DTK) (Zanzotto and Dell'Arciprete, 2012). Again, these kernels are used in the above models as $\kappa(t_a, t_b)$.

4.2 Results

Table 1 reports the results for the correlation experiments. We report the Spearman's correlations over the different sets (and different dimensions of distributed vectors) between our $DSTK_0$ and the STK_0 (first two rows) and between our $DSTK_{+1}$ and the corresponding STK_{+1} (second two rows) . The correlation is above 0.80 in average for both RTE and STS datasets in the case of $DSTK_0$ and the STK_0. The correlation between $DSTK_{+1}$ and the corresponding STK_{+1} is instead a little bit lower. This depends on the fact that $DSTK_{+1}$ is approximating the sum of two kernels the TK and the STK_0 (as STK_{+1} is the sum of the two kernels). Then, the underlying feature space is bigger with respect to the one of STK_0 and, thus, approximating it is more difficult. The approximation also depends on the size of the distributed vectors. Higher dimensions yield to better approximation: if we increase the distributed vectors dimension from 1024 to 2048 the correlation between $DSTK_{+1}$ and STK_{+1} increases up to 0.80 on RTE and up to 0.77 on STS. This direct analysis of the correlation shows that our CDSM are approximating the corresponding kernel function and there is room of improvement by increasing the size of distributed vectors. Task-based experiments confirm the above trend. Table 2 and Table 3, respectively, report the correlation of different systems on STS and the accuracies of the different systems on RTE. Our CDSMs are compared against baseline systems (Add, $Mult$, TK, and DTK) in order to understand whether in the specific tasks our more complex model is interesting, and against, again, the systems with the corresponding smoothed tree kernels in order to explore whether our DSTKs approximate systems based on STKs. For all this set of experiment we fixed the dimension of the distributed vectors to 1024. Table 2 is organized as follows: columns 2-6 report the correlation of the STS systems based on syntactic/semantic similarity (SS) and columns 7-11 report the accuracies of SS systems along with token-based similarity (SSTS). The first observation for this task is that baseline systems based only on the token similarity (first row) behave extremely well. These results are above many models presented in the 2013 Shared Task (see (Agirre et al., 2013)). This can be disappointing as we cannot appreciate differences among methods in the columns SSTS. But, focusing on the results without this important token-based similarity, we can better understand if our model is capturing both structural and semantic information, that is, if DSTKs behave similarly to STKs. It is also useless to compare results of DSTKs and STKs to the Add baseline model as Add is basically doing a weighted count of the common words

	RR					RRTWS

STK_{+1}	0.586	0.562	0.542	0.546	0.559^{*}	0.638	0.618	0.650	0.636	0.635^{*}

Table 3: Task-based analysis: Accuracy on Recognizing Textual Entailment († is different from DTK and TK wiht a stat.sig. of $p > 0.1$; $*$ the difference between the kernel and its distributed counterpart is not statistically significant.)

that is exactly what the token-based similarity is doing. Add slightly decreases the performance of the token-based similarity. The $Mult$ model instead behaves very poorly. Comparing rows in the SS columns, we can discover that $DSTK_0$ and $DSTK_{+1}$ behave significantly better than DTK and that $DSTK_0$ behave better than the standard TK. Thus, our DSTKs are positively exploitng distributional semantic information along with structural information. Moreover, both $DSTK_0$ and $DSTK_{+1}$ behave similarly to the corresponding models with standard kernels STKs. Results in this task confirm that structural and semantic information are both captured by CDSMs based on DSTs.

Table 3 is organized as follows: columns 2-6 report the accuracy of the RTE systems based on rewrite rules (RR) and columns 7-11 report the accuracies of RR systems along with token similarity (RRTS). Results on RTE are extremely promising as all the models including structural information and distributional semantics have better results than the two baseline models with a statistical significance of 93.7%. For RR models $DTSK_0$, STK_0, $DSTK_{+1}$, and STK_{+1} have an average accuracy 7.9% higher than Add and 11.4% higher than $Mult$ model. For RRTS, the same happens with an average accuracy 9.58% higher than Add and 9.2% higher than the $Mult$. This task is more sensible to syntactic information than STS. As expected (Mehdad et al., 2010), STKs behave also better than tree kernels exploiting only syntactic information. But, more importantly, our CDSMs based on the DSTs are behaving similarly to these smoothed tree kernels, in contrast to what reported in (Zanzotto and Dell'Arciprete, 2011). In (Polajnar et al., 2013), it appears that results of the Zanzotto and Dell'Arciprete (2011)'s method are comparable to the results of STKs for STS, but this is mainly due to the flattening of the performance given by the lexical token similarity feature which is extremely relevant in STS. Even if distributed tree kernels do not approximate well tree kernels with distributed vectors dimension of 1024, our smoothed versions of the distributed tree kernels approximate correctly the corresponding smoothed tree kernels. Their small difference is not statistically significant (less than 70%). The fact that our DSTKs behave significantly better than baseline models in RTE and they approximate the corresponding STKs shows that it is possible to positively exploit structural information in CDSMs.

5 Conclusions and Future Work

Distributed Smoothed Trees (DST) are a novel class of Compositional Distributional Semantics Models (CDSM) that effectively encode structural information and distributional semantics in tractable 2-dimensional tensors, as experiments show. The paper shows that DSTs contribute to close the gap between two apparently different approaches: CDSMs and convolution kernels (Haussler, 1999). This contribute to start a discussion on a deeper understanding of the representation power of structural information of existing CDSMs.

Abstract

Motivated by evidence in psycholinguistics and cognition, we propose a hierarchical distributed semantic model (DSM) that consists of low-dimensional manifolds built on semantic neighborhoods. Each semantic neighborhood is sparsely encoded and mapped into a low-dimensional space. Global operations are decomposed into local operations in multiple sub-spaces; results from these local operations are fused to come up with semantic relatedness estimates. Manifold DSM are constructed starting from a pairwise word-level semantic similarity matrix. The proposed model is evaluated on semantic similarity estimation task significantly improving on the state-of-the-art.

1 Introduction

The estimation of semantic similarity between words, sentences and documents is a fundamental problem for many research disciplines including computational linguistics (Malandrakis et al., 2011), semantic web (Corby et al., 2006), cognitive science and artificial intelligence (Resnik, 2011; Budanitsky and Hirst, 2001). In this paper, we study the geometrical structure of the lexical space in order to extract semantic relations among words. In (Karlgren et al., 2008), the high-dimensional lexical space is assumed to consist of manifolds of very low dimensionality that are embedded in this high dimensional space. The manifold hypothesis is compatible with evidence from psycholinguistics and cognitive science. In (Tenenbaum et al., 2011), the question *"How does the mind work?"* is answered as follows: cognitive organization is based on domains with similar items connected to each other and lexical information is represented hierarchically, i.e., a domain that consists of similar lexical entries may be represented by a more abstract concept. An example of such a domain is {*blue, red, yellow, pink, ...*} that corresponds by the concept of *color*. An inspiring analysis about the geometry of thought, as well as cognitive evidence for the low-dimensional manifold assumption can be found in (Gardenfors, 2000), e.g., the domain of color is argued to be cognitively represented as an one-dimensional manifold. Following the *low-dimensional manifold* hypothesis we propose to extend distributional semantic models (DSMs) into a hierarchical model of *domains* (or concepts) that contain semantically similar words. Global operations on the lexical space are decomposed into local operations on the low-dimensional domain sub-manifolds. Our goal is to exploit this hierarchical low-rank model to estimate relations between words, such as semantic similarity.

There has been much research interest on devising data-driven approaches for estimating semantic similarity between words. DSMs (Baroni and Lenci, 2010) are based on the distributional hypothesis of meaning (Harris, 1954) assuming that semantic similarity between words is a function of the overlap of their linguistic contexts. DSMs are typically constructed from co-occurrence statistics of word tuples that are extracted on existing corpora or on corpora specifically harvested from the web. In (Iosif and Potamianos, 2013), general-purpose, language-agnostic algorithms were proposed for estimating semantic similarity using no linguistic resources other than a corpus created via web queries. The key idea of this work was the construction of semantic networks and semantic neighborhoods that capture smooth

Proceedings of COLING 2014, the 25th International Conference on Computational Linguistics: Technical Papers, pages 731–740, Dublin, Ireland, August 23-29 2014.

co-occurrence and context similarity statistics. The majority of DSMs adopt high-dimensional representations, while the underlying space geometry is not explicitly taken into consideration during the design of algorithms aimed for performing several semantic tasks.

We propose the construction of a low-dimensional manifold DSM consting of four steps: 1) identify the domains that correspond to the low-dimensional manifolds, 2) run the dimensionality reduction algorithm for each domain, 3) construct a DSM for each domain, and 4) combine the manifold DSMs to come up with global measures of lexical relations. A variety of algorithms can be found in the literature for projecting a set of tokens into low dimensional sub-spaces, given a token similarity or dissimilarity matrix. Depending on the nature of the dataset, these projection algorithms may or may not preserve the local geometries of the original dataset. Most dimensionality reduction algorithms make the implicit assumption that the underlying space is metric, e.g., Multidimensional Scaling (MDS) (Torgerson, 1952) or Principal Component Analysis (PCA) (Jolliffe, 2005) or the ones using non-negative matrix factorization (Tsuge et al., 2001) and typically fail to capture the geometry of manifolds embedded in high dimensional spaces. A variety of dimensionality reduction algorithms have been developed that respect the local geometry. Some examples are the Isomap algorithm (Tenenbaum et al., 2000) that performs the projection based on a weighted neighborhood graph, Local Linear Embedings (LLE) (Roweis and Saul, 2000) that assigns neighbors to each data point, Random Projections (Baraniuk and Wakin, 2009), (Li et al., 2006) that preserves the manifold geometry by executing random linear projections and others (Hessian Eigenmaps (HLLE) (Donoho and Grimes, 2003); Maximum Variance Unfolding (MVU) (Wang, 2011)). The *manifold hypothesis* has also been studied by the representation learning community where the local geometry is disentangled from the global geometry mainly by using neighborhood graphs (Weston et al., 2012) or coding schemes (Yu et al., 2009). For a review see (Bengio et al., 2013).

A fundamental problem with all aforementioned methods when applied to lexical semantic spaces is that they do not account for ambiguous tokens, i.e., word senses. The main assumption of dimensionality reduction and manifold unfolding algorithms is that each token (word) belongs to a single sub-manifold. This in fact is not true for polysemous words, for example the word 'green' could belong both to the domain *colors*, as well as to the domain *plants*. In essence, lexical semantic spaces are manifolds that have singularities: the manifold collapses in the neighborhood of polysemous words that can be thought of *semantic black holes* that can instantaneously transfer you from one domain to another. Our proposed solution to this problem is to *allow words to live in multiple sub-manifolds*.

The algorithms proposed in this paper build on recent research work on distributional semantic models and manifold representational learning. Manifold DSMs can be trained directly from a corpus and do not require a-priori knowledge or any human-annotated resources (just like DSMs). We show that the proposed low-dimensional, sparse and hierarchical manifold representation significantly improves on the state-of-the-art for the problem of semantic similarity estimation.

2 Metrics of Semantic Similarity

Semantic similarity metrics can be broadly divided into the following types: (i) metrics that rely on knowledge resources (e.g., WordNet), and (ii) corpus-based that do not require any external knowledge source. Corpus-based metrics are formalized as Distributional Semantic Models (DSMs) (Baroni and Lenci, 2010) based on the distributional hypothesis of meaning (Harris, 1954). DSMs can be distinguished into (i) unstructured: use bag-of-words model (Iosif and Potamianos, 2010) and (ii) structured: exploitation of syntactic relationships between words (Grefenstette, 1994; Baroni and Lenci, 2010). The vector space model (VSM) constitutes the main implementation for both unstructured and structured DSMs. Cosine similarity constitutes a measurement of word similarity that is widely used on top of the VSM. The similarity between two words is estimated as the cosine of their respective vectors whose elements correspond to corpus-based co-occurrence statistics. In essence, the similarity between words is computed via second-order co-occurrences.

Direct (i.e., first-order) co-occurrences can be also used for the estimation of semantic similarity (Bollegala et al., 2007; Gracia et al., 2006). The exploitation of first-order co-occurrence statistics constitutes the simplest form of unstructured DSMs. A key parameter for such models is the definition of the context in which the words of interest co-occur: from entire documents (Bollegala et al., 2007) to paragraphs

(Véronis, 2004) and sentences (Iosif and Potamianos, 2013). The effect of co-occurrence context for the task of similarity computation between nouns is discussed in (Iosif and Potamianos, 2013). The underlying assumption is that two words that co-occur in a specified context are semantically related.

3 Collapsed Manifold Hypothesis, Low-Dimensionality and Sparsity

The intuition behind this work is that although the lexical semantic space proper is high-dimensional, it is organized in such a way that interesting semantic relations can be exported from manifolds of much lower dimensionality embedded in this high dimensional space (Karlgren et al., 2008). We assume that (at least some of) these sub-manifolds contain semantically similar words (or word senses). For example, a potential sub-manifold in the lexical space could be the one that contains the colors (e.g., *red, blue, green*). But in fact many words, such as *book, green, fruit*, are expected to belong simultaneously in semantically different manifolds because they have multiple meanings.

A simple way to bootstrap the manifold recreation process is to build a domain around each word, i.e., *the semantic neighborhood of each word defines a domain*. For example, in Figure 1 we show the semantic neighborhood of *fruit*. The connections between words indicate high semantic similarity, i.e., this is a pruned semantic similarity graph of all words in the semantic neighborhood of the word 'fruit'. It is clear from this example that in a typical neighborhood there exist word pairs that should be

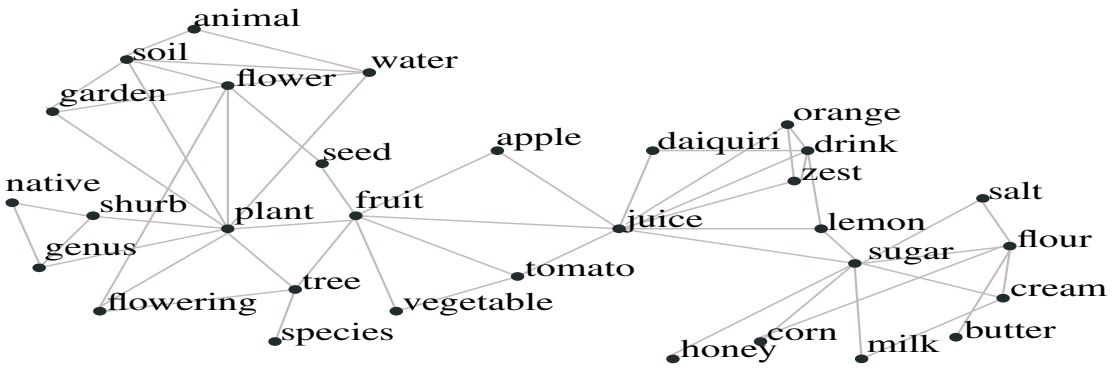

Figure 1: Visualization of the semantic neighborhood of the word 'fruit'.

'connected' to each other because they have close semantic relation, like {*flower*, *plant*} and others that should not be 'connected' because they are semantically apart, like {*garden*, *salt*}. A *sparse encoding* of the semantic similarity relations in a neighborhood is needed in order to achieve (via multi-dimensional scaling) a parsimonious representation with good geometric properties[1].

The graph connectivity or sparseness matrix identifies the word pairs that should be encoded in a neighborhood is defined as $\tilde{\mathbf{S}} \in \{0,1\}^{n \times n}$, where value $\tilde{\mathbf{S}}(i,j) = 1$ indicates that the i^{th}, j^{th} word pair is encoded, while $\tilde{\mathbf{S}}(i,j) = 0$ indicates that the pair is ignored (n is the number of words and $i,j = 1,..,n$ in the neighborhood). We define the degree of sparseness of matrix $\tilde{\mathbf{S}}$ as the percentage of 0's in the matrix.

4 Dimensionality Reduction

In this section, the Sparse Projection (SP) algorithm is described (see also Algorithm 1). SP is the core algorithm for constructing manifold DSMs presented in Section 5. SP is a dimensionality reduction algorithm that projects a set of n words into a vector space of d dimensions. The input to the algorithm is a dissimilarity or semantic distance matrix $\mathbf{P} \in \mathbb{R}^{n \times n}$, where element $\mathbf{P}(i,j)$ encodes the degree of dissimilarity between words w_i and w_j. The output of SP are the d-dimensional coordinate vectors of the n projected words that form a matrix $\mathbf{X} \in \mathbb{R}^{n \times d}$. Each row $\mathbf{x}_i \in \mathbb{R}^{1 \times d}$ of matrix $\mathbf{X} \in \mathbb{R}^{n \times d}$ corresponds to the coordinates of the i^{th} word w_i. Once $\mathbf{X}$ is estimated the dissimilarity matrix is recomputed and updated to new values, as discussed next. Each paragraph that follows corresponds to a module in Algorithm 1.

[1]Compare for example with Isomap (Tenenbaum et al., 2000) were a short- and long-distance metric is used. When using sparse encoding the long-distance metric is set to a very large fixed number (similarity set to 0). In both cases, the underlying manifold is unfolded and low-dimensional representation with (close to) metric properties are discovered.

Semantic Distance Re-estimation: Given the matrix $\mathbf{X} \in \mathbb{R}^{n \times d}$ containing the vector projections of words in the d-dimensional space, the dissimilarity matrix is re-estimated using the Euclidean distance[2]. Let $\hat{\mathbf{P}} \in \mathbb{R}^{n \times n}$ be the matrix with the new dissimilarity scores then the new dissimilarity score between words w_i and w_j is simply: $\hat{\mathbf{P}}(i,j) = \|\mathbf{x}_i - \mathbf{x}_j\|_2$, where x_i, x_j are the vectors corresponding to words w_i, w_j respectively, $i, j = 1, .., n$ and $\|.\|_2$ is the Euclidean norm.

Connectivity Graph and Sparsity: As discussed in Section 3, given a set of words only a small subset of lexical relations should be explicitly encoded between pairs of these words. Therefore, the SP algorithm should only take into account strongly related word pairs and ignore the rest. This is the main difference between our approach compared to the generic MDS algorithm proposed in (Torgerson, 1952). In order to apply the sparseness constraint, we first construct the connectivity matrix $\tilde{\mathbf{S}} \in \{0,1\}^{n \times n}$. Word pairs (w_i, w_j) with small similarity values (or equivalently large semantic distance) are penalized: zero values are assigned to their corresponding position (i,j) in $\tilde{\mathbf{S}}$ matrix. In essence, the matrix $\tilde{\mathbf{S}}$ is obtained by hard $\{0,1\}$ thresholding on the dissimilarity matrix $\mathbf{P}$: all values that are under a threshold are set to 0, while all values equal or greater to the threshold are set to 1. Let n be the number of words under investigation, then the number of word pairs is $p = \frac{n \cdot (n-1)}{2}$. The degree of sparseness is defined as the number of unordered word pairs (w_i, w_j), $i \neq j$ where $\tilde{\mathbf{S}}(i,j) = 0$ normalized over the total number of pairs p [3].

Error Criterion: The algorithm employs a local and a global error criterion defined as follows:

1. The local error corresponds to the projection error for each individual word w_i $\mathbf{e} \in \mathbb{R}^{n \times 1}$, where $i = 1...n$ and is defined as the sum of the dissimilarity matrix errors before and after projection computed only for the words that are 'connected' to w_i, as follows:

$$\mathbf{e}_i = \sum_{j=1}^{n} \tilde{\mathbf{S}}(i,j) \cdot \left(\hat{\mathbf{P}}(i,j) - \mathbf{P}(i,j) \right)^2 \quad (1)$$

2. The global error of the projection is simply the sum over local errors for all words: $e_{tot} = \sum_{i=1}^{n} \mathbf{e}_i$

Algorithm 1 Sparse projection (SP)

Require: $\mathbf{v}$ // Vocabulary: vector of n words
Require: $\mathbf{P}$ // $n \times n$ dissimilarity matrix
$\tilde{\mathbf{S}} \leftarrow$ ComputeConnectivityMatrix($\mathbf{S}$)
for each word $w_i \in \mathbf{v}$ **do**
  $\mathbf{X}_i \leftarrow$ RandomInitialization($\mathbf{X}_i$)
end for
$k = 0$ // Iteration counter: initialization
$e_{tot}^k = \inf$ // Global error: initialization
repeat
  $k = k + 1$
  for each word $w_i \in \mathbf{v}$ **do**
    for each direction z **do**
      $\mathbf{X} \leftarrow$ MoveWordToDirection(w_i, z)
      $\mathbf{e}_i^z \leftarrow$ ComputeLocalError($\tilde{\mathbf{S}}$,$\mathbf{P}$,$\mathbf{X}$,i)
    end for
    $\hat{z}_i \leftarrow$ FindDirectionOfMinLocalError($\mathbf{e}_i^z$)
    $\mathbf{X}$ = MoveWordToDirection($w_i, \hat{z}_i$)
  end for
  $e_{tot}^k \leftarrow$ UpdateGlobalError($\tilde{\mathbf{S}}$,$\mathbf{P}$,$\mathbf{X}$)
until $e_{tot}^{k-1} < e_{tot}^k$ // Stopping condition
$\hat{\mathbf{P}} \leftarrow$ SemanticDistanceReestimation($\mathbf{X}$)
$\tilde{\mathbf{P}} \leftarrow$ SparseDistanceNormalizedRanges($\hat{\mathbf{P}}$,$\tilde{\mathbf{S}}$)
return $\mathbf{X}$ // $n \times d$ matrix with coordinates;
return $\tilde{\mathbf{S}}$ // $n \times n$ matrix with connections;
return $\hat{\mathbf{P}}$ // $n \times n$ updated dissimilarity matrix;
return $\tilde{\mathbf{P}}$ // $n \times n$ sparse-normalized distances;

Random Walk SP: In function MoveWordToDirection($\cdot$) of Algorithm 1, the pseudo-variable *direction* z refers to a standard set of perturbations of each word in the d-dimensional space. For example, if the dimension of the projection is $d = 2$ then the coordinates of each word are modeled as (k_1, k_2), where $k_1, k_2 \in \mathbb{R}$. A potential set of perturbations are the following: $(k_1, k_2 + s)$, $(k_1, k_2 - s)$, $(k_1 + s, k_2)$ and $(k_1 - s, k_2)$, where s is the perturbation step parameter of the algorithm. For coordinates systems normalized in $[0,1]^d$ we chose a value of s equal to 0.1. Good convergence properties to global maxima have been experimentally shown for this algorithm for multiple runs on (noisy) randomly generated data.

[2] Other metrics, e.g., cosine similarity, have also been tested out but results are not shown here due to lack of space. Euclidean distance performed somewhat better that cosine similarity for the semantic similarity estimation task.

[3] The SP algorithm with 0% degree of sparseness is equivalent to the MDS algorithm.

Sparse Semantic Distance Normalized Ranges: This function normalizes all the distance scores of $\hat{\mathbf{P}}$ in a range of values, [0 r_1], where $r_1 \in \mathbb{R}_+$ is an arbitrary positive constant and also it imposes the sparsity constraint as follows: if $\tilde{\mathbf{S}}(i,j) = 0$ then $\tilde{\mathbf{P}}(i,j) = r_1$. If $\tilde{\mathbf{S}}(i,j) = 1$ then $\tilde{\mathbf{P}}(i,j) = r_2 \cdot \frac{\hat{\mathbf{P}}(i,j)}{r_3}$, where r_3 is the maximum distance over all 'connected' pairs, i.e. $r_3 \triangleq \max\{\hat{\mathbf{P}} \odot \tilde{\mathbf{S}}\}$, with $\odot$ denoting the Hadamard product, and $r_2 \in \mathbb{R}_+$ can be either equal to r_1 or slightly smaller than r_1. The assignment of $r_2 < r_1$ aims to differentiate the 'unconnected' pairs from the 'connected' but dissimilar ones [4].

5 Low-Dimensional Manifold DSMs

The end-to-end low-dimensional manifold DSM (LDMS) system is depicted in Figure 2. Note that $\mathrm{v}_1, \mathrm{v}_2, ..., \mathrm{v}_{|\mathrm{V}|} \in \mathrm{V}$ are the domains or sub-manifolds of the LDMS, for each domain v_i a separate DSM is built. V is the set of domains (concept vocabulary) and $|\mathrm{V}|$ denotes to the cardinality of V. The input

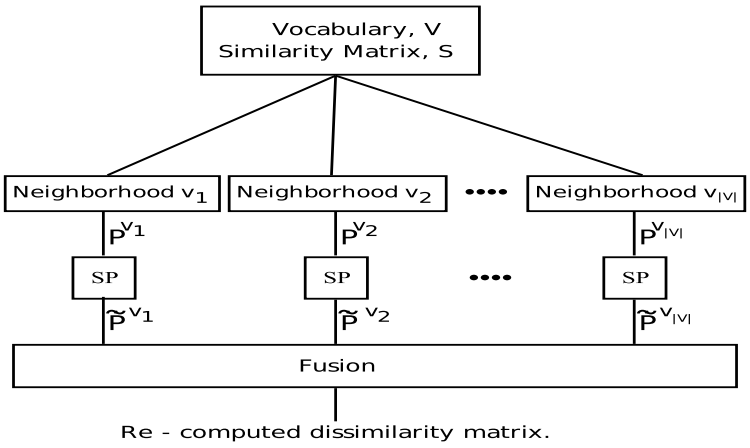

Figure 2: LDMS system.

to LDMS is a (global) similarity matrix $\mathbf{S} \in \mathbb{R}^{n \times n}$, where n is the total number of tokens (words) in the LDMS model. Note that $\mathbf{S}$ can be estimated using any of the baseline semantic similarity metrics[5] presented in Section 2. Since the SP algorithm uses as input a dissimilarity or semantic distance matrix, the pairwise word similarity matrix $\mathbf{S} \in \mathbb{R}^{n \times n}$ is transformed to a semantic distance (or dissimilarity) matrix $\mathbf{P} \in \mathbb{R}^{n \times n}$ as: $\mathbf{P}(i,j) = c_1 \cdot e^{-c_2 \cdot \mathbf{S}(i,j)}$ where $c_1, c_2 \in \mathbb{R}$ are constants and the i, j indexes run from 1 to n. In this work, we used $c_1 = c_2 = 20$. The transformation defined by (5) was selected in order to non-linearly scale and increase the relative distance of dissimilar words compared to similar ones[6].

The steps followed by the LDMS system are the following:

1. **Domain Selection**: The domains $\mathrm{v}_1, \mathrm{v}_2, ..., \mathrm{v}_{|\mathrm{V}|}$ are created as follows: for each word w_i in our model we create a corresponding domain v_i that consists of all the words that are semantically similar to w_i, i.e., the ith domain is the semantic neighborhood of word w_i. Thus in our model the vocabulary size is equal to the domain set cardinality, i.e., $n = |\mathrm{V}|$. Domain v_i is created by selecting the top N most semantically similar words to w_i based on the (global) similarity matrix $\mathbf{S} \in \mathbb{R}^{n \times n}$. We have experimented with various domain sizes N ranging between 20 and 200 neighbors; note that each word in the LDMS may belong to multiple domains.
2. **Sparse Projections on Domains**: Following the selection of domain $\mathrm{v}_i \in \mathrm{V}$ the (local) dissimilarity matrix for each domain $\mathbf{P}^{\mathrm{v}_i} \in \mathbb{R}^{N \times N}$ is defined as a submatrix of $\mathbf{P} \in \mathbb{R}^{n \times n}$. Then, the SP algorithm is applied to each domain separately, resulting in $i = 1, .., |\mathrm{V}|$ re-estimated bounded semantic distance matrices $\tilde{\mathbf{P}}^{\mathrm{v}_i}$.
3. **Fusion**: To reach a decision on the strength of the semantic relation between words w_i and w_j the semantic distance matrices from each domain $\tilde{\mathbf{P}}^{\mathrm{v}_i}$ must be combined. Only domains were both words w_i and w_j appear are relevant in this fusion process. This procedure is described next.

[4] We experimented with various values for r_1 and r_2 achieving comparable performance; we selected $r_2 \approx 0.9 r_1$ that had slightly better performance. The value of r_1 can be chosen arbitrary, the results reported here were obtained for $r_1 = 20$ and $r_2 = 18$.

[5] Here, the Google-based Semantic Relatedness was employed using a corpus of web-harvested document snippets.

[6] Similar nonlinear scaling function from similarity to distance can be found in the literature, e.g., (Borg, 2005)

5.1 Fusion

Motivation: Given a set of words $L = \{w_1, w_2, ...w_n\}$ we assume that their corresponding set of word senses[7] is $M = \{s_{11}, s_{12}, .., s_{1n_1}, .., .., s_{n1}, s_{n2}, .., s_{nn_n}\}$. The set of senses is defined as $M = \cup_{i=1}^{n} M_i$, where $M_i = \{s_{i1}, s_{i2}, ..., s_{in_i}\}$ is the set of senses for word w_i. Let $S(.)$ be a metric of semantic similarity, e.g., the metric defined in Section 2, which is symmetric, i.e., $S(x, y) \equiv S(y, x)$. The notations $S_w(.)$ and $S_s(.)$ are used in order to distinguish the similarity at word and sense level, respectively. According to the maximum sense similarity assumption (Resnik, 1995), the similarity between w_i and w_j, $S_w(w_i, w_j)$, is defined as the pairwise maximum similarity between their corresponding senses $S_s(s_{ik}, s_{jl})$:

$$S_w(w_i, w_j) \equiv S_s(s_{ik}, s_{jl}), \quad \text{where} \quad (k, l) = \underset{(p \in M_i, r \in M_j)}{\operatorname{argmax}} S_s(s_{ip}, s_{jr}).$$

Note that the maximum pairwise similarity metric (or equivalently the *minimum pairwise distance metric*) is also known as the "common sense" set similarity (or distance) employed by human cognition when evaluating the similarity (or distance) between two sets.

Fusion of local dissimilarity scores: Next we describe a domain fusion model that follows the minimum pairwise distance (dissimilarity) principle motivated by human cognition. The steps for the recomputation of the (global) dissimilarity between words w_i and w_j are:

1. Search for all the domains where w_i and w_j co-exist.
2. Let $U \subset V$ be the subset of domains from the previous step. The distances between words w_i and w_j are retrieved from domain dissimilarity matrices $\tilde{\mathbf{P}}^u$ for all $u \in U$. The distances are stored into vector $\mathbf{d} \in \mathbb{R}^{|U| \times 1}$.
3. Motivated by the maximum sense similarity assumption (see above) the dissimilarity between w_i and w_j is defined as[8]:
$$\hat{\mathbf{P}}(i, j) = \min_{k=1..|U|} \{\mathbf{d}_k\} \tag{2}$$
4. If words w_i and w_j do not co-exist in any domain then r_1 is assigned as their dissimilarity score, where r_1 is the upper bound of $\tilde{\mathbf{P}}^u$ matrices as defined in the previous section.

For example, let one pair of words (w_1, w_2) co-exists in $|U| = 3$ different domains with corresponding local distances $\mathbf{d} = [9\ 20\ 11]$ then the global distance of (w_1, w_2) is 9.

6 Evaluation

In this section, we evaluate the performance of the proposed approach with respect to the task of similarity judgment between nouns. Results are reported with respect to several domain/neighborhood sizes, sparse percentages and domain dimensions.

The performance of similarity metrics were evaluated against human ratings from three standard datasets of noun pairs, namely *WS353* (Finkelstein et al., 2001), *RG* (Rubenstein and Goodenough, 1965) *MC* (Miller and Charles, 1991). The first and the second datasets consist of the subset of 272 and 57 pairs, respectively, that are also included in SemCor3[9] corpus, while the third dataset consists of 28 noun pairs. The Pearson's correlation coefficient was selected as evaluation metric to compare estimated similarities against the ground truth.

The similarity matrix computed using the Google-based Semantic Relatedness (Gracia et al., 2006) was used as baseline, as well as to bootstrap the LDMS global similarity matrix $\mathbf{S}$, for a list of 8752 nouns extracted from the SemCor3 corpus [10]. The performance of the proposed LDMS approach is presented in Table 1. In addition, the performance of other *unsupervised* similarity estimation algorithms are reported for comparison purposes: 1) SEMNET is an alternative implementation of unstructured DSMs based on the idea of semantic neighborhoods and networks (Iosif and Potamianos, 2013) 2) WikiRelate! includes various taxonomy-based metrics that are typically applied to the WordNet hierarchy; the basic

[7] This is a simplification. In reality, some of the word senses will be the same, so strictly speaking this is not a set definition.

[8] Other fusion methods have also been evaluated, e.g., (weighted) average. Results are omitted here due to lack of space. Minimum pairwise distance fusion outperformed other fusion schemes.

[9] `http://www.cse.unt.edu/~rada/downloads.html`

[10] The baseline similarity matrix and the 8752 nouns are public available in:
`http://www.telecom.tuc.gr/~iosife/downloads.html`

idea behind WikiRelate! is to adapt these metrics to a hierarchy extracted from the links between the pages of the English Wikipedia (Strube and Ponzetto, 2006) . 3) TypeDM is a structured DSM (Baroni and Lenci, 2010), 4) AAHKPS1 constitutes an unstructured paradigm of DSM development using four billion web documents that were acquired via crawling (Agirre et al., 2009), 5) Moreover, two well-established dimensionality reduction algorithms (Isomap and LLE) that support the manifold hypothesis, were applied to the task of semantic similarity computation [11]. LDMS, Isomap and LLE were given as input the matrix $\mathbf{P} \in \mathbb{R}^{n \times n}$, where $n = 8752$ is the number of words in our models. Isomap and LLE used dimensionality reduction down to $d = 5$ and neighborhood size equal to $N = 120$. SEMNET was run for neighborhood size equal to $N = 100$. While LDMS run for dimensionality down to $d = 5$, domain/neighborhood size equal to $N = 140$ and degree of sparseness 90%. The proposed LDMS system surpassed the performance of the baseline system for all three datasets, as well as the performance of the other corpus-based approaches for the WS353 and MC datasets. The dimensionality reduction algorithms (Isomap - LLE) are shown to perform poorly for this particular task.

Datasets	Algorithm							
	Baseline	SEMNET	WikiRelate!	TypeDM	AAHKPS1	Isomap	LLE	**LDMS**
WS353	0.61	0.64	0.48	-	-	0.14	0.04	0.69
RG	0.81	0.87	0.53	0.82	-	0.04	0	0.86
MC	0.85	0.91	0.45	-	0.89	-0.04	-0.04	0.94

Table 1: Performance of various algorithms for the task of similarity judgment.

The performance (Pearson correlation) of the LDMS approach is shown in Figures 3a, 3b and 4a as a function of neighborhood size and degree of sparseness. Results are presented for all three datasets: WS353, MC, and RG. The baseline performance is also plotted (dotted line). For all three datasets, we see a clear relationship between neighborhood size, degree of sparseness and performance. Sparse representations achieve peak performance for larger neighborhood sizes. High degree of sparseness between 80 and 90% achieves the best results for domain/neighborhood sizes between 100 and 140. The figures show that there is potential for even better performance by fine-tuning the LDMS parameters.

The performance of LDMS is shown in Figure 4b as a function of the projection dimension d. The degree of sparseness is fixed at 80% and the domain/neighborhood size is equal to 100 for all experiments. It is observed that the performance for all three datasets remains relatively constant when at least $d = 3$ is used. In fact results are slightly better for $d = 3$ than for higher dimensions but the differences in performance are not significant. The results suggest that even *a 3D sub-space is adequate for accurately representing the semantics of each underlying domain.*

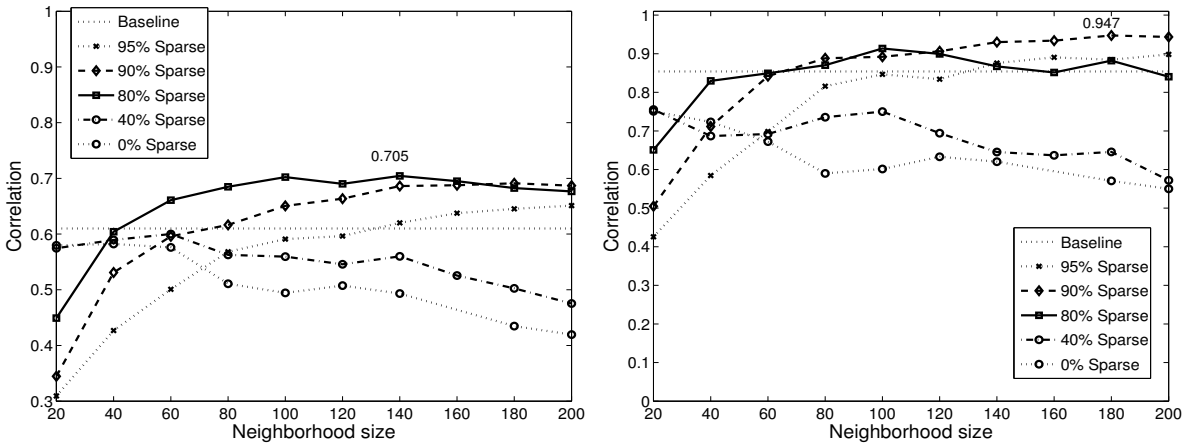

Figure 3: Performance as a function of domain size N and sparseness percentage for the (a) WS353 dataset and (b) MC dataset.

[11] LDMS is not directly comparable with Isomap-LLE algorithms because it represents only the domains in low-dimensional spaces and not the whole dataset.

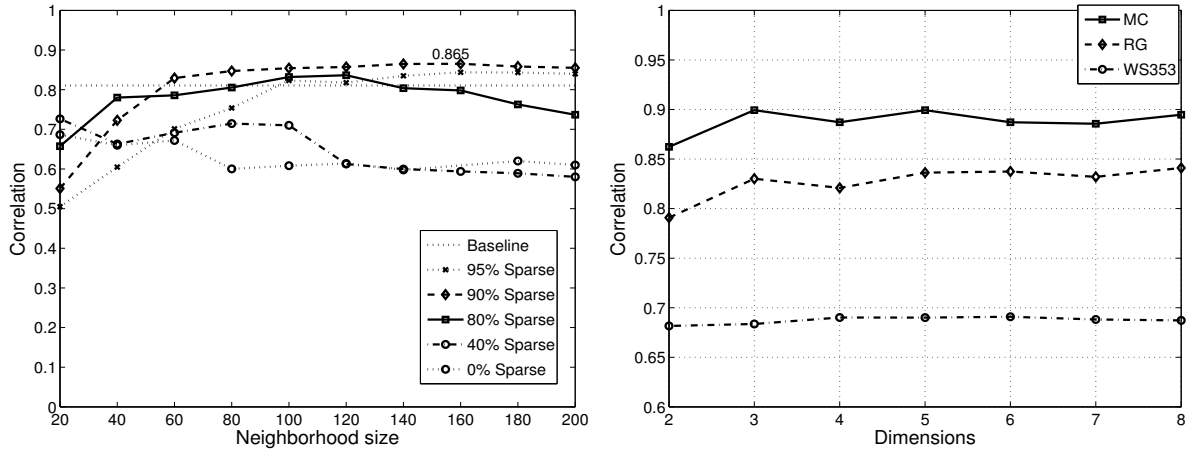

Figure 4: Performance for the (a) RG dataset as a function of domain size N and sparseness percentage and (b) WS353, MC, RG datasets as a function of projection dimension d.

7 Conclusions

In this work, we proposed a novel, hierarchical DSM that was applied to semantic relation estimation task obtaining very good results. The proposed representation consists of low-dimensional manifolds that are derived from sparse projections of semantic neighborhoods. The core idea of low dimensional subspaces was motivated by cognitive models of conceptual spaces. The validity of this motivation was experimentally verified via the estimation of semantic similarity between nouns. The proposed approach was found to be (at least) competitive with other state-of-the-art DSM approaches that adopt flat feature representations and do not explicitly include the sparsity and dimensionality as a key design parameter.

The poor performance of Isomap and LLE can be attributed to the nature of the specific application, i.e., word semantics. A key characteristic of this application is the ambiguity of word senses. These algorithms assume only one sense for each word (i.e., a word is represented as a single point in a high-dimensional space). Although the disambiguation task is not explicitly addressed, LDMS approach handles the ambiguity of words by isolating each word's senses in different domains.

Our initial intuition regarding the semantic fragmentation of lexical neighborhoods due to singularities introduced by word senses was supported by the high performance when large (i.e., 80% - 90%) degree of sparseness was imposed. The hypothesis of low-dimensional representation was validated by the finding that as little as three dimensions are adequate for representing domain/neighborhood semantics. It was also observed that the parameters of the LDMS model, i.e., number of dimensions, neighborhoodsize and degree of sparseness, are interrelated: very sparse projections achieve best results with very low dimensionality when large neighborhood sizes are used.

This is only a first step toward using ensembles of low-dimensional DSMs for semantic relation estimation. As future work we plan to further investigate the creation of domains based on more complex geometric properties of the underlying space (Kreyszig, 2007). A more formal investigation of the relation between sparseness, dimensionality and performance is also needed. Finally, creating multi-level hierarchical representations that are consistent with cognitive organization is an important challenge that can further improve manifold DSM performance.

An Entity-Centric Coreference Resolution System for Person Entities with Rich Linguistic Information

Marcos Garcia and **Pablo Gamallo**
Centro Singular de Investigación en Tecnoloxías da Información (CiTIUS)
University of Santiago de Compostela
{marcos.garcia.gonzalez, pablo.gamallo}@usc.es

Abstract

This paper presents a first version of LinkPeople, an entity-centric system for coreference resolution of person entities. The approach combines (i) a multi-pass architecture which takes advantage of entity features at document-level with (ii) a set of linguistically-motivated constraints and rules which allows the system to restrict the candidates of a given mention. The paper includes evaluations and error analysis of LinkPeople in 3 different languages, achieving promising results (more than 81% F1 in different metrics). Both the system and the corpora are freely distributed.

1 Introduction

Coreference Resolution (CR) is a crucial task for several Natural Language Processing (NLP) applications such as Text Summarization, Machine Translation or Information Extraction (IE).

Specially for IE, person entities are those which more effort have deserved from different perspectives. Evaluations such as the Knowledge Base Population (KBP) Slot Filling Task (in the Text Analysis Conference)[1] and the Person Attribute Extraction (in the Web People Search Evaluation Campaign, WePS)[2], tasks such as Personal Name Matching (Cohen et al., 2003), or different works on Relation Extraction of person entities (Mann, 2002; Garcia and Gamallo, 2013) are some examples of their importance.

Recently, entity-centric models for coreference resolution, which use features from all the mentions of an entity, have shown better performance than pair-mention systems, which carry out coreference resolution on single pairs of mentions (Lee et al., 2013).[3] Furthermore, the use of linguistic information such as syntax or semantic knowledge has proved to be essential for high-precision CR (Ng and Cardie, 2002; Ponzetto and Strube, 2006; Uryupina, 2007).

This paper presents the first version of LinkPeople, an open-source system for CR of person entities. LinkPeople is inspired by the Stanford Deterministic Coreference Resolution System (Raghunathan et al., 2010; Lee et al., 2013), using a multi-pass architecture which applies a battery of modules sorted from high-precision to high-recall.

Moreover, the system presented in this paper adds new sieves based on linguistic knowledge, for both cataphoric and anaphoric mentions: It includes a high-precision module which finds cataphoric mentions of Noun Phrases (NP) and personal and elliptical pronouns. The inclusion of this module is based on the claim that definite NPs are not primarily anaphoric (Vieira and Poesio, 2000). In addition, LinkPeople applies a set of syntactic constraints on the pronominal CR module, increasing its precision by blocking links which do not satisfy the constraints (Mitkov, 1998; Palomar et al., 2001; Chaves and Rino, 2007).

The system was evaluated in three languages (Portuguese, Spanish and Galician) with promising results (F1 $\approx$ 83%, with BLANC score). Both LinkPeople and the corpora are freely distributed.[4]

[2] http://nlp.uned.es/weps/weps-3

[3] In this paper, a *mention* is every instance of reference to a person. An *entity* is the group of all the mentions referring to the same person in the text (Recasens and Martí, 2010).

Proceedings of COLING 2014, the 25th International Conference on Computational Linguistics: Technical Papers, pages 741–752, Dublin, Ireland, August 23-29 2014.

Apart from this Introduction, Section 2 contains some related work. The architecture of the system is presented in Section 3 while its evaluation is shown in Section 4. Finally, the results of an error analysis are presented in Section 5, and some conclusions and further work are pointed out in Section 6.

2 Related Work

Coreference (and anaphora) resolution is one of the older topics in NLP, so it has been the subject of many works. Two main distinctions can be stated in coreference resolution systems: (i) mention-pair *vs* entity-centric approaches and (ii) machine learning-based *vs* rule-based models.

On the one hand, mention-pair systems classify two mentions in a text as coreferent or not, by using a feature vector obtained from this pair of mentions. On the other hand, entity-centric approaches determine if a mention (or a partial entity) belongs to another partial entity, using features from other mentions of the same (partial) entities.[5]

Machine learning classifiers for CR often use annotated corpora for training supervised models. Supervised models rely on these data in order to learn preferences and constraints (McCarthy and Lehnert, 1995; Soon et al., 2001; Ng and Cardie, 2002; Sapena et al., 2013), while unsupervised models apply clustering approaches to the coreference resolution problem (Haghighi and Klein, 2007; Ng, 2008).

Rule-based strategies make use of sets of rules and heuristics for finding the best element to link each mention to (Lappin and Leass, 1994; Baldwin, 1997; Mitkov, 1998; Bontcheva et al., 2002; Raghunathan et al., 2010; Lee et al., 2013). This last system is based on a multi-pass approach which first solves the *easy* links, then increasing the recall with more rules. Stoyanov and Eisner (2012) presented *EasyFirst*, which uses annotated corpora in order to know whether coreference links are easy or hard.

Concerning the languages LinkPeople deals with, some studies addressed pronominal CR in Portuguese (Paraboni, 1997; Chaves and Rino, 2007; Cuevas and Paraboni, 2008). Coelho and Carvalho (2005) adapted the Lappin and Leass (1994) algorithm for this language, while de Souza et al. (2008) presented a supervised approach for solving the coreference between NPs.

For Spanish, Palomar et al. (2001) presented a set of constraints and preferences for pronominal anaphora resolution. Recasens and Hovy (2009) analyzed the impact of several features for CR, then implemented in Recasens and Hovy (2010). The availability of a large coreference annotated corpus for Spanish (Recasens and Martí, 2010) also allowed other supervised systems being adapted for this language (Recasens et al., 2010).

To the best of our knowledge, there are no specific systems for coreference or anaphora resolution for Galician language.

Other related areas such as the above mentioned personal name matching perform coreference resolution of personal names by linking variants referring to the same person (Cohen et al., 2003).

The system presented in this paper uses a similar approach than Lee et al. (2013), adapting —and adding— some modules for person entities, and enriching others with linguistic-based heuristics such as cataphoric analysis and syntactic constraints.

3 Architecture of LinkPeople

LinkPeople is based on two main principles: (i) an entity-centric approach and (ii) a multi-pass architecture. On the one hand, the entity-centric approach allows the system to use all the features of an entity when a mention is evaluated. On the other hand, the multi-pass model dynamically enriches an entity (with new features) in every iteration. Thus, latter passes take advantage of the information provided by the previous coreference resolution modules.

Figure 1 shows a text with coreference annotation of person entities. It will be used to show how the system works. The input of LinkPeople needs to be pre-processed by NLP tools which provide PoS-tags, Named Entity Recognition (NER) and dependency analysis. In our experiments, FreeLing (Padró and Stanilovsky, 2012; Garcia and Gamallo, 2010) was used for tokenizing, lemmatizing and PoS-tagging. NER labeling for Spanish and Portuguese was also added by FreeLing (Carreras et al., 2003; Gamallo

[5]Partial entities are sets of mentions of the same entity.

Who was $_{1}$[the singer of the Beatles]$_{1}$. $_{2}$[The musician John Winston Ono Lennon]$_{1}$ was one of the founders of the Beatles. With $_{3}$[Paul McCartney]$_{2}$, $_{4}$[he]$_{1}$ formed a songwriting partnership. $_{5}$[Lennon]$_{1}$ was born at Liverpool Hospital to $_{6}$[Julia]$_{3}$ and $_{7}$[Alfred Lennon]$_{4}$. $_{8/9}$[$_{10}$[His]$_{1}$ parents]$_{3/4}$ named $_{11}$[him]$_{1}$ $_{12}$[John Winston Lennon]$_{1}$. $_{13}$[Lennon]$_{1}$ revealed a rebellious nature and acerbic wit. $_{14}$[The musician]$_{1}$ was murdered in 1980.

Figure 1: Example of a text with coreference annotation of person entities. Mentions appear inside brackets. Numbers on the left are mention ids, while entity ids appear in the right side.

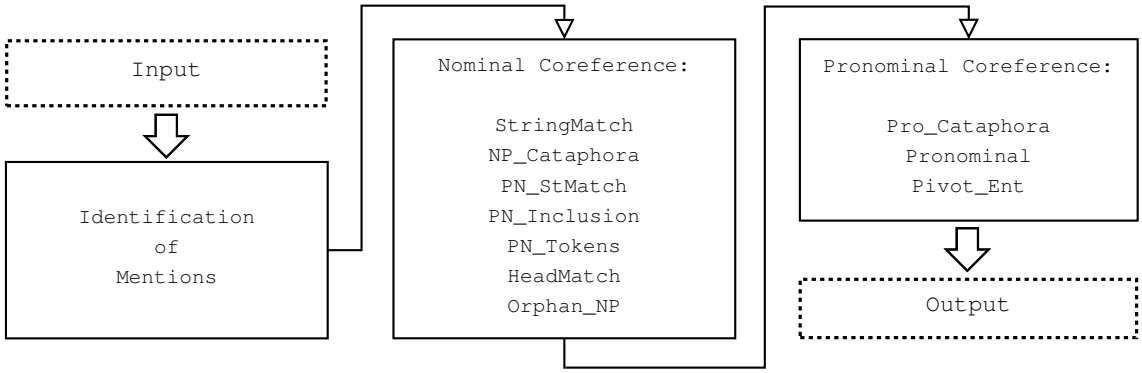

Figure 2: Architecture of the system.

and Garcia, 2011), while the named entities in Galician were classified by the system presented in Garcia et al. (2012). Finally, dependency information for the three languages was added by DepPattern (Gamallo and González López, 2011).

3.1 Coreference Resolution Modules

Figure 2 summarizes the architecture of the system, which starts by identifying the mentions. Then, a battery of nominal and pronominal CR modules is applied. Modules with high-precision are applied first, while other modules increase recall by taking advantage of the previously extracted features.

In the first stage, a specific pass identifies the mentions referring to a person entity, using the information provided by the PoS-tagger and the NER as well as applying basic approaches for NP and elliptical pronoun identification: First, personal names (and noun phrases including personal names) are identified. Then, it seeks for definite NPs whose head may refer to a person (e.g., "the singer"). Finally, this module selects singular possessives and applies basic rules for identifying relative, personal and elliptical pronouns (in sentence-initial position, after adverbial phrases and after preposition phrases) (Ferrández and Peral, 2000). At this step, each mention belongs to a different entity. Each entity contains the gender, number, head of a noun phrase, head of a Proper Noun (PN) and full proper noun as features. Once the mentions are identified, the coreference resolution modules are sequentially executed.

In order to perform CR, each module applies the following strategy (except for some exceptional rules, explained below): mentions are traversed from the beginning of the text and each one is *selected* if (i) it is not the first mention of the text and (ii) it is the first mention of its entity. Once a mention is selected, it looks backwards for *candidates* in order to find an appropriate antecedent (in the experiments, using the whole text). If an antecedent is found, mentions are merged together in the same entity. Then, the next selected mention is evaluated.

Besides the identification of mentions, current version of LinkPeople contains the following modules:

StringMatch (StM): this pass performs strict matching of the whole string of both mentions (the selected one and the candidate). In the example (Figure 1), mentions 13 and 5 are linked in this step.

NP_Cataphora (NP_C): this module verifies if the first mention —in the first paragraph— is an NP without a personal name. If so, it is considered a cataphoric mention, and the system checks if the next sentence contains a personal name as a Subject. In this case, these mentions are linked if they agree in

gender and number. Mentions 1 and 2 in the example meet these requirements, so they merge. Note that, at the end of this pass, this entity has as NP heads the words 'singer' and 'musician', and 'John Winston Ono Lennon' as the PN. This module also matches fixed synonym structures through dependency paths, such as "Person_A, also known as Person_B".

PN_StMatch (PN_St): in this stage, the system looks for mentions which share the whole PN, even if their heads are different (or if one of them does not have head). "The musician John Lennon" and "John Lennon" (not in Figure 1) would be an example.

PN_Inclusion (PN_I): here, the system verifies if the full PN of the selected mention (in the entity) includes the proper noun of the candidate mention (also in the entity), or vice-versa. In the example, mention 5 is linked to mention 2 in this step. Note that mention 7 is not linked to mention 5, because the full PN of mention 5 is now "John Winston Ono Lennon", not compatible with "Alfred Lennon". Also, mention 13 is not selected here because it is not the first mention of its entity.

PN_Tokens (PN_T): this module splits the full PN of a partial entity in their tokens, and verifies if the full PN of the candidate contains all the tokens in the same order, or vice-versa (except for some *stop words*, such as "Sr.", "Jr.", etc.). As the pair "John Winston Ono Lennon" - "John Winston Lennon" are compatible, mentions 12 and 5 are merged.

HeadMatch (HM): in this step, the system checks if the selected mention and the candidate one share the heads (or the heads of their entities). In Figure 1, mention 14 is linked to mention 13.

Orphan_NP (Orph): the last module of nominal CR applies a pronominal-based rule to orphan noun phrases. Here, a definite NP is marked as orphan if it is still a singleton and it does not contain a personal name. Thus, an orphan NP is linked to the previous PN with gender and number agreement. In the example, the mentions 8/9 are linked to 7 and 6.

Pro_Cataphora (Pro_C): similar to NP_Cataphora, this module verifies if a text starts with a personal (or elliptical) pronoun. If so, it looks in the following sentence if there are a compatible PN.

Pronominal (PRO): this is the standard module for pronominal CR. For each selected pronoun, it verifies if the candidate nominal mentions satisfy the syntactic (and morpho-syntactic) constraints (inspired by Palomar et al. (2001)). They include a set of constraints for each type of pronoun, which remove a candidate if any of the constraints is violated. Some of them are: an object pronoun (direct or indirect) cannot corefer with its subject (mention 11 *vs* mentions 8/9); a personal pronoun does not corefer with a mention inside a prepositional phrase (mention 4 *vs* mention 3), a possessive cannot corefer with the NP it belongs to (mention 10 *vs* mentions 8/9) or a pronoun prefers a subject NP as its antecedent (mentions 10 and 11 *vs* mentions 6 and 7). This way, in Figure 1 the pronominal mention 4 is linked to mention 2, and mentions 10 and 11 to mention 5. This module only looks in the same and previous sentence for candidates.

Pivot_Ent: this last module is only applied if there are orphan pronouns (not linked to any proper noun/noun phrase) at this step. First, it verifies if the text has a pivot entity, which is the more frequent personal name in a text whose frequency is at least 33% higher than the second person with more occurrences. Then, if there is a pivot entity, all the orphan pronouns are linked to its mention. If not, each orphan pronoun is linked to the previous PN/NP (with no constraint).

4 Evaluation

LinkPeople was tested on three different corpora (for Portuguese, Galician, and Spanish) with coreference annotation of person entities (Garcia and Gamallo, 2014). The annotation follows the SemEval-2010 guidelines. The corpus for Portuguese has about 51k tokens and $\approx$ 4,000 mentions. The Galician one, 42k tokens and $\approx$ 3,500 mentions. The Spanish corpus has over 46k tokens, and $\approx$ 4,500 mentions.

Some of the annotation (gender, number and syntactic labeling) was not manually revised, so it may contain errors (*regular setting*). The tests were carried out using a *gold mention* evaluation (i. e., using

as input the corpora with the mentions already identified). Moreover, no external resources (gender dictionaries of proper nouns, WordNet, etc.) were used (*closed setting*).

In order to compare the results of LinkPeople, four well-known baselines were also evaluated: (i) *Singletons* (Stons), where every mention belongs to a different entity. (ii) *All_in_One* (AOne), where all the mentions belong to the same entity; (iii) *HeadMatch* (HMb), which clusters in the same entity mentions sharing the head and classify each pronoun as a singleton, and (iv) *HeadMatch_Pro* (HMP), same as the previous one, but linking each pronoun to the previous nominal mention with gender and number agreement.[6]

Five different metrics were taken into account: MUC (Vilain et al., 1995), B^3 (Bagga and Baldwin, 1998), $CEAF_{entity}$ (Luo, 2005), BLANC (Recasens and Hovy, 2011) and ConLL (Pradhan et al., 2011). They were computed with the scorers used in SemEval-2010[7] (for BLANC) and ConLL 2011[8] (for the other metrics).

Table 1 contains the results of the four baselines and of LinkPeople in the three corpora. The first block of each language includes the results of the baseline models. The central rows show the results of the different modules of LinkPeople (see Figure 2), added incrementally. The first nine rows (StM $>$ PRO) include two default rules in order to classify mentions not covered by the active modules: (i) nominal mentions not analyzed are singletons and (ii) pronouns are linked to the previous nominal mention with gender agreement (except for those pronouns covered by PRO in this model). Furthermore, PRO systems do not restrict the number of previous sentences while looking for antecedents.

The last model (LinkP, the result of all the modules included in LinkPeople) does include a distance restriction in the Pronominal pass (see Section 3.1), so it combines Pronominal with Pivot_Ent modules.

As expected, *Singletons* and *HeadMatch* baselines produce poor results in most languages and metrics (*Singletons* values in MUC are null because this metric do not reward correctly identified singletons). However, *All_In_One* models achieved reasonable results in some scenarios (MUC and B^3). The differences between these values and those from SemEval-2010 are due to the existence (in this work) of just one type of entity. Journalistic and encyclopedic texts are often focused on just one or two persons, (i.e., there is a much lower number of entities in each text), so the precision is higher in *All_In_One* and lower in *Singletons*.

As Recasens and Hovy (2010) shown, *HeadMatch_Pro* baselines obtain good results in the three languages and with every metric ($\approx$ 60% and 67% in F1 BLANC and CoNLL, respectively).

Concerning the different passes of LinkPeople, the performance of the first matching modules depends on the distribution and structure of PNs and NPs in the corpora. In this respect, PN_StMatch works well in all the contexts. However, PN_Inclusion stands out in the Nominal modules, increasing in more than 5% (BLANC and CoNLL) the performance of the previous model. This is due to the high increase in recall together with the high-precision of this module.

It is worth noting that the addition of some modules seems to improve not only recall, but also precision. This is due to the execution of the two default rules: as the system uses more modules, the amount of (partial)entity mergings (usually) grows. Thus, the precision increases because the new mergings restrict incorrect links performed by the two default rules in the previous models.

HeadMatch module is the first one that deals with mentions without PN (except for the rules applied in NP_Cataphora, with low recall). Due to the knowledge provided by previous modules, it also benefits all the models and languages.

The performance of Orphan_NP and Pro_Cataphora also depends on the corpora and on the evaluation metric. The latter involves a 0.2% loss in Spanish with the BLANC score (but increases in 1.1% using CoNLL). However, Orphan_NP allows the system to not classify as singletons some mentions, which in turn helps to increase the performance of Pronominal modules. Similarly, Pro_Cataphora prevents the next sieve from selecting pronominal mentions that are cataphoric.

[6]Due to language differences and format issues, other coreference resolution systems could not be used for comparison (Raghunathan et al., 2010; Sapena et al., 2013).

Table 1: Results of LinkPeople compared to the baselines in Portuguese (Port.), Galician (Gal.) and Spanish (Spa.). *LinkP* contains the results of the execution of the whole system.

The standard pronominal resolution module also increases the accuracy of all the systems (with the only exception in Portuguese language with the CoNLL score, which also had a high increase with the Orphan_NP module).

Finally, one of the main contributions to the performance of LinkPeople is the combination of the Pronominal module with the Pivot_Ent one. This combination reduces the scope of the Pronominal module, thus strengthening the impact of syntactic constraints. Furthermore, Pivot_Ent looks for a prominent person entity in each text, and links the orphan pronouns to this entity. In the three languages, the improvement is noticeably better with the BLANC score.

Last row of each language shows the current results of LinkPeople in the three corpora, with macro-average values of $\approx 83\%$ and $\approx 81\%$ with BLANC and CoNLL scores, respectively.

5 Error Analysis

In order to determine the major classes of errors produced by the system, 150 errors (50 for each language) were randomly selected from the output of LinkPeople. Each error was analyzed in order to find

its source, and was classified according to its typology. This section shows the different error typologies together with some examples, sorted by their frequency in the corpora (first percentage in parenthesis is the average frequency, while the other three correspond to Portuguese, Galician and Spanish values, respectively).[9] They are real examples of incorrectly analyzed mentions (or pairs of mentions belonging to the same entity), with some simplifications due to space reasons:

5.1 Missing links between Noun Phrases and/or Proper Nouns (46%: 58% / 32% / 48%)

This category includes some error typologies that differ in the type of knowledge and analysis required by the system in order to accurately link two mentions:

Synonym heads (35.3%: 48% / 32% / 26%): The most frequent type of missing links was produced by mentions of the same entity whose heads are synonyms:

Mention A: "El *joven*" (the *young*)
Mention B: "el *muchacho*" (the *boy*)

External (real-world) knowledge (6%: 0% / 0% / 18%): This class includes mentions of the same entity which do not share the lexical features, usually because they refer to well-known entities in the real world:

Mention A: "la presidenta" (the president)
Mention B: "Cristina Kirchner"

Here, the noun phrase "the president" is used to refer "Cristina Kirchner", but the mentions are not linked because the system does not take advantage of resources that define Cristina Kirchner as a *president*.

Semantic knowledge (2.7%: 4% / 0 % / 4%): Lack of other type of semantic knowledge, such as hyponym-hypernym pairs, also involves missing links like the following:

Mention A: "o escocês" (the scotish)
Mention B: "o britânico" (the british)

Head modifiers (1.3%: 4% / 0 % / 0%): Internal modifiers of some heads may also produce missing links, as in the following example, where a mention does not contain the modifier *adjunto* (vice):

Mention A: "o *ministro* (the *minister*)
Mention B: "o *ministro-adjunto*" (the *vice-minister*)

Spelling differences (0.7%: 2% / 0% / 0%): Some personal names are spelled differently in the same text:

Mention A: "André *Villas-Boas*"
Mention B: "André *Villas Boas*"

5.2 Errors due to incorrect predicted (syntactic and morpho-syntactic) analysis (15.3%: 2% / 22% / 22%)

Since the corpora do not have PoS-tagging and dependency labels fully revised, some of these errors involve missing and spurious links between mentions.

Errors in syntactic constraints (10.7%: 0% / 16% / 16%): Direct and indirect object pronouns incorrectly labeled are not covered by some of the syntactic constraints, thus involving an incorrect link between a pronoun and its subject noun phrase.

[9] The results of 0% in some languages and categories do not mean that these languages cannot have those error typologies, but they did not appear due to the small number of errors evaluated.

Incorrect gender (2.7%: 2% / 4% / 2%): The gender of some nouns and adjectives also can be wrongly labeled, so other mentions may be incorrectly linked, or involve a missing link. For instance, the word *atleta* (sportsperson, which can be both masculine or feminine), labeled as masculine blocked a link to the feminine pronoun *ela* (she) in Galician.

Incorrect head (2%: 0% / 2% / 4%): Errors in PoS-tagging (usually between nouns and adjectives) also produce wrong dependency analysis, which in turn involve incorrect extractions of the NP heads:

> Mention: "el jugador alemán" (the german player)
> Extracted Head: *alemán (*german, instead of *jugador/player*)

5.3 Missing links due to long distance pronominal anaphora (11.3%: 14% / 18% / 2%)

This kind of errors arises when the distance between a pronoun and its nominal antecedent is outside the scope of a rule (in our case, between two and four sentences, depending on the module), and the antecedent is not the pivot entity.

5.4 Errors due to quoted speech coreference (10%: 10% / 14% / 6%)

Another category of errors includes mentions inside quoted speech. These mentions can refer to the speaker (first person) or to a third person in the quoted speech:

First person (4.7%: 6% / 6% / 2%): The 1st person of the quoted speech should be linked to the speaker instead of to a previous entity (note that the elliptical pronoun might also be a 3rd person pronoun):

> "Si $\emptyset_{1^{st}}$ tuviera que redactar [...]", resumió $\text{Lezcano}_{\text{Speaker}}$.
> "If [$I_{1^{st}}$] had to write [...]", $\text{Lezcano}_{\text{Speaker}}$ summarized.

Third person (5.3%: 4% / 8% / 4%): 3rd persons of a quoted speech should not be linked to the speaker:

> $\text{Gustavo}_{\text{Speaker}}$: "Cuando $\text{yo}_{1^{st}}$ me fui, $\text{él}_{3^{rd}}$ dejó Boca."
> $\text{Gustavo}_{\text{Speaker}}$: "When $I_{1^{st}}$ quit, $\text{he}_{3^{rd}}$ left Boca."

5.5 Spurious links in plural mentions (5.3%: 4% / 4% / 8%)

Coreference of plural mentions was performed through basic links to the previous entities, producing incorrect classifications. Also, some plural mentions include entities with different genders (e.g., *amigos* —friends— may refer to feminine and masculine entities, but the grammatical gender of the word is masculine in the three analyzed languages):

> $_1$[Hulk]$_1$, $_2$[Moutinho]$_2$ e $_3$[Álvaro Pereira]$_3$ na lista de compra de $_4$[Villas-Boas]$_4$ [...]. $_{5/6/7}$[O trio do F.C. Porto]$_{2/3/*4}$ [...].
>
> $_1$[Hulk]$_1$, $_2$[Moutinho]$_2$ and $_3$[Álvaro Pereira]$_3$ in the shopping list of $_4$[Villas-Boas]$_4$ [...]. $_{5/6/7}$[The F.C. Porto trio]$_{2/3/*4}$ [...].

In this example, the plural mention (*O trio do F.C. Porto*) is linked to the previous nominal mentions with gender agreement, so an incorrect link between mentions 7 and 4 is done.

5.6 Errors due to incorrect gender agreement (4.7%: 4% / 4% / 6%)

Some nominal phrases referring to the same entity may have different gender, thus causing wrong links:

> Mention A: la víctima (the victim: feminine)
> Mention B: el muchacho (the boy: masculine)

5.7 Errors produced by constraints and Pivot_Ent modules (4.6%: 6% / 0% / 8%)

The syntactic constraints, although precise, may restrict some correct links. This can involve (i) an incorrect discourse analysis or (ii) the application of Pivot_Ent, linking the mention to the most frequent entity, which might be incorrect:

$_1$[El escritor]$_1$ tuvo que visitar a $_2$[Martín]$_2$ en el hotel. Según $_3\emptyset_{*1}$ dijo [...]
$_1$[The writer]$_1$ had to visit $_2$[Martín]$_2$ in the hotel. As $_3$[he]$_{*1}$ said [...]

Here, the elliptical subject of *dijo* (said) is *Martín*, but the link is blocked due to a syntactic constraint: the antecedent of the (subject) elliptical pronoun should be a subject. Thus, the system incorrectly links mention 3 to mention 1.

5.8 Spurious links between Noun Phrases sharing the same head (1.3%: 0% / 4% / 0%)

In the same text, different entities can share their heads in some mentions, which may involve errors in coreference links, depending on their position and on their features. Thus, the NP "the president" may be linked to two different persons like "the president of the Academia" and "the president of the Government".

5.9 Spurious links produced by errors in previous modules (0.7%: 0% / 2% / 0%)

First modules also produce some incorrect clusters which involve errors in further modules. For instance, in the Galician corpus, NP_Cataphora incorrectly linked the noun phrase *o alcalde* (the mayor) to the proper noun "Dorribo". Then, HeadMatch merged "Dorribo" with *o alcalde Orozco*, creating an incorrect entity that contains two different persons (Dorribo and Orozco).

5.10 Errors due to fixed language structures (0.7%: 2% / 0% / 0%)

Other minor errors include some fixed structures such as the following cataphoric possessive:

Por $_1$[sua]$_1$ parte, $_2$[Cristina]$_{*2}$ [...]
For $_1$[her]$_1$ part, $_2$[Cristina]$_{*2}$ [...]

The results of the error analysis bring interesting information to further work. Thus, including some kind of semantic knowledge (synonyms), improving pronominal coreference resolution and implementing specific rules for quoted speech might solve many of the most frequent errors made by LinkPeople.

6 Conclusions and Further Work

This paper presents the first version of LinkPeople, an open-source entity-centric approach for coreference resolution of person entities which applies a battery of deterministic modules enriched with precise linguistic information.

The system was evaluated in three different languages (Portuguese, Galician and Spanish), clearly surpassing some powerful baselines and achieving promising results.

The addition of rules focused on cataphoric coreference as well as pronominal constraints based on syntactic and discourse restrictions increases the performance of similar approaches with lack of this kind of knowledge.

Current work explores better nominal (Elsner and Charniak, 2010) and pronominal constraints and dedicated handling of plural mentions. In further work, the implementation of an inheritance constraint is planned, which could prevent the merging of partial entities if their mentions were blocked by previous modules. Moreover, the extension of the system for solving the coreference of other types of entities is also planned.

Abstract

We present a new, efficient unsupervised approach to the segmentation of corpora into multiword units. Our method involves initial decomposition of common *n*-grams into segments which maximize within-segment predictability of words, and then further refinement of these segments into a multiword lexicon. Evaluating in four large, distinct corpora, we show that this method creates segments which correspond well to known multiword expressions; our model is particularly strong with regards to longer (3+ word) multiword units, which are often ignored or minimized in relevant work.

1 Introduction

Identification of multiword units in language is an active but increasingly fragmented area of research, a problem which can limit the ability of others to make use of units beyond the level of the word as input to other applications. General research on word association metrics (Church and Hanks, 1990; Smadja, 1993; Schone and Jurafsky, 2001; Evert, 2004; Pecina, 2010), though increasingly comprehensive in its scope, has mostly failed to identify a single best choice, leading some to argue that the variety of multiword phenomena must be tackled individually. For instance, there is a body of research focusing specifically on collocations that are (to some degree) non-compositional, i.e. multiword expressions (Sag et al., 2002; Baldwin and Kim, 2010), with individual projects often limited to a particular set of syntactic patterns, e.g. verb-noun combinations (Fazly et al., 2009). A major issue with approaches involving statistical association is that they rarely address expressions larger than 2 words (Heid, 2007); in corpus linguistics, larger sequences referred to as *lexical bundles* are extracted using an *n*-gram frequency cutoff (Biber et al., 2004), but the frequency threshold is typically set very high so that only a very limited set is extracted. Another drawback, common to almost all these methods, is that they rarely offer an explicit segmentation of a text into multiword units, which would be preferable for downstream uses such as probabilistic distributional semantics. An exception is the Bayesian approach of Newman et al. (2012), but their method does not scale well (see Section 2). Our own long-term motivation is to identify a wide variety of multiword units for assisting language learning, since correct use of collocations is known to pose a particular challenge to learners (Chen and Baker, 2010).

Here, we present a multiword unit segmenter[1] with the following key features:

- It is entirely unsupervised.
- It offers both segmentation of the input corpus and a lexicon which can be used to segment new corpora.
- It is scalable to very large corpora, and works for a variety of corpora.
- It is language independent.

[1]The software is available at http:/www.cs.toronto.edu/~jbrooke/ngram_decomp_seg.py .

Proceedings of COLING 2014, the 25th International Conference on Computational Linguistics: Technical Papers, pages 753–761, Dublin, Ireland, August 23-29 2014.

- It does not inherently limit possible units with respect to part-of-speech or length.
- It has a bare minimum of parameters, and can be used off-the-shelf: in particular, it does not require the choice of an arbitrary cutoff for some uninterpretable statistical metric.
- It does, however, include a parameter fixing the minimum number of times that a valid multiword unit will appear in the corpus, which ensures sufficient usage examples for relevant applications.

Our method involves three major steps: extraction of common n-grams, initial segmentation of the corpus, and a refinement of the resulting lexicon (and, by extension, the initial segmentation). The latter two steps are carried out using a simple but novel heuristic based on maximizing word prediction within multiword segments. Importantly, our method requires just a few iterations through the corpus, and in practice these iterations can be parallelized. Evaluating with an existing set of multiword units from WordNet in four large corpora from distinct genres, we show that our initial segmentation offers extremely good subsumption of known collocations, and after lexicon refinement the model offers a good trade-off between subsumption and exact matches. We also evaluate a sample of our multiword vocabulary using crowdsourcing, and offer a qualitative analysis.

2 Related Work

In computational linguistics, there is a large body of research that proposes and/or evaluates lexical association measures for the creation of multiword lexicons (Church and Hanks, 1990; Smadja, 1993; Schone and Jurafsky, 2001; Evert, 2004): there are many more measures than can be addressed here—work by Pecina (2010) considered 82 variations—but popular choices include the t-test, log likelihood, and pointwise mutual information (PMI). In order to build lexicons using these methods, particular syntactic patterns and thresholds for the metrics are typically chosen. Many of the statistical metrics do not generalize at all beyond two words, but PMI (Church and Hanks, 1990), the log ratio of the joint probability to the product of the marginal probabilities, is a prominent exception. Other measures specifically designed to address collocations of larger than two words include the c-value (Frantzi et al., 2000), a metric designed for term extraction which weights term frequency by the log length of the n-gram while penalizing n-grams that appear in frequent larger ones, and mutual expectation (Dias et al., 1999), which produces a normalized statistic that reflects how much a candidate phrase resists the omission of any particular word. Another approach is to simply to combine known $n-1$ collocations to form n-length collocations (Seretan, 2011), but this is based on the assumption that all longer collocations are built up from shorter ones—idioms, for instance, do not usually work in that way.

An approach used in corpus linguistics which does handle naturally longer sequences is the study of *lexical bundles* (Biber et al., 2004), which are simply n-grams that occur above a certain frequency threshold. This includes larger phrasal chunks that would be missed by traditional collocation extraction, and so research in this area has tended to focus on how particular phrases (e.g. *if you look at*) are indiciative of particular genres (e.g. university lectures). In order to get very reliable phrases, the threshold is typically set high enough (Biber et al. use 40 occurrences in 1 million words) to filter out the vast majority of expressions in the process.

With respect to the features of our model, the work closest to ours is probably that of Newman et al. (2012). Like us, they offer an unsupervised solution, in their case a generative Dirichlet Process model which jointly creates a segmentation of the corpus and a multiword term vocabulary. Their method, however, requires full Gibbs sampling with thousands of iterations through the corpus (Newman et al. report using 5000), an approach which is simply not tractable for the large corpora that we address in this paper (which are roughly 1000 times larger than theirs). Though the model is general, their focus is limited to term extraction, and for larger terms they compare only with the c-value approach of Frantzi et al. (2000). Other closely related work includes general tools available for creating multiword lexicons using association measures or otherwise exploring the collocational behavior of words (Kilgarriff and Tugwell, 2001; Araujo et al., 2011; Kulkarni and Finlayson, 2011; Pedersen et al., 2011). Other related but distinct tasks include syntactic chunking (Abney, 1991) and word segmentation for Asian languages, in particular Chinese (Emerson, 2005).

3 Method

3.1 Prediction-based segmentation

Our full method consists of multiple independent steps, but it is based on one central and relatively simple idea that we will introduce first. Given a sequence of words, $w_1 \dots w_n$, and statistics (i.e. n-gram counts) about the use of these words in a corpus, we first define $p(w_i|w_{j,k})$ as the conditional probability of some word w_i appearing with some contextual subsequence $w_j \dots w_{i-1}, w_{i+1} \dots w_k, 1 \leq j \leq i \leq k \leq n$. In the case $i = j = k$, this is simply the marginal probability, $p(w_i)$. We then define the word predictability of some w_i in the context $w_{1,n}$ as the log of the maximal conditional probability of the word across all possible choices of j and k:

$$pred(w_i, w_{1,n}) = \max_{j,k} \log p(w_i|w_{j,k})$$

We can define predictability for the entire sequence then as:

$$pred(w_{1,n}) = \sum_{i=1}^{n} pred(w_i, w_{1,n})$$

Now we consider the case where we have a set of possible segmentations S of the sequence, where each segmentation $s \in S$ can be viewed as a (possibly empty) set of segment boundaries $\langle s_0, s_1, \dots, s_m \rangle$. Among the available options, our optimal segmentation is:

$$\arg\max_{s \in S} \sum_{i=0}^{m-1} pred(w_{s_i, s_{i+1}-1})$$

That is, we will prefer the segmentation which maximizes the overall predictability of each word in the sequence, under the restriction that we only predict words using the context within their segments. This reflects our basic assumption that words within a good segment, i.e. a multiword unit, are (much) more predictive of each other than words outside a unit. Note that if our probabilities are calculated from the full set of n-gram counts for the corpus being segmented and the set of possible segmentations S is not constrained, a segmentation with a smaller number of breaks will generally be preferred over one with more breaks. However, in practice we will be greatly constraining S and also using probabilities based on only a subset of all the information in the corpus.

3.2 Extraction of n-grams

In order to carry out a segmentation of the corpus using this method, we first need to extract statistics in the form of n-gram counts. Given a minimum occurrence threshold, this can be done efficiently even for large corpora in an iterative fashion until all n-grams have been extracted. For all our experiments here, we limit ourselves to n-grams that appear at least once in 10 million tokens, and we did not collect n-grams for $n > 10$ (which are almost always the result of duplication of texts in the corpus). For the purposes of calculating conditional probabilities given surrounding context in our predictive segmentation, we collected both standard n-grams as well as (for $n \geq 3$) skip n-grams with a missing word (e.g. *basic* * *processes* where the asterisk indicates that any word could appear in that slot). Here we use lower-cased unlemmatized tokens, excluding punctuation, though for languages with more inflectional morphology than English, lemmatization would be advised.

3.3 Initial segmentation

Given these n-gram statistics, our initial segmentation proceeds as follows: For each sentence in the corpus, we identify all maximum length n-grams in the sentence, i.e. all those n-grams for $n \geq 2$ where there is no larger n-gram which contains them while still being above our threshold of occurrence. These n-grams represent the upper bound of our segmentation: we will never break into segments larger than these. However, there are many overlaps among these n-grams (in fact, with a low threshold the vast majority of n-grams overlap with at least one other), and for proper segmentation we need to resolve

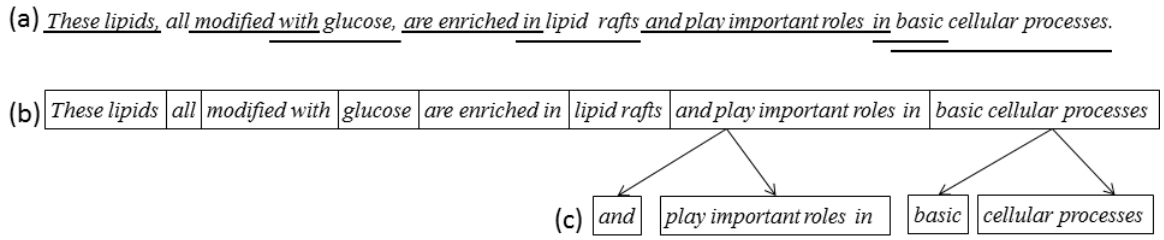

Figure 1: Three-step procedure for n-gram decomposition into multiword units. a) shows the maximal n-grams identified in the sentence, b) is the segmentation after the initial pass of the corpora, and c) shows further decomposition of segments after a pass through the lexicon resulting from b).

all overlaps between these maximal n-grams by inserting at least one break. For this we apply our prediction-based decomposition technique. In our discussion in Section 3.1, we did not consider how the possible segmentations were selected, but now we can be explicit: the set S consists of all possible segmentations which minimally resolve all n-gram overlaps. By minimally resolve, we mean that the removal of any breakpoint from our set would result in an unresolved overlap: in short, there are no extraneous breaks, and therefore no cases where a possible set of breaks is a subset of another possible set. Figure 1a shows a real example: if we just consider the last three maximal n-grams, there are two possible minimal breaks: a single break between *in* and *basic* or two breaks, one between *roles* and *in* and one between *basic* and *cellular*.

Rather than optimizing over all possible breaks over the whole sentence, which is computationally problematic, we simplify the algorithm somewhat by moving sequentially through each n-gram overlap in the sentence, taking any previous breaks as given while considering only the minimum breaks necessary to resolve any overlaps that directly influence the segmentation of the two overlapping spans under consideration, which is to say any other overlapping spans which contain at least one word also contained in at least one of overlapping spans under consideration. For example, in Figure 1a we first deal independently with each of the first two overlaps (the spans *modified with glucose* and *are enriched in lipid rafts*, and then we consider the final two overlaps together: The result is shown in Figure 1b. In development, we tested including more context (i.e. considering second-order influence) and found no benefit. Since we do not consider breaks other than those required to resolve overlapping n-grams, these segments tend to be long. This is by design; our intention is that these segments will subsume as many multiword units as possible, and therefore will be amenable to refinement by further decomposition in the next step.

3.4 Lexicon decomposition

Based on the initial segmentation of the entire corpus, we extract a tentative lexicon, with corresponding counts. Then, in order from longest to shortest, we consider decomposition of each entry. First, using our prediction-based decomposition method, we find the best decomposition of the entry into two parts; note that we only need to consider one break per lexicon entry, since breaks in the (smaller) parts will be considered independently later in the process. If the count in our lexicon is below the occurrence threshold, we always carry out this split, which means we remove the entry from the lexicon and (after all n-grams of that length have been processed, so as to avoid ordering effects) add its counts to the counts of n-grams of its best decomposition. If the count is above the threshold, we preserve the full entry (for entries of length 3 or greater) only if the following inequality is true for each subsegment $w_{j,k}$ in the full entry $w_{1,n}$:

$$\sum_{i=j}^{k} pred(w_i, w_{1,n}) - pred(w_{j,k}) > \log p(w_{j,k}) - \log p(w_{1,n})$$

That is, the ratio (expressed as a difference of logarithms) between the count of the segment and the full unsegmented entry (in our preliminary lexicon) is lower than the ratio of the predictability (as defined in our discussion of prediction-based decomposition) of the words in the segment with the context of the full entry to the predictability of words with only the context included within the segment (which is just $pred(w_{j,k})$). In other words, we preserve only longer multiword sequences in our lexicon when any decrease in the probability of the full entry relative to its smaller components[2] is fully offset by an increase in the conditional probability of the individual words of that segment when the larger context from the full segment is available. For example, after we have decided on a potential break in the phrase *basic | cellular process* from our example in Figure 1, we compare the (marginal) probability "lost" by including *basic* in a larger phrase, i.e. the ratio of counts of *basic* to *basic cellular process* in our lexicon), to the (conditional) probability "gained" by how much more predictable the segment is in this context; when the segment in question is a single word, as in this case, this is simply $p(basic|cellular\ process)/p(basic)$, and we break only when there is more gain than loss. This restriction could be parameterized for more fine-grained control of the trade-off between larger and smaller segments in specific cases, but in the interest of avoiding nuisance parameters we just use it directly. Once we have decomposed all eligible entries to create a final lexicon, we apply these same decompositions to the segments in our initial segmentation to produce a final segmentation (see Figure 1c).

4 Evaluation

Multiword lexicons are typically evaluated in one of two ways: direct comparison to an existing lexicon, or precision of the top n candidates offered by the model. There are problems with both these methods, since there are no resources that offer a truly comprehensive treatment of multiword units, defined broadly, and the top n candidates from a model for small n may not be a particularly representative sample: in particular, they might not include more common terms, which should be given more weight when one is considering downstream applications. Given the dual output of our model, evaluation using segmentation is another option, except that creating full gold standard segmentations would be a particularly difficult annotation task, since our notion of multiword unit is a broad one.

In light of this, we evaluate by taking the best from these various approaches. Given an existing multiword lexicon, we can evaluate not by comparing our lexicon to it directly, but rather by looking at the extent to which our segmentation preserves these known multiword units. There are several major advantages to this approach: first, it does not require a full lexicon or gold standard segmentation; second, common units are automatically given more weight in the evaluation; third, we can use it for evaluation in very large corpora. Our two main metrics are *subsumption* (Sub), namely the percentage of multiword tokens that are fully contained with a segment, and *exact matches* (Exact), the percentage of multiword tokens which correspond exactly to a segment. Exact matches would seem to be preferable to subsumption, but in practice this is not necessarily the case, since our method often identifies valid compound terms and larger constructions than our reference lexicon contains; for example, WordNet only contains the expression *a lot*, but when appearing as part of a noun phrase our model typically segments this to *a lot of*, which, in our opinion, is a preferable segmentation. To quantify overall performance, we calculate a harmonic mean (Mean) of the two metrics. We also looked specifically at performance for terms of 3 or more words (Mean 3+), which are less studied and more relevant to our interests.

Our second evaluation focuses on the quality of these longer terms with a post hoc annotation of output from our model and the best alternatives. We randomly extracted pairs of segments of three words or more where our model mostly but not entirely overlapped with an alternative model (750 examples per corpus per method), and asked CrowdFlower workers to choose which output seemed to be a better multiword unit in the context; they were shown the entire sentence with the relevant span underlined, and then the two individual chunks separately. To ensure quality, we used our multiword lexicon to

[2]This probability is based on the respective counts in our preliminary lexicon at this step in the process, not the original n-gram probability. One key advantage to doing the initial segmentation first is that words that appear consistently in larger units, an extreme example is the bigram *vector machine* in the term *support vector machine*, already have low or zero probability, and will not appear in the lexicon or be good candidate segments for decomposition. This rather intuitively accomplishes what the c-value metric is modeling by applying negative weights to candidates appearing in larger n-grams.

create gold standard examples (comparing known multiword units to purposely bad segmentations which overlapped with them), and used them to test and filter out unreliable workers: for inclusion in our final set, we required a minimum 90% performance on the test questions. We also limited each contributor to only 250 judgments, so that our results reflected a variety of opinions.

We considered a number of alternatives to our approach, though we limited the comparison to methods which could predict segments greater than 2 words, those that were computationally feasible for large corpora, and those which segment into single words only as a last resort: approaches which prefer single words cannot do well under our evaluation because we have no negative examples, only positive ones. The majority of our alternatives involve ranking all potential n-grams (not just the maximal) with $n \geq 2$ and then greedily segmenting them: big-n prefers longer n-grams (with a backoff to counts); c-value is used for term extraction (Frantzi et al., 2000) and was also compared to by Newman et al. (2012); ME refers to the Mutual Expectation metric (Dias et al., 1999); and PMI uses a standard extension of PMI to more than 2 words. We also tested standard (pairwise) PMI as a metric for recursively joining contiguous units (starting with words) into larger units until no larger units can be formed (PMI join), and a version of our decomposition algorithm which selects the minimal breaks which maximize total word count across segments rather than total word predictability (count decomp); the fact that traditional association metrics are not defined for single words prevents us from using them as alternatives to predictability in our decomposition approach. Finally, we also include an oracle which chooses the correct n-grams when they are available for segmentation, but which still fails for units that are below our threshold.

We evaluated our model in four large English corpora: news articles from the Gigaword corpus (Graff and Cieri, 2003) (4.9 billion tokens), out-of-copyright texts from the Gutenberg Project[3] (1.7 billion tokens), a collection of abstracts from PubMed (2.2 billion tokens)[4], and blogs from the ICWSM 2009 social media corpus (Burton et al., 2009) (1.1 million tokens). Our main comparison lexicon is WordNet 3.0, which contains a good variety of expressions appropriate to the various genres, but we also included multiword terms from the Specialist Lexicon[5] for better coverage of the biomedical domain. One issue with our evaluation is that it assumes all tokens are true instances of the multiword unit in question; we carried out a manual inspection of multiword tokens identified by string match in our development sets (5000 sentences set aside from each of the abstract and blog corpora), and excluded from the evaluation a small set of idiomatic expressions (e.g. *on it*, *do in*) whose literal, non-MWE usage is too common for the expression to be used reliably for evaluation; otherwise, we were satisfied that the vast majority of multiword tokens were true matches. When one multiword token appeared within another, we ignored the smaller of the two; when two overlapped in the text, we ignored both.

5 Results

All the results for the main evaluation are shown in Table 1. First, we observe that our initial segmentation always provides the highest subsumption, and our final lexicon always provides the highest harmonic mean, with a modest drop in subsumption but a huge increase in exact matches. The alternative models fall roughly into two categories: those which have reasonably high subsumption, but few exact matches (PMI rank seems to be the best of these) and those that have many exact matches (sometimes better than either of our models) but are almost completely ineffective for identifying multiword units of length greater than 2 (ME rank and c-value, with ME offering more exact matches): the latter phenomenon is attributable to the predominance of two-word multiword tokens in our evaluation, which means a model can do reasonably well by guessing mostly two-word units. For the corpora with more multiword units of greater length, i.e. the PubMed abstracts and the Gutenberg corpus, our method also provides the most exact matches. Our best results come in the PubMed corpus, probably because the texts are the most uniform, though results are satisfactory in all four corpora tested here, which represent a considerable range of genres.

Table 2: CrowdFlower pairwise preference evaluation, our full model versus a selection of alternatives

Comparison	**Preference for Prediction decomp, final**
Prediction decomp, final vs. ME	57.9%
Prediction decomp, final vs. Multi PMI	71.0%
Prediction decomp, final vs. Prediction decomp, initial	70.5%

For our crowdsourced evaluation, we compared our final model to the best models of each of the two major types from the first round, namely Mutual Expectation and PMI rank, as well as our initial segmentation. The results are given in Table 2. Our full model is consistently preferred over the alternatives. This is not surprising in the case of the high-subsumption, low-accuracy models, since the resulting segments often have extraneous words included: an example is *in spite of my*, which our model correctly segmented to just *in spite of*. Given that the ME ranking rarely produces units larger than 2 words, however, we might have predicted that when it does it would be more precise than our model, but in fact our model was somewhat preferred (a chi-square test confirmed that this result was statistically different from chance, $p < 0.001$). An example of an instance where our model offered a better segmentation is *call for an end to* as compared to *for an end to* from the ME model, though there are also many instances where the ME segmentation is more sensible, e.g. *what difference does it make* as compared to *difference does it make* from our model.

Looking closer at the output and vocabulary of our model across the various genres, we see a wide range of multiword phenomena: in the medical abstracts, for instance, there is a lot of medical jargon (e.g. *daily caloric intake*) but also other larger connective phrases and formulaic language (e.g. *an alternative explanation for*, *readily distinguished from*). The blogs also have (very different) formulaic language of

the sort studied using lexical bundles (e.g. *all I can say is that*, *where else can you*) and lots of idiomatic language (e.g. *reinventing the wheel*, *look on the bright side*). The idioms from the Gutenberg, not surprisingly, tend to be less clichéd and more evocative (e.g. *ghost of a smile*); there are rather stodgy expressions like *far be it from me* and conjunctions we would not see in the other corpora (e.g. *rocks and shoals*, *masters and mistresses*). By contrast, many of the larger expressions in the news articles are from sports and finance (e.g. *investor demand for*, *tied the game with*), with many that would be filtered out using the simple grammatical filters often applied in this space. However, for bigrams in particular, some additional syntactic filtering is clearly warranted.

6 Conclusion

We have presented an efficient but effective method for segmenting a corpus into multiword collocational units, with a particular focus on units of length greater than two. Our evaluation indicates that this method results in high-quality segments that capture a variety of multiword phenomena, and is better in this regard than alternatives based on relevant association measures. This result is consistent across corpora, though we do particularly well with highly stereotyped language such as seen in the biomedical domain.

Future work on improving the model will likely focus on extensions related to syntax, for instance bootstrapped POS filtering and discounting of predictability that can be attributed solely to syntactic patterns. Our method could also be adapted to decompose full syntactic trees rather than sequences of words, offering tractable alternatives to Bayesian approaches that identify recurring tree fragments (Cohn et al., 2009); this would allow us, for instance, to correctly identify constructions with long-distance dependencies or other kinds of variation where relying on the surface form is insufficient (Seretan, 2011).

With regards to applications, we will be investigating how to help learners notice these chunks when reading and then use them appropriately in their own writing; this work will eventually intersect with the well-established areas of grammatical error correction (Leacock et al., 2014) and automated essay scoring (Shermis and Burstein, 2003). As part of this, we will be building distributional lexical representations of these multiword units, which is why our emphasis here was on a highly scalable method. Part of our interest is of course in capturing the semantics of idiomatic phrases, but we note that even in the case when a multiword unit is semantically compositional, it might provide *de facto* word sense disambiguation or be stylistically distinct from its components, i.e. be very specific to a particular genre or sub-genre. Therefore, provided we have enough examples to get reliable distributional statistics, these larger units are likely to provide useful information for various downstream applications.

docrep: A lightweight and efficient document representation framework

Abstract

Modelling linguistic phenomena requires highly structured and complex data representations. Document representation frameworks (DRFs) provide an interface to store and retrieve multiple annotation layers over a document. Researchers face a difficult choice: using a heavy-weight DRF or implement a custom DRF. The cost is substantial, either learning a new complex system, or continually adding features to a home-grown system that risks overrunning its original scope.

We introduce DOCREP, a lightweight and efficient DRF, and compare it against existing DRFs. We discuss our design goals and implementations in C++, Python, and Java. We transform the OntoNotes 5 corpus using DOCREP and UIMA, providing a quantitative comparison, as well as discussing modelling trade-offs. We conclude with qualitative feedback from researchers who have used DOCREP for their own projects. Ultimately, we hope DOCREP is useful for the busy researcher who wants the benefits of a DRF, but has better things to do than to write one.

1 Introduction

Computational Linguistics (CL) is increasingly a data-driven research discipline with researchers using diverse collections of large-scale corpora (Parker et al., 2011). Representing linguistic phenomena can require modelling intricate data structures, both flat and hierarchical, layered over the original text; e.g. tokens, sentences, parts-of-speech, named entities, coreference relations, and trees. The scale and complexity of the data demands efficient representations. A document representation framework (DRF) should support the creation, storage, and retrieval of different annotation layers over collections of heterogeneous documents. DRFs typically store their annotations as stand-off annotations, treating the source document as immutable and annotations "stand-off" with offsets back into the document.

Researchers may choose to use a heavy-weight DRF, for example GATE (Cunningham et al., 2002) or UIMA (Götz and Suhre, 2004), but this can require substantial investment to learn and apply the framework. Alternatively, researchers may "roll-their-own" framework for a particular project. While this is not inherently bad, our experience is that the scope of such smaller DRFs often creeps, without the benefits of the features and stability present in mature DRFs. Moreover, some DRFs are based on object serialisation, restricting the user to a specific language. In sum, while DRFs provide substantial benefits, they can come at an opportunity cost to valuable research time.

DOCREP aims to solve this problem by proving a light-weight DRF that does not get in the way. Using a language-agnostic storage layer enables reuse across different tasks in whatever tools and programming languages are most appropriate. Efficiency is our primary goal, and we emphasise compact serialisation and lazy loading. Our streaming design is informed by the pipeline operation of UNIX commands.

Section 2 compares existing DRFs and annotation schemes. We describe and introduce DOCREP in Section 3, outlining the design goals and the problems it aims to solve. We compare DOCREP to UIMA through a case study in Section 4, converting OntoNotes to both DRFs. Section 5 discusses real world uses of DOCREP within our research group and outlines experiences of its use by NLP researchers. DOCREP

Proceedings of COLING 2014, the 25th International Conference on Computational Linguistics: Technical Papers, pages 762–771, Dublin, Ireland, August 23-29 2014.

will be useful for any researcher who wants rapid development with multi-layered annotation that performs well at scale, but at minimal technical cost.

2 Background

Easily and efficiently storing and retrieving linguistic annotations over corpora is a core issue for data-driven linguistics. A number of attempts to formalise linguistic annotation formats have emerged over the years, including Annotation Graphs (AG) (Bird and Liberman, 1999), the Linguistic Annotation Format (LAF) (Ide and Romary, 2004, 2006), and more recently, the Graph Annotation Framework (GRAF) (Ide and Suderman, 2007). GRAF is a serialisation of the LAF model, using XML stand-off annotations to store layers of annotation. The GRAF representation is sufficiently abstract as to be used as a pivot format between other annotation schemes. Ide and Suderman (2009) use GRAF as an intermediate format to convert annotations between GATE and UIMA. The MASC corpus (Ide et al., 2010) has multiple layers of annotation which are distributed in GRAF. Neumann et al. (2013) provide insight into the effectiveness of GRAF as a format for corpus distribution when they import MASC into an annotation database. These linguistic annotation formalisations provide a useful set of requirements for DRFs. While these abstract formalisations are constructive from a theoretical perspective, they do not take into account the runtime performance of abstract representations, nor their ease of use for programmers.

Several DRFs have been developed and used within the CL community. GATE (Cunningham et al., 2002; Cunningham, 2002) has a focus on the human annotation of textual documents. While it has a large collection of extensions and plugins, it was not designed in a matter than suits web-scale corpus processing. Additionally, GATE is limited to Java, making integration with CL tools written in other languages difficult. UIMA (Götz and Suhre, 2004; Lally et al., 2008) is a Java framework for providing annotations over the abstract definition of documents, providing functionality to link between different views of the same document (e.g. translations of a document). UIMA calls these different views different "subjects of analysis" (SOFA). When UIMA was adopted into the Apache Software Foundation, a C++ version of the UIMA API was developed. However, it appears to lag behind behind the Java API in development effort and usefulness, with many undocumented components, numerous external dependencies, and with substantial missing functionality provided by the Java API. Additionally, the C++ API is written in an non-idiomatic manner, making it harder for developers to use.

Publicly available CL pipelining tools have emerged in recent years, providing a way to perform a wide range of CL processes over documents. The Stanford NLP pipeline[1] is one such example, but is Java only and must be run on a single machine. CURATOR (Clarke et al., 2012) provides a cross-language NLP pipeline using Thrift to provide cross-language communication and RPC. CURATOR requires a server to coordinate the components within the pipeline. Using pipelining functionality within a framework often the inspection of per-component contributions more difficult. We are not aware of any DRFs which use a streaming model to utilise UNIX pipelines, a paradigm CL researchers are already familiar with.

3 The docrep document representation framework

DOCREP (/dɒkrɛp/), a portmanteau of *doc*ument *rep*resentation, is a lightweight, efficient, and modern document representation framework for NLP systems that is designed to be simple to use and intuitive to work with. We use the term lightweight to compare it to the existing document representation systems used within the CL community, the main one being UIMA. The overhead of using DOCREP instead of a flat-file format is minimal, especially in comparison to large bulky frameworks.

Our research group has used DOCREP as its primary data storage format in both research projects and commercial projects since mid-2012. DOCREP has undergone an iterative design process during this time as limitations and issues arose, allowing modelling issues to be ironed out and a set of best practices to be established. These two years of solid use by CL researchers has resulted in a easy to use DRF we believe is suitable for most CL applications and researchers.

DOCREP was designed with streaming in mind, facilitating from the data storage layer upwards the ability for CL applications to utilise parallel processing. This streaming model is a model that many

[1] `http://nlp.stanford.edu/software/corenlp.shtml`

CL researchers are already familiar with from writing UNIX pipelines (Church, 1994; Brew and Moens, 2002), again reducing the overhead required to use DOCREP.

DOCREP is not a new language that researchers need to learn. Instead, it is a serialisation protocol and set of APIs to interact with annotations and documents. Using DOCREP is as simple as importing the package in ones favourite programming language and annotating class definitions appropriately. Neither a separate compilation step nor an external annotation definition file are required.

3.1 Idiomatic APIs

One of the motivations for constructing DOCREP was the lack of a good document representation framework in programming languages other than Java. We have implemented DOCREP APIs in three commonly used programming languages in the CL community: C++, Python, and Java. All of these APIs are open source and publicly available on GitHub,[2] released under the MIT licence. The C++ API is written in C++11, the Python API supports version 2.7 as well as versions $\geq$ 3.3, and the Java API supports versions $\geq$ 6. All three APIs are setup to use the standard build tools for the language.

When implementing these APIs, we aimed to make the interface as similar as possible between the three languages, while still feeling idiomatic within that language. Using the API should feel natural for that language. Figure 1 shows an example set of identical model definitions in C++, Python, and Java. This example defines a `Token` type, a `Sent` type spanning over a series of sequential `Token` annotations, and a `Doc` type. The `Token` and `Sent` types include some annotation attributes. Annotation instances are stored on the document in `Stores`. Apart from the missing implementations of the `Schema` constructors in the C++ example, these are complete and runnable definitions of annotation types in DOCREP. The `Schema` classes in the C++ example are automatically induced via runtime class introspection in the Python and Java APIs; functionality which C++ does not possess.

3.2 Serialisation protocol

We chose to reuse an existing serialisation format for DOCREP. This allows developers to use existing serialisation libraries for processing DOCREP streams in languages we do not provide a DOCREP API for.

One of our design considerations when creating DOCREP was a desire for the protocol to be self-describing. With a self-describing protocol, no external files need to be associated with a serialised stream in order to know how to interpret the serialised data. This requires an efficient serialisation protocol because including the definition of the type system with each document comes at a cost. This is different to UIMA which requires its XML type definition files in order to deserialise the serialised data.

The four main competitors in the web-scale binary serialisation format space are BSON,[3] MessagePack,[4] Protocol Buffers,[5] and Thrift.[6] BSON and MessagePack are similar in their design. They both aim to provide a general purpose data serialisation format for common data types and data structures. BSON is used as the primary data representation within the MongoDB database. Protocol Buffers and Thrift work in a similar manner to one another. Their serialisation protocols are not self describing and require an external file which defines how to interpret the messages on the stream. In this external file, users define the structure of the messages they wish to serialise and deserialise, and use a provided tool to convert this external file into source code for their programming language of choice. Protocol Buffers and Thrift also provide RPC functionality, however this was not needed for our situation. Thrift is used by the CURATOR NLP pipeline (Clarke et al., 2012) to provide both serialisation and RPC functionality between cross-language disjoint components in the pipeline.

After designing the serialisation protocol for DOCREP, we implemented it on top of these binary serialisation formats in order to compare the size of the serialised data and the speed at which it could be compressed. As a simple stand-off annotation task, we chose to use the CoNLL 2003 NER shared task

```
struct Token : public dr::Ann {
  dr::Slice<uint64_t> span;
  std::string raw;
  std::string norm;
  class Schema;
};

struct Sent : public dr::Ann {
  dr::Slice<Token *> span;
  bool is_headline;
  class Schema;
};

struct Doc : public dr::Doc {
  dr::Store<Token> tokens;
  dr::Store<Sent> sents;
  class Schema;
};
```

```
struct Token::Schema : public dr::Ann::Schema<Token> {
  DR_FIELD(&Token::span) span;
  DR_FIELD(&Token::raw) raw;
  DR_FIELD(&Token::norm) norm;
  Schema(void);
};

struct Sent::Schema : public dr::Ann::Schema<Sent> {
  DR_POINTER(&Sent::span, &Doc::tokens) tokens;
  DR_FIELD(&Sent::is_headline) is_headline;
  Schema(void);
};

struct Doc::Schema : public dr::Doc::Schema<Doc> {
  DR_STORE(&Doc::tokens) tokens;
  DR_STORE(&Doc::sents) sents;
  Schema(void);
};
```

(a) C++ example

```
class Token(dr.Ann):
  span = dr.Slice()
  raw = dr.Text()
  norm = dr.Text()

class Sent(dr.Ann):
  span = dr.Slice(Token)
  is_headline = dr.Field()

class Doc(dr.Doc):
  tokens = dr.Store(Token)
  sents = dr.Store(Sent)
```

(b) Python example

```
@dr.Ann
public class Token extends AbstractAnn {
  @dr.Field public ByteSlice span;
  @dr.Field public String raw;
  @dr.Field public String norm;
}

@dr.Ann
public class Sent extends AbstractAnn {
  @dr.Pointer public Slice<Token> span;
  @dr.Field public bool isHeadline;
}

@dr.Doc
public class Doc extends AbstractDoc {
  @dr.Store public Store<Token> tokens;
  @dr.Store public Store<Sent> sents;
}
```

(c) Java example

Figure 1: Examples of identical type definitions using the DOCREP API in C++, Python, and Java.

	Self-describing	Uncompressed		DEFLATE		Snappy		LZMA	
		Time	Size	Time	Size	Time	Size	Time	Size
Original data	–	–	31.30	1.0	5.95	0.1	9.81	39	0.39
BSON	✓	2.5	188.42	5.3	30.32	0.6	56.36	441	16.22
MessagePack	✓	1.6	52.15	3.2	16.61	0.3	24.82	61	4.36
Protocol Buffers	×	1.4	51.51	3.5	18.52	0.3	29.31	67	5.13
Thrift	×	1.0	126.12	3.5	20.64	0.4	33.69	224	10.99

Table 1: A comparison of binary serialisation libraries being used as the DOCREP serialisation format. Times are reported in seconds and sizes in MB. MessagePack and BSON include the full type system definition on the stream for each document whereas Protocol Buffers and Thrift do not.

data, randomly sampling around 50 MB worth of sentences from the English training data. The serialisation stores the documents, sentences, and tokens, along with the POS and NER tags for the tokens. The appropriate message specification files were written for Protocol Buffers and Thrift, and the type system was serialised as a header for BSON and MessagePack.

Table 1 shows the results of this experiment. The reported size of the original data is smaller than the sample size as we chose to output it in a more concise textual representation than the data was originally distributed in. BSON performs noticeably worse than the others, in terms of both size and speed. While serialising slightly faster, the size of the serialised data produced by Thrift is more then double the size of both MessagePack and Protocol Buffers, and does not compress quite as well. MessagePack compressed slightly better than Protocol Buffers and was on par in terms of speed, while being self-describing on the stream. The result of this experiment and some similar others lead us to conclude that MessagePack was the best serialisation format for DOCREP to use.

At the time of writing, the Python and Java DOCREP APIs use the official MessagePack libraries for those languages. We implemented our own C++ MessagePack library to facilitate laziness.

3.3 Laziness

The serialisation protocol was designed such that we could make the streaming aspect of DOCREP as efficient as possible. Before each collection of annotation objects appears in the serialised data, the number of bytes used to store the serialised annotations is stored. If the current application is not interested in the particular annotation types that are about to be read in, it can simply skip over the correct number of bytes without having to deserialise the internal MessagePack structure.

All three of our APIs implement this laziness. Only the types of annotations that the application specifies interest in will be deserialised at runtime. The other types of annotations will simply be kept in their serialised format and written back out to the output stream unmodified. This is also true for attributes on annotations that the current application is not interested in. The Python API provides an option to fully instantiate each of the types at runtime, even if you have not defined classes for them. Unknown annotation types will have classes created at runtime based on the schema of the types described in the serialisation protocol.

3.4 Processing tools

We trade-off performance against easy inspection of files. We provide a set of command-line tools for manipulating, filtering, and distributing DOCREP streams. The command-line tools mimic the standard set of UNIX tools used to process textual files as well as some other stream introspection and statistics gathering tools. All of these tools and their uses are documented on the DOCREP website.[7] Our provided toolbox for processing DOCREP streams contains tools for counting, visualising, filtering, ordering, partitioning, and exporting DOCREP streams. Due to space limitations in this paper, we are unable to go into these tools in detail.

Below are two examples of some of the tools in action. The first example filters the documents by a regular expression comparison against their ID attribute, and then outputs the ID of the document with the most number of tokens. The second randomly chooses 10 documents from a stream, passing them to another tool, and then opens the first returned document in the stream visualiser.

```
$ dr grep 'doc.id ~ /x-\d+/' corpus.dr | dr count -s tokens | sort -rn | head -n 1
$ dr sample -n 10 corpus.dr | ./my-tool | dr head -n 1 | dr less
```

3.5 Streaming model

Emphasising the fact that the DOCREP protocol is a streaming protocol, combining multiple DOCREP files together is as simple as concatenating the files together. The DOCREP deserialisers expect an input stream to contain zero or more serialised documents. Being able to easily distribute all documents in a corpus along with their annotation layers as a single file is very attractive.

[7] https://github.com/schwa-lab/libschwa

This kind of streaming model makes distributed processing very easy using a typical work queue model. A distributed pipeline "source" can serve the documents from the DOCREP stream by reading them off the input stream without having to deserialise them (subsection 3.3) and a "sink" can simply concatenate the received documents together to the output stream, again without having to deserialise them. We provide a DOCREP source and sink distributed processing tool along with APIs for easily writing worker clients. The distribution is achieved through ØMQ[8] which allows for both scale-up and scale-out distributed processing out of the box without the need for a separate controller process to manage communication between client processes.

4 Case study: OntoNotes 5

The OntoNotes 5 corpus (Pradhan et al., 2013) is a large corpus of linguistically annotated documents from multiple genres in three different languages. This 5th release covers newswire, broadcast news, broadcast conversation, and web data in English and Chinese, a pivot corpus in English, and newswire data in Arabic. Roughly half of the broadcast conversation data is parallel data, with some of the documents providing tree-to-tree alignments. Of the 15 710 documents in the corpus, 13 109 are in English, 2002 are in Chinese, and 599 are in Arabic.

Each of the documents in the OntoNotes 5 corpus contain multiple layers of syntactic and semantic annotations. It builds upon the Penn Treebank for syntax and PropBank for predicate-argument structure, adding named entities, coreference, and word sense disambiguation layers to some documents.

The annotations in the OntoNotes 5 corpus are provided in two different formats: as a series of flat files (340 MB) per document with each file containing one annotation layer, and as a relational database in the form of a SQL file (5812 MB). Both of these data formats have usability issues. Working with the flat files requires parsing each of the different file formats and aligning the data between the files for the same document. Working with the database requires working out how the tables are related to one another, as well as knowledge of SQL, or having access to an efficient API for querying the database.

To outline the effectiveness of document representation frameworks, and in particular the efficiency of DOCREP, we provide code to convert the OntoNotes 5 corpus into both DOCREP and UIMA representations, comparing the conversion time, resultant size on disk, and ease of doing this conversion. We provide conversion scripts in all three languages for DOCREP and in Java and C++ for UIMA. Additionally, we also provide a verification script, reproducing the original OntoNotes 5 flat files from the document representation form, ensuring that no data was lost in the conversion.

4.1 Modelling decisions

The choices made on how to model the different annotation layers were almost identical in UIMA and DOCREP. The main difference occurs when you have an annotation over a sequential span of other annotations. UIMA has no way to model this directly. The most common way users choose to model this is as a normal `Annotation` subtype with its `begin` offset set to the `begin` offset of the first covered annotation and its `end` offset set to the `end` offset of the last covered annotation. An example of this situation is named entity annotations. In OntoNotes, named entities are represented as annotations over a sequence of token annotations. How this is represented in UIMA is shown in the XML snippet in Figure 2. The main disadvantage in this modelling approach is that there is then no direct representation that the named entity annotation is an annotation over a sequence of token annotations. In DOCREP, named entity annotation is directly modelled as a sequence of token annotations. The DOCREP definition for the named entity type is shown on the right hand side of Figure 2.

DOCREP does not allow for the direct modelling of cross-document information. This occurs in the OntoNotes 5 corpus in the form of the parallel document and parallel tree information. Because DOCREP is a streaming protocol, the documents are thought of as independent from one another and as such, no formal relationships between the documents can be made at the framework level. This parallel document information can still be be stored as metadata on the documents. This situation is dealt with in UIMA by the SOFA.

Size on disk	1894	3252	1257	99	2141	3252	2135	371	371	371

Table 2: A comparison of the resources required to represent the OntoNotes 5 corpus in UIMA and DOCREP. Times are reported in seconds and sizes are reported in MB.

4.2 Empirical results

In these experiments, we first load all of the data into memory from the database for the current document we are processing. This data is stored in an object structure which knows nothing about document representation frameworks. We then convert this object representation into the appropriate UIMA and DOCREP annotations, recording how long the conversion took. The UIMA and DOCREP versions of the documents are then serialised to disk, recording how long the serialisation took and the resultant size on disk. All of these performance experiments were run on the same isolated machine, running 64-bit Ubuntu 12.04, using OpenJDK 1.7, CPython 2.7, and gcc 4.8.

In order to provide a fair comparison between UIMA and DOCREP, we perform the conversion using both the Java and C++ UIMA APIs, as well as using all three DOCREP APIs (Java, C++, and Python). The code to load the data from the database and construct the in-memory object structure was common between the UIMA and DOCREP conversions. For UIMA, we serialise in all available output formats: both the XMI and XCAS XML formats, the binary format (bin), and the compressed binary (cbin) format. The UIMA C++ API does not appear to support output in the compressed binary format.

The result of this conversion process can be seen in Table 2. The first row shows the accumulated time taken to convert all of the documents from their in-memory representation into UIMA and DOCREP annotations. As visible in the table, DOCREP performs this conversion twice as fast as UIMA in Java and six times as fast as UIMA in C++ The second row shows the accumulated time taken to serialise

	Flat files	DOCREP	UIMA XMI	UIMA XCAS	UIMA bin	UIMA cbin	SQL	MySQL -indices	MySQL +indices
Uncompressed	340	371	1894	3252	1257	99	4560	4303	5812
`gzip` (DEFLATE)	52	115	268	330	375	66	646	–	–
`xz` (LZMA)	30	69	144	185	150	65	262	–	–

Table 3: A comparison of the how well each of the annotation serialisation formats compress using standard compression libraries. All sizes are reported in MB.

all of the documents to disk. DOCREP serialises up to 34 times faster than UIMA in Java, depending on the UIMA output format, and up to 30 times faster in C++ Ṫhe third row in this table shows the accumulated serialisation size on disk. Apart from the compressed binary output format in UIMA (cbin), DOCREP serialisation requires up to nine times less space than UIMA Ẇe are unsure why the sizes for the different output formats in UIMA do not match up between the Java and C++ APIs Ẇe are also unsure why the UIMA Java binary serialisation is so slow, especially in comparison to the compressed binary serialisation.

Table 3 shows how well each of the serialisation formats compress using three standard compression libraries. Each of these compression libraries were run with their default settings. The files generated by UIMA as well as the "flat file" files were first placed into a tarball so that the compression algorithms could be run over the whole corpus instead of per document. The "flat files" used were the original OntoNotes 5 flat files containing the annotation layers that were converted. The SQL numbers are using the original OntoNotes 5 SQL file. The MySQL numbers are obtained after loading the original SQL into a MySQL database and obtaining table and index sizes from the `information_schema.tables` table. The MySQL database was not altered from the initial import. Unsurprisingly, the DOCREP binary representation does not compress as well as textual serialisation formats with lots of repetition, such as XML or the original stand-off annotation files. However, under all of these reported situations, apart from the UIMA compressed binary format, our DOCREP representation is two to five times smaller than its UIMA counterpart, and 15 times smaller than the representation in MySQL. The UIMA compressed binary (cbinary) format has already been compressed so it is unsurprising that compressing it further makes little difference.

5 Usability

We have primarily evaluated the usefulness of DOCREP from an efficiency perspective, reporting time and space requirements for a complex corpus conversion. In this section, we provide feedback from NLP researchers in our lab who have been using DOCREP over the past two years for a variety of NLP tasks. As researchers ourselves, we are aware of how valuable research time is. We provide these real-world examples of DOCREP's use to solidifying that DOCREP is a valuable tool for researchers.

Coreference DOCREP *is a great tool for this project as all we want to do is develop a good coreference system; we do not want to have to worry about the storage of data. Having an* API *in Python is super convenient, allowing us to write code that changes frequently as we try new ideas.* Related publication: Webster and Curran (2014)

Event Linking *Some work on Event Linking sought to work with gold annotations on one hand, and knowledge from web-based hyperlinks on the other. For some processes these data sources were to be treated identically, and for some differently.* DOCREP*'s extensibility easily supported this use-case, while providing a consistent polymorphic abstraction that made development straightforward, while incorporating many other layers of annotation such as extracted temporal relations. Separately, describing the relationship between a pair of documents in* DOCREP *was a challenging use-case that required more engineering and fore-thought than most* DOCREP *applications so far.* Related publication: Nothman et al. (2012).

Named Entity Linking *Our approach to* NEL *uses a pipeline of components and we initially wrote our own* DRF *using Python's object serialisation. While this worked well initially, we accrued technical debt as we added features with minimal refactoring. Before too long, a substantial part of our experiment runtime was devoted to dataset loading and storage.* DOCREP *made this easier and using* UNIX *pipelines over structured document objects is a productive workflow.* Related publications: Radford et al. (2012); Pink et al. (2013).

Quote Extraction and Attribution *For this task we performed experiments over four corpora, all with distinct data formats and assumptions. Our early software loaded each format into memory, which was a slow, error-prone, and hard-to-debug process. This approach became completely unusable when we decided to experiment with coreference systems, as it introduced even more unique data formats. Converting everything to* DOCREP *greatly simplified the task, as we could represent everything we needed efficiently, and within one representation system. We also gained a nice speed boost, and were able to write a simple set of tests that examined a given* DOCREP *file for validity, which greatly improved our code quality.* Related publication: O'Keefe et al. (2013).

Slot Filling *Being one of the last stages in an* NLP *pipeline, slot filling utilises all of the document information it can get its hands on. Being able to easily accept annotation layers from prior* NLP *components allows us to focus on slot filling instead of component integration engineering. Having access to a multi-language* API *means we are able to write efficiency-critical code in C++ and the more experimental and dynamic components in Python.*

6 Conclusion

We present a light-weight and easy-to-use document representation framework for the busy NLP researcher who wants to model document structure, but does not want to use a heavy-weight DRF. We provide empirical evidence of the efficiency of DOCREP, and provide insights into its use within our research group over the past two years. We believe NLP other researchers will benefit from DOCREP as they are now able to utilise the usefulness of a DRF without it getting in the way of their research time.

Acknowledgments

We would like to thank the anonymous reviewers for their useful feedback. We would also like to thank Will Radford and Joel Nothman for their contributions to this paper as well as to DOCREP itself over the past years. This work was supported by ARC Discovery grant DP1097291 and the Capital Markets CRC Computable News project.

Abstract

In recent years, the problem of finite-state constraint grammar (CG) parsing has received renewed attention. Several compilers have been proposed to convert CG rules to finite-state transducers. While these formalisms serve their purpose as proofs of the concept, the performance of the generated transducers lags behind other CG implementations and taggers.

In this paper, we argue that the fault lies with using generic finite-state libraries, and not with the formalisms themselves. We present an open-source implementation that capitalises on the characteristics of CG rule application to improve execution time. On smaller grammars our implementation achieves performance comparable to the current open-source state of the art.

1 Introduction

Constraint grammar (CG), described originally by Karlsson (1990), is a rule-based formalism for various linguistics tasks, including morphological analysis, clause boundary detection and surface syntactic parsing. It has been used in a wide range of application areas, such as morphological disambiguation, grammar checking and machine translation (Bick, 2011). CG owns its popularity to two reasons: first, it achieves high accuracy on free text. Second, it works for languages where the annotated corpora required by statistical parsing methods are not available, but a linguist willing to work on the rules is. The original CG has since been superseded by CG-2 (Tapanainen, 1996) and lately, the free/open-source VISL CG-3 (Bick, 2000; Didriksen, 2011).

Constraint grammar, however, has its drawbacks, one of which is speed. The Apertium machine translation project (Forcada et al., 2011) uses both CG (via VISL CG-3) and n-gram based models for morphological disambiguation, and while CG achieves higher accuracy, the n-gram model runs about ten times faster.

In this paper, we investigate how using finite-state transducers (FST) for CG application can help to bridge the performance gap. In recent years, several methods have been proposed for compiling a CG to FST and applying it on text: Hulden (2011) compiles CG rules to transducers and runs them on the input sentences; Peltonen (2011) converts the sentences into ambiguous automata and attempts to eliminate branches by intersecting them with the rule FSTs; finally, Yli-Jyrä (2011) creates a single FST from the grammar and applies it on featurised input. Unfortunately, none of the authors report exact performance measurements of their systems. Yli-Jyrä published promising numbers for the preprocessing step, but nothing on the overall performance. Peltonen, on the other hand, observed that "VISL CG-3 was 1,500 times faster" than his implementation (Peltonen, 2011).

Proceedings of COLING 2014, the 25th International Conference on Computational Linguistics: Technical Papers, pages 772–780, Dublin, Ireland, August 23-29 2014.

We do not attempt here to add a new method to this list; instead, we concentrate on three practical aspects of FST-based CG. First, we report accurate measurements of the real-world performance of one of the methods above. Second, we endeavour to optimise the implementation of the selected method. All three works used *foma*, an open source FST library (Hulden, 2009b; Hulden, 2009a). We show that while *foma* is fast, relying on specialised FST application code instead of a generic library clearly benefits performance. We also demonstrate what further improvements can be achieved by exploiting the peculiarities of CG. Lastly, our research also aims to fill the niche left by the lack of openly accessible finite-state CG implementations.

Section 2 briefly introduces the method we chose to evaluate. In the rest of the paper, we present our optimisations in a way that mirrors the actual development process. We start out with a simple rule engine based on foma, and improve it step-by-step, benchmarking its performance after each modification, instead of a single evaluation chapter. We start in Section 3 by describing our evaluation methodology. Section 4 follows the evolution of the rule engine, as it improves in terms of speed. Section 5 contains a complexity analysis and introduces an idea that theoretically allows us to improve the average- and best-case asymptotic bound. Section 6 demonstrates how memory savings can be derived from the steps taken in section 4. Finally, Section 7 contains our conclusions and lists the problems that remain for future work.

2 The *fomacg* compiler and *fomacg-proc*

We have chosen Hulden's *fomacg* compiler for our study. Our reasons for this are twofold. The transducers generated by *fomacg* were meant to be run on the input directly, but they could also be applied to a finite-state automaton (FSA) representation of the input sentence via FST composition, thereby giving us more space to experiment. Peltonen's method, on the other hand, works only through FST intersection. More importantly, *fomacg* was the only compiler that is openly available.[1]

Here we briefly describe how *fomacg* works; for further details refer to (Hulden, 2011). A CG used for morphological disambiguation takes as input a morphologically analysed text, which consists of *cohorts*: a word with its possible readings. A reading is represented by a lemma and a set of morphosyntactic *tags*. For example, the cohort of the ambiguous Hungarian word *szív* with two readings "heart" and "to suck" would be `^szív/szív<n><sg><nom>/szív<vblex><pres><s3p>$`.[2] The text is tokenised into sentences based on a set of *delimiters*. CG rules operate on a sentence, removing readings from cohorts based on their context. The rules can be divided into priority levels called *section*. Most implementations apply the rules one-by-one in a loop, until no rules can further modify the sentence.

fomacg expects cohorts to be encoded in a different format; the cohort in the example above would be represented as

```
$0$ "<szív>" #BOC#         |
#0# "szív" n sg nom        |
#0# "szív" vblex pres s3p  | #EOC#
```

The rule transducers mark readings for removal by replacing the `#0#` in front of the reading by `#X#`; they act as identity for sentences they cannot be applied to.

fomacg is only a compiler, which reads a CG rule file and emits a *foma* FST for each rule. The actual disambiguator program that applies the transducers to text we implemented ourselves. It reads the morphologically analysed input in the Apertium stream format, converts it into the format expected by *fomacg*, applies the transducers to it, and then converts the result back to the stream format. To emphasise its similarity to *cg-proc*, VISL CG's rule applier, we named our program *fomacg-proc*.

3 Methodology

Apertium includes constraint grammars for several languages.[3] While most of these are wide-coverage grammars, and are being actually used for morphological disambiguation in Apertium, they are also

[1] In the Apertium software repository: `https://svn.code.sf.net/p/apertium/svn/branches/fomacg`

[2] The example is in the Apertium stream format, not in CG-2 style.

[3] `http://wiki.apertium.org/wiki/Constraint_grammar`

too big and complex to be easily used for the early stages of parser development. Therefore, we have written a small Hungarian CG, aimed to fully disambiguate a short Hungarian story, which was used as the development corpus. Since Hungarian is not properly supported by Apertium yet, morphological analysis was carried out by Hunmorph (Trón et al., 2005), and the tags were translated to the Apertium tagset with a transducer in `foma`.

The performance of `fomacg-proc` has been measured against that of VISL CG. The programs were benchmarked with three Apertium CG grammars: the toy Hungarian grammar mentioned earlier, the Breton grammar from the `br-fr` language pair (Tyers, 2010), and the version of the Finnish grammar originally written by Karlsson in the North Sámi–Finnish (`sme-fin`) pair. Seeing that in the early phases, only the Hungarian grammar was used for development, results for the other two languages are reported only for the later steps.

Each grammar was run on a test corpus. For Breton, we used the corpus in the `br-fr` language pair, which consists of 1,161 sentences. There are no Finnish and Hungarian corpora in Apertium; for the former, we used a 1,620-sentence excerpt from the 2013-Nov-14 snapshot of the Finnish Wikipedia, while for the latter, the short test corpus used for grammar development. Since the latter contains a mere 11 sentences, it was repeated 32 times to produce a corpus similar in size to the other two.[4] The Breton and Finnish corpora were tagged by Apertium's morphological analyser tools.

Since VISL CG implements CG-3, and *fomacg* only supports CG-2, a one-to-one comparison with the grammars above was not feasible. Therefore, we extracted the subset of rules from each that compiled under *fomacg*, and carried out the tests on these subsets. Table 1 shows the number of rules in the original and the CG-2 grammars.

Table 1: Grammar sizes with the running time and binary size of the respective VISL-CG grammars

Language	Rules	CG-2 rules	Binary	Time
Hungarian	33	33	8kB	0.284s
Breton	251	226	36kB	0.77s
Finnish	1207	1172	184kB	1.78s

We recorded both initialisation and rule application time for the two programs, via instrumentation in case of *fomacg-proc* and by running the grammar first on an empty file and then on the test corpus in case of *cg-proc*. However, as initialisation is a one-time cost, in the following we are mainly concerned with the time required for applying rules. The tests were conducted on a consumer-grade laptop with a 2.2GHz Core2Duo CPU and 4GB RAM, running Linux.

4 Performance optimisations

Our implementation, much like that of *fomacg* (and indeed, all recent work on finite state CG) is based on the *foma* library. We started out with a naïve implementation that used solely stock *foma* functions. Most of the improvements below stem from the fact that we have replaced these functions with custom versions that run much faster. The final implementation abandons *foma* entirely, but for the data structures. In the future, we plan to discard those as well, making our code self-contained.

The program loads the transducers produced by *fomacg* and applies them to the text. The input is in the Apertium stream format[5] and it is read cohort-by-cohort. A *foma* FST is used to convert each cohort to the format expected by the rule transducers, and to convert the final result back.

To tokenise the text to sentences, we modified *fomacg* to compile the *delimiters* set and emit it as the first FSA in the binary representation of the grammar. *fomacg-proc* reads the input until a cohort matches this set and then sends the accumulated sentence to the rule applier engine.

[4] Although we used the same corpus for development and testing for Hungarian, the experimental setup was the same for VISL-CG and fomacg. While the numbers we acquired for Hungarian are not representative of how a proper Hungarian CG would perform on unseen data, they clearly show which of our steps benefit performance.

[5] `http://wiki.apertium.org/wiki/Apertium_stream_format`

The rules are tested one-by-one, section-by-section, to see if any of them can be applied to the text. Once such a rule is found, the associated FST is executed on the text. As it is possible that a rule that was not applicable to the original text would now run on the modified one, testing is restarted from the first section after each rule application. The process ends when no more applicable rules are found.

4.1 Naïve implementation

The first version of the program used the `apply_down()` *foma* function both for rule application and format conversion. As *fomacg* generated a single FST for a rule, rule testing and execution was done in the same step, by applying the FST. Whether the rule was actually applied or not was decided by comparing the original sentence to the one returned by the function.

The first row in Table 2 shows the running time for the Hungarian grammar. At 6.4s, the naïve implementation runs more than 20 times slower than VISL-CG (see Table 1). Luckily a far cry from the 1,500 reported by Peltonen, but clearly too slow to be of practical use.

4.2 FST composition

Another way to apply a rule is to convert the input sentence into a single-path FSA with the same alphabet as the rules and compose the rule FST on top of it. To check if the rule has actually be applied, the input automaton was intersected with the result. Unfortunately, this method proved to be much slower than the application-based one; composition alone took 28.3 seconds on our corpus, while the intersection pushed it up to 45s. Therefore we decided to abandon this path altogether.

4.3 Deletion of discarded readings

The original transducers replace the `#0#` in front of discarded readings with `#X#`. Our first optimisation comes from the observation that deleting these readings instead would not make the transducers any more complex, but would shorten the resulting sentence, making subsequent tests faster. Moreover, it allows the engine to recognise actual rule application by simply testing the length of the output to the input sentence, an operation slightly faster than byte-for-byte comparison.

Table 2 reports an approximately 8% improvement. While not self-evident, this benefit remained in effect after our subsequent optimisations.

4.4 FSA-based rule testing

Theoretically, further speed-ups could be achieved by separating rule testing and application, using finite-state automata for the former. Automata are faster than transducers for two reasons: first, there is no need to assemble an output; and second, a FSA can be determinised and minimised, while *foma* can only make a FST deterministic by treating it as a FSA with an alphabet of the original input:output pairs, which does not entail determinism in the input.

As the fourth row in table 2 shows, the idea does not immediately translate well to practice. The fault lies with the `apply_down()` function, which, being the only method of running a finite-state machine in *foma*, was designed to support all features of the library. It treats automata as identity transducers, and fails to capitalise on the aforementioned advantages of the former. In order to benefit from FSA-based testing then, a custom function is required.

4.5 Custom FSA/FST application

The `apply_down()` function supports the following features (Hulden, 2009a):

- Conversion of the text to symbols (single- and multi-character)
- Regular transitions and flag diacritics
- Three types of search in the transition matrix (linear, binary and indexed)
- Deterministic and non-deterministic operation
- Iterators (multiple invocations iterate the non-deterministic outputs)

Our use-case makes most of these features surplus to requirements. *fomacg* uses multi-character symbols, but not flag diacritics. To maximise the performance gains, the rule testing automata must be minimal (hence deterministic), so there was no need for non-determinism and iterators. Finally, by modifying *fomacg* to sort the edges of all grammar machines, we could ensure that binary transition search alone suffices.

The custom FSA applier function that implements only the necessary features was employed for both rule testing and finding the delimiter cohort. As a result, running time went down to 1.45 seconds (see table 2), a 75% improvement.

A similar function was written for input-deterministic minimal transducers. While not applicable to the non-deterministic rule FSTs, it could replace `apply_down()` for the conversion between the Apertium and the *fomacg* formats, further reducing the running time to 1.275 seconds.

What we can take home from the last two sections is that when speed is paramount, relying blindly on generic libraries may not only lead to suboptimal performance, but may also produce counterintuitive results.

Conversely, libraries may benefit from including specialised implementations for different use-cases. For example, *foma* has all the information at hand to decide if a FST is deterministic, whether it supports binary search or not, etc. and so, providing specialised functions (even private ones hidden behind `apply_down()`) would improve its performance substantially in certain situations.

4.6 Exploiting CG structure

In this chapter, we review the improvements made available by the characteristics of our CG representation. The first of these is functionality: even though the rule FSTs are non-deterministic, the input-output mapping is one-to-one (Hulden, 2011). It was thus possible to implement the non-deterministic version of the FST runner function described in the last section without the need for an iterator feature, and to use it for rule application. The last usage of the generic `apply_down()` function thus eradicated, the running time dropped to 1.05 seconds (see table 2).

Internally *foma*, similarly to other FST toolkits, represents elements of the Σ alphabet as integers. The conversion of text into tokens in Σ is a step usually taken for granted in the literature, but it contributes to the execution time of an FST to a significant extent. In *foma*, token matching is performed by a trie built from the symbols in the automaton's alphabet. Our custom DFSA runner function (see section 4.5) spends about 60% of its time applying this trie.

The two enhancements below have helped to all but negate the cost of token conversion. The first of these exploits the fact that in the `fomacg` format, symbols are separated by space characters. Instead of passing the input string to each FSM, we split it along the spaces, and pass the resulting string vector to the machines. This is a rather small change, and while the Hungarian grammar benefited almost nothing, the running time of the Breton grammar improved by 40%.

The second enhancement came from the observation that all rule testing automata and rule transducers accept the same CG tags. It is thus possible to generate an automaton whose alphabet is the union of those of the other machines. This automaton could be used to convert the input sentence into a vector of Σ ids, and then this vector could be sent to the other machines, relinquishing the need of repeated conversions.

Both *fomacg* and *fomacg-proc* had to be modified to account for the changes. The former now creates the converter FSA and saves it as the second machine in the binary grammar file. Also, since the ids that correspond to a symbol are unique to each machine, we added a post-processing phase that replaces the ids with the "canonical" ones in the converter FSA. *fomacg-proc* then converts the input to ids using the converter automaton's trie, and sends the vector to the rule machines. The rule machines treat the vector as their input, with a caveat: ids not in the alphabet of the machine in question are replaced by `@IDENTITY_SYMBOL@`, so that they are handled in the same way as before.

Table 2 shows that factoring the symbol conversion out from the individual machines resulted in huge savings: the running time of the Hungarian setup improved by 70% to 0.32 second; the Breton one by 40% to 1.55 seconds.

Table 2: Effects of the optimisations on running time

Version	Hungarian	Breton

5 Complexity analysis

Tapanainen (1999) proves that the worst-case time complexity for disambiguating a sentence in his CG-2 parser is $\mathcal{O}(n^3k^2G)$, where n is the length of the sentence, k is the maximum number of readings per word, and the grammar consists of G rules. The explanation is as follows: testing a cohort with a single rule can be done in $\mathcal{O}(nk)$; the whole sentence in $\mathcal{O}(n^2k)$. This process must be repeated for each rule, yielding $\mathcal{O}(n^2kG)$. Finally, in the worst case, a rule only removes a single reading, so it takes $n(k-1)$ rounds to disambiguate the sentence, resulting in the aforementioned bound.

Hulden (2011) showed that if the rules are compiled to transducers, they can be applied to the whole sentence in $\mathcal{O}(nk)$ time, thus decreasing the complexity to $O(n^2k^2G)$, instead of the $O(n^2k)$ suggested by Tapanainen. To be more precise, applying a rule transducer takes $O(nkT)$ time, where the constant T is the size of the FST. While T may be rather large, rule transducers may be factored into bimachines, which removes the constant. Hence, a disambiguating bimachine for one CG rule can be applied to a sentence of nk tokens in $O(nk)$ (linear) time. However, *fomacg* only includes CG rule-to-transducer compilation and does not include bimachine factorization as of yet.

While this work has left the theoretical limit untouched thus far, it improved on three aspects of the complexity. First, unlike *foma*, our specialised FST application functions can take advantage of the properties of automata and bimachines, and actually run them in $\mathcal{O}(nk)$ time. Second, the constant in the $\mathcal{O}$ has been decreased as a result of extensive optimisation. Third, rule testing automata have been introduced which, being minimal, can also be applied in $\mathcal{O}(nk)$ time. Assume that in a round G_a rules can be applied to the sentence and G_u cannot, $G_a + G_u = G$. With minimal automata for rule testing the round finishes with $2G_a + G_u$ machine applications, instead of the $2G$ required by bimachines. The facts that usually $G_a << G$ and that automata can be applied faster than transducers result in a performance improvement over the pure bimachine setup.

5.1 Beyond the $\mathcal{O}(n^2k^2G)$ bound

This section presents an idea that allows the system to theoretically overcome the $\mathcal{O}(n^2k^2G)$ average complexity bound. This section describes the method, and investigates its feasibility; the next section contains the evaluation.

The idea is based on the fact that regular languages are closed under the union operator. If there are two automata, FSA_{G_a} and FSA_{G_b} that test the rules G_a and G_b, respectively, then it follows that their union, $\mathrm{FSA}_{G_{ab}}$, accepts a sentence iff either G_a or G_b is applicable to it. If $\mathrm{FSA}_{G_{ab}}$ is minimised, it runs in $\mathcal{O}(nk)$ time, the same as FSA_{G_a} and FSA_{G_b}.

The union FSA allows us to implement hierarchical rule checking. In this example, testing if any of the two rules match a sentence with only the original automata requires a check with both. Instead, we can apply $\mathrm{FSA}_{G_{ab}}$ first. If neither rule is applicable, the automaton will not accept the sentence, and no further testing is required. If one of the rules is, FSA_{G_a} (or equivalently, FSA_{G_b}) must be run against the sentence to see which. In practice, if we pick two rules from a CG in random, we shall find that the majority of the sentences will not match either, hence the number of tests may be reduced substantially.

There is no need to stop here: we can take two union automata, and merge them again. It is easy to see that if we represent the rule testing automata in a graph, where a node is a FSA, and two nodes are connected iff one was created from the other via union, then we get a binary tree. For a grammar of G rules, a binary tree of $\log G$ levels can be built. Such a tree can confirm with a single test if a sentence does not match any of the rules, or find the matching rule in $\log G + 1$ tests, if one does. Accordingly, in theory this method allows us to improve the average- and best-case complexity bounds of the system to $\mathcal{O}(n^2k^2 \log G)$ and $\mathcal{O}(nk)$, respectively. (Clearly, for grammars with several sections, instead of a single tree that contains all rules, one tree must be built for each section to preserve rule priorities. However, this does not affect the reasoning above).

The bottleneck in this method is memory consumption. The size of the FSA resulting from a non-deterministic union operation is simply the sum of the sizes of the original automata. To achieve the speed-up described above, however, the rule checking automata must be determinised, which may cause them to blow up in size exponentially. Therefore, building a single tree from all rules is not feasible. A compromise solution is to construct a forest of 2–4 level trees, which still fits into the memory and provides similar benefits to a single tree, though to a smaller extent.

5.2 Evaluation

The forest can be assembled in several ways; we experimented with two simple algorithms. Both take as input a list of rule testing automata, which are encapsulated into single-node trees. Before each step, the trees are sorted by the size of the automata in their roots.

The first algorithm, *SmallestFirst*, unifies the two smallest trees in each step, until the root FSA in each tree is above a size limit (1,000 states in our case). The second, *FixedLevel*, aims to create full, balanced binary trees: in a single step, it unifies the smallest tree with the largest, the second smallest with the second largest, etc, and repeats the process until the trees reach a predefined height.

Table 3 lists the running times and memory requirements of the resulting forests. It can be seen that hierarchical rule testing indeed improves performance: even a single level of merging results in 30-42% speedup. However, it is also immediately evident that aside from special cases, the disadvantages overweight the benefits: memory usage and binary size grow exponentially, affecting compilation and grammar loading time as well, and very soon we run into the limits of physical memory. Unless a method is found that reduces memory usage substantially, we have to give up on hierarchical rule testing.

Table 3: Performance and storage requirements of rule testing trees
* State count limit was 500 † Reached limit of physical memory

Language	Algorithm	Initialisation	Disambiguation	Memory	File size
Hungarian	(flat)	0.028s	0.32s	0.5%	60kB

6 Memory savings

The use of a single converter automaton has not only resulted in improved performance, but it has also opened a way to decrease the storage space requirements of the grammar as well. The trie that converts the machine's alphabet to integer ids in *foma* takes up space; depending on the number and length of the symbols in bytes, this trie may be responsible for a considerable portion of the memory footprint of an

automaton. Given the number of rules in an average CG grammar, it is easy to see how this trivial subtask may affect the memory consumption of the application, as well as the size of the grammar binary. As the job of token matching has been delegated to the symbol automaton (see section 4.6), we no longer maintain separate tries for all individual FSAs.

Table 4 presents the resulting memory savings. We report numbers for the raw grammars (L1), as well as for two- and three-level condition trees (L2-3). It is not surprising that the raw grammars see the largest improvements; here the tries accounted for 70-80% of the memory usage. As the trees get higher, the number of states and edges grows more rapidly than does the number of tries and the savings become more modest.

Table 4: Improvements in memory usage due to removing the sigma trie. Memory consumption is measured as a percentage of the 4GB system memory

Language	Method	Before	After	Reduction
Hungarian	L1	0.5%	0.1%	80%
Hungarian	L3	2.1%	1.5%	28.57%
Breton	L1	5.1%	1.3%	74.5%
Breton	L2	9.6%	4.4%	54.16%
Finnish	L1	21%	4.1%	80.47%
Finnish	L2	32.3%	8.9%	72.44%

We explored other options as well to reduce the size of rule condition trees. Unfortunately, most methods aimed at FSA compression in the literature are either already implemented in *foma* (e.g. as row-indexed transition matrix, see Kiraz (2001)), or are aimed at automata with a regular structure, such as morphological analysers (Huet, 2003; Huet, 2005; Drobac et al., 2014). Without further support, the approximately 30% saving achieved by our method for a three-level condition tree alone is not enough to redeem hierarchical rule checking.

A task-specific framework, one based on inward deterministic automata has been proposed for CG parsing (Yli-Jyrä, 2011). The paper reports a binary size similar to the original grammar size. However, as the framework breaks away from the practice of direct rule application followed in this paper and in related literature (Hulden, 2011; Peltonen, 2011), closer inspection remains as future work.

7 Conclusions

We set out with the goal of creating a fast constraint grammar parser based on finite-state technology. Our aim was to achieve better performance on the task of morphological disambiguation than the current state-of-the-art parser VISL CG-3. We used the CG grammars available in the Apertium machine translation project.

Our goals were partially fulfilled: while the speed of our parser falls short of that of VISL CG-3 — with the exception of the execution of very small grammars — we have made advances on the state-of-the-art free/open-source FST implementations of CG. We based our system on the *fomacg* compiler, and extended it in several ways. Our parser uses optimised FST application methods instead of the generic *foma* variant used by previous implementations, thereby achieving better performance. Further optimisations, both memory and runtime, were made by exploiting the properties of FSTs generated from a CG. We report real-world performance measurements with and without these optimisations, so their efficacy can be accurately evaluated. A new method for rule testing has also been proposed, which in theory is capable of reducing the worst-case complexity bound of CG application to $\mathcal{O}(n^2k^2 \log G)$. Unfortunately, the method has yet to be proven feasible in practice.

Our main finding is that implementation matters: an FST library which is too generic hinders performance and can even make a theoretically faster algorithm slower in practice. Using bimachines and rule testing automata should have sped up rule application, but only did so after we implemented our own, specialised FST functions. Since *foma* has all necessary information about an FST in place to decide

the right application method, incorporating our functions into it, or other FST libraries, could benefit applications beyond the scope of CG.

Language for Communication: Language as Rational Inference

Edward Gibson
Massachusetts Institute of Technology
Brain and Cognitive Sciences Department
Cambridge, MA, USA
egibson@mit.edu

Invited Speaker Abstract

Perhaps the most obvious hypothesis for the evolutionary function of human language is for use in communication. Chomsky has famously argued that this is a flawed hypothesis, because of the existence of such phenomena as ambiguity. Furthermore, he argues that the kinds of things that people tend to say are not short and simple, as would be predicted by communication theory. Contrary to Chomsky, my group applies information theory and communication theory from Shannon (1948) in order to attempt to explain the typical usage of language in comprehension and production, together with the structure of languages themselves. First, we show that ambiguity out of context is not only not a problem for an information-theoretic approach to language, it is a feature. Second, we show that language comprehension appears to function as a noisy channel process, in line with communication theory. Given si, the intended sentence, and sp, the perceived sentence we propose that people maximize $P(s_i|s_p)$, which is equivalent to maximizing the product of the prior $P(s_i)$ and the likely noise processes $P(s_i \rightarrow s_p)$.

We show that several predictions of this way of thinking of language are true:

1. the more noise that is needed to edit from one alternative to another leads to lower likelihood that the alternative will be considered;
2. in the noise process, deletions are more likely than insertions;
3. increasing the noise increases the reliance on the prior (semantics); and
4. increasing the likelihood of implausible events decreases the reliance on the prior.

Third, we show that this way of thinking about language leads to a simple re-thinking of the P600 from the ERP literature. The P600 wave was originally proposed to be due to people's sensitivity to syntactic violations, but there have been many instances of problematic data in the literature for this interpretation. We show that the P600 can best be interpreted as sensitivity to an edit in the signal, in order to make it more easily interpretable.

Finally, we discuss how thinking of language as communication can explain aspects of the origin of word order. Some recent evidence suggests that subject-object-verb (SOV) may be the default word order for human language. For example, SOV is the preferred word order in a task where participants gesture event meanings (Goldin-Meadow et al. 2008). Critically, SOV gesture production occurs not only for speakers of SOV languages, but also for speakers of SVO languages, such as English, Chinese, Spanish (Goldin-Meadow et al. 2008) and Italian (Langus and Nespor, 2010). The gesture-production task therefore plausibly reflects default word order independent of native language. However, this leaves open the question of why there are so many SVO languages (41.2% of languages; Dryer, 2005). We propose that the high percentage of SVO languages cross-linguistically is due to communication pressures over a noisy channel. We provide several gesture experiments consistent with this hypothesis, and we speculate how a noisy channel approach might explain several typical word order patterns that occur in the world's languages.

Soft Cross-lingual Syntax Projection for Dependency Parsing

Zhenghua Li , Min Zhang*, Wenliang Chen
Provincial Key Laboratory for Computer Information Processing Technology
Soochow University
{zhli13,minzhang,wlchen}@suda.edu.cn

Abstract

This paper proposes a simple yet effective framework of soft cross-lingual syntax projection to transfer syntactic structures from source language to target language using monolingual treebanks and large-scale bilingual parallel text. Here, *soft* means that we only project reliable dependencies to compose high-quality target structures. The projected instances are then used as additional training data to improve the performance of supervised parsers. The major issues for this idea are 1) errors from the source-language parser and unsupervised word aligner; 2) intrinsic syntactic non-isomorphism between languages; 3) incomplete parse trees after projection. To handle the first two issues, we propose to use a probabilistic dependency parser trained on the target-language treebank, and prune out unlikely projected dependencies that have low marginal probabilities. To make use of the incomplete projected syntactic structures, we adopt a new learning technique based on *ambiguous labelings*. For a word that has no head words after projection, we enrich the projected structure with all other words as its candidate heads as long as the newly-added dependency does not cross any projected dependencies. In this way, the syntactic structure of a sentence becomes a parse forest (ambiguous labels) instead of a single parse tree. During training, the objective is to maximize the mixed likelihood of manually labeled instances and projected instances with ambiguous labelings. Experimental results on benchmark data show that our method significantly outperforms a strong baseline supervised parser and previous syntax projection methods.

1 Introduction

During the past decade, supervised dependency parsing has made great progress. However, due to the limitation of scale and genre coverage of labeled data, it is very difficult to further improve the performance of supervised parsers. On the other hand, it is very time-consuming and labor-intensive to manually construct treebanks. Therefore, lots of recent work has been devoted to get help from bilingual constraints. The motivation behind are two-fold. First, a difficult syntactic ambiguity in one language may be very easy to resolve in another language. Second, a more accurate parser on one language may help an inferior parser on another language, where the performance difference may be due to the intrinsic complexity of languages or the scale of accessible labeled resources.

Following the above research line, much effort has been done recently to explore bilingual constraints for parsing. Burkett and Klein (2008) propose a reranking based method for joint constituent parsing of bitext, which can make use of structural correspondence features in both languages. Their method needs bilingual treebanks with manually labeled syntactic trees on both sides for training. Huang et al. (2009) compose useful parsing features based on word reordering information in source-language sentences. Chen et al. (2010a) derive bilingual subtree constraints with auto-parsed source-language sentences. During training, both Huang et al. (2009) and Chen et al. (2010a) require bilingual text with target-language gold-standard dependency trees. All above work shows significant performance gain

over monolingual counterparts. However, one potential disadvantage is that bilingual treebanks and bitext with one-side annotation are difficult to obtain. Therefore, They usually conduct experiments on treebanks with a few thousand sentences. To break this constraint, Chen et al. (2011) extend their work in Chen et al. (2010a) and translate text of monolingual treebanks to obtain bilingual treebanks with a statistical machine translation system.

This paper explores another line of research and aims to boost the state-of-the-art parsing accuracy via syntax projection. Syntax projection typically works as follows. First, we train a parser on source-language treebank, called a source parser. Then, we use the source parser to produce automatic syntactic structures on the source side of bitext. Next, with the help of automatic word alignments, we project the source-side syntactic structures into the target side. Finally, the target-side structures are used as gold-standard to train new parsing models of target language. Previous work on syntax projection mostly focuses on unsupervised grammar induction where no labeled data exists for target language (Hwa et al., 2005; Spreyer and Kuhn, 2009; Ganchev et al., 2009; Liu et al., 2013). Smith and Eisner (2009) propose quasi-synchronous grammar for cross-lingual parser projection and assume the existence of hundreds of target language annotated sentences. Similar to our work in this paper, Jiang et al. (2010) try to explore projected structures to further improve the performance of statistical parsers trained on full-scale monolingual treebanks (see Section 4.4 for performance comparison).

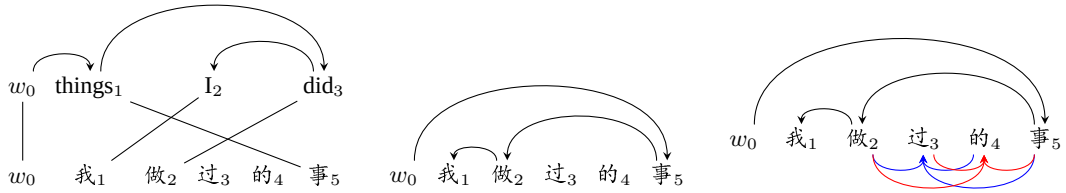
The major issues for syntax projection are 1) errors from the source-language parser and unsupervised word aligner; 2) intrinsic syntactic non-isomorphism between languages; 3) incomplete parse trees after projection. Hwa et al. (2005) propose a simple projection algorithm based on the *direct correspondence assumption* (DCA). They apply post-editing to the projected structures with a set of hand-crafted heuristic rules, in order to handle some typical cross-lingual syntactic divergences. Similarly, Ganchev et al. (2009) manually design several language-specific constrains during projection, and use projected partial structures as soft supervision during training based on posterior regularization (Ganchev et al., 2010). To make use of projected instances with incomplete trees, Spreyer and Kuhn (2009) propose a heuristic method to adapt training procedures of dependency parsing. Instead of directly using incomplete trees to train dependency parsers, Jiang et al. (2010) train a local dependency/non-dependency classifier on projected syntactic structures, and use outputs of the classifier as auxiliary features to help supervised parsers. One potential common drawback of above work is the lack of a systematic way to handle projection errors and incomplete trees.

Different from previous work, this paper proposes a simple yet effective framework of soft syntax projection for dependency parsing, and provides a more elegant and systematic way to handle the above issues. First, we propose to use a probabilistic parser trained on target-language treebank, and prune unlikely projected dependencies which have very low marginal probabilities. Second, we adopt a new learning technique based on ambiguous labelings to make use of projected incomplete trees for training. For a word that has no head words after projection, we enrich the projected structure by adding all possible words as its heads as long as the newly-added dependency does not cross any projected dependencies. In this way, the syntactic structure of a sentence becomes a parse forest (ambiguous labelings) instead of a single parse tree. During training, the objective is to maximize the mixed likelihood of manually labeled instances and projected instances with ambiguous labelings. Experimental results on benchmark data show that our method significantly outperforms a strong baseline supervised parser and previous syntactic projection methods.

2 Syntax Projection

Given an input sentence $\mathbf{x} = w_0 w_1 ... w_n$, a dependency tree is $\mathbf{d} = \{(h, m) : 0 \leq h \leq n, 0 < m \leq n\}$, where (h, m) indicates a directed arc from the *head* word w_h to the *modifier* w_m, and w_0 is an artificial node linking to the root of the sentence.

Syntax projection aims to project the dependency tree $\mathbf{d}^s$ of a source-language sentence $\mathbf{x}^s$ into the dependency structure of its target-language translation $\mathbf{x}$ via word alignments $\mathbf{a}$, where a word alignment $a_i = z$ means the target-side word w_i is aligned into the source-side word w_z^s, as depicted in Figure 1(a) and Figure 1(b). For simplicity, we avoid one-to-many alignments by keeping the one with highest



(a) Source tree and word alignments (b) Projected incomplete tree (c) Forest (ambiguous labelings)

Figure 1: Illustration of syntax projection from English to Chinese with a sentence fragment. The two Chinese auxiliary words, "过$_3$" (past tense marker) and "的$_4$" (relative clause marker), are not aligned to any English words.

marginal probability when the target word is aligned to multiple source words. We first introduce a simple syntax projection approach based on DCA (Hwa et al., 2005), and then propose two extensions to handle parsing and aligning errors and cross-lingual syntactic divergences.

Projection with DCA. If two target words w_i and w_j are aligned to two different source words $w^s_{a_i}$ and $w^s_{a_j}$, and the two words compose a dependency in the source tree $(a_i, a_j) \in \mathbf{d}^s$, then add a dependency (i, j) into the projected syntactic structure. For example, as shown in Figure 1(a), the two Chinese words "做$_2$" and "事$_5$" are aligned to the two English words "did$_3$" and "things$_1$", and the dependency "things$_1$$\curvearrowright$did$_3$" is included in the source tree. Therefore, we project the dependency into the target side and add a dependency "做$_2$$\curvearrowleft$事$_5$" into the projected structure, as shown in Figure 1(b). An obvious drawback of DCA is that it may produce many wrong dependencies due to the errors in the automatic source-language parse trees and word alignments. Even with manual parse trees and word alignments, syntactic divergences between languages can also lead to projection errors.

Pruned with target-side marginals. To overcome the weakness of DCA, we propose to use target-side marginal probabilities to constrain the projection process and prune obviously bad projections. We train a probabilistic parser on an existing target-side treebank. For each projected dependency, we compute its marginal probability with the target parser, and prune it off the projected structure if the probability is below a *pruning threshold* λ_p. Our study shows that dependencies with very low marginal probabilities are mostly wrong (Figure 2).

Supplemented with target-side marginals. To further improve the quality of projected structures, we add dependencies with high marginal probabilities according to the target parser. Specifically, if a target word w_j obtain a head word w_i after projection, and if another word w_k has higher marginal probability than a *supplement threshold* λ_s to be the head word of w_j, then we also add the dependency (k, j) into the projected structure. In other words, we allow one word to have multiple heads so that the projected structure can cover more correct dependencies.

From incomplete tree to forest. Some words in the target sentence may not obtain any head words after projection due to incomplete word alignments or the pruning process, which leads to incomplete parse trees after projection. Also, some words may have multiple head words resulting from the supplement process. To handle these issues, we first convert the projected structures into parse forests, and then propose a generalized training technique based on ambiguous labelings to make use of the projected instances. Specifically, if a word does not have head words after projection, we simply add into the projected structure all possible words as its candidate heads as long as the newly-added dependency does not cross any projected dependencies, as illustrated in Figure 1(c). We introduce three new dependencies to compose candidate heads for the unattached word "过$_3$". Note that it is illegal to add the dependency "我$_1$$\curvearrowright$过$_3$" since it would cross the projected dependency "做$_2$$\curvearrowleft$事$_5$".

3 Dependency Parsing with Ambiguous Labelings

In parsing community, two mainstream methods tackle the dependency parsing problem from different perspectives but achieve comparable accuracy on a variety of languages. Graph-based methods view the problem as finding an optimal tree from a fully-connected directed graph (McDonald et al., 2005; McDonald and Pereira, 2006; Carreras, 2007; Koo and Collins, 2010), while transition-based methods try to find a highest-scoring transition sequence that leads to a legal dependency tree (Yamada and Matsumoto, 2003; Nivre, 2003; Zhang and Nivre, 2011).

3.1 Graph-based Dependency Parser (GParser)

We adopt the graph-based paradigm because it allows us to elegantly derive our CRF-based probabilistic parser, which is required to compute the marginal probabilities of dependencies and likelihood of both manually labeled data and unannotated bitext with ambiguous labelings. The graph-based method factors the score of a dependency tree into scores of small subtrees $\mathbf{p}$.

$$Score(\mathbf{x}, \mathbf{d}; \mathbf{w}) = \mathbf{w} \cdot \mathbf{f}(\mathbf{x}, \mathbf{d}) = \sum_{\mathbf{p} \subseteq \mathbf{d}} Score(\mathbf{x}, \mathbf{p}; \mathbf{w}) \tag{1}$$

We adopt the second-order model of McDonald and Pereira (2006) as our core parsing algorithm,[1] which defines the score of a dependency tree as:

$$Score(\mathbf{x}, \mathbf{d}; \mathbf{w}) = \sum_{\{(h,m)\} \subseteq \mathbf{d}} \mathbf{w}_{dep} \cdot \mathbf{f}_{dep}(\mathbf{x}, h, m) + \sum_{\{(h,s),(h,m)\} \subseteq \mathbf{d}} \mathbf{w}_{sib} \cdot \mathbf{f}_{sib}(\mathbf{x}, h, s, m) \tag{2}$$

where $\mathbf{f}_{dep}(\mathbf{x}, h, m)$ and $\mathbf{f}_{sib}(\mathbf{x}, h, s, m)$ are feature vectors corresponding to two kinds of subtree; $\mathbf{w}_{dep/sib}$ are the feature weight vectors; the dot product gives the scores contributed by the corresponding subtrees. We adopt the state-of-the-art syntactic features proposed in Bohnet (2010).

3.2 Probabilistic CRF-based GParser

Previous work on dependency parsing mostly adopts linear models and online perceptron training, which lack probabilistic explanations of dependency trees and likelihood of the training data. Instead, we build a log-linear CRF-based probabilistic dependency parser, which defines the probability of a dependency tree as:

$$p(\mathbf{d}|\mathbf{x}; \mathbf{w}) = \frac{exp\{Score(\mathbf{x}, \mathbf{d}; \mathbf{w})\}}{Z(\mathbf{x}; \mathbf{w})}; \quad Z(\mathbf{x}; \mathbf{w}) = \sum_{\mathbf{d}' \in \mathcal{Y}(\mathbf{x})} exp\{Score(\mathbf{x}, \mathbf{d}'; \mathbf{w})\} \tag{3}$$

where $Z(\mathbf{x})$ is the normalization factor and $\mathcal{Y}(\mathbf{x})$ is the set of all legal dependency trees for $\mathbf{x}$.

3.3 Likelihood and Gradient of Training Data with Ambiguous Labelings

Traditional CRF models assume one gold-standard label for each training instance, which means each sentence is labeled with a single parse tree in the case of parsing. To make use of projected instances with ambiguous labelings, we propose to use a generalized training framework which allows a sentence to have multiple parse trees (forest) as its gold-standard reference (Täckström et al., 2013). The goal of the training procedure is to maximize the likelihood of the training data, and the model is updated to improve the probabilities of parse forests, instead of single parse trees. In other words, the model has the flexibility to distribute the probability mass among the parse trees inside the forest, as long as the probability of the forest improves. In this generalized framework, a traditional instance labeled with a single parse tree can be regarded as a special case that the forest contains only one parse tree.

The probability of a sentence $\mathbf{x}$ with ambiguous labelings $\mathcal{F}$ is defined as the sum of probabilities of all parse tree $\mathbf{d}$ contained in the forest $\mathcal{F}$:

$$p(\mathcal{F}|\mathbf{x}; \mathbf{w}) = \sum_{\mathbf{d} \in \mathcal{F}} p(\mathbf{d}|\mathbf{x}; \mathbf{w}) \tag{4}$$

[1] Higher-order models of Carreras (2007) and Koo and Collins (2010) can achieve a little bit higher accuracy, but suffer from higher time cost of $O(n^4)$ and system complexity. Our method is applicable to the third-order model.

	Train	Dev	Test
PTB	39,832	1,346	2416
CTB5	16,091	803	1,910
CTB5X	18,104	352	348
Bitext	0.9M	–	–

Table 1: Data sets (in sentence number).

Suppose the training data set is $\mathcal{D} = \{(\mathbf{x}_i, \mathcal{F}_i)\}_{i=1}^{N}$. Then the log likelihood of $\mathcal{D}$ is:

$$\mathcal{L}(\mathcal{D}; \mathbf{w}) = \sum_{i=1}^{N} \log p(\mathcal{F}_i | \mathbf{x}_i; \mathbf{w}) \tag{5}$$

Then we can derive the partial derivative of the log likelihood with respect to $\mathbf{w}$:

$$\frac{\partial \mathcal{L}(\mathcal{D}; \mathbf{w})}{\partial \mathbf{w}} = \sum_{i=1}^{N} \left(\sum_{\mathbf{d} \in \mathcal{F}_i} \tilde{p}(\mathbf{d} | \mathbf{x}_i, \mathcal{F}_i; \mathbf{w}) \mathbf{f}(\mathbf{x}_i, \mathbf{d}) - \sum_{\mathbf{d} \in \mathcal{Y}(\mathbf{x}_i)} p(\mathbf{d} | \mathbf{x}_i; \mathbf{w}) \mathbf{f}(\mathbf{x}_i, \mathbf{d}) \right) \tag{6}$$

where $\tilde{p}(\mathbf{d} | \mathbf{x}_i, \mathcal{F}_i; \mathbf{w})$ is the probability of $\mathbf{d}$ under the space constrained by the parse forest $\mathcal{F}_i$:

$$\tilde{p}(\mathbf{d} | \mathbf{x}_i, \mathcal{F}_i; \mathbf{w}) = \frac{\exp\{Score(\mathbf{x}_i, \mathbf{d}; \mathbf{w})\}}{Z(\mathbf{x}_i, \mathcal{F}_i; \mathbf{w})}; \quad Z(\mathbf{x}_i, \mathcal{F}_i; \mathbf{w}) = \sum_{\mathbf{d} \in \mathcal{F}_i} \exp\{Score(\mathbf{x}_i, \mathbf{d}; \mathbf{w})\} \tag{7}$$

The first term in Eq. (6) is the model expectations in the search space constrained by $\mathcal{F}_i$, and the second term is the model expectations in the complete search space $\mathcal{Y}(\mathbf{x}_i)$. Since $\mathcal{Y}(\mathbf{x}_i)$ contains exponentially many legal dependency trees, direct calculation of the second term is prohibitive. Instead, we can use the classic Inside-Outside algorithm to efficiently compute the second term within $O(n^3)$ time complexity, where n is the length of the input sentence. Similarly, the first term can be solved by running the Inside-Outside algorithm in the constrained search space $\mathcal{F}_i$.

3.4 Stochastic Gradient Descent (SGD) Training

With the likelihood gradients, we apply L2-norm regularized SGD training to iteratively learn the feature weights $\mathbf{w}$ for our CRF-based baseline and bitext-enhanced parsers. We follow the implementation in CRFsuite.[2] At each step, the algorithm approximates a gradient with a small subset of training examples, and then updates the feature weights. Finkel et al. (2008) show that SGD achieves optimal test performance with far fewer iterations than other optimization routines such as L-BFGS. Moreover, it is very convenient to parallel SGD since computation among examples in the same batch is mutually independent.

Once the feature weights $\mathbf{w}$ are learnt, we can parse the test data and try to find the optimal parse tree with the Viterbi decoding algorithm in $O(n^3)$ parsing time (Eisner, 2000; McDonald and Pereira, 2006).

$$\mathbf{d}^* = \arg\max_{\mathbf{d} \in \mathcal{Y}(\mathbf{x})} p(\mathbf{d} | \mathbf{x}; \mathbf{w}) \tag{8}$$

4 Experiments and Analysis

To verify the effectiveness of our proposed method, we carry out experiments on English-to-Chinese syntax projection, and aim to enhance our baseline Chinese parser with additional training instances projected from automatic English parse trees on bitext. For **monolingual treebanks**, we use Penn English Treebank (PTB) and Penn Chinese Treebank 5.1 (CTB5). For English, we follow the standard practice to split the data into training (sec 02-21), development (sec 22), and test (sec 23). For CTB5, we adopt the data split of (Duan et al., 2007). We convert the original bracketed structures into dependency

[2] http://www.chokkan.org/software/crfsuite/

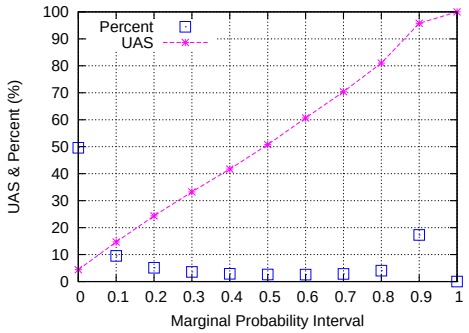


Figure 2: Distribution (Percent) and accuracy (UAS) of dependencies under different marginal probability interval for Chinese baseline parser on CTB5 development set. For example, 0.8 at x-axis means the interval $[0.8, 0.9)$.

structures using Penn2Malt with its default head-finding rules. We build a CRF-based bigram part-of-speech (POS) tagger with the features described in (Li et al., 2012b), and produce POS tags for all train/development/test datasets and bitext (10-way jackknifing for training datasets). The tagging accuracy on test sets is 97.3% on English and 94.0% on Chinese.

To compare with the recent work on syntax projection of Jiang et al. (2010) who use a smaller test dataset, we follow their data split of CTB5 and use gold-standard POS tags during training and test. We refer to this setting as CTB5X.

For **bitext**, we collect a parallel corpus from FBIS news (LDC03E14, 0.25M sentence pairs), United Nations (LDC04E12, 0.62M), IWSLT2008 (0.04M), and PKU-863 (0.2M). After corpus cleaning, we obtain a large-scale bilingual parallel corpus containing 0.9M sentence pairs. We run the unsupervised BerkeleyAligner[3] (Liang et al., 2006) for 4 iterations to obtain word alignments. Besides hard alignments, we also make use of posterior probabilities to simplify one-to-many alignments to one-to-one as discussed in Section 2. Table 1 shows the data statistics.

For training both the baseline and bitext-enhanced parsers, we set the batch size to 100 and run SGD until a maximum iteration number of 50 is met or the change on likelihood of training data becomes too small. Since the number of projected sentences is much more than that of manually labeled instances (0.9M vs. 16K), it is likely that the projected data may overwhelm manually labeled data during training. Therefore, we adopt a simple corpus-weighting strategy. Before each iteration, we randomly sample 50K projected sentences and 15K manually labeled sentences from all training data, and run SGD to train feature weights using the sampled data. To speed up training, we adopt multi-thread implementation of gradient computations in the same batch. It takes about 1 day to train our bitext-enhanced parser for one iteration using a single CPU core, while using 24 CPU cores only needs about 2 hours.

We measure parsing performance using unlabeled attachment score (UAS, percent of words with correct heads), excluding punctuation marks. For significance test, we adopt Dan Bikel's randomized parsing evaluation comparator (Noreen, 1989).[4]

4.1 Analysis on Marginal Probabilities

In order to gain insights for parameter settings of syntax projection, we analyse the distribution and accuracy of dependencies under different marginal probability interval. We train the baseline Chinese parser on CTB5 train set, and use the parser to produce the marginal probabilities of all dependencies for sentences in CTB5 development set. We discard all dependencies that have a marginal probability less than 0.0001 for better illustration. Figure 2 shows the results, where we can see that UAS is roughly proportional to marginal probabilities. In other word, dependencies with higher marginal probabilities are more accurate. For example, dependencies with probabilities under interval $[0.8, 0.9)$ has a 80% chance to be correct. From another aspect, we can see that 50% of dependencies fall in probability

Figure 3: Performance with different parameter settings of (λ_p λ_s) on CTB5 development set.

interval $[0, 0.1)$, and such dependencies have very low accuracy (4%). These observations are helpful for our parameter selection and methodology study during syntax projection.

4.2 Results of Syntax Projection on Development Dataset

We apply the syntax projection methods described in Section 2 to the bilingual text, and use the projected sentences with ambiguous labelings as additional training instances to train new Chinese parsers based on the framework described in Section 3. Figure 3 shows the UAS curves on development set with different parameters settings. The *pruning threshold* λ_p (see Section 2) balances the quality and coverage of projection. Larger λ_p leads to more accurate but fewer projections. The *supplement threshold* λ_s (see Section 2) balances the size and oracle score of the projected forest. Smaller λ_s can increase the oracle score of the forest by adding more dependencies with lower marginal probabilities, but takes the risk of making the resulted forest too ambiguous and weak to properly supervise the model during training. [5]

The *DCA* method corresponds to the results with $\lambda_p = 0.0$ and $\lambda_s = 1.0$. We can see that DCA largely decreases UAS compared with the baseline CRF-based parser. The reason is that although DCA projects many source-language dependencies to the target side (44% of target-language words obtain head words), it also introduces a lot of noise during projection.

DCA pruned with target-side marginals corresponds to the results with $\lambda_p > 0.0$ and $\lambda_s = 1.0$. Pruning with target-side marginals can clearly improve the projection quality by pruning out bad projections. When $\lambda_p = 0.1$, 31% of target-language words obtain head words, and the model outperforms the baseline parser by 0.6% at peak UAS. When $\lambda_p = 0.5$, the projection ratio decreases to 26% and the improvement is 0.3%. Based on the results, we choose $\lambda_p = 0.1$ in later experiments.

Figure 3(b) presents the results of *DCA pruned & supplemented* with different λ_s. The supplement process adds a small amount of dependencies of high probabilities into the projected forest and therefore increases the oracle score, which provides the model with flexibility to distribute the probability mass to more preferable parse trees. We can see that although the peak UAS does not increase much, the training curve is more smooth and stable than that without supplement. Based on the results, we choose $\lambda_s = 0.6$ in later experiments.

4.3 Final Results and Comparisons on Test Dataset

Table 2 presents the final results on CTB5 test set. For each parser, we choose the parameters corresponding to the iteration number with highest UAS on development set. To further verify the usefulness of syntax projection, we also conduct experiments with self-training, which is known as a typical semi-supervised method. For the standard self-training, we use Chinese-side bitext with self-predicted parse trees produced by the baseline parser as additional training instances, which turns out to be hurtful to parsing performance. This is consistent with earlier results (Spreyer and Kuhn, 2009).

[5] Please note when $\lambda_p + \lambda_s >= 1$, λ_s becomes useless. The reason is that if the probability of a projected dependency (i, j) is larger λ_p, then no other word beside w_i can have a probability larger than λ_s of being the head word of w_j.

	UAS
Baseline Supervised Parser	81.04
Standard Self-training	80.51 (-0.53)
Self-training with Ambiguous Labelings	81.09 (+0.05)
DCA	78.70 (-2.34)
DCA Pruned	81.46 (+0.42 †)
DCA Pruned & Supplemented	81.71 (+0.67 †)

Table 2: UAS on CTB5 test set. † indicate statistical significance at confidence level of $p < 0.01$.

	Supervised	Bitext-enhanced
Jiang et al. (2010)	87.15	87.65 (+0.50)
This work	89.62	90.50 (+0.88 †)

Table 3: UAS on CTB5X test set. † indicate statistical significance at confidence level of $p < 0.01$.

Then, we try a variant of self-training with ambiguous labelings following the practice in Täckström et al. (2013), and use a parse forest composed of dependencies of high probabilities as the syntactic structure of an instance. We can see that ambiguous labelings help traditional self-training, but still have no significant improvement over the baseline parser. Results in Table 2 indicate that our syntax projection method is able to project useful knowledge from source-language parse trees to the target-side forest, and then helps the target parser to learn effective features.

4.4 Comparisons with Previous Results on Syntax Projection on CTB5X

To make comparison with the recent work of Jiang et al. (2010), We rerun the process of syntax projection with CTB5X as the target treebank with the *DCA pruned & supplemented* method ($\lambda_p = 0.1$ and $\lambda_s = 0.6$).[6] Table 3 shows the results. Jiang et al. (2010) employ the second-order MSTParser of McDonald and Pereira (2006) with a basic feature set as their base parser. We can see that our baseline parser is much stronger than theirs. Even though, our approach leads to larger UAS improvement.

This work is different from theirs in a few aspects. First, the purpose of syntax projection in their work is to produce dependency/non-dependency instances which are used to train local classifiers to produce auxiliary features for MSTParser. In contrast, the outputs of syntax projection in our work are partial trees/forests where only reliable dependencies are kept and some words may receive more than one candidate heads. We directly use these partial structures as extra training data to learn model parameters. Second, their work measures the reliability of a projected dependencies only from the perspective of alignment probability, while we adopt a probabilistic parsing model and use target-side marginal probabilities to throw away bad projections, which turns out effective in handling syntactic non-isomorphism and errors in word alignments and source-side parses.

5 Related work

Cross-lingual annotation projection has been applied to many different NLP tasks to help processing resource-poor languages, such as POS tagging (Yarowsky and Ngai, 2001; Naseem et al., 2009; Das and Petrov, 2011) and named entity recognition (NER) (Fu et al., 2011). In another direction, much previous work explores bitext to improve monolingual NER performance based on bilingual constraints (Chen et al., 2010b; Burkett et al., 2010; Li et al., 2012a; Che et al., 2013; Wang et al., 2013).

Based on a universal POS tag set (Petrov et al., 2011), McDonald et al. (2011) propose to train delexicalized parsers on resource-rich language for parsing resource-poor language without use of bitext (Zeman and Resnik, 2008; Cohen et al., 2011; Søgaard, 2011). Täckström et al. (2012) derive cross-lingual clusters from bitext to help delexicalized parser transfer. Naseem et al. (2012) propose selectively sharing to better explore multi-source transfer information.

[6] In the previous draft of this paper, we directly use the projected data with in previous subsection for simplicity, and find that UAS can reach 91.39% (+1.77). The reason is that the CTB5X test is overlapped with CTB5 train. We correct this mistake in this version.

Our idea of training with ambiguous labelings is originally inspired by the work of Täckström et al. (2013) on multilingual parser transfer for unsupervised dependency parsing. They use a delexicalized parser trained on source-language treebank to obtain parse forests for target-language sentences, and re-train a lexicalized target parser using the sentences with ambiguous labelings. Similar ideas of learning with ambiguous labelings are previously explored for classification (Jin and Ghahramani, 2002) and sequence labeling problems (Dredze et al., 2009).

6 Conclusions

This paper proposes a simple yet effective framework of soft cross-lingual syntax projection. We make use of large-scale projected structures as additional training instances to boost performance of supervised parsing models trained on full-set manually labeled treebank. Compared with previous work, we make two innovative contributions: 1) using the marginal probabilities of a target-side supervised parser to control the projection quality with the existence of parsing and aligning errors and cross-lingual syntax divergences; 2) adopting a new learning technique based ambiguous labelings to make use of projected incomplete dependency trees for model training. Experimental results on two Chinese datasets demonstrate the effectiveness of the proposed framework, and show that the bitext-enhanced parser significantly outperforms all baselines, including supervised parsers, semi-supervised parsers based on self-training, and previous syntax projection methods.

Our anonymous reviewers present many great comments, especially on the experimental section. We will improve this work accordingly and release an extended version of this paper at the homepage of the first author. Such extensions include: 1) further exploring source-language parsing probabilities and alignment probabilities to help syntax projection; 2) studying the effect of the scale of source/target treebank and bilingual text.

Acknowledgments

The authors would like to thank Wanxiang Che and Jiang Guo for sharing their bilingual data, and our anonymous reviewers for their critical and insightful comments, which will certainly help our future work. Abstract

In this paper we present an in-depth study on automatic feature selection for beam-search dependency parsers. The search strategy is inherited from the one implemented in MaltOptimizer, but searches in a much larger set of feature templates that could lead to a higher number of combinations. Our models provide results that are on par with models trained with a larger set of feature templates, and this implies that our models provide faster training and parsing times. Moreover, the results establish the state of the art for some of the languages.

1 Introduction

Finding an optimal and accurate set of feature templates is crucial when training statistical parsers; in fact it is essential when building any machine learning system (Smith, 2011). In dependency parsing, the features are based on the linguistic information that is annotated within the words and the information that is being calculated during the parsing process. Researchers normally tend to include a large set of feature templates in their machine learning models, following the idea that more is always better; however some recent research on feature selection for transition-based parsing (Ballesteros, 2013; Ballesteros and Nivre, 2014) and graph-based parsing (He et al., 2013) have shown that more features are not always better, at least in the case of dependency parsing; models containing more features are always slower in parsing and training time and they do not always provide better results.

This indicates that a smart feature template selection could be the key in the trade-off for finding an accurate and fast feature model for a given parsing model. On the one hand, we want a parser that should provide the best results possible, while on the other hand, we want a parser that should provide the results in the fastest way possible. For practical applications, a fast model is crucial.

In this paper, we report the results of feature selection experiments that we carried out with the intention of obtaining accurate and faster feature models, for the transition-based Mate parser with and without graph-based completion models. The Mate parser is a beam search parser that uses a hash kernel for training, joint part-of-speech tagging, morphological tagging and dependency parsing. As a result of this research, we provide a framework that allows to find an optimal feature template set for the Mate parser (Bohnet et al., 2013). Moreover, our models provide some of the highest results ever reported for a set of treebanks.

The paper is organized as follows. Section 2 describes related work including the used agenda-based dependency parser. This section depicts the feature templates that can be used by a transition-based or a graph-based parser. Section 3 describes the feature selection algorithm that we implemented for our experiments. Section 4 shows the experimental set-up. Section 5 reports the main results of our experiments. Section 6 provides the parsing times and memory requirements. Finally, Section 7 concludes.

Proceedings of COLING 2014, the 25th International Conference on Computational Linguistics: Technical Papers, pages 794–805, Dublin, Ireland, August 23-29 2014.

Transition		Condition
LEFT-ARC$_d$	$([\sigma\|i,j],B,\Gamma) \Rightarrow ([\sigma\|j],B,\Gamma[(j,i)\in A,\delta(j,i)=d])$	$i \neq 0$
RIGHT-ARC$_d$	$([\sigma\|i,j],B,\Gamma) \Rightarrow ([\sigma\|i],B,\Gamma[(i,j)\in A,\delta(i,j)=d])$	
SHIFT$_{p,m,l}$	$(\sigma,[i\|\beta],\Gamma) \Rightarrow ([\sigma\|i],\beta,\Gamma[\pi(i)=p,\mu(i)=m,\lambda(i)=l])$	
SWAP	$([\sigma\|i,j],\beta,\Gamma) \Rightarrow ([\sigma\|j],[i\|\beta],\Gamma)$	$0 < i < j$

2 Related Work

2.1 Mate Parser

For our experiments, we used the transition-based parser of Bohnet et al. (2013). This parser performs joint part-of-speech tagging, morphological tagging, and non-projective labeled dependency parsing. The parser employs a number of techniques that lead to very competitive accuracy such as beam-search with early update (Collins and Roark, 2004), a hash kernel that can quickly cope with a large feature set, a graph-based completion model that adds scores for tree parts which a transition-based parser would not be able to consider, cf. (Zhang and Clark, 2008; Bohnet and Kuhn, 2012). The graph-based model takes into account second and third order factors and obtains a score as soon as the tree parts are completed. The parser employs a rich feature set for a transition-based model (Zhang and Nivre, 2011; Bohnet et al., 2013) as well as for a graph-based model. In total, there are 326 different feature templates for the two models. The drawback of such a large feature set is a huge impact on the speed. Important research questions include (1) whether the number of features could be reduced to speed up the parser and (2) whether languages dependent feature sets would be beneficiary.

2.2 Features in transition-based dependency parsing

Every transition-based parser uses two data structures: (1) a buffer that contains at the beginning of the parsing process all words of the sentence that have to be parsed, and (2) a stack.

The Mate parser that we used in our experiment follows Nivre's arc-standard parsing algorithm plus the SWAP transition to build non-projective dependency trees. Figure 1 depicts the transition system formally; the SHIFT transition removes the first node from the buffer and puts it on the stack. The LEFT-ARC$_d$ transition introduces a labeled dependency edge between the top element on the stack and the second element of the stack with the label d. The second top element is removed from the stack. The RIGHT-ARC$_d$ transition introduces a labeled dependency edge between the second element on the stack and the top element with the label d while the top element is removed from the stack. The SWAP transition swaps the position of the topmost nodes of the stack and the buffer.

A classifier selects transitions based on the feature templates that are composed of stack elements, buffer elements, the already created parse, and the transition sequence. For instance, if the parser contains the feature template LEMMA(S_1), it means that it may use the lemma of the word that is in the first position of the stack in any parsing state in order to select the best parsing action.

2.3 Features in graph-based dependency parsing

A Graph-based dependency parser performs an exhaustive search over trees of the words of a sentence. Frequently, dynamic programming techniques are used to find the optimal tree for each span, considering candidate spans by successively building larger spans in a bottom-up fashion. A classifier is used to decide among alternative spans. The typical feature models are based on combinations of edges (as known as, factors). A factor consists either of a single edge, two or three edges; which are called first order, second and third order factors, respectively. The later are employed in more advanced and recent parsers trading off accuracy with complexity, cf. (McDonald et al., 2005b; Carreras, 2007; Koo and Collins, 2010). The features in a graph-based algorithm consist of sets of features drawn from the

vertexes involved in the factors. A feature template of a second order factor is composed of properties drawn from up to all three vertex, e.g., the part-of-speech of the head, the dependent and a child denoted as POS(H)+POS(D)+POS(C). In our experiments, we use in addition to the transition-based model, a completion model that uses graph-based feature templates with up to third order factors to re-score the beam.

2.4 Feature Selection

There has been some recent research on trying to manually find better feature models for dependency parsers, such as Nivre et al. (2006), Hall et al. (2007), Hall (2008), Zhang and Nivre (2011), and Agirre et al. (2011). There is also research on automatic feature selection in the case of transition-based dependency parsing, a good example is MaltOptimizer (Ballesteros and Nivre, 2014) which implements a search for the best feature model that it can find, following acquired previous experience and deep linguistic knowledge (Hall et al., 2007; Nivre and Hall, 2010); Nilsson and Nugues (2010) also tried to search for optimal feature sets in the case of transition-based parsing, starting from a reduced test set using the concept of topological neighbors. Finally, He He et al. (2013) also tried automatic feature selection but for a graph-based parsing algorithm, where they pruned the feature space, removing unused features, in a first-order graph-based dependency parser, providing models that are equally accurate and faster.

Zhang and Nivre (2011) pointed out that two different parsers based on the same algorithm may need different feature templates since other design aspects of a parser might have an influence on the usefulness of feature templates such as the learning technique or the use of beam search.

3 Feature Selection Algorithm

As in MaltOptimizer (Ballesteros and Nivre, 2014), our feature selection algorithm starts with a default feature set that is based on the MaltParser's default feature model for an arc-standard parsing algorithm[1], it first tests whether the features that are in the default model are actually useful, which means that whenever we remove any of the features of the default set, the accuracy is still the same (or better).

After that, one by one, the algorithm tries to add feature templates to the feature set. For each additional feature template a parser is trained for testing and if the accuracy is higher than the accuracy of the previous step plus a Δ (threshold) then the feature in question is added to the feature set. The selection process continues until all features have been tested, and therefore each feature has been either added or rejected. Most of the feature selection is based on the forward selection algorithm shown in Figure 2, although there is also a bit of backward selection from the default set.

Let $F = \{F_1, \ldots, F_n\}$ be the full set of features,
let $M(X)$ be the evaluation metric for feature set X,
and let Δ be the threshold.

```
1   X ← ∅
2   while X ≠ F
3       B ← 0
4       Y ← ∅
5       for each X_i ∈ F \ X
6           if M(X ∪ {X_i}) + Δ > B then
7               B ← M(X ∪ {X_i})
8               Y ← X ∪ {X_i}
9       if M(X) > B then
10          return X
11      else
12          X ← Y
13  return X
```

Figure 2: Algorithm for forward feature selection.

The feature selection algorithm only has the training set as an input, and it splits it into training and development to validate the outcomes of the experiments.[2] After the feature selection, we run the parser model on a held-out test set to measure its performance.

The feature selection is pruned following similar strategies to MaltOptimizer; there are features that are deeply related and the system tries to avoid unnecessary tests when some features happen to be excluded. For instance, the algorithm will not try to select the third position of the buffer for the part-of-speech, if the second position was excluded by the feature selection algorithm.

[1] http://www.maltparser.org/userguide.html

[2] It makes a 80/20 division; 80% for training, 20% for development.

4 Experimental Set-Up

In order to set up the experiments for the feature selection algorithm, we carried out a series of tests based on the parser settings. From these experiments, we obtained the best parser settings, the threshold that provides the best results given a development set, and the best scoring method and some additional configurations, that gave us reliable results and a fast outcome.

We used the following corpora for our experiments. **Chinese:** We used the Penn Chinese Treebank 5.1 (CTB5), converted with the head-finding rules and conversion tools of Zhang and Clark (2008), with the same split as in (Zhang and Clark, 2008) and (Li et al., 2011).[3] **English:** We used the WSJ section of the Penn Treebank, converted with the head-finding rules of Yamada and Matsumoto (2003) and the labeling rules of Nivre (2006).[4] **German:** We used Tiger Treebank (Brants et al., 2002) in the improved dependency conversion by Seeker and Kuhn (2012). **Hungarian:** We used the Szeged Dependency Treebank (Farkas et al., 2012). **Russian:** We used the SynTagRus Treebank (Boguslavsky et al., 2000; Boguslavsky et al., 2002).

4.1 Parser settings

As outlined in Section 3, our feature selection experiments require the training of a large number of parsing models and applying these to the development set.[5] Therefore, we aimed to find a training setup for the parser that provided fast training times while maintaining a realistic training and optimization scenario.

A major factor for the time usage is the beam size. The beam contains the alternative syntactic structures that are considered in the parsing process, and thus it requires more time and memory while it normally provides better results. The parser uses two additional small beams to store the differently tagged syntactic structures and morphological structures, for the joint models. We explored a number of configurations and assessed the parsing performance by carrying out a set of experiments on the Penn Treebank and the training settings of Bohnet et al. (2013);[6] the results are shown in Table 1.

	transition-based model								
beam	1	3	5	8	12	20	30	40	50

Table 1: Labeled Accuracy Score (LAS) in percent, Part-of-Speech tag accuracy POS in percent and training time (TT) in milliseconds per sentence. The parser was applied on the development set and trained over the Penn Treebank.

The table provides an overview of this preliminary experiment. The upper part of the table shows the performance when only using the transition-based model. The accuracy improvements are small when the beam-size becomes larger than 5. Even when we compared the results with the results of a beam size of 30, we observed only a small accuracy improvement. Further, we observe with a larger beam size a saturation where the accuracy does not improve and the parsing results show a small variance.

[3] Training: 001–815, 1001–1136. Development: 886–931, 1148–1151. Test: 816–885, 1137–1147.

[4] Training: 02-21. Development: 24. Test: 23.

[5] All this experiments were carried out on a CPU Intel Xeon 3.4 Ghz with 6 cores.

[6] We used 25 training iterations and we took the accuracy scores from the last iteration, we used the join parser, the two best part-of-speech tags and morphological tags. The threshold for the inclusion of part-of-speech tags was set to 0.25 and that of the morphological tagger to 0.1. We selected a beam size for the alternative POS tags and morphological tags of 4.

Figure 3: Accuracy scores depending on the threshold Δ.

The feature selection starts with a default feature set that includes 20 features (cf. Section 3), and all these features are derived from the default feature models for MaltParser (Nivre et al., 2007)[7]. In total, the feature selection algorithm, for the transition-based model, may select 188 features. In Table 1 we show the training time (TT). We used this table to selected the optimal settings for the beam. After considering the trade-off between accuracy and speed, we selected for the feature selection a beam size of 8, since it obtains 90.19 LAS which is close to the highest accuracy score 90.46 and with this beam size the parser is fast. For a parser trained with all feature templates, the average parsing time per sentence is 9 milliseconds. With 20-60 features, we obtained a parsing time of 2-5 milliseconds per sentence, which is a faster and more optimal setting for the feature selection. Moreover, with a beam size of 40, we get parsing times that ranged depending on the number of features from 12 to 50 milliseconds per sentence, this is impracticable for feature selection experiments.

4.2 Selecting an Optimal Threshold

Feature templates are selected when they provide a higher accuracy compared to the previous feature set plus a threshold Δ. To determine an optimal Δ for the feature selection, we carried out a series of experiments with different Δ values. As a first step, we ran the feature selection algorithm starting from 0.05 and reducing the value stepwise to -0.05 (testing 0.05, 0.02, 0.01, 0.0, -0.01, -0.02, -0.05) with the intention of obtaining accuracy scores for all these settings. Table 3 shows the scores for our experiments on the development set for the English and German treebanks. We obtained an optimal trade-off between score and number of features with a Δ of 0.0. With higher thresholds, such as 0.02 or 0.05, the feature selection algorithm was very restrictive, and resulted in lower accuracy scores. This indicates that there are several features that are not included that could contribute to a higher accuracy; for instance, in the German case, we see that the algorithm only selects 41 features. Moreover, the accuracy for English with a Δ of 0.0 is even higher compared with the results obtained when all features were included (cf. last row: $-\infty$). For German, we see a highest accuracy score with threshold of -0.02. We might get the best accuracy with this threshold when applied to the test set; however, the downside of this threshold is that the algorithm selected 25 more feature templates, which leads to a slower parser.

Figure 4 illustrates the accuracy gain depending on the number of features included. The development set of these graphs consist of 20% of the original training set. A negative Δ leads to the inclusion of more features, which seem to provide even slightly higher results while including much more features. This outcome is not fully supported by the results from the development sets for English where we observed slightly lower results for a Δ of -0.02 compared to 0.0.

To determine the optimal threshold Δ for a language would come with a high computational cost, we carried out these experiments for English and German which show only small differences in accuracy in the threshold range around 0. Therefore, we adopted 0.0 as threshold for our further experiments on other languages as well, cf. Table 4.

Table 2: Experiments with evaluation metrics with a Δ of 0.0 on the development sets. Features: **transition-based**. The morphology results are only shown for German, because the English treebank does not contain separate morphological features.

4.3 Selecting the Best Scoring Method

We carried out a number of experiments to determine the best criterion for the inclusion of features into the model. We tested several evaluation measures that compute the results of each model, that are LAS [labeled attachment score], LUMP[8] [(labeled attachment score + unlabeled attachment score + morphology accuracy + part-of-speech accuracy)/4] and PMLAS[9] [labeled attachment score, morphology accuracy and part-of-speech accuracy]. Table 2 shows the results of the feature selection for English and German for all these scoring methods. We finally selected LAS as our scoring method given that it provides the best results for German and competitive results (at the same level) for English. LUMP is very similar, however, it seems a bit more restrictive than LAS. Moreover, PMLAS was the most restrictive measure, allowing only 31 features for German and 40 for English, which is the reason why there is a significant lower accuracy for the models selected with PMLAS.

Finally, it is worth mentioning that we explored an alternative criterion for the inclusion of features into the set. We explored the possibility to include only features that show a statistical significant improvement. However, this criterion is too strict as only very few features showed a statistical significant improvement on its own.

4.4 Selection of Feature Templates of the Graph-based Completion Model

The graph-based *completion model* re-scores the beam incrementally and leads to a higher accuracy. We tried to select the graph-based feature templates of the completion model after the selection of the

[8]LMP [(labeled attachment score + morphology accuracy + part-of-speech accuracy)/3] would have been another alternative. However, we wanted to give the syntax still a higher weight in the feature selection process.

[9]See (Bohnet et al., 2013)

transition-based feature templates. This approach could not reach the accuracy gain shown by Bohnet and Kuhn (2012). We attempted to compensate this by starting the selection procedure from the default set with the intention of maximizing potential accuracy gains. However, this procedure did not lead to a better accuracy when later combined with the selected transition-based feature templates. We tried also to relax the threshold to -0.02 in order to include more features and to achieve a higher accuracy. Since this leads to better results, we performed the feature selection for the graph-based completion model with this setting.

4.5 Morphology for English

The Penn Treebank is annotated with part-of-speech tags that include morphological features such as `NNS` (plural noun) or `VBD` (verb past tense). The corpus does not include separate morphological features. Splitting up these features could be useful because: (1) the parser might be able to generalize better when we use the word categories separated from morphological features, and (2) we might take advantage of the ability of the parser to predict morphology and part-of-speech based on the interaction with the syntax. Table 3 summarizes the results. Our transition-based parsing model shows only small differences between the scores for the original POS tag set and the tag set that separates the category and morphology.

	transition-based model				
	LAS	UAS	POS	MOR	POS&MOR
baseline dev	90.13	91.44	–	–	96.97
separate dev	90.11	91.26	97.66	98.81	97.08
baseline test	92.11	93.16	–	–	97.41
separate test	92.07	93.09	**97.88**	**97.93**	**97.35**
	transition-based model with completion model				
baseline test	92.41	93.35	–	–	97.41
separate test	**92.53**	**93.49**	97.85	98.89	97.28

Table 3: Experiments on Penn Treebank with separate representation of word category and morphology.

The results of the transition-based model, including the graph-based model shows some larger differences

The labeled and unlabeled accuracy scores are not statistically significant and we concluded that (1) and (2) do not probably hold. Splitting up the morphology is a neutral operation in terms of labeled and unlabeled accuracy scores; however, it is worth noting that our results with the separate test for the completion model is more competitive, providing an improvement of 0.14 UAS.

5 Experiments: Feature Selection

We applied the feature selection algorithm with the parameters determined in the previous sections on the corpora of Chinese, English, German, Hungarian and Russian, and we applied the outcome to parse the held-out test sets with a beam size of 40 and 25 training iterations. Table 4 shows the accuracy scores and the number of features selected for each language. The threshold for inclusion of the feature was set to 0, cf. section 4.

The first row (Full) shows the accuracy scores for the full set of features, that includes all 188 feature templates of the transition-based feature set. The second row gives the accuracy scores that have been obtained with the reduced feature set gained by the feature selection algorithm described in Section 3.

For the sole transition-based parsers trained with the selected features, we obtain for Chinese, Hungarian and Russian higher labeled and unlabeled accuracy scores. The scores for German are very similar to the ones obtained with the full set and the scores for English are slightly worse. In the case of the transition-based parser with graph-based completion model, the results are the same for Chinese, and slightly worse for the rest of the languages, with the parser at least twice as fast. It is worth noting that the number of feature templates is reduced by 2/3 across all languages which leads to a much faster parsing and training time, thus freeing up a huge amount of main memory.

Table 4: Labeled attachment score (LAS), unlabeled attachment score (UAS), part-of-speech accuracy (POS) and morphology accuracy (MOR) per language and model. The first two rows refer only to transition-based features while the last two rows include transition-based and graph-based features. **Full** refers to a model with all transition-based features. **Select** refers to a model with selected transition-based features. **Full+Cmp** refers to a model with all transition-based features and all graph-based features. **Sel+Cmp** refers to a model with selected transition-based features and all graph-based features. **Sel+Sel** refers to a model with selected transition-based features and selected graph-based features. The English and Chinese accuracy scores exclude punctuation marks.

More about parsing time, training time and memory requirements is depicted in Section 6. A comparison with state of the art results as shown in the Tables 5a to 5d reveal that the parser with the selected features of the transition-based, and graph-based model are on an equal level for Chinese, Russian and Hungarian with state-of-the-art results. With the selected transition-based and the full graph-based feature templates, the results for these languages surpass current state-of-the-art results.

6 Time and Memory Requirements

The number of feature templates has a serious impact on training time, parsing time and the amount of main memory required. The feature selection may have huge impact on the speed of a parser. Therefore, we measure the actual time and memory usage by applying the parser on the English test set of the Penn Treebank. This was done with different parsing models, and for each model, test runs were performed with an increasing number of CPU cores. Figure 6 shows an overview of the results.

The parsing model with all transition- and graph-based features takes on one CPU core 0.085 seconds per sentence (cf. Figure 6, line with rhombus). In contrast, the parser with selected transition-based features parses a sentence in less than half of the time (0.042 seconds, line with crosses). The parsing accuracy is only 0.42 percentage points worse (93.35 vs. 92.93 UAS). When we compare the first parsing model with the model with selected transition-based and graph-based features, we observe a parsing time of 0.066 seconds per sentence and a small accuracy difference of only 0.27.

If we use six CPU cores then parsing time decreases drastically to 0.016 seconds per sentence for the selected transition-based feature model, 0.023 for the selected transition- and graph-based feature model and to 0.05 seconds per sentence for the model with all features (which is much slower). demonstrate that we can double the parsing speed and maintain a very high parsing accuracy.

7 Conclusions

In this paper, we have presented the first feature selection algorithm for agenda-based dependency parsing. Our algorithm could be directly used out of the box,[10] and applied to a new data set or language to get an optimized feature model for a agenda-based parser such as the Mate tools.[11]

Our feature selection algorithm provides models with even higher accuracy for Chinese and Russian, cf.Table 4. For the remaining languages the models provide accuracy scores that are comparable to the ones obtained by models including a larger set of feature templates. For all languages, the feature models gained via feature selection are faster and require less memory, which make them very useful for practical applications. We conclude that feature models obtained with the feature selection algorithm

[10]The source code and the feature models found for each language are available at `https://code.google.com/p/mate-tools/`

[11]`https://code.google.com/p/mate-tools/wiki/ParserAndModels`

often provide a comparable accuracy level while they are considerable faster. Finally, our model for English with the separated morphology tag-set provides one of the best results reported with **93.49** UAS. Additionally, the feature selection algorithms for this setting shows competitive results with a largely reduced number of feature templates, and thus less parsing time and lower memory requirements. The parser is faster (almost double) and provides **93.05** UAS which is also among the best results.

Abstract

This paper presents predicate-argument structure analysis (PASA) for dialogue systems in Japanese. Conventional PASA and semantic role labeling have been applied to newspaper articles. Because pronominalization and ellipses frequently appear in dialogues, we base our PASA on a strategy that simultaneously resolves zero-anaphora and adapt it to dialogues. By incorporating parameter adaptation and automatically acquiring knowledge from large text corpora, we achieve a PASA specialized to dialogues that has higher accuracy than that for newspaper articles.

1 Introduction

Semantic role labeling (SRL) and predicate-argument structure analysis (PASA) are important analysis techniques for acquiring "who did what to whom" from sentences[1]. These analyses have been applied to written texts because most annotated corpora comprise newspaper articles (Carreras and Màrquez, 2004; Carreras and Màrquez, 2005; Matsubayashi et al., 2014).

Recently, systems for speech dialogue between humans and computers (e.g., Siri of Apple Inc. and Shabette Concier of NTT DoCoMo) have become familiar with the popularization of smart phones. A man-machine dialogue system has to interpret human utterances to associate them with system utterances. The predicate-argument structure could be an effective data structure for dialogue management. However, it is unclear whether we can apply the SRL/PASA for newspaper articles to dialogues because there are many differences between them, such as the number of speakers, written or spoken language, and context processing. For example, the following dialogue naturally includes pronouns, and thus anaphora resolution is necessary for semantic role labeling.

A:	$[I]_{ARG0}$ ***want*** $[an\ iPad\ Air]_{ARG1}$.
B:	$[When]_{ARGM}$ *will* $[you]_{ARG0}$ ***buy*** $[it$(=an iPad Air)$]_{ARG1}$?

Similar phenomena exist in Japanese dialogues. However, most pronouns are omitted (called zero-pronouns), and zero-anaphora resolution is necessary for Japanese PASA.

A:	$[iPad\ Air]_{NOM}$	*-ga*	***hoshii****-na.*
	iPad Air	NOM.	want
	"ϕ want an iPad Air."		
B:	*itsu*	$\phi_{NOM}\phi_{ACC}$	***kau****-no?*
	when		buy?
	"When will ϕ buy ϕ?"		

[1]Recent SRL systems assign labels of predicates and their arguments as semantic roles. Consequently, SRL and PASA are very similar tasks. We use the term predicate-argument structure analysis in this paper because most Japanese analyzers use this term.

Proceedings of COLING 2014, the 25th International Conference on Computational Linguistics: Technical Papers, pages 806–815, Dublin, Ireland, August 23-29 2014.

This paper presents predicate-argument structure analysis with zero-anaphora resolution for Japanese chat dialogues. Here, we regard the task of constructing PASA for dialogues as a kind of domain adaptation from newspaper articles to dialogues. Màrquez et al. (2008) and Pradhan et al. (2008) indicated that the tuning of parameter distribution and reducing the out-of-vocabulary are important for the domain adaptation of SRL. We also focus on parameter distribution and out-of-vocabulary to construct a PASA adapted to dialogues. To the best of our knowledge, this is the first paper to describe a PASA for dialogues that include many zero-pronouns.

The paper is organized as follows. Section 2 briefly reviews SRL/PASA in English and Japanese. Section 3 discusses characteristics of chat dialogues by comparing two annotated corpora, newspaper articles and dialogues. Section 4 describes the basic strategy of our PASA, and Section 5 shows how it was adapted for dialogues. Experiments are presented in Section 6, and Section 7 concludes the paper.

2 Related Work

2.1 Semantic Role Labeling in English

The advent of the supervised method proposed by Gildea and Jurafsky (2002) has led to the creation of annotated corpora for semantic role labeling. In the CoNLL-2004 and 2005 shared task (Carreras and Màrquez, 2004; Carreras and Màrquez, 2005), evaluations were carried out using the Proposition Bank (Palmer et al., 2005). Because the Proposition Bank was annotated to the Penn Treebank (i.e., the source texts were from the Wall Street Journal), the shared tasks were evaluated on newspaper articles. Màrquez et al. (2008) provides a review of SRL.

OntoNotes Corpus (Hovy et al., 2006) contains multiple genres such as newswire, broadcast news, broadcast conversation. The annotation to OntoNotes includes semantic role labels compliant with the Proposition Bank. It is currently used for coreference resolution (Pradhan et al., 2012), and is expected to be applied to dialogue analysis.

A few SRL studies have focused on not only verbal predicates (e.g., '*decide*') but also nominal predicates (e.g., '*decision*') (Jiang and Ng, 2006; Gerber and Chai, 2012; Laparra and Rigau, 2013). Because the subject and object of nominal predicates are frequently omitted (e.g., the object in the phrase "*the decision*" is omitted), problems similar to the Japanese zero-pronouns have to be resolved in the SRL of nominal predicates.

2.2 Predicate-Argument Structure Analyses in Japanese

Japanese material includes the NAIST Text Corpus (Iida et al., 2007)[2], which is an annotated corpus of predicate-argument structures and coreference information for newspaper articles. Argument noun phrases of the nominative, accusative, and dative cases are assigned to each predicate. The predicate and the noun phrases are not limited to the same sentence. If arguments of the predicate are represented as zero-pronouns, the antecedent noun phrases in other sentences are assigned as the arguments.

Many PASA methods have been studied on the NAIST Text Corpus (Komachi et al., 2007; Taira et al., 2008; Imamura et al., 2009; Yoshikawa et al., 2011). In Japanese, some of them simultaneously resolve the zero-anaphora caused by zero-pronouns.

Most English SRL and Japanese PASA currently target newspaper articles, and it is unclear whether the methods for newspapers can be applied to dialogue conversations.

3 Characteristics of Chat Dialogues

We first collected chat dialogues of two speakers and annotated them with the predicate-argument structure. The participants chatted via keyboard input. Therefore, fillers and repetitions, which are frequent in speech dialogues, were rare. The theme was one of 20 topics, such as meals, travel, hobbies, and TV/radio programs. Annotation of the predicate-argument structure complied with the NAIST Text Corpus. Figure 1 shows a chat dialogue example and its predicate-argument structure annotation.

[2] `http://cl.naist.jp/nldata/corpus/`. We use version 1.5 with our own preprocessing in this paper. NAIST is an acronym of "Nara Institute of Science and Technology."

	Dialogue	2,089	37.6%	7.8%	15.0%	2.5%	1.1%	36.1%

Table 2: Distribution of Arguments in Training Corpora

Table 1 shows the statistics of the NAIST Text Corpus and the Chat Dialogue Corpus we created[3]. The size of the Dialogue Corpus is about 10% of the NAIST Corpus. The NAIST Corpus is divided into three parts: training, development, and test. The Dialogue Corpus is divided into training and test.

Table 2 shows distributions of arguments in the training sets of the NAIST/Dialogue corpora. We classified the arguments into the following six categories because each argument presents different difficulties for analysis by its position and syntactic relation. The first two categories (Dep and Zero-Intra) are the ones that in which the predicate and the argument occupy the same sentence.

- Dep: The argument directly depends on the predicate and vice versa on the parse tree.
- Zero-Intra: Intra-sentential zero-pronoun. The predicate and the argument are in the same sentence, but there is no direct dependency.
- Zero-Inter: Inter-sentential zero-pronoun. The predicate and the argument are in different sentences.
- exo1/exo2/exog: These are exophoric and denote zero-pronouns of the first person, second person, and the others (general), respectively.

By Table 2, we can see that the ratios of Dep in all cases decreased in the Dialogue Corpus. In the other categories, the tendencies between the nominative case and the accusative/dative cases were different. In the nominative case, the Zero-Intra also decreased in the Dialogue Corpus, and the declines were

[3]We regard a dialogue and an utterance as an article and a sentence, respectively.

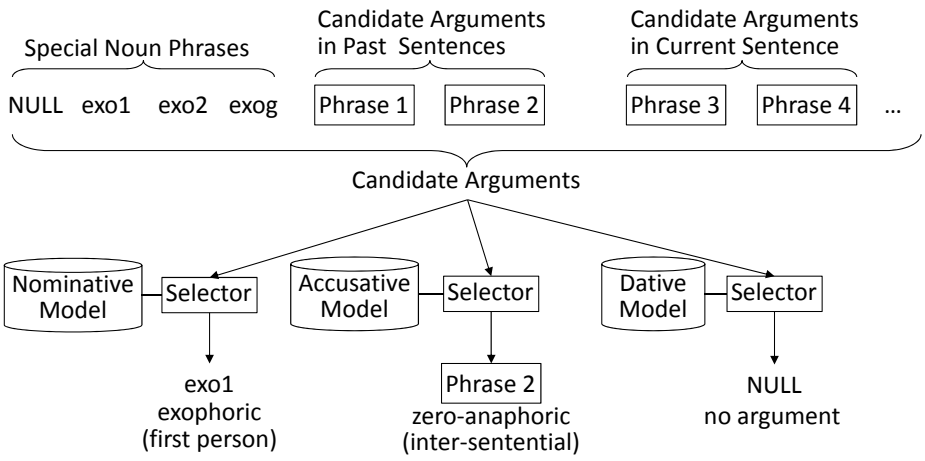

Figure 2: Structure of Argument Identification and Classification

assigned to `exo1` and `exo2`. Namely, the arguments in a sentence were reduced, and zero-pronouns increased compared with the newspaper articles. Note that many antecedents were the first or second person. On the other hand, in the accusative and dative cases, the declines of the `Dep` were assigned to the `Zero-Inter` or the `exog` in the Dialogue Corpus. Namely, anaphora resolution across multiple sentences is important to dialogue analysis. In contrast, most arguments and the predicate appear in the same sentence in the accusative/dative cases of newspapers.

4 Basic Strategy for Predicate-Argument Structure Analysis and Zero-Anaphora Resolution

4.1 Architecture

We use Imamura et al. (2009)'s method developed for newspaper articles as the base PASA in this paper. It can simultaneously identify arguments of a predicate in the sentence, those in other sentences, and exophoric arguments. The analyzer receives the entire article (dialogue) and performs the following steps for each sentence (utterance).

1. The input sentences are tagged and parsed. During parsing, the base phrases and their headwords are also identified. At this time, the part-of-speech tags and the parse trees of the Dialogue Corpus are supplied by applying the morphological analyzer MeCab (Kudo et al., 2004) and the dependency parser CaboCha (Kudo and Matsumoto, 2002). The NAIST Corpus version 1.5 already includes the part-of-speech tags and the parse trees.

2. Predicate phrases are identified from the sentences. We use the correct predicates in the corpora for the evaluation. When we build dialogue systems on PASA, predicate phrases will be identified using part-of-speech patterns that include verbs, adjectives, and copular verbs.

3. For each predicate, candidate arguments are acquired from the sentence that includes the predicate (called the current sentence) and the past sentences. Concretely, the following base phrases are regarded as candidates.

   - All noun phrases in the current sentence are extracted as intra-sentential candidates regardless of syntactic relations.
   - From the past sentences, noun phrases are contextually extracted as inter-sentential candidates. Details are described in Section 4.4.
   - Exophoric labels (`exo1`, `exo2`, and `exog`) and the `NULL` (the argument is not required) are added as special noun phrases.

4. The features are generated from the predicate phrase, candidate arguments, and their relations. The best candidate for each case is independently selected (Figure 2).

4.2 Models

The models for the selector are based on maximum entropy classification. The selector identifies the best noun phrase $\hat{n}$ that satisfies the following equations from the candidate argument set **N**.

$$\hat{n} = \operatorname*{argmax}_{n_j \in \mathbf{N}} P(d(n_j) = 1 | X_j; M_c) \quad (1)$$

$$P(d(n_j) = 1 | X_j; M_c) = \frac{1}{Z_c(X)} \exp \sum_k \{\lambda_{ck} f_k(d(n_j) = 1, X_j)\} \quad (2)$$

$$Z_c(X) = \sum_{n_j \in \mathbf{N}} \exp \sum_k \{\lambda_{ck} f_k(d(n_j) = 1, X_j)\} \quad (3)$$

$$X_j = \langle n_j, v, A \rangle \quad (4)$$

where n denotes a candidate argument, **N** denotes a set of candidate arguments of predicate v, $d(n)$ is a function that returns 1 iff candidate n becomes the argument, and M_c denotes the model of case c. In addition, $f_k(d(n_j) = 1, X_j)$ is a feature function, λ_{ck} denotes a weight parameter of the feature function, and A denotes the article from which all sentences are parsed.

Training phase optimizes the weight parameters in order to maximize the difference in posterior probabilities among the correct noun phrase and the other candidates. Specifically, the model of case M_c is learnt by minimizing the following loss function ℓ_c.

$$\ell_c = -\sum_i \log P(d(n_i) = 1 | X_i; M_c) + \frac{1}{2C} \sum_k ||\lambda_{ck}||^2 \quad (5)$$

where n_i denotes the correct noun phrase of the i-th predicate in the training set, X_i denotes the i-th tuple of the correct noun phrase, the predicate, and the article $\langle n_i, v_i, A_i \rangle$. Since the posterior probability is normalized for each set of candidate arguments of a predicate by Equation (3), the probability of the correct noun phrase approaches closer to 1.0, and the probabilities of the other candidates approach closer to 0.0 in Equation (5).

4.3 Features

Similar to other studies (e.g., (Gildea and Jurafsky, 2002)), we use three types of features: 1) predicate features, 2) noun phrase (NP) features, and 3) the relationship between predicates and noun phrases (Table 3). We also introduce combined features of the 'Noun' with all other binary features because the features aim to select the best noun phrase.

The special features in this paper are the dependency language models (three types) and the obligatory case information ('Frame' feature), which are automatically acquired from large text corpora. We discuss them in Section 5.2.

4.4 Context Processing

Contexts of dialogues and newspaper articles are different. We should employ context processing specialized for the dialogues. However, contexts, including system and user utterances, should be managed collectively by the dialogue manager from the viewpoint of dialogue systems. Thus, this study uses the same context processing for the newspaper articles and dialogues. Note that the method in this paper controls the context by selecting the inter-sentential candidates. We can easily alter context management by providing candidate arguments from an external manager.

Context processing in this paper is as follows.

- From the current sentence, trace back to the past, and find a sentence that contains the other predicate (we call this the prior sentence). This process aims to ignore utterances that do not contain predicates.

Type	Name	Value	Remark
Predicate	Pred	Binary	Lemma of the predicate.
	PType	Binary	Type of predicate. One of 'verb', 'adjective', and 'copular verb'.
	Voice	Binary	Declarative or not. If not, the passive/causative auxiliary verb is assigned.
	Suffix	Binary	Sequence of the functional words of the main clause. This feature aims to reflect the speech act of the utterance.
	Frame	Binary	Obligatory case information. The case requires argument (1) or not (0).
Noun Phrase	Noun	Binary	Headword of the NP
	Particle	Binary	Case particle of the base phrase. If the NP is a special noun phrase, this is `NULL`.
	NType	Binary	If the substance of the NP is in the article, this is 'NP'; otherwise the same value of the 'Noun' feature.
	Surround	Binary	POS tags of the surrounding words of the NP. The window size is ± 2.
Relation between Predicate and NP	PhPosit	Binary	Distance between the predicate and the NP. If they are in different sentences, or the NP is an exophora, this is `NULL`.
	Syn	Binary	Dependency path between the predicate and the NP. If they are in different sentences, or the NP is an exophora, this is `NULL`.
	Speaker	Binary	Whether the speakers of the predicate and the NP are the same (SAME) or not (OTHER).
Dependency Language Models	$\log P(n\|c, v)$	Real	Generation probability of NP n given predicate v and case c.
	$\log P(v\|c, n)$	Real	Generation probability of predicate v given NP n and case c.
	$\log P(c\|n)$	Real	Generation probability of case c given NP n.

Table 3: List of Features

- All noun phrases that lie between the prior to the current sentence are added to the candidate arguments. In addition, noun phrases that are used as arguments of any predicates are also added (called argument recycling (Imamura et al., 2009)). Argument recycling covers wide contexts because it can employ distant noun phrases if the past predicates have inter-sentential arguments.

5 Adaptation to Chat Dialogues

The method described in the previous section is common to dialogues and newspaper articles. This section describes the adaptation made to target dialogues.

5.1 Adaptation of Model Parameters

In order to tune the difference in the argument distribution, model parameters of the selectors are adapted to the dialogue domain. We use the feature augmentation method (Daumé, 2007) as the domain adaptation technique; it has the same effect as regarding the source domain to be prior knowledge, and the parameters are optimized to the target domain. Concretely, the models of the selectors are learnt and applied as follows.

1. First, the feature space is segmented into three parts: common, source, and target.
2. The NAIST Corpus and the Dialogue Corpus are regarded as the source and the target domains, respectively. The features from the NAIST Corpus are deployed to the common and the source spaces, and those from the Dialogue Corpus are deployed to the common and the target spaces.
3. The parameters are estimated in the usual way on the above feature space. The weights of the common features are emphasized if the features are consistent between the source and target. With regard to domain-dependent features, the weights in the respective space, source or target, are emphasized.
4. When the argument is identified, the selectors use only the features in the common and target spaces. The parameters in the spaces are optimized to the target domain, plus we can utilize the features that appear only in the source domain data.

5.2 Weak Knowledge Acquisition from Very Large Resources

In this paper, we use two types of knowledge to reduce the harmful effect of out-of-vocabulary in the training corpus. Both types are constructed by automatically analyzing, summing up, and filtering large

text corpora (Kawahara and Kurohashi, 2002; Sasano et al., 2008; Sasano et al., 2013). They provide information about unknown words with some confidence but they do contain some errors. We use them as the features of the models, and parameters are optimized by the discriminative learning of the selectors.

5.2.1 Obligatory Case Information (Frame Feature)

Case frames are important clues for SRL and PASA. The obligatory case information (OCI) comprises subsets of the case frames that only clarify whether the cases of each predicate are necessary or not.

The OCI dictionary is automatically constructed from large text corpora as follows. The process assumes that 1) most of the cases match the case markers if the noun phrase directly depends on the predicate, and 2) if the case is obligatory, the occurrence rate on a specific predicate is higher than the average rate of all predicates.

1. Similar to PASA in this paper (c.f., Section 4.1), predicates and base phrases are identified by tagging and parsing raw texts.
2. Noun phrases that directly depend on the predicate and accompany a case marker are extracted. We sum up the frequency of the predicate and cases.
3. Highly frequent predicates are selected according to the final dictionary size. Obligation of the cases is determined so as to satisfy the following two conditions.
   - Co-occurrence of the predicate and the case $\langle v, c \rangle$ are higher than the significance level ($p \leq 0.001$; $LLR \geq 10.83$) by the log-likelihood-ratio test.
   - The case of the predicate appears at least 10% more frequently than the average of all predicates.

We constructed two OCI dictionaries. The Blog dictionary contains about 480k predicates from one year of blogs (about 2.3G sentences,). The News dictionary contains about 200k predicates from 12 years of newspaper articles (about 7.7M sentences). The coverage of predicates in the training set of the Dialogue Corpus was 98.5% by the Blog dictionary and 96.4% by the News dictionary.

5.2.2 Dependency Language Models

Dependency language models (LMs) represent semantic/pragmatic collocations among predicate v, case c, and noun phrase n. The generation probabilities of v, c, and n are computed by n-gram models. More concretely, the following real values are computed. The purpose of the biases (probabilities involved <unk>) is to correct the values to be positive.

- $\log P(n|c, v) - \log P(\texttt{<unk>}|c, v)$
- $\log P(v|c, n) - \log P(v|c, \texttt{<unk>})$
- $\log P(c|n) - \log P(c|\texttt{<unk>})$

Each dependency LM is constructed from the tuples of $\langle v, c, n \rangle$ extracted in Section 5.2.1 using the SRILM (Stolcke et al., 2011). Note that since the obligatory case information corresponds to the generation probability of the case ($P(c|v)$), we exclude it from the dependency LMs.

Similar to the OCI dictionaries, we constructed two sets of dependency language models from the Blog and the News sentences. The coverage of triples $\langle v, c, n \rangle$ appeared in the training set of the Dialogue Corpus was 76.4% by the Blog LMs and 38.3% by the News LMs. The Blog LMs cover the Dialogue Corpus more comprehensively than the News LMs.

6 Experiments

We evaluate the accuracies of the proposed PASA on the Dialogue Corpus (Table 1) from the perspectives of parameter adaptation and the effect of the automatically acquired knowledge. The evaluation metric is F-measure of each case (includes exophora identification).

Case	Type	# of Args.	a) Adaptation OCI:Blog LMs:Blog	b) NAIST♡ OCI:Blog LMs:Blog	c) Dialogue♢ OCI:Blog LMs:Blog	d) Adaptation OCI:News♠ LMs:Blog	e) Adaptation OCI:Blog LMs:News♣

Table 4: F-measures among Methods/OCI dictionary/Dependency LMs on Dialogue Test Set
The bold values denote the highest F-measures among all methods. The marks ♡, ♢, ♠, ♣ denote significantly better methods by comparing a) with b), c), d), and e), respectively. We used the bootstrap resampling method (1,000 iterations) as the significance test, in which the significance level was 0.05.

6.1 Experiment 1: Effect of Parameter Adaptation

We compared three methods in order to evaluate parameter adaptation: a) The feature augmentation is applied to the training (Adaptation). b) Only the NAIST Corpus is used for training (NAIST Training). c) Only the Dialogue Corpus is used (Dialogue Training). The NAIST Training corresponds to a conventional PASA for newspaper articles. The results on the Dialogue test set are shown in the 4th, 5th, and 6th columns in Table 4.

First, comparing methods a) Adaptation and b) NAIST training, Adaptation was better than the NAIST training for most types (The ♡ mark denotes 'significantly better'). In particular, the total F-measures of all cases were significantly better than NAIST training. Focusing on the types of arguments, the most characteristic results were exophoras of the first/second persons (exo1 and exo2) of the nominative case. These two types dominate of the nominative case (about 28%), and exo1 (70.2%) and exo2 (46.8%) became analyzable. Other types such as the Zero-Inter and the exog of the accusative and dative cases, which could not be analyzed by NAIST training, became analyzable.

Comparing methods a) Adaptation and c) Dialogue training (c.f., ♢), the F-measures of Dialogue training approached those of Adaptation even though the size of the Dialogue Corpus was small. Only the F-measure of the dative case of Adaptation was significantly better than Dialogue training in total. This does not imply that the corpus size is sufficient. Rather, we suppose that the Adaptation strategy could not adequately utilize the advantages of the NAIST Corpus. Adding more dialogue data would further improve the accuracies on the Dialogue test set.

6.2 Experiment 2: Differences among Automatically Acquired Knowledge

The columns a), d), and e) in Table 4 show the results for the proposed method (Adaptation). Note that the combination of the OCI dictionary and the dependency language models were changed to a) ⟨Blog, Blog⟩, d) ⟨News, Blog⟩, and e) ⟨Blog, News⟩.

When the OCI dictionary was changed from a) Blog to d) News (c.f., ♠), there were no significant differences in almost all types except for the Zero-Intra of the accusative case. We suppose that this

is because the coverage of the Blog and News dictionaries were almost the same, and obligatory cases of predicates are general information regardless of the domain.

On the contrary, when the dependency LMs were changed from a) Blog to e) News (c.f., ♣), the F-measures of some types significantly dropped, especially the `Zero-Intra` and `Zero-Inter` types, which are strongly influenced by semantic relation. For example, the `Zero-Inter` type of the accusative case was changed from 30.4% to 24.3%, and the F-measure consequently decreased by 3.0 points in total in the accusative case. Zero-anaphora resolution cannot rely on syntax, and the dependency LMs that measure semantic collocation become relatively important. The Blog LMs yielded greater coverage than the News LMs in this experiment. We can conclude that high-coverage LMs are better for improving the zero-anaphora resolution.

7 Conclusion

This paper presented predicate-argument structure analysis with zero-anaphora resolution for dialogues. We regarded this task as a kind of domain adaptation from newspaper articles, which are conventionally studied, to dialogues. The model parameters were adapted to the dialogues by using a domain adaptation technique. In order to address the out-of-vocabulary issue, the obligatory case information and the dependency language models were constructed from large text corpora and applied to the selectors.

As a result, arguments that could not be analyzed by PASA for newspaper articles (e.g., zero-pronouns of the first and second persons in the nominative case) became analyzable by adding only a small number of dialogues. The parameter adaptation achieved some improvement. Moreover, we confirmed that high-coverage dependency LMs contribute to improving zero-anaphora resolution and the overall accuracy.

Although we focused on parameter distribution and out-of-vocabulary in this paper, there are the other differences between dialogues and newspaper articles. For example, we did not discuss the exchange of turns, which is a special phenomenon of dialogues. To consider further phenomena is our future work. We are also evaluating the effectiveness of our PASA by incorporating it into a dialogue system (Higashinaka et al., 2014).

Abstract

In this paper, we propose an approach to automatically learning feature embeddings to address the feature sparseness problem for dependency parsing. Inspired by word embeddings, feature embeddings are distributed representations of features that are learned from large amounts of auto-parsed data. Our target is to learn feature embeddings that can not only make full use of well-established hand-designed features but also benefit from the hidden-class representations of features. Based on feature embeddings, we present a set of new features for graph-based dependency parsing models. Experiments on the standard Chinese and English data sets show that the new parser achieves significant performance improvements over a strong baseline.

1 Introduction

Discriminative models have become the dominant approach for dependency parsing (Nivre et al., 2007; Zhang and Clark, 2008; Hatori et al., 2011). State-of-the-art accuracies have been achieved by the use of rich features in discriminative models (Carreras, 2007; Koo and Collins, 2010; Bohnet, 2010; Zhang and Nivre, 2011). While lexicalized features extracted from non-local contexts enhance the discriminative power of parsers, they are relatively sparse. Given a limited set of training data (typically less than 50k sentences for dependency parsing), the chance of a feature occurring in the training data but not in the test data can be high.

Another limitation on features is that many are typically derived by (manual) combination of atomic features. For example, given the head word (w_h) and part-of-speech tag (p_h), dependent word (w_d) and part-of-speech tag (p_d), and the label (l) of a dependency arc, state-of-the-art dependency parsers can have the combined features: $[w_h; p_h]$, $[w_h; p_h; w_d; p_d]$, $[w_h; p_h; w_d]$, and so on, in addition to the atomic features: $[w_h]$, $[p_h]$, etc. Such combination is necessary for high accuracies because the dominant approach uses linear models, which can not capture complex correlations between atomic features.

We tackle the above issues by borrowing solutions from word representations, which have been intensely studied in the NLP community (Turian et al., 2010). In particular, distributed representations of words have been used for many NLP problems, which represent a word by information from the words it frequently co-occurs with (Lin, 1997; Curran, 2005; Collobert et al., 2011; Bengio, 2009; Mikolov et al., 2013b). The representation can be learned from large amounts of raw sentences, and hence used to reduce OOV rates in test data. In addition, since the representation of each word carries information about its context words, it can also be used to calculate word similarity (Mikolov et al., 2013a), or used as additional semantic features (Koo et al., 2008).

In this paper, we show that a distributed representation can be learned for features also. Learned from large amount of automatically parsed data, the representation of each feature can be defined on the

features it frequently co-occurs with. Similar to words, the feature representation can be used to reduce the rate of unseen features in test data, and to capture inherent correlations between features. Borrowing terminologies from word embeddings, we call the feature representation **feature embeddings**.

Compared with the task of learning word embeddings, the task of learning feature embeddings is more difficult because the size of features is much larger than the vocabulary size and tree structures are more complex than word sequences. This requires us to find an effective embedding format and an efficient inference algorithm. Traditional LSA and RNN (Collobert et al., 2011; Bengio, 2009) models turn out to be very slow for feature embeddings. Recently, Mikolov et al. (2013a) and Mikolov et al. (2013b) introduce efficient models to learn high-quality word embeddings from extremely large amounts of raw text, which offer a possible solution to the efficiency issue of learning feature embeddings. We adapt their approach for learning feature embeddings, showing how an unordered feature context can be used to learn the representation of a set of complex features. Using this method, a large number of embeddings are trained from automatically parsed texts, based on which a set of new features are designed and incorporated into a graph-based parsing model (McDonald and Nivre, 2007).

We conduct experiments on the standard data sets of the Penn English Treebank and the Chinese Treebank V5.1. The results indicate that our proposed approach significantly improves parsing accuracies.

2 Background

In this section, we introduce the background of dependency parsing and build a baseline parser based on the graph-based parsing model proposed by McDonald et al. (2005).

2.1 Dependency parsing

Given an input sentence $x = (w_0, w_1, ..., w_i, ..., w_m)$, where w_0 is ROOT and w_i ($i \neq 0$) refers to a word, the task of dependency parsing is to find y^* which has the highest score for x,

$$y^* = \arg\max_{y \in Y(x)} score(x, y)$$

where $Y(x)$ is the set of all the valid dependency trees for x. There are two major models (Nivre and McDonald, 2008): the transition-based model and graph-based model, which showed comparable accuracies for a wide range of languages (Nivre et al., 2007; Bohnet, 2010; Zhang and Nivre, 2011; Bohnet and Nivre, 2012). We apply feature embeddings to a graph-based model in this paper.

2.2 Graph-based parsing model

We use an ordered pair $(w_i, w_j) \in y$ to define a dependency relation in tree y from word w_i to word w_j (w_i is the head and w_j is the dependent), and G_x to define a graph that consists of a set of nodes $V_x = \{w_0, w_1, ..., w_i, ..., w_m\}$ and a set of arcs (edges) $E_x = \{(w_i, w_j) | i \neq j, w_i \in V_x, w_j \in (V_x - \{w_0\})\}$. The parsing model of McDonald et al. (2005) searches for the maximum spanning tree (MST) in G_x.

We denote $Y(G_x)$ as the set of all the subgraphs of G_x that are valid spanning trees (McDonald and Nivre, 2007). The score of a dependency tree $y \in Y(G_x)$ is the sum of the scores of its subgraphs,

$$score(x, y) = \sum_{g \in y} score(x, g) = \sum_{g \in y} \mathbf{f}(x, g) \cdot \mathbf{w} \quad (1)$$

where g is a spanning subgraph of y, which can be a single arc or adjacent arcs, $\mathbf{f}(x, g)$ is a high-dimensional feature vector based on features defined over g and x, and $\mathbf{w}$ refers to the weights for the features. In this paper we assume that a dependency tree is a spanning projective tree.

2.3 Baseline parser

We use the decoding algorithm proposed by Carreras (2007) and use the Margin Infused Relaxed Algorithm (MIRA) (Crammer and Singer, 2003; McDonald et al., 2005) to train feature weights $\mathbf{w}$. We use the feature templates of Bohnet (2010) as our base feature templates, which produces state-of-the-art accuracies. We further extend the features by introducing more lexical features to the base features. The

Table 1: Base feature templates.

base feature templates are listed in Table 1, where h and d refer to the head, the dependent, respectively, c refers to d's sibling or child, b refers to the word between h and d, $+1$ (-1) refers to the next (previous) word, w and p refer to the surface word and part-of-speech tag, respectively, $[wp]$ refers to the surface word or part-of-speech tag, $d(h, d)$ is the direction of the dependency relation between h and d, and $d(h, d, c)$ is the directions of the relation among h, d, and c.

We train a parser with the base features and use it as the Baseline parser. Defining $\mathbf{f}_b(x, g)$ as the base features and $\mathbf{w}_b$ as the corresponding weights, the scoring function becomes,

$$score(x, g) = \mathbf{f}_b(x, g) \cdot \mathbf{w}_b \tag{2}$$

3 Feature Embeddings

Our goal is to reduce the sparseness of rich features by learning a distributed representation of features, which is dense and low dimensional. We call the distributed feature representation **feature embeddings**. In the representation, each dimension represents a hidden-class of the features and is expected to capture a type of similarities or share properties among the features.

The key to learn embeddings is making use of information from a local context, and to this end various methods have been proposed for learning word embeddings. Lin (1997) and Curran (2005) use the count of words in a surrounding word window to represent distributed meaning of words. Brown et al. (1992) uses bigrams to cluster words hierarchically. These methods have been shown effective on words. However, the number of features is much larger than the vocabulary size, which makes it infeasible to apply them on features. Another line of research induce word embeddings using neural language models (Bengio, 2008). However, the training speed of neural language models is too slow for the high dimensionality of features. Mikolov et al. (2013b) and Mikolov et al. (2013a) introduce efficient methods to directly learn high-quality word embeddings from large amounts of unstructured raw text. Since the methods do not involve dense matrix multiplications, the training speed is extremely fast.

We adapt the models of Mikolov et al. (2013b) and Mikolov et al. (2013a) for learning feature embeddings from large amounts of automatically parsed dependency trees. Since feature embeddings have a high computational cost, we also use Negative sampling technique in the learning stage (Mikolov et al., 2013b). Different from word embeddings, the input of our approach is features rather than words, and the feature representations are generated from tree structures instead of word sequences. Consequently,

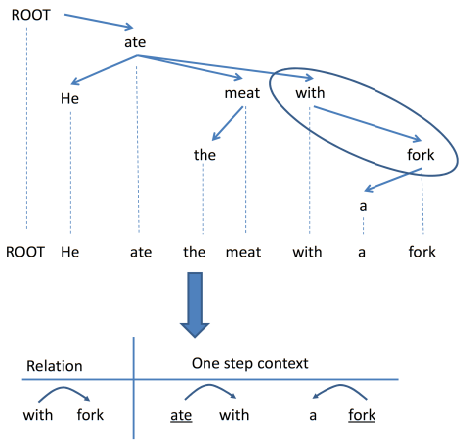

Figure 1: An example of one-step context.

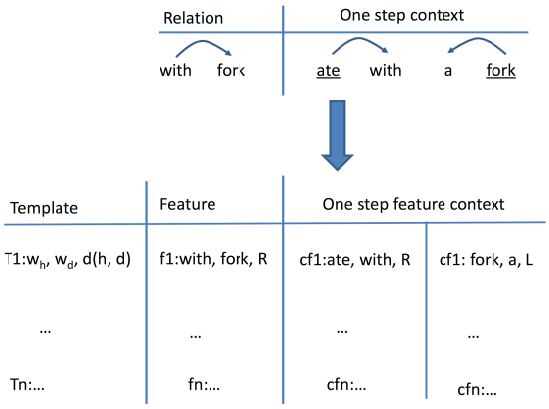

Figure 2: One-step surrounding features.

we give a definition of unordered feature contexts and adapt the algorithms of Mikolov et al. (2013b) for feature embeddings.

3.1 Surrounding feature context

The most important difference between features and words is the contextual structure. Given a sentence $x = w_1, w_2, ..., w_n$ and its dependency tree y, we define the M-step context as a set of relations reachable within M steps from the current relation. Here one step refers to one dependency arc. For instance, the one-step context includes the surrounding relations that can be reached in one arc, as shown in Figure 1. In the figure, for the relation between "with" and "fork", the relation between "ate" and "with" is in the one-step context, while the relation between "He" and "ate" is in the two-step context because it can be reached via the arc between "ate" and "with". A larger M results in more contextual features and thus might lead to a more accurate embedding, but at the expense of training speed.

Based on the M-step context, we use surrounding features to represent the features on the current dependency relations. The surrounding features are defined on the relations in the M-step context. Take 1-step context as an example. Figure 2 shows the representations for the current relation between "with" and "fork" in Figure 1. Given the current relation and the relations in its one-step context, we generate the features based on the base feature templates. In Figure 2 the current feature "f1:with, fork, R" can be represented by the surrounding features "cf1:ate, with, R" and "cf1: fork, a, L" based on the template "T1:w_h, w_d, d(h, d)". Similarly, all the features on the current relation are represented by the features on the relations in the one-step context. To reduce computational cost, we generate for every feature its contextual features based on the same feature template. As a result, the embeddings for each feature template is trained separately. In the experiments, we use one-step context for learning feature embeddings.

3.2 Feature Embedding model

We adapt the models of Mikolov et al. (2013b) and Mikolov et al. (2013a) to infer feature embeddings (FE). Based on the representation of surrounding context, the input to the learning models is a set of features and the output is feature embeddings as shown in Figure 3. For each dependency tree in large amounts of auto-parsed data, we generate the base features and associate them with their surrounding contextual features. Then all the base features are put into a set, which is used as the training instances for learning models.

In the embedding model, we use the features on the current dependency arc to predict the surrounding features, as shown in Figure 4. Given sentences and their corresponding dependency trees Y, the objective of the model is to maximize the conditional log-likelihood of context features,

$$\sum_{y \in Y} \sum_{f \in F_y} \sum_{cf \in CF_f} \log(p(cf|f)) \quad (3)$$

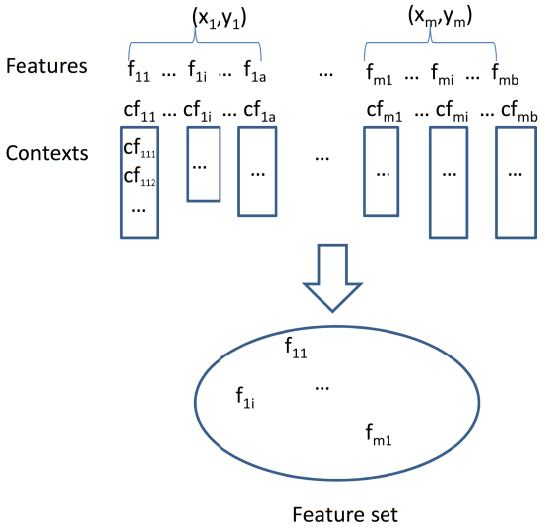

Figure 3: Input feature set.

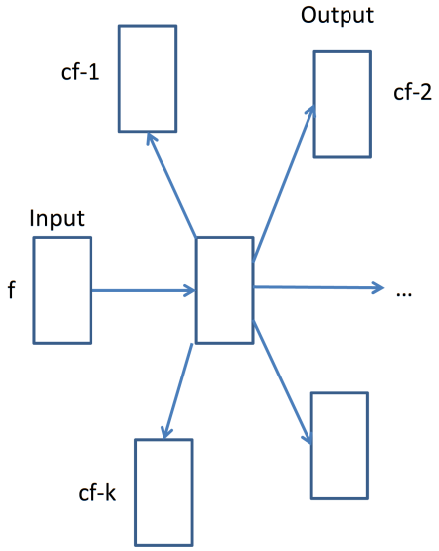

Figure 4: The feature embedding model.

where F_y is a set of features generated from tree y, CF_f is the set of surrounding features in the M-step context of feature f. $p(cf|f)$ can be computed by using the softmax function (Mikolov et al., 2013b), for which the input is f and the output is cf,

$$p(cf|f) = \frac{exp({v'_{cf}}^{\mathrm{T}} v_f)}{\sum_{i=1}^{F} exp({v'_{cf_i}}^{\mathrm{T}} v_f)} \tag{4}$$

where v_f and v'_f are the input and output vector representations of f, and F is the number of features in the feature table. The formulation is impractical for large data because the number of features is large (in the millions) and the computational cost is too high.

To compute the probabilities efficiently, we use the Negative sampling method proposed by Mikolov et al. (2013b), which approximates the probability by the correct example and K negative samples for each instance. The formulation to compute $log(p(cf|f))$ is,

$$\log \sigma({v'_{cf}}^{\mathrm{T}} v_f) + \sum_{k=1}^{K} \mathrm{E}_{cf_k \sim P(cf)} [\log \sigma(-{v'_{cf_k}}^{\mathrm{T}} v_f)] \tag{5}$$

where $\sigma(z) = 1/(1 + exp(-z))$ and $P(f)$ is the noise distribution on the data. Following the setting of Mikolov et al. (2013b), we set K to 5 in our experiments.

We predict the set of features one by one. Stochastic gradient ascent is used to perform the following iterative update after predicting the i^{th} feature,

$$\theta \leftarrow \theta + \alpha(\frac{\partial \sum_{cf} log(p(cf_i|f)}{\partial \theta}) \tag{6}$$

where α is the learning rate and θ includes the parameters of the model and the vector representations of features. The initial value of α is 0.025. If the log-likelihood does not improve significantly after one update, the rate is halved (Mikolov et al., 2009).

3.3 Distributed representation

Based on the proposed surrounding context, we use the feature embedding model with the help of the Negative sampling method to learn feature embeddings. For each base template T_i, the distributed representations are stored in a matrix $\mathcal{M}_i \in \mathbb{R}^{d \times |\mathcal{F}_i|}$, where d is the number of dimensions (to be chosen in the experiments) and $|\mathcal{F}_i|$ is the size of the features $\mathcal{F}_i$ for T_i. For each feature $f \in \mathcal{F}_i$, its vector is $v_f = [v_1, ..., v_d]$.

$< j : T(f) \cdot \Phi(v_j) >$ for $j \in [1, d]$
$< j : T(f) \cdot \Phi(v_j), w_h >$ for $j \in [1, d]$

Table 2: FE-based templates.

4 Parsing with feature embeddings

In this section, we discuss how to apply the feature embeddings to dependency parsing.

4.1 FE-based feature templates

The base parsing model contains only binary features, while the values in the feature embedding representation are real numbers that are not in a bounded range. If the range of the values is too large, they will exert much more influence than the binary features. To solve this problem, we define a function $\Phi(v_i)$ (details are given in Section 4.3) to convert real values to discrete values. The vector $v_f = [v_1, ..., v_d]$ is converted into $v_f^N = [\Phi(v_1), ..., \Phi(v_d)]$.

We define a set of new feature templates for the parsing models, capturing feature embedding information. Table 2 shows the new templates, where $T(f)$ refers to the base template type of feature f. We remove any new feature related to the surface form of the head if the word is not one of the Top-N most frequent words in the training data. We used N=1000 for the experiments, which reduces the size of the feature sets.

4.2 FE parser

We combine the base features with the new features by a new scoring function,

$$score(x, g) = \mathbf{f}_b(x, g) \cdot \mathbf{w}_b + \mathbf{f}_e(x, g) \cdot \mathbf{w}_e \tag{7}$$

where $\mathbf{f}_b(x, g)$ refers to the base features, $\mathbf{f}_e(x, g)$ refers to the FE-based features, and $\mathbf{w}_b$ and $\mathbf{w}_e$ are their corresponding weights, respectively. The feature weights are learned during training using MIRA (Crammer and Singer, 2003; McDonald et al., 2005).

We use the same decoding algorithm in the new parser as in the Baseline parser. The new parser is referred to as the FE Parser.

4.3 Discretization functions

There are various functions to convert the real values in the vectors into discrete values. Here, we use a simple method. First, for the i^{th} base template, the values in the j^{th} dimension are sorted in decreasing order L_{ij}. We divide the list into two parts for positive (L_{ij+}) and negative (L_{ij-}), respectively, and define two functions. The first function is,

$$\Phi_1(v_j) = \begin{cases} +B1 & \text{if } v_j \text{ is in top 50\% in } L_{ij+} \\ +B2 & \text{if } v_j \text{ is in bottom 50\% in } L_{ij+} \\ -B1 & \text{if } v_j \text{ is in top 50\% in } L_{ij-} \\ -B2 & \text{if } v_j \text{ is in bottom 50\% in } L_{ij-} \end{cases}$$

The second function is,

$$\Phi_2(v_j) = \begin{cases} +B1 & \text{if } v_j \text{ is in top 50\% in } L_{ij+} \\ -B2 & \text{if } v_j \text{ is in bottom 50\% in } L_{ij-} \end{cases}$$

In Φ_2, we only consider the values ("+B1" and "-B2"), which have strong values (positive or negative) on each dimension, and omit the values which are close to zero. We refer the systems with Φ_1 as M1 and the ones with Φ_2 as M2. We also tried the original continuous values and the scaled values as used by Turian et al. (2010), but the results were negative.

5 Experiments

We conducted experiments on English and Chinese data, respectively.

Gigaword Xinhua	272.3M	11.7M

Table 4: Information of raw data.

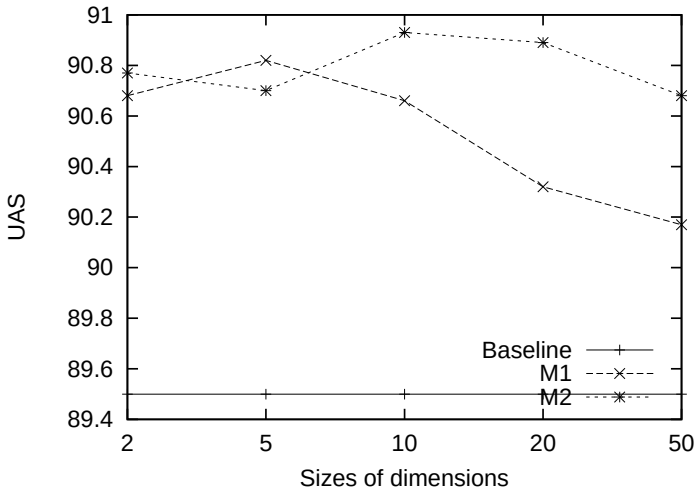

Figure 5: Effect of different sizes of embeddings on the development data.

5.1 Data sets

We used the Penn Treebank (PTB) to generate the English data sets, and the Chinese Treebank version 5.1 (CTB5) to generate the Chinese data sets. "Penn2Malt"[1] was used to convert the data into dependency structures with the English head rules of Yamada and Matsumoto (2003) and the Chinese head rules of Zhang and Clark (2008). The details of data splits are listed in Table 3, where the data partition of Chinese were chosen to match previous work (Duan et al., 2007; Li et al., 2011b; Hatori et al., 2011).

Following the work of Koo et al. (2008), we used a tagger trained on the training data to provide part-of-speech (POS) tags for the development and test sets, and used 10-way jackknifing to generate part-of-speech tags for the training set. For English we used the MXPOST (Ratnaparkhi, 1996) tagger and for Chinese we used a CRF-based tagger with the feature templates defined in Zhang and Clark (2008). We used gold-standard segmentation in the CTB5 experiments. The accuracies of part-of-speech tagging are 97.32% for English and 93.61% for Chinese on the test sets, respectively.

To obtain feature contexts, we processed raw data to obtain dependency trees. For English, we used the BLLIP WSJ Corpus Release 1.[2] For Chinese, we used the Xinhua portion of Chinese Gigaword[3] Version 2.0 (LDC2009T14). The statistical information of raw data sets is listed in Table 4. The MXPOST part-of-speech tagger and the Baseline dependency parser trained on the training data were used to process the sentences of the BLLIP WSJ corpus. For Chinese, we need to perform word segmentation and part-of-speech tagging before parsing. The MMA system (Kruengkrai et al., 2009) trained on the training data was used to perform word segmentation and tagging, and the Baseline parser was used to parse the sentences in the Gigaword corpus.

We report the parser quality by the unlabeled attachment score (UAS), i.e., the percentage of tokens (excluding all punctuation tokens) with the correct HEAD. We also report the scores on complete dependency tree matches (COMP).

5.2 Development experiments

In this section, we use the English development data to investigate the effects of different vector sizes of feature embeddings, and compare the systems with the discretization functions Φ_1 (M1) and Φ_2 (M2) (defined in Section 4.3), respectively. To reduce the training time, we used 10% of the labeled training data to train the parsing models.

Turian et al. (2010) reported that the optimal size of word embedding dimensions was task-specific for NLP tasks. Here, we investigated the effect of different sizes of embedding dimensions on dependency parsing. Figure 5 shows the effect on UAS scores as we varied the vector sizes. The systems with FE-based features always outperformed the Baseline. The curve of M2 was almost flat and we found that M1 performed worse as the sizes increased. Overall, M2 performed better than M1. For M2, 10-dimensional embeddings achieved the highest score among all the systems. Based on the above observations, we chose the following settings for further evaluations: 10-dimensional embeddings for M2.

5.3 Final results on English data

We trained the M2 model on the full training data and evaluated it on the English testing data. The results are shown in Table 5. The parser using the FE-based features outperformed the Baseline. We obtained absolute improvements of 0.96 UAS points. As for the COMP scores, M2 achieved absolute improvement of 2.74 over the Baseline. The improvements were significant in McNemar's Test ($p < 10^{-7}$) (Nivre et al., 2004).

We listed the performance of the related systems in Table 5. We also added the cluster-based features of Koo et al. (2008) to our baseline system listed as "Baseline+BrownClu" in Table 5. From the table, we found that our FE parsers obtained comparable accuracies with the previous state-of-the-art systems. Suzuki et al. (2011) reported the best result by combining their method with the method of Koo et al. (2008). We believe that the performance of our parser can be further enhanced by integrating their methods.

5.4 Final results on Chinese data

We also evaluated the systems on the testing data for Chinese. The results are shown in Table 6. Similar to the results on English, the parser using the FE-based features outperformed the Baseline. The improvements were significant in McNemar's Test ($p < 10^{-8}$) (Nivre et al., 2004).

We listed the performance of the related systems[4] on Chinese in Table 6. From the table, we found that the scores of our FE parser was higher than most of the related systems and comparable with the results of Chen2013, which was the best reported scores so far.

[4]We did not include the result (83.96) of Wu et al. (2013) because their part-of-speech tagging accuracy is 97.7%, much higher than ours and other work. Their tagger includes rich external resources.

6 Related work

Learning feature embeddings are related to two lines of research: deep learning models for NLP, and semi-supervised dependency parsing.

Recent studies used deep learning models in a variety of NLP tasks. Turian et al. (2010) applied word embeddings to chunking and Named Entity Recognition (NER). Collobert et al. (2011) designed a unified neural network to learn distributed representations that were useful for part-of-speech tagging, chunking, NER, and semantic role labeling. They tried to avoid task-specific feature engineering. Socher et al. (2013) proposed a Compositional Vector Grammar, which combined PCFGs with distributed word representations. Zheng et al. (2013) investigated Chinese character embeddings for Chinese word segmentation and part-of-speech tagging. Wu et al. (2013) directly applied word embeddings to Chinese dependency parsing. In most cases, words or characters were the inputs to the learning systems and word/character embeddings were used for the tasks. Our work is different in that we explore distributed representations at the feature level and we can make full use of well-established hand-designed features.

We use large amounts of raw data to infer feature embeddings. There are several previous studies relevant to using raw data for dependency parsing. Koo et al. (2008) used the Brown algorithm to learn word clusters from a large amount of unannotated data and defined a set of word cluster-based features for dependency parsing models. Suzuki et al. (2009) adapted a Semi-supervised Structured Conditional Model (SS-SCM) to dependency parsing. Suzuki et al. (2011) reported the best results so far on the standard test sets of PTB using a condensed feature representation combined with the word cluster-based features of Koo et al. (2008). Chen et al. (2013) mapped the base features into predefined types using the information of frequencies counted in large amounts of auto-parsed data. The work of Suzuki et al. (2011) and Chen et al. (2013) were to perform feature clustering. Ando and Zhang (2005) presented a semi-supervised learning algorithm named alternating structure optimization for text chunking. They used a large projection matrix to map sparse base features into a small number of high level features over a large number of auxiliary problems. One of the advantages of our approach is that it is simpler and more general than that of Ando and Zhang (2005). Our approach can easily be applied to other tasks by defining new feature contexts.

7 Conclusion

In this paper, we have presented an approach to learning feature embeddings for dependency parsing from large amounts of raw data. Based on the feature embeddings, we represented a set of new features, which was used with the base features in a graph-based model. When tested on both English and Chinese, our method significantly improved the performance over the baselines and provided comparable accuracy with the best systems in the literature.

Abstract

A large number of online health communities exist today, helping millions of people with social support during difficult phases of their lives when they suffer from serious diseases. Interactions between members in these communities contain discussions on practical problems faced by people during their illness such as depression, side-effects of medications, etc and answers to those problems provided by other members. Analyzing these interactions can be helpful in getting crucial information about the community such as dominant health issues, identifying sentimental effects of interactions on individual members and identifying influential members. In this paper, we analyze user messages of an online cancer support community, Cancer Survivors Network (CSN), to identity the two types of social support present in them: *emotional* support and *informational* support. We model the task as a binary classification problem. We use several generic and novel domain-specific features. Experimental results show that we achieve high classification performance. We, then, use the classifier to predict the type of support in CSN messages and analyze the posting behaviors of regular members and influential members in CSN in terms of the type of support they provide in their messages. We find that influential members generally provide more emotional support as compared to regular members in CSN.

1 Introduction

Increasingly more people turn to online health communities (OHCs) to seek social support during their illnesses (LaCoursiere, 2001; Beaudoin and Tao, 2007). When people suffering from a serious disease such as cancer or AIDS *interact* with other people who have experienced similar medical conditions, they feel emotionally supported. In addition, through these interactions, people can obtain important information about the disease, e.g., about various medications, symptoms, and side-effects. Although authoritative health-related web sites contain the information they search for, obtaining this information directly from people in OHCs adds substantial value to it. Previous studies showed that obtaining social support in OHCs can help people feel better (Dunkel-Schetter, 1984; Maloney-Krichmar and Preece, 2005; Beaudoin and Tao, 2007; Vilhauer, 2009; Qiu et al., 2011).

As a result of online interactions in OHCs, a huge volume of user-generated content exists today on various issues/problems related to specific diseases. This content comprises of important information such as people's experiences with diseases, recommendations and feedbacks about certain medications or medical procedures, and emotional support in the form of encouragement, sympathy, and success stories. Mining this content can prove to be very useful in obtaining crucial insights into community dynamics such as identifying dominant health issues or the effects of social support on community members, identifying influential members, as well as designing smart information retrieval systems for users.

In this study, we focus on an online cancer support community, the Cancer Survivors Network[1] (CSN) of the American Cancer Society. We analyze user messages of CSN to identify the two most important types of social support present in them: informational and emotional support (Davison et al., 2000). Emotional support comprises of seeking or providing caring/concern, understanding, empathy, sympathy,

[1] http://www.csn.cancer.org

Proceedings of COLING 2014, the 25th International Conference on Computational Linguistics: Technical Papers, pages 827–836, Dublin, Ireland, August 23-29 2014.

encouragement, affirmation and validation. In contrast, informational support comprises of seeking or providing knowledge such as advice, referrals, and suggestions (Bambina, 2007). We further explore the relation between the type of support present in messages and users' influence in the community.

Identifying the type of support in user messages in an OHC can potentially be used in many important applications including the following:

1. **Identify influential members in OHCs**: Every community has a set of members who influence (a much larger set of) other members in the community. These members are called leaders or influential members. The attributes of a leader in a community depends upon the community's nature (QA, Twitter, OHC, forum, blogsite, etc.). For example, high activity may not be an indicator of high influence in the blogosphere (Agarwal et al., 2008) and high popularity does not necessarily imply influence in Twitter (Romero et al., 2011). In OHCs, bringing positivity in the community and answering members' concerns effectively by posting messages that contain certain type of support (informational or emotional) may be an indicator of influence.
2. **Improve information search in OHCs**: Interactions in OHCs contain valuable information in the form of people's experiences, advice, referrals, pertaining to diseases, medications, side-effects, etc. Users embed this information often in messages containing other types of support, of which emotional support constitutes a major part. To efficiently search OHCs for this information, it must be separated from emotional support. Hence, identifying the type of support in user messages can help improve search and retrieval in OHCs.
3. **Understand social relationships in OHCs**: Emotional support is one of the dimensions of social tie strength between members in a social network (Gilbert and Karahalios, 2009). Previous studies have shown that members receiving emotional support in OHCs are more likely to remain in the community for a longer period of time as compared to members receiving informational support (Wang et al., 2012). Identifying emotional and informational support can help understand the social dynamics of an OHC. For example, it would be interesting to see if there is a correlation between the social tie strength of members and the type of support present in their interactions.

Hi X, I had a bilateral with radical on the right and prophylactic on the left. I think all you can do is gentle exercises to strengthen your back (yoga). There are also herbal painkillers that work well too. I just tolerate the pain and consider it a signal of my new limit and go down to rest. You want to talk, anytime! We are all there with you.

Table 1: A user message. Sentences in grey and black fonts are informational and emotional, respectively.

We model the task of identifying the two types of supports as a binary classification problem. Specifically, we classify each sentence in a user message as containing either emotional or informational support [2]. Table 1 shows a user message containing emotional and informational supports. We use several features computed from sentences of messages such as unigrams, part-of-speech tags, lexicon-based features and word patterns for the classification. After building the classification model, we predict the amounts of the two supports in all CSN messages and explore the following research question:

RQ: Do influential members of CSN post one of the two types of supports significantly more compared to regular members?

We analyze messages posted by regular members and messages posted by certain members, identified as *influential* by the CSN community managers and two staff members who monitor the contents of the CSN on a full time basis, for the type of support (informational and emotional) present in them. Using the classification model, we calculate the amounts of the two supports posted by influential members and regular members and compare them across the two populations (For details, see Section 3.1).

Previous works on analyzing social support in OHCs have mainly been in the field of social science (Eriksson and Lauri, 2000; Rodgers and Chen, 2005; Høybye et al., 2005; Pfeil and Zaphiris, 2007; Beaudoin and Tao, 2007; Buis, 2008; Han et al., 2011). These works used manual techniques for identifying the type of support in user messages and hence, are limited to a small number of messages as

[2] Although a sentence may belong to both the classes, we did not find such cases in our data.

compared to the real world data. In contrast, the current work builds machine learning classifiers that can automatically predict the type of support in messages. Also, to the best of our knowledge, there have been no reported works on analyzing the relationship between users' influence and the type of support present in their messages in OHCs. Next, we review related works.

2 Related Work

Many studies in social science have focused on analyzing social support in user messages of OHCs (Coursaris and Liu, 2009; Han et al., 2011; Pfeil and Zaphiris, 2007), finding impacts of social support on users (Eriksson and Lauri, 2000; Rodgers and Chen, 2005; Buis, 2008; Høybye et al., 2005), identifying information needs of users in OHCs (Rozmovits and Ziebland, 2004), etc. Among various types of social supports, emotional support and informational support have received major attention. In this section, we first review social science works on analyzing online social support, discuss works on identifying the type of social support, and, finally, compare the current problem with **subjectivity analysis**.

LaCoursiere (2001) presented an integrated theory conceptualizing online social support. She defined three channels through which online social support occurs: 1) *perceptual*: individual feeling the need of social support arising due to emotional states such as stress, etc, 2) *cognitive*: individual seeking information about certain medical entities such as procedures, medication, etc, 3) *transactional*: individual evaluating the received social support. In our case, these channels correspond to emotional support and informational support. Høybye et al. (2005) conducted a qualitative study to analyze the effects of online social support by interviewing women with breast cancer who used an online support group and found that the women were empowered by the exchanges of knowledge and experience within the online support group. Rodgers et al. (2005) conducted a longitudinal content analysis of messages of participants in a breast cancer discussion board to analyze changes in affect/sentiment of the participants towards breast cancer and found that a positive shift in sentiment occurred over the period of time. Pfeil and Zaphiris (2007) analyzed messages of SeniorNet forum to extract language patterns used to provide empathic support. Budak and Agrawal (2013) interviewed participants of group chats in Twitter and found that informational support is more important than emotional support in educational Twitter chats.

All the above works used manual methods of data preparation such as interviews with users of support groups, manual coding of messages to identify emotional and informational support and performed further qualitative and/or quantitative analyses based on that data. Since, manual methods have serious limitations in terms of scalability, the number of messages used for analysis in these studies is too small compared to the real world data which contains millions of messages. To address these limitations, we develop automatic methods for identifying the type of support in user messages in an online cancer support group using machine learning. We develop a classifier that learns on a smaller set of manually labeled messages and makes predictions on a much larger set of messages with a very high accuracy.

A recent work by Wang et al. (2012) is close to our work. They used a linear regression model to predict the amount of informational and emotional supports present in messages of a cancer forum. For a test message, the trained model predicts the amount of the two supports on a scale of $1 - 7$. Since a message may contain both types of support, it is generally difficult for human annotators to assess the amount of each support in an entire message on a particular scale for model training. In contrast, we label each sentence as belonging to either informational or emotional support class and identify the two types of support at sentence level in messages (using binary classification). Note that it is much easier and less ambiguous for a human annotator to identify the type of support present in a sentence (of a message) compared to giving a score to an entire message based on the amount of the two supports present in it.

Relationship with Subjectivity Analysis: Subjectivity analysis is an active area of research in computational linguistics. It essentially deals with separating subjective parts (e.g., expressing opinion, emotion, speculation and other private states of mind) from objective parts (presenting facts, verifiable information) of a text (Wiebe et al., 1999; Biyani et al., 2012a). It has been widely used in applications like opinion mining from product reviews (Liu, 2010), community question-answering (Li et al., 2008a; Stoyanov et al., 2005a; Somasundaran et al., 2007), summarization (Carenini et al., 2006; Seki et al., 2005), and finding opinionative threads in online forums (Biyani et al., 2014; Biyani et al., 2012b; Biyani et al., 2013a). Though the current work has some relation with subjectivity analysis in the sense that both are

text classification, there are important differences between the two problems. The two classes in subjectivity analysis (subjective and objective) are different from the two types of support that we identify. While emotional support is subjective in nature, informational support is not necessarily objective as it also contains opinions of users. Also, social support in OHCs encompasses several types of supports such as understanding, caring, concern, sympathy, empathy, knowledge about medications, etc. which are generally not provided by users in other sites such as product reviews, question-answering sites, etc. These differences make the two problems different in both the nature and the approaches that can be used to address them. For example, we use certain word patterns to identify sympathy and affirmation and use the presence of terms related to cancer medications, procedures and side-effects for computing features for classification. These features have not been used in subjectivity classification.

3 Problem Formulation

Online health communities provide social support to its members of which emotional and informational supports constitute a major part and have received major attention as compared to other supports such as companionship, community building, network support, etc. (Bambina, 2007; Meier et al., 2007; Himle et al., 1991; Wang et al., 2012; Pfeil and Zaphiris, 2007). We focus on the two supports and follow their definitions as given by Bambina (2007) in their study of social supports expressed in a cancer support group. They define *emotional* messages as the messages that have the following supports: caring/concern, understanding, empathy, sympathy, encouragement, affirmation and validation. *Informational support* is defined as providing advice, knowledge and referrals. Since a user message often contains a mixture of these supports, we identify the two supports at sentence level. Table 1 contains a user message with sentences marked with the type of support in them. Specifically, given a sentence s, in a user message, we want to classify it into one of the two classes: emotional support or informational support. We use machine learning methods for classification. After training the classifier, we use it to predict the type of support in the sentences of user messages in CSN and address our research question outlined in Section 1. We present the details of the features used for classification in Section 3.2.

3.1 Research Question

To address the research question **(RQ)**, we need to compute the amounts of the two supports in the messages of regular and influential members and then compare the two amounts. Let u denote a user and M be the set of messages posted by her such that $M = \{m_1, m_2, ...m_p\}$ where p is the total number of messages in the set M. For a message $m_k \in M$, we compute its *emotional index*, $e_{uk} = n_{ek}/(n_k)$ where n_{ek} and n_k are the number of sentences containing emotional support and the total number of sentences in m_k. Since a sentence can belong to either emotional support or informational support class, informational index of m_k, $i_{uk} = 1 - e_{uk}$. The overall emotional index of u (e_u) is the average of the emotional indices of her messages: $e_u = \frac{1}{p}\sum_{k=1}^{p} e_{uk}$. The informational index of u, $i_u = 1 - e_u$. Since, the informational index can be derived from emotional index, we compute only emotional indices for all regular and influential members and compare them between the two user populations (regular and influential). We compute the emotional indices of regular members, E_R, and emotional indices of influential members, E_I. We compare the means of the two populations of emotional indices (μ_{Re} and μ_{Ie}) and test the null hypothesis (H_0) and the alternate hypothesis (H_1) as follows:
H_0: The two populations have equal means, i.e., $\mu_{Re} - \mu_{Ie} = 0$.
H_1: The two populations have significantly different means , i.e., $\mu_{Re} - \mu_{Ie} \neq 0$.

For one of the population indices to be significantly more than the other, we should have the null hypothesis rejected. We use one-sided t-test to conduct hypothesis testing and report the results in Section 4.5. Next, we discuss the features used in the classification.

3.2 Features for Classification

3.2.1 Words and POS tags

Words and their part-of-speech tags capture basic lexical properties of text and have been extensively used in text classification problems such as subjectivity classification and sentiment classification (Li et al., 2008b; Yu and Hatzivassiloglou, 2003; Biyani et al., 2013b). We use frequency of words and their POS tags in a sentence as features in our classification model.

3.2.2 Lexicon-based Features

Emotional support expresses caring, concern, sympathy, and other kinds of sentimental support whereas informational support provides knowledge about cancer medications, cancer reports, referrals, and other kinds of information (Bambina, 2007). Due to this difference in the nature of these supports, a sentence expressing emotional support is likely to contain emotional words which are subjective in nature and a sentence containing informational support is likely to have cancer-related keywords such as drug names, names of cancer procedures, etc. To capture this difference, we use frequencies of subjective words and cancer-related keywords as features. Specifically, we design five features to code frequencies of weak subjective words (**numWeak**), strong subjective words (**numStrong**), cancer drugs (**numDrug**), side-effects of cancer medications (**numSide**), and cancer procedures (**numProc**) respectively in a sentence. We use the subjectivity lexicon compiled from the MPQA corpus (Stoyanov et al., 2005b) to get weak and strong subjective words. We compile lexicon of cancer drugs [3], and CSN staff members helped get a list of side-effects and cancer procedures. Some of the side-effects of cancer medications are hair loss, neuropathy, fatigue, fibrosis, etc.

3.2.3 Linguistic Features

We analyzed user messages to find patterns that are expressive of emotional and informational support. We found that members, generally, use certain word patterns to express similar feelings. For example, to provide affirmation and sympathy, people use positive verbs such as *know, feel, understand, sense, support*, etc. in patterns *<I $posVerb>* and *<I $aux $posVerb>*, where *$posVerb* is a positive verb and *$aux* is an auxiliary verb from the set {can, could, do, would, will, may}. Some people use *"We"* instead of *"I"* in their messages to provide support such as "**we understand** *what you are going through*". To take into account such cases, we use the same patterns by replacing *"I "* with *"We"*. Hence, we get four patterns for emotional support. For providing informational support, people often use patterns such as *<You $advice>*, *<I $opinion>*, *<I $aux $opinion>* to provide advice and opinions. *$advice* is an auxilliary verb from the set {should, must, need, might}, *$opinion* is an opinion verb from the set {recommend, advise, suggest, advocate, request}, and *$aux* is an auxilliary verb. People also give information about their experiences using patterns such as *<I too>*, *<I also>* and *<I $pastVerb>* to tell their own experiences related to similar problems as that of the support seeker where *$pastVerb* is a past tense verb such as *underwent, undergone, experienced, had, found*, etc. So, we get six patterns for informational support. We design two features (**IsEmPattern** and **IsInPattern**) to encode presence (1) or absence (0) of the two types of patterns.

For a sentence, we also use its number of words (**numWords**) and its type, question sentence (**IsQues**) and/or exclamatory sentence (**isExclaim**), as features. To identify question sentences, we see if a sentence starts with any of the 5W1H words *(what, why, who, when, where, how)* or words in the set {do, does, did} or ends with a question mark.

4 Experiments

We now describe our data and the experimental setting, and present our results.

4.1 Data Preparation

We use data from a popular online cancer support community, the Cancer Survivors' Network (CSN), developed and maintained by the American Cancer Society. CSN is an online community for cancer patients, cancer survivors, their families and friends. Its features are similar to many online forums with dynamic interactive medium such as chat rooms, discussion boards, etc. Members of CSN post in discussion boards for seeking and sharing information about cancer related issues and for seeking and providing emotional support. To conduct our experiments, we used user messages in the discussion threads of the Breast Cancer sub forum of CSN that were posted between June 2000 to June 2012. Breast cancer is the largest among all the sub-forums of CSN. A dataset of $250,868$ messages posted by 5516 users in $22,297$ discussion threads is used in this study.

To prepare the evaluation dataset for classification experiments, we randomly sampled 240 messages from 27 discussion threads. Since, our focus is on the messages that provide support, we do not consider

[3] http://www.cancer.gov/cancertopics/druginfo/alphalist

messages posted by thread starters in discussion threads as they seek support. We took help of three human annotators to tag all the sentences of all the messages in one of the two support classes. First, two annotators tagged all the sentences. The percentage agreement between them was 89%. For the remaining 11% sentences, majority vote was taken with the help of the third annotator. Following this tagging scheme, we obtained a total of 1066 sentences with 390 sentences in the informational support class and 676 sentences in the emotional support class. In many cases, members only write a few words, e.g., see you, bye, or their names at the end of a message. To deal with these situations, we filter out sentences that have less than four words.

4.2 Experimental Protocol

We experimented with various machine learning algorithms (Naive Bayes, Support Vector Machines, Logistic Regression, Bagging, Boosting, etc.) to conduct our classification experiments. Naive Bayes Multinomial gave the best performance with words & POS tags features, logistic regression with lexicon-based features and AdaBoost (with Decision Stump as the weak learner) with linguistic features. For combining the models built on the three types of features, we used the following three methods:

1. **Feature combination:** Classification model built on the feature set generated by combining the three types of features. It is denoted by **All**. We use Multinomial Naive Bayes for this model.
2. **Average confidence:** Ensemble of the three classifiers built on the three types of features respectively. The final confidence of the ensemble is calculated by taking average of the confidences outputted by the three classifiers. It is denoted by **AllAvgConf**.
3. **Highest confidence:** Similar to the **AllAvgConf** model but the final prediction of the ensemble is taken as the prediction of the most confident classifier of the three classifiers. More precisely, the prediction for an instance is given by the classifier that returns the maximum prediction confidence for one class or the other. It is denoted by **AllMostConf**.

We used Weka data mining toolkit (Hall et al., 2009) to conduct classification experiments. To evaluate the performance of our classifiers, we used macro-averaged precision, recall and F-1 score. We use F-1 score to compare performances of two classifiers and used 10-fold cross validation. A naive baseline that classifies all the instances in the majority class will have a macro-averaged precision, recall and F-1 score of 0.402, 0.634 and 0.492, respectively.

4.3 Classification Results

Table 2 presents the results of the support classification experiments. The table reports precision, recall and F-1 score of different classification models for the individual classes and the overall result. Words & POS tags are the best performing features followed by lexicon-based features and linguistic features. Further, combining all the features (model denoted as "**All**") improves the performance over individual feature types for both classes. We see that **AllMostConf** model is the best performing of all the models, particularly outperforming **All** and **AllAvgConf** models. This observation suggests that the three classifiers built on the three features types have different knowledge. For some instances, a particular classifier is more confident than the rest while for other instances, other classifiers are more confident. Hence, we see that taking prediction of the most

Model	Precision	Recall	F-1
Emotional support class			
Words & POS tags	0.855	0.858	0.857
Lexicon-based features	0.722	0.836	0.775
Linguistic features	0.698	0.837	0.761
All	0.862	0.861	0.862
AllAvgConf	0.848	0.893	0.87

Informational support class			
Words & POS tags	0.753	0.749	0.751
Lexicon-based features	0.608	0.441	0.511
Linguistic features	0.569	0.372	0.45
All	0.76	0.762	0.761
AllAvgConf	0.797	0.723	0.758
AllMostConf	0.825	0.723	**0.77**
Overall			
Words & POS tags	0.818	0.818	0.818
Lexicon-based features	0.68	0.691	0.678
Linguistic features	0.651	0.667	0.647
All	0.825	0.825	0.825
AllAvgConf	0.829	0.830	0.83
AllMostConf	0.841	0.842	**0.84**

Table 2: Classification results.

confident classifier gives the best performance. It is interesting to note that combining the three classifiers' knowledge in this fashion is more effective than simply combining all the three types of features and train a single classifier on the combined feature set. We also note that all the models have better performance for the emotional support class than for the informational support class. This can be caused by the fact that there are significantly more number of instances in the former class and, hence, more patterns to learn for the class.

4.4 Informative Features

Next, we study the importance of individual features by measuring their chi-squared statistic with respect to the class variable. We, first, study the word features and then present rankings of the other types of features. Figure 1 shows a cloud of top 26 most informative words. The size of a word is proportional to its chi-squared statistic, i.e., bigger a word, more informative it is. We see that cancer specific keywords such as herceptin, tamoxifen, chemo, dose, stage, etc and words conveying emotions such as good, hope, glad, pain, hugs, etc are highly informative for the support classification. Since, chi-square method gives feature ranking for the class variable and not for individual classes, we compute word rankings for individual classes using $tf - idf$ scores of words. Specifically, for a term t and a class c, we compute the term frequency of t by counting its number of occurrences in the instances (sentences) belonging to c and multiply the term frequency with the inverse document frequency of t (calculated from the entire corpus) to get the $tf - idf$ score of t for c. Using this method, we calculated $tf - idf$ scores for all the words and ranked them according to their scores for the two classes. Figure 2 shows top ten $tf - idf$ ranked keywords for the two classes. We see that cancer-related keywords and words expressing emotions are among the top ten most informative words for the informational and the emotional support classes respectively. We also note that most of the top ten words for the two classes in Figure 2 are in the word cloud of the top 26 words computed using chi-squared method except "keep" for the emotional support class and "after", "first", "because" and "cancer" for the informational class. These words have semantic relationships with the classes. For example, "keep" is often used by support providers in phrases such as "**keep** *you in prayers*", "*may god* **keep** *you in good health*", etc to provide emotional support and "after" and "first" are used in the context of providing one's own experience related to cancer procedures, medications, etc such as "**After** *my* **first** *chemo, I did not feel light*".

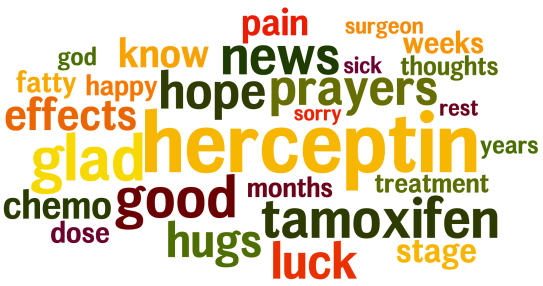

Figure 1: Top 26 words ranked by Chi-squared test.

Emotional support	Informational support
good	chemo
know	after
glad	radiation
news	first
hope	herceptin
keep	treatment
prayers	tamoxifen
luck	cancer
hugs	because
better	pain

Figure 2: Top ten words for the two classes ranked using tf-idf scheme.

We, now, discuss the ranking of non-word features: POS tags, lexicon-based and linguistic features. The chi-squared ranking for the lexicon-based and linguistic features is as follows: numStrong > numWords > isExclaim > numDrug > numSide > numProc > isInPattern > isEmPattern > numWeak > isQues. The features on the right side of > have higher rank than those on the left side. We see that the number of strong subjective words in a sentence is the most informative feature followed by number of words in a sentence. Among cancer-related terms, drug names are more informative than side-effects and cancer procedures. Also, informational support word patterns are more informative than word patterns capturing emotional support. It is interesting to note that isQues is the least informative feature, maybe due to the fact that, while providing support, people generally do not ask questions. The top 5

most informative POS tags are: cardinal number (CD) followed by singular noun (NN), participle verb (VBN), past tense verb (VBD) and preposition (IN).

4.5 Influence versus Support type

CSN managers provided a list of 62 influential members (IMs) for the breast cancer forum. IMs posted a total of $340,147$ sentences in $85,244$ messages and regular members posted $825,651$ sentences in $165,624$ messages in the breast cancer forum. As described in Section 3, we conduct statistical hypothesis testing on the two populations of emotional indices (regular members and IMs) to understand if there is a significant difference in their posting behaviors in terms of providing one of the two supports more often than the other. To test our hypothesis, we conducted one sided t-test on the two populations. We found that the mean of emotional indices of IMs (0.713) is significantly larger than that of the regular members (0.542). We also note that the posting behavior of regular members in CSN follows a power law distribution with most of the members posting very few messages ($mode = 1, median = 2, mean = 30$) and only a few members posting very many messages. To verify that this behavior does not have impacts on our hypothesis testing, we conducted three more t-tests between the two populations using a threshold on the number of messages that a member has posted. We used three threshold values on the number of messages: 1, 2, and 30 (as mode, median and mean values). For all the three t-tests, the null hypothesis was rejected at p-value< 0.001, suggesting that IMs posted significantly more emotional support than regular members. The values of Mean Emotional Indices corresponding to the three thresholds are 0.715, 0.719 and 0.746 for influential members and 0.564, 0.581 and 0.646 for regular members respectively.

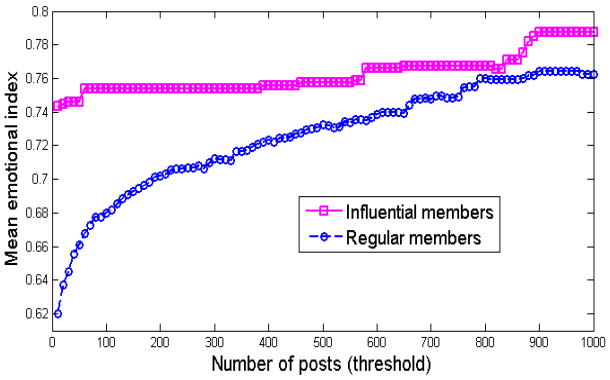

Figure 3: Plot showing the change in mean emotional indices of influential members (pink) and regular members (blue) with the threshold on the number of messages posted by them.

In our analysis, we observed an interesting behavior. As we increased the threshold, the mean of emotional indices also increased. To further investigate this finding, we plotted the means of emotional indices of regular members and IMs as the function of the threshold on the number of messages posted by them. We increased the threshold from 10 to 1000 in steps of 10. Figure 3 reports the finding. We see that the mean of emotional indices of regular members increase with the threshold suggesting that more active members post more emotional support as compared to the less active members. We also see that the mean of emotional indices of IMs is higher than that of regular members for all the thresholds. These interesting observations can be helpful in analyzing behavior of influential members in OHCs.

6 Conclusion and Future Work

We identified two types of social support, emotional and informational, provided in user messages of an online cancer support community using machine learning classification models. We used three types of features and got the best results by using ensemble of the three classifiers built on the three individual feature types. Our models achieved strong results with over 80% F-1 score. We also found that influential members provide significantly more emotional support to the community as compared to regular members. The finding can be helpful in identifying properties of influential members in online health communities. In future, we plan to analyze effects of the two types of supports on OHCs' dynamics and use it to improve information search in OHCs.

Abstract

Accessing the web has been an efficient and effective means to acquire self-help knowledge when suffering from depressive problems. Many mental health websites have developed community-based services such as web forums and blogs for Internet users to share their depressive problems with other users and health professionals. Other users or health professionals can then make recommendations in response to these problems. Such communications produce a large number of documents called psychiatric social texts containing rich emotion labels representing different depressive problems. Automatically identify such emotion labels can make online psychiatric services more effective. This study proposes a framework combining *latent semantic analysis (LSA)* and *independent component analysis (ICA)* to extract concept-level features for emotion label identification. LSA is used to discover latent concepts that do not frequently occur in psychiatric social texts, and ICA is used to extract independent components by minimizing the term dependence among the concepts. By combining LSA and ICA, more useful latent concepts can be discovered for different emotion labels, and the dependence between them can also be minimized. The discriminant power of classifiers can thus be improved by training them on the independent components with minimized term overlap. Experimental results show that the use of concept-level features yielded better performance than the use of word-level features. Additionally, combining LSA and ICA improved the performance of using each LSA and ICA alone.

1 Introduction

Sentiment analysis has been successfully applied for many applications (Picard, 1997; Pang and Lee, 2008; Calvo and D'Mello, 2010; Liu, 2012; Johansson and Moschitti, 2013; Balahur et al., 2014). Analysis of online psychiatric or mental health texts (Wu et al., 2005; Yu et al., 2009) is also an emerging field that could benefit from sentiment analysis techniques because more and more people search for help from the web when they suffered from depressive problems, which boost the development of online community-based services for Internet users to share their depressive problems with other users and health professionals. Through these services, individuals can describe their depressive symptoms via web forums and blogs. Other users or health professionals can then make recommendations in response to these problems. Figure 1 shows an example psychiatric social text collected from PsychPark (http://www.psychpark.org), a virtual psychiatric clinic, maintained by a group of volunteer professionals belonging to the Taiwan Association of Mental Health Informatics (Bai et al., 2001; Lin et al., 2003).

This example shows a subject's depressive problems and the responses recommended by the experts. Some meaningful tags called emotion labels herein are also annotated by the experts to indicate which categories the text belongs to. These emotion labels are useful information and can make online psychiatric services more effective. For instance, psychiatric retrieval systems are able to retrieve relevant documents according to the depressive problems (emotion labels) described in user queries so that the

Proceedings of COLING 2014, the 25th International Conference on Computational Linguistics: Technical Papers, pages 837–847, Dublin, Ireland, August 23-29 2014.

User Problem:	
I broke up with my dear but cruel boyfriend recently. Since then, I have often felt like crying out of nowhere, and I feel pain every day. Also, it takes me a long time to fall asleep at night. So, I think that continuing to live like this is meaningless	 <Depression> <Insomnia> <Suicide>
Recommendation:	
Feeling this way is normal when going through these kinds of struggles, but over time your emotions should level out. Suicide doesn't solve anything; think about how it would affect your family. It's only when we learn to face our despair that we can learn the value of life, and also how to help other people. There are a few things you can try to help you get to sleep at night, like doing some light exercise in the evening, drinking warm milk, and listening to relaxing music; all of these can be conducive to sleep. If you still have trouble dealing with the pain, and you feel as if your mood is getting worse, it wouldn't hurt to get seek help from a healthcare professional, who can help you work through your emotions.	
Emotion Label: <Depression>, <Insomnia>, <Suicide>	

Figure 1. Example of a psychiatric social text.

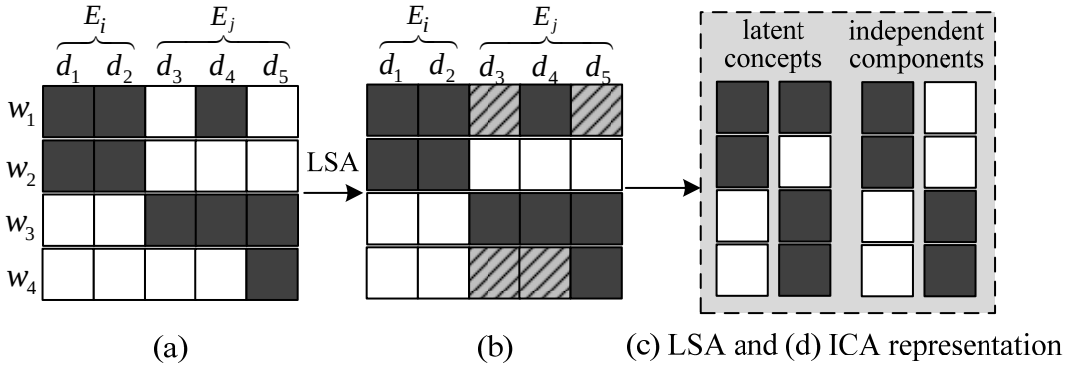

Figure 2. Comparison of LSA and ICA for feature representation.

users can learn self-help knowledge from the responses. Therefore, this study aims to identify emotion labels from psychiatric social texts. We cast this problem into a multi-label text classification task because a psychiatric social text may contain multiple emotion labels. Additionally, we propose the use of concept-level features to build classifiers instead of using surface-level features such as words, n-grams and dependency structure commonly used in the previous studies (Naughton et al., 2008; Chitturi and Hansen, 2008; Li and Zong, 2008; Kessler and Schütze, 2012; Post and Bergsma, 2013; Yu et al., 2011).

In extraction of concept-level features, latent semantic analysis (LSA) (Landauer et al., 1998) has been demonstrated its effectiveness in exploring the latent structure from a collection of documents. It uses singular value decomposition (SVD) (Golub and Van Loan, 1996) to discover latent features that do not frequently occur in the documents through the indirect associations between words and documents. Figure 2 shows an example. The original matrix, as shown in Figure 2(a), is built using five documents with two different emotion labels E_i and E_j. Suppose that the words w_1, w_2 are the useful features for E_i, and w_3, w_4 are useful for E_j, but w_4 is a latent feature because it does not frequently occur in the documents of E_j. After applying SVD, the latent features can be identified by replacing the zero entries in the original matrix with non-zero real values through the indirect associations between words and documents. For instance, w_4 originally does not occur in d_3 and d_4, but it does co-occur with w_3 in the matrix (e.g., in d_5), which means that w_4 might also occur in the documents where w_3 occurs

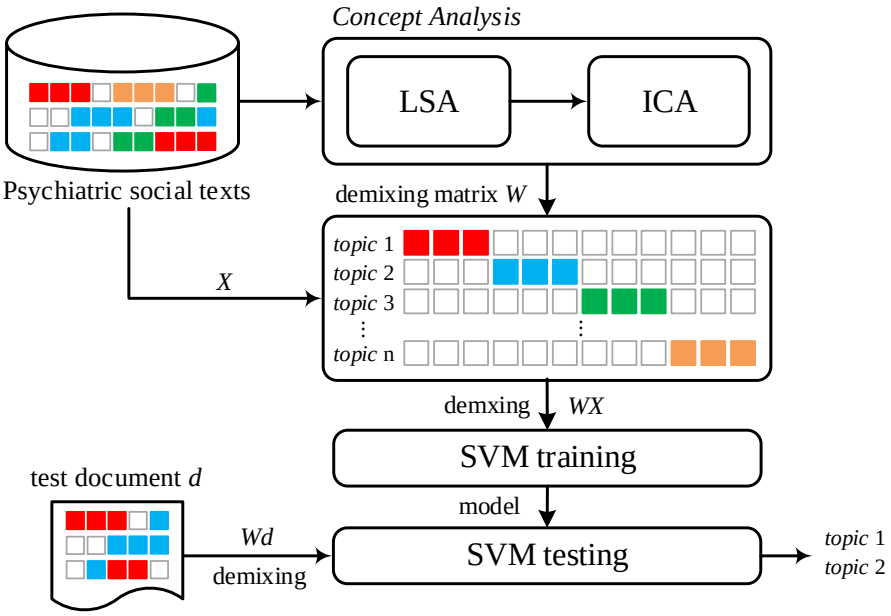

Figure 3. Framework of emotion label identification.

(e.g., d_3 and d_4). Therefore, the zero entries (w_4, d_3) and (w_4, d_4) are replaced with a non-zero value through the indirect associations between of w_3 and w_4 in d_5, as shown in Figure 2(b). This helps identify a useful latent feature w_4 for E_j. However, identifying latent features through the indirect associations cannot avoid feature overlap when different emotion labels share common words. For instance, in Figure 2(a), w_1, which is useful for E_i, still occurs in the document of E_j (e.g., d_4). Through the indirect associations between of w_1 and w_3 in d_4, the frequency of w_1 increases in the document of E_j because it may also occur in the documents where w_3 occurs (e.g., d_3 and d_5), as shown in Figure 2(b). Therefore, when all word features are to be accommodated in a low-dimensional space reduced by SVD, term overlap may occur between the latent concepts. As indicated in Figure 2(c), the two sample latent concepts which contribute to two different emotion labels share a common feature w_1. Classifiers trained on such latent vectors with term overlap may decrease classification performance.

To reduce the term overlap among concepts, we used the *independent component analysis* (ICA) (Lee, 1998; Hyvärinen et al., 2001; Naik and Kumar, 2011) because it can extract independent components from a mixture of signals and has been used in various text applications (Kolenda and Hansen, 2000; Rapp, 2004; Honkela et al., 2010; Yu and Chien, 2013). For our task, the psychiatric social texts are a mixture of emotion labels, which can be separated by ICA to obtain a set of independent components (concepts) with minimized term dependency for different emotion labels. Instead of using ICA alone, we propose a framework combining LSA and ICA for emotion label identification. The LSA is used to discover latent features that do not frequently occur in psychiatric texts, and ICA is used to further minimize the dependence of the latent features such that overlapped features can be removed, as presented in Figure 2(d). Based on this combination, the proposed framework can discover more useful latent features for different emotion labels, and the dependence between them can also be minimized. The discriminant power of classifiers can thus be improved by training them on the independent components with minimized term overlap. In experiments, we evaluate the proposed method to determine whether the use of concept-level features could improve the classification performance, and determine whether the combination method could improve the performance of using each LSA and ICA alone.

The rest of this paper is organized as follows. Section 2 describes the overall framework including LSA and ICA for emotion label identification. Section 3 summarizes comparative results. Conclusions are finally drawn in Section 4.

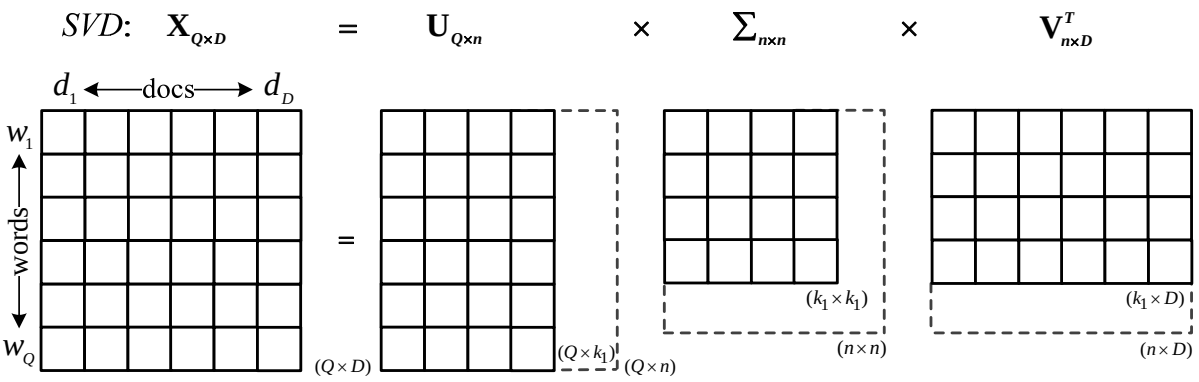

Figure 4. Illustrative example of singular value decomposition for latent semantic analysis.

2 Framework of Emotion Label Identification

Figure 3 shows the overall framework for emotion label identification. A corpus of psychiatric social texts with annotation of emotion labels are first collected from the web. This corpus which is a mixture of different emotion labels is then sequentially analyzed by LSA and ICA to generate a demixing matrix composed of a set of concepts with minimized term dependency for different emotion labels. The demixing matrix is used to separate the psychiatric social texts with mixed emotion labels into independent components for building a support vector machine (SVM) classifier. The classifier can then be benefit from the independent components to identity multiple emotion labels contained in each test example.

2.1 Latent Semantic Analysis (LSA)

LSA is a technique for analyzing the relationships between words and documents. For our task, LSA is used to identify useful latent concepts for emotion labels through indirect associations between words and documents. The first step in LSA is to build a word-by-document matrix from a corpus of psychiatric texts with different emotion labels, as shown in the sample matrix **X** in Figure 4.

The columns in $\mathbf{X}_{Q\times D}$ represent D psychiatric texts in the corpus, and the rows represent Q distinct words occurring in the corpus. Singular value decomposition (SVD) is then used to decompose the matrix $\mathbf{X}_{Q\times D}$ into three matrices as follows:

$$\mathbf{X}_{Q\times D} = \mathbf{U}_{Q\times n} \sum_{n\times n} \mathbf{V}^T_{n\times D}, \tag{1}$$

where **U** and **V** respectively consist of a set of latent vectors of words and documents, $\sum$ is a diagonal matrix of singular values, and $n = \min(Q, D)$ denotes the dimensionality of the latent semantic space. Each element in **U** represents the weight of a word, and the higher-weighted words are the useful features for the emotion labels. By selecting the largest k_1 ($\leq n$) singular values together with the first k_1 columns of **U** and **V**, the word and documents can be represented in a low-dimensional latent semantic space. The matrix $\mathbf{V}^T_{n\times D}$ can then represented with the reduced dimensions, as shown in Eq. (2).

$$\mathbf{V}^T_{k_1\times D} = \sum^{-1}_{k_1\times k_1} \mathbf{U}^T_{k_1\times Q} \mathbf{X}_{Q\times D}, \tag{2}$$

In SVM training and testing, each input psychiatric text first transformed into the latent semantic representation as follows:

$$\hat{\mathbf{t}}_{k_1\times 1} = \sum^{-1}_{k_1\times k_1} \mathbf{U}^T_{k_1\times Q} \mathbf{t}_{Q\times 1}, \tag{3}$$

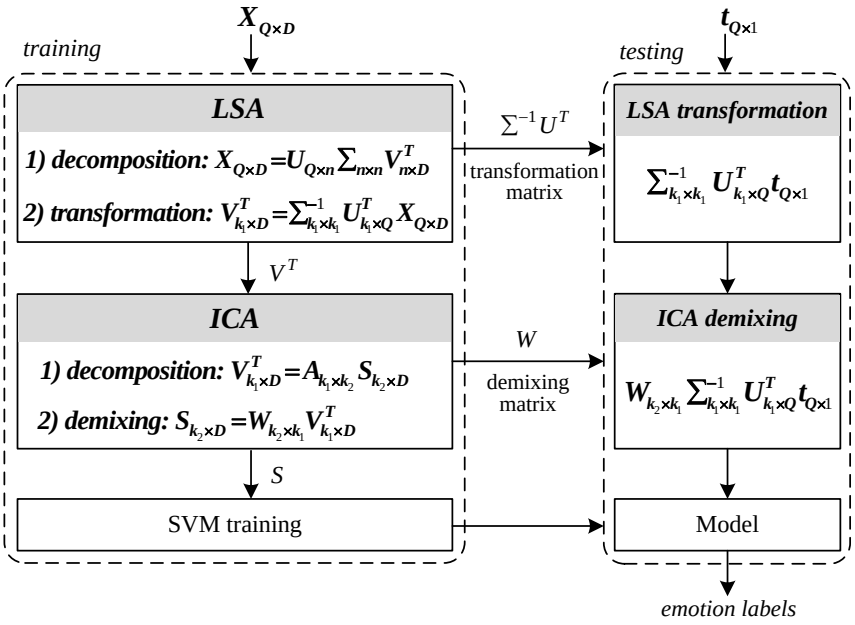

Figure 5. ICA-based method for emotion label identification.

where $\mathbf{t}_{Q\times 1}$ denotes the vector representation of an input instance, and $\hat{\mathbf{t}}_{k_1\times 1}$ denotes the transformed vector in the latent semantic space. An SVM classifier is then trained with the transformed training vectors.

2.2 Independent Component Analysis (ICA)

ICA is a technique for extracting independent components from a mixture of signals and has been successfully applied to solve the blind source separation problem (Saruwatari et al., 2006; Chien and Hsieh, 2012). The ICA model can be formally described as

$$\mathbf{X} = \mathbf{AS} \tag{4}$$

where $\mathbf{X}$ denotes the observed mixture signals, $\mathbf{A}$ denotes a mixing matrix, and $\mathbf{S}$ denotes the independent components. The goal of ICA is to estimate both $\mathbf{A}$ and $\mathbf{S}$. Once the mixing matrix $\mathbf{A}$ is estimated, the demixing matrix can be obtained by $\mathbf{W} = \mathbf{A}^{-1}$, and Eq. (4) can be re-written as

$$\mathbf{S} = \mathbf{WX} \tag{5}$$

That is, the observed mixture signals can be separated into independent components using the demixing matrix. For our problem, psychiatric texts can be considered as a mixture of signals because each of them may contain multiple emotion labels. Therefore, ICA used herein is to estimate the demixing matrix so that it can separate the psychiatric texts with mixed emotion labels to derive the independent components for each emotion label. Figure 5 shows the diagram of the proposed method.

2.1.1 LSA decomposition and transformation

In the training phase, the original matrix $\mathbf{X}_{Q\times D}$ is first processed by SVD using Eq. (1) and (2) Useful latent features that do not frequently occur in the original matrix can thus be discovered in this step.

2.1.2 ICA decomposition and demixing

The matrix $\mathbf{V}^T_{k_1\times D}$ decomposed by SVD is then passed to ICA to estimate the demixing matrix. ICA accomplishes this by decomposing $\mathbf{V}^T_{k_1\times D}$ using Eq. (6). Figure 6 shows an example of the decomposition.

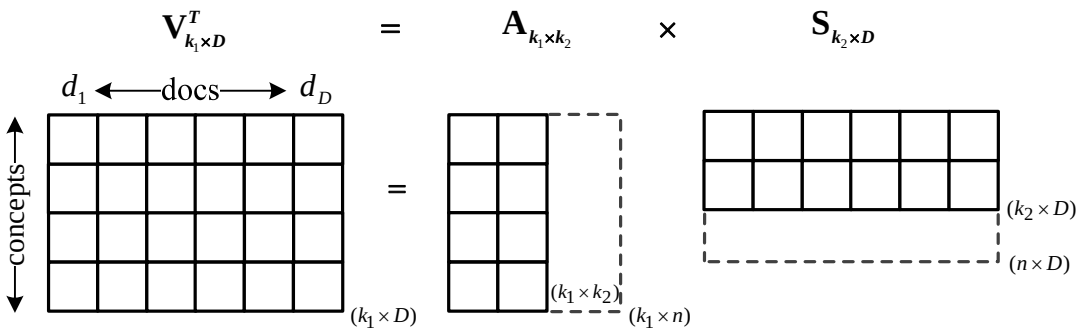

Figure 6. Illustrative example of ICA decomposition.

$$\mathbf{V}^{T}_{k_1 \times D} = \mathbf{A}_{k_1 \times k_2} \mathbf{S}_{k_2 \times D}. \tag{6}$$

Based on this decomposition, the demixing matrix can be obtained by $\mathbf{W}_{k_2 \times k_1} = \mathbf{A}^{-1}_{k_1 \times k_2}$, where k_2 ($\leq k_1$) is the number of independent components. The demixing matrix is then used to separate $\mathbf{V}^{T}_{k_1 \times D}$ to derive the independent components as follows:

$$\mathbf{S}_{k_2 \times D} = \mathbf{W}_{k_2 \times k_1} \mathbf{V}^{T}_{k_1 \times D}, \tag{7}$$

An SVM classifier is then trained with the independent components $\mathbf{S}_{k_2 \times D}$, as shown in Figure 5. In testing, each test instance $\mathbf{t}_{Q \times 1}$ is transformed using both LSA and ICA, and then predicted with the trained SVM model.

3 Experimental Results

3.1 Experiment Setup

3.1.1 Data

The data set used for experiments included 1,711 Chinese psychiatric social texts collected from the PsychPark. Each psychiatric social text was manually annotated with an emotion label by a group of volunteer mental health professionals. Table 1 shows the proportions of the emotion labels in the corpus. In calculating the proportion of each emotion label, a psychiatric social text was counted for multiple emotion labels depending on the number of emotion labels contained in it. In evaluation, 20% of psychiatric social texts in the corpus were randomly selected as a test set, and the remaining 80% were used for training.

No.	Emotion Label	Proportion
1	Depression	35.26%
2	Drug	13.38%
3	Insomnia	5.79%
4	Mood	30.04%
5	OCD (Obsessive compulsive disorder)	4.51%
6	Schizophrenia	5.36%
7	Social Anxiety	5.65%

Table 1. Distribution of emotion labels in experimental data

3.1.2 Classifiers

The classifiers involved in this experiment included PureSVM, LSA, ICA, and LSA+ICA. The PureSVM was trained on word-level features, and the others were trained on concept-level features derived using LSA, ICA, and combination of them, respectively. The implementation details for each classifier are as follows:

- **PureSVM**: An SVM classifier trained with bag-of-words features.
- **LSA:** An SVM classifier trained with the latent vectors obtained from the word-by-document matrix built from the training corpus.
- **ICA:** An SVM classifier trained with the independent components obtained by demixing the word-by-document matrix built from the training corpus.
- **LSA+ICA:** An SVM classifier trained with the independent components obtained by demixing the word-by-document matrix produced by LSA.

To identify multiple emotion labels contained in test examples, each emotion label presented in Table 1 was trained a binary classifier in the training phase. That is, for each method presented above, we built seven binary classifiers so that they can output multiple positive results to indicate that a test example contained multiple emotion labels.

3.1.3 Evaluation Metrics

The metrics used for performance evaluation included *recall*, *precision*, and *F-measure*, respectively. Recall was defined as the number of emotion labels correctly identified by the method divided by the total number of emotion labels in the test set. Precision was defined as the number of emotion labels correctly identified by the method divided by the number of emotion labels identified by the method. The F-measure (F1) was defined as $2 \times recall \times precision$ / (*recall* + *precision*).

3.2 Evaluation of LSA and ICA

This experiment compared the performance of LSA and ICA using different settings for the parameters k_1 and k_2, which respectively represent the dimensionality of the latent semantic space and the

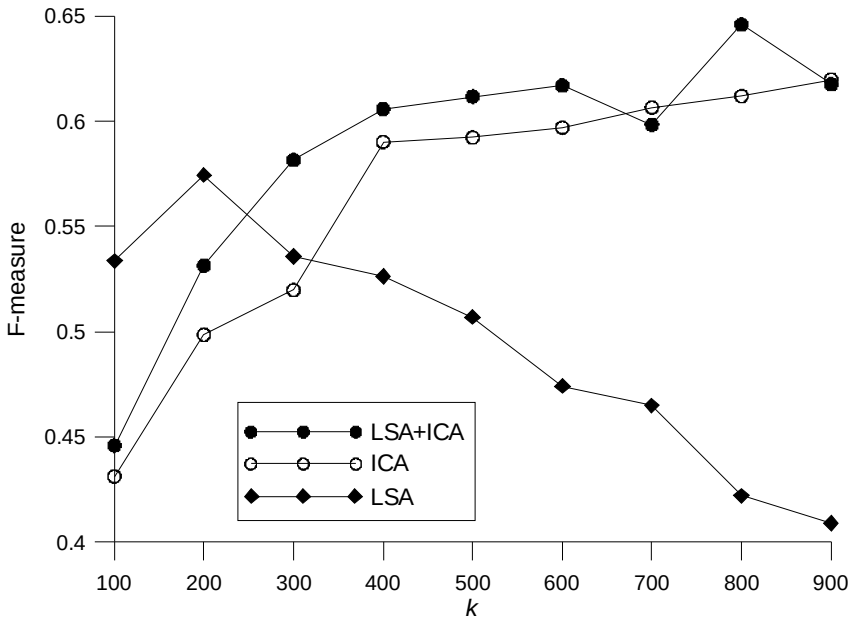

Figure 7. Performance of the LSA, ICA and LSA+ICA, as a function of *k*.

number of independent components. Figure 7 shows the F-measure of LSA, ICA, and combination of them with the setting $k = k_1 = k_2$. The F-measure is the average F-measure over the seven emotion labels. The results show that the optimal settings of LSA was *k*=200. The performance of LSA dropped dramatically as *k*>200, indicating that most useful latent features were discovered within the first 200 concepts and the remaining concepts may contain noisy features, thus reducing performance. The respective optimal settings for ICA and LSA+ICA were *k*=900 and *k*=800. In addition, both ICA and LSA+ICA outperformed LSA for most settings of *k*. The best settings of the parameters were used in the following experiments.

3.3 Comparative Results

This section reports the classification performance of PureSVM, LSA, ICA, and LSA+ICA. Table 2 shows the comparative results. Compared to the use of word-level features (i.e., PureSVM), LSA, ICA, and LSA+ICA achieved a higher F-measure. Additionally, LSA yielded a much greater recall than did PureSVM, whereas ICA yielded much greater precision. These findings indicate that the concept-level features are useful for emotion label identification. Among the three concept-based methods, LSA can discover latent concepts for emotion labels, whereas ICA can extract independent components that can minimize the term dependence within them. The results show that ICA yielded higher recall and F-measure but lower precision than did LSA. By combining LSA and ICA, the performance was improved on all measures because LSA+ICA can not only discover latent concepts but also minimize term overlap among the concepts.

Another observation is that the emotion label Depression yielded the highest F-measure while both OCD and Schizophrenia yielded the lowest. One possible reason for these results is the distribution of emotion labels in the test set (e.g., Depression and Mood are the major classes). However, the skewed distribution was just a minor factor. For example, the test set included four small classes (Insomnia, OCD, Schizophrenia and Social Anxiety) with similar proportions (5.79%, 4.51%, 5.36% and 5.65%), but their F-measures were quite different (70%, 57%, 57% and 64%). Terms overlap emotion labels could have a significant impact on classification performance. For example, Insomnia had a much higher classification performance than the other three minor classes because the words used in this class were quite distinct from those used for other classes. Conversely, the words used for OCD and Social Anxiety overlapped significantly, thus yielding lower performance. Table 3 shows some representative words (with higher weights) in the independent components for the emotion labels.

Class	PureSVM			LSA			ICA			LSA+ICA		
	R	P	F	R	P	F	R	P	F	R	P	F
Depression	58	59	59	68	74	71	72	75	73	73	78	75
Drug	60	38	47	57	71	63	51	69	59	55	72	62
Insomnia	53	66	59	49	76	60	65	76	70	66	75	70

Table 2. Performance for different classifiers. The columns R, P, and F represent recall, precision, and f-measure, respectively. (in %)

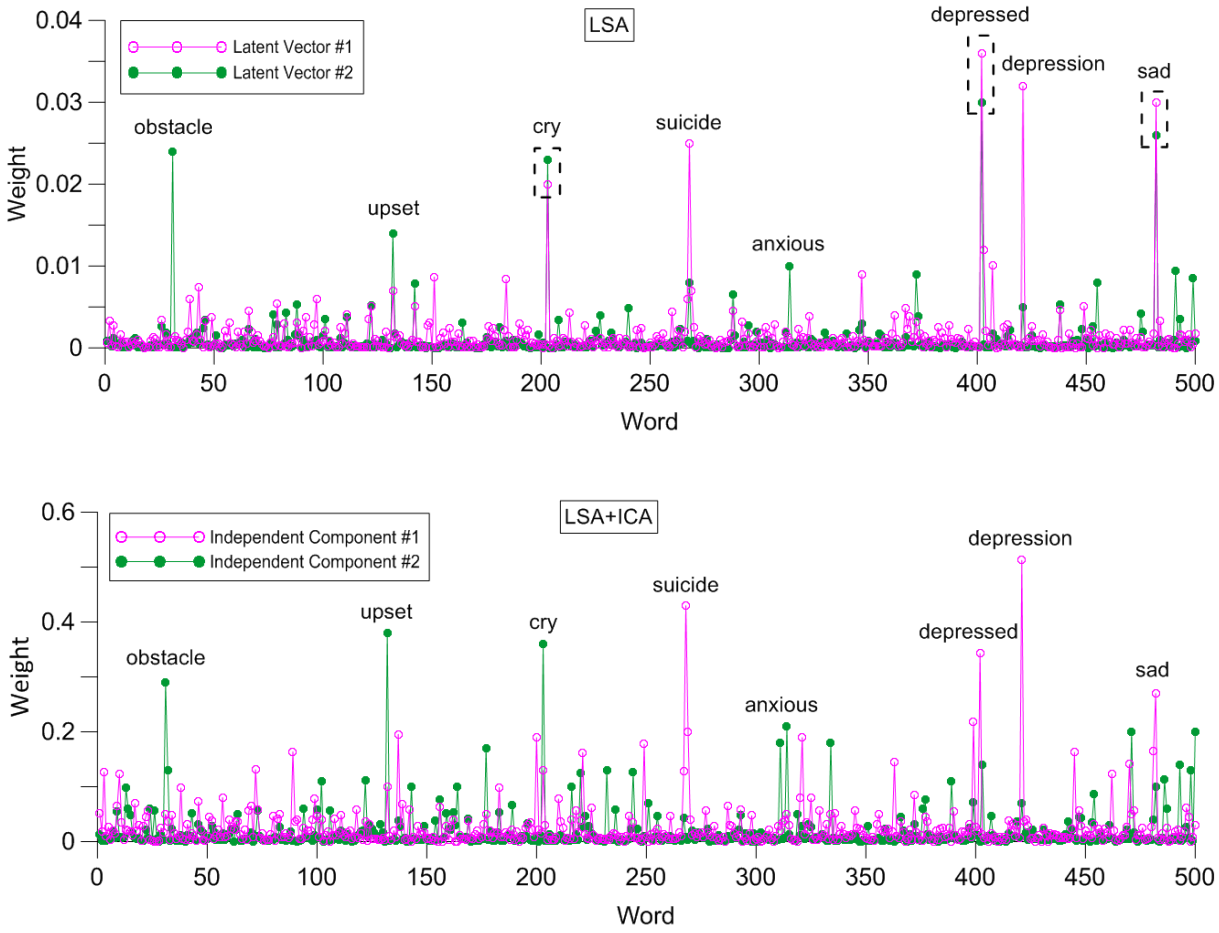

Figure 8. Examples of latent vectors, selected from $\mathbf{U}_{Q\times k}$, and independent components, selected from $\mathbf{W}_{Q\times k}^{T}$, for the emotion labels <Depression> and <Mood>.

3.4 Term Overlap Analysis

In order to investigate the term overlap in LSA and LSA+ICA, we analyze their respective corresponding matrices $\mathbf{U}_{Q\times k}$ and $\mathbf{W}_{Q\times k}^{T}$ where $\mathbf{W}_{Q\times k}^{T}$ is the transpose of the demixing matrix obtained with the input of $\mathbf{X}_{Q\times D}$ reconstructed using LSA. Each column of $\mathbf{U}_{Q\times k}$ and $\mathbf{W}_{Q\times k}^{T}$ represents a latent vector/independent component of *Q* words, and each element in the vector is a word weight representing its relevance to the corresponding latent vector/independent component. Figure 8 shows two sample latent vectors for LSA and two independent components for LSA+ICA, where the weights shown in this figure are the absolute values.

The upper part of Fig. 8 shows parts of the words and their weights in the two latent vectors, where latent vector #1 can be characterized by *depressed*, *depression*, and *sad* which are the useful features for identifying the emotion label <Depression>, and latent vector #2 can be characterized by *depressed*, *sad,* and *cry* which are useful for identifying <Mood>. Although the two latent vectors contained useful features for the respective emotion labels, these features still had some overlap between the latent vectors, as marked by the dashed rectangles. The overlapped features, especially those with higher weights, may reduce the classifier's ability to distinguish between the emotion labels. The lower part of Fig. 8 also shows two independent components for the emotion labels <Depression> and<Mood>. As indicated, the term overlap between the two independent components was relatively low. Table 3 shows some representative words (with higher weights) in the independent components for the emotion labels.

Emotion Label	Representative Words
Depression	depression, depressed, sad, down, suicide
Drug	Medication, drug, dose, sedative, withdrawal,
Insomnia	sleep, insomnia, dream, nightmare, awake
Mood	cry, upset, anxious, energy, obstacle
OCD	OCD, compulsion, weight, overeating, behavior
Schizophrenia	paranoia, fantasy, memory, split, genetic
Social Anxiety	crowd, tense, friend, stiffness, ridicule, shivering

Table 3. Representative words for the emotion labels.

4 Conclusions

This work has presented a framework combining LSA and ICA for emotion label identification. Both LSA and ICA are used to analyze concept-level features, where LSA is used to discover latent concepts that do not frequently occur in psychiatric texts, and ICA is used to further minimize the term dependence among the concepts. The experimental results show that the use of concept-level features yielded better performance than the use of word-level features. Additionally, ICA can reduce the degree of term overlap of LSA so that combining LSA and ICA can discover more useful latent concepts with minimized term dependence for different emotion labels, thus improving classification performance. Future work will focus on investigating the use of the machine-labeled emotion labels as meta-information to improve online psychiatric services such as information retrieval for self-help knowledge recommendation.

Abstract

In online social media, social action prediction and social tie discovery are two fundamental tasks for social network analysis. Traditionally, they were considered as separate tasks and solved independently. In this paper, we investigate the high correlation and mutual influence between social actions (i.e. user-behavior interactions) and social ties (i.e. user-user connections). We propose a unified coherent framework, namely mutual latent random graphs (MLRGs), to flexibly encode evidences from both social actions and social ties. We introduce latent, or hidden factors and coupled models with users, users' behaviors and users' relations to exploit mutual influence and mutual benefits between social actions and social ties. We propose a gradient based optimization algorithm to efficiently learn the model parameters. Experimental results show the validity and competitiveness of our model, compared to several state-of-the-art alternative models.

1 Introduction

With the dramatically rapid growth and great success of many large-scale online social networking services, social media bridge our daily physical life and the virtual Web space. Popular social media sites (e.g., Facebook and Twitter) and mobile social networks (e.g., Foursquare) have gathered billions of acting users and are still attracting millions of newbies everyday. Modeling *social actions* and *social ties* are two fundamental tasks in online social media. Social actions are the users' activities or behaviors in socially connected networks. For example, a social action can be "posting a tweet" on Twitter or the "check-in" behavior on Foursquare. A social tie or social relation is referred to any relationship between two or more individual users in a social network, such as the friend and colleague relationships. By understanding a user's behaviors and accordingly exploiting potentially interesting services to her/him, one can improve the user's experience and boost the revenue of social media sites. Also, precise social tie prediction will help people tap into the wisdom of crowds, to aid in making more informed decisions.

Since individual users are socially connected, social influence occurs through information diffusion in social networks. Social influence happens when one's opinions or behaviors are affected by others. It is well known that different types of social ties have essentially different influence on social actions. Intuitively, a user's trusted friends on the web affect that user's online behavior. Ma *et al.* (2009) and Ma *et al.* (2011) claimed that one user's final behavior decision is the balance between his/her own taste and her/his trusted friends' favors. On the other hand, social actions also have important influence on social ties. Obviously, users with similar preferences or behaviors are more likely to be friends than others in social media. Users with momentous activities will attract many other users to be connected with. On the contrary, no body will be interested in users with trivial or insignificant behaviors.

Consequently, we face some very interesting questions: Is there any dynamics or mutual influence between social actions and social ties? To what extent do they influence each other? A fundamental mechanism that drives the dynamics of networks is the underlying social phenomenon of *homophily* (McPherson *et al.*, 2001): people tend to follow the behaviors of their friends, and people tend to create relationships with other people who are already similar to them. This suggests that both actions and ties

Proceedings of COLING 2014, the 25th International Conference on Computational Linguistics: Technical Papers, pages 848–859, Dublin, Ireland, August 23-29 2014.

are bi-directionally correlated and mutually influenced in social media, they could be mutually reinforced if modeled jointly.

Inspired by this mechanism, we propose a single unified framework based on exponential-family random graph models ((Frank and Strauss, 1986), (Wasserman and Pattison, 1996)) to exploit homophily for simultaneous social action prediction and social tie discovery. This mutual latent random graph (MLRG) framework incorporates shared latent factors with users, users' behaviors and users' relations, and defines coupled models to encode both social action and social tie information, to capture dynamics and mutual influence between them. We propose a gradient based algorithm for learning and optimization. During the learning procedure, social actions (i.e. user-behavior interactions), social ties (i.e. user-user connections), and deep dependencies and interactions between them could be efficiently explored. Experimental results demonstrate that social actions and social ties are highly correlated and mutually helpful. By coupling actions with ties jointly in a single coherent framework, MLRG achieves significantly better performance on both social action prediction and social tie inference, compared to state-of-the-art systems modeling them independently.

2 Related Work

Social network analysis has attracted much interest in both academia and industry recently. Considerable research and engineering has been conducted for social media modeling, analytics and optimization, including social community detection (Fortunato, 2010), user behavior modeling and prediction ((Benevenuto *et al.*, 2009), (Kwak *et al.*, 2010), (Ma *et al.*, 2009), (Ma *et al.*, 2011)), social tie analysis ((Tang *et al.*, 2011), (Tang *et al.*, 2012)), social sentiment analysis ((Wasserman *et al.*, 1994), (Pang and Lee, 2008)), etc.

Social action prediction and social tie discovery are two fundamental tasks for social media and social network analysis. Traditionally, they were considered as separate tasks and solved independently without considering the bidirectional interactions and interdependencies between them. Social action investigation is essentially important in online social media. Users behaviors could be affected by various kinds of complex factors, such as users' attributes, users's historical behaviors, social influence and social network structures. Based on this motivation, Tan *et al.* (2010) proposed a noise tolerant time-varying model to track social actions. Aiming at modeling user actions more accurately and realistically, Ma *et al.* (2009) and Ma *et al.* (2011) considered connections among users and proposed social trust ensemble to fuse the users' tastes and their trusted friends' favors together. Gao *et al.* (2013) investigated users' social behaviors from a spatio-temporal-social aspect in location-based mobile social networks. In particular, Gao *et al.* (2013) focused on temporal effects in terms of temporal preferences and temporal correlations, and modeled temporal cyclic patterns to capture a user's mobile behavior to investigate correlations to the spatial context and social context in location-based social networks.

Social tie is the most basic unit to form the network structure. Tang *et al.* (2011) proposed a semi-supervised framework, the partially labeled factor graph model to infer the type of social relationships. The task was formulated as a relationship mining problem to detect the relationship semantics in real-world networks. Tang *et al.* (2012) further incorporated social theories and leveraged features based on those social theories to infer social ties across heterogeneous networks via a transfer learning framework. As can be seen, predicting social actions and inferring social ties were modeled as separate and independent tasks in the above-mentioned approaches, deep interactions and mutual influence between them were not taken into consideration. In social media users interact with one another to share the content they both create and consume. According to the homophily phenomenon, exploring bi-directional information and mutual influence between them is intuitively appealing.

We are also aware of several research work attempting to explore joint models to capture mutual benefits and deep dependencies between different tasks in NLP, data mining and information extraction research communities ((Ko *et al.*, 2007), (Yu and Lam, 2008), (Yu *et al.*, 2009), (Liu *et al.*, 2009), (Yu and Lam, 2010b), (Yu and Lam, 2010a), (Yu *et al.*, 2011), (Yu and Lam, 2012), (Zeng *et al.*, 2013)). In general, joint models aim to handle multiple hypotheses and uncertainty information and to predict many variables simultaneously such that subtasks can aid each other to boost the performance.

Ko *et al.* (2007) proposed a joint answer ranking framework based on probabilistic graphical models for question answering. Yu and Lam (2008) proposed an integrated probabilistic and logic approach based on Markov Logic Networks (MLNs) (Richardson and Domingos, 2006) to encyclopedia relation extraction. However, this modeling only captures single relation extraction task. Liu *et al.* (2009) developed a Bayesian hierarchical approach, the topic-link LDA, to perform topic modeling and author community discovery for large-scale linked documents in one unified framework. Yu *et al.* (2009) integrated two sub-models in a unified framework via Markov chain Monte Carlo (MCMC) sampling based inference algorithms. This is a loosely coupled model since parameter estimation is performed separately for the two sub-models. Yu and Lam (2012) further proposed a joint model incorporating probabilistic graphical models and first-order logic for information extraction. This joint model exploits structured variational approximation for tractable parameter learning. Zeng *et al.* (2013) presented a semi-supervised graph-based approach to joint Chinese word segmentation and POS tagging. However, none of these models has been investigated or applied to social media and social network analysis. We believe that one major reason could be the problem of high computational complexity, such as Yu *et al.* (2009) and Yu and Lam (2012). Since many social network sites contain millions of users, exploiting such models could be very challenging. Currently, research on building joint approaches is still in the infancy stage. To the best of our knowledge, there is few systematically study on building joint models to explore mutual influence for social actions and social ties.

3 Model

In this section we consider both social action prediction and social tie inference in the context of social media, where evidences for both actions and ties are available. We begin by necessary description of preliminaries and notations, we then present the mutual latent random graphs (MLRGs) model, upon which both sources of evidence could be exploited simultaneously to capture their mutual influence. We also discuss the major difference and superiority of this model against several alternative models.

3.1 Preliminaries and Notations

Let $\mathcal{G} = (\mathbf{V}, \mathbf{E})$ be a social network graph, where $\mathbf{V} = \{v_1, v_2, \ldots, v_N\}$ is the set of $|\mathbf{V}| = N$ users and $\mathbf{E} = \{e_{11}, e_{12}, \ldots, e_M\} \subset \mathbf{V} \times \mathbf{V}$ is the set of $|\mathbf{E}| = M$ connections between users. Let $\mathbf{y} = \{y_1, y_2, \ldots, y_N\}(y_i \in \mathcal{Y})$ be the set of actions associated with N users, and $\mathbf{s} = \{s_{11}, s_{12}, \ldots, s_M\}(s_{ij} \in \mathcal{S})$ be the set of corresponding social tie labels associated with M connections. The connection $e_{ij}(1 \leq i, j \leq N, i \neq j)$ between v_i and v_j might be directed or undirected. To be consistent, both $s_{ij} \neq s_{ji}$ and $s_{ij} = s_{ji}$ are valid settings. Given the observed social network data $\mathcal{D}$ constructing the graph $\mathcal{G}$, our goal is to simultaneously detect the most likely types of actions $\mathbf{y}^*$ and ties $\mathbf{s}^*$ such that both of them are optimized.

The exponential-family random graph models (ERGMs) ((Frank and Strauss, 1986), (Wasserman and Pattison, 1996)) take the form of an exponential family as $P_{y_i|\mathcal{G}} = \prod_{y_i \in \mathcal{Y}} \phi(y_i) = \frac{\exp\{\sum_{y_i \in \mathcal{Y}} \eta \boldsymbol{\xi}(y_i)\}}{\kappa_\eta}$ for the social action y_i in the social network graph $\mathcal{G}$, where $\phi(\cdot)$ is a factor, η is a vector of parameters, $\boldsymbol{\xi}(\cdot)$ is a p-vector of sufficient statistics, which captures network features of interest, its postulated dependence structure, or both. Lastly, κ_η is a normalization function to make all probabilities sum to one. The class of ERGMs is a popular framework for social network modeling to capture global network characteristics.

3.2 Modeling Social Actions

To characterize the user action y_i, we assume that for the user v_i there exist observable attributes or properties $\mathbf{m}_i$, such as the user's registered information and historical actions. Without loss of generality, we further assume that there exist some hidden, or latent properties $\mathbf{x}_{ij}$ for v_i. These properties are implicit and cannot be observed directly, such as the influence from social ties. Consequently, we denote the observable factor $\phi(y_i, v_i, \mathbf{m}_i)$ for observable properties and latent factor $\phi_h(y_i, s_{ij}, \mathbf{x}_{ij})$ for hidden properties, respectively. Given the graph $\mathcal{G}$, the probability distribution of y_i depends on both observable and latent factors as:

$$P_{y_i|\mathcal{G}} \sim \phi(y_i, v_i, \mathbf{m}_i), \quad P_{y_i|\mathcal{G}} \sim \phi_h(y_i, s_{ij}, \mathbf{x}_{ij}), \quad P_{y_i|\mathcal{G}} \sim \phi(y_i, v_i, \mathbf{m}_i)\phi_h(y_i, s_{ij}, \mathbf{x}_{ij}). \tag{1}$$

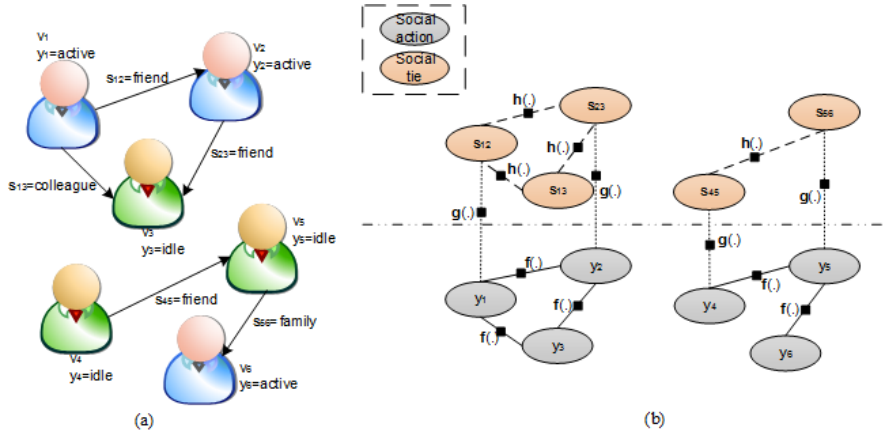

Figure 1: (a) A social network containing 6 users and 5 social ties. The social action can be active or idle, and the social tie can be friend, colleague, or family. (b) The three-dimensional graphical representation of the corresponding MLRG model. We use different lines to represent functions $\mathbf{f}(\cdot)$, $\mathbf{g}(\cdot)$, and $\mathbf{h}(\cdot)$.

The Mutual Latent Random Graph (MLRG) model	
$\forall y_i \in \mathcal{Y}$	$P_{y_i\|\mathcal{G}} \sim \phi(y_i, v_i, \mathbf{m}_i)\phi_h(y_i, s_{ij}, \mathbf{x}_{ij})$
$\forall s_{ij} \in \mathcal{S}$	$P_{s_{ij}\|(y_i,\mathcal{G})} \sim \phi'(s_{ij}, v_i, v_j, \mathbf{w}_{ij})\phi_h(y_i, s_{ij}, \mathbf{x}_{ij})$
$\forall y_i \in \mathcal{Y}, \forall s_{ij} \in \mathcal{S}$	$P_{(y_i,s_{ij})\|\mathcal{G}} \sim \phi(y_i, v_i, \mathbf{m}_i)\phi_h(y_i, s_{ij}, \mathbf{x}_{ij})\phi'(s_{ij}, v_i, v_j, \mathbf{w}_{ij})$

This modeling integrates two types of factors for both observable and latent properties. It captures not only the user-behavior dependencies, but also the influence from social ties, for exploring social actions.

3.3 Modeling Social Ties

To characterize the social tie s_{ij} between user pair (v_i, v_j), we also assume that there exist observable properties $\mathbf{w}_{ij}$, such as the posterior probability of the social tie s_{ij} assigned to (v_i, v_j). We denote the observable factor $\phi'(s_{ij}, v_i, v_j, \mathbf{w}_{ij})$ for $\mathbf{w}_{ij}$. Similarly, we further assume that there exist some latent properties to incorporate the social action influence on social ties. To be consistent, we still use the vector $\mathbf{x}_{ij}$ to represent the latent properties and the latent factor $\phi_h(y_i, s_{ij}, \mathbf{x}_{ij})$ to capture the social action influence on social ties. Note that both $\mathbf{x}_{ij}$ and $\phi_h(y_i, s_{ij}, \mathbf{x}_{ij})$ now play double duties in encoding social action dependency and social tie connection simultaneously. On the one hand, $\phi_h(y_i, s_{ij}, \mathbf{x}_{ij})$ exploits influence from social ties for modeling social actions. On the other hand, this factor exploits influence from social actions for modeling social ties. By doing so, the latent factor $\phi_h(y_i, s_{ij}, \mathbf{x}_{ij})$ is bi-directionally coupled, encoding both sources of evidence and exploring mutual influence and dynamics between social actions and social ties. Such mutual influence and dynamics are crucial and modeling them often leads to improved performance. Given the user action y_i and the graph $\mathcal{G}$, we devise the following model for the probability distribution of s_{ij} depending on both observable and latent factors as:

$$P_{s_{ij}|(y_i,\mathcal{G})} \sim \phi'(s_{ij}, v_i, v_j, \mathbf{w}_{ij}), \quad P_{s_{ij}|(y_i,\mathcal{G})} \sim \phi_h(y_i, s_{ij}, \mathbf{x}_{ij}), \quad P_{s_{ij}|(y_i,\mathcal{G})} \sim \phi'(s_{ij}, v_i, v_j, \mathbf{w}_{ij})\phi_h(y_i, s_{ij}, \mathbf{x}_{ij}). \quad (2)$$

3.4 Modeling Mutual Influence

The mutual correlation between social actions and social ties advocates joint modeling of both sources of evidence in a single unified framework. Based on the above descriptions, we define our mutual latent random graph (MLRG) based on exponential-family random graph models (ERGMs) ((Frank and Strauss, 1986), (Wasserman and Pattison, 1996)), which have gained tremendous successes in social network analysis and have even become the current state-of-the-art (Robins *et al.*, 2007). To design a concrete model, one needs to specify distributions for the dependencies for MLRGs. According to the celebrated Hammersley-Clifford theory, the joint conditional distribution $P_{(y_i,s_{ij})|\mathcal{G}}$ is factorized as a product of potential functions over all cliques in the graph $\mathcal{G}$ and we summarize the MLRG in the above table. In summary, our model consists of three factors: the factor $\phi(y_i, v_i, \mathbf{m}_i)$ measuring dependencies

of the social action y_i conditioned on $\mathcal{G}$, the factor $\phi'(s_{ij}, v_i, v_j, \mathbf{w}_{ij})$ measuring the social tie s_{ij} between two arbitrary users v_i and v_j in $\mathcal{G}$, and the latent factor $\phi_h(y_i, s_{ij}, \mathbf{x}_{ij})$ exploiting mutual influence between the social action y_i and social tie s_{ij}.

The three factors $\phi(\cdot)$, $\phi_h(\cdot)$, and $\phi'(\cdot)$ can be instantiated in different ways. In this paper, each factor is defined as the exponential family of an inner product over sufficient statistics (feature functions) and corresponding parameters. Each factor is a clique template whose parameters are tied. More specifically, we define these factors as

$$\phi(y_i, v_i, \mathbf{m}_i) = \frac{1}{Z_\alpha} \exp\{\sum_{y_i \in \mathcal{Y}} \alpha \mathbf{f}(y_i, v_i, \mathbf{m}_i)\}, \quad \phi_h(y_i, s_{ij}, \mathbf{x}_{ij}) = \frac{1}{Z_\beta} \exp\{\sum_{y_i \in \mathcal{Y}, s_{ij} \in \mathcal{S}} \beta \mathbf{g}(y_i, s_{ij}, \mathbf{x}_{ij})\},$$
$$\phi'(s_{ij}, v_i, v_j, \mathbf{w}_{ij}) = \frac{1}{Z_\gamma} \exp\{\sum_{s_{ij} \in \mathcal{S}} \gamma \mathbf{h}(s_{ij}, v_i, v_j, \mathbf{w}_{ij})\}, \tag{3}$$

where α, β, and γ are real-valued weighting vectors and $\mathbf{f}(\cdot)$, $\mathbf{g}(\cdot)$, and $\mathbf{h}(\cdot)$ are corresponding vectors of feature functions.

We denote $\Theta = \{\alpha, \beta, \gamma\}$ as the set of model's parameters, and concatenate all factor functions as $\Theta \mathbf{q}(y_i, s_{ij}) = \alpha \mathbf{f}(y_i, v_i, \mathbf{m}_i) + \beta \mathbf{g}(y_i, s_{ij}, \mathbf{x}_{ij}) + \gamma \mathbf{h}(s_{ij}, v_i, v_j, \mathbf{w}_{ij})$, the joint probability distribution shown in the above table can be rewritten as

$$P_{(\mathbf{y},\mathbf{s})|\mathcal{G}} = \prod_{y_i \in \mathcal{Y}, s_{ij} \in \mathcal{S}} \Phi(y_i, s_{ij}) = \frac{1}{Z} \exp\{\sum_{y_i \in \mathcal{Y}, s_{ij} \in \mathcal{S}} \Theta \mathbf{q}(y_i, s_{ij})\}, \tag{4}$$

where $Z = Z_\alpha Z_\beta Z_\gamma$ is the partition function of our MLRG model.

Figure 1 shows an example social network ($\mathbf{V} = \{v_1, v_2, v_3, v_4, v_5, v_6\}$, $\mathcal{Y} = \{\text{active}, \text{idle}\}$, $\mathcal{S} = \{\text{friend}, \text{colleague}, \text{family}\}$) and the corresponding 3D graphical representation of the MLRG model. The functions $\mathbf{f}(\cdot)$ model dependencies of social actions in the bottom part, and the functions $\mathbf{h}(\cdot)$ model dependencies of social ties in the upper part. More importantly, the functions $\mathbf{g}(\cdot)$ capture mutual influence and dependencies between social actions and social ties. As we will see, this modeling offers a natural formalism for exploiting bi-directional dependencies and interactions between social actions and social ties to capture their mutual influence, as well as a great flexibility to incorporate a large collection of arbitrary, overlapping and nonindependent features.

3.5 Discussion

Noticeably, our proposed MLRG model is essentially different from the standard exponential-family random graph models (ERGMs) and the prior models discussed in Section 2 mainly in two aspects. Firstly, compared to the standard ERGMs, the MLRG model defines latent factors to assume mutual and dynamical interaction between social ties and social actions. Secondly, compared to the prior models such as (Ma *et al.*, 2009) and (Tang *et al.*, 2011), MLRG provides a single unified framework to address both social action prediction and social tie inference simultaneously while enjoying the benefits of both sources of evidence.

Importantly, we give an analytical explanation on the mutual nature of our model in terms of a random walk (Lovász, 1996) perspective. A random walk on the graph $\mathcal{G}$ is a reversible Markov chain on the vertexes $\mathbf{V}$. The social influence propagation procedure occurs through information diffusion in the social graph $\mathcal{G}$. More specifically, a user v_i will propagate his/her influence to other related users, and will propagate more to the user which has a stronger relation (e.g., friendship) with v_i. The influence propagation will stop when the social graph reaches an equilibrium state, in which both social actions and social ties are mutually reinforced. Interestingly, this process is consistent with the homophily phenomenon that a user in the social network tends to be similar to his/her connected neighbors.

4 Learning and Inference

4.1 Mutual Optimization

The goal of learning MLRG model is to estimate a parameter configuration $\Theta = \{\alpha, \beta, \gamma\}$ such that the log-likelihood of observation is maximized. We define the log-likelihood objective function $\mathcal{O}(\Theta)$ of the

Algorithm 1: The Mutual Gradient Descent (MGD) algorithm

Input: The social graph $\mathcal{G}$, number of iterations n, and the learning rate η.
Output: Optimized parameters $\Theta^* = \{\alpha^*, \beta^*, \gamma^*\}$.
while *equilibrium states or a threshold number of iterations are not reached* **do**
  repeat
    Choose a random example $(y_i, s_{ij}) \in \mathcal{G}$ as a sample;
    Optimize social action parameters α **and** β:
      Compute the approximated gradients $\frac{\partial \mathcal{O}'}{\partial \alpha}$ and $\frac{\partial \mathcal{O}'}{\partial \beta}$ according to Eq. (6), Eq. (7) and stochastic approximation;
      Update α and β with learning rate η: $\alpha \leftarrow \alpha - \eta \cdot \frac{\partial \mathcal{O}'}{\partial \alpha}, \quad \beta \leftarrow \beta - \eta \cdot \frac{\partial \mathcal{O}'}{\partial \beta}$.
      `// Explore social tie influence`
    Optimize social tie parameters γ **and** β:
      Compute the approximated gradients $\frac{\partial \mathcal{O}'}{\partial \gamma}$ and $\frac{\partial \mathcal{O}'}{\partial \beta}$ according to Eq. (8), Eq. (7) and stochastic approximation;
      Update γ and β with learning rate η: $\gamma \leftarrow \gamma - \eta \cdot \frac{\partial \mathcal{O}'}{\partial \gamma}, \quad \beta \leftarrow \beta - \eta \cdot \frac{\partial \mathcal{O}'}{\partial \beta}$.
      `// Explore social action influence`
  until *converge*;
end
return α^*, β^*, *and* γ^*

observation given the graph $\mathcal{G}$ as

$$\mathcal{O}(\Theta) = \log P_{(\mathbf{y},\mathbf{s})|\mathcal{G}} - \log \Omega(\Theta) = \log[\exp\{\sum_{y_i \in \mathcal{Y}, s_{ij} \in \mathcal{S}} \Theta \mathbf{q}(y_i, s_{ij})\}] - \log Z - \log \Omega(\Theta), \tag{5}$$

where $\Omega(\Theta)$ is regularization to reduce over-fitting and a common choice is a spherical Gaussian prior with mean 0 and covariance $\delta^2 I$. $\Omega(\Theta) = \sum_{y_i \in \mathcal{Y}} \frac{\alpha^2}{2\sigma^2} + \sum_{y_i \in \mathcal{Y}, s_{ij} \in \mathcal{S}} \frac{\beta^2}{2\sigma^2} + \sum_{s_{ij} \in \mathcal{S}} \frac{\gamma^2}{2\sigma^2}$.

We propose a mutual gradient descent (MGD) algorithm based on the stochastic gradient descent (SGD) ((Lecun *et al.*, 1998), (Bottou, 2004)) framework, for estimating the parameters efficiently in a mutual and collaborative manner. Once we have optimized the social action parameters α and β, the influence and hypotheses of social action can aid the learning of the social tie parameters γ and β, and vice versa. As shown in Algorithm 1, β is coupled parameter vector for both actions and ties, and is updated twice in each iteration of MGD. By doing so, MGD not only allows learning of social action parameters to capture social tie influence, but it also optimizes social tie parameters to alleviate social action influence. This training procedure runs iteratively until converge to boost both the optimization of social actions and social ties.

Each iteration of the MGD algorithm consists of drawing an example at random and applying parameter updates by moving in the direction defined by the stochastically approximated gradient of the loss function (e.g., $\frac{\partial \mathcal{O}'}{\partial \alpha}$). We update each parameter with a learning rate η. Ideally, each parameter should have its own learning rate. If shared parameter weights are used, the best learning rate of a weight should be inversely proportional to the square root of the number of connection sharing that weight (Bottou, 2004). In our MGD implementation, for simplicity we use the same learning rate for all the parameters. We select a small subset of training data and try various learning rates on the subset, then pick the one that most reduces the loss and use it on the full dataset. We summarize the partial derivatives of the log-likelihood function $\mathcal{O}$ with respect to the parameter vectors α, β and γ as follows:

$$\frac{\partial \mathcal{O}}{\partial \alpha} = \sum_{y_i \in \mathcal{Y}} \mathbf{f}(y_i, v_i, \mathbf{m}_i) - \sum_{y_i \in \mathcal{Y}} \mathbf{f}(y_i, v_i, \mathbf{m}_i) \times P_{(\mathbf{y},\mathbf{s})|\mathcal{G}} - \sum_{y_i \in \mathcal{Y}} \frac{\alpha}{\sigma^2}, \tag{6}$$

$$\frac{\partial \mathcal{O}}{\partial \beta} = \sum_{y_i \in \mathcal{Y}, s_{ij} \in \mathcal{S}} \mathbf{g}(y_i, s_{ij}, \mathbf{x}_{ij}) - \sum_{y_i \in \mathcal{Y}, s_{ij} \in \mathcal{S}} \mathbf{g}(y_i, s_{ij}, \mathbf{x}_{ij}) \times P_{(\mathbf{y},\mathbf{s})|\mathcal{G}} - \sum_{y_i \in \mathcal{Y}, s_{ij} \in \mathcal{S}} \frac{\beta}{\sigma^2}, \tag{7}$$

$$\frac{\partial \mathcal{O}}{\partial \gamma} = \sum_{s_{ij} \in \mathcal{S}} \mathbf{h}(s_{ij}, v_i, v_j, \mathbf{w}_{ij}) - \sum_{s_{ij} \in \mathcal{S}} \mathbf{h}(s_{ij}, v_i, v_j, \mathbf{w}_{ij}) \times P_{(\mathbf{y},\mathbf{s})|\mathcal{G}} - \sum_{s_{ij} \in \mathcal{S}} \frac{\gamma}{\sigma^2}. \tag{8}$$

It is worth noting that the MGD algorithm computes approximations of the gradients, due to the intractability of the normalizing constant Z in the log-likelihood of our MLRG model. Our proposed

MGD algorithm is a generalized extension and it distinguishes from the standard SGD algorithm in two aspects: (1) MGD optimizes three types of parameters simultaneously, thus MGD is much more general than SGD, and it is more scalable and applicable to real-world problems. (2) MGD performs mutual and collaborative optimization to enable mutual influence between social actions and social ties, whereas SGD does not take such influence into account.

4.2 Complexity Analysis

Given several conditions including a suitable choice of the learning rate and a convex or pseudo-convex objective function, the MGD algorithm converges almost surely to a global optimum, otherwise it converges almost surely to a local optimum. In our experiments, this algorithm has good performance even if it does not reach the global optimum. Let D be the number of samples in the social graph $\mathcal{G}$, n be the number of iterations, and $\overline{p}$ be the average number of non-zero attributes (features) per sample, the computational complexity of our MGD algorithm takes $O(nD\overline{p})$. As can be seen, this algorithm is computationally efficient, and convergence is very fast when the training examples are redundant since only a few examples are needed to sample. Furthermore, this algorithm is online and scale sub-linearly with the amount of training data, making it very attractive for large-scale datasets.

4.3 Inference

The objective of inference is to find the most likely types of actions $\mathbf{y}^*$ and corresponding social tie labels $\mathbf{s}^*$, that is, to find $(\mathbf{y}^*, \mathbf{s}^*) = \arg\max_{(\mathbf{y},\mathbf{s})} P_{(\mathbf{y},\mathbf{s}|\mathcal{G})}$. The inference procedure is straightforward. Based on the learned parameters $\Theta^* = \{\alpha^*, \beta^*, \gamma^*\}$, we firstly predict the label of each social action y_i by finding a labeling assignment that maximizes $P_{y_i|\mathcal{G}}$ as $y_i^* = \arg\max_{y_i \in \mathcal{Y}} P_{y_i|\mathcal{G}}$. We then infer the social tie label s_{ij} such that $s_{ij}^* = \arg\max_{s_{ij} \in \mathcal{S}} P_{s_{ij}|(y_i,\mathcal{G})}$.

5 Experiments

5.1 Foursquare Data

We crawled one dataset from Foursquare[1], a popular location-based mobile social networking site for mobile devices (e.g., smartphones) for our experimental evaluation. Foursquare allows a user to check in at a physical location via his cellphone, and then let his online friends know where he is by publishing such check-in action online. Users check-in at venues using a mobile website, text messaging or a device-specific application by selecting from a list of venues the application locates nearby. Location is based on GPS hardware in the mobile device or network location provided by the application, and the map is based on data from the OpenStreetMap project. Each check-in awards the user points and sometimes badges. Figure 2 illustrates a snapshot of the Foursquare application interface on smartphones.

To alleviate the data sparsity problem for better evaluation, we selected check-in venues which have been visited by at least two distinct users, and users who have checked in at least 10 distinct venues. The resulting dataset contains 12,368 distinct users, 186,745 venues, 1,425,664 check-in behaviors and 56,395 social connections from January 2012 to December 2012. Table 1 lists the more detailed statistical information on our dataset, where the "Avg. Num. of Check-ins" is the average number of check-ins per user, and "Max. Num. of Check-ins" is the maximal number of check-ins among users (similarly for "Avg. Num. of Friendships" and "Max. Num. of Friendships"). The "Average Clustering Coefficient (ACC)" is a measure of the degree to which users in the Foursquare network tend to cluster together, and "Diameter" is the longest shortest path in the network. All user and venue information has been anonymized. Each check-in has a unique id as well as the user id and the venue id, and each social connection consists of two users represented by two unique ids.

5.2 Task

Mobile phones have become an important tool for communication and they are an ideal platform for understanding social influence and social dynamics. Using our Foursquare dataset, we can investigate the mutual influence between social actions and social ties. More specifically, we can investigate how

[1] https://foursquare.com/

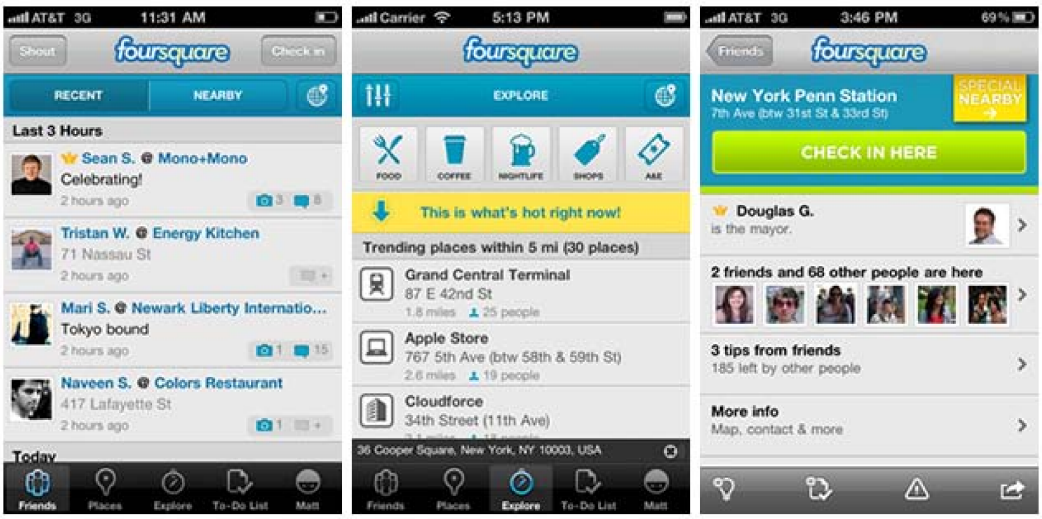

Figure 2: A snapshot of the Foursquare application interface on smartphones.

Avg. Num. of Check-ins	115.27	Max. Num. of Check-ins	657
Avg. Num. of Friendships	4.56	Max. Num. of Friendships	265
Average Clustering Coefficient (ACC)	0.42	Diameter	12

Table 1: Statistical information of our Foursquare dataset.

the friendship relations affect users' check-in behaviors, and how users' check-in behaviors affect their friendships. Figure 3 gives an illustrative example of social action prediction and social tie discovery tasks in our Foursquare dataset. Given an unseen Foursquare social network dataset, our objective is to predict whether the users have check-in behaviors and whether there are friendship relations between these users. In the right figure, we list the predicted check-in behaviors (in red color) and the inferred friendship relations between users (in green color). The probabilities associated with the predictions represent corresponding confidence scores.

5.3 Evaluation Methodology

We exploited a wide range of important features to define the factors $\phi(\cdot)$, and $\phi'(\cdot)$, including temporal and social features such as the number of check-ins and number of new check-ins in a user's history, number of friends of a user, the check-in information from a user's friends, etc. For the coupled latent factor $\phi_h(\cdot)$, we incorporated social tie evidences and hypotheses as features to capture social actions, and we also incorporated social action evidences and hypotheses as features to leverage social ties.

For quantitative performance evaluation, we used the standard measures of Precision (P), Recall (R), and F-measure (the harmonic mean of P and R: $\frac{2PR}{P+R}$) for both social action prediction and social tie inference. We performed four-fold cross-validation on this dataset, and took the average performance. We compared our approach with the following alternative methods for predicting social actions and inferring social ties:

–**SVM**: This model views social action prediction and social tie inference as two separate classification problems, and solves them independently. We used the SVM-light[2] package for this model.

–**ERGM**: This is the traditional exponential-family random graph model without the latent factor $\phi_h(\cdot)$ incorporated for social action prediction and social tie inference. Similar to SVM, this model also performs them separately.

–**DCRF**: This model is a dynamical and factorial CRF (Sutton *et al.*, 2007) used to jointly solve the two tasks. This model was originally proposed for labeling and segmenting sequence data, and we directly

ERGM	78.85	77.39	78.11
DCRF	82.45	76.56	79.40
MLRG	**84.33**	**83.89**	**84.11**

Table 3: Comparative performance of different models for social tie inference. The best results are printed in boldface.

applied it for our tasks in social network analysis.

All these models exploited standard parameter learning and inference algorithms in our experiments. To avoid over-fitting, penalization techniques on likelihood were also performed. All experiments were performed on the Linux workstation, with 24 2.5GHz Intel Xeon E5-2640 CPUs and 16 GB of memory.

5.4 Performance

Table 2 shows the performance on social action prediction and Table 3 shows the performance on social tie inference of different models, respectively. The best Precision, Recall and F1-measure of these results are highlighted. Our method consistently outperforms other comparative methods on the F-measure. The improvement is statistically and significantly better according to McNemar's paired tests. These results not only imply that there exists high correlation and mutual influence between social actions and social ties, but also demonstrate the feasibility and effectiveness of our model for exploring them.

The SVM model solves social action prediction and social tie inference independently without considering mutual influence and benefits between them, thus leading to the worst performance. The ERGM outperforms SVM by capturing social network structures. However, the performance of this model is still limited and there is a large room for improving. The DCRF model easily outperforms both SVM and ERGM by modeling social actions and social ties jointly in a single framework. However, compared to our MLRG model, there are still some shortcomings of DCRF. DCRF was proposed to label and segment sequence data, such as POS tagging and NP chunking (Sutton *et al.*, 2007). The graphical structure of DCRF is not well suited for social networks to capture mutual influence. The merits of our proposed MLRG model over other models principally come from (1) appropriate graphical structure for social network modeling, especially the coupled latent factor to exploit mutual influence simultaneously, and (2) the mutual and collaborative learning algorithm MGD to reinforce the optimization of both social actions and social ties.

5.5 Effect of Mutual Influence and Analysis

We also examined the nature and effectiveness of the associated latent factors on the mutual influence, and Figure 4 demonstrates their feasibility in our modeling. Note that if we do not incorporate the latent factors, our MLRG model becomes the traditional ERGM baseline approach. It shows that the

latent factors consistently enhance Precision, Recall, and F-measure for both social action prediction and social tie inference tasks. For example, the latent factors significantly improve the F-measure by 8.27% (from 80.19 to 88.46) for social action prediction, and improve the F-measure by 6.0% (from 78.11 to 84.11) for social tie discovery, respectively. These results not only illustrate that social actions and social ties influence each other to a large extent, but also demonstrate the feasibility and effectiveness of our latent factors for exploring them.

We performed an in-depth error analysis to provide gains of our MLRG model and some insights on the influence between users' check-in behaviors and users' friendship relations. By carefully investigating our Foursquare dataset, we found that approximately 75% users tend to cluster together to create tightly knit groups characterized by a relatively high density of friendship relations or ties, and the remaining 25% users loosely or seldom connect with each other through the friendship relations. In other words, 75% users form high density of relationship ties and the average clustering coefficient (ACC) is high (0.61). However, the tie density of the remaining 25% users is much lower, since the ACC of these users is only 0.18. Compared to the baseline methods (especially the SVM and ERGM methods), the performance improvement of our MLRG model mainly comes from 75% users with high density of friendship ties. In particular, about 20% prediction errors (including social action and social tie prediction errors) of such users made by the SVM model can be corrected by our MLRG model. This finding shows that, the mutual influence between users' check-in behaviors and users' friendship relations increases with the density growth of the friendship relations of these users. This finding is intuitively correct and is consistent with the homophily theory. More interestingly, this finding also implies the gains and merits of our MLRG model for exploiting mutual influence, especially when the users in the Foursquare network cluster together tightly with high density of ties.

5.6 Efficiency

A number of learning algorithms can be applied for parameter optimization of our MLRG model. Table 4 summarizes the efficiency of several alternative optimization algorithms for learning our model's parameters. We compared the learning time (hr.) and inference time (sec.) of the MGD algorithm to loopy belief propagation (LBP), Markov chain Monte Carlo(MCMC) Gibbs sampling (Geman and Geman, 1984), and variational mean-field (VMF) approximation algorithms (Wainwright and Jordan, 2008). Both Sutton *et al.* (2007) and Tang *et al.* (2011) used LBP for parameter estimation. LBP is inherently unstable and may cause convergence problems. When the graph has large tree-width as in our case, the LBP algorithm is inefficient, and is slow to converge. In Gibbs sampling, the candidate sample is always accepted with the probability of 1, lacking the capability of measuring quality of samples and eliminating low grade samples. The VMF approach aims to minimize the Kullback-Leibler (KL) divergence between an approximated distribution Q and the target distribution P by finding the best distribution Q from some family of distributions for which an inference is feasible. The MGD algorithm we proposed is very efficient. It is particularly notable that our MGD algorithm takes much less time than other three algorithms for learning. In particular, our proposed algorithm is over orders of magnitude faster than the LBP for running.

6 Conclusions and Future Work

Finally, we answer the questions in Section 1 to draw the conclusions of this paper as follows:

Is there any dynamics or mutual influence between social actions and social ties? Doubtlessly, social actions and social ties are highly correlated and mutually reinforced. We propose a single unified framework, mutual latent random graph (MLRG), to exploit homophily for simultaneous social action prediction and social tie discovery. The MLRG model incorporates coupled latent factors to capture dynamics and mutual influence between social actions and social ties. Moreover, we propose the mutual gradient descent (MGD) algorithm to perform mutual and collaborative optimization to reinforce both social actions and social ties. By coupling actions with ties jointly in a single coherent framework, MLRG achieves significantly better performance on both social action prediction and social tie inference on our collected Foursquare dataset, compared to several state-of-the-art existing models.

To what extent do they influence each other? We perform an in-depth analysis to show the gains and merits of our MLRG model, as well as some insights on the influence between users' check-in behaviors and users' friendship relations. The finding on our real-world Foursquare data demonstrates that social actions (users' check-in behaviors) and social ties (users' friendship relations) influence each other to a considerable degree when the users connect each other tightly with high density of ties in the network. Experimental results also illustrate the feasibility and effectiveness of our latent factors for exploring the mutual influence. In particular, the latent factors in our model significantly improve the F-measure by 8.27% (from 80.19 to 88.46) for social action prediction, and improve the F-measure by 6.0% (from 78.11 to 84.11) for social tie discovery, respectively.

Two directions of future work appear attractive: Inferring fine-grained and multiple relationships between users (such as friendship, family, colleague, and advisor-adviser, etc.) on complex social networks and extending our established optimization algorithms for parallel and distributed learning based on the Hadoop MapReduce framework to handle large scale social networks involving billions of users.

Discovering Topical Aspects in Microblogs

ankannan@microsoft.com

Abstract

We address the problem of discovering topical phrases or "aspects" from microblogging sites like Twitter, that correspond to key talking points or buzz around a particular topic or entity of interest. Inferring such topical aspects enables various applications such as trend detection and opinion mining for business analytics. However, mining high-volume microblog streams for aspects poses unique challenges due to the inherent noise, redundancy and ambiguity in users' social posts. We address these challenges by using a probabilistic model that incorporates various global and local indicators such as "uniqueness", "diversity" and "burstiness" of phrases, to infer relevant aspects. Our model is learned using an EM algorithm that uses automatically generated noisy labels, without requiring manual effort or domain knowledge. We present results on three months of Twitter data across different types of entities to validate our approach.

1 Introduction

Microblogging sites such as Twitter and Weibo are evolving into the social platforms of choice for users to express and discuss, in real-time, their thoughts and ideas on a plethora of subject matters. It is thus important to use these microblog streams to identify the "buzz" or "talking points" regarding any topic or entity of interest, including organizations, products and social issues. This has several applications: For businesses, identifying what its customers are mostly talking about allows them to better engage with their customer base (Burton and Soboleva, 2011; Patino et al., 2012), fine-tune brand awareness and marketing campaigns (Popescu and Jain, 2011), and provide real-time feedback about customer preferences and complaints. Similarly, policy makers and think tanks would benefit from understanding the buzz around various socio-cultural or environmental issues, that could enable them to make well-informed choices and decisions. Infering such key talking points in social media also enables higher layer social-analytics applications such as trend detection, event tracking, and fine-grained opinion and sentiment analysis.

The goal of this paper is to automatically infer such entity-specific buzz in social media, which we represent using key phrases identified from microblog posts about the entity. Following past literature (Kobayashi et al., 2007; Mukherjee and Liu, 2012), we call these topical phrases as *aspects*. Thus, given a stream of microblog posts about an entity of interest, we devise an algorithm that *automatically discovers a ranked list of the top aspects that succinctly represent the buzz or key talking points among users about the entity.* As an illustrating example, Figure 1 shows the top 10 aspects discovered for each month by our aspect discovery algorithm for the Microsoft Surface tablet using 6 month of Twitter data. For each month we depict the key events and news stories (below the timeline) related to the Surface, along with the set of discovered aspects (above the timeline). As seen from the figure, several of the top aspects do not reflect product features or attributes, but instead capture the buzz among Twitter users around recent events or news related to the Surface. For example, the aspects "surface pricing" and "surface preorders" in October refer to the discussions on Twitter following a press release providing details of the Surface pricing and preorder dates. Similarly, the aspect "Oprah tweets" in November corresponds

Proceedings of COLING 2014, the 25th International Conference on Computational Linguistics: Technical Papers, pages 860–871, Dublin, Ireland, August 23-29 2014.

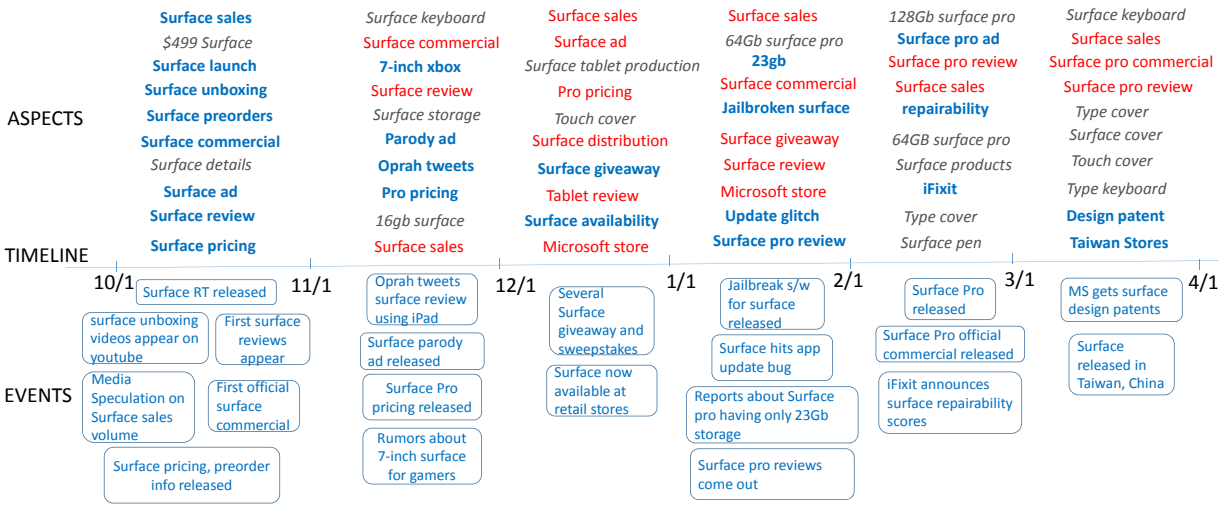

Figure 1: Temporal evolution of top monthly aspects for 'Microsoft Surface' over 6 months (October 2012 to March 2013). The aspects identified by our algorithm (for each month) is shown above the time line, while key events regarding the product is shown below. Aspects that directly relate to the events are shown in bold blue, while aspects that have no bearing to the news are shown in italics. The aspects that were related to an event in previous months but has persisted as an aspect are shown in red using normal font.

to discussions around media coverage of how Oprah Winfrey tweeted a review of the Surface tablet from her iPad. The aspects "iFixit" and "repairability" refer to the unveiling of the iFixit repairability report for the Surface in February. On the other hand, we also see more traditional product feature or attributes that are not correlated to external events but are key discussion points across multiple months, such as "keyboard" or "touch cover".

While there exists a rich line of work (refer to (Liu, 2012) for a comprehensive survey) in aspect identification from customer reviews, blogs or discussion forums, mostly for fine-grained opinion mining for products, there has been little work in the context of aspect discovery from large scale microblog posts. Microblogs pose a unique set of challenges that makes it difficult to directly apply existing methods from prior work. For example, in several papers, frequently occurring noun phrases is used as the building block for detecting aspects (Hu and Liu, 2004a; Hu and Liu, 2004b; Ku et al., 2006). However, for microblogs, frequency of a noun phrase alone is an insufficient indicator of an aspect, due to the inherent noise (unlike reviews, microblog posts are short and often not as focused) and redundancy (*e.g.,* due to retweeting in the context of Twitter). Yet another challenge unique to microblog streams is that the brevity of the posts provide inadequate context and structure. In addition, they are also noisy, with a single tweet often containing both relevant and irrelevant content for a given entity. Due to these reasons, well-known probabilistic approaches (*e.g.,* Topic Models (Mei et al., 2007; Titov and McDonald, 2008) or Conditional Random Fields (Jakob and Gurevych, 2010)), that work well for aspect identification from reasonably long and syntactically well-formed documents such as reviews and blogs, becomes immediately inappropriate in the microblog setting. Additionally, the high volume and velocity of social media streams calls for a scalable, fully automated approach that seamlessly works for a variety of entities and requires no domain-specific knowledge.

We address these challenges inherent in aspect discovery from microblog streams in a principled way: we propose quantifiable indicator measures of "uniqueness", "diversity" and "burstiness" based on insights that are fairly intuitive and yet are generic enough to model the characteristics of relevant aspects for a range of diverse entities. We represent candidate phrases in terms of these three indicators. We propose a probabilistic model for scoring the candidate phrases (§ 2.3) corresponding to an entity of interest. For every entity, the model automatically clusters the indicators and for each cluster, learns relative importance between the indicators for scoring the candidate aspects. Given a collection of <candidate aspects, noisy label> pairs where the noisy label reflects if the corresponding candidate is an aspect

(albeit, noisly), we use an Expectation-Maximization algorithm for training the model. We also present an approach to leverage web search engine results (§ 2.4) to automatically obtain noisy labelled data for any entity. While being entity specific, our approach is highly scalable, entity-agnostic and does not require any manual effort. We validate our results on diverse entities, using *all* tweets from Twitter corresponding to a three month period from January 2013 to March 2013.

Related Work: To the best of our knowledge, the only works related to aspect discovery from microblog posts are (Spina et al., 2012) and (Zhao et al., 2011). In (Spina et al., 2012), four information retrieval functions were compared for identifying aspects from a set of tweets about companies. They showed that a TF-IDF based approach performed the best. Their experiments were however not performed across multiple domains, and used a very small number of tweets for each company. Furthermore, our 'uniqueness' based ranking (§ 2.2) that we use as one baseline is quite similar to their TF-IDF approach, and in our large scale evaluation over diverse domains, we show that TF-IDF or uniqueness alone is not sufficient for efficient aspect discovery (§ 3). The work by (Zhao et al., 2011) proposes an unsupervised approach for keyphrase ranking based on measures of "interestingness" (which is similar to our uniqueness indicator) and "relevance". However, as we show in our experiments (§ 3), the performance of this method is entity–dependent and does not naturally scale to all entities.

The rest of the paper is organized as follows. We describe our algorithm in § 2, including the various indicators that we use to characterize an aspect, the automatic label generation, and our probabilistic model. In § 3, we present experimental results and evaluation of our algorithm along with other baselines on the three month Twitter data set. We conclude in § 4 with remarks on future work.

2 Approach

We formulate the problem of identifying aspects as follows: **Problem statement:** Let e be an entity and s be a time period of interest. We use $\mathcal{T}^s$ to denote the set of all tweets in time period s, and $\mathcal{T}_e^s \subset \mathcal{T}^s$ to be the set of all tweets about e in time period s [1]. Then, we wish to identify the set of k phrases from $\mathcal{T}_e^s$ which are most likely to be valid aspects of e.

Solution overview: Given e, we first identify a set of candidate phrases for aspects from $\mathcal{T}_e^s$ (§2.1). For each phrase, we compute a global indicator, *uniqueness*, that measures how strongly the phrase is correlated with e by comparing its occurrence in $\mathcal{T}_e^s$ and $\mathcal{T}^s$. We also compute two local indicators, *diversity* that measures how diversely the phrase is used in $\mathcal{T}_e^s$, and *burstiness* that measures the temporal activity around the phrase usage in $\mathcal{T}_e^s$ (§ 2.2). We train a probability model (§ 2.3) that captures non-linear relationships between the indicators using a combination of linear decision surfaces. The training labels are obtained using a completely automated approach (§ 2.4). The model is trained independently for each entity, and subsequently used in inferring aspects for the entity during the time period of interest.

2.1 Candidate Aspects

We expect an aspect of an entity to be a phrase on which users can say something subjective. This intuitive requirement is enforced by restricting candidate aspects to be noun phrases (Hu and Liu, 2004b; Popescu and Etzioni, 2007) that are qualified with an adjective within short proximity (around four words) in at least one tweet (Blair-Goldensohn et al., 2008). We use a Twitter-specific part-of-speech tagger (Owoputi et al., 2013) to identify a candidate set of noun phrases in $\mathcal{T}_e^s$ that are used in conjunction with an adjective. After resolving plural nouns to their singular forms, this results in a few thousand candidate phrases per entity for a month of tweets.

2.2 Indicators

We represent a phrase using measurements across three dimensions that captures "diversity", "uniqueness" "burstiness" of usage. These are described in detail below.

[1] While accurately classifying microblog posts to extract posts relevant to an entity is a research problem in itself, this is outside the scope of this work. In this work, we use keyword based classifiers for our entities.

2.2.1 Diversity

Intuitively, a genuine aspect of an entity is more likely to have been discussed on Twitter in the context of that entity, compared to other noun phrases. While one can consider a metric like occurrence frequency (*e.g.,* (Liu, 2012)) to capture this intuition, in microblog settings like Twitter, this can overestimate the importance of a phrase because of redundancy of content due to (a) simple retweeting by followers, (b) multiple users posting the same or very similar content, especially when talking about news and events, and (c) same user posting multiple versions of the same tweets due to automated tweet applications. As an example, the most frequently used noun phrase on Twitter for the entity 'Microsoft Surface' during March was "tablet-a-day giveaway". However, all the tweets containing this phrase referred to a lottery contest that required users to tweet a pre-specified sentence about the Surface. Hence, this phrase cannot be considered a relevant aspect.

We propose factoring out such redundancy by using a notion of "diversity" of content about that aspect. To this effect, for each candidate aspect, its "Diversity" indicator is obtained by computing a score based on the amount of diverse content in the set of tweets about the aspect. To efficiently compute this diversity score, we use the Simhash algorithm (Charikar, 2002) based on Locality Sensitive Hashing (Indyk and Motwani, 1998). Simhash measures the similarity of two tweets t_1 and t_2 by hashing them into small f-bit fingerprints (we use $f = 128$), and comparing the Hamming distance between them. The Locality Sensitive Hash function H used by Simhash ensures that

$$Pr[H(t_1) = H(t_2)] = Sim(t_1, t_2),$$

where $Sim(t_1, t_2)$ is the cosine similarity between t_1 and t_2.

Thus, it suffices to compute a diversity score on the (much smaller) set of 128-bit fingerprints of the tweets containing the aspect. We define this score as the cardinality of the largest subset $S \subset \mathcal{T}_e^s$ of tweets such that the Hamming distance d between the fingerprints of any pair in S is at most 90% of the fingerprint length. While this is a combinatorially hard problem, we use a greedy heuristic to approximate this score using the following steps: 1) Initialize S to a random tweet $r \in T_e^s$. 2) At each iteration, let $t \in \mathcal{T}_e^s \setminus S$ maximize $D(S, t)$. (Here we define $D(S, t) = \min_{x \in S} d(H(x), H(t))$). If $D(S, t) > 0.9$, add t to S. Else return $|S|$.

2.2.2 Uniqueness

Another property of a relevant aspect for an entity is a notion of "uniqueness" to that entity. Intuitively, an aspect should have a higher propensity of being used in tweets about that entity, compared to a generic set of tweets. For example, in the case of Microsoft Surface, several commonly used noun-phrases might have a high frequency of occurrence or a high diversity score such as "news" or "store". However such phrases are arguably too generic to be considered as an aspect of Microsoft Surface. Hence we need to evaluate a candidate noun phrase in terms of its frequency in the set of tweets for that entity, versus its frequency across all tweets in the same time window. In particular, we define the uniqueness indicator of a phrase p in a time period s as:

$$\text{uniqueness}_e^s[p] = \frac{\sum_{t \in \mathcal{T}_e^s} I[\text{p} \in t]}{\sum_{t \in \mathcal{T}^s} I[\text{p} \in t] + \theta}, \tag{1}$$

where $I[\text{p} \in t]$ is an indicator that evaluates to 1 if the tweet t contains the phrase p, and 0 otherwise. θ enforces minimal support (θ tweets from $\mathcal{T}_e^s$) required for p to be unique. We used $\theta = 10$.

Note that this is reminiscent of the tf-idf metric in information retrieval and also used in (Spina et al., 2012); The numerator corresponds to the notion of term-frequency and the denominator to document frequency. This can also be interpreted probabilistically, by considering a bernoulli variable Z that models how unique the phrase is to e. Then the above definition is similar to a maximum-likelihood estimate of Z using a Beta distribution with θ as the prior.

2.2.3 Burstiness

Another indicator of a relevant aspect of an entity is a noun phrase that has an unexpected surge in its frequency of occurrence among tweets of the entity, in a short period of time. This could be due to an

emerging news story, event or talking point about the entity and hence indicate that the phrase is strongly related to the entity, even if the overall frequency of the phrase over a larger time period might be low.

We capture this notion using the "burstiness" indicator. For each candidate noun-phrase, we create a time-series of its occurrences in tweets of the entity within the specific time window. We then use the burst model due to Kleinberg (Kleinberg, 2002) to extract a burstiness score for the noun-phrase. Kleinberg's model uses a finite-state automaton with different states corresponding to different emission frequencies, where state transitions from a low-frequency state to a high-frequency state signify the onset of a burst. We use an R-implementation (url, 2014) of this algorithm on the time series of occurrences of a noun-phrase to identify the corresponding burst levels, and define the burstiness score of the noun-phrase as the sum of these burst levels. For example, the aspect "shipping lanes" detected by our algorithm for the entity "Global Warming" has relatively low frequency of occurrence overall, however it was a topic of intense discussion on Twitter during a week when mainstream news media reported on a PNAS article discussing opening up of new shipping lanes through the Arctic ocean due to global warming(url, 2013).

2.3 Probabilistic model for aspect identification

Given a candidate phrase and its measurements of indicators, we would like to rank these based on a learned model that takes into account these varied interactions between the indicators. One approach is to directly train a linear classifier such as logistic regression using a training set of <phrase,binary label> pairs. As we show in § 3, this approach does not capture the non-linear dependencies among the indicators and the label, resulting in poor performance. In this paper, we jointly model the space of indicator variables and their labels, which we describe next.

2.3.1 Model specification

A candidate phrase is represented by a three-dimensional continuous-valued random variable $\mathbf{x}$, where x_1 corresponds to 'Diversity', x_2 to 'Uniqueness' and x_3 to'Burstiness'. The relationship between these indicators is captured by a probabilistic Gaussian mixture model. Let c be a random variable with discrete distribution over m components. Then,

$$p(\mathbf{x}, c) = p(c)p(\mathbf{x}|c) = \pi_c \mathcal{N}(\mathbf{x}|\mu_c, \Phi_c), \tag{2}$$

where $p(c)$ is a Multinomial distribution with probability π_c for the c^{th} component such that $\sum_c \pi_c = 1$ and $p(\mathbf{x}|c)$ is a Gaussian distribution for c^{th} component with mean vector μ_c and covariance matrix, Φ_c. Let y be the Bernoulli random variable representing whether a phrase is an aspect, such that:

$$p(y = 1|\mathbf{x}, c) = \frac{1}{1 + \exp(-(\mathbf{w}_c^T \mathbf{x} + b_c))}. \tag{3}$$

Then, the joint distribution over the variables is

$$p(\mathbf{x}, y, c) = p(c)p(\mathbf{x}|c)p(y|\mathbf{x}, c) \tag{4}$$

Note that unlike a mixture of logistic regressors (Bishop, 2007), this formulation captures $p(\mathbf{x}|c)$ which is central to modeling the correlation between the indicators. One can view our formulation as a variant of mixture of experts (Jacobs et al., 1991) wherein the gating functions are represented using the posterior over the mixture model components, as opposed to the soft-max function typically used.

2.3.2 Learning

Given a set of training examples,$[\mathbf{X}, \mathbf{y}] = \{\mathbf{x}_n, y_n\}_{n=1}^N$, the model parameters $\{\mu_c, \Phi_c, \pi_c, \mathbf{w}_c, b_c\}_{c=1}^K$ are learned so as to maximize the probability of observations, $p(\mathbf{X}, \mathbf{y})$. Assuming the training examples are independent and identically distributed, we use an Expectation-Maximization algorithm to learn parameters that maximize the probability of observations, $p(\mathbf{X}, \mathbf{y}) = \prod_{n=1}^N p(\mathbf{x}_n, y_n)$ or equivalently, its log:

$$\log p(\mathbf{X}, \mathbf{y}) = \sum_n \sum_c p(c|\mathbf{x}_n, y_n) \log \frac{p(c_n, \mathbf{x}_n, y_n)}{p(c|\mathbf{x}_n, y_n)} \tag{5}$$

$$= \sum_n \sum_c p(c|\mathbf{x}_n, y_n) \log \frac{p(c)p(\mathbf{x}_n|c)p(y_n|\mathbf{x}_n, c)}{p(c|\mathbf{x}_n, y_n)}, \tag{6}$$

where $p(c|\mathbf{x}_n, y_n)$ is the posterior distribution over c. The parameters are learned using the EM algorithm. by iterating between Expectation(E)-step in which $p(c|\mathbf{x}_n, y_n)$ is estimated for each training instance, and the Maximization(M)-step in which parameters of the model are estimated:
E-step: In this step, $p(c|\mathbf{x}_n, y_n)$ is computed for each training instance by taking derivative of eq. 6 with respect to $p(c|\mathbf{x}_n, y_n)$ and setting to zero, so that $p(c = j|\mathbf{x}_n, y_n) \propto p(\mathbf{x}_n, y_n, c = j)$.
M-step: The mixture component parameters (means and covariances) are updated as weighted averages and deviations from the mean, weighted by the posterior computed in the E-step:

$$\mu_c = \frac{\sum_{n=1}^{N} p(c = j|\mathbf{x}_n, y_n)\mathbf{x}_n}{\sum_{n=1}^{N} p(c = j|\mathbf{x}_n, y_n)} \qquad \Phi_c = \frac{\sum_{n=1}^{N} p(c = j|\mathbf{x}_n, y_n)(\mathbf{x}_n - \mu_c)(\mathbf{x}_n - \mu_c)^T}{\sum_{n=1}^{N} p(c = j|\mathbf{x}_n, y_n)} \quad (7)$$

The weight vector,$\mathbf{w}_c$, for each of the logistic component is estimated using the re-weighted least squares (IRLS) algorithm (Bishop, 2007):

$$\mathbf{w}_c = \arg\max_{\mathbf{w}} \sum_n p(c|\mathbf{x}_n, y_n) \log p(y_n|\mathbf{x}_n, c). \quad (8)$$

Scoring Function: Once the model is trained, it is used to score a candidate phrase for being an aspect. For any phrase with indicator vector $\mathbf{x}$, the probability of it being an aspect is given by the convex combination (weighted by $p(c|\mathbf{x})$) of the outputs from all the regressors: $p(y|\mathbf{x}) = \sum_c p(c|\mathbf{x})p(y|\mathbf{x}, c)$

Choice of number of components: The number of components m is a free parameter in our model, and its value is a function of the training dataset. We use Bayesian information criteria (BIC) (Schwarz, 1978) to choose the optimal number of components for training. In particular, we train models by varying K and pick the one with the largest BIC given by $\log p(\mathbf{X}, \mathbf{y}|\theta_m) - \frac{|\theta_m|}{2} \log N$ where θ_m is the model with m components having $|\theta_m|$ parameters, N is the number of data points and $\log p(\mathbf{X}, \mathbf{y}|\theta_m)$ for fixed θ_m is given by eq. 6.

2.4 Automatic generation of training data

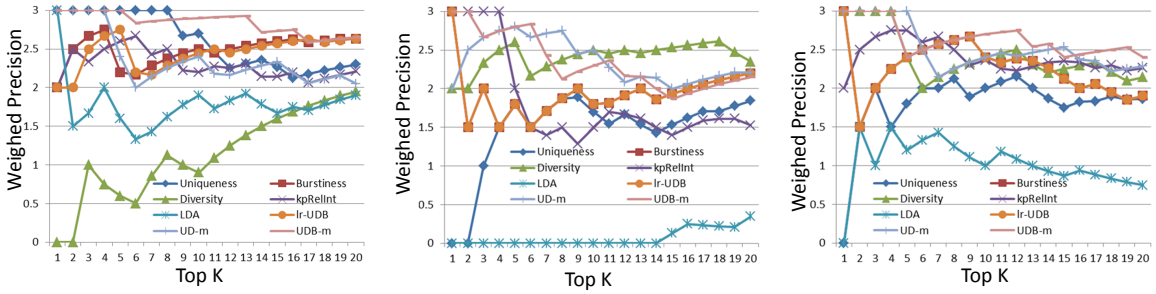
We use a fully automated approach to (noisily) label candidate phrases. The approach is based on the premise that a phrase that is related to the entity and is also popular on the web is more likely to be a potential aspect for the entity. We operationalize this by issuing each phrase to be labeled as a query to a web search engine and retrieve top 50 results. Then, we label it as an aspect if, at least 10% of the top 50 web results have web page titles that are relevant to the entity (determined by the same rules that is used for tweet classification (§ 3.1)) and all the unigrams in the phrase is contained in them.

This approach can result in noisy labels since a candidate phrase that have huge web presence may not be an aspect, and vice versa. In spite of this, we observed reasonable correlation between the propensity of a phrase on Twitter to be a true aspect and the quality of web search result that we can retrieve. Thus, this approach results in generating large noisily labeled datasets, which can often be more effective than a small dataset with high quality labels (Fuxman et al., 2009).

3 Evaluation

We compare our algorithm described in § 2.3 (which we denote *UDB-m*) against the following algorithms: (1) *kpRelInt*: the keyphrase ranking algorithm of (Zhao et al., 2011) applied to our candidate aspects, (2) *lr-UDB*: ranking based on probabilities obtained using a trained, single-component logistic regression model using uniqueness, diversity and burstiness indicators as features, (3) *UD-m*: ranking based on our probabilistic mixture model of § 2.3 where we only used Uniqueness and Diversity indicators but not Burstiness and (4) *LDA*: an approach based on training a 50 component Latent Dirichlet Allocation (Blei et al., 2003) on tweets of that entity, from which we then manually constructed aspects from the best 20 topics.

We also consider rankings based solely on the various indicator scores themselves: uniqueness (*U*), diversity (*D*) and burstiness (*B*), to understand the effectiveness of each of these indicators. Note that *U* is a stronger baseline than the TF-IDF metric (Spina et al., 2012).



(a) Windows 8 (b) Global Warming (c) Microsoft Surface

Figure 2: Weighted Precision across entities

3.1 Dataset

We studied six entities from varied domains including products, environmental issues and personalities:"Windows 8", "Microsoft Surface", "Hyundai", "Organic Food", "Global Warming", and "Tiger Woods". We obtained the set of all English language tweets posted in a three month time period from Jan 1, 2013 to March 31, 2013. For each entity, we classified the tweets pertaining to that entity by using simple keyword-based classifiers. For instance, for the entity 'windows 8', the keywords corresponded to the set {"windows 8", "win8", "windows8", "win 8", "#win8", "#windows8", "#microsoftwindows8"}. In total, we obtained about three million English tweets across all the six entities that we used, with around $100,000$ to $800,000$ tweets for each entity.

Train/Test split: We used data from January to train *UDB-m*, *UD-m* and *lr-UDB* algorithms. We evaluated all algorithms on data from February and March, and obtained qualitatively similar results for both months. We present results only from March, due to space constraints.

3.2 Precision analysis of inferred aspects

The goal of this experiment is to obtain a precision measure for the various algorithms in inferring relevant aspects. Since it is impractical to manually create a ground truth test set of aspects for each entity by inspecting all the tweets, we take an approach used in (Spina et al., 2012). For each entity and month, we pooled together the top 20 aspects identified by all the algorithms under consideration. We used three judges in our organization as human assessors who manually annotated these candidate aspects on a 4-point relevance scale (with '3' being most relevant and '0' being irrelevant to the entity).

Metrics: Let S be the list of top K phrases identified as aspects by an algorithm, with $S[i]$ being the i^{th} phrase. For every phrase $p \in S$, let $R(p) \in [0,3]$ be the average of the relevance rating provided by the three judges. Then, $\text{WeightedPrecision @K}$ of the algorithm at the top K rank is given by $\frac{\sum_{i=1}^{K} R(S[i])}{K}$ (Sakai, 2007). Note that *Weighted Precision @ K* lies in the range [0,3] with higher values indicating that the list of top K aspects is more precise.

Results: Figure 3 shows the Weighted Precision at top K ranks ($K = 1, \ldots, 20$) for each algorithm, averaged across all the entities. For each algorithm and value of K, the marker size of each point in the plot is proportional to the variance in the algorithm's weighted precision. Observe that *UDB-m* consistently has high Weighted Precision scores across all values of K and has the lowest variance, showing its efficacy in discovering aspects with high precision across all entities. Contrast this with the relatively poorer performance of *lr-UDB* that uses a simpler logistic regression model on the same three indicators. This highlights the importance of using a multiple-component mixture model (as opposed to a single component) to capture the non-linear dependencies among the three indicators for an entity. We discuss this further in § 3.4.

The next closest contender after *UDB-m* is *UD-m* that uses only the uniqueness and diversity indicators. The non-trivial gap between *UDB-m* and *UD-m* indicates the importance of incorporting burstiness. The *kpRelInt* algorithm of Zhao et al. (Zhao et al., 2011) actually performs quite poorly. We observed two reasons for this: first, the interestingness score in *kpRelInt* that is based on the ratio of retweets to

tweets does not capture key aspects that may have been frequently used by tweets (but not necessarily retweeted often), and secondly it gives undue importance to words in tweets that are meant to be retweeted by design (for example, as part of a contest, announcement or giveaway). Indeed, the former reason is precisely addressed by our diversity indicator, whose importance is be seen from the fact that among all the three indicators, *D* performs the best.

We note that methods that use only one of the indicators (*U*, *D* and *B*) have large variance in their performance across entities emphasizing the entity-specific nature of these algorithms (we comment on this shortly) making them ill-suited for large scale domain-agnostic applications. Finally, we see that *LDA* performs the worst among our baselines, due to the inherent brevity, ambiguity and noise in tweets.

Entity-specific analysis: Consider Figure 2 that compares entity-specific performances of the algorithms considered. Figure 2a shows their performance for 'Windows 8'. For this entity, *U*, *UD-m* and *UDB-m* all perform equally well for small values of K, however the performance of *UDB-m* stays stable even for large values of K, while that of *U* and *UD-m* deteriorate. Contrast the relatively poor performance of *B* for Windows 8 with its performance for 'Global Warming' in Figure 2b. We see that the precision of *UDB-m*, which is still higher than most of the other algorithms, aligns with that of *B* for small K. This is due to the inherent nature of this entity, for which much of the chatter on Twitter tends to revolve around major news events. We discuss this in more detail in § 3.5. *UD-m*, which performed very well for the Windows 8 entity, does not have as good precision in this case, because it does not factor in this important effect of burstiness. Figure 2c shows the performance of the algorithms for the 'Microsoft surface' tablet. Again, *UDB-m* mostly outperforms the other methods across the range of K values, but is matched by *UD-m* and, to a lesser extent, by *D* for small K. Burstiness no longer plays such an important role - the tweets for Surface in March tend to be mostly comments on the features, commercials and accessories related to the product, and not so much related to news.

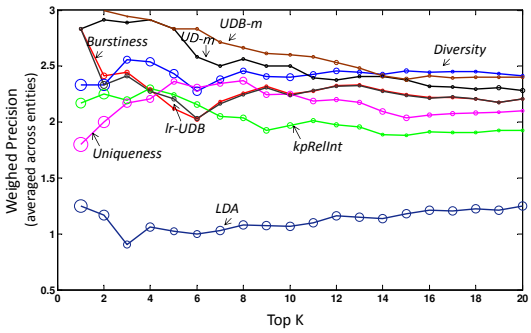


Figure 3: Average and variance (over all entities) for Weighted Precision for various algorithms. (Best viewed in color)

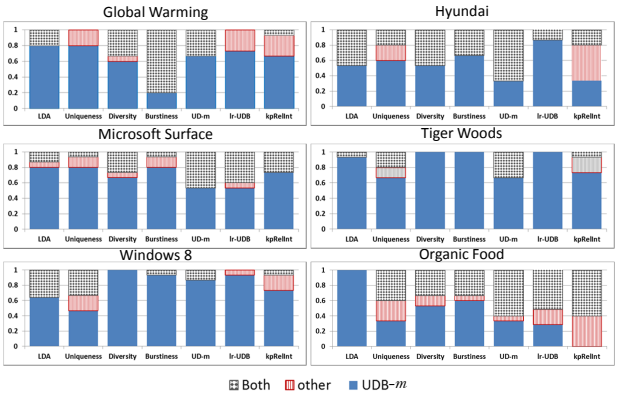

Figure 4: Pairwise preferences (at top 10) between *UDB-m* and other algorithms studied

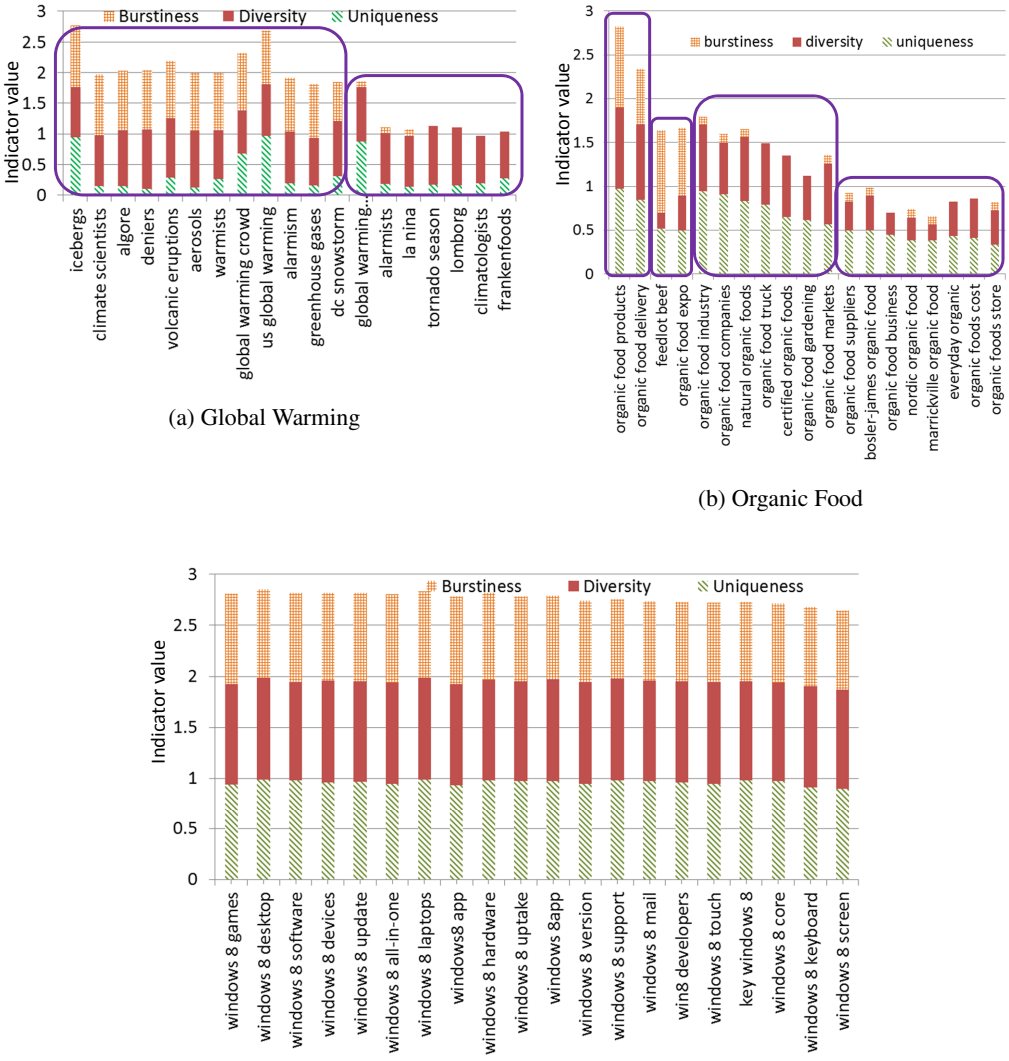
3.3 Pairwise Preference comparison of inferred aspects

Here, we quantify the overall precision of the ranked list of aspects identified by various algorithms. We conduct pairwise evaluation using Amazon Mechanical Turk. Each Human Intelligence Tasks (HIT) consists of a pair of top 20 ranked aspect lists for an entity, with one list from *UDB-m* and the other chosen from one of the baseline algorithms. For each pair, we randomly permuted the order for each HIT (considered 5 random orderings). Each pair was judged by 5 judges, resulting in 25 judgments for each <entity, *UDB-m*, baseline-algorithm> triplet. Each judge was asked to study the two lists and specify which of the two was more relevant (or choose "Both are comparable"). Since the judges do not have access to the tweets, they were given instructions to perform a web search using the aspect and the entity name as a query string, restricted to the appropriate month. They were then asked to use the search results to guide them in determining which of the ranked lists was more relevant. We computed the Fleiss-κ inter-annotator agreement across each entity and method to be 0.68 on average, showing substantial agreement among the judges.



(a) Global Warming

(b) Organic Food

(c) Windows 8

Figure 5: Strengths of indicators for top 20 aspects (sorted according to the components)

Results: Figure 4 plots the results of the pairwise preference evaluations for all the entities for the month of March. Each of the seven bars corresponds to the preference results obtained by comparing *UDB-m* versus one of *lr-UDB*, *kpRelInt*, *LDA*, *UD-m*, *U*, *D* and *B*. For each pair, we plot the fraction of the 25 judges that 1) voted for *UDB-m* 2) voted for the other algorithm, or 3) answered "both are comparable". We observe that for almost all the entities, the fraction of votes for *UDB-m* was higher than the votes for the other algorithms. The only exception was organic food for which *kpRelInt* performed better than *UDB-m*. There were some cases for which a majority of judges said both aspect lists were comparable. These cases mostly involved comparisons of *UDB-m* versus *UD-m* which suggests that after *UDB-m* the next best performing algorithm was *UD-m* (We had observed the same effect in precision analysis § 3.2). Another case where both aspect lists are comparable was *UDB-m* vs *B* for the entity 'global warming'. As described in § 3.5, the buzz around this entity is often centered around news events and hence the top 10 aspects identified by our algorithm coincides closely with burstiness of the phrases. Hence, *UDB-m* and *B* perform quite comparably.

3.4 Importance of Multiple Components

UDB-m uses multiple components to model the data, with actual number of components inferred using BIC. Here, we demonstrate the importance of using varied number of components for each entity. Figure 5 shows the top 20 aspects identified for three of the entities. For ease of exposition, we group

Global Warming	Hyundai	Microsoft Surface	Tiger Woods	Windows 8	Organic Food
volcanic eruptions	hyundai santafe	surface keyboard	tiger woods commercial	windows 8 games	organic food delivery
deniers	hyundai sonata	surface sales	us skier	windows 8 desktop	organic food truck
aerosols	starex	surface pro commercial	tiger woods #2	windows 8 software	certified organic foods
tornado season	fuel cell	surface pro review	cadillac championship	windows 8 devices	organic food business
al gore	hyundai genesis	type cover	arnold palmer invitational	update windows 8	everyday organic
lomborg	tucson	surface review	tiger woods #3	windows 8 all-in-one	organic food gardening
global warming awareness	r-spec	touch cover	tiger woods number	windows 8 laptops	organic foods cost
us global warming	i-deal	type keyboard	tiger woods video	windows8 app	cafe bahrain
dc snowstorm	elantra	benchmarks surface	tiger woods house	windows 8 hardware	nordic organic food
icebergs	entourage	surface tablet line	skier lindsey vonn	windows 8 uptake	organic food industry

Table 1: Top 10 aspects identified by our algorithm for various entities

aspects list based on which component they belonged to (the one with largest posterior probability). For each aspect, we show a stacked bar representing the values for the three indicators (hence the maximum length of the bar is 3).

Consider Figure 5a corresponding to 'Global Warming'. Here, only a two component model was trained: one to model large values for diversity and burstiness, and another to model large values for diversity. While highly bursty and diverse aspects such as 'volcanic eruptions' are explained by the component that captures large diversity and burstiness values, aspects such as "tornado season" and "lomborg" that are widely discussed in diverse contexts but are not bursty are captured in another component.

Contrast this with Figure 5b for 'organic food'. This entity was automatically trained using a six component model out of which four participated in identifying the top 20 aspects. The aspect 'organic food products' from the first component has large values for all three indicators. In contrast, the aspects 'organic food truck' and 'organic food gardening' from the third component have high uniqueness and diversity values but low values for burstiness, indicating that they are consistently talked about through the month. The aspect 'feedlot beef' in the second component has low values for diversity, but has large values for burstiness indicating a spike in chatter around feedlot beef in the context of organic food.

Figure 5c shows the corresponding plot for 'Windows 8'. All the top aspects come from a single component. While one may be tempted to use only one component for this entity, our model used six components in order to explain the high variance in the training data. The remaining components were useful in weeding out noise. This can also be seen from the improved performance of *UDB-m* in comparison to *lr-UDB* which uses only a linear classifier (Figure 2a).

3.5 Qualitative Results

Table 1 shows the top 10 aspects identified by our algorithm for the month of March 2013. Consider the entity, 'global warming'. In Twitter, we found that discussions around this entity were highly news (or event) driven and this is reflected in the identified aspects. For instance, 'volcanic eruptions' and 'aerosols' corresponds to news reports of a study that showed how aerosols from modest volcanic eruptions may mask global warming effects. The aspect 'lomborg', referring to Bjorn Lomborg was the subject of much discussion in March; With his article in WSJ on heavy carbon–di–oxide emissions from electric cars charging, Lomborg created a stir among environmentalists.

In contrast, the top ranking aspects for Hyundai on Twitter corresponded mostly to chatter about various car models. Hyundai's announcement in March of their intention to offer fuel-cell cars in the US led to a lot of buzz around this topic, as aptly identified by the aspect 'fuel cells'.

There were three major events in March about Tiger Woods that created buzz on Twitter (and mainstream news media): his Cadillac Championship performance that led to his regaining the number one spot in golf, his relationship with the US skier Lindsey Vonn, and his rivalry with Graeme McDowell during the Cadillac championship. All these events are identified as aspects for the entity 'Tiger Woods'.

4 Concluding Remarks

In this paper, we studied the problem of inferring the key talking points or *aspects* about entities from microblog streams. We presented a probabilistic model to automatically infer these aspects from microblog streams for any specified domain, with *no* manual effort or domain knowledge about the entity.

We presented indicators such as "uniqueness", "diversity" and "burstiness" to capture characteristics of aspects in the microblog context. Our large scale empirical evaluation over three months of Twitter data for entities from various categories validated the efficacy of our approach.

A key direction for future work is the problem of clustering semantically similar aspects pertaining to an entity (*e.g.,* 'volcanic eruptions' and 'aerosols' for 'global warming') to get a more succinct representation of the aspects. Another line of work is to leverage the temporality of these aspects in building temporal aspect discovery models.

Abstract

Story highlights form a succinct single-document summary consisting of 3-4 highlight sentences that reflect the gist of a news article. Automatically producing news highlights is very challenging. We propose a novel method to improve news highlights extraction by using microblogs. The hypothesis is that microblog posts, although noisy, are not only indicative of important pieces of information in the news story, but also inherently "short and sweet" resulting from the artificial compression effect due to the length limit. Given a news article, we formulate the problem as two rank-then-extract tasks: (1) we find a set of indicative tweets and use them to assist the ranking of news sentences for extraction; (2) we extract top ranked tweets as a substitute of sentence extraction. Results based on our news-tweets pairing corpus indicate that the method significantly outperform some strong baselines for single-document summarization.

1 Introduction

People in this era are overloaded by their daily exposure to large amount of online information. To make life easier, some news websites like CNN.com and USAToday.com provide "Story Highlights" in their news articles for readers to get the gist of story quickly. The highlights of an article typically contain 3-4 summary sentences in bullet-points form that are representative of and shorter than the original new sentences in the article. An example of story highlights of an article is shown in Figure 1 (marked in red rectangle) that are written in a compact, almost telegraphic style. In contrast to the original content of the article, significant compression is obtained by shortening and paraphrasing.

Unfortunately, the production of such good-quality highlights needs to be done manually which is very expensive. Existing methods face grand technical challenges for automating the process. The task is complex in nature due to a broad range of linguistic constraints which ultimately requires wide-coverage of language understanding beyond the capabilities of current NLP technology (Woodsend and Lapata, 2010). Most automatic systems simplify the problem using extractive approach. By using linguistic or statistical information or both, the key units or concepts can be identified from sentences or across multiple documents, and then the sentences are scored and extracted according to their informativeness with the presence of the key components.

The extractive approach has two salient problems: (1) it is commonly ineffective to locate key sentences, meaning that the presence of linguistically and/or statistically important units does not necessarily indicate a highlight sentence. This is evidenced by the fact that sophisticated systems for Document Understanding Conference (DUC) summarization task cannot significantly outperform a trivial baseline that simply selects first n sentences of the document (Nenkova, 2005); (2) sentence extracts as highlights are extraordinarily verbose in general, which need to be post-processed for substantial compression. But sentence compression may breach the readability or grammaticality (Clarke and Lapata, 2008).

With the popularity of social media, online news providers are moving towards offering more interaction with news readers via microblogging service like Twitter. Many Twitter users also post tweets

Work conducted at Qatar Computing Research Institute (QCRI) when the first author was employed as an intern

Proceedings of COLING 2014, the 25th International Conference on Computational Linguistics: Technical Papers, pages 872–883, Dublin, Ireland, August 23-29 2014.

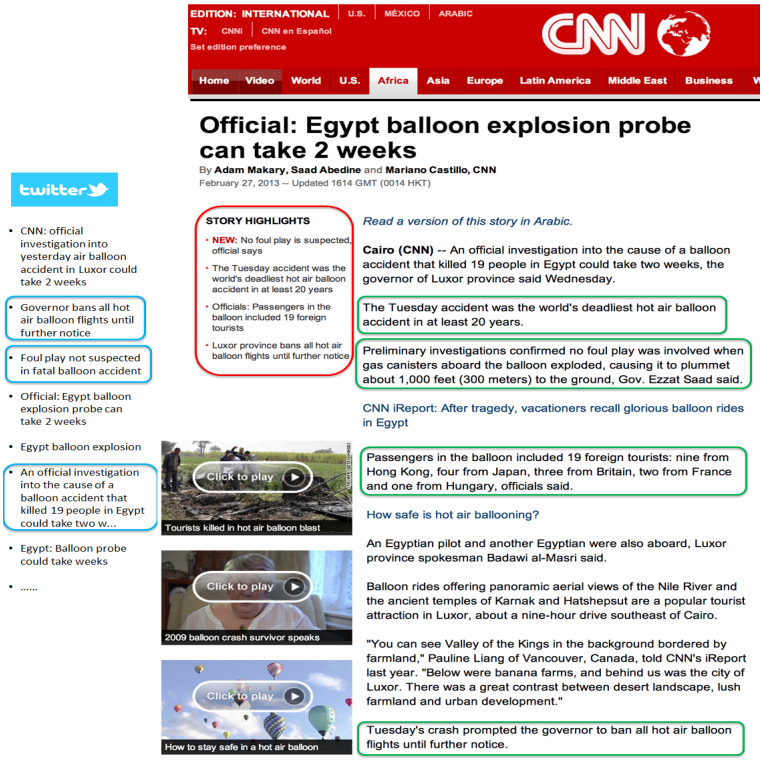

Figure 1: A CNN news article with story highlights (Highlights are marked by red rectangle, and the news sentences related to the highlights are enclosed in green rectangles) and some relevant tweets one can observe independently on Twitter (marked by light blue rectangles on the left)

about news together with their URLs. Such increased cross-media interaction recasts the role of different information sources that are useful for this task in a sense that interesting correlations between the news and relevant microblogs could be captured and leveraged to boost the performance.

To address these considerations, we make two hypotheses based on our observation that can be crucial to highlights extraction. (1) *Indicative effect:* microblog users' mentioning about the pieces of news is indicative of the importance of the corresponding sentences; (2) *Human compression effect:* important portions of a news article have been rewritten by microblog users in a more condensed style owing to length limit. Accordingly, we formulate our problem as two independent rank-then-extract tasks: firstly, we find a set of indicative tweets and use them to assist the ranking of news sentences for extraction; secondly, we extract top-ranked tweets (with the help of news sentences) as a substitute of sentences extraction since they are typically shorter. Based on our news-tweets pairing corpus, the results of experiments following both directions indicate that our methods outperform some strong baselines for single-document summarization.

2 Related Work

Our work intersects the summarization of single document and microblogs. Single-document summarization has been studied for years starting from Luhn and Peter (1958). Based on local content information of a document (Wong et al., 2008; Barzilay et al., 1997; Marcu, 1997), researchers proposed various statistical or semantic approaches using classification (Wong et al., 2008), Integer Linear Programming (ILP) (Li et al., 2013), sequential models (Shen et al., 2007) and graphical models (Litvak and Last, 2008; Hirao et al., 2013). For the concision of summary, sentence compression or word deletion was used (Knight and Marcu, 2002) for preprocessing. Joint models combining compression and selection of sentences were also studied (Woodsend and Lapata, 2010; Li et al., 2013).

Summarizing microblog content is to distill the large quantities of tweets into a concise and representative description of a target event. Sharifi et al. (2010) proposed a graph-based phrase reinforcement

algorithm (PRA) to generate a one-sentence summary from a collection of tweets. By using linguistic features, Judd and Kalita (2013) improved the performance of PRA. Sharifi et al. (2010) and Inouye et al. (2011) presented a hybrid TF-IDF approach for extracting tweets with the presence of important terms. More fine-grained summarization was proposed by considering sub-events and combining the summaries extracted from each sub-topic (Nichols et al., 2012; Zubiaga et al., 2012; Duan et al., 2012).

The research for coupling news and microblogs attracted much attention recently. Subašić and Berendt (2011) and Zhao et al. (2011) independently compared tweets to online news to identify features for news detection in tweets. Phelan et al. (2011) used tweets to recommend news articles based on user preferences. Gao et al. (2012) produced cross-media news summaries by capturing the complementary information from both sides. Kothari et al. (2013) and Štajner et al. (2013) investigated detecting news comments from Twitter for extending news information provided. Guo et al. (2013) proposed a graphical model to identify news for a given tweet to provide contextual support for NLP tasks.

Some work attempted to use different kinds of resources to help document summarization, such as Wikipedia and query log of search engine (Svore et al., 2007), clickthrough data (Sun et al., 2005), users' comments on news (Hu et al., 2008), and social media context of the articles (Yang et al., 2011). Our work is closely related to Svore et al. (2007) that considered incorporating third-party resource in the ranking process, but the access to query logs is extremely limited, and Wikipedia content is relatively static which cannot reflect timely information like social media.

We also share the same testbed with Woodsend and Lapata (2010). They selected and compressed news sentences with a joint model using ILP by considering phrase as basic extract element. Their method requires a large training corpus for deriving accurate salient scores of phrases, and also the feasible solution of ILP model with hard constraints does not necessarily exist.

Yang et al. (2011) proposed a unified supervised model called dual wing factor graph to simultaneously summarize Web documents and tweets based on structural mining from social context. Despite of similar motivation, our work has some key differences from theirs: (1) Our ground-truth come from standard news highlights, and our target summary keeps consistent no matter which source of information our highlights are extracted from. They built ground-truth summaries separately for each side by manually choosing no less than 5 tweets and 10 news sentences. So, our standard is more difficult to reach since our ground-truth summaries are not extracts of the original sentences or tweets; (2) Our approach is very different. We use ranking-based algorithm which is more adequate than their classification approach because there are much fewer positive candidates than negative ones, and the class distribution is very imbalanced (like information retrieval tasks). Also, they were focused on mining the implicit structural information from retweeting and user following networks, while we focus on content-based correlations.

3 Corpus Construction

There is no news-tweets coupling data set publicly available for the purpose of news highlights production[1]. We constructed the first of such corpus for this application by our own, for which an event-oriented strategy was adopted to collect the highlights-document-tweets couplings by using a social search engine. We manually identified 17 salient news events taking place in recent two years. For each event, we manually generated a set of core queries which were used to retrieve the relevant tweets via Topsy[2] search API. Then we gathered the retrieved tweets containing embedded URLs that point to the news articles on CNN and USAToday websites that provide story highlights, and extracted the content of the news articles and the associated highlights.

For each article, we collected all the tweets in the retrieved tweet set above that contain links to the article to form our highlights-document-tweets couplings based on the following rules: (1) We delete those extremely short tweets with less than 5 tokens and the tweets that are suspected copies from news title and highlights. For example, we try our best to remove all the suspectable tweets including the cases

[1]We realize the news-tweets coupling data set released recently for NLP tasks by Guo et al. (Guo et al., 2013). However, this data set is not suitable for our task for two reasons: (1) There are 12,704 news articles but only 34,888 tweets. Although part of the news are from CNN which contain story highlights, the number of tweets per article is too limited, not to mention finding useful candidates; (2) The full text of news content is not provided, with only the first few sentences of articles instead.

cause of the Super Bowl blackout	2	8	482	Total	121	455	78,419

Table 2: Distribution of documents, highlights and tweets with respect to different events

like "RT @someone HIGHLIGHT URL"; (2) If there are more than 100 tweets linked to an article, the article is kept, otherwise the artcile is removed. Note that using explicit hyperlinks is not the only way for identifying the couplings but the most straightforward one. Here we simply resort to this straightforward method to build the corpus for verifying our two hypotheses raised in Section 1. Thorough investigation on the construction of an enhanced highlights-oriented coupling corpus is left for our future work.

The statistics of the resulted corpus are given in Table 1 which is also made accessible[3]. As shown in the table, the average number of relevant tweets to a document is about 648. Since some of the events are much more popular than others, the standard deviation of the number of tweets associated with a document is as high as 1,162. The highlights are characterized as high compression rate compared to the length of news articles. In addition, a single highlight sentence on average is only 2/3 the length of a news sentence, and more interestingly the average length of tweets is very close to that of highlight sentences, which suggests that the relevant tweets can be a reasonable source of candidates for extraction.

Table 2 shows the distribution of documents, highlights and tweets with respect to the 17 news events we collected.

4 Our Approach

Given a news article containing n sentences $S = \{s_1, s_2, ...s_n\}$ and a set of m relevant tweets $T = \{t_1, t_2, ..., t_m\}$, we aim to extract x sentences from the set S or the same number of tweets from set T as highlights covering the main theme of the article. We define the two tasks as follows:

- **Task 1 – sentences extraction:** Given auxiliary T, extract x elements $H(S) = \{s^{(1)}, s^{(2)}, ..., s^{(x)} | s^{(i)} \in S, 1 \leq i \leq x\}$ from S as highlights.
- **Task 2 – tweets extraction:** Given auxiliary S, extract x elements $H(T) = \{t^{(1)}, t^{(2)}, ..., t^{(x)} | t^{(i)} \in T, 1 \leq i \leq x\}$ from T as highlights.

Most single-document summarization methods (Woodsend and Lapata, 2010; Yang et al., 2011) treat the extraction as a classification problem which assigns either positive or negative label to the extract candidates. We argue that it is more adequate to model it as a ranking problem because there is far more unsuitable candidates than suitable ones for being the highlights. Such kind of imbalanced class distribution makes classification a secondary solution.

Our model learns to rank all the candidate sentences in task 1 or candidate tweets in task 2, and then extracts the top-x ranked instances as output highlights. We adopt an effective pair-wise ranking model RankBoost (Freund et al., 2003) for that using the RankLib package[4]. RankBoost takes pairs of instances

[4] http://sourceforge.net/p/lemur/wiki/RankLib/

Category	Name	Description
Local Sentence Feature (LSF)	IsFirst	Whether s is the first sentence in the news
	Pos	The position of s in the news
	TitleSimi	Token overlap between s and news title
	ImportUnigram	Importance score of s according to the unigram distribution in the news
	ImportBigram	Importance score of s according to the bigram distribution in the news
Local Tweet Feature (LTF)	Length	Token number in t
	HashTag	HashTag related features (presence and count)
	URL	URL related features (count)
	Mention	Mention related features (presence and count)
	ImportTFIDF	Importance score of t based on unigram Hybrid TF-IDF algorithm (Sharifi et al., 2010)
	ImportPRA	Importance score of t based on phrase reinforcement algorithm (Sharifi et al., 2010)
	TopicNE	Named entity related features (NE count and seven binary values indicating the presence of each category)
	TopicLDA	LDA-based topic model features (maximum relevance with sub-topics, etc.)
	QualityOOV	Out-of-vocabulary words related features (count and percentage)
	QualityLM	Quality score of t according to language model (Unigram, bigram and trigram)
	QualityDepend	Quality score of t according to dependency bank (Han and Baldwin, 2011)
Cross-Media Feature (CCF)	MaxCosine	Maximum cosine value between the target instance and auxiliary instances
	MaxROUGE1F	Maximum ROUGE-1 F score between the target instance and auxiliary instances
	MaxROUGE1P	Maximum ROUGE-1 precision value between the target instance and auxiliary instances
	MaxROUGE1R	Maximum ROUGE-1 recall value between the target instance and auxiliary instances
	LeadSenSimi*	ROUGE-1 F score between leading news sentences and t
	TitleSimi*	ROUGE-1 F score between news title and t
	MaxSenPos*	The position of sentences that obtain maximum ROUGE-1 F score with t
	SimiUnigram	Similarity based on the distribution of (local) unigram frequency in the auxiliary resource
	SimiUniTFIDF	Similarity based on the distribution of (local) unigram TF-IDF in the auxiliary resource
	SimiTopEntity	Similarity based on the (local) presence and count of most frequent entities in the auxiliary resource
	SimiTopUnigram	Similarity based on the (local) presence and count of most frequent unigrams in the auxiliary resource

Table 3: Feature description (t: a tweet; s: a news sentence; *: features used in task 2 only)

(I_i, I_j) as input for training and their preference order as labels. In our case, instance pair can be the pair of sentences or tweets, and the pairwise order is determined by the salient score of each instance that is the maximum ROUGE-1 (Lin, 2004) F-value between the instance and the corresponding ground-truth highlight sentences. Given the gold standard highlights $H^g = \{h_1, h_2, ..., h_x\}$, the salient score of an instance is calculated as $score(I_i) = max_k\{\text{ROUGE-1}(I_i, h_k)\}$.

Note that in task 2 the number of tweets pairs generated in training can be extremely large because of the number of tweets in popular topical news articles (see Table 2) that may degrade the efficiency of training. Some ad-hoc workaround is employed to make the problem tractable. As opposed to using all the possible pairs, we divide the tweets into b bins, where the bins are bounded by continuous ranges of salient scores. We fix the length of different ranges by fitting the distributions of salient score values. Tuned on a subset with 20% randomly selected training instances, the value of b is determined as 4. Then, the pairs are formed across these brackets.

5 Feature Design

The feature space of the two tasks are designed to intersect at the cross-media correlation part. The local features describe the instance to be ranked (i.e., either a news sentence or a tweet), and the cross-media correlation features capture the similarity of the instance with the counterparts in the auxiliary resource.

The features consist of three subsets of informativeness measures including local sentence features (LSF), local tweet features (LTF) and cross-media correlation features (CCF). In task 1, we can use LSF or both LSF and CCF for rank learning; and in task 2, we can use LTF or combine LTF and CCF. The full feature list is described in Table 5. For local sentence features, we implement the 5 document features defined in (Svore et al., 2007) for single-document summarization task. This is for the ease of comparison with the existing approach. In this section, we will only describe the local tweet features and the cross-media correlation features in more detail.

5.1 Local Tweet Features

Local tweet features are proposed to capture the importance of a tweet based on local information in three aspects, including twitter-specific, topic-related, and writing-quality measures.

5.1.1 Twitter-specific measures

Twitter-specific features indicate the basic content-based characteristics of a tweet such as length, the characteristics specifically provided by Twitter platform such as hashtags, mentions and embedded urls, and two scoring functions used by state-of-the-art tweet summarization algorithms including Hybrid TF-IDF (Sharifi et al., 2010) and PRA (Sharifi et al., 2010). Hybrid TF-IDF is a variant of traditional TF-IDF weighting for tweets collection which treats each tweet as a document when computing IDF while the whole tweets set as a document when computing TF. We calculate the feature *ImportTFIDF* of a tweet based on the TF and IDF values of its tokens. PRA is a phrase reinforcement algorithm that can produce a one-sentence summary for a given tweets set. We follow the idea of PRA to generate the token graph of our tweets set and compute the weight for each token node. We then measure the importance of a tweet by summating the weights of all its tokens, which becomes the *ImportPRA* feature.

5.1.2 Topic-related measures

Topic-related features are used to capture important tweets based on the topical information embodied by named entities (NE) or latent topic semantics. *TopicNE* is proposed to utilize NE as indicator for describing an event. We resort to Stanford Name Entity Recognizer[5] to extract seven types of named entities including time, location, organization, person, money, percent and date. Based on that, we count entities in the tweet, and then obtain seven additional binary values indicating the presence of each category. *TopicLDA* is used to capture sub-topics. Intuitively, if a tweet is highly related to some sub-topic in the event, it is more important. We use LDA (Blei et al., 2003) to identify the sub-topics in the tweets set. Based on the resulted sub-topics and term distribution, we first calculate the maximum relevance value between the tweet and all sub-topics as a feature. Then, we obtain the distribution of relevance values of the tweet with respect to all sub-topics and compute the entropy of this distribution as another feature. The lower the entropy is, the higher the degree of topical concentration for the tweet. We use the default setting of the toolkit mallet[6] and set the number of sub-topics as 10 empirically.

5.1.3 Writing-quality measures

Writing-quality features indicate if a tweet is written in a formal way. Intuitively if more formally a tweet is written, it is more likely to be extracted. *QualityOOV* measures to what extent a tweet contains out-of-vocabulary (OOV) tokens. We simply calculate the number and the percentage of the OOV words in the tweet as features[7]. *QualityLM* measures writing quality of a tweet based on language model. We train uni-gram, bi-gram and tri-gram language models using maximum-likelihood estimation. By summating the probabilities of all the tokens in the tweet regarding the three different language models, we obtain three n-gram-based writing-quality features. *QualityDepend* measures the writing quality based on dependency relation. The dependency feature is generated following Han et al. (2011). Instead of using the technique for normalizing tweet text, we apply it for assessing the grammaticality of tweets[8].

5.2 Cross-media Correlation Features

We observe that Twitter users like to quote or rewrite the important pieces of new content in the posts. If a news sentence is referred or paraphrased by many tweets, it is assumed to be indicated as more important. On the other hand, a tweet, besides its local importance indicator, may be more important if it is similar to the theme of the news content. Therefore, cross-media correlation features are designed to incorporate the auxiliary information source for helping instance ranking. In task 1, news articles are local content and the corresponding tweets are considered auxiliary, and in task 2 their roles are reversed.

5.2.1 Instance-level similarities

Instance-level similarities indicate if there are auxiliary instances similar to the current local instance and to what extent they are similar. These features reveal if the current instance has strong correlation

[5] `http://nlp.stanford.edu/software/CRF-NER.shtml`

[6] `http://mallet.cs.umass.edu/index.php`

[7] The words not found in a common English dictionary, GNU aspell dictionary v0.60.6, are treated as OOV

[8] Both dependency bank and language model here are based on New York Times corpus (`http://www.ldc.upenn.edu/Catalog/CatalogEntry.jsp?catalogId=LDC2008T19`)

across the media boundary. We use four general metrics including cosine, ROUGE-1 F-value, ROUGE-1 precision score and ROUGE-1 recall score to measure the surface similarity between news sentence and tweet. And the other three features, namely *LeadSenSimi*, *TitleSimi* and *MaxSenPos* are only used in task 2 for ranking tweets when news sentences are considered as auxiliary. This is because leading sentences and title of news are considered as the most informative content. The more similar a tweet to them, the more important it can be. Also, position information is often used for document summarization. We borrow the position of the most similar sentence as bridge to measure the importance of a given tweet.

5.2.2 Semantic-space-level similarities

Semantic-space-level similarities reflect the importance of the current local instance based on the distribution of its semantic units in the auxiliary resource. We propose two features to represent the distribution of the semantic units that are based on unigram frequency and unigram TF-IDF, and named as *SimiUnigram* and *SimiUniTFIDF*, respectively. We first obtain a unigram distribution on the auxiliary space, and compute the similarity of a local instance by summing over the probabilities of all its unigrams in the distribution. Additionally, we also identify some most frequent named entities and unigrams in the auxiliary information source, and then compute the presence and the count of them in the current local instance as additional features, which are named as *SimiTopEntity* and *SimiTopUnigram*.

6 Experiments and Results

6.1 Setup

Task 1 extracts highlights from *news articles*. For comparison, we use the following approaches: (1) *Lead sentence* chooses the first x sentences from the given news article, which is a strong baseline that no DUC system could beat with large margin (Nenkova, 2005); (2) *Phrase ILP* (Woodsend and Lapata, 2010) generates highlights from news with the joint model combining sentence compression and selection, which treats phrases and clauses as extract unit; (3) *Sentence ILP* (Woodsend and Lapata, 2010) is a variant of *Phrase ILP* that treats sentence as extract unit; (4) *LexRank (news)* summarizes the given news using the typical multi-document summarization algorithm LexRank (Erkan and Radev, 2004); (5) *Ours (LSF)* is our ranking method based on the local sentence features which are equivalent to the features used by Svore et al. (2007); (6) *Ours (LSF+CCF)* is our method combining LSF and CCF.

Task 2 extracts highlights from *tweets* where we use the following approaches: (1) *LexRank (tweets)* uses LexRank (Erkan and Radev, 2004) with tweets as the mere input; (2) *Ours (LTF)* is our ranking method based on local tweet features; (3) *Ours (LTF+CCF)* is our method combining LTF and CCF.

Unlike single news document where redundant sentences are rare, the redundancy of tweets is serious. Many summarization algorithms are sensitive to redundancy in the input. It is thus problematic for tweets as the source of extraction. Hence we apply Maximal Marginal Relevance (MMR) (Carbonell and Goldstein, 1998) for reducing tweets redundancy in task 2. The parameter in MMR used to gauge the threshold of redundancy is tuned based on 20% randomly selected training data. Overall, we conduct 5-fold cross-validation for evaluation. The highlights of each news article are used as ground truth. In the output, we fix the number of highlights extracted x as 4. We report ROUGE-1 and ROUGE-2 scores with ROUGE-1 as the major evaluation metric.

6.2 Results

The overall performance can be seen in Table 4, from which we have the following findings:

– Indeed, *Lead sentence* is a very strong baseline that performs much better than most of other methods. It is only a little worse than *LexRank (news)* and much worse than *Ours (LSF+CCF)*.

– *LexRank (news)* performs the second best in task 1. However, the performance of *LexRank (tweets)* is the worst in task 2. This is because LexRank is proposed for summarizing regular documents and its performance is affected seriously by the short, noisy texts like tweets.

– *Sentence ILP* and *Phrase ILP* perform similarly and do not show clear advantage over other baselines. This is different from what Woodsend and Lapata (2010) has obtained. This implies that their model is sensitive to the size of training data where the ILP model may be undertrained here with the

Approach	ROUGE-1			ROUGE-2		
	F	P	R	F	P	R
Lead sentence	0.263	0.211	0.374	0.101	0.080	0.147
LexRank (news)	*0.264*	0.226	0.332	0.088	*0.074*	0.112
Sentence ILP	0.238	0.209	0.293	0.068	0.058	0.088
Phrase ILP	0.236	*0.215*	0.281	0.069	0.061	0.086
Ours (LSF)	0.256	0.214	0.345	0.093	0.076	0.129
Ours (LSF+CCF)	**0.292**	**0.239**	**0.398**	**0.110**	**0.089**	**0.155**
LexRank (tweets)	0.212	0.204	0.226	0.064	0.061	0.068
Ours (LTF)	0.264	0.280	0.274	0.095	0.106	0.098
Ours (LTF+CCF)	**0.295**	**0.320**	**0.295**	**0.105**	**0.118**	**0.105**

Table 4: Overall performance (**Bold**: best performance of the task; Underlined: significance ($p < 0.01$) compared to our best model; *Italic*: significance ($p < 0.05$) compared to our best model)

amount of training data available. In addition, we find there are lots of infeasible solutions for the ILP model, indicating that the hard constraints are not relaxed enough for the relatively small data set.

– *Ours (LSF+CCF)* and *Ours (LTF+CCF)* achieve the best performance on task1 and task2, respectively, and they significantly outperform all other methods in terms of ROUGE-1 F-score based on the result of paired two-tailed t-test. By incorporating CCF, we improve the performance of local features significantly. This justifies that cross-media correlations are indeed useful for improving the quality of exaction from both directions.

– Comparing *Ours (LSF+CCF)* and *Ours (LTF+CCF)*, although their ROUGE-1 F-scores are comparable, the former is better on ROUGE-1 recall and the ROUGE-1 precision of the latter is much higher. This is because news sentences are usually longer than tweets. So the highlights extracted from news article cover more highlight tokens than those from tweets. The length of generated summary and ground truth can be seen in Table 5, where tweet extracts are much closer to the ground-truth highlights. And tweets appear to be a more suitable source for highlights extraction because of the human compression effect on the tweets.

	Tokens # per sentence	Tokens # per summary
Ground-truth highlights	13.2±3.2	49.6±10.0
Ours (LSF+CCF)	24.3±11.8	91.3±18.4
Ours (LTF+CCF)	16.1±5.4	55.3±16.1

Table 5: Comparison of the length of extracted highlights and that of ground truth

6.3 Analysis

Table 6 shows an example for analyzing our extracted highlights compared to the ground-truth. In example 1 (left column), with the help of tweets, *Ours (LSF+CCF)* can output good highlight sentences N2 and N3 which cannot be extracted by *Ours (LSF)*. On the side of tweets, T2 is newly extracted by *Ours (LTF+CCF)* after considering CCF. Furthermore, highlights extracted from tweets also bring extra good highlight T3 which is similar to H1. We find that H1 is rewritten from an original sentence which is three times longer, so it is difficult for extractive method to locate the original sentence in the article. Even if the sentence could be identified, the information was verbose still. Interestingly, some Twitter user produces a tweet like T3 by paraphrasing and shortening which is captured by the algorithm.

Although cross-media correlations are helpful, two out of four ground-truth highlight sentences are covered by the extracted good highlights in example 1. Also, the good extracts from different sources may not cover the same set of ground-truth. Therefore, maybe we can try to combine the extracts from both sides for further improvement.

Table 6: Examples of extracted highlights (H&HH items are the ground-truth highlights, N&NN items are the highlights extracted from news by *Ours (LSF+CCF)*, and T&TT items are the highlights extracted from tweets by *Ours (LTF+CCF)*; Bold: Good highlight; [+]: Newly extracted highlights using correlation features; [-]: Lost highlights after adding correlation features)

Example 2 (right column) shows tweets may not be always useful. *Ours (LSF+CCF)* adds a bad highlight NN4 but removes a good one NN. We find that NN4 is very similar to TT1. So the introduction of NN4 is believed as the result of influence from TT1. NN is squeezed out of the summary since we find it lack of tweets in our set similar to NN. Currently, we only use explicit links for tweets-document couplings. It might be helpful if we could expand the set to cover more informative tweets.

6.4 Contribution of Features

We further investigate the contribution of different features in our feature set (see Table 5) to the learned ranking models. We choose the best models from the two tasks, i.e., *Ours (LSF+CCF)* and *Ours (LTF+CC)*, and find out the top-10 weighted features for each model. To get the feature weights, for each feature we aggregate the weight values of its corresponding weak ranker selected during the iteration in RankBoost training, that is, for a weak ranker repeatedly selected in different rounds, its weights obtained from those rounds are added up to obtain as the feature weight. Table 7 lists the top-10 features and their corresponding weight values.

Cross-media correlation features, which are underlined, appear overwhelmingly important to the sentences extraction task with the model *Ours (LSF+CCF)*, where they take eight places in the top-10 feature list. This confirms the indicative effect of tweets. In tweets extraction task, the model *Ours (LTF+CCF)* does not seem to be so dependent on the cross-media correlation features, but still there are five of them appearing important in the list. In particular, the similarities between tweets and the leading news sentences such as *SimiTopUnigram* and *LeadSenSimi* are shown very helpful. This is because the leading part of the article can be more indicative of important tweets. Besides, the writing-quality measures of tweets are also very useful as it is shown that all the three quality-related features are among the top ten.

7 Conclusion and Future work

In this paper, we explore to utilize microblogs for automatic highlights extraction from two perspectives using learning-based ranking models. Firstly, we extract important sentences from news article by using a set of relevant tweets that provide indicative support for the informativeness of candidate sentences; Secondly, we extract important tweets from the relevant tweets set associated with the given article by taking the advantage of the fact that tweets are comparably concise as highlights. The results show that our methods significantly outperform state-of-the-art baseline approaches for single-document sum-

Table 7: Top 10 features and their weights resulting from the best ranking models in the two tasks (underline: Cross-media correlation features)

marization. Our feature study further discovers that the cross-media correlations are overwhelmingly important to sentence extraction, and for tweets extraction the quality-related features are comparably important as cross-media correlation measures. Also, tweets extraction appears more suitable for producing highlights owing to the human compression effect of tweets.

For the future work, we plan to enlarge the relevant tweets collection by including relevant tweets not linked by URLs; we can combine the extracts from both sides for further improvement; we can also strengthen our model by capturing some deeper or latent linguistic and semantic correlations with deep learning formalism.

A Step Towards Usable Privacy Policy: Automatic Alignment of Privacy Statements

Fei Liu Rohan Ramanath Norman Sadeh Noah A. Smith

Pittsburgh, PA 15213, USA
{feiliu, rrohan, sadeh, nasmith}@cs.cmu.edu

Abstract

With the rapid development of web-based services, concerns about user privacy have heightened. The privacy policies of online websites, which serve as a legal agreement between service providers and users, are not easy for people to understand and therefore offer an opportunity for natural language processing. In this paper, we consider a corpus of these policies, and tackle the problem of aligning or grouping segments of policies based on the privacy issues they address. A dataset of pairwise judgments from humans is used to evaluate two methods, one based on clustering and another based on a hidden Markov model. Our analysis suggests a five-point gap between system and median-human levels of agreement with a consensus annotation, of which half can be closed with bag of words representations and half requires more sophistication.

1 Introduction

Privacy policies are legal documents, authored by privacy lawyers to protect the interests of companies offering services through the web. According to a study conducted by McDonald and Cranor (2008), if every internet user in the U.S. read the privacy notice of each new website she visited, it would take the nation 54 billion hours annually to read privacy policies. It is not surprising that they often go unread (Federal Trade Commission, 2012).

Users, nonetheless, might do well to understand the implications of agreeing to a privacy policy, and might make different choices if they did. Researchers in the fields of internet privacy and security have made various attempts to standardize the format of privacy notices, so that they are easier to understand and to allow the general public to have better control of their personal information. An early effort is the Platform for Privacy Preferences Project (P3P), which defines a machine-readable language that enables the websites to explicitly declare their intended use of personal information (Cranor, 2002). Many other studies primarily focus on the qualitative perspective of policies and use tens of carefully selected privacy notices. For example, Kelley et al. (2010) proposed a "nutrition label" approach that formalizes the privacy policy into a standardized table format. Breaux et al. (2014) map privacy requirements encoded in text to a formal logic, in order to detect conflicts in requirements and trace data flows (e.g., what data might be collected, to whom the data will be transferred and for what purposes).

The need for automatically or semi-automatically generating simple, easy-to-digest privacy summaries is further exacerbated by the emergence of the mobile Web and the Internet of Things, with early efforts in this area including the use of static analysis to identify sensitive data flows in mobile apps (Lin et al., 2012) and the development of mobile app privacy profiles (Liu et al., 2014).

Increased automation for such efforts motivates our interest in privacy policies as a text genre for NLP, with the general goal of supporting both user-oriented tools that interpret policies and studies of the contents of policies by legal scholars.

In this paper, we start with a corpus of 1,010 policies collected from widely-used websites (Ramanath et al., 2014),[1] and seek to automatically align segments of policies. We believe this is a worthwhile first

Table 1: Example privacy statements from Amazon.com (left) and Walmart.com (right). The statements are concerned with the websites' cookie policy. The top-most level section subtitles are shown in bold.

step toward interpretation of the documents of direct interest here, and also that automatic alignment of a large set of similarly-constructed documents might find application elsewhere.

Consider the example in Table 1, where we show privacy statements from Amazon.com[2] and Walmart.com.[3] These statements are concerned with the usage of cookies—small data files transferred by a website to the user's computer hard drive—often used for tracking a user's browsing behavior. Cookies are one issue among many that are addressed by privacy policies; by aligning segments by issue, across policies, we can begin to understand the range of policy approaches for each issue.

We contribute pairwise annotations of segment pairs drawn from different policies, for use in evaluating the quality of alignments, an analysis of the inter-annotator reliability, and an experimental assessment of three alignment methods, one based on clustering and two based on a hidden Markov model. This paper's results refine the findings of Ramanath et al. (2014). Our key finding is that these unsupervised methods reach far better agreement with the consensus of crowdworkers than originally estimated, and that the gap between these methods and the "median" crowdworker is about half due to the greedy nature of such methods and about half due to the bag of words representation.

2 Privacy Dataset and Annotations

For completeness, we review the corpus of privacy policies presented by Ramanath et al. (2014), and then present the new annotations created for evaluation of alignment.

2.1 Corpus

We collected 1,010 unique privacy policy documents from the top websites ranked by Alexa.com.[4] These policies were collected during a period of six weeks during December 2013 and January 2014. They are a snapshot of privacy policies of mainstream websites covering fifteen of Alexa.com's seventeen categories (Table 2).[5]

Finding a website's policy is not trivial. Though many well-regulated commercial websites provide a "privacy" link on their homepages, not all do. We found university websites to be exceptionally unlikely to provide such a link. Even once the policy's URL is identified, extracting the text presents the usual challenges associated with scraping documents from the web. Since every site is different in its placement of the document (e.g., buried deep within the website, distributed across several pages, or mingled together with Terms of Service) and format (e.g., HTML, PDF, etc.), and since we wish to preserve as much document structure as possible (e.g., section labels), full automation was not a viable solution.

Table 2: Fifteen website categories, average number of sections and paragraphs per document in that category, and average length in word tokens.

We therefore crowdsourced the privacy policy document collection using Amazon Mechanical Turk. For each website, we created a HIT in which a worker was asked to copy and paste the following privacy policy-related information into text boxes: (i) privacy policy URL; (ii) last updated date (or effective date) of the current privacy policy; (iii) privacy policy full text; and (iv) the section subtitles in the top-most layer of the privacy policy. To identify the privacy policy URL, workers were encouraged to go to the website and search for the privacy link. Alternatively, they could form a search query using the website name and "privacy policy" (e.g., "Amazon.com privacy policy") and search in the returned results for the most appropriate privacy policy URL. Each HIT was completed by three workers, paid \$0.05, for a total cost of \$380 (including Amazon's surcharge). After excluding dupliates, the dataset contains 1,010 unique documents.[6]

Given the privacy policy full text and the section subtitles, we partition the full privacy document into different sections, delimited by the section subtitles. To generate paragraphs, we break the sections by lines, and consider each line as a paragraph. We require a paragraph to end with a period, if not, it will be concatenated with the next paragraph. Using this partition scheme, sections contain 12 sentences on average; and paragraphs contain 4 sentences on average. More statistics are presented in Table 2.

2.2 Pairwise Annotations

Ramanath et al. (2014) described an evaluation method in which pairs of privacy policy sections were annotated by crowdworkers.[7] A sample of section pairs from different policies was drawn, stratified by cosine similarity of unigram tfidf vectors. In a single task, a crowdworker was asked whether two sections broadly discussed the same topic. The question was presented alongside three answer options, essentially a strong yes, a yes, and a no. In that initial exploration, each item was annotated at least three times, and up to fifteen, until an absolute majority was reached.

The annotations conducted for this study were done somewhat differently. Our motivations were to enable a more careful exploration of inter-annotator agreement, which was complicated in the earlier work by the variable number of annotations per pair, from three to fifteen. We also sought to explore a more fine-grained problem at the paragraph level.

We sampled 1,000 document pairs from each of the 15 categories, then generated pairs (separately of sections and of paragraphs) by choosing one at random from each document. In total, 1,278,204 section pairs and 7,968,487 paragraph pairs were produced. These pairs were stratified by cosine similarity intervals: [0, 0.25], (0.25, 0.5], (0.5, 0.75], (0.75, 1], as in Ramanath et al. (2014). We sampled 250 pairs from each interval, resulting in 1,000 pairs each of sections and paragraphs.

These pairs were annotated on Amazon Mechanical Turk. The crowdworkers were instructed to carefully read the privacy statements and answer a "yes/no" question, indicating whether the two texts are discussing the same privacy issue or not. Several key privacy issues are provided as examples, including

[6]Note that different websites may be covered by the same privacy policy provided by the parent company. For example, `espn.go.com`, `abc.go.com`, and `marvel.com` are all covered under the Walt Disney privacy policy.

[7]Another evaluation, based on text selected by humans in a separate, unrelated task, was also explored. Because such an evaluation seems less broadly applicable, we did not pursue it here.

	Sections					Paragraphs				
Cosine similarity:	[0, .25]	(.25, .5]	(.5, .75]	(.75, 1]	All	[0, .25]	(.25, .5]	(.5, .75]	(.75, 1]	All
5 workers agree	36.4	**12.4**	28.0	85.2	40.5	42.4	**12.0**	32.8	77.6	41.2
4 workers agree	42.8	**42.4**	42.0	13.6	35.2	39.6	**36.8**	35.6	17.6	32.4
3 workers agree	20.8	**45.2**	30.0	1.2	24.3	18.0	**51.2**	31.6	4.8	26.4
Consensus-yes	4.4	**45.2**	87.2	99.2	59.0	9.2	**66.0**	88.8	98.0	65.5
Consensus-no	95.6	**54.8**	12.8	0.8	41.0	90.8	**34.0**	11.2	2.0	34.5

Table 3: Inter-annotator agreement of section and paragraph pairs.

collection of personal information, sharing of information with third parties, cookies and other tracking techniques, data security, children policies, and contact of the websites. To encourage the crowdworkers to carefully read the privacy statements, we also asked them to copy and paste 1–3 keywords from each section/paragraph, before answering the question.[8] Each section/paragraph pair was judged by five crowdworkers and was rewarded $0.05. In total, $550 was spent on the annotations.

On average, it took a crowdworker 2.15 minutes to complete a section pair and 1.67 minutes for a paragraph pair. Interestingly, although a section is roughly three times the length of a paragraph (see Table 2), the time spent on annotation is not proportional to the text length.

In Table 3, we present the inter-annotator agreement results for section and paragraph pairs, broken down by cosine-similarity bin and by the majority answer. 75.7% (73.6%) of section (paragraph) pairs were agreed upon by four or more out of five annotators. Unsurprisingly, disagreement is greatest in the $(.25, .5]$ similarity bin. Cosine similarity is a very strong predictor of the consensus answer (Pearson correlation 0.72 for section pairs, 0.67 for paragraphs, on this stratified sample).

Ramanath et al. (2014) considered only sections. A different method was used to obtain consensus annotations; we simply kept adding annotators to a pair until consensus was reached. For a fair comparison with the new data, we calculated pairwise agreement among three annotators per item, randomly selected if there were more than three to choose from. On the old section-level data, this was 60.5%; on the new data, it was 71.3% (using five annotators). Although a controlled experiment in the task setup was not conducted, we take this as a sign that our binary question with keywords led to a higher quality set of annotations than the three-way question in the older data. Our experiments in this paper use only the new data.

2.3 Discussion

We had expected higher agreement at the paragraph level, since paragraphs are shorter, presumably easier to read and compare, and presumably more focused on a smaller number of issues. This was not borne out empirically, though a slightly different analysis presented in §4.2 suggests that, among crowdworkers who completed ten or more tasks, paragraphs were easier to agree on.

Privacy policies are generally written by attorneys with expertise in privacy law, though there are automatic generation solutions available that allow a non-expert to quickly fill in a template to create a policy document.[9] Example 1 in Table 4 shows a case of very high text overlap (five out of five annotators agreed on a "yes" answer for this pair). While this kind of localized alignment is not our aim here, we believe that such "boilerplate" text, to the extent that it occurs in large numbers of policies, will make automatic alignment easier.

A case where annotators seem not to have understood, or not taken care to read carefully, is illustrated by Example 2 in Table 4. Both sections describe "opt-out" options for unsubscribing from mailing lists that send promotional messages, though the first is more generally about "communications" and the second only addresses email. Three out of five crowdworkers labeled this example with"no." Achieving better consensus might require more careful training of annotators about a predefined set of concepts at the right granularity.

[8] We have not used these keywords for any other purpose.

Table 4: Privacy policy excerpts. Example 1 (a pair of paragraphs) illustrates the likely use of boilerplate; identical text is marked in gray. Example 2 shows a pair of sections where our intuitions disagree with the annotations.

3 Problem Formulation

Given a collection of privacy policy documents and assuming each document consists of a sequence of naturally-occurring text segments (e.g., sections or paragraphs), our goal is to automatically group the text segments that address the same privacy issue, without pre-specifying the set of such issues. We believe this exemplifies many scenarios where a collection of documents follow a similar content paradigm, such as legal documents and, in some cases, scientific literature. Our interest in algorithms that characterize each individual document's parts in the context of the corpus is inspired by biological sequence alignment in computational biology (Durbin et al., 1998).

In our experiments, we consider a hidden Markov model (HMM) that captures local transitions between topics. The motivation for the HMM is that privacy policies might tend to order issues similarly, e.g., the discussion on "sharing information to third parties" appears to often follow the discussion of "personal information collection." If each of these corresponds to an HMM state, then the regularity in ordering is captured by the transition distribution, and each state is characterized by its emission distribution over words. In this section, we discuss the HMM and two estimation procedures based on Expectation-Maximization (EM) and variational Bayesian (VB) inference.

3.1 Hidden Markov Model

Assume we have a sequence of observed text segments[10] $O = [O_1, O_2, ..., O_T]$, and each O_t represents a text segment in a privacy document ($t \in \{1, 2, ..., T\}$). We denote $O_t = [O_t^1, O_t^2, ..., O_t^{N_t}]$, where each O_t^j corresponds to a word token in the tth text segment; N_t is the total number of word tokens in the segment; T represents the total number of segments in the observation sequence. Each text segment O_t is associated with a hidden state S_t ($S_t \in \{1, 2, \ldots, K\}$, where K is the total number of states). Given an observation sequence O, our goal is to decode the corresponding hidden state sequence S.

We employ a first-order hidden Markov model where the next state depends only on the previous state. A notable difference from the familiar HMM used in NLP (e.g., as used for part-of-speech tagging) is that we allow multiple observation symbols to be emitted from each hidden state. Each symbol corresponds to a word token in the text segment. Hence the likelihood for a single document can be written as:

$$L(\theta, \phi) = \sum_{S \in \{1,...,K\}^T} p(O, S \mid \theta, \phi) = \sum_{S \in \{1,...,K\}^T} \prod_{t=1}^{T+1} \theta_{S_t|S_{t-1}} \prod_{j=1}^{N_t} \phi_{O_t^j|S_t} \quad (1)$$

[10]We use *segments* to refer abstractly to either sections or paragraphs. In any given instantiation, one or the other is used, never a blend.

E-step:

$$\textit{Forward pass:} \quad \alpha_1(\cdot) = 1; \quad \alpha_t(k) = \sum_{k'=1}^{K} \alpha_{t-1}(k') \cdot \theta_{k|k'} \cdot \prod_{j=1}^{N_t} \phi_{O_t^j|k}, \;\; \forall t \in \{2, \ldots, T\}, \forall k \in \{1, \ldots, K\} \tag{2}$$

$$\textit{Backward pass:} \quad \beta_{T+1}(\cdot) = 1; \quad \beta_t(k) = \sum_{k'=1}^{K} \theta_{k'|k} \cdot \prod_{j=1}^{N_t} \phi_{O_t^j|k'} \cdot \beta_{t+1}(k'), \;\; \forall t \in \{T, \ldots, 1\}, \forall k \in \{1, \ldots, K\} \tag{3}$$

$$\textit{Likelihood:} \quad p(O \mid \theta, \phi) = p(O_1, O_2, ..., O_T \mid \theta, \phi) = \sum_{k=1}^{K} \alpha_t(k) \cdot \beta_t(k) \textit{ (for any t)} \tag{4}$$

$$\textit{Posteriors:} \quad \gamma_t(k) = p(S_t = k \mid O, \theta, \phi) = \frac{\alpha_t(k) \cdot \beta_t(k)}{p(O \mid \theta, \phi)} \tag{5}$$

$$\textit{Pair posteriors:} \quad \xi_t(k, k') = p(S_t = k, S_{t+1} = k' \mid O, \theta, \phi) = \frac{\alpha_t(k) \cdot \theta_{k'|k} \cdot \left(\prod_{j=1}^{N_{t+1}} \phi_{O_{t+1}^j|k'} \right) \cdot \beta_{t+1}(k')}{p(O \mid \theta, \phi)} \tag{6}$$

M-step (in EM):

$$\textit{Transitions:} \quad \theta_{k'|k} = \frac{\sum_{t=1}^{T} \xi_t(k, k')}{\sum_{t=1}^{T} \sum_{k''=1}^{K} \xi_t(k, k'')}; \qquad \textit{Emissions:} \quad \phi_{v|k} = \frac{\sum_{t=1}^{T} \gamma_t(k) \cdot \sum_{j=1}^{N_t} \mathbf{1}\{O_t^j = v\}}{\sum_{t=1}^{T} \gamma_t(k) \cdot N_t} \tag{7}$$

Variational update (in VB):

$$\theta_{k'|k} = \frac{\exp \Psi \left(\sum_{t=1}^{T} \xi_t(k, k') + \lambda \right)}{\exp \Psi \left(\sum_{t=1}^{T} \sum_{k''=1}^{K} \xi_t(k, k'') + \lambda \cdot K \right)}; \qquad \phi_{v|k} = \frac{\exp \Psi \left(\sum_{t=1}^{T} \gamma_t(k) \cdot \sum_{j=1}^{N_t} \mathbf{1}\{O_t^j = v\} + \lambda' \right)}{\exp \Psi \left(\sum_{t=1}^{T} \gamma_t(k) \cdot N_t + \lambda' \cdot V \right)} \tag{8}$$

Table 5: Equations for parameter estimation of the HMM with multiple emissions at each state and a single sequence. K is the number of states, V is the emission vocabulary size, and T is the length of the sequence in sections. $\Psi(\cdot)$ is the digamma function.

$\theta_{k'|k}$ denotes the probability of transitioning to state k' given that the preceding state is k. $\phi_{v|k}$ denotes the probability that a particular symbol emitted during a visit to state k is the word v. As in standard treatments, we assume an extra final state at the end of the sequence that emits a stop symbol.

Ramanath et al. (2014) considered three variants of the HMM, with different constraints on the transitions, such as a "strict forward" variant that orders the states and only allows transition to "later" states than the current one. In the evaluation against direct human judgments, they found a slight benefit from such constraints, but they increased performance variance considerably. Here we only consider an unconstrained HMM.

3.2 EM and VB

We consider two estimation methods, neither novel. Both are greedy hillclimbing methods that locally optimize functions based on likelihood under the HMM.

The first method is EM, adapted for the multiple emission case; the equations for the E-step (forward-backward algorithm and subsequent posterior calculations) and the M-step are shown in Table 5.

We also consider Bayesian inference, which seeks to marginalize out the parameter values, since we are really only interested in the assignment of sections to hidden states. Further, Bayesian inference has been found favorable on small datasets (Gao and Johnson, 2008). We assume symmetric Dirichlet priors on the transition and emission distributions, parameterized respectively by $\lambda = 1$ and $\lambda' = 0.1$. We apply mean-field variational approximate inference as described by Beal (2003), which amounts to an EM-like procedure. The E-step is identical to EM, and the M-step involves a transformation of the expected counts, shown in Table 5. (We also explored Gibbs sampling; performance was less stable but generally similar; for clarity we do not report the results here.)

3.3 Implementation Details

In modeling, the vocabulary excludes 429 stopwords,[11] words whose document frequency is less than ten, and a set of terms specific to website privacy polices: *privacy*, *policy*, *personal*, *information*, *service*, *web*, *site*, *website*, *com*, and *please*. After lemmatizing, the vocabulary contains $V = 2{,}876$ words. We further exclude sections and paragraphs that contain less than 10 words. Many of these are not meaningful statements, e.g., "return to top." This results in 9,935 sections and 27,594 paragraphs in the experiments.

During estimation, we concatenate all segments into a single sequence, delimited by a special boundary symbol. This does not affect the outcome (due to the first-order conditions; it essentially conflates "start" and "stop" states), but gave some efficiency gains in our implementation.

EM or VB iterations continue until one of two stopping criteria is met: either 100 iterations have passed, or the relative change in log-likelihood (or the variational bound in the case of VB) falls below 10^{-4}; this consistently happens within forty iterations.

After estimating parameters, we decode using the Viterbi algorithm.

4 Experiments

Our experiments compare three methods for aligning segments of privacy policies, at both the paragraph and the section level:

- A greedy divising clustering algorithm, as implemented in CLUTO.[12] The algorithm performs a sequence of bisections until the desired number of clusters is reached. In each step, a cluster is selected and partitioned so as to optimize the clustering criterion. CLUTO demonstrated robust performance in several related NLP tasks (Zhong and Ghosh, 2005; Lin and Bilmes, 2011; Chen et al., 2011).

- The Viterbi state assignment from the EM-estimated HMM. We report averaged results over ten runs, with random initialization.

- The Viterbi state assignment after VB inference, using the mean field parameters. We report averaged results over ten runs, with random initialization.

Our evaluation metrics are precision, recall, and F-score on the identification of section or paragraph pairs annotated "yes."

4.1 Results

In Figure 1, we present performance of different algorithms using a range of hidden state values $K \in \{1, 2, \ldots, 20\}$. The top row shows precision, recall and F-scores on section pairs, the bottom row on paragraph pairs.

The algorithms mostly perform similarly. At the section level, we find the clustering algorithm to perform better in terms of F-score than the HMM with larger K; at $K = 10$ the two are very close.[13] CLUTO's best performance, 85%, was achieved by $K = 14$.

At the paragraph level, the HMMs outperform clustering in the $K \in [5, 15)$ range, and this is where the peak F-score is obtained (87%). We do not believe these differences among algorithms are especially important, noting only that the HMM's advantage is that it does not require pairwise similarity calculations between all section pairs.

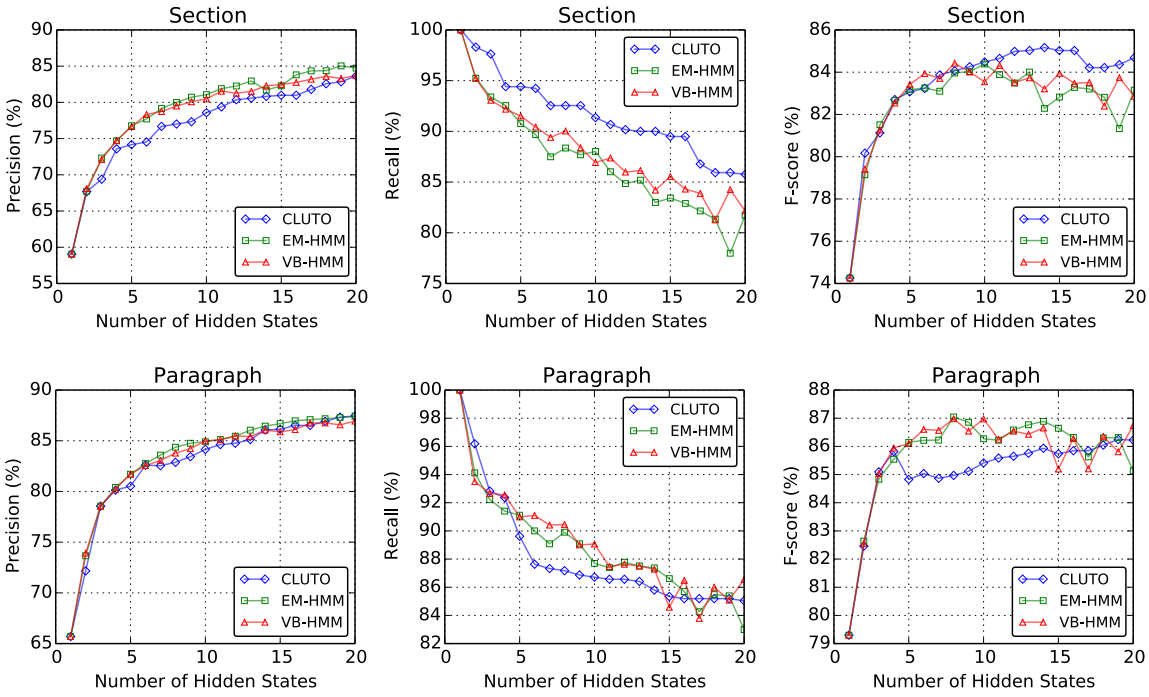

Figure 1: Performance results against pairwise annotations when using different number of hidden states $K \in \{1, \ldots, 20\}$. The top row is at the section level, the bottom row at the paragraph level.

4.2 Upper Bounds

How do these automatic alignment methods compare with the levels of agreement reached among crowdworkers? We consider the agreement rate of each method, at varying values of K, with the majority vote of the annotators. Note that this is distinct from the positive-match–focused precision, recall, and F-score measures presented in §4.1. For each crowdworker who completed ten tasks or more, and therefore for whom we have hope of a reliable estimate, we calculated her agreement rate with the majority. For sections, this set included 65 out of 162 crowdworkers; for paragraphs, 76 out of 197.

In Figure 2 we show the three quartile points for this agreement measure, across the pool of ten-or-more-item crowdworkers, in comparison to the various automatic methods. For sections, our systems perform on par with the 25% of crowdworkers just below the median. For paragraphs, which show a generally higher level of agreement among this subset of crowdworkers, our systems are on par with the lowest 25% of workers. We take all of this to suggest that there is room for improvement in methods overall.

Given the observation in §2 that cosine similarity of two segments' tfidf vectors is a very strong predictor of human agreement on whether they are about the same issue, we also consider a threshold on cosine similarity for deciding whether a pair is about the same issue. This is not a complete solution to the problem of alignment, since pairwise scores only provide groupings if they are coupled with a transitivity constraint. The clustering and HMM methods can be understood as greedy approximations to such an approach. We therefore view cosine similarity thresholding as an upper bound for bag of words representations on the pairwise evaluation task. Figure 2 includes agreement levels for oracle cosine similarity thresholding.[14]

[11] `http://www.lextek.com/manuals/onix/stopwords1.html`

[12] `http://glaros.dtc.umn.edu/gkhome/cluto/cluto/overview`

[13] Ramanath et al. (2014) only considered $K = 10$ and found a $K = 10$ HMM to outperform clustering at the section level; the scores reported there, on the earlier dataset, are much lower and not comparable to those reported here. There are numerous differences between the setup here and the earlier one. The most important, we believe, are the improved quality of the dataset and greater care given to preprocessing, most notably the pruning of documents and vocabulary, in the present experiments.

[14] For comparison with the results in §4.1, we found that, for sections, oracle thresholding (at 0.3) achieved F-score of 0.87, and for paragraphs, oracle thresholding (at 0.2) achieved 0.90.

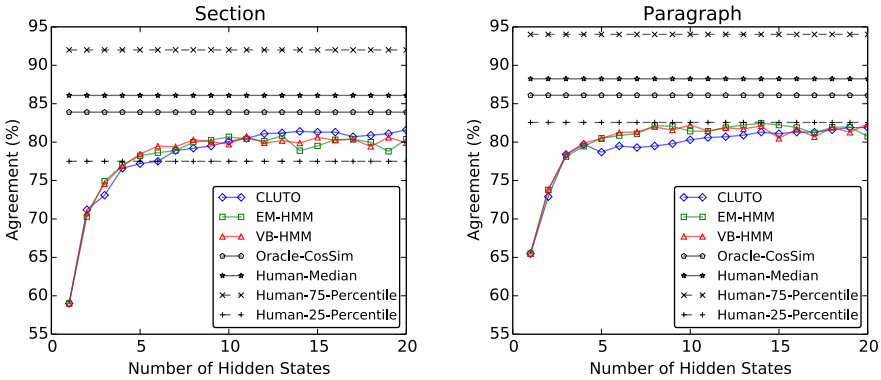

Figure 2: Agreement rates, as compared to crowdworkers and a cosine similarity oracle.

Taken together, this analysis suggests that—in principle—an automated approach based on word-level similarity could close about half of the gap between our methods and median crowdworkers, and further gains would require more sophisticated representations or similarity measures.

5 Related Work

There has been little work on applying NLP to privacy policies. Some have sought to parse privacy policies into machine-readable representations (Brodie et al., 2006) or extract sub-policies from larger documents (Xiao et al., 2012). Machine learning has been applied to assess certain attributes of policies (Costante et al., 2012; Costante et al., 2013), e.g., compliance of privacy policies to legal regulations (Krachina et al., 2007) or simple categorical questions about privacy policies (Ammar et al., 2012; Zimmeck and Bellovin, 2014).

Our alignment-style analysis is motivated by an expectation that many policies will address similar issues,[15] such as collection of a user's contact, location, health, and financial information, sharing with third parties, and deletion of data. This expectation is supported by recommendation by privacy experts (Gellman, 2014) and policymakers (Federal Trade Commission, 2012); in the financial services sector, the Gramm-Leach-Bliley Act *requires* these institutions to address a specific set of issues. Sadeh et al. (2013) describe our larger research initiative to incorporate automation into privacy policy analysis.

Methodologically, the HMM used above is very similar to extensive previous uses of HMMs for POS tagging (Merialdo, 1994), including with Bayesian inference (Goldwater and Griffiths, 2007; Johnson, 2007; Gao and Johnson, 2008). Bayesian topic models (Blei et al., 2003) are a related set of techniques, and future exploration might consider their use in automatically discovering document sections (Eisenstein and Barzilay, 2008), rather than fixing section or paragraph boundaries.

6 Conclusion

This paper presents an exploration of alignment-by-paragraph and -section of website privacy policies. We contribute an improved annotated dataset for pairwise evaluation of automatic methods and an exploration of clustering and HMM-based alignment methods. Our results show that these algorithms achieve agreement on par with the lower half of crowdworkers, with about half of the difference from the median due to the bag of words representation and half due to the inherent greediness of the methods.

Abstract

Authorship detection is a challenging task due to many design choices the user has to decide on. The performance highly depends on the right set of features, the amount of data, in-sample vs. out-of-sample settings, and profile- vs. instance-based approaches. So far, the variety of combinations renders off-the-shelf methods for authorship detection inappropriate. We propose a novel and generally deployable method that does not share these limitations. We treat authorship attribution as an anomaly detection problem where author regions are learned in feature space. The choice of the right feature space for a given task is identified automatically by representing the optimal solution as a linear mixture of multiple kernel functions (MKL). Our approach allows to include labelled as well as unlabelled examples to remedy the in-sample and out-of-sample problems. Empirically, we observe our proposed novel technique either to be better or on par with baseline competitors. However, our method relieves the user from critical design choices (e.g., feature set) and can therefore be used as an off-the-shelf method for authorship attribution.

1 Introduction

Automatically attributing a piece of text to its author is one of the oldest problems studied in linguistics (Mendenhall, 1887). Despite being an old problem, authorship attribution is still highly topical and todays applications range from plagiarism detection (Maurer et al., 2006), identifying the origin of anonymous harassments in emails, blogs, and chat rooms (Tan et al., 2013) to copyright and estate issues as well as resolving historical questions of disputed authorship (Mosteller and Wallace, 1964; Fung, 2003).

Intrinsically, the goal of authorship detection is to identify the characteristic traits of an author. The idea is that, these traits distinguish an author from others in terms of writing style, use of words, etc. Thus, prior work often focuses on designing and extracting features from text to capture these traits. There is a great deal of features proposed for authorship detection, including word or character n-grams (Burrows, 1987; Houvardas and Stamatatos, 2006), part-of-speech (Stamatatos et al., 2001), probabilistic context-free grammars (Raghavan et al., 2010), or linguistic features (Koppel et al., 2006). However, indicative features for one author do not necessarily help to characterise another. A major problem in authorship detection is therefore to find the right set of features for a given task at hand (Forman, 2003).

Algorithmically, a variety of different models have been studied in the context of authorship detection, ranging from probabilistic approaches (Seroussi et al., 2011) and similarity-based methods (Koppel et al., 2011) to vector space models (Fung, 2003; Li et al., 2006). The approaches either treat documents as independent (instance-based) or concatenate documents by the same author (profile-based). Intuitively, the latter is helpful if an author has a concise way of expressing herself so that the concatenated document allows to extract a statistic that is sufficient for capturing her style. On the other hand, instance-based approaches are better suited for expressive authors and have advantages in sparse data scenarios.

Another aspect in authorship attribution is the application scenario of the final model. In transductive (in-sample) settings, the unlabelled documents of interest are already included in the training process

Proceedings of COLING 2014, the 25th International Conference on Computational Linguistics: Technical Papers, pages 895–904, Dublin, Ireland, August 23-29 2014.

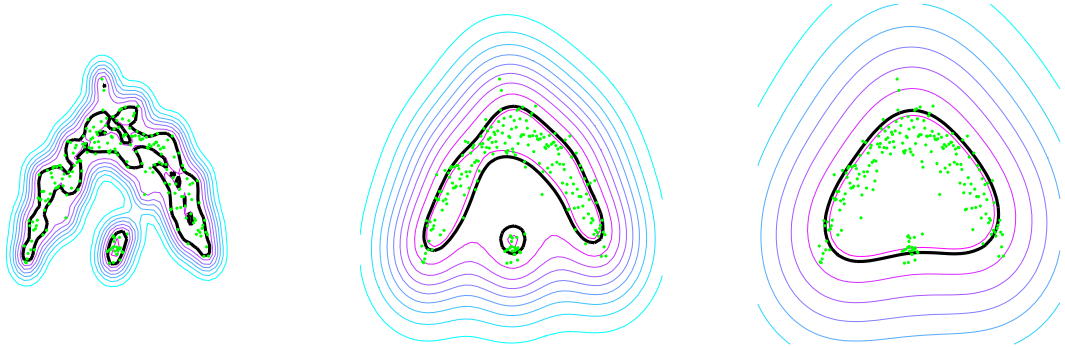

Figure 1: Three solutions of an anomaly detection problem where data is represented by RBF kernels with different band-width parameters. Combining anomaly detection with multiple kernel learning allows to include all three kernels simultaneously in the optimisation and to find the optimal linear mixture of the three (or more) kernels together automatically for a given task.

and the model does not necessarily perform well on new and unseen texts. By contrast, inductive (out-of-sample) scenarios generally allow to learn models that can be applied to any future text but require larger training samples to achieve accurate performances.

In this paper, we propose a general machine learning-based approach to authorship detection. Our approach remedies the above mentioned problems by fusing existing techniques: (i) We cast authorship attribution as an anomaly detection problem where one model is learned for every author. The idea is to identify a concise region in feature space that contains (most of) the documents of the author of interest while other documents are considered outliers. Thus, the model can be viewed as a profile-based approach in feature space while the data is treated on an instance-based level. (ii) We remedy the in-sample / out-of-sample problem by providing a semi-supervised extension of the commonly unsupervised outlier detection framework. By doing so, we may include authorship labels for the already known documents and leave the disputed ones unlabelled. (iii) Finally, we devise our model consequentially as a member of the multiple kernel learning family to automatically include a mathematically well founded feature selection framework that renders the method generally applicable. The optimal solution is given by a (possibly sparse) linear mixture of kernel functions.

Empirically, we observe that our approach consistently outperforms baseline competitors or confirms common knowledge with respect to the authorship of disputed articles. The main advantage of the method however lies in its simplicity. Practitioners do not need to take critical design choices in terms of which features to use and which not. By contrast, all features (kernels) can be used in the optimisation and the method itself finds the optimal combination for the problem at hand.

The remainder of this paper is structured as follows. Section 2 reviews related work. Our main contribution is presented in Section 3. We report on empirical results in Section 4 and Section 5 concludes.

2 Related Work

Authorship attribution using linguistic and stylistic features has a long tradition and can be dated back to the nineteenth century. As a first attempt, Mendenhall (Mendenhall, 1887) uses features based on word lengths to characterise the plays of Shakespeare. Later in the first half of the 20th century, different textual statistics, such as Zipf's distribution (Zipf, 1932) and Yule's k-statistic (Yule, 1944) have been proposed to quantify textual style. A study conducted by (Mosteller and Wallace, 1964) is one of the most influential modern work in authorship attribution. They use a Bayesian approach to analyse frequencies of a small set of function words for *The Federalist Papers*, a series of 85 political essays written by John Jay, Alexander Hamilton, and James Madison. Until the late 1990s, research in *stylometry* has been dominated by feature engineering to quantify writing style (Holmes, 1998) and about 1,000 different measures have been proposed (Rudman, 1997).

Document representation is essential for author attribution tasks. Features aim to capture characteristic traits of authors that persist across topics. Traditional stylometric features include function and high-frequency words, hapax legomena, Yules k-statistic, syllable distributions, sentence length, word length and word frequencies, vocabulary richness functions as well as syntactic features. Many studies combine features of different types using multivariate analyses. Some researchers use punctuation symbols while others experiment with n-grams (Diederich et al., 2003). Grammatical style markers with natural language processing techniques are also used to extract features from the documents.

Also in terms of technical approaches, authorship attribution has been studied with a wide range of different approaches. The deployed techniques can be broadly divided into three categories: machine learning (Diederich et al., 2003), multivariate/cluster analysis (Khmelev, 2000), and natural language processing (Stamatatos et al., 2000). Principal components analysis (PCA) is one of the widely used techinques for authorship studies, for instance, (Holmes and Crofts, 2010) apply PCA to identify the authorship of unknown articles that have been attributed to Stephen Crane. In addition, machine learning-based approaches, including neural networks (Neme et al., 2011) and support vector machines (SVMs) (Diederich et al., 2003), are frequently used to discriminate documents by different authors. An excellent survey on the diversity of approaches for authorship detection is provided by (Stamatatos, 2009).

Density level set estimation, also known as one-class learning (Tax and Duin, 1999; Schölkopf et al., 1999), is the problem of learning a representation of a single class of interest, rejecting data points that deviate from the learned model of normality. Thus, it has been proven very successful in anomaly detection scenarios such as network intrusion detection (Görnitz et al., 2009). Various extensions have been proposed, i.e. to incorporate prior and additional knowledge (Görnitz et al., 2013; Blanchard et al., 2010) in a semi-supervised fashion (Chapelle et al., 2006) and to learn linear combinations of kernels (Kloft et al., 2011; Rakotomamonjy et al., 2008) which is especially usefull whenever the right choice of representation is unknown.

3 Methodology

In this section, we cast semi-supervised anomaly detection as an instance of multiple kernel learning. The rational for this idea is shown in Figure 1. The figure shows three solutions for an anomaly detection task. The data is represented by RBF kernels with different band-width parameters. As shown in the figure, the choice of the band width parameter is crucial and leads to very different solutions. Usually, kernel parameters are thus included in the model selection and their optimisation is often time consuming. Fusing the anomaly detection with multiple kernel learning allows to include all three kernels simultaneously in the optimisation and to find the best linear mixture of the three (or more) kernels together with model parameters for the data at hand.

We briefly review anomaly detection and semi-supervised anomaly detection in Sections 3.1 and 3.2, respectively, and present our main contribution, multiple kernel learning for anomaly detection, in Section 3.3.

3.1 Preliminaries

Anomaly detection is often cast as an unsupervised one-class problem where the goal is to find a hyperplane that separates the majority of the input examples from the origin with maximum margin, so that, by definition, points not exceeding the hyperplane are considered outliers. Analogously, we aim to learn a separating hyperplane for articles by an author of interest, such that documents not exceeding the learned hyperplane are written by other authors.

Given a n articles $\boldsymbol{x}_1, \ldots, \boldsymbol{x}_n$ of possibly different authors, a straight forward optimisation problem that identifies the hyperplane in terms of its normal vector $\mathbf{w}$ and threshold ρ is known as one-class support vector machine (Tax and Duin, 1999; Schölkopf et al., 1999) and given by

$$\begin{aligned} \min_{\mathbf{w},\rho,\boldsymbol{\xi}\geq 0} \quad & \frac{1}{2}\| \mathbf{w} \|_2^2 - \rho + \eta_u \sum_{i=1}^{n} \xi_i \\ \text{s.t.} \quad \forall_{i=1}^{n} : \quad & \langle \mathbf{w}, \phi(\boldsymbol{x}_i) \rangle \geq \rho - \xi_i. \end{aligned}$$

The hyperplane is realised by the decision function

$$f(\boldsymbol{x}) = \langle \mathbf{w}, \phi(\boldsymbol{x}) \rangle - \rho$$

and new articles are credited to the author if $f(\boldsymbol{x}) > 0$ and are considered work by someone else if $f(\boldsymbol{x}) \leq 0$. The threshold ρ can be interpreted as a measure of expressiveness of an author. E.g., authors who have a very clear and concise style realise smaller thresholds than expressive authors that may adopt to different writing styles.

3.2 Semi-supervised Anomaly Detection

Using only unlabelled data is usually leading to inaccurate models in the presence of only a few data points. We therefore extend the problem setting to include m labeled examples $(\boldsymbol{x}_{n+1}, y_{n+1}), \ldots, (\boldsymbol{x}_{n+m}, y_{n+m})$ in addition to the n unlabelled ones. Labels $y_i \in \{+1, -1\}$ are considered binary, that is in case $y_i = +1$, document $\boldsymbol{x}_i$ belongs to the author of interest. To combine sums and hence, improve readability, we introduce labels $y_i = +1 \; \forall \, i = 1, \ldots, n$ for all unlabelled examples and an indicator function $\mathbb{I}_c \equiv [c > n]$ to mask labeled examples; the function $\mathbb{I}_c$ simply returns 1 if $c > n$ and 0 otherwise.

A semi-supervised generalisation of the hypersphere model of the previous section is the convex semi-supervised anomaly detection (SSAD) (Görnitz et al., 2013) which uses an L_2-regularizer together with the hinge-loss. Let γ be the margin for the labeled examples and κ, η_u, and η_l trade-off parameters, the optimisation problem becomes

$$\begin{aligned} \min_{\mathbf{w}, \rho, \gamma \geq 0, \boldsymbol{\xi} \geq 0} \quad & \frac{1}{2} \| \mathbf{w} \|_2^2 - \rho - \kappa\gamma + \sum_{i=1}^{n+m} (\mathbb{I}_i \eta_l + (1 - \mathbb{I}_i)\eta_u)\xi_i \\ \text{s.t.} \quad & \forall_{i=1}^{n+m} : \; y_i \langle \mathbf{w}, \phi(\boldsymbol{x}_i) \rangle \geq y_i \rho + \mathbb{I}_i \gamma - \xi_i. \end{aligned}$$

The solution $\boldsymbol{w}$ admits a dual representation and can be written as

$$\boldsymbol{w} = \sum_{i=1}^{n+m} \alpha_i y_i \phi(\boldsymbol{x}_i)$$

and hence, the decision function depends only on inner products of the input examples wich paves the way for kernel functions $K_\phi(\boldsymbol{x}, \boldsymbol{x}') = \langle \phi(\boldsymbol{x}), \phi(\boldsymbol{x}') \rangle$ (see (Müller et al., 2001) for an introduction to kernels). It holds

$$f(\boldsymbol{x}) = \sum_{i=1}^{n+m} \alpha_i y_i \langle \phi(\boldsymbol{x}_i), \phi(\boldsymbol{x}) \rangle - \rho = \sum_{i=1}^{n+m} \alpha_i y_i K_\phi(\boldsymbol{x}_i, \boldsymbol{x}) - \rho.$$

We omit the subscript ϕ in the remainder to not clutter notation unnecessarily.

3.3 Multiple Kernel Learning for Anomaly Detection

Learning linear combinations of multiple kernels is an appealing strategy when the right choice of representations is unknown. We therefore generalise the semi-supervised anomaly detection of the previous section as a member of the multiple kernel learning framework (Lanckriet et al., 2004). Thus, we aim to learn a weighted combination of T kernels with mixing coefficients $\boldsymbol{\beta} = (\beta_1, \ldots, \beta_T)$:

$$\begin{aligned} K_{\text{MKL}}(\boldsymbol{x}, \boldsymbol{x}') &:= \sum_{t=1}^{T} \beta_{\text{t}} \, K_t(\boldsymbol{x}, \boldsymbol{x}') = \sum_{t=1}^{T} \beta_{\text{t}} \langle \phi_t(\boldsymbol{x}), \phi_t(\boldsymbol{x}') \rangle \\ &= \sum_{t=1}^{T} \langle \sqrt{\beta_{\text{t}}} \phi_t(\boldsymbol{x}), \sqrt{\beta_{\text{t}}} \phi_t(\boldsymbol{x}') \rangle. \end{aligned}$$

In general, properties of the mixing coefficients include (i) non-negativity, hence $\beta_{\mathrm{t}} \geq 0$ and (ii) normalisation $\| \boldsymbol{\beta} \|_p = 1$. Recent work (Kloft et al., 2011) suggests to use the more general p-norm instead of a common 1-norm (Lanckriet et al., 2004; Bach et al., 2004; Rakotomamonjy et al., 2008). The latter usually leads to sparse mixing coefficients which is not appealing in every situation whereas p-norm with $1 \leq p \leq \inf$ admits sparsity adjustments for the problem at hand and thus adds flexibility. Incorporating multiple feature representations in our model introduced in Section 3.1 leads to

$$f_{\mathrm{MKL}}(\boldsymbol{x}) = \sum_{t=1}^{T} \langle \hat{\mathbf{w}}_t, \sqrt{\beta_{\mathrm{t}}} \phi_t(\boldsymbol{x}) \rangle - \rho = \sum_{t=1}^{T} \sqrt{\beta_{\mathrm{t}}} \langle \hat{\mathbf{w}}_t, \phi_t(\boldsymbol{x}) \rangle - \rho. \tag{1}$$

Due to technical reasons, i.e. to preserve convexity, we substitute the model parameters $\mathbf{w}_t = \sqrt{\beta_t} \hat{\mathbf{w}}_t$ and arrive at the revised primal MKL-SSAD optimisation problem:

$$\begin{aligned} \min_{\{\mathbf{w}_t\}, \rho, \gamma \geq 0, \boldsymbol{\xi} \geq 0, \boldsymbol{\beta} \geq 0} \quad & \frac{\lambda}{2} \| \boldsymbol{\beta} \|_p^2 + \frac{1}{2} \sum_{t=1}^{T} \frac{1}{\beta_{\mathrm{t}}} \| \mathbf{w}_t \|_2^2 - \rho - \kappa\gamma + \sum_{i=1}^{n+m} (\mathbb{I}_i \eta_l + (1 - \mathbb{I}_i) \eta_u) \xi_i \\ \text{s.t.} \quad & \forall_{i=1}^{n+m} : \; y_i \sum_{t=1}^{T} \langle \mathbf{w}_t, \phi_t(\boldsymbol{x}_i) \rangle \geq y_i \rho + \mathbb{I}_i \gamma - \xi_i. \end{aligned} \tag{2}$$

(Kloft et al., 2011) prove the equivalence of Tikhonov and Ivanov regularisation which allows to move the regulariser on the mixing coefficients in the objective function. We will exploit this relation on various occasions in this section. Deriving the Lagrange dual problem, we arrive at the intermediate saddle point problem

$$\begin{aligned} \max_{\boldsymbol{\alpha}} \min_{\{\mathbf{w}_t\}, \boldsymbol{\beta} \geq 0} \; & \frac{\lambda}{2} \| \boldsymbol{\beta} \|_p^2 + \frac{1}{2} \sum_{t=1}^{T} \frac{1}{\beta_{\mathrm{t}}} \| \mathbf{w}_t \|_2^2 - \sum_{i=1}^{n+m} \alpha_i y_i \sum_{t} \langle \mathbf{w}_t, \phi_t(\boldsymbol{x}_i) \rangle \\ \text{s.t.} \quad & \kappa \leq \sum_{i=1}^{n+m} \mathbb{I}_i \alpha_i \quad \text{and} \quad 0 \leq \alpha_i \leq \mathbb{I}_i \eta_l + (1 - \mathbb{I}_i) \eta_u \quad \forall\, i \end{aligned}$$

We are solving the optimisation problem in a block-coordinate descent fashion by alternating between $\mathbf{w}$ and $\boldsymbol{\beta}$. This enables us to compute the latter analytically assuming fixed variables $\mathbf{w}$ and setting the partial derivative to zero:

$$\lambda \, {\beta_{\mathrm{t}}}^{p-1} \| \boldsymbol{\beta} \|_p^{2-p} - \frac{\| \mathbf{w}_t \|_2^2}{{\beta_{\mathrm{t}}}^2} = 0.$$

Therefore, given $\Upsilon \geq 0$ we get

$$\beta_{\mathrm{t}} = \Upsilon \| \mathbf{w}_t \|_2^{\frac{2}{p+1}}.$$

Furthermore, it holds that at any optimal point $\| \boldsymbol{\beta} \|_p = 1$ and solving for Υ gives $\Upsilon = 1/(\sum_{t=1}^{T} \| \mathbf{w}_t \|_2^{\frac{2p}{p+1}})^{\frac{1}{p}}$. Putting things together, gives the analytical update rule

$$\beta_{\mathrm{t}} = \frac{\| \mathbf{w}_t \|_2^{\frac{2}{p+1}}}{(\sum_{t=1}^{T} \| \mathbf{w}_t \|_2^{\frac{2p}{p+1}})^{\frac{1}{p}}} \tag{3}$$

which, since only norms are involved, ensures non-negativity for the mixing coefficients. Substituting $\mathbf{w}_t$ using the representer theorem $\mathbf{w}_t = \beta_{\mathrm{t}} \sum_{i=1}^{n+m} \alpha_i \boldsymbol{y}_i \phi_t(\boldsymbol{x}_i)$ yields the final optimisation problem for

Algorithm 1 Proposed optimization algorithm for MKL-SSAD (2)

Require: $\boldsymbol{x}, \boldsymbol{y}, \eta_u, \eta_l, \kappa$ & $p-$ norm
  Initialize kernel mixture coefficients such that $\| \boldsymbol{\beta}^{z=0} \|_p = 1$
  while Until Convergence **do**
    Step 1: solve the convex SSAD problem as stated in Eqn. (4)
    $\boldsymbol{\alpha}^{z+1} = \text{argmax}_{\boldsymbol{\alpha}: 0 \leq \alpha_i \leq \mathbb{I}_i \eta_l + (1-\mathbb{I}_i)\eta_u} J(\boldsymbol{\alpha}, \boldsymbol{\beta}^z) \quad \text{s.t.} \quad \kappa \leq \sum_{i=1}^{n+m} \mathbb{I}_i \alpha_i$
    Step 2: optimize the weights according to Eqn. (3)
    $\boldsymbol{\beta}^{z+1} = \text{argmin}_{\boldsymbol{\beta} \geq 0} J(\boldsymbol{\alpha}^{z+1}, \boldsymbol{\beta}) \quad \text{s.t.} \quad \| \boldsymbol{\beta} \|_p^2 \leq 1$
    z=z+1
  end while
  return Trained parameter vector $\boldsymbol{\alpha}^\star$, weights $\boldsymbol{\beta}^*$

MKL-SSAD:

$$\max_{\boldsymbol{\alpha}} \min_{\boldsymbol{\beta}: \| \boldsymbol{\beta} \|_p^2 \leq 1} \overbrace{-\frac{1}{2} \sum_{i,j} \alpha_i \alpha_j y_i y_j \sum_{t=1}^{T} \beta_t K_t(\boldsymbol{x}_i, \boldsymbol{x}_j)}^{=: J(\boldsymbol{\alpha}, \boldsymbol{\beta})} \tag{4}$$
$$\text{s.t.} \quad \kappa \leq \sum_{i=1}^{n+m} \mathbb{I}_i \alpha_i \quad \text{and} \quad 0 \leq \alpha_i \leq \mathbb{I}_i \eta_l + (1 - \mathbb{I}_i)\eta_u \quad \forall\, i$$

As a block-coordinate descent method, we can iteratively alternate between the two optimisation blocks and every limit point of Algorithm 1 is a globally optimal point (cmp. also (Kloft et al., 2011)). Algorithm 1 summarises the proposed optimisation procedure.

4 Empirical Results

In this section, we empirically evaluate the benefit of fusing semi-supervised anomaly detection with multiple kernel learning. We experiment on two data sets, the Reuters-50-50 corpus in Section 4.1 and the Federalist Papers in Section 4.2

4.1 Reuters 50-50

We use a subset of the Reuters 50-50 data set[1] to evaluate the performance of the aforementioned approaches. The reduced data contains 1000 articles written by 10 authors, Aaron Pressman, Alan Crosby, Alexander Smith, Benjamin Kang Lim, Bernard Hickey, Brad Dorfman, Darren Schuettler, David Lawder, Edna Fernandes, and Eric Auchard.

We deploy the following four kernels to represent documents: the first kernel is made of 484 function words taken from (Koppel and Schler, 2003), the second contains part-of-speech (POS) tags, the third is assembled by 3-letter suffixes, the last one simply a bag-of-words (BOW) kernel. We split the data into training (90%) and test (10%) sets and conduct a 10-fold cross-validation on the training set for model selection. The best performing models are then evaluated on the test set. In this set of experiments, we use a transductive setting where all training instances are labeled and only holdout and test articles are unlabelled. We compare the performance of our approach with different p-norms to the SSAD which uses one kernel at a time. For our MKL-based approach we use p-norms in the set $p \in \{1, 1.7783, 3.1623, 5.6234, 10\}$.

The results in terms of averaged micro- and macro-F_1 measures are shown in Table 1. MKL consistently outperforms the single-kernel baseline for all p-norms. That is, instead of extensively experimenting with SSAD and different kernel functions and parameter selections, a single run with our MKL already leads to better performances in both metrics. The rightmost column in the table shows the result for SSAD using a sum of the input kernels. Apparently, the performance is worse than using a bag-of-words kernel alone. This result underlines the necessity of effective feature selection techniques for

[1] https://archive.ics.uci.edu/ml/datasets/Reuter_50_50

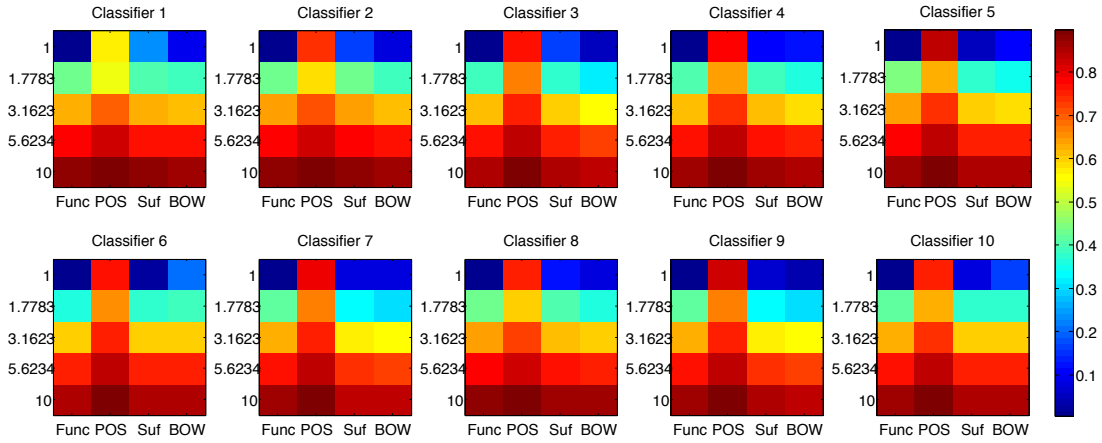

Figure 2: Kernel mixture coefficients for the 10 classes

authorship attribution. Note that our method can actually be viewed as an ensemble method that combines several models as shown in Equation (1). However, compared to traditional ensembles, our method uses a convex combination and hence returns the optimal ensemble given the data.

Table 1: F-scores for the subset of Reuters 50-50

	p-norm MKL					SSAD				
	1	1.7783	3.1623	5.6234	10	func-w	POS	Suffix-3	BOW	$\sum$
F_{micro}	73.46	73.08	73.84	73.89	74.23	63.08	54.62	70.01	72.85	61.76
F_{macro}	79.23	78.86	79.63	79.76	80.07	68.66	58.03	74.01	78.09	70.93

Figure 2 visualises the resulting mixing coefficients for the 10 authors/classifiers. While the models are very similar at first sight, small deviations indicate differences in the style of the authors. Consider for instance the top-left matrix. The contribution of the part-of-speech tag kernel (second column) to the final solution is less than for the other authors. By contrast, the importance of the Suffix-3 kernel has (slightly) more impact than for the remaining authors. This result shows that author-dependent mixtures are found that help to capture characteristic traits of the respective writing styles.

4.2 Revisiting the Federalist Papers

The Federalist Papers are a series of 85 articles and essays written during 1787–1788. They were published anonymously to persuade the citizens of the State of New York to ratify the Constitution. Later, these papers were credited to Alexander Hamilton, John Jay, and James Madison; 73 of the documents are uniquely associated with one of the three authors while the remaining 12, also known as the disputed papers, have been claimed by both, Hamilton and Madison. Three of the 73 articles are considered joint work by Hamilton and Madison. Previous studies often assign all 12 disputed papers to Madison which we assume as ground-truth in the remainder (Mosteller and Wallace, 1964; Fung, 2003).

To confirm or refuse these previous findings, we conduct an experiment using same four kernels as in the previous section, that is, a function words kernel (Koppel and Schler, 2003), a part-of-speech (POS) tag kernel, a Suffix-3 kernel, and a bag-of-words (BOW) kernel. We compare the performance of our approach (MKL) with semi-supervised anomaly detection (SSAD) (Görnitz et al., 2013), support vector data description (SVDD) (Tax and Duin, 1999), and the one-class SVM (OCSVM) (Schölkopf et al., 1999). As before, the baselines cannot use all kernels at a time and are evaluated on every kernel separately. For simplicity, we show only the MKL results for parameter $p = 2$ as all other p-norms that we tried out lead to the same result.

We randomly divide the undisputed papers into training (80%) and holdout (20%) and use the 12 disputed papers for testing. We make sure that training sets contain at least three examples of every author and two articles written jointly by Hamilton and Madison. Otherwise we discard and draw again. We repeat experiments five times with randomly drawn training and holdout sets and report on averaged accuracies for the disputed test set.

Table 2: Results for the disputed articles of the Federalist papers.

	kernel	H&M	M	J	H
MKL	(all)	0	**12**	0	0
SSAD	484fw	0	**12**	0	0
	POS	9	0	3	0
	Suffix3	0	**12**	0	0
	BoW	0	0	0	12
SVDD	484fw	12	0	0	0
	POS	12	0	0	0
	Suffix3	12	0	0	0

	Suffix3	12	0	0	0
	BoW	12	0	0	0

The results are shown in Table 2. The one-class SVM and SVDD constantly credit the 12 disputed articles as joint work by Hamilton and Madison. The outcome of SSAD highly depends on the kernel function; while the part-of-speech kernel distributes the papers on Jay (3) and Hamilton and Madison (9), respectively, the bag-of-words kernel assigns all documents to Hamilton. By contrast, SVDD with function word and Suffix-3 kernels attribute the articles to Madison. The same outcome is observed for our novel MKL that also credits the 12 papers to Madison. Thus, MKL and SSAD with function words and BoW kernel confirm todays assumption that all 12 papers have been written by Madison. However, choosing SSAD as the base classifier in the absence of prior knowledge leaves much room for interpretations and the user in the need of deciding between three solutions, depending on which kernel she prefers. By using our MKL, selecting features and or kernel functions is no longer necessary as the learning algorithm itself picks the right combination of kernels for the problem at hand. Thus, the more kernels are thrown into, the richer the decision space for the MKL.

5 Conclusion

We proposed a universal method for authorship detection. Our approach built upon semi-supervised anomaly detection and generalised existing techniques to utilise multiple kernels; a requirement which is particularly beneficial for authorship attribution as features are usually tailored to tasks at hand and do not necessarily translate well to other authors. Our method is proven to converge to the optimal solution and simple to implement. Our empirical results show the robustness of our approach as it consistently outperforms baseline competitors on a subset of Reuters 50-50 or confirms common knowledge wrt the authorship of disputed articles of the Federalist Papers. The main advantage of the method however lies in its simplicity. Practitioners do not need to take critical design choices in terms of which features to use and which not. By contrast, all features (kernels) can be used in the optimisation and the method itself finds the optimal combination for the problem at hand.

Abstract

This paper investigates the problem of automated text aesthetics prediction. The availability of user generated content and ratings, e.g. Flickr, has induced research in aesthetics prediction for non-text domains, particularly for photographic images. This problem, however, has yet not been explored for the text domain. Due to the very subjective nature of text aesthetics, it is difficult to compile human annotated data by methods such as crowd sourcing with a fair degree of inter-annotator agreement. The availability of the Kindle "popular highlights" data has motivated us to compile a dataset comprised of human annotated aesthetically pleasing and interesting text passages. We then undertake a supervised classification approach to predict text aesthetics by constructing real-valued feature vectors from each text passage. In particular, the features that we use for this classification task are word length, repetitions, polarity, part-of-speech, semantic distances; and topic generality and diversity. A traditional binary classification approach is not effective in this case because non-highlighted passages surrounding the highlighted ones do not necessarily represent the other extreme of unpleasant quality text. Due to the absence of real negative class samples, we employ the MC algorithm, in which training can be initiated with instances only from the positive class. On each successive iteration the algorithm selects new *strong negative* samples from the unlabeled class and retrains itself. The results show that the mapping convergence (MC) algorithm with a Gaussian and a linear kernel used for the mapping and convergence phases, respectively, yields the best results, achieving satisfactory accuracy, precision and recall values of about 74%, 42% and 54% respectively.

1 Introduction

Since their inception, Amazon Kindle device[1] and Apps for other general purpose hand-held devices, have led to a massive increase in the trend of reading e-books over paper printed ones. The Amazon Kindle and the Kindle Apps provide a very simple mechanism for highlighting a piece of text and sharing it on social media. The most popular highlighted pieces of text are shown in the Kindle device with an intention to help readers focus on passages that are pleasing or interesting to the greatest number of people. Every month, Kindle customers highlight millions of book passages that are meaningful to them[2]. The general trend among Kindle readers, while reading the classic English literary works, is to highlight text passages that are associated with a high aesthetic quality. An example highlighted passage is shown in Figure 1.

With the availability of such highlighted text, which may be considered as text passages which most readers find pleasing to read, an interesting research problem is to attempt automatic prediction of highlighted pieces of text. In other words, given a text passage, the objective is to

Proceedings of COLING 2014, the 25th International Conference on Computational Linguistics: Technical Papers, pages 905–916, Dublin, Ireland, August 23-29 2014.

It was the best of times, it was the worst of times, it was the age of wisdom, it was the age of foolishness, it was the epoch of belief, it was the epoch of incredulity, it was the season of Light, it was the season of Darkness, it was the spring of hope, it was the winter of despair.

Figure 1: Passage from *A tale of two cities* (Charles Dickens), highlighted by 6843 Kindle readers.

determine the likelihood of it being aesthetically pleasing and interesting. Such an automated approach of identifying aesthetically pleasing text passages may potentially be used to endorse a newly released book on e-commerce websites with an aim to increase its sales. Moreover, such an approach may also, in principle, be used as a tool by an author to determine how likely it is for readers to appreciate a newly written text passage.

The key challenge in solving this problem is to determine the characteristic attributes of a popular highlighted text passage. An intuitive assumption is that the popularity of a highlighted passage depends on its aesthetic quality. Generally speaking, passages inclined towards expressing an author's view on a subject, which may often be philosophical in nature, with considerable application of atypical figures of speech, e.g. anaphora, alliteration, antithesis, metaphor, simile, personification etc., are more likely to be highlighted than a straight-forward story narrative passage. For example, the highlighted passage in Figure 1 is rich in anaphora (repetition of the same word or group of words in a paragraph, e.g. "times", "age", "epoch" etc.) and antithesis (juxtaposition of opposing or contrasting ideas, e.g. "best of times", "worst of times"; "wisdom", "foolishness" etc). An automated approach of aesthetic quality prediction thus has to take into account these different features of a text passage. The idea of using these features for text aesthetics prediction, in fact, forms a core part of our work.

It is particularly interesting to see that this problem of automatically predicting text aesthetics is largely different from the standard well researched problem of document text classification (Sebastiani, 2002). The reason is as follows. The problem of text categorization can effectively be solved by the application of discrete categorical features, such as character n-gram frequencies and word frequencies. In other words, the presence of characteristic words from a particular domain is a good indicator of the class of a document, e.g. the presence of the words "soccer", "goal" etc. in a document is a good indicator that the document is of the sports genre, whereas the presence of words such as "money", "bank" etc. would indicate that the genre is finance. Consequently, the generative framework of a multinomial Naive Bayes (NB) model with character n-gram and word n-grams based features works effectively for this class of problems (McCallum and Nigam, 1998).

In the case of aesthetic quality prediction, however, the mere presence of a particular word or character n-gram can hardly be a good indicator of the inherent literary quality of the text. The output classes of this classification problem, namely *aesthetic* or *not aesthetic*, do not comprise a small vocabulary of domain-specific representative terms such as in the case of the sports or finance domains. The vocabularies of the respective classes in this classification problem are largely unrestricted and mutually indistinguishable.

The rest of the paper is organized as follows. Section 2 presents related research. In Section 3, we present our proposed approach to solve the text aesthetics problem. Section 4 describes our experimental settings, following which Section 5 presents the results. In Section 6, we investigate the contribution from individual features and then the relative importance of the features when used in combination. Finally, Section 7 concludes the paper.

2 Related Work

A computational viewpoint of aesthetic quality, in general, takes into account the subjectivity of an observer and postulates that among several observations, the aesthetically most pleasing one

is the one with the shortest description, given the observer's previous knowledge (Schmidhuber, 2010). An agent driven reinforcement based learning algorithm can then be used in principle to produce creative (novel and interesting) outputs (Schmidhuber, 2010). Our work in this paper is largely different from the general reinforcement learning paradigm, because we focus on the particular problem of text aesthetics viewing the problem as a supervised classification task. Moreover, the proposition of minimum description length as an attribute of aesthetic quality (Schmidhuber, 2010) is counter-intuitive for literary works.

There has been considerable research interest in automatically predicting visual aesthetic quality of images (Dhar et al., 2011) and layout of web pages (Reinecke et al., 2013). Most empirically successful approaches to image aesthetics prediction first transform an image into a feature vector of characteristic attributes that play a pivotal role in differentiating an *interesting* image from a *non-interesting* one. Generally speaking, some of these attributes which determine whether an image is aesthetically pleasing are the presence of salient objects (indicated by a low depth of field), compositional attributes (e.g. the rule of thirds), the effect of light in natural landscapes, etc. The next step is to apply a supervised learning algorithm, e.g. support vector machine (SVM), to learn a two-class prediction model. Useful features, extracted from images for this classification task include: i) colourfulness, contrast, symmetry, vanishing point and facial features (Jiang et al., 2010); ii) face poses, between-face distances, and the consistency of expressions on multiple faces (Li et al., 2010); iii) high level describable attributes, such as compositional attributes (e.g. rule of thirds image layout), content attributes related to the presence of people, animals, sky illumination attributes etc. (Dhar et al., 2011).

Our proposed method of text aesthetics prediction is similarly based on extracting characteristic features from the text passages. However, in the case of literature, it is worth mentioning that in contrast to image aesthetics it is more difficult to describe the subtle attributes which differentiate an aesthetically pleasing text from its counterpart.

Although the authors are not aware of any reported research on text aesthetics, there has been a considerable amount of research in the somewhat closely related problem of detecting metaphors in text. Automated approaches to metaphor detection involve both supervised and unsupervised approaches, some of which include: i) supervised classification on extracted verbal target feature vectors of sentences (Gedigian et al., 2006); ii) expectation maximization (EM) based unsupervised approach to non-literal word sense detection (Birke and Sarkar, 2006); iii) unsupervised approach using hierarchical graph factorization clustering (Shutova and Sun, 2013).

In general, it is intuitive to assume that metaphorical or figurative parts of text are aesthetically pleasing and interesting, which makes the problem of text aesthetics prediction somewhat similar to that of metaphor detection. Unfortunately, this assumption is not often true, and this is particularly the case for literary works due to the availability of a large number of figures of speech at an author's disposal (metaphor just being one of them). For example, the sample Kindle highlighted passage shown in Section 1 has an obvious aesthetic appeal to a large number of readers, in spite of it being not metaphorical.

3 Our Approach to the Text Aesthetics Prediction Problem

In this section, we describe the details of our approach to text aesthetics prediction. We hypothesize that a NB classifier with word or character n-gram based features is not suitable for this particular problem due to the mutual overlap and lack of domain specific restriction in the vocabulary of the output classes (i.e. aesthetic and non-aesthetic). One thus needs to extract a set of characteristic features from the text passages which may be useful to solve the classification problem. We describe the features used in our approach in Section 3.1. In Section 3.2, we propose to use the mapping convergence (MC) algorithm for the text aesthetics problem, where the intention is to learn a classifier only from positive samples.

The truth is rarely pure and never simple. Modern life would be very tedious if it were either, and modern literature a complete impossibility!

Figure 2: Passage from *The Importance of Being Earnest* (Oscar Wilde).

3.1 Feature Vector Encoding of Text Passages

In this section, we introduce the various features used for the text aesthetics classification task. Each feature is a function which maps a passage of text $P = \{w_1 \dots w_N\}$ comprising N words into a real number.

3.1.1 Word-based Features

In Section 1, we illustrated that that an anaphora is a rheoteric device used by authors to emphasize a text passage, which in turn indicates that such a passage is likely to attract the attention of readers and hence are likely to be highlighted by them. Moreover, the closer the repetitions are, the stronger is the emphasis.

On the basis of this reasoning, we employ an average positional difference weighted count of word repetitions in a passage. To be more precise, for each word in a passage we compute the number of times a word w_i is repeated, divide this count by the difference between the repeating position (say at position j), and average the sum of counts for all repeating words over the passage length, as shown in Equation 1. In Equation 1, $\mathbb{1}(w_i = w_j)$ is the indicator function which is 1 if and only if $w_i = w_j$ and 0 otherwise.

The second word level feature which we use, is the average length of words in a passage. The reasoning behind using this feature is that authors tend to use relatively longer words (e.g. superlatives) to emphasize a passage. Equation 2 shows how this is computed.

$$W_1(P) = \frac{2}{N(N-1)} \sum_{i=1}^{N} \sum_{j=i+1}^{N} \frac{\mathbb{1}(w_i = w_j)}{j - i} \tag{1}$$

$$W_2(P) = \frac{1}{N} \sum_{i=1}^{N} len(w_i) \tag{2}$$

3.1.2 Topic-based Features

An attribute which can be considered responsible for the aesthetic quality of a text passage is the diversity of topics it expresses. It is reasonable to assume that a text passage expressing a broad idea or opinion of an author, often philosophical in nature, is likely to be appealing to readers. Such general themed text passages typically cover a broad range of topics, as a result of which the constituent words of such text passages involve collocation of seemingly unrelated terms. For example, in the text passage shown in Figure 2, the word pairs (*truth*, *tedious*), and (*literature*, *impossibility*) would typically appear in different topic classes, where by a topic we mean a set of words with high co-ocurrence likelihood estimated from a collection of documents by standard topic modelling techniques such as the Latent Dirichlet allocation (LDA) (Blei et al., 2003). To encode this diversity of topics as a real valued feature function, we use Equation 3.

$$T_1(P) = \frac{2}{N(N-1)} \sum_{i=1}^{N} \sum_{j=i+1}^{N} \frac{\mathbb{1}[z(w_i) \neq z(w_j)]}{(j - i)} \tag{3}$$

In Equation 3, $z(w)$ denotes the topic class of the word w obtained with the help of LDA. A mismatch in the topic class is divided by the distance between the mismatches to assign more weight to the close mismatches. As an example, the mismatch between (*literature*, *impossibility*) bears more importance than the mismatch between (*modern*, *impossibility*).

The second topic-based feature which we use pertains to predicting the abstractness of the content of a passage. It has been reported that words highly representative of topics are generally

not metaphorical. We apply a similar reasoning to hypothesize that since an interesting piece of text is more likely to be philosophical or abstract in nature in comparison to a story narrative, the constituent words are less likely to be the representatives of their topic classes. Formally speaking in terms of LDA, these words are expected to have smaller values of $\max_k \phi_k(w)$. Recall that a topic representative word in LDA exhibits a skewed distribution with a peak for one topic class (with a high value of $\max_k \phi_k(w)$), whereas a less representative word exhibits a more uniform distribution of $\phi_k(w)$ values over the topic classes (thus a low value of $\max_k \phi_k(w)$). We use Equation 4 to compute the average topic concreteness of a text passage.

$$T_2(P) = \frac{1}{N} \sum_{i=1}^{N} \max_k \phi_k(w_i) \tag{4}$$

3.1.3 Part of Speech Feature

We hypothesize that another attribute of an aesthetic passage is that it is likely to contain a rich usage of adjectives (mostly of superlative type for the sake of emphasis) and adverbs. We therefore employ the part of speech tag (POS) information of the constituent words of a text passage as one of our features. To be more specific, we use the average number of adjectives and adverbs of a text passage as the feature value. This is shown in Equation 5.

$$POS(P) = \frac{1}{N} \sum_{i=1}^{N} (\#adjectives + \#adverbs) \tag{5}$$

3.1.4 Sentiment Feature

We pointed out in Section 1 that authors often use the *antithesis* figure of speech to express contrasting concepts. Thus, another feature which we can use is the aggregated absolute difference values between the sentiment polarities of words in a text paragraph. This again is weighted by the difference in position between a positive sentiment word and its negative counterpart to assign more importance to closely occurring opposite sentiment concepts.

To obtain the sentiment values of the constituent words, we used the SentiWordNet[3]. To illustrate with an example, consider the closely occurring opposite sentiment word pairs (*best* (0.75), *worst* (-0.75)), (*wisdom* (0.375), *foolishness* (-0.375)) etc. of Figure 1 and the word pairs (*complete* (0.625), *impossibility* (-0.25)) of Figure 2, where the numbers in the parentheses show the positive or the negative sentiment value (a normalized number between 0 and 1). Equation 6 shows the real-valued function derived from the sentiment information of word pairs, where the function $s(w)$ denotes the sentiment value associated with the word w.

$$SENT(P) = \frac{2}{N(N-1)} \sum_{i=1}^{N} \sum_{j=i+1}^{N} \frac{|s(w_i) - s(w_j)|}{(j-i)} \tag{6}$$

3.1.5 Inter-word Semantic Distance Feature

An alternative way to represent the topic diversity is to capture the likelihood of the event of occurrence of two words in close vicinity. The higher this likelihood is, the better is the semantic relation or coherence between the words. We make use of the DISCO[4] tool to compute the semantic relation between two words in a word pair. In DISCO, these semantic relations between the words are precomputed on the basis of co-occurrence likelihoods from a large corpus, e.g. the Wikipedia (Kolb, 2008). DISCO provides two similarity measurements (named the first order and the second order similarities) between two input words. While the first order similarity between two input words is computed based on their collocation sets, the second order similarity is computed based on their sets of distributionally similar words (Kolb, 2008). We denote the

[3] `http://sentiwordnet.isti.cnr.it/`

[4] `http://www.linguatools.de/disco/disco_en.html`

first order and the second order similarities between words w_i and w_j respectively as $ds_1(w_i, w_j)$ and $ds_2(w_i, w_j)$ respectively.

In relation to text aesthetics, we expect a small value of average first order and second order similarity values between word pairs in a highlighted piece of text in comparison to a non-highlighted one. Similar to our earlier features, we divide these similarity values by the positional difference between the words in order to put more emphasis on semantic diversity between closely occurring words. Equation 7 shows the two features extracted making use of these similarity values.

$$SD_k(P) = \frac{2}{N(N-1)} \sum_{i=1}^{N} \sum_{j=i+1}^{N} \frac{|ds_k(w_i) - ds_k(w_j)|}{(j-i)},\ k = \{1, 2\} \tag{7}$$

3.2 Learning from Positive Examples: The MC Algorithm

Binary classifiers, such as SVMs, work particularly well with a sufficient number of both positive and negative class instances for training. In the case of text aesthetics prediction problem, the passages highlighted by Kindle readers serve as the positive class samples. Although it might be intuitive to use the non-highlighted passages as instances of the negative type, there can be problems associated with this approach.

Firstly, the non-highlighted passages are not essentially instances of the negative class because the non-highlighted passages are not necessarily aesthetically unpleasing. Secondly, there is an element of cognitive bias associated with the highlighting process because a reader, who can already see popular highlights while reading a page, may be biased to highlight the same passage himself, and may not in fact highlight some other passage which he himself found interesting.

Note that this observation in fact makes our problem more challenging to solve in comparison to aesthetics prediction in other domains, such as images, where information such as Flickr[5] photo ratings can be used as strong positive or negative indicators of an image interestingness or aesthetic quality, leading to effective classification results using a standard binary classification approach (Dhar et al., 2011).

Due to the presence of incompletely labeled examples, we apply the *mapping convergence* (MC) algorithm (Yu et al., 2003) for this task. The objective of the MC algorithm is to predict the positive samples from a test data, given a mixture of positive and unlabeled samples. These unlabeled samples in the MC algorithm can be treated as instances of either the positive or the negative class in order to obtain maximum classification effectiveness.

The two stages of the MC algorithm are summarized as follows.

1. The *mapping* stage identifies from the unlabeled samples the strong negative ones, i.e. the points distinctly different from the positive samples.
2. The *convergence* stage is an iterative step to learn a binary classification model, e.g. SVM, using the positive and the strong negative samples. Each iterative step of convergence classifies the remaining unlabeled samples to collect more strong negative samples. The convergence step is repeated until no more strong negative samples are found.

The objective of the convergence step of the MC algorithm is to maximize margin to make progressively better approximation of the negative data. At the end of the iteration, the class boundary eventually converges to the boundary around the positive data set in the feature space (Yu et al., 2003).

In our approach to the text aesthetics prediction task, we implement the mapping stage of the MC algorithm with the help of standard one-class classifiers, namely the one class SVM (OSVM) (Schölkopf et al., 1999) and the support vector data descriptor (SVDD) (Tax and Duin, 2004). The OSVM separates all the data points in the feature space from the origin, with the help of a separating hyperplane with maximum distance from the origin. The OSVM is thus

[5] `https://www.flickr.com/`

able to separate out regions in the input space with high probability densities (Schölkopf et al., 1999). SVDD, on the other hand, instead of a planar, takes a spherical approach to the one class problem. The algorithm obtains a spherical boundary in feature space around the data. The volume of this hypersphere is minimized to minimize the effect of incorporating outliers in the solution (Tax and Duin, 2004).

It is worth mentioning here that although the OSVM and the SVDD can be trained with positive samples only, these models are prone to over-fitting or under-fitting due to a small number of support vectors modeled from a small number of positive samples (Yu et al., 2003). In contrast, a binary SVM can model data more robustly due to the presence of the additional negative samples. Hence, OSVM and the SVDD are typically used as a weak classifier to obtain a set of initial strong negative samples in order to initiate the convergence step of the MC algorithm.

4 Experiment Settings

In this section, we describe the dataset and the tools used for our experiments.

4.1 Dataset Construction

The standard practice to evaluate the metaphor detection problem, which is somewhat similar to the text aesthetics prediction, is to make extensive use of manually annotated data typically obtained under controlled user-based studies, where the users or the participants are instructed to perform some given objectives, such as manually label metaphors in a collection of documents, e.g. (Hovy et al., 2013). The main difficulties with this approach are that: i) it takes a considerable amount of time to collect data; ii) the quality of the data depends largely on controlled experimental settings, e.g. the data quality may be susceptible to errors caused by targeted, malicious work efforts, since there is often a financial incentive to complete tasks quickly rather than effectively (Ipeirotis et al., 2010); and iii) it is very difficult to compare the effectiveness of two methods on two different datasets obtained under different controlled user study settings.

The availability of fairly large amounts of highlighted text on the Amazon website has ensured a reliable and fast way to construct the dataset for carrying out the text aesthetics experiments. The advantages are as follows. Firstly, it is not necessary to conduct crowd sourcing experiments for data collection. Secondly, since the data is not generated by controlled crowd sourcing, the quality of the data is more reliable because there is no financial incentive to complete tasks quickly. Thirdly, since the data is publicly available, it is possible to achieve a fair comparison between different problem solving approaches.

The Amazon "Popular Highlights"[6] web page presents a ranked list of the most highlighted passages, sorted in descending order by the number of highlights. However, at the time of writing this paper, Amazon has neither made the data publicly downloadable nor provided an API to access it. For conducting our experiments with this data, we therefore had to automatically crawl data from the Popular Highlights web page.

In addition to the highlighted passages (serving as the positive class samples in our dataset), we also need the non-highlighted ones (meant to serve as the unlabeled samples). The text from the non-highlighted passages, however, are not available in the Popular Highlights web page. This data was thus extracted from those books, the passages of which are popularly highlighted. In order to ensure free access to book content, we had to restrict our dataset to the 50 most popular highlighted classic English fictions.

More precisely speaking, for every highlighted passage found while crawling the Amazon Popular Highlights page, our crawler checks if the book is available on project Gutenberg[7]. If not, then we examine the next highlighted passage, otherwise we craw the full text of the book,

[6] `https://kindle.amazon.com/most_popular/highlights_all_time/`
[7] `http://www.gutenberg.org/`

in which the current highlighted passages belongs, from project Gutenberg website. The crawler continued to run until we had collected highlighted passages from 50 different literature classics.

The dataset for the prediction task is then constructed as follows. First, we add the text of all highlighted passages as instances of the positive class. Next, for each highlighted passage, we add the paragraph preceding and succeeding it into the dataset as the unlabeled samples. Note that selecting the unlabeled samples this way is better than random selection of non-highlighted passages from full text, because this way of choosing negative samples ensures a meaningful representation of reader judgments to highlight a particular passage of text from within a surrounding context.

We then partition the dataset comprised of the positive and unlabeled samples into equal sized training and test sets. In Table 1, we outline the characteristics of the dataset.

Dataset	# Books	Vocab.	# Passages		
		Size	Highlighted	Unhighlighted	Total
Train	25	9560	168	305	473
Test	25	7883	169	319	488
Total	50	13496	337	624	961

Table 1: Dataset characteristics

4.2 Implementation Details

For each passage in the dataset, we extract the features described in Section 3.1. To compute the topic modeling based features we used Mallet[8]. The number of topics (K) in LDA was set to 100. The POS tag feature was extracted with the help of the Stanford POS tagger[9]. For extracting the sentiment feature, we made use of the Java API of the SentiWordNet[10]. For the semantic word distance feature, we used the DISCO Java API[11].

For the naive Bayes experiment, we used the Stanford classifier[12]. The SVM experiments (binary SVM, one-class SVM, SVDD) were conducted with the libSVM software[13].

4.3 Evaluation Metrics

For all the experiments reported in this paper, the classification effectiveness mainly focuses on precision and recall with respect to the positive class. Consequently, precision, recall and the F-score measures, shown in Tables 2 and 3, are measured with respect to the positive class only.

Ideally, for this problem one would want to obtain a high recall, i.e. identify as many highlighted passages correctly as possible. In this situation, recall is thus more important than precision. Achieving a good precision is desirable, nonetheless, to minimize the false positives. Although we report accuracy, we emphasize that accuracy alone is not a good measure of classification effectiveness in this case, because correct identification of negative instances is not important for this problem.

5 Results

Before conducting experiments with the MC algorithm, we obtained baseline results by classifying the dataset using NB and SVMs. In the case of NB, instead of using the real valued features from the text passages (as proposed in Section 3.1), we simply used the character n-gram and word n-gram features (maximum value of n was set to 5) from the text, automatically extracted

SVDD	BSVM	Gaussian	Linear	56.76	42.90	74.64	**54.42**
SVDD	BSVM	Gaussian	Gaussian	47.34	38.60	88.17	53.69

Table 3: Text aesthetics prediction results by the MC algorithm with different settings.

by the Stanford classifier. The result of this experiment (see Table 2) shows that the recall value is very low, which in turn indicates that word vocabulary based features, typically used for text categorization, are not effective for this task.

The next classification method that we employ is standard binary class SVM (denoted as BSVM). The training phase of the BSVM used the non-highlighted passages as negative class instances. We experimented with both linear and Gaussian kernels. For all reported results which use the Gaussian kernel, the parameter γ was set to the default value of 1/(#features) as per the libSVM implementation. Although the accuracy achieved is comparable to NB, the recall achieved is worse, which shows that treating non-highlighted passages as negative class instances is not reasonable for this problem (see Section 6.2 for an illustration).

The recall value is significantly increased with the help of one-class SVM (OSVM). SVDD performs even better in terms of recall. However, SVDD significantly underfits the data because it classifies almost every test data point as an instance of the positive class, thus achieving low accuracy and precision due to the presence of too many false positives.

Our next set of experiments involves the MC algorithm for classification. Since, the mapping phase makes use of only the positive data, we employed both the one-class classifiers used in the experiments of Table 2, i.e. OSVM and SVDD, for this purpose. Mapping with OSVM results in an improvement in the accuracy at the cost of sacrificing recall, which is not desirable for this problem. However, note that the negative samples obtained with the OSVM mapping (with Gaussian kernel) improves the classification effectiveness of the BSVM (compare the fourth row of Table 3 with the second row of Table 2), which indicates that the MC algorithm does improve the classification effectiveness, confirming our hypothesis that it is reasonable not to consider every non-highlighted passage as negative samples.

The problem of SVDD underfitting (as evident from the SVDD results of Table 2) is alleviated by the MC approach. The most effective MC approach uses Gaussian/linear kernels for mapping/convergence (see the seventh row of Table 3). Accuracy is increased to around 56% with a satisfactory recall of around 74%. The use of Gaussian kernel during both the mapping and convergence steps yields a higher recall but at the cost of more false positives (lower accuracy, precision and F-score).

Feature combination vector				Evaluation Metrics			
Word	Topics	POS/Polarity	Semantic	Accuracy	Precision	Recall	F-score
1	0	0	0	36.06	34.88	97.63	51.40
0	1	0	0	37.91	35.74	99.40	52.58
0	0	1	0	36.05	35.01	98.81	51.70

6 Posthoc Analysis

In this section, we comment on the importance of the features used for classification, and also illustrate how the MC algorithm helps in increasing the separability between the classes.

6.1 Feature Importance

First, we investigate the importance of the different features by a selective choice of only one group of features at at time for the classification. The classifier we use for this experiment is MC with a Gaussian SVDD kernel for mapping and a linear SVM kernel for convergence (as per the best settings of Table 3). The results are shown in Table 4 from which it can be seen that the best accuracy is obtained with the use of the semantic distance features.

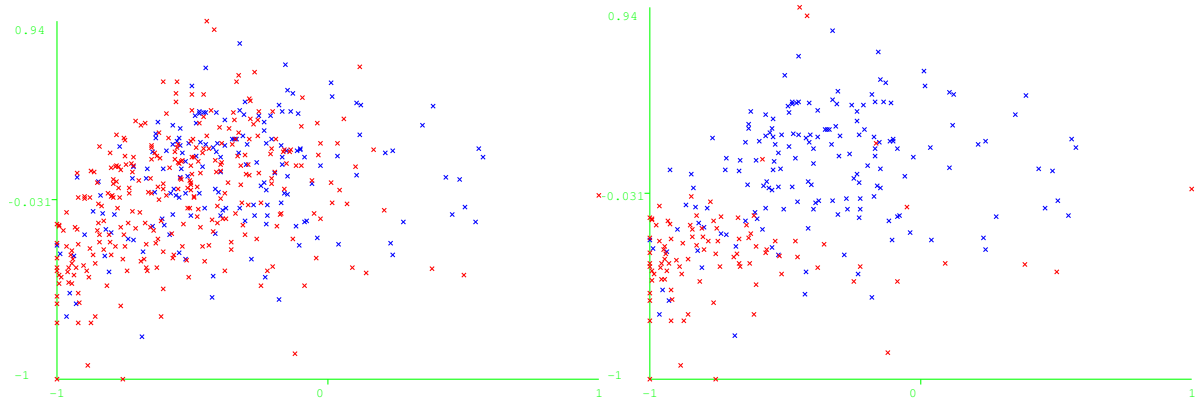
It can be observed that the accuracy values obtained with a single category of features, such as word-based (length and repetition), topic-based (generality and diversity) and so on, are considerably lower than the accuracy value obtained with a combination of all the features (the last row of Table 4. The precision values achieved with these individual feature groups are also considerably lower than the precision of 42.90% of the overall combination.

Next, we find out the relative importance of each feature in their overall combination by ranking the features with the help of a standard feature quality estimator, called *information gain* (*igain*) (Quinlan, 1986). The results are presented in Table 5. It can be seen that the topic diversity is the most discriminative feature having an igain value significantly higher than the second most important one in the list. This observation verifies our hypothesis that aesthetically appealing passages are those constituting terms from diverse topics.

The sentiment and the word repetition features, having close igain values, are second and third respectively in the list. The usefulness of the sentiment feature suggests that contrasting concepts packed in close vicinity of a sentence are likely to be aesthetically pleasing to read. The word repetition feature, on the other hand, suggests that the anaphora figure of speech is likely to be be associated with aesthetically pleasing text.

6.2 Illustration of the usefulness of the MC Algorithm

This section investigates the usefulness of the MC algorithm for the text aesthetics classification. In particular, we show that for this one class classification problem, the MC algorithm can selectively refine the set of unlabeled samples and retrain the model for better separability



(a) Before MC. (b) After MC convergence (5 iterations).

Figure 3: Visualization of the training set in the two most discriminating dimensions, i.e. topic diversity (Y-axis) and sentiment (X-axis).

between the positive and the unlabeled classes.

To illustrate our claim, we first plot the initial training set in two dimensional subspace before the application of MC, i.e. when all the unlabelled instances are treated as negative class samples; this is shown in Figure 3a. The two dimensions that we use for plotting this figure, are the two features having the highest igain values, i.e. the topic diversity (T_1) and sentiment ($SENT$) features. Figure 3a shows that the highlighted text passages (shown in blue) are not well separated from the non-highlighted ones (shown in red).

Next, in Figure 3b, we plot the training set with a reduced number of samples from the negative (non-aesthetic) class obtained after running the MC algorithm. Figure 3b clearly shows that after convergence the MC algorithm has retained only the strong negative samples for training, as is evident from a better visual separation between the classes. A binary classifier, trained on the dataset of Figure 3b, is thus likely to be more effective than that trained with Figure 3a.

7 Conclusions

This paper investigated the problem of automated text aesthetics prediction. As distinguishing features for text aesthetics identification, we applied different statistical features such as word repetitions, topic diversity, part-of-speech, word polarity etc. We collected aesthetically pleasing text passages from the Kindle "popular highlights" website for conducting our experiments. Due to the presence of only positive class samples, i.e. the highlighted passages, in this dataset, we apply the MC algorithm to iteratively train a binary classifier with the strongly negative samples.

The results of our experiments show that the MC algorithm with a Gaussian and a linear kernel applied for the mapping and convergence phases respectively, yields the best results achieving satisfactory recall, precision and F-score values of about 74%, 42% and 54% respectively. Moreover, the results also demonstrate that the topic diversity, word polarity and word repetition are the three most distinguishing features for text aesthetics identification. Furthermore, our results are comparable to those of a somewhat similar problem of figurative text detection where the best reported F-score values achieved are about 54% (Birke and Sarkar, 2006) and 64% (Shutova and Sun, 2013).

Triple based Background Knowledge Ranking for Document Enrichment

Muyu Zhang, Bing Qin*, Ting Liu, Mao Zheng
Research Center for Social Computing and Information Retrieval
Harbin Institute of Technology, China
{myzhang,qinb,tliu,mzheng}@ir.hit.edu.cn

Abstract

Document enrichment is the task of retrieving additional knowledge from external resource over what is available through source document. This task is essential because of the phenomenon that text is generally replete with gaps and ellipses since authors assume a certain amount of background knowledge. The recovery of these gaps is intuitively useful for better understanding of document. Conventional document enrichment techniques usually rely on *Wikipedia* which has great coverage but less accuracy, or *Ontology* which has great accuracy but less coverage. In this study, we propose a document enrichment framework which automatically extracts "$argument_1, predicate, argument_2$" triple from any text corpus as background knowledge, so that to ensure the compatibility with any resource (e.g. *news text*, *ontology*, and *on-line encyclopedia*) and improve the enriching accuracy. We first incorporate source document and background knowledge together into a triple based document-level graph and then propose a global iterative ranking model to propagate relevance score and select the most relevant knowledge triple. We evaluate our model as a ranking problem and compute the MAP and $P\&N$ score to validate the ranking result. Our final result, a MAP score of 0.676 and $P\&20$ score of 0.417 outperform a strong baseline based on search engine by 0.182 in MAP and 0.04 in $P\&20$.

1 Introduction

Document enrichment is the task to acquire background knowledge from external resources and recover the omitted information automatically for certain document. This task is essential because authors usually omit basic but well-known information to make the document more concise. For example, author omits "*Baghdad is the captain of Iraqi*" in the text of Figure 1 (a), which is well-known to readers. During reading process, these gaps will be automatically plugged effortlessly by the background knowledge in human brain. However, the situation is different for machine because it lacks the ability to acquire and select the proper background knowledge, which limits the performances of certain NLP applications. Document enrichment has been proved helpful in these tasks such as web search (Pantel and Fuxman, 2011), coreference resolution (Bryl et al., 2010), document cluster (Hu et al., 2009) and entity disambiguation (Bunescu and Pasca, 2006; Sen, 2012).

In the past, there are mainly two kinds of document enrichment researches according to the resource they relying on. The first line of works make use of *WikiPedia*, the largest available on-line encyclopedia as resource and link the entity (e.g. *Baghdad*) of document to its corresponding Wiki page (e.g. *Baghdad* [1] in WikiPedia), so that to enrich the document with the context of Wiki page (Bunescu and Pasca, 2006; Cucerzan, 2007; Han et al., 2011; Kataria et al., 2011; Sen, 2012; He et al., 2013). Despite the great success of these methods, there remain a great challenge that not all information in the linked Wiki page is helpful to the understanding of corresponding document. For example, the Wiki page of *Baghdad* contains lots of information about city history and culture, which are not quite relevant to the semantic of context in Figure 1 (a). So treating the whole Wiki page as the enrichment to document may cause noise

*Corresponding author.

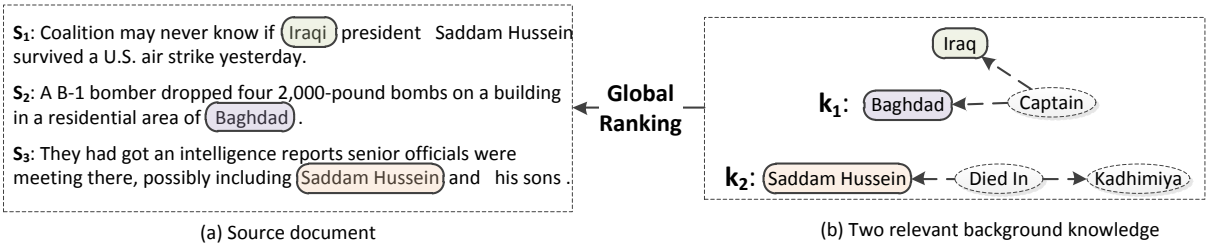
Proceedings of COLING 2014, the 25th International Conference on Computational Linguistics: Technical Papers, pages 917–927, Dublin, Ireland, August 23-29 2014.



(a) Source document

(b) Two relevant background knowledge

Figure 1: An example of document enrichment with background knowledge: (a) source document talking about a U.S. air strike aiming at Saddam in Baghdad (b) two important relevant information, which is omitted in source document but acquired by our model and enriched as background knowledge .

problem. Another line of works rely on the Ontologies constructed with supervision or even manually which have great accuracy but less coverage (Motta et al., 2000; Passant, 2007; Fodeh et al., 2011; Kumar and Salim, 2012). Besides, these methods usually rely on special ontology which is rather difficult to construct and in turn limits the coverage and application of these methods.

Ideally, we would wish to integrate both coverage and accuracy, where an triple based background knowledge ranking model may help. Our framework extracts knowledge from any corpus resource including WikiPedia to ensure coverage and present knowledge as "$argument_1, predicate, argument_2$" triple to reduce noise. This model ranks background knowledge triples according to their relevance to the source document. The key idea behind the model is that document is constructed by several units of information, which can be extracted automatically. For every background knowledge b extracted automatically from a relevant corpus, the more units are relevant to b and the more important they are, the more relevant b becomes to the source document. Thus, we extract both source document information and background knowledge automatically and present them together in a document-level graph. Then we propagate the relevance score from the source document information to the background knowledge during an iterative process. After convergence, we obtain the $Top\ n$ relevant background knowledge, rather than retrieving all of them without filtering.

To evaluate our model, we use ACE [2] corpus as source documents and output the ranked list of background knowledge. Then we train three annotators to check the ranking result and annotating whether certain knowledge is relevant to corresponding source document separately. We totally annotated more than 7000 background knowledge by three annotators. We evaluate their annotation consistence by computing the $Fleiss'\ Kappa$ (Fleiss, 1971), a famous criterion in multi-annotator consistence evaluation. We achieve a $Fleiss'\ Kappa$ of value 0.8066 in best situation and 0.7076 in average, which indicates the great consistence between three annotators. The ranking result is evaluated with MAP score and $P\&N$ score (Voorhees et al., 2005). We finally achieve a MAP score of 0.676 and $P\&20$ score of 0.417 in $Top\ 20$ background knowledge, which are higher by 0.182 and 0.04 than a strong baseline based on search engine. We also evaluate the effect of the automatically extraction to source document and background knowledge, which is key to the performance of our method in real application.

2 Triple Graph based Document Representation

We believe that different parts of document are related to each other, rather than isolated. Hence, we propose a *triple graph* based document representation to incorporate source document information and background knowledge. In this presentation, "$argument_1, predicate, argument_2$" triple serves as node and the edge between nodes indicates their semantic relevance. In this part, we introduce *triple graph* and the way to extract source document information and background knowledge automatically.

2.1 Motivation for triple presentation

Compared to Wiki Page, triple based enrichment helps to reduce noise illustrated in Section 1. Compared to bag of words, triple based presentation help to reduce ambiguity of single word which is shown in

[2] http://catalog.ldc.upenn.edu/LDC2006T06

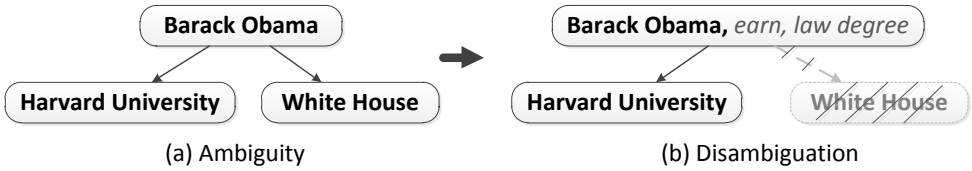


Figure 2: The motivation for the form of triple (a) relevance ambiguity of single word *Obama*, which is related to Harvard and White House (b) disambiguation with the help of other triple elements, where "*earn, law degree*" help to limit *Obama* to the graduate of Harvard.

Figure 2. Figre 2 (a) shows that the single word of *Obama* is related to multiple semantic information such as *Harvard University* as a law graduate and *White House* as the president. After introducing the information from other elements of the triple, "*earn, law degree*" help to disambiguate and limit *Obama* to the law graduate of Harvard University only in Figure 2 (b). The form of triple has been used as the presentation of knowledge in some researches such as knowledge base (Hoffart et al., 2013).

2.2 Nodes in the Graph

There are two kinds of nodes in the triple graph: source document nodes (*sd-nodes*) and background knowledge nodes (*bk-nodes*). Both of them are extracted automatically with *Open Information Extraction (Open IE)* technology which focuses on extracting assertions from massive corpora without a pre-specied vocabulary (Banko et al., 2007). Open IE systems are *unlexicalized*-formed only in terms of syntactic tokens and closed-word classes, instead of specific nouns and verbs at all costs.

There are existing Open IE systems such as TextRunner (Banko et al., 2007), WOE (Wu and Weld, 2010), and StatSnowball (Zhu et al., 2009). The output of these systems has been used to support many NLP tasks such as learning selectional preference (Ritter et al., 2010), acquiring sense knowledge (Lin et al., 2010), and recognizing entailment (Schoenmackers et al., 2010). In this work, we use the famous Open IE system ***Reverb*** (Etzioni et al., 2011), which is generated from TextRunner (Etzioni et al., 2008), to extract source document information and background knowledge automatically. We use the newest version of *ReVerb* (version 1.3) without modification, which is free download on-line [3].

Source document node (*sd-node*) Sd-nodes consists of the information extracted from source document automatically by open information extraction technology (Banko et al., 2007), especially Reverb, the famous Open IE system developed by University of Washington (Etzioni et al., 2011). The output of ReVerb is formed as "$argument_1, predicate, argument_2$", which is naturally presented as triple. In this study, we use ACE corpus as source documents and all sd-nodes are extracted by ReVerb. The setup of automatic extraction makes our method usable in many real applications. To evaluate the effect of automatic extraction, we also use the golden annotation within ACE (Doddington et al., 2004) corpus as source document information and compare the performance that with automatic extraction.

Background knowledge node (*bk-node*) Bk-nodes consist of the background knowledge extracted from external corpus resources automatically by Reverb too. We do not rely on certain existed knowledge base and extract background knowledge from external corpus resources for corresponding source document. This setup makes our methods usable in many real applications. Although we do not rely on special knowledge base, we do adapt our method for the existed knowledge base such as YAGO (Hoffart et al., 2013) and compare the performance to evaluate the effect of different knowledge sources.

2.3 Edges in the Graph

The edges between two nodes indicate their semantic relevance, which is evaluated in Section 3.1. There are two kinds of edges: (1) *sd-node* to *sd-node* (2) *sd-node* to *bk-node*, both of them are undirected. Considering all the relevance score originating from sd-nodes, we connect no edge between *bk-nodes*.

[3] http://reverb.cs.washington.edu/

Edges between sd-nodes All sd-nodes are extracted from the same document, so they should be related to each other. We connect each pair of sd-nodes with an edge and set the weight of edge as their semantic relevance computed in Section 3.1. With this setup, we combine the source document as a whole where different parts affect each other through the edge.

Edges between sd-node and bk-node The basic idea of our model is to propagate relevance score from the sd-nodes to bk-nodes. Hence, we connect each pair of sd-node and bk-node with an edge and set the weight of the edge as their relevance computed in Section 3.1. These edges are all undirected, which indicates that bk-nodes also affect the relevance score of the sd-nodes during the ranking process.

3 Global Ranking Model

In this study, source document *D* is presented as the graph of sd-nodes. For every background knowledge *b*, the task of evaluating the relevance between *b* and *D* is naturally converted into evaluating the relevance between *b* and the graph of sd-nodes. So the relevance between *b* and document *D* can be computed by propagating the *relevance score* from every sd-node of *D* to *b* iteratively. After the convergence, the relevance between *b* and *D* can be evaluated by the *relevance score* of *b*. Intuitively, three factors affect their relevance:

- How many sd-nodes is *b* relevant to ?
- How relevant is *b* to these sd-nodes?
- How important are these sd-nodes ?

For the first factor, *b* should be more relevant to source document *D* if more sd-nodes are relevant to *b*. We capture this information by allowing *b* to receive relevance score from all the sd-nodes. For the second factor, *b* should be more relevant to *D* if more relevant *b* is to sd-nodes. We consider this information by evaluating the relevance between *b* and every sd-node (Section 3.1). For the last factor, important sd-nodes should have higher impact. We consider this information by evaluating the importance of sd-nodes and assigning higher initial value to importance ones (Section 3.3). We combine all factors in the global ranking process to select the top-n relevant background knowledge (Section3.2).

3.1 Relevance Evaluation between Nodes

In this section, we evaluate the semantic relevance between different nodes which is the weight of the edge between them. We introduce *Search Engine* as a resource, which has been proven effective in relevance evaluation (Gligorov et al., 2007). This method is motivated by the phenomenon that the number of results returned by search engine for query $p \cap q$indicates the relevance between p and q.

However, considering the different popularization of queries, this number alone can not accurately express their semantic relevance. For example, query $car \cap automobile$ gets $294,300,000$ results, whereas query $car \cap apple$ gets $683,000,000$, which is 2 times higher than the previous one. Obviously, $automobile$ is more relevant to car rather than $Apple$. The reason of this phenomenon is that $apple$ is far more popular than $automobile$, which increase its possibility of co-occurrence with car. So we consider the number of results for $p \cap q$ together with p and q with $WebJaccard\,Coefficient$ (Bollegala et al., 2007) to evaluate the relevance between p and q according to Formula 1, where $H(p)$, $H(q)$, and $H(p \cap q)$ indicate the number of results for query p, p, and $p \cap q$.

$$WebJaccard(p,q) = \begin{cases} 0 & \text{if } H(p \cap q) \leq C \\ \frac{H(p \cap q)}{H(p)+H(q)-H(p \cap q)} & \text{otherwise.} \end{cases} \quad (1)$$

To convert one "$argument_1, predicate, argument_2$" triple into query, we use $argument_1 \cap argument_2$ as the query for one triple. We have tried $argument_1 \cap predicate \cap argument_2$ which

is usually very sparse. Besides, the combination of two arguments usually maintain better semantic completeness of triple compared to other combinations according to our analysis. So this setup aims to balance completeness and sparseness. Accordingly, two triples are combined as $argument_1 \cap argument_2 \cap argument_1^{'} \cap argument_2^{'}$. Considering the scale and noise in the Web data, it is possible for two words to appear together accidentally. To reduce the adverse effects attributed to random co-occurrences, we set 0 to the $WebJaccard\ Coefficient$ of query $p \cap q$, if the number of result is less than a threshold C.

3.2 Iterative Relevance Propagation

Here we propose the relevance propagation based iterative process to evaluate the relevance between certain background knowledge and source document. Note that standard label propagation mainly focuses on classification task (Wang and Zhang, 2008). However, we focus on a ranking problem where the best ranking result is computed during an iterative process in this study. So we make two modifications to suit the ranking problem better: not reseting the relevance score and introducing the propagation between source document information during iteration.

Propagation possibility The edge between $node_i$ and $node_j$ is weighted by $r(i,j)$ to measure their relevance. However, $r(i,j)$ cannot completely present the propagation possibility because one node can be equally relevant to all of its neighbors. Thus, we define $p(i,j)$ based on $r(i,j)$ in formula 2 to indicate the propagation possibility between $node_i$ and $node_j$.

$$p(i,j) = \frac{r(i,j) \times \delta(i,j)}{\sum_{k \in N} r(k,j) \times \delta(k,j)} \tag{2}$$

N is the set of all nodes, $\delta(i,j)$ denotes whether an edge exists between $node_i$ and $node_l$ in the triple-graph or not, which indicates whether they may propagate to each other or not. E is the set of edges.

$$\delta(i,j) = \begin{cases} 1 & \text{if } (i,j) \in E \\ 0 & \text{otherwise} \end{cases} \tag{3}$$

Iterative propagation There are $n \times n$ pairs of nodes, the $p(i,j)$ of them is stored in a matrix P. we use $\vec{W} = (w_1, w_2, \cdots, w_n)$ to denote the relevance score of all nodes, in which w_i indicates the relevance between $node_i$ and source document D. Here the $node_i$ can indicate both sd-nodes and bk-nodes because they are processed during one fellow step. So that we keep updating both sd-nodes and bk-nodes and do not distinguish them explicitly. The only difference between them is that we initialize the w_i of sd-nodes as its importance to D (Section 3.1) while bk-nodes as 0 at the beginning. We use matrix P together with $\delta(i,j)$ to compute the $\vec{W}$ during a iterative process, where $\vec{W}$ is updated to $\vec{W'}$ during the end of every iteration. The matrix $\vec{W'}$ is updated according to the following Formula 4:

$$\begin{aligned} \vec{W'} &= \vec{W} \times P \\ &= \vec{W} \times \begin{bmatrix} p(1,1) & p(1,2) & \cdots & p(1,n) \\ p(2,1) & p(2,2) & \cdots & p(2,n) \\ \cdots & \cdots & \cdots & \cdots \\ p(n,1) & p(n,2) & \cdots & p(n,n) \end{bmatrix} \end{aligned} \tag{4}$$

each w_i in $\vec{W}$ is updated to $w_i^{'}$ according to the formula 5, where w_i is propagated from all the other $w_j (j \neq i)$ according to their propagation possibility $p(j,i)$. We also introduce the propagation from bk-nodes to sd-nodes, where bk-nodes serve as intermediate to help mining latent semantics.

$$\begin{aligned} w_i^{'} &= w_1 \cdot p(1,i) + w_2 \cdot p(2,i) + \cdots + w_n \cdot p(n,i) \\ &= \sum_{k \in N} w_k \cdot p(k,i) \\ &= \sum_{k \in N} w_k \cdot \left(\frac{r(i,j) \times \delta(i,j)}{\sum_{k \in N} r(k,j) \times \delta(k,j)} \right) \end{aligned} \tag{5}$$

3.3 Importance Evaluation for sd-nodes

The main idea of our model is to propagate relevance score from sd-nodes to bk-nodes (Section 3.2). So the initialization of sd-node is important, which indicates the importance of different source document information. This section solves this problem by evaluating the importance of sd-nodes to source document. We use v_j to denote the initialization of sd-nodes, which indicates the importance of $node_j$ ($node_j \in$ set of sd-nodes) to source document. In this section, we propose a modified relevance propagation method to evaluate v_j for sd-notes. We first construct a triple-graph consisting of sd-nodes only. Then we initialize the relevance score of sd-nodes according to a simple approach based on text frequency (Kohlschütter et al., 2010). We use similar relevance propagation process without resetting the relevance score at the beginning of every iteration, until a global stable state is achieved. Finally, we normalize all the relevance scores to get $\vec{V}$, which indicates the importance of sd-nodes to the source document. We return $\vec{V}$ to the global ranking model (Section 3.2) as part of the input. The initial importance of bk-nodes is set as 0 at the beginning, which denotes that all bk-nodes are ir-relevant to source document before the starting of global ranking process.

4 Experiment

We treat our task as a ranking problem, which takes a document as input and output the ranked list of background knowledge. We evaluate our method as a ranking problem similarly to information retrieval task and focus on the performances of models with different setups.

4.1 Data Preparation

The experiment data consists of two parts: source document information and corresponding background knowledge. To select source documents, we use the *ACE corpus* (Doddington et al., 2004) for 2005 evaluation [4] which consists of 599 articles from multiple sources. We use ReVerb to extract these documents into multi-triples. For background knowledge, we first retrieve relevant web pages with simply term matching method and then extract these pages with ReVerb into a set of triples serving as background knowledge. To ensure the quality, we filter them according to the confidence given by ReVerb.

Besides automatic extraction, we also adapt our system to the golden annotation of ACE as source document information and standard YAGO knowledge base [5] as background knowledge (Hoffart et al., 2013). We compare its performance with that in fully automatic system and evaluate the effect of automatic extraction. For better comparison with YAGO, we retrieve relevant pages from WikiPedia although our automatic extraction method is applicable to any corpus resources.

For every outputted list, three trained annotators check the result and decide which background knowledge is relevant to source document. They work separately and check the same list, so that we can evaluate their annotation consistence. They totally annotated more than 7000 background knowledge and achieved a $Fleiss'\ Kappa$ value of 0.8066 in best situation and 0.7076 in average between three annotators, which is a good consistence between multi-annotator (Fleiss, 1971). When collision happened, we choose the label selected by more annotators.

4.2 Baseline system

Although we treat our task as a ranking problem, it is difficult to apply corresponding methods in traditional ranking tasks such as information retrieval (IR) (Manning et al., 2008) and entity linking (EL) (Han et al., 2011; Kataria et al., 2011; Sen, 2012) directly in our task. First, both *IR* and *EL* make use of the link structure between web or Wiki pages. However, our task takes single document as input and no link exists between documents which makes it difficult to apply *IR* and *EL* methods such as page rank (Page et al., 1999) and collective method (Han et al., 2011; Sen, 2012) in this task directly. Second, *EL* usually evaluate the text similarity between certain document and target page in WikiPedia. However, our task focuses on the ranking of "$argument_1, predicate, argument_2$" triple, which contains little text information. Lack of text information also limits the application of corresponding methods in our task.

[4] http://catalog.ldc.upenn.edu/LDC2006T06

[5] http://www.mpi-inf.mpg.de/yago-naga/yago

Setup	MAP	P&20
Baseline	0.494	0.377
AutoSD + AutoBK + NoInitial	0.504	0.378
AutoSD + AutoBK + WithInitial	0.531	0.406
GoldSD + AutoBK + NoInitial	0.564	**0.417**
GoldSD + AutoBK + WithInitial	0.553	0.406
GoldSD + YAGO + NoInitial	0.676	0.328
GoldSD + YAGO + WithInitial	**0.676**	0.328

Table 1: The result of our model in different setups: *GoldSD* indicates using annotation of ACE corpus as source document information; *YAGO* indicates using YAGO knowledge base as background knowledge; *AutoSD* and *AutoBK* means aotomatic extraction to source document and background knowledge; *NoInitial* and *WithInitial* means whether using different initial importance to source document information.

For better comparison, we introduce search engine as resource which is proved effective in relevance evaluation (Gligorov et al., 2007) and propose a search engine based strong baseline. As illustrated before, the relevance R_i between background knowledge b_i and source document D has been converted into the relevance between b_i and the triples of D. Hence, we compute R_i by accumulating all r_{ij}, the relevance scores between b_i and every sd-node s_j with the same method in Section 3.1 ($R_i = \sum_{s_j \in S} r_{ij}$, S is the set of sd-nodes). Then we rank all background knowledge according to the value of R_i and output the ranked list as final result. We extract source document and background knowledge automatically in the baseline system, which makes it applicable in different setups.

4.3 Experiment setup

We evaluate our model in different setups. First, we extract both source document information and background knowledge automatically. Second, we use golden annotation of ACE as source document information but extract background knowledge automatically. Third, we use golden annotation of ACE and introduce standard YAGO as background knowledge. For all of them three, we evaluate the different performances with and without initial importance of sd-nodes(Section 3.3). We evaluate the performance with two famous criteria in ranking problem: MAP (Voorhees et al., 2005) requires more accuracy and focuses on the knowledge in higher position; $P\&N$ which require more coverage and pays more attention to the number of relevant ones in $Top\ N$ knowledge. Note that we do not evaluate the $Recall$ performance because there can be millions of background knowledge to be ranked for every document. It is impossible to check all of them. So we focus on the $Top\ N$ candidates and evaluate the performance with MAP and $P\&N$. In this study, we evaluate the $Top\ 20$ background knowledge triples which are most easily to be viewed by users.

4.4 Experiment Result

The performance of our model is shown in Table 1. Our search engine based baseline system achieve a rather good performance: a *MAP* value of 0.494 and 0.377 in *P&20*. At the same time, our model outperforms the baseline system in almost every setup and evaluation criterion. The best performance of *MAP* is achieved by *GoldSD+YAGO* (0.676), while the best performance of *P&20* is achieved by *GoldSD+AutoBK* (0.417). To analyze the result further, we find that the initial importance, automatic extraction to source document, and to background knowledge have different effect on the final performance.

4.4.1 Effect of automatic extraction to source document

We use ACE corpus as source documents, which contain golden annotation to document information. So we can evaluate the effect of automatic extraction to source document by comparing the performance with and without golden annotation. The performance without golden annotation is shown in *AutoSD+AutoBK* of Table 1, while the other one shown in *GoldSD+AutoBK*. We can find that the performance of *GoldSD+AutoBK* is better than that of *AutoSD+AutoBK* in both *MAP* and *P&20*, which indicates that golden annotation do help to improve the ranking result.

We further analyze the result and find an interesting phenomenon: these two systems performs greatly different with the setup of *NoInitial*, but equally with the setup of *WithInitial*, which indicates that the performance of *AutoSD+AutoBK* has been improved by evaluating the importance of source document information (Section 3.3). So we can naturally infer that, with a better importance evaluating method in *AutoSD+AutoBK*, we may achieve similar performance compared to that in golden annotation. Note that, *AutoSD+AutoBK* is compatible with any corpus which is more useful in real applications.

4.4.2 Effect of automatic extraction to background knowledge

We evaluate the effect of automatic extraction to background knowledge by comparing the performances between *GoldSD+AutoBK* and *GoldSD+YAGO*. In *GoldSD+AutoBK*, the background knowledge is extracted automatically with ReVerb, which has greater coverage but less accuracy. In contrast, the *GoldSD+YAGO* make use of YAGO as background knowledge, which is less coverage but better accuracy. This difference are reflected on the system performance, where *GoldSD+YAGO* achieves much better result in *MAP*, but much worse in *P&20*. This is partly because that *MAP* focus on the background knowledge in higher position which requires more accuracy, while *P&20* pays more attention to the number of relevant background knowledge which require more coverage.

In general, automatic extraction system has better coverage but less accuracy compared to YAGO based system. However, automatic extraction to background knowledge may help in real applications by improving coverage greatly. Besides, the loss of accuracy is partly due to the technology of information extraction which may be improved in the future. In addition, we can also combine these two ways to acquire background knowledge to balance coverage and accuracy in the future.

4.4.3 Effect of initial importance to source document information

Initial importance to source document information (Section 3.3) is important to the performance of our models as shown in Table 1. The model *AutoSD+AutoBK+WithInitial* outperforms the *AutoSD+AutoBK+NoInitial* compared to other setups, which indicates the help of initial importance to the ranking result. Especially, initial importance to source document information helps most in the setup of *AutoSD+AutoBK*, which is most useful in real applications. So we can naturally infer that, by proposing better importance evaluating method, we may further improve the performance of *AutoSD+AutoBK+WithInitial*, which will great helpful in the future application of this method.

5 Related Work

Document enrichment focuses on introducing external knowledge into source document. There are mainly two kinds of works in this topic according to the resource they relying on. The first line of works make use of *WikiPedia* and enrich source document by linking the entity to its corresponding Wiki page (Bunescu and Pasca, 2006; Cucerzan, 2007). In early stage, most researches rely on the similarity between the context of the mention and the definition of candidate entities by proposing different measuring criteria such as dot product, cosine similarity, KL divergence, Jaccard distance and more complicated ones (Bunescu and Pasca, 2006; Cucerzan, 2007; Zheng et al., 2010; Hoffart et al., 2011; Zhang et al., 2011). However, these methods mainly rely on text similarity but neglect the internal structure between mentions. So another kind of works explore the structure information with collective disambiguation (Kulkarni et al., 2009; Kataria et al., 2011; Sen, 2012; He et al., 2013). These methods make use of structure information within context and resolve different mentions based on the coherence among decisions. Despite the success, the entity linking methods rely on WikiPedia which has great coverage but less accuracy.

Another line of works try to improve the accuracy of enrichment by introducing ontologies (Motta et al., 2000; Passant, 2007; Fodeh et al., 2011; Kumar and Salim, 2012) and structured knowledge such as WordNet (Nastase et al., 2010) and Mesh (Wang and Lim, 2008). In these studies, resources usually provides word or phrase semantic information such as synonym (Sun et al., 2011) and antonym (Sansonnet and Bouchet, 2010). However, these methods rely on special ontologies constructed with supervision or even manually, which is difficult to expand and in turn limits the application of them.

6 Conclusion and Future Work

This study presents a triple based background knowledge ranking model to acquire most relevant background knowledge to certain source document. We first develop a triple graph based document presentation to combine source document together with the background knowledge. Then we propose a global iterative ranking model to acquire $Top\ n$ relevant knowledge, which provide additional information beyond the source document. Note that, both source document information and background knowledge are extracted automatically which is useful in real application. The experiments show that our model achieves better results over a strong baseline, which indicates the effectiveness of our framework.

Another interesting phenomenon is that *YAGO* based enrichment model achieved better ranking accuracy, but less coverage compared to automatic extraction model. To combine these two sources of background knowledge may help to overcome both coverage and accuracy problem. So exploiting proper way to incorporate knowledge base and automatic extraction is an important topic in our future work.

Finally, we believe that this background knowledge based document enriching technology may help in those semantic based NLP applications such as coherence evaluation, coreference resolution and question answering. In our future work, we will explore how to make use of these background knowledge in real applications, hopefully to improve the performance significantly in the future.

Abstract

This paper proposes an architecture for an open-domain conversational system and evaluates an implemented system. The proposed architecture is fully composed of modules based on natural language processing techniques. Experimental results using human subjects show that our architecture achieves significantly better naturalness than a retrieval-based baseline and that its naturalness is close to that of a rule-based system using 149K hand-crafted rules.

1 Introduction

Although task-oriented dialogue systems have been extensively researched over the decades (Walker et al., 2001; Williams et al., 2013), it is only recently that non-task-oriented dialogue, open-domain conversation, or chat has been attracting attention for its social and entertainment aspects (Bickmore and Picard, 2005; Ritter et al., 2011; Bessho et al., 2012). Creating an open-domain conversational system is a challenging problem. In task-oriented dialogue systems, it is possible to prepare knowledge for a domain and create understanding and generation modules for that domain (Nakano et al., 2000). However, for open-domain conversation, such preparation cannot be performed. Since it is difficult to handle users' open-domain utterances, to create workable systems, conventional approaches have used hand-crafted rules (Wallace, 2004). Although elaborate rules may work well, the problem with the rule-based approach is the high cost and the dependence on individual skills of developers, which hinders systematic development. Another problem with the rule-based approach is its low coverage; that is, the inability to handle unexpected utterances.

The recent increase of web data has propelled the development of approaches that use data retrieved from the web for open-domain conversation (Shibata et al., 2009; Ritter et al., 2011). The merit of such retrieval-based approaches is that, owing to the diversity of the web, systems can retrieve at least some responses for user input, which solves the coverage problem. However, this comes at the cost of utterance quality. Since the web, especially Twitter, is inherently noisy, it is, in many cases, difficult to sift out appropriate sentences from retrieval results.

In this paper, we propose an architecture for an open-domain conversational system. The proposed architecture is fully composed of modules based on natural language processing (NLP) techniques. Our stance is not just to hand-craft or to search the web for utterances, but to create a system that can fully understand and generate utterances. We want to show that it is possible to build an open-domain conversational system by combining NLP modules, which will open the way to a systematic development and improvement. We describe our open-domain conversational system based on our architecture and present results of an evaluation of its performance by human subjects. We compare our system with rule-based and retrieval-based systems, and show that our architecture is a promising direction. In this work, we regard the term open-domain conversation to be interchangeable with non-task-oriented dialogue, casual conversation (Eggins and Slade, 2005), chat, or social dialogue (Bickmore and Cassell, 2000). We use the term to denote that user input is not restricted in any way as in open-domain question answering

Proceedings of COLING 2014, the 25th International Conference on Computational Linguistics: Technical Papers, pages 928–939, Dublin, Ireland, August 23-29 2014.

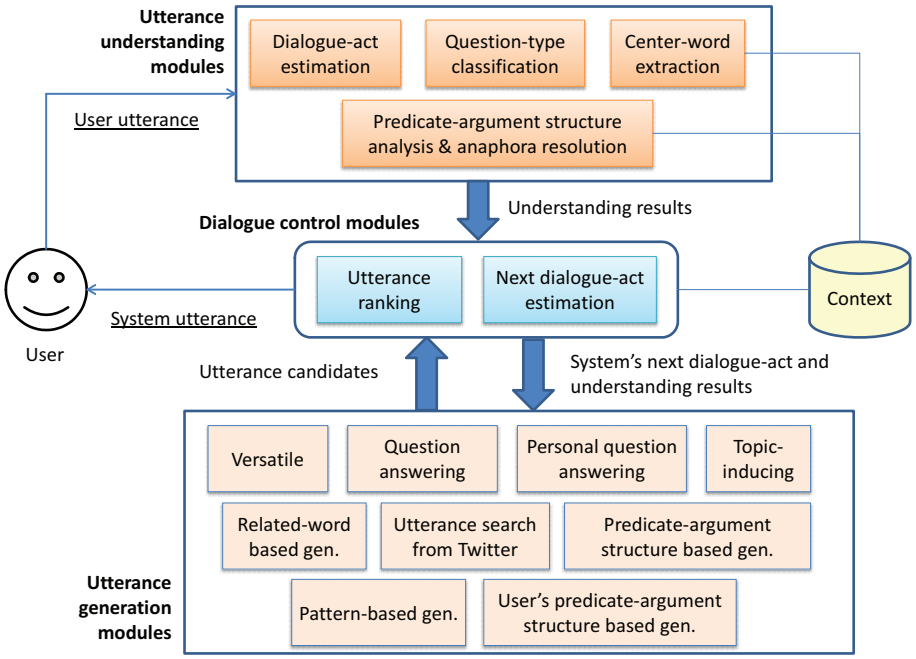

Figure 1: System architecture.

(QA) (Voorhees and Tice, 2000) and open information extraction (Etzioni et al., 2008). The application here in mind is one that can chat with users like chatbots. It should also be noted that we deal with Japanese text chat in this paper, although we believe the architecture to be largely language-independent and extendable with other modalities.

In Section 2, we describe the architecture and its underlying modules. In Section 3, we describe the rule-based and retrieval-based systems that we use for comparison. In Section 4, we describe the experiment we performed to evaluate our system. Section 5 summarizes the paper.

2 Architecture and System Description

Figure 1 shows the architecture we propose for an open-domain conversational system. The architecture has three main components: utterance understanding, dialogue control, and utterance generation. Following the literature on discourse theory (Grosz and Sidner, 1986), we regard *intention* (intentional structure), *topic* (attention state), and *content* (linguistic structure) as three important elements in conversation, and seek to create a system that can understand and generate on the basis of them in a general way. The dialogue control component works by ranking utterance candidates using a general coherence criterion (Hovy, 1991). Note that the overall architecture is roughly the same as conventional dialogue systems; however, the internal architecture is different so as to allow open-domain conversation. To give a rough idea of how the system works, Figure 2 shows an example dialogue between our system and a user (one of the subjects in our experiment). As this example shows, the system can handle various user utterances. Below, we describe how this is achieved.

2.1 Utterance Understanding Modules

We identify dialogue-act, question-type, center-word, and predicate-argument structure (PAS). Dialogue-act and question-type correspond to intention, center-word to topic, and PAS to content. We use PASs because they can represent an arbitrary sentence. For languages other than Japanese, instead of PASs, semantic role labeling (SRL) can be used (Palmer et al., 2010). Below, we describe each module.

Dialogue-act estimation: As a dialogue-act tag set, we use the one proposed by Meguro et al. (2013). Although their tag set is designed for annotating listening-oriented dialogue (LoD), since speakers in LoD are allowed to speak freely, the tag set can cover diverse utterances, making it suitable for

open-domain conversation. There are 33 dialogue-acts in the tag set. See (Meguro et al., 2013) for details. We used 1259 LoDs annotated with dialogue-acts and trained a classifier using a support vector machine (SVM). The features used are word N-grams, semantic categories (obtained from a Japanese thesaurus Goi-Taikei (Ikehara et al., 1997)), and character N-grams. Here, unless otherwise noted, we use JTAG (Fuchi and Takagi, 1998) for morphological analysis in this work. When we use the LoD data for training and testing, by a ten-fold cross validation, the estimation accuracy is 45%, which is reasonable when considering that the inter-annotator agreement rate is 59%. For reference, the majority baseline, which estimates the dialogue-acts of all utterances to be information-provision, has 12% accuracy.

Question-type classification: We use the question taxonomy by Nagata et al. (2006) because it was derived by analyzing questions from the general public and therefore covers diverse questions. The taxonomy has 23 question types under five main categories: name, quantity, explanation, yes-no, and other. Since some types could be too specific, by merging similar ones, we shrinked the 23 types into 13: name-other, name-person, quantity-other, quantity-date, quantity-period, quantity-money, yes-no, explanation-reason, explanation-definition, explanation-method, explanation-reputation, explanation-association, and other. Using an in-house data set of about 48K questions annotated with the 13 types, we trained a logistic-regression-based classifier that achieves a classification accuracy of 92.5% by a five-fold cross validation. The majority baseline that always classifies to name-other has 39.5% accuracy.

Center-word extraction: We define a center-word as a noun phrase (NP) that denotes the topic of a conversation. We hypothesize that an utterance has at most one NP suitable for a center-word. To extract an NP from an utterance, we use conditional random fields (Lafferty et al., 2001); NPs are extracted directly from a sequence of words without creating a parse tree. For the training and testing, we prepared 10K sentences with center-word annotation. Here, the sentences were those randomly sampled from the open-domain conversation corpus (See Section 2.2). The feature template uses words, part-of-speech (POS) tags, and semantic categories of current and neighboring words. The extraction accuracy is 83.4% by a five-fold cross validation. This module has access to the context. When there are already center-words (represented by a stack) in the context, the center-word of the current utterance is placed at the top of the stack.

PAS analysis and anaphora resolution: In PAS analysis, predicates and their arguments are detected. A predicate can be a verb, adjective, or copular verb, and the arguments are NPs associated with cases in case grammar. As cases, we use standard cases `ga` (nominative), `wo` (accusative), `ni` (dative) as well as `de` (locative/instrumental), `to` (with), `kara` (source), `made` (goal). We use the PAS analyzer described in (Imamura et al., 2009; Imamura et al., 2014a; Imamura et al., 2014b). The analyzer works statistically by ranking NPs in the context using supervised learning with an obligatory case information dictionary and a large-scale word dependency language model. For the ranking, NPs in the current utterance and the center-words in the context are considered. Also considered are the special NPs 'I', 'YOU', 'exog (exophora general)', and 'null'. Here, 'exog' means that there should be some argument for a case but it is missing in the context, and 'null' means that no argument is required for a case. When arguments are filled with NPs from the context, this means that zero pronoun resolution (a type of anaphora resolution) has been performed. The analyzer is reported to have an accuracy of 57-62% for `ga`, `wo`, and `ni` cases for dialogue data (Imamura et al., 2014b). When a zero pronoun is resolved, the NP used for the resolution is placed at the top of the center-word stack because such an elided NP is grounded among the conversational participants and is likely to be the focus of conversation (Walker et al., 1994).

2.2 Dialogue Control Modules

We have two modules for dialogue control. The next dialogue-act estimation module roughly decides the next user utterance on the intention level (dialogue-act level). The utterance ranking module ranks utterance candidates (See Section 2.3 for how utterance candidates are created) by a coherence criterion.

	Utterance (English translation by the authors)	DA	Gen. Module
SYS1	Doumo desu (Hi)	Greeting	Initial prompt
USR1	Doumo. Genki desuka? (Hi. How are you?)	Greeting	
SYS2	Saikin no oishii mono ni tsuite kikasete kudasai (Tell me about delicious food that you've had recently)	Q-Plan	Topic-Inducing
USR2	Karei ni hamatterunda! (I'm now into curry!)	S-Disc Fact	
SYS3	Aishou ga ii desuka (Does it go together well with you?)	Confirmation	PAS
USR3	Toku ni tai karei wa aishou ga yoimitai (Thai curry especially goes together well with me)	S-Disc Pref. Pos.	
SYS4	Guzai ga gorogoro shitete, natsukashii karei ga sukidesu (I like nostalgic curry with large chunks of ingredients)	S-Disc Pref. Pos.	Twitter
USR4	Yokosuka no karei nanka, soudayone (Curry in Yokosuka is like that, isn't it?)	Information	
SYS5	Watashi mo daisuki desu! (I like it very much!)	S-Disc Pref. Pos.	Versatile
USR5	Yokosuka, ikimasuka? (Do you go to Yokosuka?)	Q-Fact	
SYS6	Yokosuka sunderunde, nanka ureshii desu (I live in Yokosuka, so I'm flattered)	S-Disc Fact	Twitter

Figure 2: Example dialogue with our proposed system [Prop (tri); See Section 4.1]. DA denotes recognized dialogue-acts for user utterances and those chosen by the system for system utterances. Gen. Module indicates the generation module used. Underlined words denote newly recognized center-words.

Next dialogue-act estimation: Using the same approach as Sugiyama et al. (2013), this module takes into account three previous dialogue-acts in the context to estimate the system's next dialogue-act. We trained an SVM-based dialogue-act estimator using 1259 LoDs. Using 1,000 dialogues as training data and 259 as test data, the trained estimator can predict the next dialogue-act with the accuracy of 28% (NB. majority baseline has 15% accuracy). Although the accuracy is low, since the task is subjective and there is no definite answer, we consider the estimator to have sufficient ability to choose a reasonable next dialogue-act.

Utterance ranking: We adopt coherence as a general criterion for ranking utterances because it is a well-recognized measure of discourse and can be applied to arbitrary sentences (Lapata, 2003; Barzilay and Lapata, 2008). We hypothesize that an utterance that is the most cohesive to the current context should be chosen for the output of the system. To create the ranker, we first collected a data set of 3,680 open-domain conversations (hereafter, open-domain conversation corpus; 134K utterances) between humans, and from 3,496 of them (184 were held out for development), created dialogue snippets (excerpts) by taking N consecutive utterances. We use these dialogue snippets as references (positive examples). We also create counter-references (pseudo negative examples) by swapping the last utterance of each snippet with a randomly selected one from the dialogue from which the snippet was taken. This is similar to how Barzilay and Lapata (2008) created their training data for their coherence models. We then train a ranker by ranking SVM (Joachims, 2002) in the same manner as (Higashinaka and Isozaki, 2008). The ranker is trained so that references are ranked higher than counter-references. Following Lapata (2003), who used pairs of words for sentence ordering, we use, as features, the pairs of words, POS-tags, and semantic categories between the last utterance and each of the previous utterances. For example, when the last utterance U_l has k words and one of its previous utterance U_p has m words, we create $k \times m$ features by combining them. This feature generation is done also for POS-tags and semantic categories and is iterated over all previous utterances. We trained two rankers using 2 and 3 for N. When N is 2, we have 124,213 snippets. When N is 3, we have 120,717. By using four-fifths of the data for training and using the remaining one-fifth for testing, the rankers achieve 66.7% and 66.4% accuracies for N=2 and N=3, respectively. Here, the random baseline's accuracy is 50%. We only use 2 and 3 for N here since a larger N could lead to the explosion of features. By default, we use the ranker trained with N=3. The trained ranker ranks utterance candidates (generated by the modules in Section 2.3) and outputs the top one as a system utterance.

2.3 Utterance Generation Modules

We prepared nine modules for generation. The versatile, QA, and personal QA modules generate on the basis of dialogue-acts and question-types (intention). The topic-inducing, related-word, Twitter, and

PAS modules generate on the basis of center-words (topic). The pattern and user PAS modules generate by using the surface string and PASs of user utterances (content). Note that, for all modules, the system's next dialogue-act is taken into account; that is, wherever necessary, the aforementioned dialogue-act estimation module is applied to generated utterances so that utterances whose estimated dialogue-acts match the system's next dialogue-act are returned.

Versatile: This module receives the system's next dialogue-act and returns utterances randomly chosen from the list of utterances for that dialogue-act. To create lists for dialogue-acts, we first extracted frequent utterances for each dialogue-act in the LoD corpus. Then, we selected context-independent utterances for the dialogue-act. We call such utterances "versatile utterances" because they can be used in various situations. For example, we have "I like it", "It is good", and "That's great" for S-Disc Pref. Pos. (a dialogue-act that discloses one's positive preference).

QA: When the user dialogue-act is a question and the question-type requires a named entity as an answer (i.e., when the question-type starts with a 'name' or 'quantity'), we call an off-the-shelf QA API that is publicly available[1]. The API returns top-N answers (NEs) for a natural language query (Uchida et al., 2013; Higashinaka et al., 2013). We refer to this API with the user input sentence as a query and obtain the top-five answers. This module returns these answers as utterance candidates.

Personal QA: When the user dialogue-act is a question, this module is called for answering personal questions. Answering such questions is important in chat (Batacharia et al., 1999) or even in task-oriented dialogue (Takeuchi et al., 2007). We use the same method as (Sugiyama et al., 2014b; Sugiyama et al., 2014a) and create a person database (PDB) of question-answer pairs for a persona. In the PDB, the questions are given category labels (e.g., favorite sport, whether the persona likes dogs, etc.) as well as question-types based on our taxonomy. Given a question, the answer is obtained by searching the PDB by the category label and the question-type for the question. To obtain the category label, a separately-trained logistic-regression-based classifier is used. We prepared a PDB for a persona 'Aiko' (a 29 year-old Japanese woman). The PDB contains 4,428 question-answer pairs. This module searches Aiko's PDB and returns obtained answers as utterance candidates.

Topic-inducing: When there is no center-word, this module returns utterances that introduce topics (e.g., "Let's talk about favorite foods!"). The utterances are chosen randomly from a list of utterances that we extracted from the dialogue-initiating utterances in the LoDs.

Related-word: The input to this module is the top center-word (C) and the next dialogue-act. For given C, we first get its related-words. Although we cannot describe details for lack of space, as related-words, we have attributes, question words, associative words, and category words. Such words are mined from blogs, Twitter, and Wikipedia by using lexico-syntactic patterns (Hearst, 1992). By combining related-words with a small number of templates, utterances are created. For example, we have a template "C wa ADJ desune (C is ADJ)" where ADJ is an adjectival attribute of C. The created utterances are returned as utterance candidates. This approach is similar to that used by (Higuchi et al., 2008) and (Sugiyama et al., 2013) in that words obtained from large text data are combined with templates for generation.

Twitter: We use the same approach as (Higashinaka et al., 2014), who created a database of Twitter sentences by word-level and syntactic-level filtering. The database is searched by a query expanded with its related-words so that tweets relevant to the query can be accurately retrieved. It has been reported that only 6% of the retrieved results are judged as inappropriate by subjective evaluation. Using the same database and method as (Higashinaka et al., 2014), this module returns the top-ten retrieved sentences from the database using the top center-word as a query. The database contains about 7M sentences.

[1] https://dev.smt.docomo.ne.jp/?p=docs.api.page&api_docs_id=6

PAS: We created a database of PASs by processing more than three years' of blogs. For fear of noise, we only harvested PASs that have just a predicate and an argument for `ga` (nominative) with its topic (an NP) explicitly marked by a topic marker `wa`. From the blogs, we obtained 146K PASs for 50K topics. Given the top center-word and the next dialogue-act, this module looks for PASs whose topic matches the top center-word. Then, it converts the PASs into sentences so that they can convey the intention of the system's next dialogue-act. This conversion is automatic: we first convert the PASs into declarative sentences using a simple rule. Then, their sentence-end expressions (NB. In Japanese, modalities are mostly expressed by sentence-end expressions) are swapped with those matching the target dialogue-act. The sentence-end expressions used here are those automatically mined from dialogue-act annotated dialogue data. This module returns the converted sentences.

Pattern: In everyday conversation, there are typical exchanges of utterances like adjacency pairs (Schegloff and Sacks, 1973). To obtain such exchanges, we mined Twitter. We first collected about 919M tweets. Then, by extracting tweets connected with an in-reply-to relationship, we created a Twitter conversation corpus (20M conversations containing 90M tweets). By taking two consecutive tweets in the corpus and retaining only the frequent ones by a cut-off threshold of ten occurrences, we obtained 22K utterance pairs. The input to this module is the user utterance string, and the module outputs utterances from matched utterance pairs.

User PAS: This module uses the PASs of the user utterance and the next dialogue-act. It performs the same operation as the PAS-based generation and returns the converted sentences. The merit of this module is that the system can use the user's content in its utterance, which has been found to be useful in casual conversation for showing understanding (Ivey et al., 2013) and entraining with users (Nenkova et al., 2008).

3 Rule-based and Retrieval-based Systems

For comparison, we prepared a rule-based system and a retrieval-based one. Since there is no off-the-shelf rule-based system in Japanese, we created one on our own. Because we wanted to compare our system with a state-of-the-art rule-based system, we put a great deal of effort in its development. Remember that creating rules is still the standard way of creating an open-domain conversational system. Last year's Loebner Prize (a chatbot contest) winner, Mitsuku, was based on rules written in artificial intelligence markup language (AIML) (Wallace, 2004). Beating a reasonably created rule-based system is a hard task. As for the retrieval-based system, we use a large Twitter database to replicate the current best retrieval-based system, which we regard as our baseline.

3.1 Rule-based System

We had a seasoned engineer, who specializes in text analysis, create rules in AIML for two and a half months. We used only one person to ensure consistency in the rules. He first created some initial rules by referring to the AIML rules of A.L.I.C.E. (Wallace, 2004). The rules here include common exchanges of utterances (e.g., compliments of the season) as well as those to evade weak topics, changes of topics, and innocuous utterances. Then, he used the open-domain conversation corpus (with 10% held out for evaluation as we describe later) to extract two consecutive utterances and coded them as rules, making the first utterance the matching pattern and the second utterance the output sentence (called a template in AIML). This process involved replacing certain words with asterisks (wildcard) to widen the coverage of patterns and modifying templates if necessary. To augment the rules, he also used the topic-based utterance corpus that we created. The corpus contains 25K utterances conceived by 20 individuals for 250 topic words. The instruction given to the individuals was to come up with an interesting utterance that you think you would like to hear for a given topic word. Here, the topic words are frequent NPs in the open-domain conversation corpus. The pairs of a topic word and its utterance were coded as rules. To enable the system to answer personal questions, the Aiko PDB was employed. Since the PDB comprises a set of question-answer pairs, the PDB was straightforwardly incorporated into AIML with minor modifications. The rules were loaded by ProgramD, an AIML interpreter (http://aitools.org/Program_D), and were tested

	Utterance (English translation by the authors)

Figure 4: Example dialogue with the retrieval-based system.

by an external human checker. The checker randomly extracted 100 utterances from the remaining 10% of the open-domain conversation corpus and put each utterance into ProgramD and subjectively evaluated the adequacy of each output. If more than 90% of the output was judged adequate, the rule creation process ended; otherwise, the rules had to be improved for another check. After several iterations, the 90% criterion was met, resulting in 149,300 rules. As this process illustrates, the rules were meticulously crafted. Our rule-based system uses ProgramD loaded with these rules. Figure 3 shows an example dialogue with the rule-based system (collected in our experiment; see Section 4.1).

3.2 Retrieval-based System

We used the Twitter conversation corpus (See Section 2.3) to create a database for retrieval. We extracted two consecutive utterances as input-output pairs and indexed them using the text search engine Lucene (http://lucene.apache.org/core/). For a given utterance as a query, the top-ten utterance pairs are retrieved on the basis of the similarity between the query and the input-part of the indexed pairs. Here, the similarity is the cosine similarity of TF-IDF weighted word vectors. Then, one of the retrieved pairs is randomly selected to produce the system's next utterance. Here, we adopt random selection so that the same utterance won't be uttered for the same input. Since the amount of indexed tweets is large (90M), we consider this to be a reasonable baseline. This system is our replication of IR-Status in (Ritter et al., 2011). Figure 4 shows an example dialogue with the retrieval-based system.

4 Experiment

We evaluated our proposed system in an experiment using human judges. We compared it with the rule-based and retrieval-based systems.

Questionnaire	(a) Rule	(b) Retrieval	(c) Prop (noTW)	(d) Prop (noPAS)	(e) Prop (bi)	(f) Prop (tri)
Q1 Naturalness	**3.88**^{bbe}	***2.68***	3.60^{bb}	3.48^{bb}	3.33^{bb}	3.44^{bb}
Q2 Generation	**4.40**^{bbe}	***2.80***	4.03^{bb}	3.98^{bb}	3.80^{bb}	3.92^{bb}
Q3 Understanding	**3.73**^{bb}	***2.61***	3.46^{bb}	3.33^{bb}	3.16^{b}	3.25^{bb}
Q4 Informativeness	**3.00**^{bb}	***2.24***	2.70	2.65	2.62	2.80^{b}
Q5 Diversity	**3.58**	3.44	***3.08***	3.17	3.27	3.38
Q6 Continuity	**3.87**^{bbf}	***2.63***	3.44^{bb}	3.38^{bb}	3.41^{bb}	3.23^{bb}
Q7 Willingness	**3.60**^{bb}	***2.64***	3.25^{b}	3.14^{b}	3.12^{b}	3.12^{b}
Q8 Satisfaction	**3.62**^{bb}	***2.72***	3.24^{b}	3.21^{b}	3.13	3.13

Table 1: Subjective evaluation results: ratings averaged over all dialogues for each system. Superscripts a–f next to the numbers indicate that the number is statistically better than systems (a)–(f), respectively. Double-letters (e.g., bb) mean $p < 0.01$; otherwise $p < 0.05$. For the statistical test, we used a Steel-Dwass multiple comparison test (Dwass, 1960). The largest and smallest numbers in a row are indicated by bold and bold italic font, respectively.

4.1 Experimental Procedure

We recruited 30 human subjects (14 males and 16 females, ages from 18 to 55). They were paid for their participation. Each participant took part in 24 dialogue sessions, talking four times to each of six different systems. The systems used were (a) the rule-based system, (b) the retrieval-based system, and four different configurations of our proposed system: (c) Prop (noTW), in which utterance search from Twitter is disabled; (d) Prop (noPAS), in which PAS-based generation is disabled; (e) Prop (bi), where N=2 is used for utterance ranking (See Section 2.2); and (f) Prop (tri), in which no module is disabled. All systems start a conversation with a greeting prompt. Each dialogue session lasted for two minutes. Two-minute interaction could be short, but we wanted to test the systems with different topics that can change dialogue-by-dialogue. The participants were instructed to enjoy the conversation with the systems. No dialogue topic was specified. No prior knowledge was provided about the systems, including the number of systems they were to talk to. The order of the systems was randomized. Since the rule-based and retrieval-based systems require less computation, four seconds of delay was inserted before their utterances. After each dialogue, each participant filled out a questionnaire comprising eight items (See the column Questionnaire in Table 1) asking for his/her subjective evaluation of the dialogue on a seven-point Likert scale, where 1 is the worst and 7 the best. We asked the participants not to take into account the delay of system responses for their evaluation. After all 24 sessions, each participant filled in a free-form opinion sheet to end the participation.

4.2 Results and Analyses

Table 1 shows the results of subjective evaluations. As can be seen from the table, the rule-based system performed the best and the retrieval-based system performed the worst. The retrieval-based system was the worst for all questionnaire items except Q5 (Diversity of system utterances); at least the large Twitter database produced diverse utterances. Our proposed systems placed between the rule-based and retrieval-based systems. The averaged scores and the results of statistical tests indicate that our systems are significantly better than the retrieval-based baseline and that our systems' performance is close to that of the rule-based system. The difference between the rule-based and our proposed systems is not statistically significant (except for a small number of cases). When we focus on Q1 (Naturalness of dialogue), Prop (noTW) attained a score of 3.6, which is close to that of the rule-based system (3.88). This indicates that our system has the ability to perform reasonably natural conversation and that it is possible to create a system of rule-based-level naturalness with our architecture. As for other questionnaire items, the difference between our systems and the rule-based system is a little wider in mean scores. Although further examination is needed, this is probably because user satisfaction is related to more sensitive issues such as politeness, linguistic style, consistency, and users' preferences.

When we look at the difference in the four configurations, we see that Prop (noTW) is consistently

System		# Uniq utt	# Uniq word	# Utt	# Word	# Word/Utt	Perplexity

User PAS	0.046 (40)	0.046 (40)	0.042 (37)	0.021 (18)

Table 3: Selected ratios (raw counts in parentheses) for the generation modules. Bold and bold italic font indicate max and min in each column.

better than the others except for Q4 and Q5. Since the main difference is whether Twitter sentences are used, this is probably the cause. The reason could be the inconsistency of linguistic styles in Twitter or the noise that could not be suppressed by the filtering. Since Twitter sentences surely augment diversity, we would like to consider ways to make better use of them, for example, by normalizing the linguistic style and applying stricter filters. There is a slight tendency for Prop (tri) to be preferred to Prop (bi), which is reasonable because it uses more context for deciding the next utterance. In the future, we would like to pursue methods that can exploit longer context, such as entity grids (Barzilay and Lapata, 2008) and co-reference structures (Swanson and Gordon, 2012).

We performed a brief analysis of the collected dialogues. Table 2 shows, for each system, the number of unique utterances, unique words, utterances, words, words per utterance, and perplexity. It can be seen that the utterances of the rule-based system are very rigid: the perplexity is very low (23.46) and there are only 353 unique utterances, which is about half of that of the other systems. It is interesting that, despite this fact, the rule-based system was perceived to produce the most diverse utterances by questionnaire. Since the rule-based system produced much longer utterances (8.182), this probably had a positive effect for the perceived diversity. In terms of natural interaction, it is not desirable for one participant to contribute more than the other. In this respect, our proposed systems seem appropriate because the users and the systems exchange a similar number of words per utterance.

Table 3 shows the selected ratios for the generation modules. It can be seen that all modules contributed to conversation. The most frequent ones were Twitter and PAS-based generation, followed by the versatile and topic-inducing modules. Although QA and personal QA were not used as frequently for output, when we examined the logs, we found that there were many cases where these modules could not obtain any answer from the QA API or the PDB. Since answering questions is a basic function in conversation, this needs to be improved. Similarly, we also want to evaluate the contribution of each module quantitatively, for example, by associating the behavior of each module with user subjective evaluations in a framework similar to PARADISE (Walker et al., 2000). Enabling this kind of analysis is a clear benefit of having an architecture such as the one we proposed.

5 Summary

This paper proposed an architecture for an open-domain conversational system and evaluated an implemented system. The results indicate that our architecture enables better dialogue than a retrieval-based baseline using a large Twitter database. Although our system could not reach the level of a carefully crafted rule-based system and still has a number of limitations, our architecture can achieve naturalness close to that of the rule-based system. The contributions of this paper are that we introduced a viable architecture for an open-domain conversational system and experimentally verified its effectiveness. Rather than creating rules on the basis of developers' intuition, our architecture will enable module-by-module development, which will lead to rapid improvement in open-domain conversational systems in the future.

Abstract

Previous work by Lin et al. (2011) demonstrated the effectiveness of using discourse relations for evaluating text coherence. However, their work was based on discourse relations annotated in accordance with the Penn Discourse Treebank (PDTB) (Prasad et al., 2008), which encodes only very shallow discourse structures; therefore, they cannot capture long-distance discourse dependencies. In this paper, we study the impact of deep discourse structures for the task of coherence evaluation, using two approaches: (1) We compare a model with features derived from discourse relations in the style of Rhetorical Structure Theory (RST) (Mann and Thompson, 1988), which annotate the full hierarchical discourse structure, against our re-implementation of Lin et al.'s model; (2) We compare a model encoded using only shallow RST-style discourse relations, against the one encoded using the complete set of RST-style discourse relations. With an evaluation on two tasks, we show that deep discourse structures are truly useful for better differentiation of text coherence, and in general, RST-style encoding is more powerful than PDTB-style encoding in these settings.

1 Introduction

In a well-written text, utterances are not simply presented in an arbitrary order; rather, they are presented in a logical and coherent form, so that the readers can easily interpret the meaning that the writer wishes to present. Therefore, coherence is one of the most essential aspects of text quality. Given its importance, the automatic evaluation of text coherence is one of the crucial components of many NLP applications.

A particularly popular model for the evaluation of text coherence is the entity-based local coherence model of Barzilay and Lapata (B&L) (2005; 2008), which extracts mentions of entities in the text, and models local coherence by the transitions, from one sentence to the next, in the grammatical role of each mention. Since the initial publication of this model, a number of extensions have been proposed, the majority of which are focused on enriching the original feature set. However, these enriched feature sets are usually application-specific, i.e., it requires a certain expertise and intuition to conceive good features.

In contrast, we seek insights of better feature encoding from a more general problem: discourse parsing (to be introduced in Section 2). Discourse parsing aims to identify the discourse relations held among various discourse units in the text. Therefore, one can expect that discourse parsing provides useful information to the evaluation of text coherence, because, essentially, the existence and the distribution of discourse relations are the basis of the coherence in a text.

In fact, there is already evidence showing that discourse relations can help better capture text coherence. Lin et al. (2011) use a PDTB-style discourse parser (to be introduced in Section 2.1) to identify discourse relations in the text, and they represent a text by entities and their associated discourse roles in each sentence. In their experiments, using discourse roles alone, their model performs very similar or even better than B&L's model. Combining their discourse role features with B&L's entity-based transition features further improves the performance.

Proceedings of COLING 2014, the 25th International Conference on Computational Linguistics: Technical Papers, pages 940–949, Dublin, Ireland, August 23-29 2014.

S_1: The dollar finished lower yesterday, after tracking another rollercoaster session on Wall Street.
S_2: [Concern about the volatile U.S. stock market had faded in recent sessions]$C_{2.1}$, [and traders appeared content to let the dollar languish in a narrow range until tomorrow, when the preliminary report on third-quarter U.S. gross national product is released.]$C_{2.2}$
S_3: But seesaw gyrations in the Dow Jones Industrial Average yesterday put Wall Street back in the spotlight and inspired market participants to bid the U.S. unit lower.

Three discourse relations are presented in the text above:

1. Implicit *EntRel* between S_1 as Arg1, and S_2 as Arg2.
2. Explicit *Conjunction* within S_2: $C_{2.1}$ as Arg1, $C_{2.2}$ as Arg2, with *and* as the connective.
3. Explicit *Contrast* between S_2 as Arg1 and S_3 as Arg2, with *but* as the connective.

Figure 1: An example text fragment composed of three sentences, and its PDTB-style discourse relations.

However, PDTB-style discourse relations encode only very shallow discourse structures, i.e., the relations are mostly local, e.g., within a single sentence or between two adjacent sentences. Therefore, in general, features derived from PDTB-style discourse relations cannot capture long discourse dependency, and thus the resulting model is still limited to being a local model. Nonetheless, long-distance discourse dependency could be quite useful for capturing text coherence from a global point of view.

Therefore, in this paper, we study the effect of deep hierarchical discourse structure in the evaluation of text coherence, by adopting two approaches to perform a direct comparison between models that incorporate deep hierarchical discourse structures and models with shallow structures. To evaluate our models, we conduct experiments on two datasets, each of which resembles a real sub-task in the evaluation of text coherence: **sentence ordering** and **essay scoring**. On both tasks, the model derived from deep discourse structures is shown to be more powerful than the model derived from shallow discourse structures. Moreover, for sentence ordering, combining our model with entity-based transition features achieves the best performance. However, for essay scoring, the combination is detrimental.

2 Discourse parsing

Discourse parsing is the problem of identifying the discourse structure within a text, by recognizing the specific type of its discourse relations, such as *Contrast*, *Explanation*, and *Causal* relations. Although discourse parsing is still relatively less well-studied, a number of theories have been proposed to capture different rhetorical characteristics or to serve different applications.

Currently, the two main directions in the study of discourse parsing are PDTB-style and RST-style parsing. These two directions are based on distinct theoretical frameworks, and each can be potentially useful for particular kinds of downstream applications. As will be discussed shortly, the major difference between PDTB- and RST-style discourse parsing is the notion of deep hierarchical discourse structure, which, according to our hypothesis, can be very useful for recognizing text coherence.

2.1 PDTB-style Discourse Parsing

The Penn Discourse Treebank (PDTB), developed by Prasad et al. (2008), is currently the largest discourse-annotated corpus, consisting of 2159 Wall Street Journal articles. The annotation in PDTB adopts the predicate-argument view of discourse relations, where a discourse connective (e.g., *because*) is treated as a predicate that takes two text spans as its arguments. The argument that the discourse connective structurally attaches to is called Arg2, and the other argument is called Arg1. In PDTB, relations are further categorized into *explicit* and *implicit* relations: a relation is explicit if there is an explicit discourse connective presented in the text; otherwise, it is implicit. PDTB relations focus more on *locality* and *adjacency*: explicit relations seldom connect text units beyond local context; for implicit relations,

S_1: [The dollar finished lower yesterday,]e_1 [after tracking another rollercoaster session on Wall Street.]e_2
S_2: [Concern about the volatile U.S. stock market had faded in recent sessions,]e_3 [and traders appeared content to let the dollar languish in a narrow range until tomorrow,]e_4 [when the preliminary report on third-quarter U.S. gross national product is released.]e_5
S_3: [But seesaw gyrations in the Dow Jones Industrial Average yesterday put Wall Street back in the spotlight]e_6 [and inspired market participants to bid the U.S. unit lower.]e_7

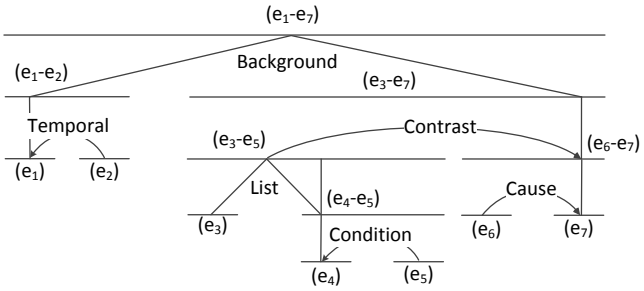

Figure 2: An example text fragment composed of seven EDUs, and its RST discourse tree representation.

only adjacent sentences within paragraphs are examined for the existence of implicit relations.

The PDTB-style discourse parsing is thus the type of framework in accordance with the PDTB, which extracts the discourse relations in a text, by identifying the presence of discourse connectives, the associated discourse arguments, and the specific types of the relations. An example text fragment is shown in Figure 1, consisting of three sentences, S_1, S_2, and S_3. A sentence may further contain clauses, e.g., $C_{2.1}$ and $C_{2.2}$ in S_2. The three PDTB-style discourse relations in this text are explained below the text.

2.2 RST-style Discourse Parsing

RST-style discourse parsing follows the theoretical framework of Rhetorical Structure Theory (RST) (Mann and Thompson, 1988). In the framework of RST, a coherent text can be represented as a discourse tree whose leaves are non-overlapping text spans called *elementary discourse units* (EDUs); these are the minimal text units of discourse trees. Adjacent nodes can be related through particular discourse relations to form a discourse subtree, which can then be related to other adjacent nodes in the tree structure. RST-style discourse relations can be categorized into two types: mononuclear and multi-nuclear. In mononuclear relations, one of the text spans, the *nucleus*, is more salient than the other, the *satellite*, while in multi-nuclear relations, all text spans are equally important for interpretation.

Consider Figure 2, in which the same example as in Figure 1 is chunked into seven EDUs (e_1-e_7), segmented by square brackets. Its discourse tree representation is shown below in the figure, following the notational convention of RST. The two EDUs e_1 and e_2 are related by a mononuclear relation *Temporal*, where e_1 is the more salient span; e_4 and e_5 are related by *Condition*, with e_4 as the nucleus; and e_6 and e_7 are related by *Cause*, with e_7 as the nucleus. Then, the spans (e_3-e_5) and (e_6-e_7) are related by *Contrast* to form a higher-level discourse structure, and so on. Finally, a *Background* relation merges the span (e_1-e_2) and (e_3-e_7) on the top level of the tree.

As can be seen, thanks to the tree-structured representation of RST, compared to PDTB-style representation, we have a full hierarchy of discourse relations in the text: discourse relations exist not only in a local context, but also on higher text levels, such as between S_1 and the concatenation of S_2 and S_3.

3 Entity-based Local Coherence Model

The entity-based local coherence model was initially developed by Barzilay and Lapata (B&L) (2005; 2008). The fundamental assumption of this model is that a document makes repeated reference to elements of a set of entities that are central to its topic.

For a document d, an entity grid is constructed, in which the columns represent the entities referred

S_1: [**The dollar**]$_{\mathbf{S}}$ finished lower [**yesterday**]$_{\mathbf{X}}$, after tracking [**another rollercoaster session**]$_{\mathbf{O}}$ on [**Wall Street**]$_{\mathbf{X}}$.
S_2: [**Concern**]$_{\mathbf{S}}$ about [**the volatile U.S. stock market**]$_{\mathbf{X}}$ had faded in [**recent sessions**]$_{\mathbf{X}}$, and [**traders**]$_{\mathbf{S}}$ appeared content to let [**the dollar**]$_{\mathbf{S}}$ languish in [**a narrow range**]$_{\mathbf{X}}$ until [**tomorrow**]$_{\mathbf{X}}$, when [**the preliminary report**]$_{\mathbf{S}}$ on [**third-quarter U.S. gross national product**]$_{\mathbf{X}}$ is released.
S_3: But [**seesaw gyrations**]$_{\mathbf{S}}$ in [**the Dow Jones Industrial Average**]$_{\mathbf{X}}$ [**yesterday**]$_{\mathbf{X}}$ put [**Wall Street**]$_{\mathbf{O}}$ back in [**the spotlight**]$_{\mathbf{X}}$ and inspired [**market participants**]$_{\mathbf{O}}$ to bid [**the U.S. unit**]$_{\mathbf{S}}$ lower.

	dollar	**yesterday**	**session**	**Wall Street**	**concern**	**market**	**sessions**	**traders**	**range**	**tomorrow**	**report**	**GNP**	**gyrations**	**DJIA**	**spotlight**	**participants**
S_1	S	X	O	X	-	-	-	-	-	-	-	-	-	-	-	-
S_2	S	-	-	-	S	X	S	X	X	X	S	X	-	-	-	-
S_3	S	X	-	O	-	-	-	-	-	-	-	-	S	X	X	O

Table 1: The entity grid for the example text with three sentences and eighteen entities. Grid cells correspond to grammatical roles: subjects (S), objects (O), or neither (X).

to in d, and rows represent the sentences. Each cell corresponds to the grammatical role of an entity in the corresponding sentence: subject (S), object (O), neither (X), or nothing ($-$), and an entity is defined as a class of coreferent noun phrases. If the entity serves in multiple roles in a single sentence, then we resolve its grammatical role following the priority order: $\mathrm{S} \succ \mathrm{O} \succ \mathrm{X} \succ -$. Consider the text in our previous examples; its entity grid is shown in Table 1, and the entities are highlighted in boldface in the text above[1]. A local transition is defined as a sequence $\{\mathrm{S},\mathrm{O},\mathrm{X},-\}^n$, representing the occurrence and grammatical roles of an entity in n adjacent sentences. Such transition sequences can be extracted from the entity grid as continuous subsequences in each column. For example, the entity *dollar* in Table 1 has a bigram transition $\{\mathrm{S},\mathrm{S}\}$ from sentence 1 to 2. The entity grid is then encoded as a feature vector $\Phi(d) = (p_1(d), p_2(d), \ldots, p_m(d))$, where $p_t(d)$ is the normalized frequency of the transition t in the entity grid, and m is the number of transitions with length no more than a predefined length k. $p_t(d)$ is computed as the number of occurrences of t in the entity grid of document d, divided by the total number of transitions of the same length. Moreover, entities are differentiated by their salience — an entity is deemed to be salient if it occurs at least l times in the text, and non-salient otherwise — and transitions are computed separately for salient and non-salient entities.

3.1 Extension: Lin et al.'s Discourse Role Matrix

As mentioned previously, most extensions to B&L's entity-based local coherence model focus on enriching the feature set, including the work of Filippova and Strube (2007), Cheung and Penn (2010), Elsner and Charniak (2011), and Lin et al. (2011). To the best of our knowledge, the only exception is Feng and Hirst (2012a)'s extension from the perspective of improving the learning procedure.

Among various extensions to B&L's entity-based local coherence model, the one most related to ours is Lin et al. (2011)'s work on encoding a text as a set of entities with their associated discourse roles. Lin et al. observed that coherent texts preferentially follow certain relation patterns. However, simply using such patterns to measure the coherence of a text can result in feature sparseness. To solve this problem, they expand the relation sequence into a discourse role matrix, as shown in Table 2. Columns correspond to the entities in the text and rows represent the contiguous sentences. Each cell $\langle E_i, S_j \rangle$ corresponds to the set of discourse roles that the entity E_i serves as in sentence S_j. For example, the entity *yesterday* from S_3 takes part in Arg2 of the last relation, so the cell $\langle yesterday, S_3 \rangle$ contains the role *Contrast*.Arg2.

[1]Text elements are considered to be a single entity with multiple mentions if they refer to the same object or concept in the world, even if they have different textual realizations; e.g., *dollar* in S_1 and *U.S. unit* in S_3 refer to the same entity.

	dollar	**yesterday**	**session**	**Wall Street**	**concern**	**market**
S_1	*EntRel*.Arg1	*EntRel*.Arg1	*EntRel*.Arg1	*EntRel*.Arg1	*nil*	*nil*
S_2	*EntRel*.Arg2 *Conj*.Arg2 *Contrast*.Arg1	*nil*	*nil*	*nil*	*EntRel*.Arg2 *Conj*.Arg1 *Contrast*.Arg1	*EntRel*.Arg2 *Conj*.Arg1 *Contrast*.Arg1
S_3	*Contrast*.Arg2	*Contrast*.Arg2	*nil*	*Contrast*.Arg2	*nil*	*nil*

Table 2: A fragment of Lin et al.'s PDTB-style discourse role matrix for the example text with the first six entities across three sentences.

An entry may be empty (with a symbol *nil*, as in $\langle yesterday, S_2 \rangle$) or contain multiple discourse roles (as in $\langle dollar, S_2 \rangle$). Next, the frequencies of the discourse role transitions of lengths 2 and 3, e.g., *EntRel*.Arg1 $\rightarrow$ *Conjunction*.Arg2 and *EntRel*.Arg1 $\rightarrow$ *nil* $\rightarrow$ *Contrast*.Arg2, are calculated with respect to the matrix. For example, the frequency of *EntRel*.Arg1 $\rightarrow$ *Conjunction*.Arg2 is $1/24 = 0.042$ in Table 2.

4 Methodology

As discussed in Section 1, the main objective of our work is to study the impact of deep hierarchical discourse structures in the evaluation of text coherence. In order to conduct a direct comparison between a model with features derived from deep hierarchical discourse relations and a model with features derived from shallow discourse relations only, we adopt two separate approaches: (1) We implement a model with features derived from RST-style discourse relations, and compare it against a model with features derived from PDTB-style relations. (2) In the framework of RST-style discourse parsing, we deprive the model of any information from higher-level discourse relations and compare its performance against the model that uses the complete set of discourse relations. Moreover, as a baseline, we also re-implemented B&L's entity-based local coherence model, and we will study the effect of incorporating one of our discourse feature sets into this baseline model. Therefore, we have four ways to encode discourse relation features, namely, entity-based, PDTB-style, full RST-style, and shallow RST-style.

4.1 Entity-based Feature Encoding

In entity-based feature encoding, our goal is to formulate a text into an entity grid, such as the one shown in Table 1, from which we extract entity-based local transitions. In our re-implementation of B&L, we use the same parameter settings as B&L's original model, i.e., the optimal transition length $k = 3$ and the salience threshold $l = 2$. However, when extracting entities in each sentence, e.g., *dollar*, *yesterday*, etc., we do not perform coreference resolution; rather, for better coverage, we follow the suggestion of Elsner and Charniak (2011) and extract all nouns (including non-head nouns) as entities. We use the Stanford dependency parser (de Marneffe et al., 2006) to extract nouns and their grammatical roles. This strategy of entity extraction also applies to the other three feature encoding methods to be described below.

4.2 PDTB-style Feature Encoding

To encode PDTB-style discourse relations into the model, we parse the texts using an end-to-end PDTB-style discourse parser[2] developed by Lin et al. (2014). The F_1 score of this parser is around 85% for recognizing explicit relations and around 40% for recognizing implicit relations. A text is thus represented by a discourse role matrix in the same way as shown in Table 2. Most parameters in our PDTB-style feature encoding follow those of Lin et al. (2011): each entity is associated with the fully-fledged discourse roles, i.e., with type and argument information included; the maximum length of discourse role transitions is 3; and transitions are generated separately for salient and non-salient entities with a threshold set at 2. However, compared to Lin et al.'s model, there are two differences in our re-implementation, and evaluated on a held-out development set, these modifications are shown to be effective in improving the performance.

[2] `http://wing.comp.nus.edu.sg/~linzihen/parser/`

	dollar	yesterday	session	Wall Street	concern	market
S_1	*Background*.N *Temporal*.N	*Background*.N *Temporal*.N	*Temporal*.S	*Temporal*.S	*nil*	*nil*
S_2	*List*.N *Condition*.N *Contrast*.S	*nil*	*nil*	*nil*	*List*.N *Contrast*.S	*List*.N *Contrast*.S
S_3	*Contrast*.N *Background*.N *Cause*.N	*Cause*.S	*nil*	*Cause*.S	*nil*	*nil*

Table 3: A fragment of the full RST-style discourse role matrix for the example text with the first six entities across three sentences.

First, we differentiate between intra- and multi-sentential discourse relations, which is motivated by a finding in the field of RST-style discourse parsing — distributions of various discourse relation types are quite distinct between intra-sentential and multi-sentential instances (Feng and Hirst, 2012b; Joty et al., 2012) — and we assume that a similar phenomenon exists for PDTB-style discourse relations. Therefore, we assign two sets of discourse roles to each entity: intra-sentential and multi-sentential roles, which are the roles that the entity plays in the corresponding intra- and multi-sentential relations.

Second, instead of Level-1 PDTB discourse relations (6 in total), we use Level-2 relations (18 in total) in feature encoding, so that richer information can be captured in the model, resulting in $18 \times 2 = 36$ different discourse roles with argument attached. We then generate four separate set of features for the combination of intra-/multi-sentential discourse relation roles, and salient/non-salient entities, among which transitions consisting of only *nil* symbols are excluded. Therefore, the total number of features in PDTB-style encoding is $4 \times (36^2 + 36^3 - 2) \approx 192$K.

4.3 Full RST-style Feature Encoding

For RST-style feature encoding, we parse the texts using an end-to-end RST-style discourse parser developed by Feng and Hirst (2014), which produces a discourse tree representation for each text, such as the one shown in Figure 2. For relation labeling, the overall accuracy of this discourse parser is 58%, evaluated on the RST-DT.

We encode the RST-style discourse relations in a similar fashion to PDTB-style encoding. However, since the definition of discourse roles depends on the particular discourse framework, here, we adapt Lin et al.'s PDTB-style encoding by replacing the PDTB-style discourse relations with RST-style discourse relations, and the argument information (Arg1 or Arg2) by the nuclearity information (nucleus or the satellite) in an RST-style discourse relation. More importantly, in order to reflect the hierarchical structure in an RST-style discourse parse tree, when extracting the set of discourse relations that an entity participates in, we find all those discourse relations that the entity appears in the main EDUs of each relation[3] and represent the role of the entity in each of these discourse relations. In this way, we can encode long-distance discourse relations for the most relevant entities. For example, considering the RST-style discourse tree representation in Figure 2, we encode the *Background* relation for the entities *dollar* and *yesterday* in S_1, as well as the entity *dollar* in S_3, but not for the remaining entities in the text, even though the *Background* relation covers the whole text. The corresponding full RST-style discourse role matrix for the example text is shown in Table 3.

As in PDTB-style feature encoding, we differentiate between intra- and multi-sentential discourse relations; we use 17 coarse-grained classes of RST-style relations in feature encoding; the optimal transi-

[3]The main EDUs of a discourse relation are the EDUs obtained by traversing the discourse subtree in which the relation of interest constitutes the root node, following the nucleus branches down to the leaves. For instance, for the RST discourse tree in Figure 2, the main EDUs of the *Background* relation on the top level are $\{e_1, e_7\}$, and the main EDUs of the *List* relation among (e_3-e_5) are $\{e_3, e_4\}$.

tion length k is 3; and the salience threshold l is 2. The total number of features in RST-style encoding is therefore $4 \times (34^2 + 34^3 - 2) \approx 162$K, which is roughly the same as that in PDTB-style feature encoding.

4.4 Shallow RST-style Feature Encoding

Shallow RST-style encoding is almost identical to full RST-style encoding, as introduced in Section 4.3, except that, when we derive discourse roles, we consider shallow discourse relations only. To be consistent with the majority of PDTB-style discourse relations, we define shallow discourse relations as those relations which hold between text spans of the same sentence, or between two adjacent sentences. For example, in Figure 2, the *Background* relation between (e_1-e_2) and (e_3-e_7) is not a shallow discourse relation (it holds between a single sentence and the concatenation of two sentences), and thus will be excluded from shallow RST-style feature encoding.

5 Experiments

To evaluate our proposed model with deep discourse structures encoded, we conduct two series of experiments on two different datasets, each of which simulates a sub-task in the evaluation of text coherence, i.e., **sentence ordering** and **essay scoring**. Since text coherence is a matter of degree rather than a binary classification, in both evaluation tasks we formulate the problem as a pairwise preference ranking problem. Specifically, given a set of texts with different degrees of coherence, we train a ranker which learns to prefer a more coherent text over a less coherent counterpart. Accuracy is therefore measured as the fraction of correct pairwise rankings as recognized by the ranker. In our experiments, we use the SVM^{light} package[4] (Joachims, 1999) with the ranking configuration, and all parameters are set to their default values.

5.1 Sentence Ordering

The task of sentence ordering, which has been extensively studied in previous work, attempts to simulate the situation where, given a predefined set of information-bearing items, we need to determine the best order in which the items should be presented. As argued by Barzilay and Lapata (2005), sentence ordering is an essential step in many content-generation components, such as multi-document summarization.

In this task, we use a dataset consisting of a subset of the Wall Street Journal (WSJ) corpus, in which the minimum length of a text is 20 sentences, and the average length is 41 sentences. For each text, we create 20 random permutations by shuffling the original order of the sentences. In total, we have 735 source documents and $735 \times 20 = 14,700$ permutations. Because the RST-style discourse parser we use is trained on a fraction of the WSJ corpus, we remove the training texts from our dataset, to guarantee that the discourse parser will not perform exceptionally well on some particular texts. However, since the PDTB-style discourse parser we use is trained on almost the entire WSJ corpus, we cannot do the same for the PDTB-style parser.

In this experiment, our learning instances are pairwise ranking preferences between a source text and one of its permutations, where the source text is always considered more coherent than its permutations. Therefore, we have $735 \times 20 = 14,700$ total pairwise rankings, and we conduct 5-fold cross-validation on five disjoint subsets. In each fold, one-fifth of the rankings are used for testing, and the rest for training.

5.2 Essay Scoring

The second task is essay scoring, and we use a subset of International Corpus of Learner English (ICLE) (Granger et al., 2009). The dataset consists of 1,003 essays about 34 distinct topics, written by university undergraduates speaking 14 native languages who are learners of English as a Foreign Language. Each essay has been annotated with an organization score from 1 to 4 at half-point increments by Persing et al. (2010). We use these organization scores to *approximate* the degrees of coherence in the essays. The average length of the essays is 32 sentences, and the average organization score is 3.05, with a standard deviation of 0.59.

[4] `http://svmlight.joachis.org/`

Model		sentence ordering	essay scoring
No discourse structure	Entity	95.1	66.4
Shallow discourse structures	PDTB	97.2	82.2
	PDTB&Entity	97.3	83.3
	Shallow RST	98.5	87.2
	Shallow RST&Entity	98.8	87.2
Deep discourse structures	Full RST	99.1	**88.3**
	Full RST&Entity	**99.3**	87.7

Table 4: Accuracy (%) of various models on the two evaluation tasks: sentence ordering and essay scoring. For sentence ordering, accuracy difference is significant with $p < .01$ for all pairs of models except between PDTB and PDTB&Entity. For essay scoring, accuracy difference is significant with $p < .01$ for all pairs of models except between shallow RST and shallow RST&Entity. Significance is determined with the Wilcoxon signed-rank test.

In this experiment, our learning instances are pairwise ranking preferences between a pair of essays on the same topic written by students speaking the same native language, excluding pairs with the same organization score. In total, we have 22,362 pairwise rankings. Similarly, we conduct 5-fold cross-validations on these rankings.

In fact, the two datasets used in the two evaluation tasks reflect different characteristics by themselves. The WSJ dataset, although somewhat artificial due to the permuting procedure, is representative of texts with well-formed syntax. By contrast, the ICLE dataset, although not artificial, contains occasional syntactic errors, because the texts are written by non-native English speakers. Therefore, using these two distinct datasets allows us to evaluate our models in tasks where different challenges may be expected.

6 Results

In this section, we demonstrate the performance of our models with discourse roles encoded in one of the three ways: PDTB-style, full RST-style or shallow RST-style, and compare against their combination with our re-implemented B&L's entity-based local transition features. The evaluation is conducted on the two tasks, sentence ordering and essay scoring, and the accuracy is reported as the fraction of correct pairwise rankings averaged over 5-fold cross-validation.

The performance of various models is shown in Table 4. The first section of the table shows the results of our re-implementation of B&L's entity-based local coherence model, representing the effect with **no** discourse structure encoded. The second section shows the results of four models with **shallow** discourse structures encoded, including the two basic models, PDTB-style and shallow RST-style feature encoding, and their combination with the entity-based feature encoding. The last section shows the results of our models with **deep** discourse structures encoded, including the RST-style feature encoding and its combination with the entity-base feature encoding. With respect to the performance, we observe a number of consistent patterns across both evaluation tasks.

First, with **no** discourse structure encoded, the entity-based model (the first row) performs the worst among all models, suggesting that discourse structures are truly important and can capture coherence in a more sophisticated way than pure grammatical roles. Moreover, the performance gap is particularly large for essay scoring, which is probably due to the fact that, as argued by Persing et al. (2010), the organization score, which we use to approximate the degrees of coherence, is not equivalent to text coherence. Organization relates more to the logical development in the texts, while coherence is about lexical and semantic continuity; but discourse relations can capture the logical relations at least to some extent.

Secondly, with **deep** discourse structures encoded, the RST-style model in the third section significantly outperforms ($p < .01$) the models with shallow discourse structures, i.e., the PDTB-style and

shallow RST-style models in the middle section, confirming our intuition that deep discourse structures are more powerful than shallow structures. This is also the case when entity-based features are included.

Finally, considering the models in the middle section of the table, we can gain more insight into the difference between PDTB-style and RST-style encoding. As can be seen, even without information from the more powerful deep hierarchical discourse structures, shallow RST-style encoding still significantly outperforms PDTB-style encoding on both tasks ($p < .01$). This is primarily due to the fact that the discourse relations discovered by RST-style parsing have wider coverage of the text[5], and thus induce richer information about the text. Therefore, because of its ability to annotate deep discourse structures and its better coverage of discourse relations, RST-style discourse parsing is generally more powerful than PDTB-style parsing, as far as coherence evaluation is concerned.

However, with respect to combining full RST-style features with entity features, we have contradictory results on the two tasks: for sentence ordering, the combination is significantly better than each single model, while for essay scoring, the combination is worse than using RST-style features alone. This is probably related to the previously discussed issue of using entity-based features for essay scoring, due to the subtle difference between coherence and organization.

7 Conclusion and Future Work

In this paper, we have studied the impact of deep discourse structures in the evaluation of text coherence by two approaches. In the first approach, we implemented a model with discourse role features derived from RST-style discourse parsing, which represents deep discourse structures, and compared it against our re-implemented Lin et al. (2011)'s model derived from PDTB-style parsing, with no deep discourse structures annotated. In the second approach, we compared our complete RST-style model against a model with shallow RST-style encoding. Evaluated on the two tasks, sentence ordering and essay scoring, deep discourse structures are shown to be effective for better differentiation of text coherence. Moreover, we showed that, even without deep discourse structures, shallow RST-style encoding is more powerful than PDTB-style encoding, because it has better coverage of discourse relations in texts. Finally, combining discourse relations with entity-based features is shown to have an inconsistent effect on the two evaluation tasks, which is probably due to the different nature of the two tasks.

In our future work, we wish to explore the effect of automatic discourse parsers in our methodology. As discussed previously, the PDTB- and RST-style discourse parsers used in our experiments are far from perfect. Therefore, it is possible that using automatically extracted discourse relations creates some bias to the training procedure; it is also possible that what our model actually learns is the distribution over those discourse relations which automatic discourse parsers are mostly confident with, and thus errors (if any) made on other relations do not matter. One potential way to verify these two possibilities is to study the effect of each particular type of discourse relation to the resulting model, and we leave it for future exploration.

Abstract

This paper presents an investigation of lexical chaining (Morris and Hirst, 1991) for measuring discourse coherence quality in test-taker essays. We hypothesize that attributes of lexical chains, as well as interactions between lexical chains and explicit discourse elements, can be harnessed for representing coherence. Our experiments reveal that performance achieved by our new lexical chain features is better than that of previous discourse features used for this task, and that the best system performance is achieved when combining lexical chaining features with complementary discourse features, such as those provided by a discourse parser based on rhetorical structure theory, and features that reflect errors in grammar, word usage, and mechanics.

1 Introduction

Coherence, the reader's ability to construct meaning from a document, is greatly influenced by the presence and organization of cohesive elements in the text (Halliday and Hasan, 1976; Moe, 1979). The lexical chain (Morris and Hirst, 1991) is one such element. It consists of a sequence of related words that contribute to the continuity of meaning based on word repetition, synonymy and similarity. In this paper we explore how lexical chains can be employed to measure coherence in essays. Specifically, our goal is to investigate how attributes of lexical chains can encode discourse coherence quality, such as adherence to the essay topic, elaboration, usage of varied vocabulary, and sound organization of thoughts and ideas. To do this, we build lexical chains and extract linguistically-motivated features from them. The number of chains and their properties, such as length, density and link strength, can potentially reveal discourse qualities related to focus and elaboration. In addition, features that capture the interactions between chains and explicit discourse cues, such as transition words, can show if the cohesive elements in text have been organized in a coherent fashion.

The main contributions of this paper are as follows: We use lexical chaining features to train a discourse coherence classifier on annotated essays from six different essay-writing tasks which differ in essay genre and/or test-taker population. We then perform experiments to measure the effect of the features when they are used alone and when they are combined with state-of-the-art features to classify the coherence quality of essays. Our results indicate that lexical chaining features yield better results than discourse features previously explored for this task and that the best performing feature combinations contain lexical chaining features. We also show that lexical chaining features can improve system performance across multiple genres of writing and populations. Our efforts result in the creation of a higher performing state-of-the-art feature set for measuring coherence in test-taker writing.

The rest of the paper is organized as follows: In Section 2, we describe our intuitions about lexical chains and how they can be used for measuring discourse coherence quality in essays. Section 3 describes our data, and Section 4 describes our experiments in predicting discourse coherence quality. We discuss related work in Section 5 and conclude in Section 6.

2 Lexical Chains and Discourse Coherence Quality

According to Morris and Hirst (1991), *lexical cohesion* is the result of chains of related words that contribute to the continuity of lexical meaning. These sequences are characterized by the relations between the words, as well as by their distance and density within a given span. Lexical chains do not stop at sentence boundaries – they can connect a pair of adjacent words or range over an entire text. Morris and Hirst also observe that lexical chains tend to delineate portions of text that have a strong unity of meaning. In this paper, we use this underlying principle of cohesion to detect the *quality of coherence* in a discourse. Specifically, we employ lexical chains to quantify and represent expectations for coherent discourse in test-taker essays. Presumably, violations of these expectations would indicate lack of (or poor) coherence. We believe lexical chains have the potential to reveal the following characteristics about discourse coherence in essays:

Text unity: Textual continuity is vital for the reader's ability to construct meaning from the text (Halliday and Hasan, 1976). Coherent essays generally maintain focus over the main theme, so lexical chains constructed over such essays will have chains representing the central topic running through most of the length of the essay. These types of chains would presumably represent the main claim or position in persuasive texts, the main object or person in descriptive texts, and the main story-line in narrative texts. On the other hand, incoherent texts that jump from one topic to another, or do not adhere to a central idea, will exhibit no chains or chains with very few member words.

Elaboration and Detailing: A function of elaboration in discourse is to overcome misunderstanding or lack of understanding, and to enrich the understanding of the reader by expressing the same thought from a different perspective (Hobbs, 1979). Good writers usually initiate topics, ideas or claims and provide clear elaborations or reasons. That is, a sequence of many related words and phrases will be evoked to explain an idea or provide an account of the writer's reasoning. This development and detailing will be exhibited by lexical chains with a good number of member words.

Variety: While cohesiveness is vital for coherence, too much repetition of the same word can, in fact, harm the discourse quality (Witte and Faigley, 1981). Using a variety of words to express an idea or elaborate on a topic is generally a characteristic of skillful writing. Lexical chains corresponding to such writing will have a variety of similar words within the same chain.

Organization: In addition to cohesion (as represented by lexical chains in our case), one other factor must be present for text to have coherence – organization (Moe, 1979; Perfetti and Lesgold, 1977). Thus, it is important to organize ideas using clear discourse transitions. Transitions from one topic to another, or from a topic to its subtopic, should be clearly cued in order to assist the reader's understanding of the discourse. Consequently, in coherent writing, we would expect lexical chain patterns to synchronize with discourse cues. For example, we would expect some chains to start after a new (sub) topic initiation cue, such as "Secondly" or "Finally", and at least some chains (corresponding to the previous topic) to end immediately before the cue. Similarly, we would expect at least some chains to cross over discourse cues indicating elaboration or reason (e.g. "because") due to topic continuity.

2.1 Features for Measuring Discourse Coherence

In order to measure discourse coherence quality, we create features based on attributes of lexical chains extracted from essays. These features are then used to train a machine learning model, using essays manually labeled for overall discourse coherence quality.

2.1.1 Lexical Chain Construction

Lexical chains in a text are composed of words and terms that are related. Based on Hirst and St-Onge (1995), these relations can be exact repetitions, called *extra-strong relations*, close synonyms, called *strong relations*, or words with weaker semantic relations, called *medium-strong relations*. We implement the lexical chaining program described in Hirst and St. Onge (1995), where if a word or phrase is potentially chainable, it is considered a candidate *node* for existing chains. First, an extra-strong relation is sought throughout all existing chains, and if one is found, the word is added to it. If not, strong relations are sought, but for these, the search scope is limited to the words in any chain that is

no farther away than the previous six sentences in the text; the search ends as soon as a strong relation is found. Finally, if no relationship has yet been found, medium-strong relations are sought with the search scope limited to words in chains that are no farther away than the previous three sentences. If the node cannot be added to any existing chains, it forms its own single-node chain.

In this work, nouns are the focus of the lexical chains. Nouns, adjective-noun and noun-noun structures are identified as potential chain participants. Lin's thesaurus (Lin, 1998) is used to measure similarity between words and phrases. Candidate pairs receiving similarity scores greater than 0.8 are considered to have an extra-strong relationship (word repetition receives a similarity score of 1), pairs with similarity greater than 0.172 are considered to have a strong relation, and pairs with similarity scores greater than 0.099 are considered to have a medium-strong relation. These thresholds were chosen after qualitative inspection of a separate development data set of essays, and are also based on a previous finding (Burstein et al., 2012) that 0.172 is the mean similarity value across different parts of speech in the Lin thesaurus.

We created two feature sets to capture the intuitions described above. The first set, *LEX-1*, encodes the characteristics of text unity, elaboration and variety, while the second, *LEX-2*, encodes organization.

2.1.2 LEX-1 feature set

In order to capture text unity and detailing, we create features such as: *total number of chains in the essay*, *average chain size*, *number (and percentage) of large chains* (chains having more than four nodes are considered to be large chains[1]). As discussed previously, essays that show ample chaining might do so because they adhere to themes and their development, while the presence of large, dense chains might be an indicator that a topic is being discussed in detail. To represent variety, we employ features such as *number (and percentage) of chains that have a variety of words* (chains containing more than one word/phrase type are considered to have variety), as well as *number (and percentage) of large chains with a variety of words*. To encode the characteristics of cohesive relationships, we look at the nature of the links. Examples of these features are: *number and percentage of each link type*, *number (and percentage) of links of each type in large chains as well as in small chains*. Corresponding to each feature that uses counts (e.g. total number of chains) we also created normalized versions of the numbers to account for the essay length. LEX-1 has a total of 38 features.

2.1.3 LEX-2 feature set

LEX-2 features capture the interactions between discourse transitions, indicated by explicit discourse cues, and lexical chaining patterns. For this, we use a discourse cue tagger described in Burstein et al. (1998) that was specifically developed for tagging discourse cues in the essay genre. Using patterns and syntactic rules, the tagger automatically identifies words and phrases used as discourse cues, and assigns them a discourse tag. Each tag has a primary component, indicating whether an argument (or topic) is being initialized (*arg-init*) or developed (*arg-dev*), and a secondary component indicating the specific type of discourse initialization (e.g. *CLAIM*, *SUMMARY*), or development (e.g. *CLAIM*, *CONTRAST*). Examples of the discourse tags and their cues are: *arg-init:SUMMARY* (e.g. *all in all*, *in conclusion*, *in summary*, *overall*), arg-init:TRANSITION (e.g. *let us*), arg-init:PARALLEL (e.g. *firstly*, *similarly*, *finally*), arg-dev:CONTRAST (e.g. *nonetheless*, *however*, *on the contrary*, *rather than*, *even if*), arg-dev:EVIDENCE (e.g. *because of*, *since*), arg-dev:INFERENCE (e.g. *as a result*, *consequently*, *therefore*), arg-dev:DETAIL (e.g. *as well as*, *in this case*, *in addition*, *such as*), arg-dev:REFORMULATION (e.g. *in other words*, *that is*).

For each discourse cue tagged in the text, we replace the cue with its tag and measure the number of chains that (1) start after it, (2) end before it, and (3) continue over it (chains having nodes before and after the tag). We create such features for the tags in the original form (e.g. *arg-dev:DETAIL*), as well as for the primary component alone (e.g. *arg-dev*) and the secondary component alone (e.g. *DETAIL*). This alleviates the data sparseness that we see with certain tags, and results in a total of 138 tags for the LEX-2 feature set.

[1]This number was chosen after inspecting chains in a separate development data set.

3 Data

We use essays from different essay-writing tasks, representing different genres, writing proficiency and populations. Specifically, our essays consist of the following six subsets:

1. *PE-G-N*: **P**ersuasive/**E**xpository essays written by **g**raduate school applicants who are a mix of **n**ative and non-native speakers. (e.g. "As people rely more and more on technology to solve problems, the ability of humans to think for themselves will surely deteriorate. Discuss the extent to which you agree or disagree ... ") [n= 145 essays]

2. *AC-G-N*: **A**rgumentation **c**ritique essays written by **g**raduate school applicants who are a mix of **n**ative and non-native speakers. ("Examine the stated and/or unstated assumptions of the argument. Be sure to explain how the argument depends on the assumptions and what the implications are if the assumptions prove unwarranted ...") [n= 138 essays]

3. *PE-UG-NN*: **P**ersuasive/**E**xpository essays written by **u**ndergraduate and **g**raduate school applicants, who are **n**on-**n**ative speakers. [n= 146 essays]

4. *CS-UG-NN*: **C**ontrastive **s**ummary essays written by **u**ndergraduate and **g**raduate school applicants who are **n**on-**n**ative speakers. Here, the prompt focuses on a specific type of summarization, where ideas from an audio lecture are to be contrasted with ideas from a written passage. [n= 147 essays]

5. *S-G-N*: **S**ubject matter essays written by **g**raduates in a professional licensure exam who are a mix of **n**ative and non-native speakers. [n= 150 essays]

6. *M-K12-N*: A **M**ix of expository, persuasive, descriptive and narrative essays written by **K**-**12** school students who are a mix of **n**ative and non-native speakers. [n= 150 essays]

Of the total of 876 essays, 40 essays were used for system development, and the rest were used for cross-validation experiments. Each essay in the data set was manually annotated for overall discourse coherence quality by annotators not involved in this research. The discourse coherence score was assigned using a 4-point scale (with score point 4 for excellent discourse coherence). Twenty percent of the essays were double annotated and the rest were annotated by one of the annotators. Inter-annotator agreement over the doubly annotated essays, calculated using quadratic weighted kappa (QWK), was 0.61 (substantial agreement). The data distribution for each score point was: 1% for score 1, 9% for score 2, 27% for score 3, 63% for score 4.

4 Experiments

4.1 Baseline Features

A review by Burstein et al. (2013a) describes the several systems that measure discourse coherence quality across various text genres including test-taker essays. Features used to evaluate the discourse coherence quality systems in this study include those previously discussed in Burstein et al. (described below). In addition to comparing our features with previously explored features, our goal is to see if the state-of-the-art feature set can be extended with the use of lexical chaining features.

Entity-grid transition probabilities (entity). Entity-grid transition probabilities (Barzilay and Lapata, 2008) are intended to address unity, progression and coherence by tracking nouns and pronouns in text. An entity grid is constructed in which all entities (nouns and pronouns) are represented by their syntactic roles in a sentence (i.e., Subject, Object, Other). Entity grid transitions track how the same word appears in a syntactic role across adjacent sentences.

Type/Token Ratios for Entities (type/token). These are modified entity-grid transition probabilities. While the entity grid only captures, for example "Subject-Subject" transitions, type/token ratios capture the proportion of unique words that make such transitions. Higher ratios indicate that more concepts are being introduced in a given syntactic role, and lower ratios indicate fewer concepts.

RST-derived features (RST). Rhetorical relations (Mann and Thompson, 1988) derived from an RST parser (Marcu, 2000) are used to evaluate if and how certain rhetorical relations, combinations of rhetorical relations, or rhetorical relation tree structures contribute to discourse coherence quality. These include: (a) relative frequencies of n-gram rhetorical relations in the context of the RST parse tree structure (*unigrams*, or occurrences of a single relation (e.g., ThemeShift); *bigrams*, (e.g., "ThemeShift -> Elaboration"); and *trigrams*, (e.g., "ThemeShift -> Elaboration -> Circumstance")); (b) relative proportions of leaf-parent relation types in the tree structure; and (c) counts of root node relation types in the trees.

Maximum LSA Value for Distant Sentence Pairs (maxLSA). This feature set is the maximum Latent Semantic Analysis (LSA) similarity score found between pairs of sentences that are separated by at least 5 intervening sentences in the essay. It captures reintroduction of topics later in an essay, consistent with a backward inference strategy (Van den Broek et al., 1993; Van den Broek, 2012). LSA has also been employed to measure semantic relatedness between texts for discourse coherence (Foltz et al., 1998).

Grammatical error features (gramErr). These features address errors in grammar that could interfere with a reader's ability to construct meaning and have been used in previous studies (e.g. (Attali and Burstein, 2006; Burstein et al., 2013b)). Specifically, they are based on more than 30 kinds of errors in grammar, such as subject-verb agreement errors, in word usage, such as missing article errors, and in spelling. We use e-rater®, an essay scoring engine developed by Educational Testing Service (ETS), to detect the grammar errors. Aggregate counts of these errors are used as features for predicting discourse coherence.

Program Features (program). This is a single feature for identifying the data type listed in Section 3. Genre and population play an important role with respect to discourse coherence – essays written by more advanced writers, such as those at the graduate level, are typically more coherent than essays written by populations where English is a second language, or by K-12 school students. Note that the program feature is not linguistically motivated – it does not capture the writing construct or a writing skill. However, it is a strong feature as it can reliably bias the system to change its expectations about the discourse quality based on population and task.

4.2 Principal Components Analysis

To reduce the number of lexical chain features, a Principal Components Analysis (PCA) was calculated on an independent set of 6000 essays randomly sampled from the six task types. For 38 LEX-1 features, a 4-component solution accounted for about 0.70 of the feature variance. An 8-component solution explained about 0.30 of the feature variance for the 138 LEX-2 features. (While the variance was lower for this PCA solution, the components were fairly clean.) The component scores were then computed for the 876 essays in our annotated data set. The 4-component scores were used as LEX-1 features, and the 8-component scores were used as LEX-2 features. PCA was used for lexical chaining features in order to reduce the number of features used to build the models rather than using a much larger number of correlated features. PCA was not applied to features from previous work, as we wanted to reproduce their performance.

4.3 Results

A 10-fold cross-validation was run with an unscaled, gradient boosting regressor[2] tuned using quadratic weighted kappa[3]. Specifically, we used the standard Gradient Boosting Regressor in the scikit-learn toolkit[4] (Pedregosa et al., 2011). The learner was trained to assign 4-point coherence quality scores using different combinations of the feature sets described in sections 2.1 and 4.1. In addition to each of the individual features in Section 4.1, we tested two baseline feature combinations: *Baseline-1*, a system using all discourse-based features from Section 4.1, and *Baseline-2*, a system using all features described in Section 4.1.

[2]We experimented with SVMs and Random Forest learners too, but the best results were obtained with the regressor.

[3]The software for the regressor can be found at https://github.com/EducationalTestingService/skll/

[4]http://scikit-learn.org/stable/modules/generated/sklearn.ensemble

Performance was calculated using Quadratic Weighted Kappa (QWK) (Cohen, 1968), which measures the agreement between the system score and the human-annotated coherence score. QWK corrects for chance agreement, and it penalizes large disagreements more than small disagreements. The formula for QWK is as follows:

$$\kappa = 1 - \frac{\sum_{i=1}^{k}\sum_{j=1}^{k} w_{ij}o_{ij}}{\sum_{i=1}^{k}\sum_{j=1}^{k} w_{ij}e_{ij}}$$

where k is the total number of categories (4 in our case), o_{ij} is the observed value in cell i, j of the confusion matrix between system predictions and human scores, e_{ij} is the expected value for cell i, j, and w_{ij} is the weight given to the discrepancy between $category_i$ and $category_j$. The expected value e_{ij} is calculated as:

$$e_{ij} = \frac{\sum_{j=1}^{k} o_{ij} \sum_{i=1}^{k} o_{ij}}{\sum_{i=1}^{k}\sum_{j=1}^{k} o_{ij}}$$

For quadratic weighted kappa, w_{ij} is calculated as:

$$w_{ij} = 1 - \frac{(i-j)^2}{(k-1)^2}$$

where i and j are categories, and k is the total number of categories. We use QWK as it is the standard evaluation metric used in automated essay scoring, and it also helps us to compare our results with previous work.

Table 1 reports the results for our proposed features and for each individual feature set investigated in previous work. Here, feature sets explicitly targeting discourse phenomena are grouped under *Discourse-based Features*. The features grouped under *Non-Discourse Features* also capture coherence quality; however they are based on grammatical errors or data type information. The best performing system in each group is shown in **bold**. We see that the full set of lexical chaining features (LEX-1 + LEX-2) is the best performing discourse-based feature set. It performs better than each of the other discourse-based features used alone, and also better than Baseline-1, which uses a combination of *all* discourse-based features from previous work. Notice that the performance of each discourse-based system is below the performance of both *gramErr* and *program*, indicating that they can play an important role in predicting text coherence.

While grammar (*gramErr*) and data type (*program*) are powerful features, it is also important to incorporate capabilities for detecting and evaluating discourse-specific phenomena to ensure construct relevance, as the grading guidelines for essays specify the need for proper organization of ideas (e.g."sustains a well-focused, well-organized analysis, connecting ideas logically"). Lack of construct relevance has been a major criticism of automated scoring methods (Deane, 2013; Shermis and Burstein, 2013). Additionally, discourse-relevant features will allow for interpretable, useful, explicit feedback to students regarding discourse coherence and its breakdown.

In Table 1 we also see that no individual discourse-based system outperforms Baseline-2, comprising all features from the state-of-the-art (Section 4.1). In fact, the human-system agreement obtained by Baseline-2 surpasses the human-human agreement (QWK of 0.61) reported in Section 3. This phenomenon is not uncommon in essay scoring. For example, Bridgeman et al. (2012) performed detailed analyses and found that across all test populations, human-automated system score correlations surpassed human-human score correlations.

Because the *gramErr* and *program* features contain information that is complementary to discourse-based features, we combined the discourse features, first with gramErr features, and then with gramErr+program features. Table 2 reports the results from these experiments. The best performing system for each column is in **bold**, and all features with QWK higher than Baseline-2 are in *italics*. Here,

Feature set	QWK
Discourse-based features	
LEX-1+ LEX-2	**0.316**
LEX-1	0.176
LEX-2	0.246
entity	0.249
type/token	0.178
RST	0.295
maxLSA	0.171
Baseline-1	0.302
Non-Discourse Features	
gramErr	**0.592**
program	0.387
Baseline-2	0.631

Table 1: Performance of individual feature sets.

Feature set	+gramErr	+gramErr +program
LEX-1+ LEX-2	0.608	*0.646*
LEX-1	0.611	*0.650*
LEX-2	0.577	***0.654***
entity	**0.621**	0.609
type/token	0.600	0.623
RST	0.612	*0.649*
maxLSA	0.592	*0.650*
gramErr+program	*0.644*	

Table 2: Performance (QWK), of individual discourse-based features when *gramErr* is added (column 2) and *gramErr* and *program* are added (column 3)

we see that, when combined with *gramErr+program*, the full set of lexical chaining features (LEX-1+LEX-2), as well as LEX-1 and LEX-2 individually, perform above Baseline-2. Surprisingly, we find that when some individual discourse features from previous work are combined with *gramErr+program*, they achieve better performance than Baseline-2 indicating that using the full combination of discourse features may not result in the best system. In the last row, we see that the combination of gramErr and program features alone (*gramErr+program*) is more competitive that Baseline-2, underscoring their usefulness for detecting coherence quality.

Finally, we performed full ablation studies to see which feature set combination produces the best system for identifying discourse coherence quality. Different combinations of the 8 feature sets resulted in 255 different systems, which we ranked based on their performance. Table 3 lists some of the systems, with their respective ranks and QWK values.

First, we observe that the best performing system contains the full set of lexical chaining features and achieves a QWK of 0.673. In fact, all of the top-5 performing systems contain either *LEX-1* or *LEX-2*. The best performance produced by a system not containing any lexical chaining features ranks eighth (*gramErr+ maxLSA+ program+ RST*). Notice that *gramErr+program* is at rank 31, Baseline-2 is at rank 61, and Baseline-1 is at rank 235. Interestingly, RST features are also seen in all of the top-5 systems, indicating that RST features and lexical chaining features capture complementary information about discourse quality. Surprisingly, maxLSA features, which have the same underlying principle of cohesion in text as lexical chains, are in some of the top-performing feature combinations (at ranks 4 and 5), indicating that, in addition to how ideas and themes are presented throughout the essay, the re-introduction of topics is also important.

We tested the statistical significance of the performance differences between our best system (*gramErr + LEX-2+ LEX-1+ maxLSA+ program+ RST*, at rank 1 in Table 3) and three other systems (Baseline-1, Baseline-2 and *gramErr+program*) by drawing 10,000 bootstrap samples (Berg-Kirkpatrick et al., 2012) from our manually scored essays. For each sample, QWKs were calcuated between the human scores and the predictions of our best system, and between the human scores and each of the other three systems' predictions. For each sample, the differences in QWKs were recorded, and the distributions of differences were used for significance testing. Results show that our best performing system is significantly better than Baseline-1 ($p < 0.001$) and Baseline-2 ($p < 0.01$), and it marginally outperformed the system with *gramErr+program* features ($p < 0.06$).

These results show that lexical chaining information is a reliable indicator of discourse quality, and that it can be combined synergistically with other complementary features to extend the state-of-the-art for measuring discourse coherence quality.

Feature set	QWK	Rank
gramErr + LEX-2+ LEX-1+ maxLSA+ program+ RST	**0.673**	1
gramErr+ LEX-1+ program+ RST	0.661	2
gramErr+ LEX-2+ program+ RST	0.661	3
gramErr+ LEX-2+ maxLSA+ program+ RST	0.660	4
gramErr+ LEX-1+ maxLSA+ program+ RST	0.659	5
gramErr+ maxLSA+ program+ RST	0.656	8
gramErr+ program	0.644	31
Baseline-2: entity+ gramErr+ RST+ maxLSA+ program+ type/token	0.631	61
Baseline-1: entity+ RST+ maxLSA+ type/token	0.302	235

Table 3: Performance (QWK), and ranks of systems using different feature combinations

4.4 Analysis by Data Type

In the previous section we saw that features based on lexical chaining are able to successfully encode and predict the quality of discourse coherence. We now examine if this impact is uniform across all essay genres and populations of writers. Table 4 shows the performance of *gramErr +program* (in column 2), the best performing features and their respective performance (**Best system**, columns 3 and 4), and the best feature set when lexical chaining features are removed, with their respective performance (**Best Minus LEX-1 and LEX-2**, columns 5 and 6). Here we use *gramErr +program* as an additional baseline, as it was found to be more competitive than both Baseline-1 and Baseline-2.

Program	gramErr +prog	Best system		Best Minus LEX-1 and LEX-2	
		Features	QWK	Features	QWK
CS-UG-NN	0.418	gramErr+ maxLSA+ RST	**0.523**	gramErr+ maxLSA+ RST	**0.523**
PE-UG-NN	0.406	gramErr + LEX-2 + maxLSA + RST	**0.468**	gramErr	0.406
PE-G-N	0.614	gramErr + LEX-1 + maxLSA	**0.676**	gramErr + maxLSA	0.650
AC-G-N	0.744	gramErr + LEX-2 + maxLSA	**0.839**	gramErr + maxLSA + type/token	0.766
S-G-N	0.414	entity + gramErr+ LEX-1+ RST+ type/token	**0.532**	gramErr+ RST+ type/token	0.487
M-K12-N	0.635	gramErr + LEX-2 + maxLSA	**0.656**	gramErr + maxLSA + RST + type/token	0.649

Table 4: Performance of feature sets by data type. Best performance is shown in **bold**.

In general, for all data types, addition of discourse features produces improvement over just using a combination of *gramErr* and *program* features. Also, the addition of lexical chaining features produces performance improvement for most data types. Specifically, there is substantial improvement in performance for persuasive writing (PE-UG-NN and PE-G-N), expository subject writing (S-G-N) and writing involving critical argumentation (AC-G-N). M-K12-N, which is composed of a mix of genres and writing proficiency, shows a minor improvement. Interestingly, for contrastive summarization (CS-UG-NN), the best system for predicting discourse coherence does not employ any lexical chaining features. For this type of writing, the best feature set using lexical chaining features achieved a QWK of 0.465, which improves over *gramErr+program* but is lower than the best performing feature set. This is perhaps because the discourse phenomena targeted by our lexical chaining features (topical detailing, variety and organization) are already provided for the writer in the source document and the audio lecture, i.e., the materials that are to be referred to in writing this type of essay. Thus, other features play a more prominent role, such as the RST features that capture local discourse organization which is needed, for example, when drawing a contrast between two sources of conflicting information.

5 Related Work

5.1 Discourse coherence quality

A number of models for measuring the quality of discourse coherence have been based on Centering Theory (Grosz et al., 1995). For example, Barzilay and Lapata (2008) construct entity grids based on syntactic subjects and objects. Their algorithm keeps track of the distribution of entity transitions between adjacent sentences and computes a value for all transition types based on their proportion of occurrence in a text. The algorithm has been evaluated with three tasks using well-formed newspaper corpora: text ordering, summary coherence evaluation, and readability assessment. Along similar lines, Rus and Niraula (2012) find centered paragraphs based on prominent syntactic roles. Similarly, Miltsakaki and Kukich (2000) use manually marked centering information and find that higher numbers of Rough Shifts within paragraphs are indicative of a lack of coherence. Using well-formed texts, Pitler and Nenkova (2008) show that a text coherence detection system yields the best performance when it includes features using the Barzilay and Lapata (2008) entity grids, syntactic features, discourse relations from the Penn Discourse Treebank (Prasad et al., 2008), and vocabulary and length features. Wang, Harrington, and White (2012) combine the approaches from Barzilay and Lapata (2008), and Miltsakaki and Kukich (2000) to detect coherence breakdown points. The biggest difference between our approach and the approaches based on Centering Theory is that we do not use syntactically prominent items or try to establish a center. Instead, multiple concurrent thematic chains can "flow" through the paragraph, and their length, density, and interaction with discourse markers are used to model coherence.

In other related work, Lin et al. (2011) use discourse relations from Discourse Lexicalized Tree Adjoining Grammar (D-LTAG) and compile sub-sequences of discourse role transitions to see how the discourse role of a term varies through the progression of the text. Our work, in contrast, traces how chains or thematic threads are organized with respect to the discourse. Our approach also differs from models that measure local coherence between adjacent sentences (Foltz et al., 1998), in that lexical chains can run though the length of the entire text, and hence the features derived from them are able to capture aggregate thematic properties of the entire text such as number, distribution and elaboration of topics.

Discourse coherence models have been previously employed for the task of information-ordering in well-formed texts (e.g., (Soricut and Marcu, 2006; Elsner et al., 2007; Elsner and Charniak, 2008)). In our tasks, discourse coherence quality is influenced by many factors including, but not limited to, ordering of information, such as text unity, detailing and organization.

Higgins et al. (2004) implemented a genre-dependent system to predict discourse coherence quality in essays. Their approach, however, was reliant on organizational structures particular to expository and persuasive essays, such as thesis statement and conclusion.

5.2 Lexical Chaining and Cohesion

Lexical chaining has been used in a number of applications such as news segmentation (Stokes, 2003), question-answering (Moldovan and Novischi, 2002), summarization (Barzilay and Elhadad, 1997), detection and correction of malapropisms (Hirst and St-Onge, 1995), topic detection (Hatch et al., 2000), topic tracking (Carthy and Sherwood-Smith, 2002), and keyword extraction (Ercan and Cicekli, 2007).

In a closely related study, Feng et al. (2009) use lexical chains to measure readability. Lexical chain features are employed to indicate the number of entities/concepts that a reader must keep in mind while reading a document, and two of their features (number of chains in the document and average length of chains) overlap with our LEX-1 features. Our work also differs from systems using cohesion to measure writing quality (e.g., (Witte and Faigley, 1981; Flor et al., 2013)), in that we focus on predicting the quality of discourse coherence.

6 Conclusion

In this paper, we investigated the use of lexical chaining for measuring discourse coherence quality. Based on intuitions about what makes a text coherent, we extracted two sets of features from lexical chains, one encoding how topical themes and cohesive elements are addressed in the text, and another

encoding how the topical themes interact with explicit discourse organizational cues. We performed detailed experiments which showed that lexical chaining features are useful for predicting discourse coherence quality. Specifically, when compared to other previously explored discourse-based features, we found that our lexical chaining features are best performers when used alone. We then experimented with various feature combinations and showed that top performing systems contain lexical chaining features. Our analyses also indicated that lexical chaining features can improve performance on various genres of writing by different populations of writers. Our future work on measuring discourse coherence quality involves extending chains by using verb information and by exploring finer distinctions within the chains themselves (e.g., topical and sub-topical chains).

Improving Cloze Test Performance of Language Learners Using Web N-Grams

Martin Potthast Matthias Hagen Anna Beyer Benno Stein
Bauhaus-Universität Weimar, Germany
<first name>.<last name>@uni-weimar.de

Abstract

We study the effectiveness of search engines for common usage, a new category of search engines that exploit n-gram frequencies on the web to measure the commonness of a formulation, and that allow their users to submit wildcard queries about formulation uncertainties often encountered in the process of writing. These search engines help to resolve questions on common prepositions following verbs, common synonyms in given contexts, and word order difficulties, to name only a few. Until now, however, it has never been shown that search engines for common usage have a positive impact on writing performance.

Our contribution is a large-scale user study with 121 participants using the Netspeak search engine to shed light on this issue for the first time. Via carefully designed cloze tests we show that second language learners who have access to a search engine for common usage significantly and effectively improve their test performance as opposed to not using them.

1 Introduction

When writing texts in a second language, uncertainties on specific formulations regularly come up. Even experienced second language writers may sometimes be in doubt about the preposition following a verb or what word order to choose. In this paper, we study search engines for common usage (usage search engines, for short) that aim at assisting second language writers to cope with their uncertainties. These search engines allow for phrasal queries that include wildcards at positions where a user is not sure what to write. The search results typically consist of a list of phrases matching the query's expression—the wildcards filled with formulations. The returned phrases are ranked by their commonness of being used in everyday writing, where a phrase's commonness is estimated by its occurrence frequency in a collection of web n-grams. The occurrence frequencies are usually not hidden from the user but displayed alongside each phrase, either implicitly or explicitly. This way, the users of usage search engines have a way of judging whether a phrase is commonly used by others. Figure 1 (left) shows an example search result.

Target audience of usage search engines is language learners who have mastered basic vocabulary and grammar but whose language proficiency in terms of their feeling for language usage is still worse than that of a native speaker. Until recently, there has been hardly any technological support for them, so they could only resort to studying abstract style guides, consuming foreign language media, and language study travels in order to improve their usage skills. Today, three public usage search engines are available. The first one, called Netspeak (Stein et al., 2010), is developed at our group since 2008. It was followed by PhraseUp and Linggle (Boisson et al., 2013), which have been released in 2011 and 2013.[1] Moreover, there is Google's N-Gram Viewer prototype (Michel et al., 2011), which has a different purpose and target audience but visualizes n-gram usage over time.

All of these search engines provide a way to quantify the commonness of a phrase and thus have the potential to become important tools for second language learners. That is, if they work as advertised. Until now, it has not at all been clear whether writers can actually benefit from the information distilled from analyzing n-gram occurrence frequencies, or whether they are easily misled, for example, by noisy

[1] Netspeak is freely available at www.netspeak.org, PhraseUp at www.phraseup.com, and Linggle at www.linggle.com.

Proceedings of COLING 2014, the 25th International Conference on Computational Linguistics: Technical Papers, pages 962–973, Dublin, Ireland, August 23-29 2014.

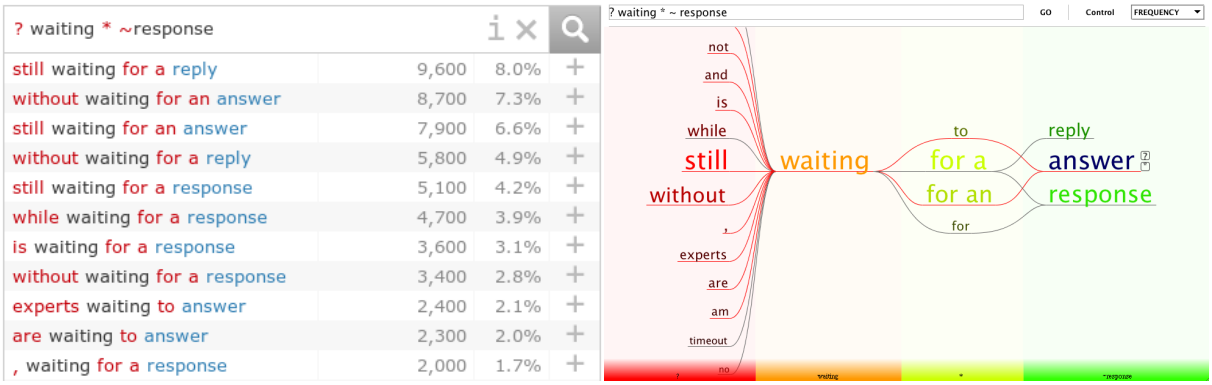

Figure 1: Netspeak's two alternative interfaces: search results can either be displayed as textual ranked list of phrases alongside frequencies (left), or as WordGraph visualization (right) (Riehmann et al., 2011), where the frequencies determine various aspects of the visualization. The WordGraph is particularly suited to handling multiple wildcards per query. The participants of our user study used primarily the textual interface, since they did not require more than one or two wildcards for solving the cloze tests.

data. Our contribution is to shed light on this issue for the first time and to conduct a large-scale user study with 121 language learners aged 14–18, measuring their performance when using our Netspeak search engine to solve cloze tests. The study ascertains the positive impact of Netspeak and by extension, usage search engines in general; moreover, it shows the low barrier to entry of Netspeak's user interface.

The paper is organized as follows: after a detailed discussion of related work in Section 2, Netspeak's retrieval engine is formally described in Section 3 as background for the design of our user study and as an example of how such search engines work internally. Section 4 reports on our user study and provides a statistical analysis of our findings. The paper closes with a conclusion and an outlook into future work.

2 Related Work

Carrying out research and development on usage search engines is an interdisciplinary effort that requires expertise from information retrieval, information visualization and interface design, as well as domain knowledge from computer linguistics. Therefore, we divide our review of related work into four parts: (1) existing search engines and web services, (2) retrieval engines and wildcard search from the perspective of information retrieval, (3) search result visualization, and, (4) writing support systems dedicated to second language writers.

2.1 Public Search Engines and Web Services

There are currently three public search engines and one public prototype that fall into the category of search engines for common usage, namely Netspeak (Stein et al., 2010), PhraseUp, Linggle (Boisson et al., 2013), and the Google N-Gram Viewer (Michel et al., 2011). All of them index large n-gram corpora, and their search interfaces are primarily dedicated to returning results that allow their users to judge the commonness of a phrase compared to alternative phrases. We distinguish the former three search engines from the latter mainly by its target audience. While the former target average web users, the latter targets professional linguists and humanities researchers. To the best of our knowledge, our paper is the first to investigate the effectiveness of such search engines for the use case of assisting writers, thereby underpinning these efforts.

Moreover, a number of other linguistic search engines are available, such as WebCorp Live (Kehoe and Renouf, 2002), WebAsCorpus (Fletcher, 2007), and the Linguist's Search Engine (Resnik and Elkiss, 2005). These search engines cannot be readily used for usage search as defined above, since they work more like concordancers in that they only retrieve usage examples and present them in context, disregarding usage commonness. Again, their target audience is professional linguists rather than laymen users, let alone second language learners. While they may still be applied in the context of language learning, the search interfaces of these search engines are not sufficiently tailored to this domain.

Another category of related web services that are readily available to second language learners include style and grammar checkers, such as Grammarly, PaperRater, SlickWrite, AfterTheDeadline (Mudge, 2010), the Hemingway App, GrammarBase, etc. From what can be said by analyzing their features, all of these services are based on a collection of basic style and grammar rules that can be checked automatically with some degree of confidence in their recommendations. However, none of the services we found make any recommendations with regard to usage commonness, i.e., they do not identify uncommon formulations or make recommendations for more common ones.

2.2 Information Retrieval Models and Indexes for Wildcard Search

The retrieval models employed by usage search engines are hardly ever discussed in the literature cited above. One of the few exceptions is Netspeak (Stein et al., 2010), where the retrieval model has been a contribution in itself since it is tailored specifically to its application domain. For the lack of discussion of the finer details of how the above search engines work, it can be assumed that they do not employ a specifically tailored retrieval approach. Nevertheless, when reviewing the information retrieval literature for retrieval models that support linguistic queries or wildcard queries, a number of sources can be found.

Cafarella et al. (2005, 2007) study indexing methods that are particularly suited to support queries comprising parts-of-speech as wildcards. They introduce so-called neighborhood indexes whose disk accesses required to answer a query are on the order of the number of non-wildcard terms in a query. Rafiei and Li (2009) develop a wildcard search engine that supports linguistically rich wildcards in order to support information extraction from the web, which employs a preprocessor for queries, and a postprocessor for search results on top of a traditional web search engine. The approach does not create a tailored index but translates the wildcard queries into flat queries that can be answered by traditional search engines. Sekine (2008) explores the trie data structure as an alternative to inverted indexes when indexing large-scale n-gram corpora. The approach is limited to short n-grams ($n < 10$) to be feasible, which can be a strong point in terms of retrieval speed. Netspeak's retrieval engine is also intentionally restricted to small values of n, but uses minimal perfect hash functions instead of tries to maximize retrieval performance.

While all of the aforementioned approaches support shallow linguistic wildcards, or only basic wildcards, Tsang and Chawla (2011) propose a method to support regular expressions. Doing so involves various trade-offs between retrieval performance and index size. Further, a search engine like this may be only useful to experts, but not second language learners. Again, all of the aforementioned contributions target either professional linguists or they are meant to facilitate automatic usage, instead of supporting average writers.

2.3 Visualization of Usage Search Results

An important part of every search engine is its user interface. Since usage search engines are still in their infancy, their user interfaces have not been studied in-depth, so far. As a first attempt to close this gap, we developed and analyzed two alternative user interfaces for Netspeak in a previous work, one textual interface and one using a tailored visualization that was specifically developed for usage search engines, the so-called WordGraph (Riehmann et al., 2011). Figure 1 shows them side-by-side. The textual interface displays search results in the form of a tabular list, where each row lists an n-gram matching the wildcard query alongside its absolute and relative occurrence frequency. If a query comprises more than one wildcard, situations arise where this linear ranking of n-grams is insufficient to grasp the true distribution of formulations that may be used instead of the wildcards. The WordGraph therefore visualizes the search results as a horizontal graph, so that the i-th word of an n-gram is displayed as a node on the i-th level of the graph. Paths from left to right through the graph correspond to n-grams found in the result set returned by Netspeak. A user study that investigated the fitness of the WordGraph to serve as a user interface for specific search tasks found that study participants prefer the WordGraph over the textual user interface when the number of wildcards increases (Riehmann et al., 2012). The user study we report on in this paper is based solely on the textual user interface, since most of our cloze tests can be solved by using one wildcard.

2.4 Writing Support for Second Language Learners

"*For writers of English as a Second Language (ESL), useful editorial assistance geared to their needs is surprisingly hard to come by*," and "[...] *there has been remarkably little progress in this area over the last decade*," observe Brockett et al. (2006) about the state of the art. This is despite the fact that English is the second language of most people who speak English today.[2] A recent overview of technology to detect grammatical errors of language learners is given by Leacock et al. (2010), whereas computer feedback for second language learners is mostly studied within pedagogical research under the label of computer-aided language learning (CALL). There, classroom systems are being deployed on a small scale to measure their effects on student learning performance. The development of usage search engines in general, our Netspeak engine in particular, and the user study contributed in this paper may be considered first steps toward the development of new, better technologies that specifically target the needs of second language learners and writers.

3 Netspeak: A Search Engine for Common Usage Based on Web N-Grams

As a background for our user study and as an example of how usage search engines work internally, this section briefly describes Netspeak and its retrieval engine.[3] The main building block of Netspeak is a query processor tailored to the following task: given a wildcard query q and a set D of n-grams, retrieve those n-grams $D_q \subseteq D$ that match the pattern defined by q. To solve this task, we have developed an index-based wildcard query processor addressing the three steps indexing, retrieval, and filtering, as illustrated in Figure 2 (middle).

3.1 Query Language

Netspeak utilizes a query language defined by the EBNF grammar shown in Figure 2 (left). A query is a sequence of literal words and wildcard operators, wherein the literal words must occur in the expression sought after, while the wildcard operators allow to specify uncertainties. Currently five operators are supported:

- the question mark (`?`), which matches exactly one word;
- the asterisk (`*`), which matches any sequence of words;
- the tilde sign in front of a word (∼`<word>`), which matches any of the word's synonyms;
- the multiset operator (`{<words>}`), which matches any ordering of the enumerated words; and,
- the optionset operator (`[<words>]`), which matches any one word from a list of options.

The textual interface displays the search results for the given query as a ranked list of phrases, ordered by decreasing absolute and relative occurrence frequencies. This way, the user can find confidence in choosing a particular phrase by judging both its absolute and relative frequencies. For example, a phrase may have a low relative frequency but a high absolute frequency, or vice versa, which in both cases indicates that the phrase is not the worst of all choices. Furthermore, the textual web interface offers example sentences for each phrase, which are retrieved on demand when clicking on a plus sign next to a phrase. This allows users who are still in doubt to get an idea of the larger context of a phrase.

3.2 Retrieval Engine

The indexing step is done offline. Let V denote the set of all words found in the n-grams D, and let $D^\wedge$ denote the set of integer references to the storage positions of the n-grams in D on hard disk. During indexing, an inverted index $\mu : V \rightarrow \mathcal{P}(D^\wedge)$ is built that maps each word $w \in V$ to a sorted list $\mu(w) \subseteq D^\wedge$, where $\mu(w)$ is comprised of exactly all references to the n-grams in D that contain w.

[2] `http://en.wikipedia.org/wiki/English_language#Geographical_distribution`

[3] Extended versions of this section can be found in previous publications on Netspeak's WordGraph visualization (Riehmann et al., 2011; Riehmann et al., 2012).

EBNF grammar of Netspeak's query language

query	=	{ word | wildcard }$_1^5$
word	=	([apostrophe] (letter { alpha })) | ","
letter	=	"a" | ... | "z" | "A" | ... | "Z"
alpha	=	letter | "0" | ... | "9"
apostrophe	=	"'"
wildcard	=	"?" | "*" | synonyms | multiset | optionset
synonyms	=	"~" word
multiset	=	"{" word { word } "}"
optionset	=	"[" word { word } "]"

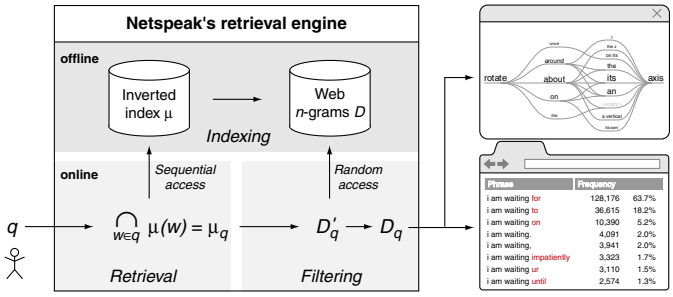

Figure 2: Netspeak at a glance (Riehmann et al., 2012): the left table shows Netspeak's query language as an EBNF grammar, the middle figure overviews its retrieval engine, and the right figure shows an example of search results as shown to its users. Given a query q, the intersection of relevant postlists yields a tentative postlist μ_q, which then is filtered and presented as a ranked list. The index μ exploits essential characteristics that are known a-priori about possible queries and the n-gram set D.

The list $\mu(w)$ is referred to as posting list or postlist. Since D is invariant, μ can be implemented as an external hash table with $O(1)$-access to $\mu(w)$. For μ being space-optimal, a minimal perfect hash function based on the CHD algorithm is employed (Belazzougui et al., 2009).

The two online steps, retrieval and filtering, are taken successively when answering a query q. Within the retrieval step, a tentative postlist $\mu_q = \bigcap_{w \in q} \mu(w)$ is constructed; μ_q is the complete set of references to n-grams in D that contain all words in q. The computation of μ_q is done in increasing order of postlist length, whereas each $\mu(w)$ is read sequentially from hard disk. Within the filtering step, a pattern matcher is compiled from q, and D_q is constructed as the set of those n-grams referenced in μ_q that are accepted by the pattern matcher. Constructing D_q requires random hard disk access. Basically, this approach corresponds to how web search engines retrieve documents for a given keyword query before ranking them. In what follows, we briefly outline how the search in D is significantly narrowed down.

With an inverted index that also stores specific n-gram information along with the keywords, the filtering of μ_q can be avoided. In this regard, we distinguish the queries that can be formulated with Netspeak's query language into two classes: fixed-length queries and variable-length queries. A fixed-length query contains only wildcard operators that represent an a-priori known number of words, while a variable-length query contains at least one wildcard operator that expands to a variable number of words. For example, the query `fine ? me` is a fixed-length query since only 3-grams in D match this pattern, while the query `fine * me` is a variable-length query since n-grams of length $2, 3, 4, \ldots$ match. Obviously, fixed-length queries can be answered with less filtering effort than variable-length queries: simply checking an n-gram's length suffices to discard many non-matching queries. The query processor first reformulates a variable-length query into a set of fixed-length queries, which then are processed in parallel, merging the results.

Moreover, the retrieval engine employs pruning strategies so that only relevant parts of a postlist are read during retrieval, presuming sorted postlists. Head pruning means to start reading a postlist at some entry within, without compromising recall. Given a query q, let τ denote an upper bound for the frequencies of the n-grams in q's result set D_q, i.e., $d \in D_q$ implies $f(d) \leq \tau$. Obviously, in all postlists that are involved within the construction of D_q, all entries whose n-gram frequencies are above τ can safely be skipped, whereas τ is determined in a preprocessing step as the lowest occurrence frequency of a sub-sequence of q that does not include wildcards. Up to this point, the retrieval of n-grams matching a query q is exact—but, not all n-grams that match a query are of equal importance. We consider this fact by applying tail pruning for postlists that are too long to be read at once into main memory. As a consequence, less frequent n-grams that might match a given query can be missed.

3.3 The Web n-Gram Collection

To provide relevant suggestions, a wide cross-section of written text on the web is required. Currently, Netspeak indexes the Google n-gram corpus "Web 1T 5-gram Version 1" (Brants and Franz, 2006),

which consists of 42 GB of phrases up to a length of $n = 5$ words along with their occurrence frequencies on the web in 2006. This corpus has been compiled from approximately 1 trillion words extracted from the English portion of the web, totaling more than 3 billion n-grams. Two post-processing steps were applied: case reduction and vocabulary filtering. For the latter, a white list vocabulary V was compiled and only n-grams whose words appear in V were retained. The vocabulary V consists of the words found in the Wiktionary and various other dictionaries, complemented by words from the 1-gram portion of the Google corpus whose occurrence frequency exceeds 10 000. After post-processing, the size of the corpus has been reduced by about 54%.

3.4 Retrieval Performance in Practice and Public Availability

In practice, the described techniques enable Netspeak to provide search results at a speed similar to modern web search engines. Results are usually returned within a couple of milliseconds. Whenever a user stops typing for more than 300 milliseconds, the current input is submitted as an "instant" query without need for a click. That way, the "search experience" with Netspeak is similar to what users expect from web search engines.

Netspeak is freely available online and has about 300 distinct users on a working day who submit about 2500 queries (half the workload on weekends). Most of its users are returning users. From their feedback and from our own experience, we know that Netspeak helps to resolve uncertainties on formulations in the daily process of writing papers, proposals, etc. However, in the following section we attempt to capture Netspeak's effectiveness in a controlled user study.

4 User Study on the Effectiveness of Usage Search Engines

It is generally assumed that usage search engines are useful, say, that they provide valuable feedback that leads to improved writing. To empirically confirm this "usefulness" assumption, we conduct systematic tests with experienced language learners and analyze whether a usage search engine enables them to improve their writing. We choose Netspeak as a representative of usage search engines for our study.

Our study's underlying rationale is to model the use case of usage search engines by solving cloze tests. In a cloze test, a word or a phrase is removed from a sentence and the participant has to replace the missing words. Although we followed standard procedures on constructing cloze tests (Sachs et al., 1997), it should be noted that our usage of cloze tests is not as originally intended (Taylor, 1953). We do not assess a language learner's reading skills, but use the cloze test to model word choice, which resembles the use case of usage search engines very well. For each participant, we provide two different cloze test questionnaires. The first has to be solved without any help, whereas for the second, participants are allowed to use the search engine. Besides evaluating the answers, we also analyze the submitted search queries.

4.1 Experiment 1: General Usage, Average Learners

In the first experiment, we examine whether the search engine in general can support users in resolving uncertainties on formulations modeled by cloze tests. Our hypothesis is that using a usage search engine helps to improve a human's performance in such tests.

Experimental Design To test our hypothesis, we conduct an empirical study with a within-subjects design (Lazar et al., 2010). This means that our participants are exposed to a cloze test without the help of a search engine and then to another cloze test where our chosen usage search engine is allowed.

The to-be-solved cloze tests are carefully constructed under the guidance of a university-level English teacher who is a native English speaker. From several language learner textbooks, we selected questions in order to have an equal mix of two easy, four medium, and three hard questions for two different cloze test questionnaires A and B (see Appendix A and B).

In order to have objectively comparable test cases, the English teacher provided four possible answers for each of the nine questions from test A and B, from which participants had to choose one in each case. This way, the participants do not have to rely on their subjective own vocabulary knowledge.

Table 1: Results of our user study on the impact of usage search engines on language learners.

Experiment	Question difficulty	Questions answered: manually ✓	manually ×	manually –	manually sum	with search engine available, but not used ✓	but not used ×	but not used –	and used ✓	and used ×	and used –	and used sum
Average Learners	easy	17	41	0	**58**	7	2	1	42	6	0	**58**
	medium	61	100	3	**164**	25	16	1	88	34	0	**164**
	hard	37	72	2	**111**	4	22	2	18	62	1	**111**
	all	115	213	5	**333**	36	40	4	149	102	1	**333**
Highly Experienced Learners	easy	11	5	0	**16**	10	1	0	4	1	0	**16**
	medium	27	17	0	**44**	24	2	0	14	3	1	**44**
	hard	18	12	0	**30**	8	8	0	4	10	0	**30**
	all	56	34	0	**90**	42	11	0	22	14	1	**90**
Specific Operators	easy	147	29	1	**177**	28	2	1	135	11	0	**177**

	hard	135	40	2	**177**	31	5	2	130	18	1	**177**
	all	399	126	6	**531**	79	13	4	378	53	4	**531**
		Search engine not used							**Search engine used**			

Experiment	Search engine used vs not used: p-value	effect size	
Average Learners	**0.0000**	0.73	large
Highly Exp. Learners	0.7030	0.12	small
Specific Operators	**0.0000**	0.58	large

In the left table, ✓ denotes correct answers, × denotes wrong answers, and – denotes unanswered questions.

To evaluate the statistical significance and the effect size, we distinguished cloze test answers for the conditions "Search engine not used" and "Search engine used" in the left table.

The brackets below the bottom row of the left table indicate which cases fall under what condition.

The English teacher first chose the questions independent of knowing the indexed n-grams of the search engine. In a "postprocessing" step, the chosen answers for the questions are checked for existence in the n-gram vocabulary of the search engine. This always was the case, although sometimes the queries required to retrieve them were different from the exact context around the cloze test's missing word. This check ensured that there was a chance of answering each individual question in the cloze tests with the search engine.

During the experiment, the use or non-use of the search engine is the independent variable. The dependent variable is the number of correct answers per questionnaire. There also are confounding variables like whether our engine really was used when it was allowed, the time needed to type queries, or the different numbers of answered questions with and without the search engine. We will further elaborate on how we deal with these variables in the following description of the experimental process.

Experimental Process From three different local high schools, 43 German pupils (23 female, 20 male; mean age 16.2, $SD = 1.2$) with five or more years of English courses participated in six groups. None of the participants had any previous experience with any usage search engine.

When a group arrived in our lab, they were randomly assigned to a lab seat; questionnaire A or B were distributed ensuring that neighboring participants had a different question set. This way, the test distribution was random and the participants could not collaborate (which was also ensured by their accompanying "watchdog" teachers). After seven minutes, the first questionnaires were collected and a short five minute introduction to the search engine and its operator set was given. To ensure that the pupils really followed the introduction, we provided the chance of winning small prices based on correctly answering a question on the underlying technique of usage search engines—the index—in an exit questionnaire. After that, each participant had to solve the opposite questionnaire (A when the first was B, and vice versa) but was allowed to use the search engine this time. In pilot studies, we noticed that pupils of that age often need a lot of time for typing their search queries on a standard keyboard. Thus, we allowed 10 minutes for the second questionnaire. This confounding variable of different timing for the questionnaires could not be avoided. Otherwise, most participants would not have had the chance to complete all questions. In order to check whether our participants actually used the search engine, we logged their querying behavior and manually identified the questions which they had answered without using the search engine.

Results and Discussion Since not all participants answered all questions for both cloze tests, we excluded the six participants from the following analyses, who had a difference of more than one between the number of answered questions for either test.

The aggregated numbers on questionnaire performance for the remaining 37 individuals are given in the first block of rows of Table 1 ("Average Learners"). Note that the ratio of correct vs. incorrect answers goes up when the search engine was used: on average, an individual answered two more questions correctly. Especially interesting is that the short five minute introduction was sufficient for that effect

which shows the strength of the textual interface. To statistically estimate the per-individual effect, we compare the ratio of correct answers among all answers when the search engine was used to the ratio when it was not used (note that this includes the questions where the engine was allowed but was not used; i.e., columns "manually" and "but not used" in Table 1). According to the Shapiro-Wilk test (Razali and Wah, 2011), the individual participants' ratios are not normally distributed for either condition (engine used vs. not used) such that we choose a non-parametric significance test (Lazar et al., 2010). For our within-subjects design with ratio data and two to-be-compared samples, the Wilcoxon signed rank test is known as a suitable significance test (Lazar et al., 2010). For the 37 participants' ratios we get a p-value below 0.001 and thus can reject the null hypothesis that the ratios' distributions are equal. Further estimating the effect size for the Wilcoxon signed rank test, we obtain a value of 0.73 which corresponds to a large effect (Cohen, 1988; Fritz et al., 2012). This result supports our prediction that the search engine can help resolve writing uncertainties.

We also studied the query logs of our participants. Per cloze test question, they submitted 4–5 queries with 2–3 terms on average (a wildcard is counted as a term). The last query in each such "search session" for a single question typically was 3–4 terms long. Almost all participants only used the `?`-operator and most participants chose the strategy of querying with context before and after the operator. Having only context before or only after the operator are less successful strategies with higher error ratios.

4.2 Experiment 2: General Usage, Highly Experienced Learners

In our neighborhood, there also is an international high school, where German pupils have all their classes taught in English. Obviously, such pupils have a much higher experience speaking and writing English than our participants from Experiment 1. For a second experiment, we invited pupils from the international school to our lab. Our hypothesis is that the pupils from the international school will have to use the search engine less frequently but still can benefit from it for individual questions.

Experimental Design and Process We used the same questionnaires, time constraints, and logging strategies as in Experiment 1. From the international school, 12 German pupils (7 female, 5 male; mean age 16.5, $SD = 0.7$) participated in two groups. These pupils are taught all their courses in English for five and more years. None of them had any previous experience with usage search engines. The experimental process was as in Experiment 1.

Results and Discussion Again, not all participants answered all questions for both cloze tests; we excluded the two participants from the following analyses, who had a difference of more than one between the number of answered questions for either test.

The aggregated numbers on questionnaire performance for the remaining 10 individuals are given in the second block of rows of Table 1 ("Highly Experienced Learners"). As expected, the highly experienced pupils used the search engine very rarely. This is not too surprising since our questionnaires were designed with an average German pupil in mind; many questions seemed too easy to the internationals which they also indicated in their exit questionnaires. Still, on a per-question basis, for the medium and difficult questions where the pupils used the search engine, they slightly improved their performance. However, the sample and the effect size are too small to draw any reliable conclusions.

The experiment shows that the highly experienced pupils indeed did not use our engine often. However, the predicted benefit for them cannot be confirmed from our small sample. It is thus an interesting open task to conduct a larger study with highly experienced users and more difficult questions.

4.3 Experiment 3: Specific Operators, Average Learners

Our first experiment revealed that most participants used the `?`-operator to solve the tasks. We thus designed a third experiment specifically targeted at the options, synonyms, and word-order operators of our Netspeak search engine. Our hypothesis is that each individual operator helps improve a human's performance in cloze tests targeted at the individual operator.

Experimental Design As in Experiment 1, we asked the university-level English teacher to design two cloze test questionnaires (see Appendix C and D); for each operator with an easy, a medium, and

a hard question. Here, the questions for the option operator are of a similar kind as the questions from Experiment 1. Four alternatives are given, but the participants are asked to use the option operator `[]` and not the `?`-operator. For synonyms, a complete sentence is given and for a specified word, the best among four given potential synonyms is requested. As for the word order operator, a two-word phrase is missing from the sentence and the two different word orders are provided as options. Like in Experiment 1 and 2, the explicit answer options ensure that the test is objective and not subjective. In a second development step, the questions were checked for solvability using the search engine just like in Experiment 1.

Experimental Process From three different local schools, 66 pupils (45 female, 21 male; mean age 15.9, $SD = 1.4$) participated in six groups. None of the pupils participated in Experiment 1 or 2 nor had they any previous experience with usage search engines. These pupils have learned English in their schools for at least five years. The schedule was similar to Experiment 1 with an emphasis on the three tested operators in the introductory explanations on Netspeak. In the questionnaires, the pupils were asked to use only the specific operator for the respective queries. Logging their queries, we are able to exclude solutions obtained by using a not-allowed operator.

Results and Discussion Again, not all participants answered all questions for both cloze tests; we excluded the seven participants from the following analyses, who had a difference of more than one between the number of answered questions for either test.

The aggregated numbers on questionnaire performance for the remaining 59 individuals are given in the third block of rows of Table 1 ("Specific Operators"). Note that the ratio of correct vs. incorrect answers goes up when the search engine was used: one to two more questions correctly answered on average. As in Experiment 1, the short five minute introduction is sufficient for that effect which shows the strength of our interface. To statistically estimate the per-individual effect, we compare the ratio of correct answers among all answers when the search engine was used to the ratio when it was not used (note that this includes the questions where the engine was allowed but was not used; i.e., columns "manually" and "but not used" in Table 1). For the 59 participants' ratios, we get a p-value below 0.001 and thus can reject the null hypothesis that the ratios' distributions are equal. Further, estimating the effect size for the Wilcoxon signed rank test, we obtain a value of 0.58 which corresponds to a large effect (Cohen, 1988; Fritz et al., 2012). Again, the result supports our prediction that usage search engines can help resolve writing uncertainties.

However, a deeper analysis reveals that the large effect is due to the synonym operator. Only for that operator, a statistically significant performance difference and a large effect size can be shown. For the other two operators, the null hypothesis of no performance difference cannot be rejected. This is in line with the exit questionnaire findings, where the pupils reported the synonym operator to be very helpful while the other questions were perceived as rather easy. In the query log analyses, we found that context before and after the wildcard had a similarly positive effect as before and was generally better than adding context only before the wildcard.

5 Conclusion and Future Work

Search engines for common usage have the potential to become an important tool for second language writers and learners. The possibility to check one's language against what is commonly written forms a unique opportunity to improve one's writing on-the-fly. Such information has not been available at scale so far. Our user study shows that usage search engines can indeed help second language writers solve uncertainties about formulations. Modeling writing uncertainties by carefully designed cloze tests, we are able to show a significant improvement when experienced language learners use the search engine.

Highly experienced language learners represented by our study participants from an international school, however, did not use the search engine often enough to draw meaningful conclusions. This can probably be attributed to the fact that the cloze tests were not tailored to their level of language proficiency. Therefore, the question of whether also highly experienced writers and learners, or even native speakers, can benefit from such search engines remains open and is left for future work.

Another missing piece in determining the effectiveness of usage search engines is whether their users

actually learn something while using them, or whether users frequently submit the same or similar queries again and again. Our user study was not designed to answer this question, since our participants were only around for about 30 minutes for organizational reasons. Even measuring effects on short-term memory is rendered infeasible in this time frame. A longitudinal study would be ideal, in this case, but we also see an exciting, data-driven way to approach this. By analyzing the query logs of Netspeak, which is currently being used hundreds of times per day, we can track returning users. We can then study their online search behavior to determine if and how often they return to submit similar queries, which allows us to draw conclusions about their learning success. More generally, the query logs of usage search engines may form a unique opportunity to observe language learners "in the wild" as opposed to the laboratory.

Finally, regarding the user interface of usage search engines, our user study has revealed ways to improve them. For example, the interface must be optimized for faster typing (especially on mobile devices) as we observed that the pupils were not adept to entering special characters on standard keyboards, which resulted in slow typing speed. Besides this, our user study also showed that the current state of Netspeak's textual user interface as well as the simplified wildcard query language is easy enough to be understood in less than a minute by any newcomer, which demonstrates the low barrier to entry that search engines for common usage have right now.

Appendix

A Questionnaire A from Experiments 1 and 2

1. I really prefer just anything _____ watching television.
   × against ✓ to × about × on
2. Has Tony's new book _____ yet?
   ✓ come out × published × developed × drawn up
3. If this plan _____ off, I promise you you'll get the credit for it.
   × lets × goes × gets ✓ comes
4. Helen had great admiration _____ her history teacher.
   × in × to ✓ for × on
5. I just couldn't _____ over how well the team played!
   ✓ get × turn × make × put
6. The problem stems _____ the government's lack of action.
   × out ✓ from × under × for
7. It's too late to phone Jill at work, at any _____ .
   × case × time × situation ✓ rate
8. I'm afraid I'm not very good _____ children.
   × about × for ✓ with × at
9. We are _____ no obligation to change goods which were not purchased here.
   × with ✓ under × to × at

B Questionnaire B from Experiments 1 and 2

1. Don't worry about the lunch. I'll _____ to it.
   × look × prepare × care ✓ see
2. I am afraid that these regulations have to be _____ with.
   × provided ✓ complied × faced × met
3. Our thoughts _____ on our four missing colleagues.
   × based ✓ centred × laid × depended
4. Carol doesn't have a very good relationship _____ her mother.
   ✓ with × at × for × to

5. It seems to be your boss who is _____ fault in this case.
   × under × with ✓ at × for
6. Being rich doesn't count _____ much on a desert island.
   × on × to × of ✓ for
7. The policeman _____ me off with a warning as it was Christmas.
   × sent × gave ✓ let × set
8. Tina is an authority _____ Byzantine architecture.
   ✓ on × for × with × in
9. I was _____ the impression that you liked Indian food.
   × at × with × of ✓ under

C Questionnaire A from Experiment 3

Choose the word which fits best using the options operator `[<words>]`.

1. If you spend so much money every day, you will _____ out of money before the end of the month.
   × pay × use ✓ run × take
2. You need to take _____ all your other clothes before you put on your swimming costume.
   × down × away × out ✓ off
3. I'm afraid I'm not very good _____ history.
   × about × for ✓ at × with

Choose the best synonym for the underlined word using the synonym operator ∼`<word>`.

4. I love studying geometry the most.
   × hate × absent ✓ enjoy × difficult
5. My ambition is to become a computer scientist.
   × thought × reward × study ✓ dream
6. Your action will have serious consequences.
   ✓ effects × events × reasons × affects

Choose the correct word order using the word order operator `{<words>}`.

7. The _____ bird! I'm going to help it!
   ✓ poor little × little poor
8. She was wearing a _____ dress.
   × green beautiful ✓ beautiful green
9. I plan on wearing my _____ coat.
   ✓ long black × black long

D Questionnaire B from Experiment 3

Choose the word which fits best using the options operator `[<words>]`.

1. Sometimes Julia speaks very quickly so the other students have to ask her to slow _____ .
   ✓ down × up × out × off
2. The missing plane has apparently disappeared without a _____ .
   × sign × news × word ✓ trace
3. When Gabriel's credit card stopped, he cut it _____ many small pieces.
   × out ✓ into × apart × in

Choose the best synonym for the underlined word using the synonym operator ∼`<word>`.

4. I choose to study the differences between alligators and crocodiles.
   × make × buy ✓ prefer × wash
5. I cannot find my money. Can you get me my billfold?
   ✓ wallet × pocket × watch × bag
6. This is a very rough environment for elephants to live in.
   ✓ harsh × abrasive × coarse × beneficial

Choose the correct word order using the word order operator `{<words>}`.

7. She sold the _____ chairs at a yard sale.
   × wooden old ✓ old wooden
8. The _____ years were fantastic.
   × two first ✓ first two
9. It's close to the _____ building.
   ✓ big blue × blue big

A Framework for Translating SMS Messages

Vivek Kumar Rangarajan Sridhar, John Chen, Srinivas Bangalore, Ron Shacham
AT&T Labs
1 AT&T Way, Bedminster, NJ 07921
vkumar,jchen,srini,rshacham@research.att.com

Abstract

Short Messaging Service (SMS) has become a popular form of communication. While it is predominantly used for monolingual communication, it can be extremely useful for facilitating cross-lingual communication through statistical machine translation. In this work we present an application of statistical machine translation to SMS messages. We decouple the SMS translation task into normalization followed by translation so that one can exploit existing bitext resources and present a novel unsupervised normalization approach using distributed representation of words learned through neural networks. We describe several surrogate data that are good approximations to real SMS data feeds and use a hybrid translation approach using finite-state transducers. Both objective and subjective evaluation indicate that our approach is highly suitable for translating SMS messages.

1 Introduction

The preferred form of communication has been changing over time with advances in communication technology. The majority of the world's population now owns a mobile device and an ever increasing fraction of users are resorting to Short Message Service (SMS) as the primary form of communication.

SMS offers an easy, convenient and condensed form of communication that is being embraced by the younger demographic. Due to the inherent limit in the length of a message that can be transmitted, SMS users have adopted several shorthand notations to compress the message; some that have become standardized and many that are invented constantly. While SMS is predominantly used in a monolingual mode, it has the potential to connect people speaking different languages. However, translating SMS messages has several challenges ranging from the procurement of data in this domain to dealing with noisy text (abbreviations, spelling errors, lack of punctuation, etc.) that is typically detrimental to translation quality. In this work we address all the elements involved in building a cross-lingual SMS service that spans data acquisition, normalization, translation modeling, messaging infrastructure and user trial.

The rest of the paper is organized as follows. In Section 4, we present a variety of channels through which we compiled SMS data followed by a description of our pipeline in Section 5 that includes normalization, phrase segmentation and machine translation. Finally, we describe a SMS translation service built using our pipeline in Section 6 along with results from a user trial. We provide some discussion in Section 7 and conclude in Section 8.

2 Related Work

One of the main challenges of building a machine translation system for SMS messages is the lack of training data in this domain. Typically, there are several legal restrictions in using consumer SMS data that precludes one from either using it completely or forces one to use it in limited capacity. Only a handful of such corpora are publicly available on the Web (Chen and Kan, 2013; Fairon and Paumier, 2006; Treurniet et al., 2012; Sanders, 2012; Tagg, 2009); they are limited in size and restricted to a few language pairs.

The NUS SMS corpus (Chen and Kan, 2013) is probably the largest English SMS corpus consisting of around 41000 messages. However, these messages are characteristic of Singaporean chat lingo and not an accurate reflection of SMS style in other parts of the world. A corpus of 30000 French SMS messages

Proceedings of COLING 2014, the 25th International Conference on Computational Linguistics: Technical Papers, pages 974–983, Dublin, Ireland, August 23-29 2014.

was collected in (Fairon and Paumier, 2006) to study the idiosyncrasies of SMS language in comparison with standard French. More recently, (Pennell and Liu, 2011) have used twitter data as a surrogate for SMS messages. Most of these previous efforts have focused on normalization, i.e., translation of SMS text to canonical text while we are interested in translating SMS messages from one language into another (Eidelman et al., 2011).

Several works have addressed the problem of normalizing SMS text. A majority of these works have used statistical machine translation (character-level) to translate SMS text into standard text (Pennell and Liu, 2011; Aw et al., 2009; Kobus et al., 2008). (Beaufort et al., 2010) used a finite-state framework to learn the mapping between SMS and canonical form. A beam search decoder for normalizing social media text was presented in (Wang and Tou Ng, 2013). All these approaches rely on supervised training data to train the normalization model. In contrast, we use an unsupervised approach to learn the normalization lexicon of word forms in SMS to standard text.

While several works have addressed the problem of normalizing SMS using machine translation, there has been little to no work on the translation of SMS messages across languages on a large scale. Machine translation of instant messages from English-to-Spanish was proposed in (Bangalore et al., 2002) where multiple translation hypotheses from several off-the-shelf translation engines were combined using consensus decoding. However, the approach did not consider any specific strategies for normalization and the fidelity of training bitext is questionable since it was obtained using automatic machine translation. Several products that enable multilingual communication with the aid of machine translation in conventional chat, email, etc., are available in the market. However, most of these models are trained on relatively clean bitext.

3 Problem Formulation

The objective in SMS translation is to translate a foreign sentence $\mathbf{f}^{sms} = f_1^{sms}, \cdots, f_J^{sms}$ into target (English) sentence $\mathbf{e} = e_1^I = e_1, \cdots, e_I$. In general it is hard to procure such SMS bitext due to lack of data and high cost of annotation. However, we typically have access to bitext in non-SMS domain. Let $\mathbf{f} = f_1, \cdots, f_J$ be the normalized version of the SMS input sentence. Given $\mathbf{f}^{sms}$, we choose the sentence with highest probability among all possible target sentences,

$$\hat{\mathbf{e}}(\mathbf{f}^{sms}) = \arg\max_{\mathbf{e}} \{\mathrm{P}(\mathbf{e}|\mathbf{f}^{sms})\} \tag{1}$$

$$P(\mathbf{e}|\mathbf{f}^{sms}) \approx P(\mathbf{e}) \sum_{\mathbf{f}} P(\mathbf{f}^{sms}, \mathbf{f}|\mathbf{e}) \tag{2}$$

$$= P(\mathbf{e}) \sum_{\mathbf{f}} P(\mathbf{f}^{sms}|\mathbf{f}, \mathbf{e}) P(\mathbf{f}|\mathbf{e}) \tag{3}$$

If one applies the max-sum approximation and assumes that $P(\mathbf{f}^{sms}|\mathbf{f}, \mathbf{e})$ is independent of $\mathbf{e}$,

$$\hat{\mathbf{e}}(\mathbf{f}^{sms}) = \arg\max_{\mathbf{e}} P(\mathbf{f}^*|\mathbf{e}) P(\mathbf{e}) \tag{4}$$

where $\mathbf{f}^* = \arg\max_{\mathbf{f}} P(\mathbf{f}^{sms}|\mathbf{f})$. Hence, the SMS translation problem can be decoupled into normalization followed by statistical machine translation[1].

4 Data

Typically, one has access to a large corpus of general bitext $\{\mathbf{f}, \mathbf{e}\}$ while data from the SMS domain $\{\mathbf{f}^{sms}, \mathbf{e}\}$ is sparse. Compiling a large corpus of SMS messages is not straightforward as there are several restrictions on the use of consumer SMS data. We are not aware of any large monolingual or bilingual corpus of true SMS messages besides those mentioned in Section 2. To compile a corpus of SMS messages, we used three sources of data: transcriptions of speech-based SMS collected through

[1] One can also use a lattice output from the normalization to jointly optimize over $\mathbf{e}$ and $\mathbf{f}$

smartphones, data collected through Amazon Mechanical Turk[2] and Twitter[3] as a surrogate for SMS-like messages. We describe the composition of each of these data sources in the following subsections.

Corpus	Message	#count	Corpus	Message	#count
Speech SMS	*i love you*	988157	Amazon Mechanical Turk	*ily2*	N/A
	hello	881635		*n a meeting*	
	hi	607536		*check facebook*	
	how are you	470999		*kewl*	
	what's up	251044		*call u n a few*	
	what are you doing	218289	Twitter	*lol*	472556
	where are you	191912		*haha*	232428
	call	191430		*lmao*	102018
	lol	105618		*omg*	709504
	how's it going	102977		*thanks for the rt*	300254

Table 1: Examples of English messages collected from various sources in this work

4.1 Speech-based SMS

In the absence of access to a real feed of SMS messages, we used transcription of speech-based SMS messages collected through a smartphone application. A majority of these messages were collected while the users used the application in their cars. We had access to a total of 41.3 million English and 2.4 million Spanish automatic transcriptions. To avoid the use of erroneous transcripts, we sorted the messages by frequency and manually translated the top 40,000 English and 10,000 Spanish messages, respectively. Our final English-Spanish bitext corpus from this source of data consisted of 50,000 parallel sentences. Table 1 shows the high frequency messages in this dataset.

4.2 Amazon Mechanical Turk

The SMS messages from speech-based interaction does not consist of any shorthands or orthographic errors as the decoding vocabulary of the automatic speech recognizer is fixed. We posted a task on Amazon Mechanical Turk, where we took the speech-based SMS messages and asked the turkers to enter three responses to each message as they would on a smartphone. We iteratively posted the responses from the turkers as messages to obtain more messages. We obtained a total of 1000 messages in English and Spanish, respectively. Unlike the speech data, the responses contained several shorthands.

4.3 Twitter

Twitter is used by a large number of users for broadcasting messages, opinions, etc. The language used in Twitter is similar to SMS and contains plenty of shorthands, spelling errors even though it is typically not directed towards another individual. We compiled a data set of Twitter messages that we subsequently translated to obtain a bilingual corpus. We used the Twitter4j API[4] to stream Twitter data for a set of keywords (function words) over a week. The raw data consisted of roughly 106 million tweets. Subsequently, we performed some basic normalization (removal of @user, #tags, filtering advertisements, web addresses) to obtain SMS-like tweets. Finally, we sorted the data by frequency and picked the top 10000 tweets. Eliminating the tweets present in either of the two previous sources resulted in 6790 messages that we manually translated.

5 Framework

The user input is first stripped of any accents (Spanish), segmented into short chunks using an automatic punctuation classifier. Subsequently, any shorthand in the message is expanded out using expansion dictionaries (constructed manually and automatically) and finally translated using a phrase-based translation

[2]https://www.mturk.com
[3]https://twitter.com
[4]http://twitter4j.org/en/

model. Our framework allows the use of confusion networks in case of ambiguous shorthand expansions. We describe each component of the pipeline in detail in the following sections.

5.1 Tokenization

Our initial analysis of SMS messages from users, especially in Spanish indicated that while some users use accented characters in orthography, several others omit it for the sake of faster responses and convenience. Hence, we decided to train all our models on unaccented characters. Given a message, we convert all accented characters to their corresponding unaccented forms, e.g., baño → bano, followed by lowercasing of all characters. We do not perform any other kind of tokenization.

5.2 Unsupervised SMS Normalization

In Section 5.2, we described a static lookup table for expanding abbreviations and shorthands typically encountered in SMS messages, e.g., *4ever→forever*. While a static lookup table provides a reasonable way of handling common SMS abbreviations, it has limited coverage. In order to build a larger normalization lexicon, we used distributed representation of words to induce the lexicon in an unsupervised manner. Distributed word representations (Bengio et al., 2003; Collobert and Weston, 2008; Turian et al., 2010) induced through deep neural networks have been shown to be useful in several natural language processing applications. We use the notion of distributional similarity that is automatically induced through the word representations for learning automatic normalization lexicons.

Canonical form	Noisy form
love	loveeee, loveeeee, looove, love, wuv, wove, love, laffff, love, wuvvv, luhhhh, love, luvvv, luv

Table 2: Examples from the unsupervised normalization lexicon induced through deep learning

We started with the 106 million tweets described in Section 4.3 and used a deep neural network identical to that used in (Collobert and Weston, 2008), i.e., the network consisted of a lookup table, hidden layer with 100 nodes and a linear layer with one output. However, we used a context of 5 words and corrupted the centre word instead of the last word to learn the distributed representations. We performed stochastic gradient minimization over 1000 epochs on the twitter data. Subsequently, we took the English and Spanish vocabularies in our translation model and found the 50 nearest neighbors using cosine distance for each word. We trained the above representations using the Torch toolkit (Collobert et al., 2011).

Feature	English		Spanish	
dimension	Precision	Recall	Precision	Recall
100	70.4	97.4	69.8	97.3
200	72.2	97.5	79.2	100
300	70.4	97.4	71.6	100

Table 3: Performance of the unsupervised normalization procedure. Only 1-best for each word was considered.

Once we obtained the 50 nearest neighbors for each word in the clean vocabulary, we used a combination of cosine metric threshold and Levenshtein distance (weighted equally) between the consonant

skeleton of the strings to construct the mapping lexicon. Finally, we inverted the table to obtain a normalization lexicon. Our procedure currently finds only one-to-one mappings. We took 60 singleton entries from the static normalization tables reported in Section 5.2 and evaluated the performance of our approach. The results are shown in Table 3 and some examples of learned normalizations are shown in Table 2.

5.3 Phrase Segmentation

In many SMS messages, multiple clauses may be concatenated without explicit punctuation. For example, the message *hi babe hope you're well sorry i missed your call* needs to be interpreted as *hi babe. hope you're well. sorry, i missed your call.* We perform phrase segmentation using an automatic punctuation classifier trained on SMS messages with punctuation. The classifier learns how to detect end of sentence markers, i.e. periods, as well as commas in the input stream of unpunctuated words.

An English punctuation classifier and a Spanish punctuation classifier was trained. The former was trained on two million words of smartphone data described in Section 4.1 while the latter was trained on 223,000 words of Spanish subtitles from the OpenSubtitles[5] corpus. From each of these data sets, a maximum entropy classifier was trained. Both classifiers utilized both unigram word and part of speech (POS) features of a window size of two words around the target word to be classified. A POS tagger trained on the English Penn Treebank provided English POS tags. Likewise, a Spanish POS tagger provided Spanish POS tags. The training data for the Spanish tagger, 1.6 million words in size, was obtained by running the Spanish Freeling parser over the Spanish version of TED talk transcripts. Results are shown in Table 4. Both phrase segmenters detect end of sentence well. The Spanish phrase segmenter detects commas better than the English one. This might be due to differences in the training sets; commas appear about 20 times more often in the Spanish data than in the English data.

	Class	Precision	Recall	F-measure
English	*period*	89.7	90.9	90.3
	comma	61.1	10.9	18.5
Spanish	*period*	94.3	87.4	90.7
	comma	74.2	37.4	49.7

Table 4: Performance of automatic phrase segmentation (numbers are in %)

5.4 Machine Translation

We used a phrase-based translation framework with the phrase table represented as a finite-state transducer (Rangarajan Sridhar et al., 2013). Our framework proceeds by using the standard procedure of performing word alignment using GIZA++ (Och and Ney, 2003) and obtaining phrases from the word alignment using heuristics (Zens and Ney, 2004) and subsequently scoring them. The phrase table is then represented as a finite-state transducer (FST). The FST decoder was used with minimum error rate training (MERT) to compute a set of weights for the log-linear model. It is important to note that the cost of arcs of the FST is a composite score (dot product of scores and weights) and hence requires an additional lookup during the N-best generation phase in MERT to obtain the component scores. The model is equivalent to Moses (**?**) phrase translation without reordering.

We noticed from the data collected in Section 4 that in typical SMS scenarios, a lot of phrases are stock phrases and hence caching these phrases may result in high accuracies instead of deriving the translation using a statistical model. We took the data created in Section 4 and created a FST to represent the sentences. The motivation is to increase the precision of common entries as well as reduce the latency involved in retrieving a translation from a statistical model. An example of the FST translation paradigm is shown in Figure 1

We experimented with the notion of using a consensus-based word alignment by combining the alignment obtained through different alignment tools. We used GIZA++ (Och and Ney, 2003), Berkeley

Alignment strategy	en2es	es2en
GIZA++	28.45	31.83
Pialign	28.08	33.48
Berkeley aligner	27.82	32.01
Union	28.01	33.14
Majority voting	27.32	32.96

Table 5: BLEU scores obtained using different alignment strategies. Only the statistical translation model was used in the evaluation.

aligner (Liang et al., 2006) and the Phrasal ITG aligner (Pialign) (Neubig et al., 2011). We combined the alignments in two different ways, taking the union of alignments or majority vote for each target word. For training the translation model, we used a total of 28.5 million parallel sentences obtained from the following sources: Opensubtitles (Tiedemann and Lars Nygaard, 2004), Europarl (Koehn, 2005), TED talks (Cettolo et al., 2012) and Web. The bitext was processed to eliminate spurious pairs by restricting the English and Spanish vocabularies to the top 150k frequent words as evidenced in a large collection of monolingual corpora. We also eliminated bitext with ratio of English to Spanish words less than 0.5. The initial model was optimized using MERT over 1000 parallel sentences from the SMS domain. Results of the machine translation experiments are shown in Table 5. The test set used was 456 messages collected in a real SMS interaction (see Section 6.1). The results indicate that consensus alignment procedure is not superior to the individual alignment outputs. Furthermore, the BLEU scores obtained through both the consensus procedures are not statistically significant with respect to the BLEU score obtained from the individual alignment tools. Hence, we used with the phrase translation table obtained using the Phrasal ITG aligner in all our experiments.

6 SMS Translation Service

In order to test the SMS translation models described in the previous sections, we created the infrastructure to intercept SMS messages, translate and deliver them in the preferred language of the recipient. The users were simply asked to register their numbers with a particular language through a Web portal and subsequently, all messages received by a user would be in the registered language. Some screenshots of interaction between users is shown in Figure 2. For the messages that are translated, we show both the original and translated messages. In cases where the translated message is longer than the character limit per message, we split the message over two message boxes.

6.1 User Evaluation

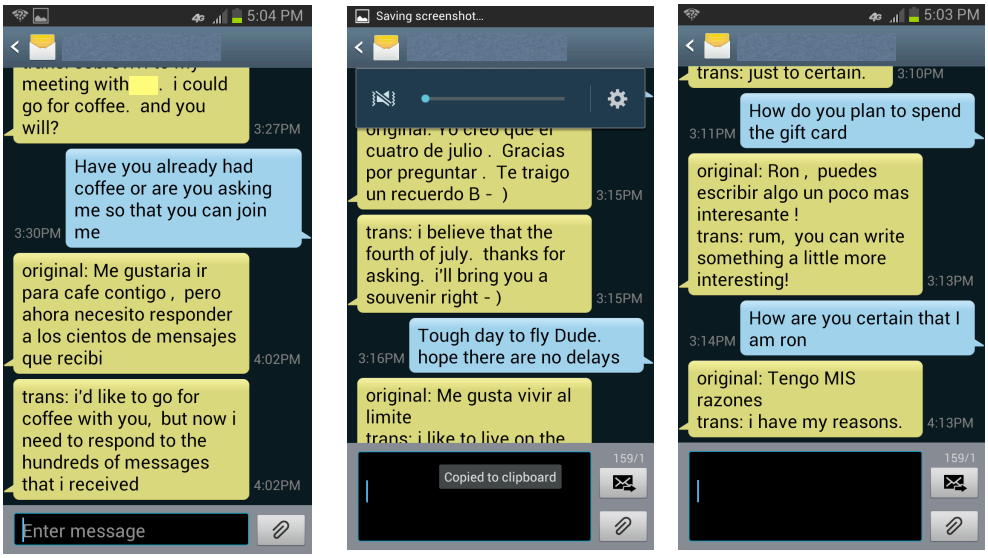

Figure 2: Screenshots of the SMS interface with translation

In order to test the SMS translation models described in the previous sections, we created the infrastructure to intercept SMS messages, translate and deliver them in the preferred language of the recipient. For the messages that are translated, we show both the original and translated messages. In cases where the translated message is longer than the character limit per message, we split the message over two message boxes. As part of the study we enrolled 20 English and 5 Spanish participants. The Spanish participants were bilingual while the English users had little to no knowledge of Spanish. Some of these interactions turned out to be short while others were had a large number of turns. We collected the messages exchanged over 2 days that amounted to 241 English and 215 Spanish messages.

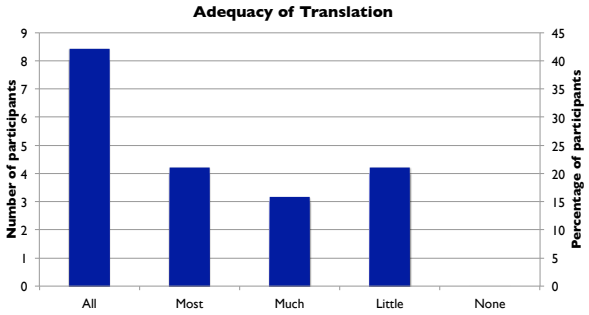

Figure 3: Subjective ratings regarding the adequacy of using SMS translation

We manually translated the 456 messages to create a test data set for evaluation purposes. In the absence of real SMS feeds in training, this test set is the closest we have to real SMS field data. The BLEU scores using the entire pipeline (normalization, punctuation, cached and statistical machine translation) for English-Spanish and Spanish-English was 31.25 and 37.19, respectively. We also created a survey for the participants to evaluate fluency and adequacy (LDC, 2005) Figures 3 and 4 show the survey results for adequacy and fluency, respectively. The results indicate that a majority of the people found the translation quality to be sufficiently adequate while the fluency was between *good* and *non-native*.

7 Discussion

The SMS bitext described in Section 4 consists of a total 58790 unique parallel sentences in the SMS domain. While the bulk of the data (speech-based) does not contain abbreviations and spelling errors, it

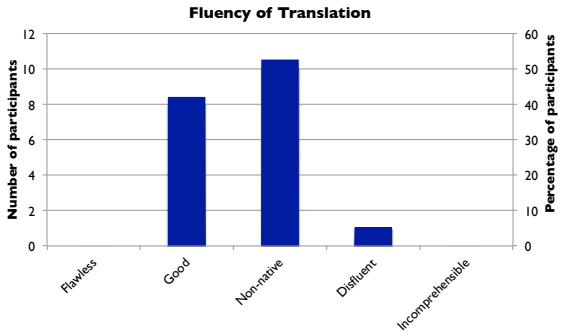

Figure 4: Subjective ratings regarding the fluency of using SMS translation

is highly representative of SMS messages and in fact is perfectly suited for statistical machine translation that typically uses normalized and tokenized data. The iterative procedure using Amazon Mechanical Turk is a good approach to procuring surrogate SMS data. We plan to continue harvesting data using this approach.

The unsupervised normalization lexicon learning using deep learning performs a good job of learning SMS shorthands. However, the induced lexicon contains only one-to-one word mappings. If one were to form compound words for a given dataset, the procedure can be potentially used for learning many-to-one and many-to-many mappings. Our framework also learns spelling errors rather well. It may also be possible to use distributed representations learned through log-linear models (Mikolov et al., 2013) for our task. However, this is beyond the scope of the work presented in this paper. Finally, we used only 1-best match for the unsupervised lexicon used in this work. One can potentially use a confusion network and compose it with the FST model to achieve higher accuracies. Our scheme results in fairly high precision with almost no false negatives (recall is extremely high) and can be reliably applied for normalization. The unsupervised normalization scheme did not yield significant improvements in BLEU score since our test set contained only 4 instances where shorthands were used.

Conventionally, sentence segmentation has been useful in improving the quality of statistical machine translation (Matusov et al., 2006; Matusov et al., 2005). Such segmentation, albeit into shorter phrases, is also useful for SMS translation. In the absence of phrase segmentation, the BLEU scores for English-Spanish and Spanish-English drop to 29.65 and 23.95, respectively. The degradation for Spanish-English messages is quite severe (drop from 37.19 to 23.95) as the lack of segmentation greatly reduces the use of the cached table. In the absence of segmentation, the cached table was used for 12.8% and 14.4% of the total phrases for English-Spanish and Spanish-English, respectively. However, with phrase segmentation the cached table was used for 29.2% and 39.2% of total phrases.

The subjective results obtained from the user trial augur well for the real use of translation technology as a feature in SMS. One of the issues in the study was balancing the English and Spanish participants. Since we had access to more English participants (20) in comparison with Spanish participants (5), the rate of exchange was slow. However, since SMS messages are not required to be real-time, participants still engaged in a meaningful conversation. Subjective evaluation results using LDC criteria indicate that most users were happy with the adequacy of translation while the fluency was rated as average. In general, SMS messages are not very fluent due to character limit imposed on the exchanges and hence machine translation has to use potentially disfluent source text.

8 Conclusion

We presented an application of statistical machine translation for translating SMS messages. We decoupled SMS translation into normalization followed by translation. Our unsupervised SMS normalization approach exploits the distributional similarity of words and learns SMS shorthands with good accuracy. We used a hybrid translation approach to exploit the repetitive nature of high frequency SMS messages. Both objective and subjective evaluation experiments indicate that our system generates translation with high quality while addressing the idiosyncrasies of SMS messages.

Abstract

Despite considerable research on the topic of Arabic Named Entity Recognition (NER), almost all efforts focus on a traditional set of semantic classes, features and token representations. In this work, we advance previous research in a systematic manner and devise a novel method to represent these features, relying on a dependency-based structure to capture further evidence within the sentence. Moreover, the work also describes an evaluation of the method involving the capture of global features and employing the clustering of unannotated textual data. To meet this set of goals, we conducted a series of evaluations to evaluate different aspects that demonstrate great improvement when compared with the baseline model.

1 Introduction

Traditionally, the focus of Arabic NER has been on a very limited number of semantic classes, i.e. PERSON, ORGANISATION and LOCATION, utilising the newswire domain such as those described by Benajiba and Rosso (2008), Benajiba et al. (2010) and Abdul-Hamid and Darwish (2010) . This limits higher-level applications (such as question answering) from extracting in-depth knowledge and working on a relatively open domains.

This paper addresses the issue of a fine-grained NER of 50 classes for Arabic and presents a comprehensive set of experiments that evaluate innovative means of representing the features set. Thus, the contribution of this paper falls into different categories with unique outcomes, as follows:

1. A novel approach to representing the features is used, relying on dependency representation. This representation overcomes the drawback of current window-based representations of features.

2. The representation of global evidence involves clustering unannotated textual data, employing hierarchical clusters (Brown et al., 1992).

3. Due to the fact that there is no comparable work to use as a comparison in the task of Arabic fine-grained NER, a baseline model was developed, based on Conditional Random Fields (CRF), using the best features, as established and used elsewhere in the literature.

4. Development of publically available gold-standard fine-grained NER corpora[1] from two different genres, i.e. Newswire and Wikipedia.

Each contribution is discussed in more detail during in the remainder of this paper.

2 Arabic Fine-grained Named Entity Corpora

The majority of Arabic NER approaches are supervised, ensuring that the machine learns from an annotated corpus and aims to predict unseen text. This approach requires a reasonable bank of labelled data. This section examines the availability of such an annotated dataset at the fine-grained level, and the creation of gold-standard corpora.

Proceedings of COLING 2014, the 25th International Conference on Computational Linguistics: Technical Papers, pages 984–995, Dublin, Ireland, August 23-29 2014.

2.1 Available Corpora

One of the earliest corpora publically released was ANERcorp, developed by Benajiba et al. (2007). This is a newswire based corpus and follows the CoNLL format. It annotates into four coarse-grained classes: PERSON, ORGANISATION, LOCATION, and MISCELLANEOUS. This dataset has been extensively used such as in (Benajiba et al., 2008b; Benajiba et al., 2010; Abdul-Hamid and Darwish, 2010).

Among corpora applying a fine-grained level of classes are those released by the Linguistic Data Consortium[2] (LDC). They released two multilingual NE corpora including Arabic (Mitchell et al., 2005; Walker et al., 2006). Both corpora were used in the Automatic Content Extraction (ACE) technology evaluation, at the coarse-grained level only. However, these corpora are governed by a costly annual license, which prevents the researcher from accessing and utilising them. At present, we are not aware of a study tackling fine-grained Arabic NER using this dataset.

Alotaibi and Lee (2013) released fine-grained Arabic NE corpora - WikiFANE$_{Selective}$ and WikiFANE$_{Whole}$. These were built automatically using the Arabic version of Wikipedia and released under the Creative Commons Attribution-ShareAlike 3.0 Unported Licence.[3]. These corpora apply a similar annotation taxonomy to that of the ACE corpus, but deliver increased coverage through the inclusion of a new class, i.e. PRODUCT, which includes Books, Movies, Sound, Hardware, Software, Food, Drugs and Other. Moreover, the corpora divide the PERSON class into 10 fine-classes, in order to provide wider coverage (i.e. Politician, Athlete, Businessperson, Artist, Scientist, Police, Religious, Engineer and Group). It is notable that this taxonomy can be easily mapped into CoNLL and ACE at either the coarse or fine-grained levels.

2.2 Creating Gold-standard Fine-grained Named Entity Corpora

Since the aim of this paper is to conduct an in-depth experiment for fine-grained Arabic NE, we manually created gold-standard fine-grained NE corpora for Arabic, drawing on two different genres. This gives a critical benchmark for evaluation and comparison with the automatically constructed corpus.

The first corpus is newswire-based, using the same textual data appearing in ANERcorp. The complete corpus was re-annotated to the fine-grained level. The second corpus is drawn from the Arabic version of Wikipedia. The selection of articles was made using a random heuristic, i.e. selecting articles discussing a named entity and maintaining a fair level of distribution among the classes. Moreover, the amount of textual data drawn from the Wikipedia article was restricted by avoiding such elements as lists, headings, and captions on images and tables.

2.3 Annotation Strategy and Quality Evaluation

For both corpora, the two-level taxonomy presented by Alotaibi and Lee (2013) was applied. This consists of 8 coarse-grained classes and 50 fine-grained classes. An in-house tool to facilitate the annotation process was developed. Two independent graduate-level Arabic native speakers were engaged to annotate the entire corpora. They were provided with extended instructions to guide them in the annotation process and a number of feedback sessions were conducted in the early stages of the process to ensure that any difficulties could be resolved.

After its completion, the quality of the annotation was evaluated by calculating the inter-annotator agreement between both annotators. The entity F-measure was used to evaluate the inter-annotation agreement as in (Hripcsak and Rothschild, 2005; Zhang, 2013). The corpora were named NewsFANE$_{Gold}$ and WikiFANE$_{Gold}$, referring to News-based, and Wikipedia-based, Fine-grained Arabic Named Entity Gold corpus, respectively. Micro-averaging was used while matching exact phrases, in order to calculate the agreement. The size and the inter-annotator agreement of NewsFANE$_{Gold}$ is 170K of tokens and 91% while WikiFANE$_{Gold}$ is 500K of tokens and 89% .

Corpus	Token level	Phrase level
NewsFANE$_{Gold}$	10.7	6.7
WikiFANE$_{Gold}$	13.1	7.4
WikiFANE$_{Selective}$	10.8	6.4
WikiFANE$_{Whole}$	7.08	4.9

Table 1: The density of NEs on token and phrase levels

Corpus	Length							
	1	2	3	4	5	6	7	8
NewsFANE$_{Gold}$	58.19	30.77	8	1.73	0.82	0.21	0.2	0.04
WikiFANE$_{Gold}$	51.75	31.55	10.88	3.48	1.34	0.46	0.21	0.12
WikiFANE$_{Selective}$	48.27	37.95	10.22	2.98	0.41	0.11	0.05	0.01
WikiFANE$_{Whole}$	66.22	25.85	6.02	1.58	0.05	0.02	0.01	0.01

Table 2: The distribution of NE phrases relative to length.

3 Corpus-based Evaluation and Comparison

It is important to closely evaluate and compare different corpora. The nature of the distribution of NE phrases is expected to differ to some extent, affecting the performance of learning the probabilistic model. Therefore, the coverage of NE phrases related to different aspects was studied, including the distribution of density, length and semantic classes.

3.1 The Density of NE

The density represents the coverage of NEs at the level of tokens and phrases. As can be seen in Table 1, WikiFANE$_{Gold}$ has the greater density at both levels. This demonstrates that the Wikipedia-based gold corpus tends to represent more NE phrases in context than that of the newswire-based. Although WikiFANE$_{Gold}$ is 0.7% denser than NewsFANE$_{Gold}$ in the phrase level, it reveals a notable difference (2.4%) in the token level. This indicates that WikiFANE$_{Gold}$ possess a greater variety in the length of NE phrases than the newswire-based corpus. However, the automatically developed corpus, WikiFANE$_{Selective}$, has a similar density of coverage as NewsFANE$_{Gold}$ whereas the WikiFANE$_{Whole}$ demonstrates a low level of density, due to its method of compilation.

3.2 The Distribution of the Length of Named Entity Phrases

It can be seen in Table 2, NewsFANE$_{Gold}$ and WikiFANE$_{Whole}$ tend to have more single-word NE phrases than other corpora. When it comes to the newswire corpus, this is due to differences in the way the NE phrases are written in a newswire domain. On the other hand, the boundaries of multi-word NE phrases are difficult to detect, in Arabic, due to the fact that the language has a complex morphology. This is demonstrated in the Wikipedia corpora, i.e. the gold and the selective - less than half the NE phrases in WikiFANE$_{Selective}$ are single-word, with a slightly higher rate found in WikiFANE$_{Gold}$.

3.3 The Distribution of the Fine-grained Classes

This demonstrates the distribution of NE phrases into fine-grained classes according to their annotation. As shown in Figure 1, the majority of classes tend (to some extent) to have a relatively harmonic distribution. In general, the newswire-based corpus tends to include more NE phrases related to politics, government, commerce, nations and cities, whereas the automatically-built corpora score a very high frequency on NE types such as 'Nation' and 'Population-centre'. Moreover, WikiFANE$_{Gold}$ shows wide distribution on most of the fine-grained classes of 'PERSON', 'LOCATION', 'FACILITY', 'VEHICLE' and 'PRODUCT', compared to other corpora.

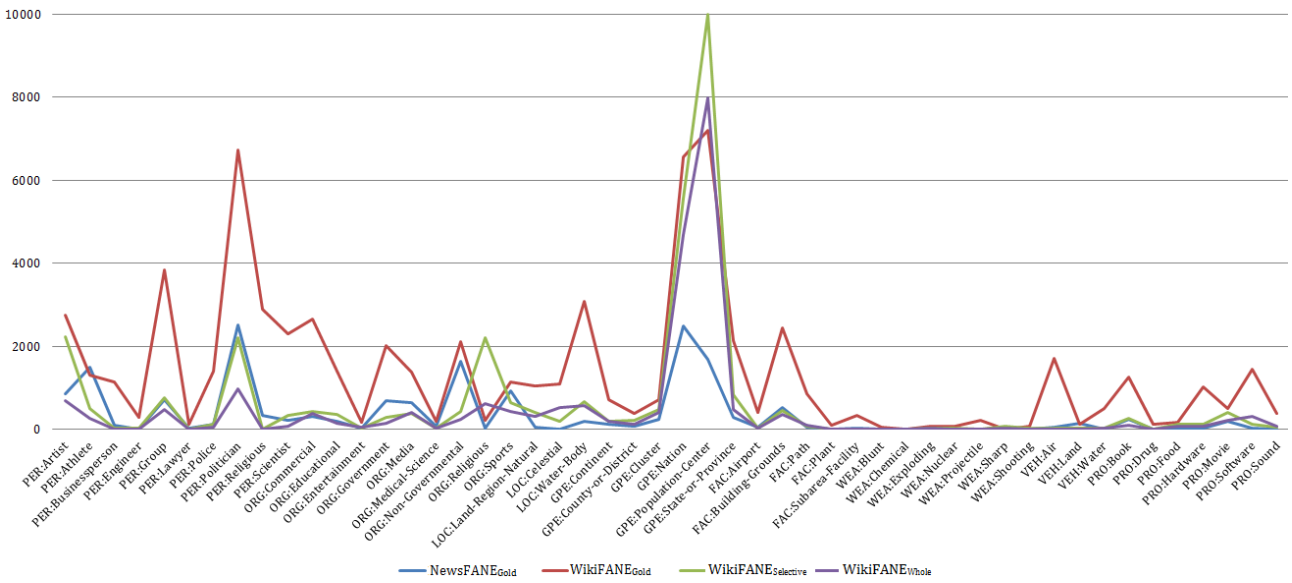

Figure 1: Distribution of Fine-grained Classes

4 The Baseline Model for Fine-grained Arabic NER

In order to prepare the baseline model and conduct successive experiments, the dataset for each corpus was divided into training, development and test. It is important to emphasise that, due to the limitations of computation power and the space allocated for the machine used, only a portion of WikiFANE$_{Selective}$ and WikiFANE$_{Whole}$ were selected with a size of ˜500K tokens each. The following table shows each corpus and its size.

Corpus	Type	Training	Dev	Test
NewsFANE$_{Gold}$	gold-standard	120K	25K	25K
WikiFANE$_{Gold}$	gold-standard	350K	75K	75K
WikiFANE$_{Selective}$	automatically-developed	354K	73K	73K
WikiFANE$_{Whole}$	automatically-developed	356K	72K	72K

Table 3: The size of the training, development and test for each corpus

Since there is no comparative work in the form of a fine-grained Arabic NER to use as a comparison, a baseline model based on Conditional Random Fields (CRF) was developed. It was decided to use the most successful features of the coarse-grained NER. For this purpose, the following features were extracted: ***Lexical and contextual features*** (current token, two tokens before and after the current token, first and last three characters of the token, and length of the token); ***Morphological features*** (gender, number and person); ***Syntactical features*** (part of speech and base phrase chunk); and ***External knowledge*** (the presence of the token in the gazetteer developed by Alotaibi and Lee (2013)). It was decided to use the BILOU scheme representation for the baseline model and successive experiments, as suggested by Ratinov and Roth (2009). The performance of the baseline model is presented in Table 4.

Corpus	Development			Test		
	P	R	F	P	R	F
NewsFANE$_{Gold}$	79.58	57.87	67.01	73.07	53.34	61.67
WikiFANE$_{Gold}$	62.19	43.67	51.31	68.13	44.78	54.04
WikiFANE$_{Selective}$	89.01	68.92	77.69	88.69	60.37	71.84
WikiFANE$_{Whole}$	82.35	49.83	62.09	84.27	58.63	69.15

Table 4: The results of the baseline model by learning CRF classifier with traditional features

5 Dependency based Features Representation

The current representation of the sequence tagging classifier involves using a predefined window of tokens (e.g. with size 5, including the current token) in order to capture local evidence. This representation has the following three drawbacks:

1. It is restricted to only capturing local evidence.
2. It fails to capture the relationship between dependent tokens, particularly for long sentences and multiword NE phrases.
3. Since Arabic has a relatively free word order, the window-based feature representation cannot capture the order variation for different examples.

In this paper, a new approach has been devised to utilise further evidence within a sentence in the classification process. The key idea informing this approach was to rely on the dependency-based representation of sentences in order to extract valuable features.

The dependency structure is one of syntactical representations, where a sentence is analysed by connecting its words in a word-to-word relationship. These relationships specify the head and dependent tokens in context, and assign a grammatical role for each token, e.g. subject, object and modifier.

To elaborate on the amount of knowledge that can be utilised based on the dependency structure, consider the following sentences:

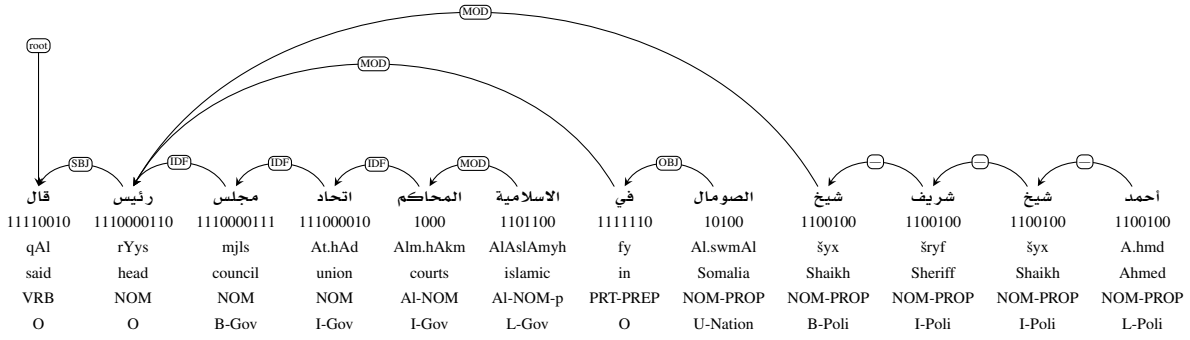
- (قال رئيس مجلس اتحاد المحاكم الاسلامية في الصومال شيخ شريف شيخ أحمد ...الخ /qAl rŷys mjls AtHAd AlmHAkm AlAslAmyħ fy AlSwmAl šyx šryf šyx OHmd fy ...Alx/ 'The head of the Council of the Islamic Courts Union, Sheikh Sharif Sheikh Ahmed, said in Somalia ...etc.')
- (يقول شارلز مورفي السياسي الانجليزي بعد الزيارة الأخيرة التي قام بها جون ميجور رئيس وزراء بريطانيا ...الخ /yqwl šArlz mwrfy AlsyAsy AlAnjlyzy bς d AlzyArħ AlOxyrħ Alty qAm bhA jwn myjwr rŷys wzrA' bryTAnyA ...Alx/ 'Charles Murphy, the English politician, said after the recent visit by John Major, Britain's prime minister ... etc.')
- (يذكر أن صلاد حسن انتخب رئيساً للصومال في اغسطس آب ٢٠٠٠ /yðkr On SlAd Hsn Antxb rŷysAã llSwmAl fy AγsTs Āb 2000/ 'It was mentioned that, Salad Hassan was elected as president of Somalia in August 2000')

The dependency representation and an English gloss of each example are shown in Figure 2. The parsed output includes a new set of information, which can be utilised as features, as follows:

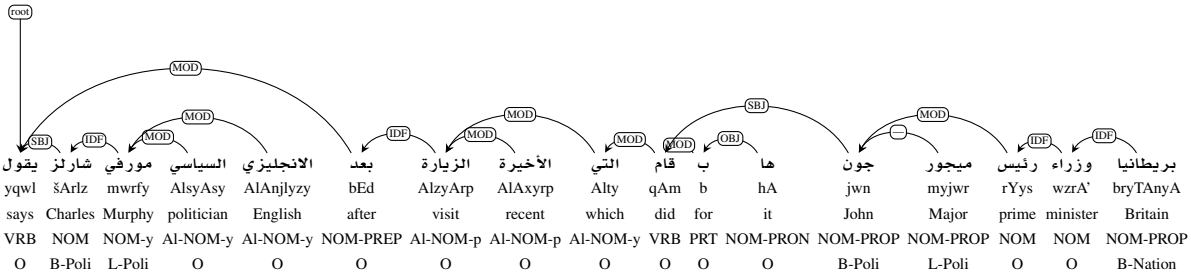
1. Head and Dependent Relation: The relationship between the head and the dependent is one of the most important features to capture. Consider the token (شيخ /šyx/ 'Shaikh'), in Figure 2a; the head (رئيس /rŷys/ 'the head of') is located far away and cannot be captured in the local window-based representation. Moreover, the vice versa relationship between the dependent and head is also useful. Consider the example in Figure 2b: the token (جون /jwn/ 'John') has two dependents (ميجور /myjwr/ 'Major') and (رئيس /rŷys/ 'Prime')[4] where the latter dependent (i.e. 'رئيس') gives a useful clue of the way in which it has been used in political contexts. The sequence of heads or dependents can also be utilised in the same way.

2. Sibling Relation: The sibling tokens are those dependent on the same head. Siblings can be located near each other in context, or appear at a distance. For example: the sibling of the token (شيخ /šyx/ 'Shaikh') is (مجلس /mjls/ 'council'), in Figure 2a, is expected to appear in a political context, which gives a clue towards the target NE class. Meanwhile, the token (في /fy/ 'in') is also a sibling, and can be avoided as it is a stop word. This is also the case in the example presented in Figure 2c, where the token (صلاد /SlAd/ 'Salad') is a sibling to the token (انتخب /Antxb/ 'elected'), which relates to the political context.

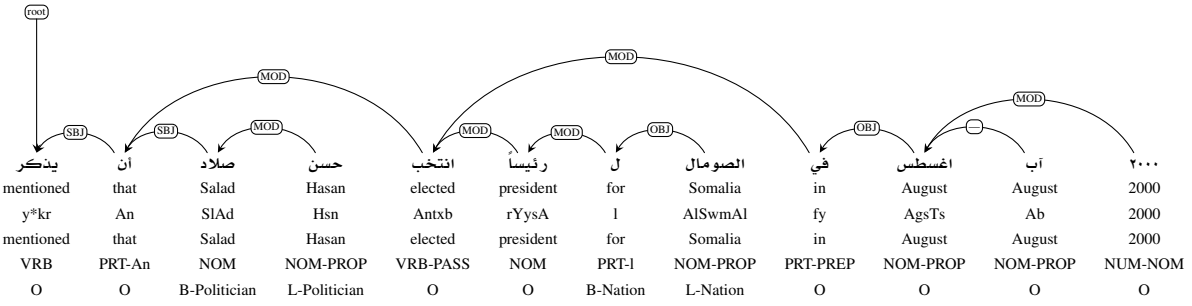
[4]Different contexts yield different English translation of the token "رئيس" as "the head of" and "Prime"



(a) The first example. (The second row represents the clusters according to the Brown algorithm)



(b) The second example



(c) The third example

Figure 2: The examples of a dependency structure. The rows show the Arabic token, Buckwalter transliteration, English gloss, POS and NE tag, respectively (the sentence is displayed left to right).

3. Syntactic Roles: The syntactical roles also benefit by being utilised to capture NE phrases in context. Among those with concern for NER are:

a. SBJ and OBJ: defines which subject and object roles are assigned to the head token of the NE phrase. For example, the tokens (**صلاد** /SlAd/ 'Salad') and (**شارلز** /šArlz/ 'Charles') are tagged as subjects.

b. IDF[5]*:* the Idafa chain is another important syntactical role, which helps to identify multiword NE phrases. For example: the token (**مورفي** /mwrfy/ 'Murphy') is tagged as an IDF of its previous token (**شارلز** /šArlz/ 'Charles'), where this indicates a multiword NE phrase. This is also the case for the example (**مجلس اتحاد المحاكم الإسلامية** /mjls AtHAd AlmHAkm AlIslAmyħ/ 'Council of the Islamic Courts Union') where all tokens are assigned an IDF role except the last token.

c. Flat relation (—): is a special role used by a CATiB pipeline parser for the sequence of proper nouns. For example: NE phrases such as (**شيخ شريف شيخ أحمد** /šyx šryf šyx OHmd/ 'Sheikh Sharif Sheikh Ahmed'), in which all tokens are assigned a flat relation.

[5]The naming of this abbreviation is used in CATiB to represent the syntactical role of idafa.

Corpus	Development			Test			+|-

WikiFANE$_{Selective}$	87.00	73.55	79.71	85.78	69.18	76.59	+4.75
WikiFANE$_{Whole}$	88.58	66.97	72.22	85.15	59.01	69.71	+0.56

Table 5: The results of the dependency-based features representation. ("+|-" represents the variation compared with the previous experiment)

5.1 Dependency-based Features set

The representation of the dependency structure presents each token as a node. A particular token (T) should have one node and only one head (H), except for the root, and zero or more dependents (D). A token (T) can have zero or more siblings (S), where they are connected, (i.e. are dependent), to the same head. Therefore, the following set of features has been extracted:

1. The current token T
2. POS of T
3. The presence of T in the Gazetteer
4. Syntactical role of T
5. Token of 1st, 2nd and 3rd Head H
6. Syntactical role of 1st, 2nd and 3rd H
7. POS of 1st, 2nd and 3rd H
8. Token of 1st, 2nd and 3rd Dependent D or 'NA' otherwise
9. Syntactical role of 1st, 2nd and 3rd D or 'NA' otherwise
10. POS of 1st, 2nd and 3rd D or "NA" otherwise
11. Token of 1st, 2nd and 3rd Sibling S or 'NA' otherwise
12. Syntactical role of 1st, 2nd and 3rd S or 'NA' otherwise
13. POS of 1st, 2nd and 3rd S or 'NA' otherwise

The 1st, 2nd and 3rd 'H' represent the parent, grandparent and great grandparent heads; while the 1st, 2nd and 3rd 'S' represent the first three siblings (if any).

5.2 Evaluation

It was decided to use the CATiB pipeline tool[6] (produced by Marton et al. (2013)), to parse all corpora and produce the set of features presented in the previous section. Since the POS tag set produced using the CATiB pipeline tool is very limited, it was decided instead to rely on the output of the AMIRA tokeniser and POS tagger produced by Diab (2009). The same classifier (CRF) was used, with a similar encoding scheme. Two experiments were conducted: the first was intended to evaluate the dependency-based representations. This was important in examining the effectiveness of the approach, compared with the window-based representation of local evidence. This is shown in Table 5, where in all corpora the performance of dependency-based representation alone outperforms that with window-based representation. The recall metrics reveal improvement across corpora, suggesting that the dependency-base representation has the ability to capture an increased number of NE phrases comparing to the traditional window-based representation.

The second experiment is intended to evaluate the integration in the classification process of dependency-based and window-based representations. This evaluation is expected to attain maximum benefit from both approaches in one model. The results in Table 6 demonstrate that the classifier tends to efficiently utilise both dependency-based and window-based representations in all corpora, apart from WikiFANE$_{Whole}$. The reason behind the degradation of the performance over the WikiFANE$_{Whole}$ dataset is due to the nature of the compiling of the corpus. Alotaibi and Lee (2013) state that this version includes entire sentences from Wikipedia articles, with no further filtering, ensuring that it is

possible to have sentences including NE phrases that are mistakenly assigned to 'O' class when using an automatic approach, as these NE phrases have no known destination in a Wikipedia article. This variety of mis-annotation is expected to propagate at this stage. It is worth noting that NewsFANE$_{Gold}$ and WikiFANE$_{Gold}$, as gold-standard corpora of different genres, reveal notable improvements of 4.03 and 4.63 F-measure respectively by using hybrid representation.

6 Further Exploiting of Global Evidences

Thus far, this study has examined the window-based and dependency-based representation of evidence, in order to increase the performance of the classification process. However, there is still room for improvement. Both approaches focus only at the sentence level. This section will investigate the approach to capturing global evidence. One means of achieving this is by utilising unannotated textual data, by clustering tokens into semantic groups based on context similarity. The reasoning behind this approach is that a NE token such as (الطائف /AlTAŷf/ 'Taif') (which is not seen in the training process) cannot be correctly classified, as it contains neither window-based nor dependency-based evidence in the training phase. Meanwhile, the token 'الطائف' is assigned to the same cluster of (لندن /lndn/ 'London') where the classifier knows that 'لندن' is a location. In this way, the knowledge capacity of the classifier has been broadened to a global level. A number of efforts have been undertaken for languages other than Arabic that demonstrate the usefulness of injecting clustering into NLP tasks, e.g. PCFG parsing (Candito and Crabbé, 2009) and dependency parsing (Koo et al., 2008). Utilising unannotated textual data in the supervised NER has already been variously studied with reference to English. The studies in (Turian et al., 2009; Turian et al., 2010; Tkachenko et al., 2012; Ratinov and Roth, 2009; Miller et al., 2004) reveal improvements when using the Brown clustering algorithm (Brown et al., 1992) to extract useful features.

This paper focuses on extracting a useful set of features from unannotated Arabic textual data, by relying on the Brown algorithm. We are not aware of any other study employing the Brown algorithm to Arabic textual data and in an Arabic NER task.

6.1 Brown Clustering and NER

The Brown clustering algorithm works by maximising the mutual information of bigrams. It uses hierarchical representation for the clusters. The hierarchal representation of the Brown clusters algorithm allows inclusion of different semantic levels of granularity. The output from the clustering delivers valuable information, which can be utilised by NER. This information can be divided into three categories:

1. The cluster of tokens belongs to the named entity category. For example, (شيكاغو /šykAγw/ 'Chicago') and (طوكيو /Twkyw/ 'Tokyo') belong to the same cluster, where both are NE type 'LOCATION'. In addition, (هديل /hdyl/ 'Hadeel') and (ممدوح /mmdwH/ 'Mamdooh') fall into similar clusters, and are both Personal NE.

2. The cluster of keyword tokens that have an informal insight to the target NE classes. For example, (كتائب /ktAŷb/ 'Brigades') and (منظمة /mnĎmħ/ 'Organisation') are keywords which infer the context of organisational NE. The context is expressed, for instance, as (كتائب شهداء الأقصى /ktAŷb šhdA' AlOqSý/ 'Al Aqsa Martyrs Brigades') or (منظمة العفو الدولية /mnĎmħ Alςfw

Aldwlyħ/ ‘Amnesty International’). Both head tokens in the NE phrases refer to the same cluster, which indicates the ‘ORGANISATION’.

3. The cluster of the head and dependent tokens the current token is pointing to. For example, the token (شيخ /šyx/ ‘Shaikh’), as shown in Figure 2a, is pointed to the head token (رئيس /rŷys/ ‘President’) where the ‘رئيس’ belongs to the cluster ‘1110000111’. This clustering knowledge permits the building of an abstract semantic representation for tokens. This implies that the token ‘رئيس’ can be replaced as (مدير /mdyr/ ‘Manager’) in other sentences where both tokens belong to the same cluster.

Further examples are presented in the Figure 3, where the group’s heading shows both name and cluster.

Locations: 0101101100	**First names: 000011111111101**
(بكين /bkyn/ ‘Beijing’)	(هديل /hdyl/ ‘Hadeel’)
(تكساس /tksAs/ ‘Texas’)	(حميدان /HmydAn/ ‘Homaidan’)
(طوكيو /Twkyw/ ‘Tokyo’)	(ممدوح /mmdwH/ ‘Mumdooh’)
Last names: 0000110001(01|10)	**Organisational keywords: 0111111111111011000**
(الساهر /AlsAhr/ ‘Alsaher’)	(كتائب /ktAŷb/ ‘battalions’)
(البخاري /AlbxAry/ ‘Albokhari’)	(جبهة /jbhħ/ ‘front’)
(الحازمي /AlHAzmy/ ‘Alhazmi’)	(منظمة /mnĎmħ/ ‘organization’)
Locational keywords: 011110110000	**Facility-related keywords: 101101100111011**
(مستوطنة /ktAŷb/ ‘settlement’)	(استاد /AstAd/ ‘stadium’)
(ضاحية /DAHyħ/ ‘suburb’)	(جسر /jsr/ ‘bridge’)
(محمية /mHmyħ/ ‘protectress’)	(مطار /mTAr/ ‘airport’)

Figure 3: Examples of the output of the Brown algorithm when applied to Arabic textual data.

6.2 Evaluation

The goal of this experiment was to evaluate the usefulness of injecting the clustering information from Brown algorithm into the supervised model. However, the actual size of the corpora mentioned in section 2.3 is too small to apply the Brown algorithm. Instead, a different set of different unannotated corpora, of a reasonably large size from different sources, was prepared for use in this experiment, as shown in Table 7.

Source of unannotated dataset	Size	Used for
NewsFANE$_{Gold}$ + Gigaword	1.17M	NewsFANE$_{Gold}$
WikiFANE$_{Gold}$ + 1/2(WikiFANE$_{Selective}$ & WikiFANE$_{Whole}$)	2.1M	WikiFANE$_{Gold}$
WikiFANE$_{Selective}$	2M	WikiFANE$_{Selective}$
WikiFANE$_{Whole}$	2M	WikiFANE$_{Whole}$

Table 7: Different textual data used in Brown algorithm

The first and second columns in Table 7 show the source of the unlabelled textual data used in the Brown algorithm and the respective size. The final column shows the target corpus using the knowledge in the CRF classifier.

Random stories were selected from Arabic Gigaword (Parker et al., 2011) as well as textual data from NewsFANE$_{Gold}$, to form unannotated data sized as 1.17M tokens. The Gigaword subset was selected due to the similarity of its genre to NewsFANE$_{Gold}$. The textual data for WikiFANE$_{Gold}$, and half of both WikiFANE$_{Selective}$ and WikiFANE$_{Whole}$ were compiled into one in order to induce clustering knowledge for WikiFANE$_{Gold}$.

The Brown algorithm was run in order to cluster the tokens into 1000 clusters, as suggested in (Miller et al., 2004; Liang, 2005; Ratinov and Roth, 2009; Tkachenko et al., 2012). The output of the Brown algorithm (which involves 1000 clusters) was injected as a set of features by extracting the clustering

Corpus	Development			Test			+|-
	P	R	F	P	R	F	
NewsFANE$_{Gold}$	86.13	70.38	77.46	81.66	68.36	74.42	+4.74
WikiFANE$_{Gold}$	77.80	62.36	69.23	79.87	60.19	68.64	+5.76
WikiFANE$_{Selective}$	89.17	74.04	80.90	88.64	73.18	80.17	+2.36
WikiFANE$_{Whole}$	90.39	69.97	78.88	84.98	65.00	73.66	+11.63

Table 8: The results of the injecting the output of Brown clustering into the CRF model

bits of (4, 6, 8, 10, 12) in a way that is similar to that presented by (Turian et al., 2010; Tkachenko et al., 2012). The reason behind this representation of the output is to allow a flexible level of grouping tokens into semantic clusters. For example, the tokens '**البخاري**' and '**الحازمي**' are clustered into '000011000101' and '000011000110', respectively, where both are personal NE. They share the first 10 bits of the cluster. This information allows for the extraction of useful knowledge to classify both tokens into the same class.

Table 8 shows notable improvement across all corpora. WikiFANE$_{Whole}$ and WikiFANE$_{Gold}$ score the highest, while other corpora gain improvements. It can be seen that the recall has sharply improved for approximately 7 to 13 points for NewsFANE$_{Gold}$, WikiFANE$_{Gold}$ and WikiFANE$_{Whole}$. This implies that the injecting of Brown clusters has improved the recall metric as a means of delimiting an increased number of NE phrases.

7 Related Work

This paper has addressed a series of issues, along with a discussion of the literature relevant to the context discussed in each section. Additional works of particular relevance are noted here. A large number of studies undertaking traditional Arabic NER have been developed, using a variety of methodologies to attain different goals. Using machine learning for the traditional task of NER has been addressed in different dimensions. Sequence labelling has also emerged, i.e. Maximum Entropy (Benajiba et al., 2007; Benajiba and Rosso, 2007); Support Vector Machine (Benajiba et al., 2008a); Conditional Random Fields (Benajiba and Rosso, 2008) and Structured Perceptron (Farber et al., 2008). Other hybrid approaches reliant on rule-based and ML are presented by (Shaalan and Oudah, 2013), a semi-supervised pattern is described in (AbdelRahman et al., 2010; Althobaiti et al., 2013) and the involvement of machine translation system to boost the performance of NER presented by (Zitouni and Florian, 2008). The researcher is not aware of any study tackling the fine-grained level of Arabic NER. Even that which has been developed for other languages (such as English) remains limited (Ling and Weld, 2012).

In terms of the representation of features, almost all studies in the Arabic NER apply the predefined window-based representation as examples when using this approach (Shaalan and Oudah, 2013; Benajiba et al., 2009). In English, Ratinov and Roth (2009) implemented two ways of capturing non-local features. The first approach is 'context aggregation'. This works by searching the entire document for a given token and returning the context of size two around each matched token. Ratinov and Roth (2009) limited the search to within 200 tokens. The second approach is 'extended prediction history', which looks up the 1000 previous tokens and counts the frequency of the label of the target class.

8 Conclusion

The majority of attempts to date to address NER focus on a limited number of semantic classes. This limitation has implications for other applications, such as question answering. This paper has presented an extended series of experiments and ideas, with the aim of constructing a fine-grained NER detailing resource creation to evaluation. Two approaches have been presented that rely on the output of the dependency parser and the clustering algorithm, instead of on a local window-based representation.

Prior-informed Distant Supervision for Temporal Evidence Classification

Ridho Reinanda

derijke@uva.nl

Abstract

Temporal evidence classification, i.e., finding associations between temporal expressions and relations expressed in text, is an important part of temporal relation extraction. To capture the variations found in this setting, we employ a distant supervision approach, modeling the task as multi-class text classification. There are two main challenges with distant supervision: (1) noise generated by incorrect heuristic labeling, and (2) distribution mismatch between the target and distant supervision examples. We are particularly interested in addressing the second problem and propose a sampling approach to handle the distribution mismatch. Our prior-informed distant supervision approach improves over basic distant supervision and outperforms a purely supervised approach when evaluated on TAC-KBP data, both on classification and end-to-end metrics.

1 Introduction

Temporal relation extraction is the problem of extracting the temporal extent of relations between entities. A typical solution to the temporal relation extraction problem has three main components: (1) *passage retrieval*, (2) *temporal evidence classification*, and (3) *temporal evidence aggregation*. A community-based effort to evaluate temporal relation extraction was introduced in 2011 as a TAC Knowledge Base Population task: Temporal Slot Filling, or TSF for short (Ji et al., 2011).

An illustration of temporal slot filling is as follows. Having identified a `per:spouse` relation between two entities (Freeman Dyson, Imme Dyson), a system must establish the temporal boundaries from its supporting sentence. In the case of the sentence "*In 1958, he married Imme Dyson*", the goal is to find that the relation lasts from 1958 until the present day. Within the TSF setting, the boundaries are represented as beginning and ending intervals in a tuple (T_1, T_2, T_3, T_4) instead of an exact time expression, so as to allow uncertainty in the system output. We investigate temporal relation extraction following this setting. We focus on the temporal evidence classification part.

One of the challenges with relation extraction is the limited amount of training data available to capture the variations in a target corpus: temporal relation extraction faces the same challenge. Employing distant supervision (Mintz et al., 2009) is a way to address the challenge. But generating example training data in the temporal setting is not straightforward: we have to find not only the query and related entity, but also the time expression, in a single text segment.

Employing distant supervision for temporal evidence classification will introduce noise, in the form of labels and additional contexts (e.g., lexical features). A lot of previous work in distant supervision has been dedicated to reducing noise in distant supervision (Bunescu and Mooney, 2007; Riedel et al., 2010; Wei et al., 2012). We are interested in another phenomenon: the class distributions found in training data generated by a distant supervision approach. These distributions become an issue if the distant supervision corpus has a different structure and different characteristics compared to the target corpus, e.g., Wikipedia vs. news articles. We observe that in the case of temporal evidence, news articles and Wikipedia do indeed contain different class distributions. Our working hypothesis is that incorporating prior information about temporal class distribution helps improve our distant supervision approach. We

Proceedings of COLING 2014, the 25th International Conference on Computational Linguistics: Technical Papers, pages 996–1006, Dublin, Ireland, August 23-29 2014.

test this hypothesis by comparing a distant supervision strategy with class priors to a distant supervision without class priors. We also demonstrate the effectiveness of our method by contrasting it with a purely supervised approach. In addition, we investigate how the difference in performance in temporal evidence classification affects the final score obtained in the overall end-to-end task.

We discuss related work in Section 2. In Section 3, we describe our distant supervision approach for temporal evidence classification. Our experimental setup is detailed in Section 4. We follow with results in Section 5 and a conclusion in Section 6.

2 Related Work

We discuss two groups of related work: on temporal slot filling and on distant supervision.

2.1 Temporal slot filling

Some previous work uses a pattern-based approach (Byrne and Dunnion, 2011); patterns are defined in terms of query entity, temporal expression, and slot value. For example, the word *divorce* should trigger that the relation *per:spouse* is ending. Other work uses temporal linking between time expressions and events in an event-based approach (Burman et al., 2011), where the source documents are annotated with TimeML event annotations (Pustejovsky et al., 2003); the authors use intra-sentence event-time links, and inter-sentence event-event links, following a TempEval approach (UzZaman et al., 2012). Garrido et al. (2012) use a graph-based document representation; they convert document context to a graph representation and use TARSQI to determine links between time expressions and events in documents and later map the resulting links into five temporal classes.

Li et al. (2012) combine flat and structured approaches to perform temporal classification. Their approach relies on a custom SVM kernel designed around flat (window and shallow dependency) features and structured (dependency path) features. The structured approach is designed to overcome the long context problem. They use a distant supervision approach for the temporal classification part, obtained on Freebase relations. They further extend their approach with self-training and relabeling (Ji et al., 2013).

Finally, Surdeanu et al. (2011) use n-grams around temporal expressions to train a distant supervision system. To be able to use Freebase facts, they find example sentences in Wikipedia, and use a window of five words from the temporal expression, using Freebase facts as *start* and *end* trigger. They use Jaccard correlation between n-grams to determine the association to *start* and *end*. Sil and Cucerzan (2014) performed distant supervision using facts obtained from Wikipedia infoboxes. From Wikipedia infoboxes, they retrieve the relevant sentences and build n-gram language models of the relations. In a slightly different setting (exploratory search), Reinanda et al. (2013) establish the temporal extent of entity associations simply by looking at their co-occurrence within documents in the corpus.

Our approach to temporal evidence classification differs from most existing approaches in its distant supervision scheme. We use distant supervision to directly perform a multi-class classification of temporal evidence against the five main temporal classes (including the *before* and *after* class), where most of the previous systems train a model to detect the beginning and ending of relationships only.

2.2 Reducing noise in distant supervision

With distant supervision (Mintz et al., 2009), indirect examples in the form of relations from a knowledge base such as Freebase and DBPedia are used. From these relation tuples, instances of relations in the form of sentences in the corpus are searched. Text features are later extracted from these sentences that are then used to train classifiers that can identify relations in the text corpus.

Reducing noise is an important ingredient when working with a distant supervision assumption. Relabeling is one such approach; Tamang and Ji (2012) perform relabeling based on semi-supervised lasso regression to reduce incorrect labeling. Wei et al. (2012) show that instances may be labeled incorrectly due to the knowledge base being incomplete. They propose to overcome the problem of incomplete knowledge bases for distant supervision through passage retrieval model with relation extraction.

Ritter et al. (2003) focus on the issue of missing data for texts that contain rare entities that do not exist in the original knowledge base. Riedel et al. (2010) work with a relaxed distant supervision assumption; they design a factor graph to explicitly model whether two entities are related, and later train this model with a semi-supervised constraint-driven algorithm; they achieve a 31 percent error reduction.

Bunescu and Mooney (2007) introduce multiple instance learning to handle the weak confidence in the assigned label. They divide the instances into a positive bag (at least one positive example) and a negative bag (all negative examples). They design a custom kernel to work with this weaker form of supervision. Surdeanu et al. (2012) operate on the same principle, but model the relation between entities and relation classes using graphical models. Hoffmann et al. (2011) also use multi-instance learning, but focus on overlapping relations.

What we add on top of existing work is the use of sampling techniques to correct for skewed distributions introduced through distant examples. We propose prior sampling, correcting the distributions of the classes in the generated examples to fit the target corpora.

3 Method

The temporal slot filling task is defined as follows: given a relation R = (q, r, s), where q is a query entity, r is a related entity, and s is a slot type, one must find T_R, a tuple of four dates (T_1, T_2, T_3, T_4) where R holds, where T_1 and T_2 form the beginning interval of the relation, and T_3 and T_4 is the ending interval. A system first must retrieve all passages or sentences expressing the relation between q and r. Each sentences and any time information within them will serve as intermediate evidence. This temporal evidence will later be aggregated and converted to tuple representation T_R.

In this paper, we focus on *temporal evidence classification*. That is, assuming the passage retrieval component has retrieved the relevant passages as intermediate evidence of temporal relations, we must classify whether the time expression t in the passage belongs to one these classes: BEGINNING, ENDING, BEFORE, AFTER, and WITHIN. In the training and evaluation data available to us, only the offsets of the time expression within the document are given for each intermediate evidence, therefore we first extract the paragraph and find the context sentence mentioning t.

Distant supervision for temporal classification The temporal slot filling task, as specified by TAC-KBP, defines 7 types of temporal-intensive relations. In our distant supervision approach, we use a separate knowledge base to find instances of the equivalent relations. We use Freebase as our reference knowledge base. That is, we use the temporal information found in Freebase to generate training examples. We manually map the TAC-KBP's 8 temporal relations into 6 Freebase mediator relations. The complete mapping of the relations can be found in Table 1.

In an article, entities and time expressions are not always referred to using their full mentions within a single sentence. Sometimes information is scattered around several sentences: the query entity q in the first sentence, later referred to using a pronoun in the second sentence that contains a time expression, etc. One common way to deal with this problem is to run full co-reference resolution, therefore ensuring all mentions are resolved. We handle this problem by relaxing the distant supervision rule. Rather than retrieving sentences, we retrieve passages containing the query entity q, and related entity r instead. We later replace every pronoun found within the passage with q. Based on our analysis of the Wikipedia articles, this simple heuristic should work, because most Wikipedia articles are entity-centric, and a lot of the pronouns mentioned in the articles will refer to the query entity q.

Each relation that we mapped from Freebase has temporal boundaries *from* and *to*. Following Li et al. (2012), we use Algorithm 1 to generate the training examples, but adapt it suit to our assumption.

Sampling the DS examples We manually compared our main corpus (TAC document collection) and our distant supervision corpus (Wikipedia) and noticed some discrepancies. The main corpus mainly consists of newswire articles; one of the main difference between Wikipedia articles and newswire articles is that Wikipedia articles mainly consist of milestone events. In terms of class distribution, this means that most of the generated examples will be in the form of BEGINNING and ENDING class, followed by the BEFORE and AFTER class, with the smallest number of examples belonging to the

TAC Relations	Freebase Relations
per:spouse	marriage
per:title	employment-tenure, goverment-position-held
per:employee-of	employment-tenure
per:member-of	political-party-tenure
per:cities-of-residence	places-lived
per:stateorprovinces-of-residence	places-lived
per:countries-of-residence	places-lived
org:top-employees/members	organization-leadership

Table 1: Relation mapping to Freebase.

Data: Freebase temporal relation (q, r, $from$, to)
Result: labeled training examples
Retrieve the Wikipedia article of the query entity q;
Split article into passages;
Retrieve the passages containing q, r;
Extract all time expressions from the passages;
for *time-expression* t **do**
    Retrieve the context sentence s containing t;
    If t is $from$: use s, t as BEGINNING example;
    If t is to : use s, t as ENDING example;
    If t before $from$: use s, t as BEFORE example;
    If t after to : use s, t as AFTER example;
    If t between $from$ and to : use s, t as WITHIN example;
end

Algorithm 1: Training data generation.

WITHIN class. In newswire, however, we tend to see something different; most of the time expressions will belong to the WITHIN class.

We argue that using the training data with a "smarter" prior is important. More data not only means more information, but may also mean more noise. This is particularly important with the *relaxed distant supervision* assumption that we have. Therefore, we choose to sample instead of using all of the generated training examples.

We employ two sampling strategies: *uniform*, sampling from our generated training data and deliberately fitting them to a uniform distribution; and *prior-sampling*, where we deliberately construct training data to fit a prior distribution. One way to estimate such a prior is by looking at the distributions of classes in the gold-standard training data that we have. In the case where gold-standard data is not available, we can use a heuristic to estimate the distributions of temporal classes based on domain knowledge or on observations of the target corpora.

In summary, we generate the final training data according to the following steps. First, generate training data with the DS approach described before. Next, estimate class distributions from the (supervised) training data. Then, sample examples from the generated DS data with the probability estimated from the supervised training data (i.e., the empirical prior). Keep sampling the training examples until we

reach the target percentage of the DS data. Finally, use the sampled training data to train the multi-class classifier.

Feature representation Both for the training, evaluation, and DS data, we extract the context sentence, i..e, the sentence containing the relation and time expression t.

We normalize the context sentence as follows. First, we detect named entities within the sentence and replace the mentions with their entity types (PERSON, ORGANIZATION, or LOCATION). Second, we detect other time expressions within the context and normalize them with regard to the main time expression t, i.e., by normalizing them into TIME-LT and TIME-GT. The idea is to capture the relationships between time expressions as features.

We extract lexical features from the normalized sentence. This comprises tokens surrounding the query entity, related entity (slot filler), and time expression. We consider the following four models as our feature representations:

Model-1: bag-of-words All tokens within the normalized sentences are used as features.

Model-2: context window All tokens within the proximity of 3 tokens from the query entity, related entity, and time expression are used as features.

Model-3: context window with trigger words lexicon All tokens within the proximity of 3 token from the query entity, related entity, and time expression are used as features. In addition, a list of keywords which might indicate the beginning and ending of relationships are used as gazetteer features. These list of keywords are expanded by using WordNet to extract related terms.

Model-4: context window with position All tokens within the proximity of 3 tokens from the query entity, related entity, and time expression are used as features. Rather than considered as bag-of-words tokens, the positions of word occurrences are now taken into account as features.

4 Experimental Setup

We introduce the dataset and the setup of our experiments. Before that we formulate our research questions as these dictate our further choices.

Research questions We aim to answer the following research questions:

RQ1 How does a purely supervised approach with different features and learning algorithms perform on the task of temporal evidence classification?

RQ2 How does the performance of a distant supervision approach compare to that of a supervised learning approach on the task of temporal evidence classification?

RQ3 How does the performance of a prior-informed distant supervision approach compare to that of a basic distant supervision approach on the task of temporal evidence classification?

RQ4 How do the approaches listed above compare in terms of their performance on the end-to-end temporal relation extraction task?

Corpora and knowledge base We use the TAC 2011 document collection, which contains 1.7M documents, consisting of news wires, web texts, broadcast news, and broadcast conversation. We use a recent version of Freebase (October 2013) as our knowledge base and retrieve the latest version of Wikipedia as our distant supervision corpus.

Ground truth We use the TAC-KBP 2011 Temporal Slot Filling Task dataset (Ji et al., 2011) as the ground truth in our experiments. The ground truth comes in two forms: intermediate evidence (with classification labels) and tuples (boundaries of each relation). We use the intermediate evidence to evaluate our temporal evidence classification framework. We later use the provided tuples to evaluate the end-to-end result.

The dataset contains 173 examples in the training set and 757 examples in the evaluation set. The distribution of the classes is shown in Table 2.

Class	Training	Evaluation	DS Training
WITHIN	66	357	6,129
BEGINNING	59	217	22,508
ENDING	30	110	16,775
BEFORE	9	45	24,932
AFTER	9	28	12,499

Table 2: Class distribution statistics.

Evaluation metric We use F1 as the main evaluation metric for the temporal evidence classification task. For the end-to-end temporal information extraction task, we use the evaluation metric proposed in TAC-KBP 2011, i.e., the Q score. Given a relation r and the ground truth interval tuple G_r, $Q(T_r)$, the quality score of a tuple T_r returned by system S is computed as follows:

$$Q(T_r) = \frac{1}{4} \sum_{i=1}^{4} \frac{1}{1+d_i},$$

where d_i is the absolute difference between T_i in system response and the ground truth tuple G_i (measured in years). To obtain an overall system Q score, we average the Q scores obtained from each relation tuple returned.

Experiments We run four contrastive experiments. In Experiment 1, we contrast the performance on the temporal evidence classification task of the different choices for our supervised methods (Model-1, -2, -3, -4), using either Support Vector Machine, Naive Bayes, Random Forest, or Gradient Boosted Regression Tree. In Experiment 2 we examine our distant supervision method and contrast its performance with the supervised methods from Experiment 1. In Experiment 3, we contrast different sampling methods for our distant supervision method.

In Experiment 4 we consider the overall performance on the temporal relation extraction task of our methods; in this experiment we use three "oracle runs" that we have not introduced yet: first, the *Label-Oracle* run uses the actual temporal classification label from the ground truth, use these ground truth label to aggregate the evidence and create the temporal tuples, and compute the end-to-end score; second, *Within-Oracle* assigns all temporal evidence to the WITHIN class; third, *Nil-Baseline* is a lower-bound run that assigns NIL to every element of the temporal tuples.

We use the implementations of the learning algorithms in the Scikit-learn machine learning package (Pedregosa et al., 2011).

5 Results and Discussion

We present the outcomes of the four experiments specified in the previous section.

5.1 Preliminary experiment

To answer RQ1, *How does the performance of the supervised learning approaches on the temporal evidence classification task vary with different representations and learning algorithms?*, we start with a preliminary experiment. The aim of this experiment is to get an idea of the classification performance with a purely supervised approach. The results are shown in Table 3.

As shown in Table 3, Model-4 with the SVM and NB classifiers achieves the best overall performance. There seems to be a gradual increase in performance from the simpler to the more complex model with SVM and NB classifiers, with the exception of RF. Interestingly, GBRT seems only slightly affected by the different choice of model in this supervised setting.

5.2 Distant supervision experiments

Next, we evaluate the distant supervision approach. We aim to answer RQ2, *How does the performance of the distant supervision approach compare to that of the supervised learning approach?* We generate

Model	SVM	NB	RF	GBRT
Model-1	0.405	0.361	0.402	0.422
Model-2	0.409	0.417	0.354	0.420
Model-3	0.412	0.418	0.361	0.420
Model-4	**0.426**	0.424	0.241	0.422

Table 3: Experiment 1. Supervised approaches to temporal evidence classification.

training examples with the approach described in Section 3, and use the full generated training data to train SVM and Naive Bayes classifiers with the same representation models that we use in the previous experiments. The results are shown in Table 4.

Model	Supervised	DS	DS-uniform	DS-prior
Model-1 SVM	0.405	0.212	0.379	0.408
Model-2 SVM	0.409	0.185	0.389	0.450
Model-3 SVM	0.412	0.183	0.384	0.452
Model-4 SVM	0.426	0.200	0.400	0.463
Model-1 NB	0.361	0.413	0.379	0.431
Model-2 NB	0.417	0.299	0.372	0.451
Model-3 NB	0.418	0.300	0.368	0.446
Model-4 NB	0.424	0.270	0.400	**0.486**
Model-1 RF	0.402	0.162	0.406	0.397
Model-2 RF	0.354	0.177	0.399	0.418
Model-3 RF	0.361	0.176	0.391	0.403
Model-4 RF	0.241	0.171	0.399	0.446
Model-1 GBRT	0.422	0.142	0.316	0.344
Model-2 GBRT	0.420	0.137	0.343	0.418
Model-3 GBRT	0.420	0.138	0.343	0.403
Model-4 GBRT	0.422	0.140	0.399	0.433

Table 4: Experiment 2 and 3. Supervised, distant supervision, and distant supervision with sampling approaches to temporal evidence classification.

We observe that the distant supervision approach trained on the full set of generated examples (the column labeled "DS") performs poorly, well below the supervised approach. We hypothesize that the accuracy drops due to the amount of noise generated with our distant supervision assumption trained from full data, and different class distribution statistics.

In Section 3, we proposed our prior-sampling approach for distant supervision. The next experiment is meant to answer RQ3, *How does the performance of our prior-informed distant supervision approach compare to that of the basic distant supervision approaches?* We sample 20 percent of the generated examples datasets with the following strategies: *uniform* and *prior*. The results are also shown in Table 4, in the columns labeled "DS-uniform" and "DS-prior," respectively.

By observing the results in Table 4, we notice that distant supervision with prior sampling performs the best, for every combination of model and classification method. *Uniform* sampling already helps in improving the performance, and prior sampling successfully boosts the performance of the basic distant supervision (for all four models) further. Distant supervision with prior sampling also performs consistently better than the supervised approaches (Table 3) in many cases—interestingly, for GBRT, DS-prior only outperforms the supervised methods with sufficiently complex queries (Model-4 GBRT).

5.3 End-to-end experiments

Next, we answer RQ4. That is, we consider how the classification performance on temporal evidence classification affects the end-to-end result. We take the best performing models from the previous experiments and evaluate their end-to-end scores. The results are shown in Table 5.[1]

Model	Avg-Q	F1
Label-Oracle	0.925	1.000
Within-Oracle	0.676	0.302
Nil-Baseline	0.393	N/A
Supervised		
Model-4 SVM	0.657	0.426
Model-4 NB	0.648	0.424
Model-4 RF	0.573	0.241
Model-4 GBRT	0.649	0.422
Distant supervision		
Model-4 SVM	0.669	0.463
Model-4 NB	0.679	0.486
Model-4 RF	0.653	0.446
Model-4 GBRT	0.669	0.433

Table 5: Experiment 4. End-to-end scores (Avg-Q) next to F1 scores for temporal evidence classification.

From Table 5, we see that Model-4 RF (F1 on temporal evidence classification 0.446) and Model-4 GBRT (F1 on temporal evidence classification 0.433) translate into 0.653 and 0.669, respectively, in terms of Q-score. This means that the misclassifications that Model-4 RF produces have a larger impact than those of Model-4 GBRT. However, the difference in performance is not large.

The evaluation of this end-to-end task is important because not every misclassification has a similar cost. Misclassification of class A into class B can result in a huge increase/decrease in performance. First, the classification performance does not directly map to the end-to-end score. Second, several relations have more pieces of evidence than others; performing misclassifications on relations that have a lot of supporting evidence would probably have less effect on the final score.

The state of the art performance, using distant supervision (Li et al., 2012), achieves an end-to-end Avg-Q score of 0.678 (on training data), where we achieve 0.679 (on evaluation data). However, our scores are not directly comparable since we reduce the number of classes (and the amount of evidence) in our evaluation. It is important to note that Li et al. (2012) use a complex combination of flat and structured features as well as the web, where we use relatively simple features with Wikipedia and prior sampling.

Furthermore, our approach manages to achieve the same level of end-to-end performance as the Within-Oracle run, while achieving a significantly better F-score. More pieces of evidence were actually classified correctly, though this was not reflected directly in the end-to-end score due to issues described above.

5.4 Error Analysis

We proceed to analyse parts of our end-to-end results to see what is causing errors in the temporal evidence classification task. We found several common problems.

Semantic inference Some problems had to do with the fact that several snippets require semantic inference. The fact that someone dies effectively ends any relationships that this person had. Another example is when someone marries someone (A marries C), and this beginning of relationships effectively

[1] As the Nil-Baseline is applied directly to the final tuples rather than the classification labels, there are is no F1 score for this run.

means the end of relationships for previous relations (A and B). A more complex method to deal with this type of semantic inference is needed, simple classification does not work so well. Here is an example:

> *Angela Merkel is married to Joachim Sauer, a professor of chemistry at Berlin's Humboldt University, since 1998. Divorced from Ulrich Merkel. No children.*

For this example the fact is that the time expression 1998 happens *after* with regard to the *spouse* relation between Angela Merkel and Ulrich Merkel.

Concise temporal representations Newspaper articles contain lots of temporal information in a concise way. For example in the form (X–Y). This implicit interval range is not expressed in a lexical context but rather with symbolic conventions. In several articles, the information encoded is almost tabular rather than expressed in explicitly. For example:

> *Elected as german chancellor Nov. 22, 2005. Chairwoman, christian democratic union, 2000-present. Chairwoman, christian democratic parliamentary group, 2002–2005.*

Complex time-inference BEFORE and AFTER are especially tricky to deal with because they require additional inference. Even if a passage contains the word *after*, the time expression linked to it would probably contain the *before* relation.

> *He was called up by the Army in the spring of 1944, after marrying bea silverman in 1943, and was sent to The Philippines.*

For the above example, 1943 happens *before* the "person joined the Army" event.

We observe quite a number of these cases on the evaluation data. Furthermore, the lack of context on some examples and evidence that is scattered around multiple sentences complicates the problem even more. Because of semantic and implicit evidence, temporal evidence classification remains a challenging task. In order to achieve a better absolute performance, collective classification/inference of evidence seems an interesting option.

6 Conclusion

We have presented a distant-supervision approach to temporal evidence classification. The main feature of our distant supervision approach is that we consider the prior distribution of classes in the target domain in order to better model the task. We show that our prior-informed distant supervision approach manages to outperform a purely supervised approach. Our method also achieves state-of-the-art performance on end-to-end temporal relation extraction with fewer and simpler features than previous work.

Our error analysis on the temporal evidence classification task revealed several issues that inform our future work aimed at further improving the performance on the subtask of temporal evidence classification, and the overall temporal relation extraction task. In particular, we intend to deal with the challenging aspect of semantic inference over relations found in the evidence passage. Another interesting direction that we aim to tackle is dealing with evidence that is scattered across multiple sentences.

Abstract

This paper proposes the definition, classification and structure of the Kazakh basic phrases, and sets up a framework for classifying them according to their syntactic functions. Meanwhile, the structure of the Kazakh basic phrases were analyzed; and the determination of the Kazakh basic phrases collocation and extraction of the Kazakh basic phrases based on rules were followed. The Maximum Entropy (ME) model uses for the identification of the phrases from texts and achieved a result of automatic identification of Kazakh phrases with an accuracy of 78.22% based on rules System and additional artificial modification. Design feature of this ME model join rely on templates of Kazakh Word, part of speech, affixes. Experimental results show that the accuracy rate reached 87.89%.

1 Introduction

Automatic phrase identification is an important task in natural language processing. A phrase is a group of words that work together. Phrase recognition is a grammatical unit agent between words and sentences in natural language processing. Phrase identification Parser has been developed for different languages, for example, the Church's Base NP Recognition for English (Church, 1988). The rule-based Model and Maximum Entropy Model (ME) are the most commonly used technology for phrase representation and parsing.

Kazakh Language belongs to the Turkish Language group in the Altaic language family. It is an agglutinative language with word structures formed by adding derivational or inflectional affixes to root words. Phrase identification is also an indispensable part for Kazakh information processing. In the past a few year, we have put forward methods for Kazakh morphological analysis, which includes stem extraction, part of speech(POS) tagging, spelling check, etc. Recently, we are working on syntax parsing, analysis of phrase structure, automatic identification of phrase and in-depth analysis of sentence structure.

Kazakh phrases are syntactic units consisting of two or more than two words. The phrases can be classified into two categories, which are free phrase and fixed phrase. We are exploring methods which are more suitable for shallow syntactic parsing of Kazakh according to the nature of Kazakh language. The research includes a systematic study on information regularity and disambiguation of the Kazakh phrase, and automatic recognition of basic phrases of Kazakh language. We have developed a rule-based method for the automatic recognition of Kazakh basic phrases, and automatic identification of verb phrase, noun phrase and adjective phrase based on maximum entropy in Kazakh language at the same time. Moreover, the ambiguity of structures is also resolved based on rules.
This study solves the problem of Kazakh phrase recognition by providing some effective methods. This sets up a basis for further syntactic process and tree bank building. This research also provides a way to build database for various fields like knowledge acquisition, syntactic understanding, Chinese-Kazakh machine translation, the process of large-scale corpus, etc.

Proceedings of COLING 2014, the 25th International Conference on Computational Linguistics: Technical Papers, pages 1007–1014, Dublin, Ireland, August 23-29 2014.

In this paper, our work focuses on identifying noun phrases, adjective phrase and verb phrases, which are the most difficult aspects of Kazakh phrase recognition analysis. This is achieved by using rules are ME method.

2 Related work

There are a variety of techniques used for phrase recognition, which include rule-based technique, statistical technique, and a combination of them. Church's (1988) approach used manual or semi-automatic annotation phrase corpus as a training corpus. Another popular method is to use a Chunk parsing for statistics model to determine the boundary (Koeling, 2000). Chunk parsing was first introduced by Abney (1991), which is one of the most widely used syntactic parsing methods. The main idea of chunk parsing lies in seeking the appropriate breakthrough point, and decomposing the full parsing problems into a syntax topology statistical structure and syntactic relations. Zhao and Huang (1998) are pioneers in Chinese phrase studies; Tsinghua University had also completed its TCT (Tsinghua Chinese Treebank) for Chinese (Zhou, 2004). The method has been also applied into studies of other languages, such as Kazakh Base NP recognition (Altenbek et al, 2009), and Uyghur Base VP Recognition by CRF (Mamatmin et al, 2012).

Maximum Entropy was first introduced to NLP area by Berger et al (1996) and Della Pietra et al. (1997). Maximum Entropy is an extremely flexible technique for linguistic modelling. It can use a virtually unrestricted and rich feature set in the framework of a probability model. It is a conditional, discriminative model and allows mutually dependent variables (Ratnaparkhi, 1999).

3 Kazakh Phase Parsing

3.1 Kazakh Morphology

Morphological analysis is an important task in natural language processing research. It was developed for different languages, included English (Porter, 1980), Finnish (Karttunen, 1983), Turkish (Oflazer, 1994; Gülşen, 2004), and Arabic (Beesley, 1996).
Comparing with other languages, the Kazakh morphological system uses a large number of suffixes and a small number of prefixes. Every word has a root, or a stem (Milat, 2003;Zhang 2004). The basic Kazakh phrase is an adjacent and non-nested phrase which does not contain recursive structure.

3.2 The Categories of Kazakh Phrase

Parsing is one of the most basic and fundamental components in natural language processing. Chunk parsing intends to obtain a fragment without thinking deeply.

A Kazakh phrase is composed of two or more than two words which connected with meaning and grammatical structure. There is only a core word in a Kazakh phrase. In the case of Kazakh, Kazakh phrases can be divided into fixed phrases and temporary phrases by the meanings of the phrases.

Abney propose the first complete description of lexical chunks system. In this study the basic phrase chunks base was found according to Abney's system. The five most common phrase in Kazakh are

NO.	Category	Explanation	Example (Kazakh)	Example (English)
1	NP	noun phrase	التىن كۇز	The golden autumn
2	VP	verb phrase	مۇراتقا جەتۋ	Achieve dreams
3	ADJP	adjective phrase	تاپ – تازا	Very clean
4	NUMP	Numeral phrases	سەگىز توعىز مىڭ	Eight & nine thousand
5	ADVP	Adverb phrase	مڭ الدىندا عى	The front of

Table 1. Part of Kazakh phrase categories.

noun phrase, verb phrase, adjective phrase, Numeral phrases, Adverb phrase as shown in table 1. Kazakh language is rich in the external morphology which shows prominent in phrase structure.

3.3 The Basic Kazakh phrase mark specification

Basic Kazakh phrase marks both its own attribute, for example part of speech, stems and affixes, and types of phrase. We used IOB Tagging to mark the start and end of chunks.

Basic Kazakh phrase	start of chunks	Inner tag of chunks	Out tag of chunks
noun phrase	B-NP	I-NP	O
verb phrase	B-VP	I-VP	
adjective phrase	B-ADJP	I-ADJP	
Adverb phrases	B-ADVP	I-ADVP	
Numeral phrase	B-NUMP	I-NUMP	

Table 2. The Basic Kazakh phrase IOB Tagging.

4 Statistics and Analysis of Kazakh Phrase Structure

Referring to modern Kazakh grammar (Milat, 2003; Dingjing Zhong. 2004), the basic rules of phrase structure of Kazakh language was summarized. The phrase structures are extracted from the corpus, and a set of rules are created based on it as well.

In the representation of basic phrase structures, the following part of speech tagging symbols are used in XML documents of Kazakh corpus: v (verb), n. (noun), adj. (adjective), num. (number), adv. (adverb), pron. (pronoun), ono. (onomatopoeia), int.(interjections), conj. (conjunction), part. (partical). The Kazakh phrases Structure divided by the function of phrases in our system are shown below.

Kazakh verb phrase structure:

1) n+v; 2) v+v; 3) adv+v; 4) adj+v; 5) v+adv; 6) v+v+v; 7) pron+v; 8) n+part+v; 9) n+conj+v; 10) ono+v; 11) int+v; 12) v+part+v; 13)v+part; 14) v+conj+v; 15)pron+part+v.

Kazakh noun phrase structure:

1) n+n; 2) n+conj+n; 3) pron+conj+pron; 4) pron+n; 5) adj+conj+adj; 6) adj+n; 7) adj+adv+n;
8) num+n; 9) v+n; 10) [ ]+n.

Kazakh adjective phrase structure:

1) adj+n; 2) adj+v; 3) adj+n+v; 4) pron+adj; 5) adv+adj+n; 6) adj+adj+n; 7) num+adv+n;

Collocations, like v+adv, n+part+v, pron+adv, v+part+v, v+part, also exist in other phrase except verb phrase. These conditions easily cause ambiguity.

5 Rule-based phrase tagging

Kazakh language has two characteristics that have to be taken into account: agglutinative morphology and rather free word order with explicit case marking.

The corpus we used in this process has been already segmented. The way we extracted stem and affix was briefly mentioned in the paper. In this paper we used the segmented results of early work, as it is not the core part of the algorithm.

Input: word segmentation (extraction stem and affix) and POS tagged corpus (test.xml);

Output: First: Phrase tagged file; Second: Phrase file;

Based on the basic rules of phrase, we have done extraction of phrases from POS tagged Kazakh corpus. The extraction process is as follows:

(a) First roughly segmented XML corpus. The common segmentation marks include semicolon, comma, full stop, exclamation mark, question mark.

(b) For the segmented data, we extract the three elements of basic phrase: part of speech (POS), affix, and the word.

(c) Look for the matched rule in the rule set. If found, save the basic phrase. Otherwise go back step 1. According to combination rules of basic Kazakh phrase, basic phrase was extracted from corpus and modified by manual work. The correct combination of basic Kazakh phrase was marked.

6 Analysis of Kazakh phrase structure ambiguity

Ambiguity computer analysis of language structure has been one of the difficulties problems. This article from the delimitation ambiguity and structural relationship is to study two aspects of phrase structure ambiguity.

One of the difficulties in Kazakh phrase research is the phrase disambiguation problem. Ambiguous reasons is word POS ambiguity, phrase boundaries is not easy to determine, POS with the same sequence, E.g. there are five ambiguous forms:

(1) VD form (v + adv)

Eg.1a : adv/تومەندەۋ v/قابىلداۋى is verb phrase. (Admission to reduce)

Eg.1b : adv/مەكشە v/قابىلدۇى is adverb phrase. (Admission to more than)

(2) ND for (n+adv, pron+adv)

Eg.2a : adv/جاڭالاۋ n/كيىمىن is verb phrase.(Change a new clothes)

Eg.2b : adv/كەرەمەت n/ناتيجەسى is adverb phrase.(Good record)

(3) NPV form （ n+part+v, pron+part+v)

Eg.3a : v /ۇيرەنۋ part /تۇرالى n /بىرلىك is verb phrase.(Learn about unity)

Eg.3b : v /دەى part / عانا n / اسان is noun phrase.(only Ashan)

(4) VPV form (v+part+v)

Eg.4a : v /كەتتى part /دە v / كەلدى is verb phrase.(came then left)

Eg.4b : v / تۇسىنۋ part /تۇرالى v / زەرتتەۋ is adverb phrase. (Relevant research to understand)

(5) VP form (v+part)

Eg.5a : part / بۇرىندىاۋ v / سويلەۋدەن is verb phrase.(Speaking before)

Eg.5b : part / جونىندە v /رەتتەۋ is verb phrase.(Organize the relevant)

For these ambiguities, we can't simply use the rules to match ways to eliminate, but rather to use maximum entropy model to solve the problem.

7 Kazakh Phrase Identification based Maximum Entropy Model

Maximum Entropy Model is an effective machine learning model which is proposed to solve the POS tagging problem, it using ME model is the ability to incorporate various features into the conditional probability. The Kazakh phrase recognition task is presented as follow.

The entropy model P: $H(p) \equiv -\sum_{x,y} p(x,y)\log(x,y)$ (1)

Note: X represents the environmental context words to be marked and y is the output.

Maximum Entropy Model： Such a model can be shown to have the following form:

$$p^* = \arg\max_{p \in C} H(p) \quad (2)$$

Goal: select a distribution p from a set of allowed distributions that maximizes H(y|X).

7.1 Feature defined

Kazakh language is an agglutinative language with word structures formed by adding derivational, inflectional affixes or suffixes to root words. The features include words, part of speech (POS), inflectional affixes of the training corpus. It seems that the features are naïve. However, these three kinds of features are the most important components of Kazakh language, and they reflect the characteristic of Kazakh language.

According to its own characteristics of a Kazakh, this feature space is defined as follows:

(1) *the word*, including the current word, the previous word and next word.

(2) *part of speech(POS)*, including the part-of-speech types of the current word, previous word and next word.
(3) *Affix ingredients*, including the current word and the word about the additional ingredient infomation.
(4) *Phrase tag* that contains the current word and the words to the right and the left two words Phrase marker.

This rule-based approach was applied to generate the maximum entropy model training corpus. Based on Kazakh linguistics, the atomic feature space is as shown in table 3.

Feature tag	Feature explanation	Feature tag	Feature explanation
W(-1)	previous one word	POS (-2) POS (-1)	POS of previous two word and POS of previous one word
W(0)	the current word	POS (-1) POS (0)	POS of previous one word and POS of the current word
W(+1)	next one word	POS (0) POS (+1)	POS of the current word and POS of next one word
W(-1) W(0)	previous one word and the current word	POS (+1) POS (+2)	POS of next one word and POS of next two word
W(0) W(+1)	the current word and next one word	POS (-2） POS (-1) POS (0)	POS of previous two word and POS of previous one word and POS of the current word
W(-1) W(0） W(+1)	previous one word and the current word and next one word	POS (-1) POS (0) POS (+1)	POS of previous one word and POS of the current word and POS of next one word
POS (-2)	POS of previous two word	POS (0) POS (+1) POS (+2)	POS of the current word and POS of next one word and POS of next two word
POS (-1)	POS of previous one word	Affix(-1)	affix of previous word
POS (0）	POS of the current word	Affix(0)	affix of current word
POS (+1)	POS of next one word	Affix(1)	affix of next one word
POS (+2)	POS of next two word		

Table 3. Atomic feature templates.

7.2 Feature selection

Basic phrases with statistical model recognition need to select a high correlation, and the Kazakh language features to train with good effect. Establish model based on rule of the language, this work selected feature through templates. After several rounds of experimental debugging, then used artificial selection, twenty one templates were selected for Kazakh verb phrase, only considered important features. According to each one's feature, templates were defined as follow.

No.	template	No.	template	No.	template
1	LPos,Cpos,RPos	8	CVP,RVP,RRVP	15	CWord,RWord
2	LLPos,Lpos,CPos	9	LVPCPosRVP	16	LPos,LVP
3	CPos,Rpos,RRPos	10	LPos, LAffix, LVP	17	RWord,RPos
4	CPos,CAffix,RPos	11	Cpos, CAffix, CVP	18	RPos,RVP
5	LPosLAffixCPos	12	CWord,RWord,RAffix	19	CPos,RPos
6	LVP,CVP,RVP	13	CWord,CPos	20	LPos,CPos
7	LLVP,LVP,CVP	14	LWord,LPos	21	LWord,LVP

Table 4. Combined feature of Kz Base VP.

In order to get the best template, this work structured and processed six template based on Table 4.

Each information function valued in the context of current word, combine the various function values into the premise of features, got the characteristics of the movement through the word tag, then it can extract features.

Template A: [RRPos, RRVP, RWord, RAffix, RPos, RVP, CPos, CVP, CWord, CAffix, LLPos, LLVP, LWord, LAffix, LPos, LVP] Observation of effects of all the words in the feature space on the result of the experiment.

Template B: [CPos, CVP, CWord, CAffix, LLPos, LLVP, LWord, LAffix, LPos, LVP] Observation of effects of left side two words of the candidate word on the result of the experiment.

Template C:[RRPos, RRVP, RWord, RAffix, RPos, RVP, CPos, CVP, CWord,CAffix] Observation of effects of right side two words of the candidate word on the result of the experiment.

Template D:[RWord, RAffix, RPos, RVP, CPos, CVP, CWord,CAffix, LWord, LAffix, LPos, LVP] Observation of effects of each side one word of the candidate word on the result of the experiment.

Template E:[RWord, RAffix, RPos, RVP, CPos, CVP, CWord, CAffix, LLPos, LLVP, LWord, LAffix, LPos, LVP] Observation of effects of left side two words and right side one word of the candidate word on the result of the experiment.

Template F:[RRPos, RRVP, RWord, RAffix, RPos, RVP, CPos, CVP, CWord, CAffix, LWord, LAffix, LPos, LVP] Observation of effects of left side one word and right side two words of the candidate word on the result of the experiment.

We selected some corpus from *Xinjiang Daily* tested on six features above, we got different influences of different characters. It shows that the C and F template give us the most highest result, namely the two words on the right have the biggest influence to the result. It proves Kazakh verb phrases are commonly at the end of the sentence.

7.3 General threshold selection

There are two general feature selection methods: incremental feature selection and feature selection of based on frequency threshold. The frequency is greater than a threshold value equal to a characteristic. Through repeating them many times, the frequency threshold value was characterized k = 5, characterized in that the use of the frequency characteristic is greater than 5.

8 Kazakh Phrase Recognition System

Kazakh phrase recognition system, which based on Maximum Entropy Model, consists of four modules, namely, pre-processing module, training module, Feature selection module, identification module. System training process as shown flow as figure 1.

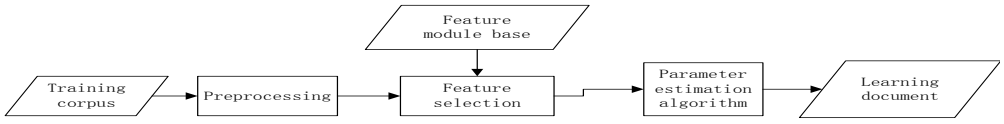

Figure 1. Training data flow diagram.

System testing process as shown flow as figure 2.

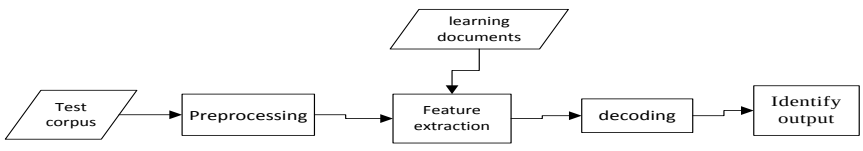

Figure 2. Testing data flow diagram.

The Kazakh basic verb phrase recognition results such as shown figure 3:

```
‹kaza_xml›
 ‹article id="&lt;*1b_1jN01001*&gt;"›
  ‹title›التاي شارۋالارى شەتەلگە شىعىپ جۇمىس ىستەپ، كىرىس تاپتى‹/title›
  ‹paragraph id="1"›
   ‹word pos="n" stem="ءتىلشى" affix="/ىمىز" var="0" vp="O"›ءتىلشىمىز‹/word›
   ‹word pos="n" stem="چىن" affix="" var="3" vp="O"›چىن‹/word›
   ‹word pos="n" stem="چىن" affix="" var="3" vp="O"›چىن‹/word›
   ‹word pos="n" stem="التاي" affix="/دان" var="4" vp="B"›التايدان‹/word›
   ‹word pos="v" stem="حابارلايدى" affix="" var="0" vp="I"›حابارلايدى‹/word›
   ‹punction›،‹/punction›
   ‹word pos="n" stem="قۇربان" affix="" var="5" vp="O"›قۇربان‹/word›
   ‹word pos="n" stem="ايت" affix="" var="1" vp="O"›ايت‹/word›
   ‹word pos="v" stem="كەل" affix="/ۋ" var="0" vp="B"›كەلۋ‹/word›
   ‹word pos="prep" stem="جونىندە" affix="" var="0" vp="I"›جونىندە‹/word›
   ‹punction›،‹/punction›
```

Figure 3. The Kazakh language basic verb phrase recognition.

By following a comprehensive analysis of Kazakh words, the following is the Kazakh shallow parsing process:

（1）Sentence：

قوڭىر كۇز كەلىپتى، قامبار سول جەرگە، قوي باعىپ كەلسە، ازىناعان كۇزدىڭ جەلى سوعىپ تۇرىپتى.

Golden autumn is coming, Hambar came to the place whish has very strong winds together with sheep.

（2）POS:

قوڭىر/n كۇز/n كەلىپتى/v، قامبار/n سول/pron جەرگە/n، قوي/n باعىپ/v كەلسە/v، ازىناعان/adj كۇزدىڭ/n جەلى/n سوعىپ/v تۇرىپتى/v.

（3）Phrase POS:

[[قوڭىر/n (Golden) كۇز/n (autumn) NP[كەلىپتى/v (is coming) VP[، [قامبار(Hamubar)/n سول/pron جەرگە/n] NP[[ازىناعان/adj كۇزدىڭ/n (the جەلى] AP]]] [كەلسە/v (came) VP[، [باعىپ/v VP] [قوي/n (sheep) NP[RP[، [سوعىپ/v very strong winds) NP[[تۇرىپتى/v (blowing. VP].

9 Experiment Results and Analysis

9.1 Data set

In this paper, according to the data set, we used the data of January 2008 of the *Xinjiang Daily* (Kazakh version) corpus. The corpus consists of the raw texts and the POS tagged XML format texts, experiments were done for phrase extraction.

9.2 Experiment results

The experiments of the accuracy rates are evaluated using as follow standard evaluation measures:

Precision: $P = \frac{a}{b} \times 100\%$ (3)

Recall $R = \frac{c}{d} \times 100\%$ (4)

F-measure $F = \frac{2 \times R \times P}{R + P}$ (5)

Note: a is number of correctly identified phrases. b is number of identified phrases. c is number of all phrases, d is number of should correct identify.

In the test corpus, there are 3000 correct tagged sentences as training data, and other 1000 sentences are for the test.

Method	Precision (%)	Recall (%)	F-measure (%)
Rule	78.22	70.01	85.25
ME	87.89	83.13	87.46

Table 5. Phrase recognition test.

10 Conclusion

This paper provided solution for identifying Kazakh basic phrases. We have tried rule-based and the maximum entropy methods. The Kazakh words, part of speech, affixes context information are used to design template of features for maximum entropy model. Based on statistical methods, higher accuracy could be obtained in the test, but it was requires more training data.

The recognition of basic Kazakh phrase could simplify sentence structure, reduce the difficulty of syntactic analyzer. This work put maximum entropy model into recognition of basic Kazakh phrase. However, there are still space for improvement on scale and accuracy rate comparing to English and Chinese. In the future, our work will focus on completing of corpus and other models.

Abstract

Most of the world's languages are under-resourced, and most under-resourced languages lack a writing system and literary tradition. As these languages fall out of use, we lose important sources of data that contribute to our understanding of human language. The first, urgent step is to collect and orally translate a large quantity of spoken language. This can be digitally archived and later transcribed, annotated, and subjected to the full range of speech and language processing tasks, at any time in future. We have been investigating a mobile application for recording and translating unwritten languages. We visited indigenous communities in Brazil and Nepal and taught people to use smartphones for recording spoken language and for orally interpreting it into the national language, and collected bilingual phrase-aligned speech recordings. In spite of several technical and social issues, we found that the technology enabled an effective workflow for speech data collection. Based on this experience, we argue that the use of special-purpose software on smartphones is an effective and scalable method for large-scale collection of bilingual audio, and ultimately bilingual text, for languages spoken in remote indigenous communities.

1 Introduction

Past the top one to three hundred economically significant languages, there are few prospects for resourcing the production of annotated corpora. Advances in natural language processing have relied on such corpora – including treebanks and wordnets – though they are expensive to produce and depend on substantial prior scholarship on the language. An alternative is to collect bilingual aligned text, relating a low-resource language to a high-resource language, and then infer lexical and syntactic information from the high-resource language via alignments (Abney and Bird, 2010; Baldwin et al., 2010; Palmer et al., 2010; Das and Petrov, 2011).

This approach only works for written languages. Over half the world's languages lack a literary tradition. In some cases they have a writing system, but it is not in regular use and so these languages remain effectively unwritten. Collecting data for unwritten languages necessarily involves speech.

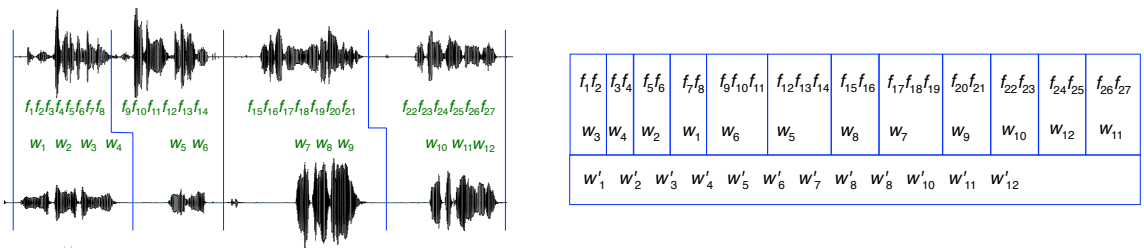

Figure 1: The Vision: phrase-aligned bilingual audio from an unwritten language to a language of wider communication, along with extracted acoustic features and crowdsourced transcription (left); interlinear glossed text with word segmentation, word-level glosses, and sentence-level translations (right).

Proceedings of COLING 2014, the 25th International Conference on Computational Linguistics: Technical Papers, pages 1015–1024, Dublin, Ireland, August 23-29 2014.

While the physical isolation of these languages presents a logistical challenge, it is still possible to collect hundreds of hours of speech using mobile devices (de Vries et al., 2014). Furthermore, there are promising signs that natural language processing methods and speech processing methods can be integrated (Zhang et al., 2004; Dredze et al., 2010; Vu et al., 2011; Siniscalchi et al., 2012; Lee and Glass, 2012). Thus, the challenge is to collect substantial quantities of bilingual aligned audio, transcribe the translations, extract phonetic features from the source language and, ultimately, produce bilingual aligned text (see Figure 1).

We have chosen to focus on endangered languages because of the interesting and difficult challenges that are faced in collecting data. However, the resource problem exists even for vital languages having large speaker populations. For example, Shanghainese (Wu) is spoken by 77 million people in China, but is almost never written down because written Chinese is based on Mandarin; Oromo is spoken by 17 million people in Ethiopia, but few of its speakers know how to write it. Such languages are collectively spoken by billions, yet remain seriously under-resourced. Thus, while our focus is on endangered languages, the approach applies to under-resourced languages in general.

Several other promising approaches to the problems raised by endangered languages are being actively pursued in computational linguistics, however they typically focus on written language with annotations, often with the goal of making optimal use of human expertise (Probst et al., 2002; Levin et al., 2006; Clark et al., 2008; Palmer et al., 2010; Bender et al., 2012; Beale, 2012; Bender et al., 2013). The research reported here is unique in its focus on securing spoken language data in a form and on a scale that will be usable even once the languages in question are no longer spoken.

This paper explores ways that networked smartphones can be used for collecting bilingual aligned audio. We have used a prototype Android application for collecting audio and phrase-aligned translations (or consecutive interpretations). We took a set of phones to villages in Brazil and Nepal, and worked with languages Tembé, Nhengatu and Kagate. We visited at the invitation of the local communities and collaborated closely with them in each stage of the process, including setting the goals and agreeing on the form of dissemination, cf. (Rice, 2011). We compiled small collections of recorded texts and translations in each language.

We describe and evaluate this novel resource-creation activity, and argue that it can be used effectively for large-scale collection of bilingual aligned audio. This paper is organised as follows. In section 2, we give an overview of the mobile software. The next three sections report the activities in the three communities. We reflect on the work in section 6.

2 Mobile applications for recording and translating endangered languages

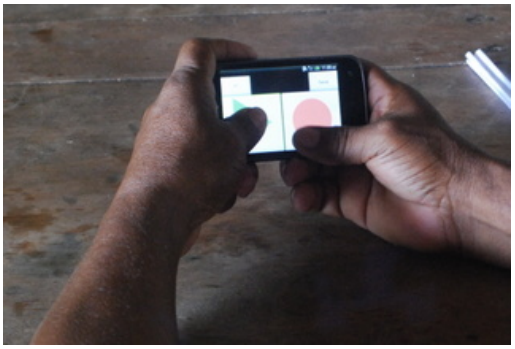
Smartphones are proliferating: they are part of the vanguard of technologies that make it into many isolated communities. Even in the most remote villages, many people own a mobile phone, keep it on their person, and are able to get it charged when mains electricity is unreliable or non-existent. These phones can be inexpensive (US$100-200) and some models have sufficient audio quality to be useful for speech data collection. With suitable software it is possible to collect metadata along with recordings, including location, date, the identity of the speaker, and possibly some information about the content such as the title and genre. The networking capability of a smartphone facilitates wireless sharing and backup.

The speech collection task calls for a variety of individual contributions. The best speakers of the language are not necessarily the best translators; they may be monolingual. Similarly, the best translators may not be the best transcribers; they may be illiterate. Thus, for reasons of skill, not just scale, we need to involve a whole team of people in the data collection activity. In the medium term, we assume that this work would take place under the supervision of a linguist who provides hardware and training, and who monitors the balance of the collection, including coverage of various discourse types, getting everything translated, and so forth).

Aikuma is open source software that supports recording of speech directly to phone storage (Hanke and Bird, 2013; Bird et al., 2014). Recordings are synchronized with other phones that are connected to the same WiFi LAN, so that any user can listen to recordings made on any phone in the same local

network. A user can "like" a recording to improve its overall ranking. A user can also provide a phrase-by-phrase spoken translation of the recording, using the interface shown in Figure 2. This functionality is based on the protocol of "Basic Oral Language Documentation" (Reiman, 2010; Bird, 2010).

(a) Recording a Tembé narrative



(b) Translating Tembé into Portuguese

Figure 2: Recording and translating using the Aikuma Android app

Users press and hold the left *play* button to hear the next segment of audio source. They can press it multiple times to hear the same segment over again. Once ready, they press the right *record* button and speak a translation of the source. This process continues until the source has been fully translated. It generates a second audio file that is time-aligned with the source (cf Figure 1). The app supports playback of the source, the translation, and the source with interleaved translation.

Aikuma maintains a database of speakers and synchronizes this to the other phones along with the recordings and titles, and keeps track of which speaker provided which recording. In this way, basic metadata resides with the recordings, and recordings are effectively backed up several times over. If the contents of one phone are periodically archived, then we have a permanent copy of all the recordings and metadata from all of the phones.

We used HTC Desire C and HTC Desire 200 phones which cost US$160 each. We chose these phones for their support of Android 4 and their recording quality. Unlike a professional audio set-up, mobile phone audio recording includes built-in noise suppression that is optimised for near-field voice sources and attenuates background noise. The software stores audio in uncompressed 16kHz 16-bit mono. The quality of the audio from these phones is more than sufficient to support phonetic analysis (Bettinson, 2013). We expect these materials to be considered of archival quality in those cases where the original recording environment was quiet and where the content itself has linguistic and cultural value.

Another advantage of smartphones compared with professional recording equipment is ease of recharging. Many remote indigenous communities without mains electricity are still able to keep phones charged with the help of generators and car batteries. By choosing to use mobile phones, we can piggy-back on the existing infrastructure.

The cost and usability of smartphones relative to professional recording equipment makes it easy to consider giving them out to people to make recordings in their own time. Apart from significantly increasing the amount of recorded and translated material that a linguist can collect, this gives speakers direct control over the content and context of the recordings, and it may lead to the collection of more naturalistic materials. In some cases, speakers already own an Android phone and can simply install the software and get started.

In the following three sections we report on our experience of using these phones with indigenous communities in the Amazon and the Himalayas.

3 Tembé, Pará State, Brazil

The Tembé language is spoken by approximately 150 people amongst a larger community numbering about 1,500, in a group of villages in the Reserva Alto Rio Guam in the vicinity of Paragominas in the Pará state of Brazil. Bird, Gelbart, and McAlister spent five days in the village of Cajueiro (*Akazu'yw*),

the gateway to several other Tembé villages that can only be accessed by river. Like many Indian villages, Cajueiro is laid out around a soccer field. The village was connected to the electricity grid ten years ago.

We recorded 14 texts from 8 speakers, mostly personal narratives but also a song and a dialogue. Most texts were orally translated; some were translated twice. Of two hours of source audio, 35 minutes were orally translated, producing an extra 25 minutes of audio.

Our visit to Cajueiro is mostly interesting for the great variety of unanticipated challenges, and how we were still able to use the platform to collect data.

Previous contact with the Tembé community was mediated by staff at the Goeldi Museum in Belém. The Tembé community had been discussing prospects for installing an antenna in Cajueiro to enable an Internet connection. On arrival, the chief asked about our plans to set up Internet access, and we explained that we were not able to do this because there was no signal for 100km. After this, the chief lost interest in our activities and we were not able to hold a village meeting as we had hoped, in order to discuss our work, invite participation, and demonstrate the use of the technology for recording and translation. Instead, we could only work one-on-one.

Our first 24 hours in the village was spent on video documentation of a coming-of-age ceremony. More elaborate versions of this ceremony had been filmed in the past, so there was minimal documentary value in recording this event. However, it was the basis for our invitation to the village, cf. (Crowley, 2007, 80), and it enabled us to meet the whole community and to observe the limited social interaction, almost exclusively conducted in Portuguese.

In the following days, we went around the village showing the app to people, explaining our work, playing existing recordings in Tembé and other languages, and trying to find fluent speakers who were motivated to preserve Tembé linguistic heritage. Few people claimed to be fluent and we only found six who were willing to be recorded, all men. No women would consent to being recorded until a Tembé man, trained as a computer technician, learnt how to use the app and took a handset and found two female speakers and recorded them. They were in their thirties, less confident with the language, and could only read haltingly from a small storybook. For the fluent speakers we were able to find, the documentary activity proceeded naturally; they easily recounted histories and gave phrase-by-phrase translations. We prepared a selection from our recordings and made audio CDs to give away for people to play on their personal stereos.

We experienced a variety of technical difficulties with the smartphones, none of which had been apparent during lab testing. The most obvious were due to people's unfamiliarity with smartphones. Signing in required entering the participant's name using a touchscreen keyboard, then selecting an ISO 639 language code via a search interface, then taking a photo using the phone. The photo could not be taken easily by the participant as the phones lacked a front-facing camera. Consequently, we generally took care of these tasks on behalf of speakers. Similarly, upon completion of a recording, the participant was prompted to enter a name for the recording, and we would reclaim the phone and enter a title after a brief discussion with the participant about a suitable choice.

Further problems concerned the translation task. A couple of participants began to give a Portuguese paraphrase immediately on finishing a story. Despite the obvious value of capturing an immediate paraphrase from the same speaker, the software was not designed for this and we had no way to capture the paraphrase as a separate audio file and link it back to the original. The thumb-controlled interface (Figure 2b) was also slightly problematic. Often a speaker would still be holding down the play button with his left thumb at the moment he went to press the record button with his right thumb. Sometimes, speakers would begin to speak and then notice that playback was still continuing, and only then release the play button. By the time they had pressed the record button again, they had already spoken a word or two, and this speech was not captured by the app. This problem happened often enough to interfere with the flow of the translation task. Possible solutions are to have the controls operated by a single thumb, or else to change the behavior of the app so that the most recent thumb gesture overrides a existing button press. Several other interactional issues with the software were identified and resolved with similar minor changes to behavior.

A final set of issues concerned dissemination. Many Indian villages are now equipped with computer

rooms and have desktop machines with CD burners, though mains electricity may be intermittent, or else depend on a generator. We were able to transfer files from the phones to a local machine using a USB connection, though it was a slow process to identify the recordings of interest to the participants and to compile an audio CD. Instead, we realised that any user of a phone should be able to export selected recordings to a local folder that could be burnt to CD.

The key problem for us, however, was lack of participation. The main reason for this, we believe, was the limited local interest in the Tembé language. A secondary factor was the misunderstanding about our contribution ("bringing the Internet") and the fact that the product, a CD of stories, was not necessarily something that the community wanted.

4 Nhengatu, Amazonas State, Brazil

The Nhengatu language is a creole spoken by 10,000 people across a wide area, including the village of Terra Preta, 50km NW of Manaus. Nhengatu used to be the language of communication amongst Indians from different tribes along the Rio Negro, and between Indians and non-Indians in the Brazilian Amazon. Although most of the inhabitants of Terra Preta are ethnically Baré, the only indigenous language spoken in the village is Nhengatu. Younger generations are monolingual in Portuguese. Unusually, there are also some non-Indians living in the village. The villagers were open to receiving us, partly due to their proximity to Manaus and the fact they were accustomed to meeting tourists and showing white people around and selling handcrafts. Compared with Cajueiro, there was a stronger sense of community in Terra Preta: on weekends they would have breakfast together in a communal meeting place, and agree on community service tasks for the weekend.

We made a preliminary visit and presented our work at a public meeting. We called for a volunteer to tell a story to the group and then invited another volunteer to provide an oral translation. Both individuals did a perfect job even though neither one had used the software before. One of them, a former village chief, addressed the group and explained the significance of our work. He then asked if we would help in the preparation of a DVD. Since we did not have the necessary equipment, we offered to create a bilingual storybook instead. They agreed, and said this could be used in their local school. We had already intended to propose this as our contribution to the community after our experience with Tembé, where most people did not grasp the value of us only leaving audio recordings. A booklet would be a natural extension to our documentary goals, and it offered to draw in the whole community including the children who could provide illustrations.

Three weeks later, once the necessary approvals had been obtained, we arrived in Terra Preta and launched our activities with another public meeting. At this meeting, and again at public meetings on the following two mornings, we invited anyone who was interested to take a phone and record a story. Sometimes a storyteller held a phone while addressing a small group (often involving children), and recounted a folktale.

After three days, we recorded 35 texts from nine speakers (including two children), mostly folklore and personal narratives. Most texts were orally translated. Of 2.5 hours of source audio, approximately one hour of recordings were orally translated (some two or more times), producing an extra two hours of audio. Seven short texts by children or directed at children were delivered in Portuguese, and we did not translate these back into Nhengatu.

During the second half of the visit, four men who were literate in Nhengatu joined us in the task of transcribing the stories, focussing on those that would be most interesting for inclusion in the storybook. They worked in parallel, playing back the recordings on the phones, transcribing them on paper, then bringing the sheets back to be typed and proof-read. This work was arduous, continuing through the heat of the day, but they were keen to process as many stories as possible.

Two weeks after our visit, we published a small booklet of stories and translations and sent copies back to the village, and posted a digital copy in the Internet Archive (Bird et al., 2013).

We encountered some additional technical difficulties that we had not experienced in Cajueiro. First, a bug in the recording app which appeared on the last day caused one recording to overrun and produced a three hour (350MB) file. After this, WiFi synchronisation was too slow to be effective, and it was

necessary to perform synchronisation manually, copying the files from all phones onto a laptop, then copying the collection back onto each phone. Second, the presence of an audience for some stories encouraged the storyteller to speak loudly. Since speakers were holding the phone close to their mouths, this resulted in clipped audio. Third, at the height of our intensive transcription and translation process, we needed to keep track of the activities of several participants, and created a checklist. Finally, there was an issue with the power supply. Unlike Cajueiro, Terra Preta is not attached to the electricity grid, but it has a generator which is turned on for four hours every evening, and sometimes during the mornings for brief periods. We could use this to keep the phones charged and to power the router for long enough to synchronise the phones a couple of times each day. But the village became very noisy when power was available, thanks to an abundance of stereo systems and power tools, and this made it difficult to get good quality recordings during these times.

In spite of these problems, there were some successes. The most notable was that participants took no more than a minute to become adept with the recording functionality and the thumb-controlled oral translation functionality (Figure 2b). Second, the availability of multiple networked recording devices meant that we could collect materials in parallel. For example, we could discuss a story we wanted to record and then send several people off at the same time to record their own versions. Then they could synchronise their recordings and hear what each other said. Finally, automatic synchronisation greatly facilitated concurrent transcription activities. We could assign people to transcribe or translate a particular source recording without having to keep track of device it had been recorded with: it was already available on all of the phones.

Figure 3: Transcribing a spoken translation

5 Kagate, Ramechhap district, Nepal

A third field test with a later version of the app was undertaken in Nepal. Kagate, known to its speakers as Syuba, is a Tibeto-Burman language spoken by around 1,500 people in the Ramechhap district, east of Kathmandu. Handsets with the Aikuma app were taken by Gawne and were deployed in parallel, in the context of a project to video record traditional folk narratives and history. Twelve original recordings were made, totalling 80 minutes. Four of these recordings were translated into Nepali, and two recordings were also carefully "respoken" to aid later written transcription (Woodbury, 2003). Although the recordings represent a more modest total than at other fieldsites, this field test demonstrates that Aikuma can operate in conjunction with, and to the benefit of, more traditional field methods. A number of challenges were addressed.

The first challenge was the lack of mains electricity, with the village only having a number of small solar panels for charging mobile phones and running small lights. Much like at the Nhengatu site, mobile phones enabled work to proceed in the absence of mains electricity. Indeed, this was greatly beneficial because it meant that more recordings could be made without rapidly depleting the video camera battery, which required charging at a village a one hour walk away. The lack of proximal mains electricity meant that it was not possible to run the router and synchronise the data on each phone. As a result of this (and participation issues discussed below) the researcher only kept two devices in use at a time, making it easier to keep track of what was on each device. This field trip demonstrated that even without the data synchronization feature Aikuma is still a useful fieldwork tool.

The second challenge was fostering participation. As a number of anthropologists working in related communities have observed, the centre of village life for Kagate people is the household (Fürer-Haimendorf, 1964; Desjarlais, 1992). Relationships beyond this are negotiated through extended familial relations of reciprocity. Therefore, there were no opportunities to arrange community meetings as in

Terra Preta, or even to find an individual who was an officially designated leader. As a result, much time was spent engaging a small number of enthusiastic participants and working with them to engage other members of the community through existing social networks. The benefit of the mobile devices was that they could be carried about and then demonstrated to people during a lull in other activities. Because of this portability and ease of demonstration, the mobile phones became a key part of negotiations with all participants, even those who the community members wanted to video record. Having the handsets meant that we could immediately show people the outcome of a recording session. Sometimes, even after this demonstration, people were reluctant to participate in recording with video cameras or phones. We took this as a positive sign that participants had a better level of informed consent with which to make this choice than they otherwise would have. Many community members were reluctant to take the phones, as even basic smartphones that we chose for their affordability are an expensive commodity and out of the price bracket of many. A small number of people became comfortable enough to take the phones away to work with, but would return them immediately after a specific task had been completed. With a longer period of presence in the village it is likely more people would become more comfortable with the process.

The final issue, like at other sites, concerned the process of saving recordings once they had been made. Processes that are taken for granted with some audiences, like naming a recording, presume a great deal of cultural knowledge about iconography, the layout of keyboards, and spelling conventions. It was only on the final day that one of the more frequent participants saved a file without assistance. Fortunately, an import feature had been built into the app, which meant that when participants returned with files that they had not managed to save they could still be loaded into the list. While some of the issues faced can be overcome through further refining the design, others are useful educational tools to help familiarize participants with key features of digital literacy.

Throughout the above discussion we have touched on some benefits to using Aikuma at this field site. There are some other advantages that are also worth noting. The first is that the portability of the handsets meant that there was a wider range of participants recorded. The limited electricity available for the parallel video documentation, and community attitudes about who was a suitable participant in that work, meant that only a small section of the community (mostly older males) would have been documented. The lower formality of using the phones, compared with a bulky video camera, meant that people also felt quite relaxed, often telling stories with an audience present.

The use of phones also meant that there were fewer missed opportunities for recording. One evening we used the phones when the light was too poor for video. Another morning when the researcher was unwell, she gave one of the handsets to a member of the community who recorded some traditional stories with an older man who had not been able to remember them the day before. On yet another occasion, a man took one of the handsets away and recorded a translation while the researcher was filming a video with another participant. Although the linguist was still needed for the saving of recordings, people became less dependent on her presence to do their own documentation work.

6 Discussion

Reflecting on our experience in the Tembé, Nhengatu, and Kagate communities, further issues warrant discussion.

The mobile device was a major attraction. People gathered round to see how it was used, then explained it to others in their native language. They brought elders to see the work, and encouraged them to tell stories. This impact convinced us that the mobile phone is an effective platform for engaging with participants and helping them quickly grasp the collection and dissemination aspects of language documentation work, cf. (Rice, 2011). Note that the phones were not equipped with SIM cards, and so there was no distraction of them being used for voice calls or for downloading extraneous software.

However, the device was also an obstacle. Although some people had used smartphones, few had experienced touchscreens. Creating a user profile required entering a name using the touchscreen keyboard. It seemed like overkill to train individuals to use a keyboard and to go through a process they would only perform once. Moreover, the language selection process displayed a searchable list of 7,000 languages,

and it would have been easier to have a small selection of local languages to choose from. In Tembé, the man who was trained as a computer technician learned to create user profiles for other people. By the time of the Kagate experiment, we added support for default languages, and set these as Kagate and Nepali. This simplified the task, though it also meant that we did not capture information about people's competencies in other languages. These issues with the device only occurred at the outset, and highlight the need to simplify the metadata collection process. The impact of the problem would be reduced with improved software design.

The device helped with the process of obtaining informed consent. We played an existing recording, either one collected during an earlier phase of documenting the language, or one from another endangered or extinct language. In this way we communicated the idea that language recordings can be preserved and transmitted over distance and time, even once the language is no longer spoken. We also asked what people thought about the idea of others hearing their language, and they were generally enthusiastic. In the case of a further Brazilian language, one community leader asked for substantial donations of hardware and another cited intellectual property concerns, and so we did not record this language. A related open issue concerns the process for *documenting* informed consent, particularly when working with monolingual speakers.

Most of the collected material consisted of personal narratives, folklore, and a limited amount of singing. Other discourse types that we did not collect include dialogue, oratory, and procedural discourse, cf. (Johnson and Aristar Dry, 2002). On many occasions, people listened to a traditional narrative and then asked to recount their own version. Consequently, we see the possibility for achieving substantial lexical overlap in recordings by different speakers, which could help with speech modelling, dialect identification, and lexicon production.

7 Conclusions

We have investigated the use of Aikuma, an Android app designed for recording and translating unwritten languages. We taught members of indigenous communities in Brazil and Nepal to use smartphones for recording spoken language and for orally interpreting it into the national language, and we collected a sample of bilingual phrase-aligned speech in the languages. We collected approximately 8.5 hours of audio, approximately 100,000 words, and in the process, we demonstrated that the platform is an effective way to engage indigenous communities in the task of building phrase-aligned bilingual speech corpora. The built-in networking capability of the phone was used to good effect in Nhengatu for leveraging the contribution of multiple members of the community who have differing linguistic aptitudes.

We identified several areas for additional functionality: support for adding a paraphrase as soon as a story has been told; support for exporting playlists to CD; a checklist that shows which recordings have been translated; permitting handwritten transcriptions to be photographed and linked back to the original audio; and redesigning the interface to remove some remaining English prompts and confusing icons. These and other enhancements are being developed in our open source project.[1]

Above all, we have found that this approach to linguistic data collection greatly facilitates work on indigenous languages that are falling out of use. It bypasses the need for expensive equipment by piggybacking on the burgeoning adoption of mobile phones and wireless broadband networks. We are optimistic about the prospects of using this approach to collect substantial new corpora for supporting linguistic research and language technology development, even for some of the most isolated linguistic communities in the world.

Abstract

We test the Distributional Inclusion Hypothesis, which states that hypernyms tend to occur in a superset of contexts in which their hyponyms are found. We find that this hypothesis only holds when it is applied to relevant dimensions. We propose a robust supervised approach that achieves accuracies of .84 and .85 on two existing datasets and that can be interpreted as selecting the dimensions that are relevant for distributional inclusion.

1 Introduction

One of the main criticisms of distributional models has been that they fail to distinguish between semantic relations: Typical nearest neighbors of *dog* are words like *cat*, *animal*, *puppy*, *tail*, or *owner*, all obviously related to *dog*, but through very different types of semantic relations. On these grounds, Murphy (2002) argues that distributional models cannot be a valid model of conceptual representation. Distinguishing semantic relations are also crucial for drawing inferences from distributional data, as different semantic relations lead to different inference rules (Lenci, 2008). This is of practical import for tasks such as Recognizing Textual Entailment or RTE (Geffet and Dagan, 2004).

For these reasons, research has in recent years started to attempt the detection of specific semantic relationships, and current results suggest that distributional models can, in fact, distinguish between semantic relations, given the right similarity measures (Weeds et al., 2004; Kotlerman et al., 2010; Lenci and Benotto, 2012; Herbelot and Ganesalingam, 2013; Santus, 2013). Because of its relevance for RTE and other tasks, much of this work has focused on hypernymy. Hypernymy is the semantic relation between a superordinate term in a taxonomy (e.g. *animal*) and a subordinate term (e.g. *dog*).

Distributional approaches to date for detecting hypernymy, and the related but broader relation of lexical entailment, have been unsupervised (except for Baroni et al. (2012)) and have mostly been based on the Distributional Inclusion Hypothesis (Zhitomirsky-Geffet and Dagan, 2005; Zhitomirsky-Geffet and Dagan, 2009), which states that more specific terms appear in a subset of the distributional contexts in which more general terms appear. So, *animal* can occur in all the contexts in which *dog* can occur, plus some contexts in which *dog* cannot – for instance, *rights* can be a typical cooccurrence for *animal* (e.g. "animal rights"), but not so much for *dog* (e.g. #"dog rights").

This paper takes a closer look at the Distributional Inclusion Hypothesis for hypernymy detection. We show that the current best unsupervised approach is brittle in that their performance depends on the space they are applied to. This raises the question of whether the Distributional Inclusion Hypothesis is correct, and if so, under what circumstances it holds. We use a simple supervised approach to relation detection that has good performance (accuracy .84 on BLESS, .85 on the lexical entailment dataset of Baroni et al. (2012)) and works well across different spaces.[1] Furthermore, we show that it can be interpreted as selecting dimensions for which the Distributional Inclusion Hypothesis does hold. So, our answer is to propose the *Selective Distributional Inclusion Hypothesis*: The Distributional Inclusion Hypothesis holds, but only for relevant dimensions.

2 Background

Distributional models. Distributional models represent a word through the contexts in which it has been observed, usually in the form of a vector representation (Turney and Pantel, 2010). A target word is represented as a vector in a high-dimensional *space* in which the *dimensions* are context items (for example, other words) and the coordinates of the vector indicate the target's degree of association with each context item. In this paper, we also use dimensionality reduced spaces in which dimensions do not stand for individual context items anymore.

Pattern-based approaches to inducing semantic relations. Early work on automatically inducing semantic relations between words, starting with Hearst (1992), uses textual patterns. For example, "[NP_1] and other [NP_2]" implies that NP_2 is a hypernym of NP_1. Pattern-based approaches have been applied to meronymy (Berland and Charniak, 1999; Girju et al., 2003; Girju et al., 2006), synonymy (Lin et al., 2003), co-hyponymy (Snow et al., 2005), hypernymy (Cimiano et al., 2005), and several relations between verbs (Chklovski and Pantel, 2004). Pantel and Pennachiotti (2006) generalize the idea to a wide variety of relations. Turney (2006) uses vectors of patterns to determine similarity of semantic relations. A task related to semantic relation induction is the extension of an existing taxonomy (Buitelaar et al., 2005). Snow et al. (2006) do this by using hypernymy and co-hyponymy detectors.

Lexical entailment, hypernymy, and the Distributional Inclusion Hypothesis. Weeds et al. (2004) introduce the notion of *distributional generality*, where v is distributionally more general than u if u appears in a subset of the contexts in which v is found, and speculate that hypernyms (v) should be more distributionally general than hyponyms (u). Zhitomirsky-Geffet and Dagan (2005; 2009) introduce the term *Distributional Inclusion Hypothesis* for the idea that distributional generality encodes hypernymy or the more loosely defined relation of *lexical entailment*.

Weeds and Weir (2003) measure distributional generality using a notion of precision (eq. 1). Here and in all equations below, u is the narrower term, and v the more general one. Abusing notation, we write u for both a word and its associated vector $\langle u_1, \ldots, u_n \rangle$. Kotlerman et al. (2010) predict lexical entailment with the *balAPinc* measure, a modification of the Average Precision (AP) measure (eq. 2). The general notion is that scores should increase with the number of dimensions of v that u shares, and also give more weight to the highly ranked dimensions (i.e. largest magnitude) of the narrower term u. This is captured in *APinc* by computing precision $P(r)$ at every rank r among u's dimensions – where precision is the fraction of dimensions shared with v –, and weighting by the rank of the same dimension in the broader term, $rel'(v, r, u)$. The final measure, *balAPinc*, smooths using the *LIN* similarity measure (Lin, 1998). (We only sketch this measure here due to its complexity; details are given in Kotlerman et al. (2010).)

$$1(x) = \begin{cases} 1 \text{ if } x > 0; \\ 0 \text{ otherwise} \end{cases}$$

$$WeedsPrec(u, v) = \frac{\sum_{i=1}^{n} u_i \cdot 1(v_i)}{\sum_{i=1}^{n} u_i} \tag{1}$$

$$\text{APinc}(u, v) = \frac{\sum_{r=1}^{|1(u)|} P(r) \cdot rel'(v, r, u))}{|1(u)|} \tag{2}$$

$$\text{balAPinc}(u, v) = \sqrt{\text{APinc}(u, v) \cdot \text{LIN}(u, v)}$$

The *ClarkeDE* measure (Clarke, 2009) computes degree of entailment as the degree to which the narrower term u has lower values than v across all dimensions (eq. 3). Lenci and Benotto (2012) introduce the *invCL* measure, which uses *ClarkeDE* to measure both distributional inclusion of u in v and distributional *non-inclusion* of v in u (eq. 4). While all other measures interpret the Distributional Inclusion Hypothesis as the degree to which a $\subseteq$ relation holds, Lenci and Benotto test the degree to which proper inclusion $\subsetneq$ holds. They consider not only the degree to which the contexts of the narrower terms are included in the contexts of the wider term, but also determine the degree to which the wider term has contexts that the narrower term does not have.

$$\text{CL}(u, v) = \frac{\sum_{i=1}^{n} \min(u_i, v_i)}{\sum_{i=1}^{n} u_i} \tag{3}$$

$$\text{invCL}(u, v) = \sqrt{\text{CL}(u, v) \cdot (1 - \text{CL}(v, u))} \tag{4}$$

Like Lenci and Benotto, we focus on the stricter hypernymy relation, rather than lexical entailment. We believe that the different relations that make up lexical entailment have different distributional indications and that, for that reason, it will be easier to detect the relations separately than together.

Baroni et al. (2012) proposes a supervised approach to hypernymy detection that represents two words as the concatenation of their vectors. They also mention in passing another supervised approach that represents two words as the component-wise difference of their vectors. These are broadly the two approaches that we test, though we introduce significant modifications.

3 Data

3.1 Distributional Vector Spaces

We use three standard types of distributional spaces.

U+W2: This space is based on a concatenation of the Gigaword, BNC, English Wackypedia and ukWaC corpora (Baroni et al., 2009). The corpora are POS-tagged and lemmatized. We keep only content words (nouns, proper nouns, adjectives and verbs) with a corpus frequency of 500 or larger. The resulting U+ corpus has roughly 133K word types and 2.8B word tokens. We created a vector space by counting co-occurrences of these word types within a window of two words on the left and the right, using the top 20k most frequent content words as dimensions. The space was transformed using Positive Pointwise Mutual Information (PPMI).

U+Sent: The U+Sent space is constructed the same way as U+W2, but uses full sentence contexts instead of 2-word windows.

TypeDM: This space is extracted from the TypeDM tensors (Baroni and Lenci, 2011). TypeDM contains a list of weighted tuples, $\langle\langle w_1, l, w_2\rangle, \sigma\rangle$, where w_1 and w_2 are content words, l is a corpus-derived syntagmatic relationship between the words, and σ is a weight estimating saliency of the relationship. We construct vectors for every unique w_1 using the set of $\langle l, w_2\rangle$ pairs as dimensions and corresponding σ values as dimension weights. We select TypeDM for its excellent performance in previous comparisons of distributional hypernymy measures (Lenci and Benotto, 2012).

Reduced Spaces: In some experiments, we use dimensionality reduced spaces. We reduce all three spaces to 300 dimensions using Singular Value Decomposition. We use a subscript to denote reduced spaces, e.g. U+W2$_{300}$. When necessary, we use the term *original dimensions* to refer to the vector dimensions from the original, non-reduced spaces (e.g. U+W2); the term *latent dimensions* refers to the dimensions in the reduced spaces (e.g. U+W2$_{300}$).

3.2 Evaluation Data Sets

BLESS: The BLESS data set (Baroni and Lenci, 2011) covers 200 *concepts*, or concrete and unambiguous terms (divided into 17 different general *concept classes*, including *vehicle* and *ground mammal*), and their relationships to other nouns, called *relata*. Example concepts include *van* and *horse*. Each concept is related to several relata through different *semantic relations*. Following Lenci and Benotto (2012), we focus on the four semantic relations where both concepts and relata are nouns, for a total 14K data points: Hypernymy, denoting a superset relationship (e.g. *animal-dog*); Co-hyponymy, denoting words that share a common hypernym (e.g. *dog-cat*); Meronymy, denoting a part-whole relationship (e.g. *tail-dog*); and Random, denoting no relationship between the words (e.g. *dog-computer*).

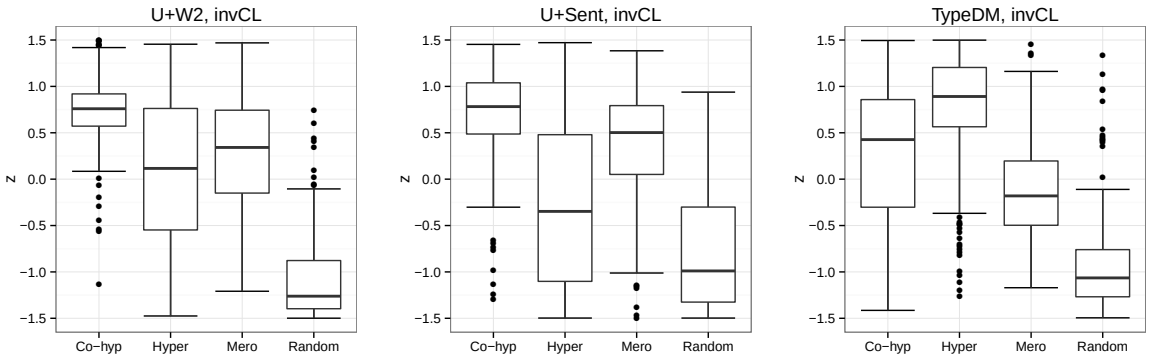

Figure 1: Distributions of relata *invCL* scores for the U+W2, U+Sent, and TypeDM spaces for each of the semantic relations, after per-concept z-normalization.

ENTAILMENT: (Baroni et al., 2012): The ENTAILMENT data set consists of 2,770 word pairs, balanced between positive (*house-building*) and negative (*leader-rider*) examples of hypernymy, with 1376 unique hyponyms and 1016 unique hypernyms. The positive examples were generated by selecting direct hypernym relationships from WordNet, the negative examples by randomly permuting the hypernyms of the positive examples, and then manually checking correctness.

4 Distributional Inclusion across Spaces

We test several unsupervised distributional approaches to hypernymy detection from the literature, focusing on the underlying vector space representation as the main parameter that we vary. We use the three spaces described in Section 3. We test four hypernymy detection approaches, all of them similarity measures based on the Distributional Inclusion Hypothesis: *WeedsPrec*, *balAPinc*, *ClarkeDE*, and *invCL*. Our baseline is the standard *cosine* measure. We evaluate on the BLESS dataset.

To evaluate on BLESS, we follow the evaluation scheme laid out in Baroni and Lenci (2011). Given a space and similarity measure, we compute similarity for each concept and relatum. For each concept, we select its nearest neighbors (according to the given similarity measure) in each of the four relations (CO-HYP, HYPER, MERO, RANDOM), and transform the corresponding four similarities to z-scores. Across all concepts, this yields four sets of z-normalized similarity scores, one for each relation. These four sets describe the relative similarity of concepts to their nearest neighbors in different relations. Tukey's Honestly Significant Difference test is used for testing whether scores differ significantly between relations (threshold: $p < 0.05$).

Figure 1 shows the distributions of z-scores for *invCL* for the four relations, with one graph for each of the three spaces we consider. For this illustration, we focus on *invCL* because it shows the overall best performance at identifying hypernymy. The rightmost plot in Figure 1 replicates the analysis of Lenci and Benotto (2012), who used the TypeDM space. It confirms their finding that *invCL* gives significantly higher values to hypernyms than co-hyponyms – at least on this space. However, in the U+W2 and U+Sent spaces (leftmost and middle plot), *invCL* clearly loses any ability to rank hypernyms the highest; indeed, in both spaces, co-hyponymy and meronymy both have significantly higher z-scores than hypernymy. Concerning the other measures, we found that they patterned with *invCL*. On TypeDM, *ClarkeDE* and *WeedsPrec* had significantly higher nearest-neighbor values for hypernyms than co-hyponyms.[2] On U+W2 and U+Sent, all measures ranked co-hyponyms significantly higher than hypernyms. With the baseline measure, *cosine*, the similarity ratings for the CO-HYP relation are always the highest, no matter the space, followed by HYPER, MERO, RANDOM in this order.

Following Kotlerman et al. (2010) and Lenci and Benotto (2012), we also report the performance of the measures using Mean Average Precision (MAP). Average Precision (AP) is a measure often used in

[2] *balAPinc* could not be evaluated on TypeDM due to computational issues.

Measure	CO-HYP	HYPER	MERO	RANDOM
U+W2				
cosine	.68	.20	.27	.27
ClarkeDE	.66	.19	.28	.28
invCL	.60	.18	.31	.28

cosine	.78	.19	.20	.29
ClarkeDE	.45	.35	.25	.32
invCL	.38	.36	.27	.33

Table 1: Mean Average Precision for the unsupervised measures on three spaces.

the Information Retrieval community with a maximal AP score of 1 when all relevant documents (relata with the right relationship, in our case) are ranked at the top. We compute AP on a per-concept basis and report the mean over all 200 AP values. An advantage of MAP is that, while the BLESS analysis method focuses on nearest neighbors, MAP evaluates the ranking of all relata. A disadvantage of MAP is that it does not test the degree to which a similarity measure separates different semantic relations, like Tukey does, so it may overstate the discriminative power of a particular measure. However, it provides a more intuitive accuracy-like number compared to the BLESS evaluation.

Table 1 shows the Mean Average Precision values for *cosine*, *ClarkeDE*, and *invCL* on all three spaces. We also computed *WeedsPrec* and *balAPinc* results, obtaining the same picture; we focus on *ClarkeDE* and *invCL* because *ClarkeDE* is a component of *invCL*, and *invCL* is the current best measure. The results corresponding to Lenci and Benotto's are shown in the lowest part of Table 1, where we report numbers for TypeDM. Like Lenci and Benotto, we find that unsupervised measures other than *invCL* rank co-hyponyms the highest, and obtain relatively low results for hypernyms. For *invCL* in TypeDM, Lenci and Benotto obtain 0.38 MAP for co-hyponyms and a slightly higher 0.40 for hypernyms, though they do not report significance testing results. We obtain 0.38 for co-hyponyms and 0.36 for hypernyms, and the difference is not significant.[3] Even though our results are slightly different from those in Lenci and Benotto (2012), both our results and theirs point to at most a weak preference of *invCL* for hypernyms over co-hyponyms. Moreover, in the U+W2 and U+Sent spaces we see that all three measures are very poor at identifying hypernyms, and the co-hyponymy relation stubbornly persists as most relevant to all three measures, by a large margin.

Our results thus constitute a puzzle for the Distributional Inclusion Hypothesis. It seems that there must be some merit to the hypothesis: On one particular space, namely TypeDM, the nearest neighbors in the hypernymy relation had higher similarity scores than any other relation by a significant margin. This was true for all the hypernymy detectors we studied. But even on TypeDM, the MAP evaluation showed at most a weak hypernymy signal, and when spaces other than TypeDM were used, the effect vanished altogether. So how strong an indication for hypernymy can we expect from distributional inclusion measures in general? We will return to this question below, where our answer will be: The Distributional Inclusion Hypothesis seems to hold after all, but it needs to be applied to the right kind of dimensions – and a supervised approach can help in picking the right dimensions.

As the unsupervised approaches struggle to detect hypernymy and do not seem robust to changes in standard space parameters, we think it is time to consider supervised approaches. In the next section, we explore two simple supervised approaches that show good performance and are robust to changes in the underlying space.

[3] Wilcoxon signed-rank test.

5 Supervised Hypernymy Detection

We use two simple, supervised models for predicting BLESS and ENTAILMENT relations. The first (Concat) is a model previously proposed by Baroni et al. (2012). The second (Diff) takes up an idea from a footnote in Baroni et al. (2012), but while that footnote stated that the approach in question did not work, we find that, with a few modifications, it obtains the best performance – and can be interpreted as a supervised version of the Distributional Inclusion Hypothesis. Note that while we used unreduced spaces in the previous section, we now use reduced spaces throughout (these are the spaces with the $_{300}$ subscript), in order not to have more features than data points.

5.1 Models, Features, and Method

Concat: We use a standard Support Vector Machine (SVM) classifier with a concatenation of vectors as input features. SVMs are binary classifiers which learn the maximum margin hyperplane separating the two classes. SVMs employ kernel functions to find the hyperplanes in higher dimensional spaces which are nonlinear in the original space. As feature vectors for the classifier, we follow Baroni et al. (2012) and use the concatenation of the latent dimension vectors representing words. For the ENTAILMENT dataset, we use the concatenation of the hyponym latent vector and the hypernym latent vector for each word pair as training features, and the *entails/doesn't entail* annotations as binary targets. For BLESS, we use the concatenation of the concept latent vector and the relatum latent vector as training features, and the four relationship classes as targets. We choose the four-way task rather than a "hypernymy vs. other" classification because BLESS contains many more co-hyponymy and random than hypernymy pairs, which would give a very high baseline in the two-way task. Additionally, the other relations in BLESS, in particular meronymy, may be interesting in their own right.

Since SVMs are binary classifiers, we use SciKit-Learn's default setting to train 6 pairwise-relation one-vs-one classifiers which vote on the final answer. We use a polynomial kernel with a degree of 3 and a penalty term of $C = 1.0$, and all other hyperparameters are chosen using the SciKit-Learn default values (Pedregosa et al., 2011). No hyperparameters are tuned in any experiment.

Diff: Our second classifier is a Logistic Regression (aka MaxEnt) model trained on difference vectors. Logistic Regression is a statistical model for binary classification. It learns a linear hyperplane separating the classes and estimates a probability for classes using a logistic function. We selected Logistic Regression over other possible linear classifiers for its natural ability to give likelihood estimates, which we believe will be useful in future work in an application of hypernymy classification to RTE.

As feature vectors, we use a Mikolov-inspired method of representing word pairs as the *difference vectors* between the two words.[4] Baroni et al. (2012) suggested the use of difference vectors as input to a classifier, but reported them as unsuccessful. We found difference vectors to be excellent features, with three important modifications: a linear classifier is better than a nonlinear one; vectors must be normalized to have a magnitude of 1 before taking the difference; and squared difference vectors must also be included as features. So, we represent each word pair with latent vectors (u, v) as a two part vector $\langle f; g \rangle$, where

$$f_i = \frac{u_i}{\|u\|} - \frac{v_i}{\|v\|},$$
$$g_i = {f_i}^2.$$

These differences features[5] are analogous to a *supervised* distributional inclusion measure. The difference between two words on a particular dimension captures the degree of distributional inclusion on that dimension. The primary distinction between the difference features and the unsupervised measures is that the supervised classifier learns to weight the importance of different dimensions. The f features encode directional aspects of distributional inclusion: that the hyponym contexts should be included in

[4] After recent work using subtraction to represent analogy in certain neural-network spaces (Mikolov et al., 2013).

[5] We also tried variations, such as not normalizing vectors and removing the difference squared vector, but found this setting the best. We also tried the Diff features with an SVM and other nonlinear classifiers, but they performed worse.

Data set	BLESS		ENTAILMENT	
Baseline	.46		.50	
Classifier	Concat	Diff	Concat	Diff
U+W2$_{300}$	.76	**.84**	.81	**.85**
U+Sent$_{300}$	.73	.80	.78	.82
TypeDM$_{300}$	-	.82	.65	**.85**

Table 2: Average accuracy of Concat and Diff on BLESS and ENTAILMENT using different spaces for feature generation.

those of the hypernym (the weight learned is positive), and the hypernym contexts should not be included in those of the hyponym (the weight learned is negative). So like *invCL*, this model uses a "proper subset" interpretation of the Distributional Inclusion Hypothesis, but only considers selected dimensions (i.e. those that the model assigns nonzero weights).

The difference-squared features (g), on the other hand, typically identify dimensions that are *not* indicative of hypernymy, by learning negative weights on them (more about this in Section 6). Thus, rather than helping identify hypernyms, they help separate random relations from the rest.

We use a L1 regularizer with a strength of $C = 1.0$. All other hyperparameters are chosen using the SciKit-Learn defaults. Since Diff is also a binary classifier, we use SciKit-Learn's default setting of training 4 one-vs-all classifiers for BLESS, with the most confident classifier choosing the final answer.

Method: For evaluation on BLESS, we hold out one concept and train on the remaining 199 concepts. We also exclude from the training set any pair containing a relatum which appears in the test set. This way, no word that appears in the test set has been seen in training. We report the average accuracy across all concepts. We use the most frequent relation type (random) as our baseline. For the ENTAILMENT data set, we hold out one hyponym and train on all remaining hyponyms. Again, we exclude from training any pair containing a hypernym which appears in the test set. We report average accuracy across all hyponyms. The data set is balanced, so the baseline is 0.5.

5.2 Results

Table 2 shows the performance of the two classifiers, Concat and Diff, on both the BLESS and ENTAILMENT datasets, using three underlying spaces. We use the reduced versions of the three spaces, indicated by the subscript $_{300}$. Note that the Concat classifier could not converge using features from TypeDM$_{300}$, so we omit the result. With both methods, we obtain a high accuracy on the two datasets, with results around .8 against baselines around .5. Our best result is .84 on BLESS and .85 on ENTAILMENT. Moreover, both approaches are in general robust to changes in space parameters (with TypeDM/Concat an outlier). Still, the U+W2$_{300}$ space seems to be the best for this task: Its scores are significantly[6] higher than the rest, except for TypeDM on ENTAILMENT, which achieves the same score as U+W2$_{300}$. Diff achieves significantly higher results than Concat.

When provided more information, Concat outperforms Diff. For instance, if cross-validation is done over all pairs in BLESS in the U+W2$_{300}$ space, Concat achieves .98 accuracy, while Diff obtains .90. However, in this setting the same words appear in the training and test sets (albeit in different pairs). We take this to mean that Concat is memorizing, rather than learning the hypernymy relation. This emphasizes the need for our stricter evaluation that prevents repetition between training and test sets.

Clearly, both classifiers do fairly well at predicting hypernymy relations between words, regardless of space. Naturally, one should ask what are the classifiers capturing that the unsupervised measures are missing? We propose that the supervised classifiers perform essentially the same operation as the unsupervised measures, but are learning to determine the relevance of dimensions. In particular, Diff is learning weights on vector difference features. This is equivalent to doing selective distributional inclusion. In the next section, we test this Selective Distributional Inclusion Hypothesis.

[6]Wilcoxon signed-rank test, $p < .001$.

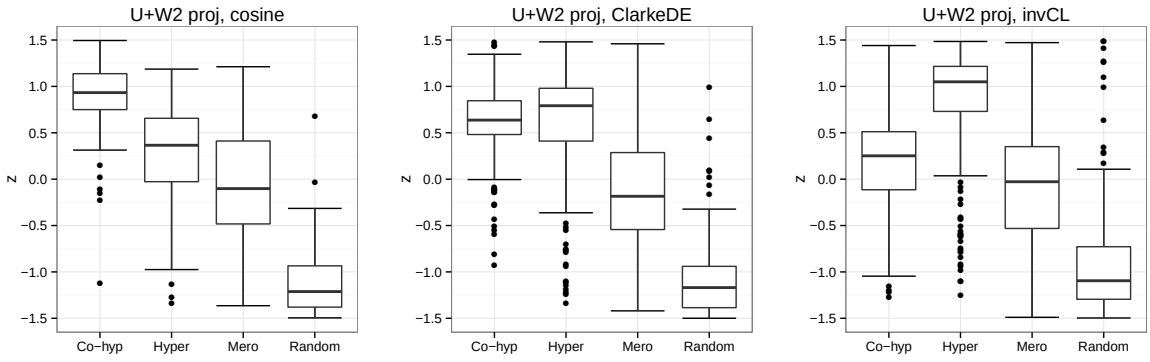

Figure 2: Distributions of relata scores across concepts using the *cosine*, *ClarkeDE*, and *invCL* measures (after per-concept z-normalization). Here we use the selected dimensions of the U+W2$_{proj}$ space.

6 Selective Distributional Inclusion

In order to test how well our supervised model is capturing the notion of selective distributional inclusion, we test each of the unsupervised measures on a smaller space, limited only to the dimensions preferred by the classifier. We emphasize that we do *not* aim to show that our supervised method outperforms unsupervised methods, but rather that the unsupervised methods benefit greatly from feature selection. Additionally, we analyze which dimensions are selected by the classifier to facilitate understanding of why these dimensions are important.

6.1 Experiment

We train the Diff classifier using the dimensionality-reduced U+W2$_{300}$ space with the same method we use in Section 5. We take the classifier's learned hyperplane separating hypernyms from other relations, and project the hyperplane back into the original U+W2 space.[7] We select the 500 dimensions in the original space that are most relevant according to the classifier weights, and test the unsupervised measures on this new space, which we denote as U+W2$_{proj}$.[8]

The 500 most relevant dimensions are selected as follows: We select the 250 most negatively weighted original dimensions using the difference features f. These are the features that have smaller values for hyponyms (e.g. *dog*) than for hypernyms (e.g. *animal*), so they characterize hypernymy. We further select the 250 most positively weighted original dimensions using the squared-differences features g. These are the ones where a large difference does not indicate hypernymy.

Figure 2 shows the boxplots for the BLESS analysis: the distributions of nearest-neighbor similarity scores for the four different semantic relations, for the measures *cosine*, *ClarkeDE*, and *invCL*. We see that *invCL* now easily discriminates hypernymy from the other relations in the backprojected space. (The difference of HYPER and CO-HYP is significant.) This is even though the space is based on U+W2, where *invCL* failed to rate hypernyms higher than co-hypernyms in Section 4. Unsurprisingly, *cosine*, which does not measure distributional inclusion, still prefers CO-HYP.

Table 3 shows the MAP scores for three of the measures in the new U+W2$_{proj}$ space. (The results for *balAPinc* and *WeedsPrec* are slightly worse than *ClarkeDE*.) All measures except for *cosine* assign higher scores to hypernyms than they did in the original space (compare to U+W2 part of Table 1). But it is only *invCL* that ranks hypernyms significantly higher than co-hyponyms.[9]

[7] Ideally we would train on the original space to inspect the relevant dimensions. However, there are more dimensions than examples, so we train on the SVD space and backproject.

[8] Note that U+W2$_{proj}$ varies slightly from concept to concept, since the hyperplane is learned on a per-concept basis. It is important that we use the linear Diff classifier for this reverse-projection procedure, as the separating hyperplane *must* be linear in order to complete the projection. In particular, the hyperplane in the Concat classifier cannot be easily backprojected, since it exists in a higher dimensional space than the projection matrix. Furthermore, it is important that we use a classifier trained using the difference features because of its analogy to the Distributional Inclusion Hypothesis.

[9] Wilcoxon signed-rank test, $p < .001$. To check that the measures are being improved by the dimension selection and not

Measure	CO-HYP	HYPER	MERO	RANDOM
U+W2$_{proj}$				
cosine	.69	.20	.24	.28
ClarkeDE	.55	.39	.24	.29
invCL	.42	**.58**	.24	.29

Table 3: Mean Average Precision for the unsupervised measures after selecting the top dimensions from a supervised model.

For this experiment, we train on all of BLESS except for one concept and then evaluate the unsupervised models on the held-out concept – that is a setting that could, in principle, be used as a hypernymy detector. If we instead train the supervised model on all of BLESS to determine an upper bound of how well dimension selection can do on this dataset, MAP for *invCL* rises to .67.

Overall, these experiments provide strong evidence for the Selective Distributional Inclusion Hypothesis: The Distributional Inclusion Hypothesis holds, but only for relevant dimensions. In addition, hypernymy detectors need to test for "proper inclusion" of distributional contexts in order to really find hypernyms.

Analysis of Selected Dimensions. We examine the 500 dimensions selected by the above procedure, in order to see what the classifier is learning. As this is for analysis only, the dimensions were selected by training on all data.

Recall that the difference-squared g features can be interpreted as dimensions that the classifier deems not indicative of hypernymy. 200 out of the 250 most relevant dimensions by g are Computer Science related terms like *software*, *configure*, or *Linux*. Since ukWaC, the largest corpus we use, is web-based, it makes sense that it has many CS-related terms, which are noise when it comes to hypernymy detection for BLESS concepts. Also, we find that while the supervised approach needs the negative information from the g features (for Diff in the U+W2$_{300}$ space, omitting g features yields a drop from .84 to .8), the unsupervised measures cannot use it. Dropping g features improves *invCL* results from .58 to .61. The g-based dimensions are explicitly those for which distributional inclusion should *not* hold, so they constitute noise to the unsupervised approaches.

The f features can be interpreted as dimensions that characterize hypernyms. An inspection reveals two clear patterns. First, the features are topically relevant for the BLESS dataset. The 17 concept classes in the dataset belong to three broader groups: animals, plants, and artifacts. An annotation of the 250 dimensions by one of the authors showed that 58 dimensions are typical of animals (*parasite*, *extinct*), 14 typical of vegetables (*flora*, *nutrient*), 80 typical of artifacts (*repair*, *mechanical*), 49 are general terms (*find*, *worthy*), and 49 have no clear interpretation (*thee*, *enigmatic*). Second, the features are general terms. For instance, for animals we find terms like *animal*, *insect*, *creature*, *fauna*, *species*, *evolutionary*, *pathogen*, *nature*, *ecology*. We also find many hypernyms, including many concept class names.

Clearly, the selected features are domain dependent; most are directly related to the concepts and concept classes of BLESS. We expect that our method should work well for other data sets, given its high accuracy and the strict training procedure. However, these features are unlikely to be global indicators of hypernymy. This emphasizes the need, in future work, to find a way to automatically determine relevance on a per-word basis.

7 Conclusion

In this paper, we have tested the Distributional Inclusion Hypothesis, the basis for distributional approaches to hypernymy. We have found that the hypothesis only works if inclusion is selectively applied to a set of relevant dimensions.

just by restricting to a smaller space, we evaluated the similarity measures on a variation of the U+W2 space which uses 500 randomly selected dimensions from the original space. The results are approximately unchanged from those on the original U+W2 space.

We have tested two simple supervised approaches to distributional hypernymy detection and have found that they show good performance, and are robust to changes in the underlying space. Our best classifier achieves .84 accuracy on BLESS and .85 on the ENTAILMENT dataset of Baroni et al. (2012). It uses features that encode dimension-wise difference between vectors. This classifier can be interpreted as selecting the dimensions necessary for the Distributional Inclusion Hypothesis to work, thus as an effective way to implement *selective* distributional inclusion.

The next natural step is to use the supervised features to guide development of an unsupervised measure for hypernymy detection: Now that we have examples, we hope to propose a method which selects relevant features automatically. We also would like to explore detection of other relationships, such as meronymy. Finally, we would like to perform an extrinsic evaluation of our hypernymy detection approach in an actual RTE system.

Abstract

Natural languages (NL) can be classified as prepositional or postpositional based on the order of the noun phrase and the adposition. Categorizing a language by its adposition typology helps in addressing several challenges in linguistics and natural language processing (NLP). Understanding the adposition typologies for less-studied languages by manual analysis of large text corpora can be quite expensive, yet automatic discovery of the same has received very little attention till date. This research presents a simple unsupervised technique to automatically predict the adposition typology for a language. Most of the function words of a language are adpositions, and we show that function words can be effectively separated from content words by leveraging differences in their distributional properties in a corpus. Using this principle, we show that languages can be classified as prepositional or postpositional based on the rank correlations derived from entropies of word co-occurrence distributions. Our claims are substantiated through experiments on 23 languages from ten diverse families, 19 of which are correctly classified by our technique.

1 Introduction

Adpositions form a subcategory of *function words* that combine with noun phrases to denote their semantic or grammatical relationships with verbs, and sometimes other noun phrases. NLs can be neatly divided into a few basic typologies based on the order of the noun phrase and its adposition. If the adposition is placed *before* the noun phrase, it is called a *preposition*. *Postpositions* and *inpositions*, on the other hand, are adpositions that are placed after and inside noun phrases respectively. If prepositions are predominantly used in the language, for example in English, Bulgarian and Russian, then the language is said to be *prepositional*. Similarly, Japanese, Hindi and Turkish are some examples of *postpositional languages*, which predominantly use postpositions. These two are the most commonly found adposition typologies across the globe. Out of 1185 languages analyzed on the World Atlas of Language Structures (WALS)[1] (Dryer and Haspelmath, 2011), there are 577 postpositional, 512 prepositional and only 8 inpositional languages. There are a few (30 and 58 respectively) languages which use no or both kinds of adpositions. The order of adpositions is strongly correlated with many other word order typologies. For instance, postpositional languages usually have Object-Verb ordering, whereas prepositional languages have Verb-Object ordering (Greenberg, 1963). Daumé and Campbell (2007) present a statistical model for automatically discovering such implications from a large typological database and discuss many other typological implications involving adpositions.

Motivation. Knowledge of the typological characteristics of languages is not only of interest to linguists, but also very useful in NLP for two main reasons. First, typological information, if appropriately exploited while designing computational methods, can lead to very promising results in tasks like coreference resolution and machine translation (Haghighi and Klein, 2007; Moore and Quirk, 2007). Second, as Bender and Langendoen (2010) have pointed out, in order to claim that a computational technique

Proceedings of COLING 2014, the 25th International Conference on Computational Linguistics: Technical Papers, pages 1037–1046, Dublin, Ireland, August 23-29 2014.

is truly language independent, one must show its usefulness for languages having diverse typological features. However, there is very little work on the automatic discovery of typological characteristics, primarily because it is assumed that such information is readily available. However, Hammarström et al. (2008) argue that documenting a language and its typological features is a time consuming process for the linguists and therefore, automatic methods for bootstrapping language description is a worthwhile effort towards language preservation. Lewis and Xia (2008) mine inter-linearized data from the Web and infer typological features for "low-density" languages, i.e. languages represented in scarce quantities on the Web. We argue that apart from documenting and understanding the typology of "low-density" languages, unsupervised discovery of adposition typology is also useful for analyzing undeciphered languages and scripts, such as the Indus valley script (Rao et al., 2009) and the Cypro-Minoan syllabary (Palaima, 1989), as well as newly emerging languages, such as the language of Web search queries (Saha Roy et al., 2012) or the Nicaraguan sign language (Meir et al., 2010). While the former cases are interesting from historical and language change perspectives, the latter cases are useful for more practical reasons (for example, improvement in query understanding leading to better Web search, and development of interactive systems for deaf children).

Approach. In this work, we show that some simple word co-occurrence statistics, that can easily be computed from any medium-sized text corpus, can be used as reliable predictors of adposition typology of a language. These statistics have been arrived at based on two fundamental assumptions: (a) adpositions constitute a large fraction of function words; and (b) the strict ordering between the adposition and the noun phrase leads to differential co-occurrence characteristics on the left and right sides of the adposition. Therefore, if the function words of a language are automatically detected and the co-occurrence statistics on the left and right of those words are appropriately analyzed, then it should be possible to tell the prepositional languages apart from the postpositional ones. Specifically, we measure counts and entropies of left, right and total (either side) co-occurrence distributions for each word. We show that left co-occurrence statistics are better indicators of function words for prepositional languages, while right co-occurrence statistics perform better for postpositional languages. Interestingly, the performance of total co-occurrence statistics lie in between the two for both types of languages. Thus, the nature of the difference in performances of left (or right) and total co-occurrences is likely to be indicative of the adposition typology of the language. We formalize this intuition to devise our test for adposition typology. We demonstrate our technique on 23 languages from ten language families, of which 14 are prepositional and 9 are postpositional. Our technique is able to consistently predict the correct adposition typology for 19 of these languages. The remaining four languages are highly *inflectional* and *agglutinating* in nature, and hence not amenable to the present technique.

Organization. The rest of this paper is organized as follows. In Sec. 2, we present our method for function word detection using word co-occurrence statistics, along with results showing the effectiveness of such an approach. In Sec. 3, we propose our test for discovering the adposition typology of a language based on correlations inferred from different co-occurrence statistics. Sec. 4 discusses experiments conducted on diverse languages and inferences drawn from the observations. Finally, Sec. 5 summarizes our contribution and indicates possible directions for future work.

2 Function Word Detection

Our method for the prediction of the adposition typology of a language relies on the facts that most adpositions are function words, and the distributional properties of function words are very different from those of content words. We exploit this difference to first formulate a method for extracting the function words of a language from a corpus. We then proceed to use the same underlying principle to automatically discover the adposition typology for languages, where we do not assume that the true function word lists are available.

By function words, we refer to all the *closed-class* lexical items in a language, e.g., pronouns, determiners, prepositions, conjunctions, interjections and other particles (as opposed to open-class items, e.g., nouns, verbs, adjectives and adverbs). For the function word detection experiments, we shall look at four languages from different families: English, Italian, Hindi and Bangla. English is a *Germanic*

Language	Corpus source	S	N	V	Function word list source	F
English	Leipzig Corpora[a]	$1M$	$19.8M$	342157	Sequence Publishing[b]	229
Italian	*-do-*	$1M$	$20M$	434680	*-do-*	257
Hindi	*-do-*	$0.3M$	$5.5M$	127428	Manually constructed by linguists and augmented by extracting pronouns, determiners, prepositions, conjunctions and interjections from POS-tagged corpora available at LDC[c]	481
Bangla	Crawl of *Anandabazar Patrika*[d]	$0.05M$	$16.2M$	411878	*-do-*	510

Table 1: Details of NL corpora for function word detection experiments.

language, Italian is a *Romanic* language, and Hindi and Bangla belong to the *Indo-Aryan* family. English and Italian are prepositional languages with *subject-verb-object* word order, while Hindi and Bangla are postpositional, relatively free word order with preference for *subject-object-verb*. Therefore, any function word characterization strategy that works across these languages is expected to work for a large variety of languages.

The details of the corpora used for these four languages are summarized in Table 1. M in the value columns denotes million. S, N, V and F denote the *numbers* of all sentences, all words, unique words (vocabulary size) and function words, respectively. We note that the Indian languages have almost twice as many function words as compared to the European ones. This is due to morphological richness and the existence of large numbers of modal and vector verbs.

Frequency is often used as an indicator for detecting function words, but the following factors affect its robustness. If the corpus size is not large, many function words will not occur a sufficient number of times. For example, even though `the` and `in` will be very frequent in most English corpora, `meanwhile` and `off` may not be so. As a result, if frequency is used as a function word detector with small datasets, we will have a problem of low recall. In our experiments, we measure corpus size, N, as the total number of words present. If our language corpus is restricted, or sampled only from specific domains, words specific to those domains will have high frequencies and will get detected as function words. For example, the word `government` will be much more frequent in political news corpora than `although`. The number of unique words in a corpus, or the vocabulary size, V, is a good indicator of its diversity. For restricted domain corpora, V grows much more slowly with N than in a general domain corpus.

We now introduce other properties of function words that may help in more robust detection. We observe the following interesting characteristics about the syntactic distributions of function and content words in NL, which can be summarized by the following two postulates.

Postulate I. Function words, in general, tend to co-occur with a larger number of distinct words than content words. What can occur to the immediate left or right of a content word is much more restricted than that in the case of function words. We hypothesize that even if a content word, e.g., *government*, might have high frequency owing to the nature of the domain, there will only be a relatively fewer number of words that can co-occur immediately after or before it. Therefore, the co-occurrence count may be a more robust indicator of function words.

Postulate II. The co-occurrence patterns of function words are less likely to show bias towards specific words than those for content words. For example, `and` will occur beside several other words like `school`, `elephant` and `pipe` with more or less equally distributed co-occurrence counts with all of these words. In contrast, the co-occurrence distribution of `school` will be skewed, with more bias towards `to, high` and `bus` than `over, through` and `coast`, with the list of words occurring beside `school` also being much smaller than that for `and`.

In order to test Postulate I, we measure the number of distinct words that occur to the immediate left,

right and either side of each unique word in the sub-sampled corpora. We shall refer to these statistics as *left*, *right* and *total co-occurrence counts* (LCC, RCC and TCC) respectively. To test Postulate II, we compute the *entropy* of the co-occurrence distributions of the words occurring to the *left*, *right* and either side (i.e., *total*) contexts of a word w:

$$\text{Entropy}(w) = -\sum_{t_i \in \text{context}(w)} p_{t_i|w} \log_2(p_{t_i|w}) \tag{1}$$

where, $\text{context}(w)$ is the set of all words co-occurring with w either in the left, the right or the total contexts, and $p(t_i|w)$ is the probability of observing word t_i in that specific context.

Context. In this paper, the left, right and total *contexts* of a word w respectively denote the immediately preceding (one) word, immediately succeeding (one) word and both the immediately preceding and the immediately succeeding words for w respectively, in sentences of the corpus. The definition of context (i.e., whether it includes the preceding or the succeeding one or two or three words) will change the absolute values of our results, but all the trends are expected to remain the same.

We shall refer to the co-occurrence entropies as *left, right* and *total Co-occurrence Entropies* (LCE, RCE and TCE respectively). Due to their pivotal role in syntactically connecting the different words or parts of a sentence to each other, we would expect LCC, RCC or TCC of function words to be higher than that of content words due to *Postulate I*; similarly, due to *Postulate II* we can expect the LCE, RCE or TCE to be higher for function words than for content words. If the LCE or LCC of a word w is high, it means that a large number of distinct words can *precede* w in the language (additionally, almost with equal probabilities for high LCE). Thus, predicting the *previous* word of w is difficult. Similarly, if RCE or RCC of w is high, it means that a large number of words can *follow* w in the language (additionally, almost with equal probabilities for high RCE). Thus, predicting the *next* word of w is difficult. A high TCE for a word implies that the word can be preceded and followed by a large number of words, making the prediction of either the next or the previous word (or both) for w difficult.

2.1 Experiments and Results

In our approach, the output is a ranked list of words sorted in descending order of the corresponding property. Here we adopt a popular metric, *Average Precision* (AP), used in Information Retrieval (IR) for the evaluation of ranked lists. More specifically, let $w_1, w_2, \ldots, w_n$ be a ranked list of words sorted according to some corpus statistic, say, frequency. Thus, if $i < j$, then frequency of w_i is greater than the frequency of w_j. *Precision at rank k*, denoted by P@k, is defined as

$$\text{P@}k = \frac{1}{k}\sum_{i=1}^{k} f(w_i) \tag{2}$$

where, $f(w_i)$ is one if w_i is a function word, and is zero otherwise. This function can be computed based on the gold standard lists of function words. Subsequently, *average precision at rank n*, denoted by AP@n, is defined as

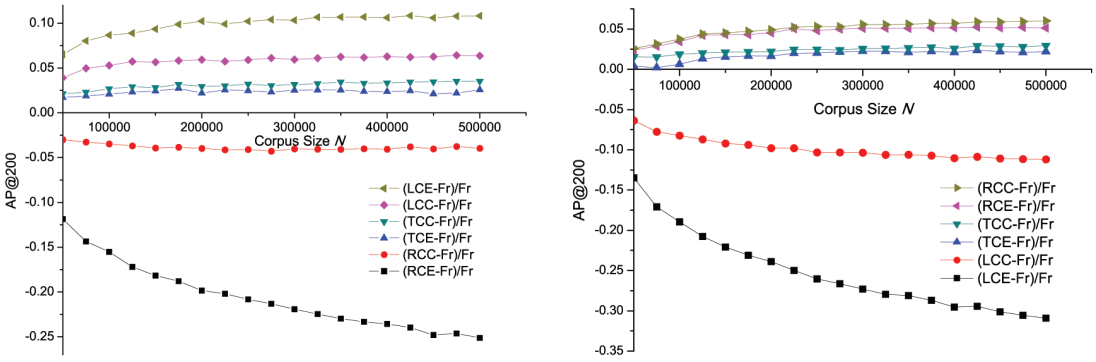
$$\text{AP@}n = \frac{1}{n}\sum_{k=1}^{n} \text{P@}k \tag{3}$$

AP@n is a better metric than P@k because P@k is insensitive to the rank at which function words occur in the list. In our experiments, we compute AP@n averaged over $\mathcal{N}$ corpus sub-samples, which is given by $\frac{1}{\mathcal{N}}\sum_{r=1}^{\mathcal{N}}(\text{AP@}n)_r$ where $(\text{AP@}n)_r$ is the AP@n for the r^{th} sub-sample. We note that there are other metrics popularly used in IR, e.g. the Normalized Discounted Cumulative Gain (nDCG). However, these are more sensitive to the correctness of the top few items in the list and hence, are not suitable for us. Knowing that the number of function words in a popular NL is at least 200 (Table 1), we compute AP@200 with respect to the gold standard lists of function words for all our experiments.

Language	Typology	Fr	LCC	LCE	TCC	TCE	RCC	RCE
English	Prepositional	0.663	**0.702**†	**0.729**†	**0.684**†	**0.679**†	0.637	0.527
Italian	Prepositional	0.611	**0.639**†	**0.645**†	**0.636**†	**0.620**	0.606	0.601
Hindi	Postpositional	0.682	0.614	0.510	**0.698**†	**0.694**†	**0.716**†	**0.713**†
Bangla	Postpositional	0.648	0.684†	0.691†	**0.730**†	**0.763**†	**0.741**†	**0.757**†

The four highest values in a row are marked in **boldface**. Statistically significant improvement over frequency is marked by †. The paired t-test was performed and the null hypothesis was rejected if p-value < 0.05.

Table 2: AP@200 for all indicators, averaged over 200 (N, V) pairs for each language.



(a) (b)

Figure 1: (Colour online) Performance of co-occurrence statistics for (a) English, and (b) Hindi, with respect to frequency for AP@200 with variation in N.

We now sort the list of all words in descending order of each of the seven indicators. We then compute AP@200 for these seven lists. To bring out the performance difference of each of the six co-occurrence features with respect to frequency, we plot (in Figs. 1 and 2) the following measure against N:

$$\text{Value plotted} = \frac{\text{Metric for indicator} - \text{Metric for Fr}}{\text{Metric for Fr}} \tag{4}$$

The x-axis can now be thought of as representing the performance of frequency. In Fig. 1, for a particular N, the data points were averaged over all (N, V) pairs (we had 20 (N, V) pairs for each N). For Fig. 2, V was binned into five zones, and for each zone, the AP was averaged over all corresponding (N, V) pairs. The observations (both N and V variation) for French and Italian were similar to that of English, while those for Hindi and Bangla were similar to each other. Table 2 reports AP values for all statistics for the four languages. From Table 2, we see that for all the languages, AP for some of the co-occurrence statistics are higher than AP obtained using frequency.

Regular improvements over frequency. From the plots and Table 2, it is evident that some of the co-occurrence statistics consistently beat frequency as indicators. In fact, as evident from Figs. 1 and 2, use of co-occurrence statistics results in systematic improvement over frequency with variations in N and V, and hence, are very robust indicators. Among the co-occurrence statistics, both entropies and counts are observed to have comparable performance.

3 Detection of Adposition Typology

From the results presented above, we observe that the best function word indicator depends upon language typology. Interestingly, while LCE and LCC are the best indicators of function words for the two prepositional languages of English and Italian, RCE and RCC perform better for Hindi and Bangla, the postpositional languages. This observation can be explained as follows. For a prepositional language, the function words, which are often the adpositions, precede the content word it is linked to. Therefore, the words following an adposition (or a function word) mark the beginnings of syntactic units such as

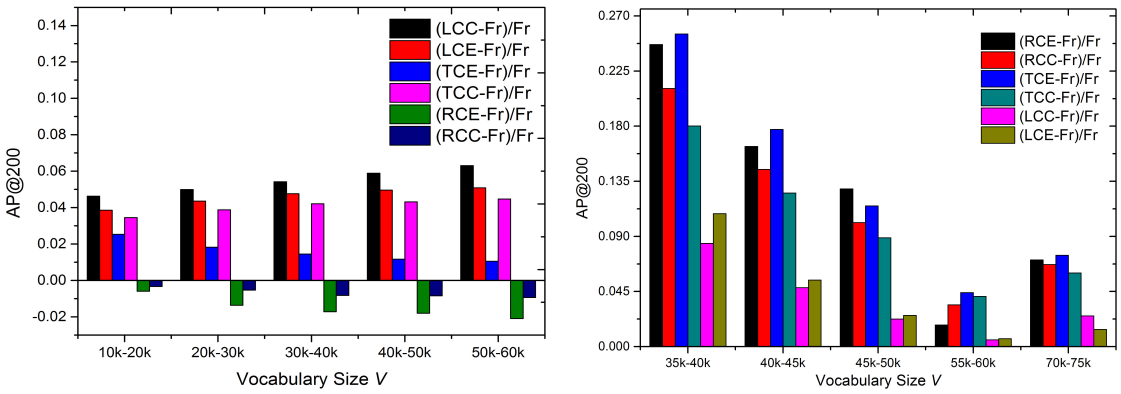


Figure 2: (Colour online) Performance of co-occurrence statistics for (a) Italian, and (b) Bangla, with respect to frequency for AP@200 with variation in V.

noun phrases and are typically restricted to certain syntactic categories. However, the words that precede the adpositions have no or much weaker syntactic restrictions. Hence, the LCE and LCC are higher and consequently better and more robust indicators of function words for prepositional languages. For very similar reasons, the RCE and RCC are better indicators of function words for postpositional languages. Importantly, we observe that TCE and TCC seem to be reasonably good predictors of function words irrespective of the typology, with performances lying in between the poorest indicators (RCE and RCC for prepositional languages and LCE and LCC for postpositional languages) and the best indicators (LCE and LCC for prepositional languages and RCE and RCC for postpositional languages) for all the four languages. This makes them safe indicators to rely on when not much is known about the language syntax. In fact, the philosophy of this research is to be of assistance in these less-known cases. Thus, co-occurrence statistics have potential in predicting the adposition typology of a new language, which we leverage in this research.

We now describe our intuition and method behind our tests for automatically detecting the adposition typology of a language. In this context, we *do not know* the actual function words or adpositions of the language under consideration. Let us take the three lists of the top 200 words from a language corpus, sorted according to the statistics TCE, LCE and RCE. For a prepositional language, we can expect to see the highest number of function words towards the top of the list when sorted according to LCE, followed by the number of function words towards the top of the TCE list. The RCE list would be expected to be the poorest in this regard. Thus, we expect a higher overlap between the top 200 word lists for TCE and LCE, than for TCE and RCE. The reverse is expected to be true for postpositional languages. Similar arguments can be presented for LCC, RCC and TCC as well. We quantify this correlation between the lists using two different statistics – the *Pearson's correlation coefficient* (r) and *Spearman's Rank Correlation Coefficient* (ρ).

For computing Pearson's coefficients, we use the actual values of the distributional statistics, while for Spearman's rank coeffcients, we use the ranks of the words. Let $r(\mathrm{TL})$ and $\rho(\mathrm{TL})$ respectively denote the Pearson's and Spearman's Rank correlation coefficients of the lists sorted by TCE and LCE (or TCC and LCC), and similarly, let $r(\mathrm{TR})$ and $\rho(\mathrm{TR})$ denote the respective coefficients for the lists sorted by TCE and RCE (or TCC and RCC).

Postulate. For a prepositional language, the top-200 words by LCE will have a higher correlation with the top-200 words by TCE than the corresponding correlation of RCE with TCE. For a postpositional language, the top-200 words by RCE will have a higher correlation with the top-200 words by TCE. Formally, for *prepositional languages*, $r(\mathrm{TL}) > r(\mathrm{TR})$, and $\rho(\mathrm{TL}) > \rho(\mathrm{TR})$, while for *postpositional languages* $r(\mathrm{TL}) < r(\mathrm{TR})$ and $\rho(\mathrm{TL}) < \rho(\mathrm{TR})$.

Language	Family	ρ(TL)	ρ(TR)	ρ(Diff.)	Predicted	True

Misclassified languages are marked in gray.

Table 3: Detecting adposition typology using Spearman's rank correlation coefficients on entropy lists.

4 Experimental Results and Observations

In this section, we first present our datasets, followed by detailed experiments on adposition typology detection and inferences drawn from the observations.

4.1 Datasets

For all our typology detection experiments, we use datasets from the publicly available Leipzig Corpora[2]. We selected 23 languages from various families that are typologically diverse. A $(300,000)$-sentence corpora was used for all the languages so as to ensure similar-sized corpora for all the languages (many languages do not have a larger corpus). All languages examined have been listed in Table 3, along with their families and true adposition typologies (accompanied by appropriate references).

4.2 Experiments and Results

We extracted the top-200 words by TCE, LCE and RCE, and TCC, LCC and RCC from the $300k$-sentence corpora. We then computed $r(\mathrm{TL})$, $\rho(\mathrm{TL})$, $r(\mathrm{TR})$ and $\rho(\mathrm{TR})$, for both entropies and counts. As per our postulate, if $\rho(\mathrm{TL}) - \rho(\mathrm{TR})$ (= $\rho(\mathrm{Difference})$) is positive, the language is prepositional; if it is negative, the language is postpositional. The same can be expected for $r(\mathrm{Difference})$.

The performance of ρ as a predictor was found to be better than r. Results when the entropy lists are used are presented in Table 3. For only 4 out of 23 languages, the typology predictions are incorrect. We observe that three of these misclassified languages are from the Uralic family that are *synthetic* in nature characterized by extensive regular *agglutination* of modifiers to verbs, nouns, adjectives and numerals.

[2] http://corpora.informatik.uni-leipzig.de/download.html

Corpus Size	Entropy lists (r)	Entropy lists (ρ)	Count lists (r)	Count lists (ρ)
$10k$	$17/23$	$\mathbf{21/23}$	$17/23$	$13/23$
$100k$	$17/23$	$\mathbf{19/23}$	$18/23$	$13/23$
$300k$	$16/23$	$\mathbf{19/23}$	$16/23$	$13/23$

The highest value in a row is marked in **boldface**.

Table 4: Correct predictions by strategy with varying factors.

The average number of characters in words of these languages were found to be in the relatively higher range of nine to eleven. Thus, function words, especially the adpositions, seldom occur as free words in these languages and hence our method cannot capture the distributional characteristics of the adpositions. It is worthwhile to note that the method can predict the correct typology for other languages that employ agglutination to a lesser degree (Bulgarian, Dutch, German, Tamil and Turkish). Lithuanian, though not synthetic, is a highly inflectional language and therefore, instead of adpositions it makes extensive use of case-markers. With ρ(Difference) very close to zero, our prediction for Lithuanian is inconclusive.

A note on synthetic languages: For synthetic languages, the difference between the two rank correlation coefficients are close to zero, which provides us with a direct way to identify them. One could also employ unsupervised morphological analysis to automatically identify and segment affixes, which will provide deeper insight into the morpho-syntactic properties of the language. Nevertheless, affixes (like infixes in Arabic or case-marking suffixes in Bangla) are technically not considered as adpositions, and therefore, they do not really determine the adposition typology. Languages are divided into four classes according to their adposition usage: prepositional, postpositional, ambi-positional (use both types) and adposition-less (use none). Thus, as far as adposition typology is concerned, it suffices to identify whether a language is primarily adposition-less, which our technique is potentially capable of doing (we demonstrate it for four languages, but we believe more experimentation is needed to establish this claim). Note that a language may use case-marking affixes along with adpositions. In such cases our method is able to correctly determine the typology, as demonstrated for Bangla.

4.3 Experimental variations

We repeated the above experiments with lists of TCC, LCC and RCC instead of the co-occurrence entropies. The performance was found to be poorer than the entropy lists, with nine classification errors instead of the earlier four. Performance of these lists by co-occurrence counts was found to be poorer in other cases as well (Table 4). We systematically experimented with r instead of ρ. To test the performance of our method with even smaller corpora, we sub-sampled 3 and 30 corpora containing $100k$ and $10k$ sentences respectively from the $300k$ corpus. We computed the correlation between the original top 200 words obtained using TCE (or TCC) from the $300k$ corpus and the corresponding LCE and RCE (or LCC and RCC) lists obtained from the smaller corpora. For a given language, the mean of ρ(Difference) and r(Difference) were used to predict the typology (observed standard deviations were very low, of the order of 10^{-3}). The results of these experiments are summarized in Table 4. Out of 23 languages, 21 and 19 were correctly classified by ρ for corpora of $10k$ and $100k$ sentences. The corresponding number for r are 18 for both $10k$ and $100k$, and 17 for $300k$ corpora. Thus, the sensitivity of the method improves with slightly smaller corpora, provided that the TCE list, which is being used as a proxy for the gold standard function word list, is computed from a slightly larger corpus. Finally, we note that using Spearman's rank correlation coefficient with lists constructed by co-occurrence entropy consistently produces the best results.

5 Conclusions and Future Work

Knowing the adposition typology of a natural language can be useful in several NLP tasks, and can be especially useful in understanding new or undeciphered languages. In this research, we have taken one

of the first steps towards automatic discovery of adposition typology. First, we have shown, through experiments on two prepositional and two postpositional languages, that function words can be effectively extracted from medium-sized corpora using word co-occurrence statistics, and such measures usually outperform simple frequency when used for the same task. Next, difference in behavior of various co-occurrence statistics for prepositional and postpositional languages has been exploited to devise a simple strategy for predicting the adposition typology of a language. Simple differences of rank correlation coefficients among total, left and right word co-occurrence entropies have been shown to be potent signals towards automatic discovery of adposition and noun phrase typology in a language. Results show sufficient promise through an extensive evaluation over 23 languages.

We ventured into this study while solving a very practical and important problem: query understanding through analysis of the structure of Web search queries. While queries seem to have an emergent syntax, it is unclear whether they have function words, and if so what role they play in determining the query grammar. To this end, we conducted the current study. Thus, we envisage that this technique will be applicable for any such emergent linguistic system, such as pidgins, creoles, and computer mediated communications (CMCs) like SMS and chats, where there is a large amount of text data available but the grammar is emerging or yet to be analyzed. Other examples are that of undeciphered languages, e.g., Indus valley language or script. In fact, our method can be applied to any system of symbols, be it linguistic or non-linguistic, such as musical note sequences.

As future work, it is important to improve our prediction accuracy further, while including more languages in the experimental setup. Combining clues from other sources to resolve uncertain cases and devising better ways of choosing corpus size and significance thresholds are some of the avenues in which effort may be channelized. Extending our approach to a morpheme-level analysis would also be beneficial in dealing with highly agglutinative and inflectional languages.

What good are 'Nominalkomposita' for 'noun compounds': Multilingual Extraction and Structure Analysis of Nominal Compositions using Linguistic Restrictors

Patrick Ziering **Lonneke van der Plas**
Institute for Natural Language Processing
University of Stuttgart, Germany
{Patrick.Ziering, Lonneke.vanderPlas}@ims.uni-stuttgart.de

Abstract

Finding a definition of compoundhood that is cross-lingually valid is a non-trivial task as shown by linguistic literature. We present an iterative method for defining and extracting English noun compounds in a multilingual setting. We show how linguistic criteria can be used to extract compounds automatically and vice versa how the results of this extraction can shed new lights on linguistic theories about compounding. The extracted compound nouns and their multilingual contexts are a rich source that serves several purposes. In an additional case study we show how the database serves to predict the internal structure of tripartite noun compounds using spelling variations across languages, which leads to a precision of over 91%.

1 Introduction

Compounding is a phenomenon that is studied extensively in linguistic literature. Also in computational linguistics, compounds are enjoying more and more attention (Ó Séaghdha, 2008; Hendrickx et al., 2013). Compounding is a very productive word formation. Already 2-year-olds are able to form new words by using compounds consisting of two morphemes (Clark, 1981). As a consequence, compounds are a very common word type but many occur with a very low token count. In an analysis of the German APA corpus, Baroni et al. (2002) found that almost half (47%) of the word types were compounds. At the same time, the compounds accounted for a small portion of the overall token count (7%), which suggests that many of them are rare (83% of the compounds had a corpus frequency of 5 or lower). For English, more than half of the two-noun compounds (e.g., *car park*) in the BNC occur exactly once (Kim and Baldwin, 2006). The high productivity of compounds makes compositional approaches to automatic processing indispensable: listing all possible compounds in a dictionary would be as infeasible as listing all possible adjective-noun combinations. Even for compound nouns that occur 10 times or more in the BNC, static English dictionaries provide only 27% coverage (Tanaka and Baldwin, 2003).

Being abundant as a phenomenon but scarce in terms of individual examples (the combination of high type frequency and low token frequency) makes the analysis of these compound nouns particularly problematic for statistical techniques that need high token frequencies to make accurate predictions. Data sparsity is expected to lead to low performance. However, the correct analysis of compound nouns is important for a number of NLP tasks, for example in machine translation (Bouillon et al., 1992; Rackow et al., 1992; Johnston and Busa, 1999; Navigli et al., 2003). The accurate translation of compounds is non-trivial, because we find a large amount of variation in the way languages deal with compounding. Some languages such as German use closed compounding (i.e., they create one-word compounds, e.g., *Todesstrafe* (*death penalty*)) whereas others do not. In Romance languages, such as French, compounds are not as productive, instead postmodifying prepositional phrases (e.g., *peine de mort*) and adjectives (*peine capitale*) are used to construct complex nominals.

Another challenge in compound translation is due to the fact that the amount of underspecification in compound surface structure varies between languages. For example, whereas English leaves the compound relation (i.e., the semantic relation between two components, e.g., N_2 *made of* N_1 as in *iron door*)

Proceedings of COLING 2014, the 25th International Conference on Computational Linguistics: Technical Papers, pages 1047–1058, Dublin, Ireland, August 23-29 2014.

covert, in French we find prepositions that correlate with the relation type (Girju, 2007; Celli and Nissim, 2009). *Chocolate cake*, cake **made of** chocolate, is translated with *gateau **au** chocolat*, whereas *wedding cake*, cake **made for** a wedding, is *gateau **de** marriage*.

The first aim of this study is to extract a large database of compounds and their translations in context from a parallel corpus. This database will serve multiple purposes. For example, it will be used to study compounding across different languages, and we will exploit the cross-lingual variation for compound processing. In the second part of this paper, we will show a case study of how the extracted database can be used for analysing the structure of noun phrases, more specifically, we exploit spelling variations across languages for bracketing three-noun compounds (3NCs) such as *air traffic control*, which could be indicated as LEFT bracketing using the German phrase *Kontrolle des Luftverkehrs* (*control of air traffic*).

Compounding is an important subject of study in theoretical linguistics, because it constitutes a continuum from fully compositional to idiosyncratic word formation and is found at the boundary between words and phrases. However, there is virtually no reliable and universally accepted criterion for distinguishing compounds from phrases or other types of word formations, as stated by Lieber and Stekauer (2009). They discuss reasons for the complexity that arises when defining noun compounds, that we will review in the next section. They do, however, also describe a number of linguistic tests, each with their own advantages and drawbacks.

This brings us to the second aim of this paper. We propose an iterative method that, in absence of a clear definition, validates several linguistic tests on corpus data and continuously refines the definition. We show how we use linguistic tests to extract compounds automatically and vice versa how the results of this extraction can shed new lights on linguistic theory about compoundhood. The multilingual nature of our data (we work on parallel corpora) has the additional advantage that a cross-lingual definition can be sought by studying compounds in context and their translation across several languages.

In Section 2, we discuss the problem of defining noun compounds (NCs) as described by Lieber and Stekauer (2009) and present an iterative method for defining and extracting English NCs starting with an initial definition based on some linguistic tests. In Section 3, we present our method for extracting English NCs and their translations to several languages from a parallel corpus using a set of extraction rules. An experimental setup and results are presented in Section 4. In Section 5 we show in a case study of bracketing three-noun compounds how our database serves for exploiting multilingual spelling variations. Section 6 describes related work and finally Section 7 concludes.

2 Iterative method for the definition and extraction of noun compounds

In this section, we outline the controversy of defining compoundhood as described in linguistic literature. We present several linguistic tests for distinguishing compounds and show how we implement some linguistic criteria that can be used for identification and extraction of noun compounds and how these constitute the initial definition.

2.1 Definition of compounds and linguistic criteria

When we seek to find a working definition of noun compounds (NCs), we have to keep in mind that not only the definition but also the existence of such an NC is controversial. Lieber and Stekauer (2009) present a discussion about this controversy sketched below. While Bauer (2003) defines a compound as a "formation of a new lexeme by adjoining two or more lexemes", Marchand (1967) argues that there is no compounding word formation at all. Instead, he uses the word formation EXPANSION, which combines prefixed words like *reheat* with such as *steamboat* using the criterion of a free head. Lieber and Stekauer (2009) highlight two reasons for the complexity that arises when defining noun compounds. Firstly, in some languages, constituents are not free but stems or roots. For example, the Slovak term *rýchlovlak* (express train) starts with the stem of the adjective *rýchly* (as in the phrase *rýchly vlak* (fast train)). The lack of inflection in English makes compositional and phrasal structures (i.e., *fast train* as phrase or as compound (*express train*)) collapse. Secondly, sometimes phrases and derivations cannot be distinguished from compounds. While *blackboard* (in opposition to a *black board*) can be classified as compound without dissent, a *tomato bowl* that just happens to hold tomatoes might not be regarded as a

single lexeme (conforming Bauer's (2003) definition).

So, the only way for getting a suitable definition is to find solid criterions. Although Lieber and Stekauer (2009) come to the conclusion that there is almost no reliable and universally accepted criterion, they mention several plausible tests. Compounds can be identified by prosody. While in the phrase *black bird*, the head (*bird*) is stressed, in the compound *blackbird* the stress is on the first syllable (*black*). A syntactic test mentioned by Lieber and Stekauer (2009) is inseparability, i.e., there must not be any element intervening a compound's components. While *black bird* can be understood as compound, *black ugly bird* is a phrase. Another promising syntactic criterion is the inability to modify the first element (i.e., the modifier) of a compound. In a phrase like *social person*, the first element (*social*) can be modified (i.e., *very social person*). This is not possible for compounds (e.g., very *social policy*). A last syntactic criterion, the inability to replace the second noun of a nominal compound with a proform such as *one* (e.g., *black bird* vs. *black one*), would need human support. A morphological criterion states that in compounds only the head is inflected. Although this assumption does not always hold (as shown in examples like *overseas investor* or *girls club*), this seems to be a promising criterion when investigating inflectional behaviour in aligned languages that show strong morphology, e.g., French. Conversely, determining compoundhood on the basis of spelling is discarded by Lieber and Stekauer (2009). English orthography is highly inconsistent: some compounds usually occur as a closed compound (e.g., *football*), some occur hyphenated and some occur as an open compound (e.g., *waiting room* or *rule of law*). For some compounds, several spellings are possible (e.g., *flowerpot*, *flower-pot*, *flower pot* or *pot of flowers*).

In our study, we focus on written language as given in a parallel corpus. Since we do not have any speech data, we cannot use any phonological features such as stress for the extraction of noun compounds. For the inability to replace the second noun of a nominal compound with a proform, we cannot assess if the meaning of a sentence would have changed (e.g., *We see blackbirds* vs. *We see black ones*).
