In this paper, we focus on criteria that are most suitable with the current data. Although Lieber and Stekauer (2009) exclude spelling as a reliable criterion of compoundhood, we take it as starting point. The parallel corpus we use for the extraction includes several languages. Spelling variations between languages can be exploited to find compounds (e.g., *social policy* can be written as one word in German (*Sozialpolitik*)). We account for the English spelling variations by defining part-of-speech (PoS) patterns that cover most plausible spellings. These PoS patterns treat each noun or adjective as a compound's component and thus, this way of extraction inherently implements the criterion of inseparability. We exploit multilingual evidence in terms of cross-lingual differences in spelling to extract compounds. Diverse language families have different declinations of forming a closed compound. While languages like Danish and German prefer closed compounding, English and Romance languages like Spanish use open compounds. It is this spelling variation that we base our first set of extraction rules on with the aim of having a set of English NCs and their translations in up to 9 European languages. We will show that cross-lingual closed compounding is a promising feature for extracting English NCs.

The inability to modify the first element of a compound seems to be a promising test. Since there are many linguistic factors that have to be taken into account (e.g., morphological agreement in gender, number or case), we plan to include this criterion for several languages and any combination of contextual modifier and potential noun compound. We will implement this and further morphological criteria in future work.

2.2 Initial definition for compound extraction

With a focus on multilingual validity, we adapt the definition of Bauer (2003) to our multilingual setting. Inspired by Behagel's (1909) First Law ("Elements that belong close together intellectually will also be placed close together"), we associate a closed compounding language realising an English word sequence as a closed NC with an indicator for compoundhood:

Initial definition: *A noun compound is a nominal composition of several lexemes that are represented as a one-word expression in some of the languages studied.*

This definition covers both target single words (e.g., *blackbird* translates to German as *Amsel*) or target

closed compounds (e.g., *football match* translates to Dutch as *voetbalwedstrijd*).

We are aware of the fact that this definition leads to some controversial cases for English word sequences including pre-nominal adjectives. While some of them are commonly accepted such as *social policy* (German: *Sozialpolitik*), others are less accepted such as *strong wind* (German: *Starkwind*) or *small car* (German: *Kleinwagen*). This is not an unwanted side-effect. On the contrary, these controversial cases are an essential part of the iterative process we described, as they will foster linguistic discussions. Although the German *Starkwind* can be regarded as partly compositional, it is frequently used with a concrete definition (in contrast to the phrase *starker Wind*) and cannot occur in a context violating this definition, as shown in the table below.

1 a)	Als Starkwind wird meist eine Windstärke zwischen 6 und 7 Beaufort bezeichnet.
1 b)	A {strong wind} usually refers to a wind force of 6-7 Beaufort.
2 a)	Am Samstag weht ein starker Wind mit Windstärke 8 von Westen.
2 b)	On Saturday, a strong wind with wind force 8 will blow from the west.
3 a)	*Am Samstag weht ein Starkwind mit Windstärke 8 von Westen.
3 b)	On Saturday, a *{strong wind} with wind force 8 will blow from the west.

3 Multilingual extraction of NCs

This method is based on the initial definition for compound extraction described in Section 2.2 and can be adapted in succeeding iterations. English NCs are extracted from a parallel corpus that includes English and some closed compounding languages (e.g., German).

3.1 Preprocessing the parallel data

In Section 4.1, we describe the tokenization, sentence alignment, word alignment and PoS tagging we apply to the parallel data in more detail. In addition, we perform a binary compound splitter on each word that is tagged as a noun by following a variant of the methods of Stymne et al., (2013). This unsupervised splitter checks each noun for all possible segmentations into at most two components with at least two characters. All possible segmentations are scored with the geometric mean of the components' frequencies in the parallel corpus. The highest-scored segmentation (possibly with no split point) is used.

3.2 Preselection of English noun compounds using PoS patterns

As a basis for the extraction of English NCs, we use a set of possible English PoS sequences that can constitute an NC. These PoS patterns account for the various ways of composing English NCs and for the inseparability property as described in Section 2.1. Table 1 lists all plausible PoS patterns for bipartite and tripartite NCs with some examples (cf. the Penn Treebank tag set (Marcus et al., 1993)). For all examples in Table 1, we found translations to a closed compound in German, which satisfies our initial definition described in Section 2.2, e.g., *overall recovery rate* has been translated to *Gesamtrückforderungsquote*. Although the larger the number of components, the sparser the number of (correct) extractions, we create a regular expression for PoS patterns that cover English NCs with n components (where $2 \leq n \leq 10$). This regular expression combines all possible combinations of observed NC types. In the next step, we will filter noise, that occurs mostly in longer word sequences.

3.3 Noise filters

The selection of English NCs and their translations is based on automatic preprocessing, which leads to some noise due to false PoS tags or flaws in word alignment. With increasing word sequence length, the amount of noise increases. We apply several filters on each preselected NC and on their alignments to all other languages in the corpus and keep only those that pass all filters.

3.3.1 PoS filters

1. Two filters are applied to all languages: we disqualify word sequences including nouns or adjectives that (1) consist of only one character or (2) are contained in a stop list[1].

[1] ranks.nl/stopwords

PoS pattern	Example
Bipartite noun compounds	
NN	marketplace
NN NN	death penalty
JJ NN	structural policy
NN POS NN	children's development
NN IN NN	fall in population
NN IN DT NN	concussion of the brain
Tripartite noun compounds	
NN NN NN	energy security goal
JJ NN NN	overall recovery rate
NN IN NN IN NN	income per head of population
Regular expression for 2–10 components	
NN ((IN (DT)?|POS))? NN){1,9}	greenhouse gas emission allowance trading scheme
JJ NN ((IN (DT)?|POS))? (JJ)? NN){1,8}	internal energy market package

Table 1: English PoS sequences for noun compounds

2. Then, to account for PoS tagging errors in English, we collect all words and their PoS tags in the parallel corpus. For each word, we compute the probability of being tagged as a noun or adjective as given in (1).

$$P(noun/adj \mid word) = \frac{f((noun \cup adj) \cap word)}{f(word)} \quad (1)$$

We disqualify English word sequences, if they contain a noun or adjective w with $P(noun/adj \mid w) < \theta$. After testing several values for θ, we have decided to choose $\theta = 0.15$ because it has turned out to be a promising trade-off between coverage and precision (e.g., accepting words like *human* but rejecting words like *anywhere*).

3.3.2 Word alignment filter

Shortcomings in word alignment quality are remedied with three word alignment filters.

1. We truncate extraneous words (i.e., determiners, prepositions and (ad)verbs) from the border of the word sequence (adjectives are removed from the right border for Germanic languages and from the left border for Romance languages).

2. We disqualify the word sequence as being phrasal if it contains two consecutive nouns with verbs or adjectives in between or if the nouns are more than ϕ tokens apart from each other. When analysing many instances of Romance phrases aligned to an English noun compound, we observed that $\phi = 3$ is the maximum token distance two nominal components can be apart (usually separated by preposition or preposition+determiner). If the word sequence is qualified as phrasal, we add determiners and prepositions that occur in the context between the nouns, otherwise the word sequence remains unchanged.

3. We remove the word sequence if it does not contain at least one noun.

The resulting set of English word sequences that conform to the regular expression in Table 1 and their aligned and filtered word sequences are stored as a set of m-tuples of word sequences. Subsequently, we will refer to this set as the *basic set*. The basic set still contains English word sequences that do not comply with our initial definition for compound extraction (Section 2.2), i.e., that are not aligned to a closed compound. In the next step, we apply a restrictor to all NCs in the basic set and keep only those instances that pass the restrictor.

3.4 Closed compound restrictor

An English word sequence is considered to be an NC if it is represented as a one-word expression in some of the closed compounding languages (e.g., Dutch, German, Swedish, ...). Given a parallel corpus with $n > 1$ closed compounding languages, this definition leaves space for investigating the degree of cross-lingual closed compounding (deg_{closed}) which is necessary for optimal extraction quality (i.e., optimal precision and recall). Because the rules described in Section 3.3.2 still leave some word alignment errors (i.e., English word sequences that are aligned to only a part of the true translation), a single compounding language realising the English word sequence as one word (i.e., $deg_{closed} = 1$) might not be restrictive enough.

The closed compound restrictor with $deg_{closed} \geq i$ retains only English word sequences that are aligned to at least i one-word expressions in the aligned closed compounding languages. We will refer to this restrictor as $CCR(i)$ and to the resulting data set as $closed\ compound(i)$.

4 Experiments for NC Extraction

4.1 Setup

Data and preprocessing. We use the 7th release of the Europarl corpus[2]. Although the Europarl corpus comprises 21 European languages, the amount of common data they cover is rather small. This means, the more languages we use, the smaller the amount of common data. In order to get a good trade-off between cross-lingual coverage and language variation exploitation, we decided on a set of 10 languages: English, the closed compounding languages Danish, Dutch, German and Swedish, as well as Greek and the Romance languages French, Italian, Portuguese and Spanish. Instead of preprocessing the parallel corpus on our own, we exploit the already preprocessed Europarl resource of OPUS[3] (Tiedemann, 2012). This preprocessed resource is PoS tagged using TreeTagger (Schmid, 1995) for English, Dutch, German, French, Italian and Spanish and the Hunpos[4] tagger for Danish, Portuguese and Swedish. We additionally tagged the Greek data using the MATE[5] tagger. The sentence alignment provided by OPUS is restricted to language pairs. As we need a sentence representation that is parallel in all 10 languages, we apply the OPUS sentence aligner (with English as pivot) on our language set and extract a total of 884,164 parallel sentence representations. The word alignment information provided by OPUS was also based on language pairs. This means, the sentence-wise token indices has to be adapted to our updated sentence representation (which is different due to a larger language set). In OPUS, the word alignment tool GIZA++ (Och and Ney, 2003) has been used with the symmetrisation heuristics (grow-diag-final-and (Koehn et al., 2007)).

4.2 Evaluation procedure and scoring

In order to compare the added value in terms of recall and precision of each closed compound restrictor (i.e., $CCR(1)$ to $CCR(4)$), we randomly select 50 accepted and 50 rejected English word sequences for each restrictor. We rate the correctness of acceptance and rejection and compute precision and recall as given in (2) and (3). F-Score is defined as harmonic mean of precision and recall.

$$Precision = \frac{accepted \cap correct}{accepted} \tag{2}$$

$$Recall = \frac{accepted \cap correct}{(accepted \cap correct) \cup (rejected \cap incorrect)} \tag{3}$$

The precision of the basic set is measured as the accuracy of a 50 sample subset. We do not compute recall and F-Score for the basic set.

[2] statmt.org/europarl

[3] opus.lingfil.uu.se

[4] code.google.com/p/hunpos/downloads/list

[5] code.google.com/p/mate-tools

We measure the amount of closed NCs in a given closed compounding language (ccl) and for a given set of NCs (Set) by using the frequency of closed NCs relative to the number of all word sequences ($N_{Set,cll}$) (word sequences removed in Section 3.3 are excluded). Since the alignment to single words is still somewhat noisy (i.e., our compound splitter does not work error-free and there are still deficiencies in the word alignment), we select a set of 50 closed noun compound samples and rate the accuracy. The final amount of closed NCs is the product of relative frequency and accuracy, as given in (4).

$$p_{ccl}(Set) = \frac{f_{Set}(closed\ NC)}{N_{Set,cll}} \cdot acc_{ccl}(Set) \tag{4}$$

4.3 Results

Set	Size	Precision	Recall	F-Score	p_{en}
Basic set	3,178,661	38.0%	—	—	1.5%
closed compound (1)	795,518	84.0%	71.2%	77.1%	4.7%
closed compound (2)	495,837	92.0%	74.2%	82.1%	6.6%
closed compound (3)	316,330	98.0%	65.3%	78.4%	9.2%
closed compound (4)	143,121	98.0%	63.6%	77.2%	10.4%

Table 2: Extraction quality of the basic set after restrictor application

Table 2 shows the results when applying the four different degrees of the closed compound restrictor to the basic set. The first result is that using only a PoS-based method leads to a very poor extraction accuracy (38%). For the applications of the closed compound restrictors, the result is that increasing deg_{closed} means increasing precision but decreasing recall in NC extraction. The reason for this is that an aligned closed NC is generally a sufficient condition for an English NC (except for controversial cases such as *strong wind*) but not a necessary condition (i.e., a true English NC may be aligned to only periphrastic constructions). The highest F-Score (82.1%) is achieved using $CCR(2)$. We can conclude that the closed compound restrictor is a reliable method for extracting English NCs. In future work, we will use a large set of human annotators with different backgrounds in order to get a widely distributed sense of compoundhood. Moreover, instead of a binary rating, we will consider compoundhood as a continuum and compare rating scores with the amount of aligned closed compounding languages realising a closed compound in a larger parallel corpus.

The last column in Table 2 shows the amount of closed English NCs in each respective set. Since deg_{closed} correlates with the amount of closed English NCs, we can conclude that, despite the cross-lingual differences in spelling conventions attested in linguistic literature, there is a bias for a universal consensus in closed compounding.

Language	p_{ccl}
German	71.2%
Danish	63.3%
Swedish	62.2%
Dutch	58.7%

Table 3: The amounts of closed noun compounds

Table 3 shows the amounts of closed noun compounds in the closed compounding languages Danish, Dutch, German and Swedish, extracted from the closed compound (1) set. Our result shows that German is the most productive language in closed compounding (71.2%), while the other languages have a similar productivity (58-63%).

The result of our extraction method is a database of English NCs and their translations in up to 9 European languages. As described in the introduction, this database will serve several purposes. One is to study cross-lingual variation. Table 4 shows some examples of multilingual noun compound extractions from closed compound (2).

English	German	Dutch	French	Italian
automotive sector	Automobilmarkt	automobielsector	secteur automobile	mercato dell' automobile
fishing techniques	Fischfangtechniken	visserijmethoden	techniques de pêche	tecniche di pesca
timetable	Zeitplan	tijdschema	calendrier	calendario
highways	Autobahnen	snelwegen	autoroutes	autostrade
trading system	Handelssystem	handelsbestel	système commercial	sistema di scambi

Table 4: Examples of multilingual noun compounds

The examples show that English noun compounds have various realisations in European languages. Although French and Italian are open compounding languages, we do find closed compounding (e.g., *autoroutes*). Compounds such as *timetable* can also be aligned to single nouns such as *calendrier* (calendar). We found three common word formation types in Romance languages for bipartite noun compounds: (1) two nouns and a preposition in between, (2) one noun and a post-nominal adjective and (3) a single (possibly compounding) noun. Although Romance languages usually agree with respect to the word formation type, they may disagree as is the case for French and Italian for the example concerning *trading system*. One interesting observation is that while the head of *highways* (*ways*) is translated fairly literally, the modifier (*high*) is replaced by alternative aspects. On highways, cars (***Auto**bahnen* (*car-ways*)) usually drive fast (***snel**wegen* (*fast-ways*)). In future work, we will use this database for researching the nature of compoundhood in a cross-lingual perspective. The resource is publicly available for future research[6].

5 Bracketing three-noun compounds

In this section, we show a case study of how our extracted database can be used to predict the structure of NPs, more specifically to bracket tripartite noun compounds (3NCs), i.e., a composition of three bare nouns that function as one unit. Given a 3NC, we can either have RIGHT bracketing, as in *baby [bicycle seat]*, or LEFT bracketing, as in *[human rights] abuses*.

5.1 The cross-lingual bracketing method

We first start with six phrase patterns that correspond to foreign phrases that are aligned to an English 3NC, as shown in Table 5, where SN refers to a single (non-compounding) noun, FC refers to a functional context (i.e., a sequence of functional words), ADJ refers to an adjective and CNC refers to a closed (bipartite) NC (based on the splitter described in Section 3.1). Each phrase pattern contains a complex unit that is separated from the rest, e.g., a closed NC or a combination of adjective and single noun. For each pattern, we know what is the head and what is the modifier: the first phrase pattern contains only one nominal component, that can be identified as head. For the other patterns, the order is: head, FC, modifier. Based on the assumption that the aligned head corresponds to the English head, we can infer the English bracketing from the complexity of the aligned head. If the aligned head is the complex unit, the English bracketing label is RIGHT, otherwise LEFT. The third column in Table 5 shows the inferred labels for the English 3NC based on the foreign phrase pattern. For an English 3NC, we check all aligned languages for a matching phrase pattern and collect, in the case of a match, the inferred label. The majority label determines the final bracketing label.

The examples below illustrate instances for each phrase pattern, where the indices correspond to those in Table 5.

[6] www.ims.uni-stuttgart.de

	Phrase pattern in foreign language	Label for English 3NC
(1)	ADJ CNC	RIGHT
(2)	CNC FC SN	RIGHT
(3)	SN FC CNC	LEFT
(4)	SN FC ADJ SN	LEFT
(5)	ADJ SN FC SN	RIGHT
(6)	SN ADJ FC SN	RIGHT

Table 5: Phrase pattern and inferred label

(1) de: *staatliche Steueraufsichtsbehörden*
state {tax inspectorates}
"state tax inspectorates"

(2) de: *Absatzmarkt für Fahrzeuge*
{sales market} for vehicles
"car sales market"

(3) nl: *methode voor geboortebeperking*
method for {birth control}
"birth control method"

(4) sv: *brottet mot mänskliga rättigheterna*
abuses of {human rights}
"human rights abuses"

(5) da: *gennemsnitlige overførsel af data*
{average transfer} of data
"data transfer rate"

(6) es: *consumo final de energía*
{consumption final} of energy
"energy end consumption"

We observed that the initial assumption (saying that the aligned head corresponds to the English head) is not always true. Sometimes the English head and modifier are swapped in aligned languages, as illustrated in example (7).

(7) nl: *stabiele wisselkoersen*
stable {exchange rate}
"exchange rate stability"

To solve this problem, we inspect the word alignment from the phrase pattern of language l_j to the English nouns N_1, N_2 and N_3 in a 3NC. If the complex unit is aligned to $\{N_2, N_3\}$ or to $\{N_1, N_3\}$, l_j provides the label RIGHT. If the complex unit is aligned to $\{N_1, N_2\}$, l_j votes for LEFT. If the complex unit is aligned to all three nouns, this is an indicator for a word alignment error. In this case, l_j will not perform any prediction. In all other cases, the inferred label from the phrase pattern is used.

5.2 Evaluation for cross-lingual bracketing

As there are only two possible structures for 3NCs, namely LEFT or RIGHT branching, we regard this task as a binary classification and score the accuracy of class agreement. As basis, we use the basic set created in Section 3, because alignments to closed compounds are not of interest for the bracketing task. Two trained human annotators (of which one is one of the authors) individually bracket a sample of 100 randomly selected 3NCs in context. Contextual cues can help the annotator to disambiguate the structure of the English NC, so the accompanying sentences are shown to the annotator. The annotators are no domain experts and since terms in Europarl can be quite domain specific, they are allowed to look up the meaning of the constituents in a dictionary or check Google. Annotators are asked to label 3NCs as LEFT or RIGHT, or UNDECIDED if they are unclear. Furthermore, the annotators are asked to mark extraction errors. When inspecting the inter-annotator agreement for the bracketing classes (LEFT/RIGHT; i.e., 76 of 100 samples), we achieved an agreement rate of 89% and $\kappa = 0.693$ (Cohen, 1960), which means substantial agreement (Landis and Koch, 1977). Afterwards, the annotators discuss disagreements and revise their annotations. This has led to a perfect agreement in our setting. The 8 UNDECIDED labellings show that in some cases the bracketing remains ambiguous even in context. In future work, we would like to investigate if larger contexts or domain knowledge is necessary for the disambiguation process or if the NCs are inherently flat (i.e., if LEFT or RIGHT bracketing does not make any difference in meaning). We evaluate our cross-lingual bracketing system for (1) inferred label of a phrase pattern and (2) word

alignment information for phrase pattern with inferred label as back-off. We compare the bracketing performance against the LEFT class baseline.

5.3 Results

Method	Accuracy
LEFT baseline	71.1 %
Inferred phrase pattern labels	89.0† %
Word alignment for phrase patterns	91.6† %

Table 6: Bracketing performance; † indicates significantly higher than the LEFT baseline

Table 6 shows the results of our system compared to the LEFT class baseline. The first result is that both inferred label and word alignment information for phrase pattern outperform the LEFT class baseline significantly[7]. Bracketing with word alignment information for phrase pattern outperforms bracketing based on the inferred labels.

6 Related Work

Our methods for extracting and structuring English NCs rely on the spelling of various aligned languages. Previous work on multilingual extraction include Morin and Daille (2010) and Weller and Heid (2012). These type-based approaches focus on bilingual terminology extraction using comparable corpora. Our token-based extraction method includes 10 languages and we extract both the NCs and their context. While the aforementioned work serves as resource for improving machine translation (MT) systems, we focus on NC research and how multilingual evidence can help analysing and interpreting English NCs.

This multilingual perspective on a considerable number of languages has been adopted as well by Macherey et al., (2011), who present a multilingual language-independent approach to compound splitting. Moreover, they learned morphological operations on compounding automatically. Here, Macherey et al., (2011) extract training instances using a method related to Garera and Yarowsky (2008): select a single word f in a language l translated to several English words e_i . If there is a translation for each e_i to a word g_i that shows a (partial) substring match with f, $(f; e_1, \ldots, e_n; g_1, \ldots, g_n)$ is extracted. While Macherey et al., (2011) extract training instances type-based in a bilingual setting, we directly extract NC instances with a set of four closed compounding languages. This token-based perspective has the advantage that we can process English NCs for which there is no literal translation to the target language (e.g., *health insurance* aligned to *Krankenversicherung* (lit. invalid insurance)).

In cross-lingual annotation transfer (Yarowsky and Ngai, 2001; Padó, 2007; Van der Plas et al., 2011) human annotations are transferred from one language to the other in parallel data. In this paper, we use the structural differences between languages as found in parallel corpora to generate annotations on the target language and do not rely on annotations on the source language.

Bracketing methods for both three-noun compounds and complete base NPs have been designed both supervised and unsupervised. Vadas and Curran (2007) used a supervised bracketing method on manually annotated data. Pitler et al. (2010) used the data from Vadas and Curran (2007) for a parser applicable on base NPs of any length including coordinations. Their supervised classifier exploited web-scale N-grams. Although supervised methods outperform unsupervised methods by far, the need for annotated data is a drawback of supervised approaches. Bergsma et al. (2011) used crosslingual data as additional supervision to make the need for manual annotations less pressing. Unsupervised methods use N-gram statistics (Marcus, 1980; Lauer, 1995; Nakov and Hearst, 2005) or semantic information (Kim and Baldwin, 2013).

7 Conclusion

In this paper, we discussed the complexity related to the definition of compoundhood and presented an iterative method that tries to refine existing definitions by tentatively demonstrating the efficacy of

[7] Approximate randomization test (Yeh, 2000), $p < 5\%$

linguistic criteria on corpus data. The initial implementation of two linguistic criteria, based on cross-lingual spelling conventions and the inseparability of a compound's components, achieved an F-Score of 82.1% on the task of extracting English compounds.

The extracted multilingual database of compounds in contexts serves multiple purposes. For example, it can be used to study cross-lingual variations in compounding. We showed in an additional experiment how the cross-lingual evidence found in the multilingual database can be used to bracket English three-noun compounds using cross-lingual spelling variation with a set of six phrase patterns. We achieved a bracketing accuracy of 91.6% that is very close to human performance.

In future work, we plan to continue refining the definition of compoundhood in a cross-lingual setting. We will experiment with additional linguistic criteria defined over multiple languages. This way, we hope to improve the quality of the multilingual database that we will further explore for compound analysis and translation.

Abstract

Definiteness expresses a constellation of semantic, pragmatic, and discourse properties—the communicative functions—of an NP. We present a supervised classifier for English NPs that uses lexical, morphological, and syntactic features to predict an NP's communicative function in terms of a language-universal classification scheme. Our classifiers establish strong baselines for future work in this neglected area of computational semantic analysis. In addition, analysis of the features and learned parameters in the model provides insight into the grammaticalization of definiteness in English, not all of which is obvious a priori.

1 Introduction

Definiteness is a morphosyntactic property of noun phrases (NPs) associated with semantic and pragmatic characteristics of entities and their discourse status. Lyons (1999), for example, argues that definite markers prototypically reflect *identifiability* (whether a referent for the NP can be identified by the discourse participants or not); other aspects identified in the literature include *uniqueness* of the entity in the world and whether the hearer is already *familiar* with the entity given the context and preceding discourse (Roberts, 2003; Abbott, 2006). While some morphosyntactic forms of definiteness are employed by all languages—namely, demonstratives, personal pronouns, and possessives—languages display a vast range of variation with respect to the form and meaning of definiteness. For example, while languages like English make use of definite and indefinite articles to distinguish between the discourse status of various entities (***the*** *car* vs. ***a*** *car* vs. *cars*), many other languages—including Czech, Indonesian, and Russian—do not have articles (although they do have demonstrative determiners). Sometimes definiteness is marked with affixes or clitics, as in Arabic. Sometimes it is expressed with other constructions, as in Chinese (a language without articles), where the existential construction can be used to express indefinite subjects and the *ba-* construction can be used to express definite direct objects (Chen, 2004).

Aside from this variation in the form of (in)definite NPs within and across languages, there is also variability in the mapping between semantic, pragmatic, and discourse functions of NPs and the (in)definites expressing these functions. We refer to these as *communicative functions* of definiteness, following Bhatia et al. (2014). Croft (2003, pp. 6–7) shows that even when two languages have access to the same morphosyntactic forms of definiteness, the conditions under which an NP is marked as definite or indefinite (or not at all) are language-specific. He illustrates this by contrasting English and French translations (both languages use definite as well as indefinite articles) such as:

(1) He showed **extreme care**. (unmarked)
Il montra **<u>un</u> soin extrême**. (indef.)

(2) I love **artichokes** and asparagus. (unmarked)
J'aime **<u>les</u> artichauts** et les asperges. (def.)

(3) His brother became **<u>a</u> soldier**. (indef.)
Son frère est devenu **soldat**. (unmarked)

Figure 1: CFD (Communicative Functions of Definiteness) annotation scheme, with frequencies in the corpus. Internal (non-leaf) labels are in bold; these are not annotated or predicted. +/− values are shown for ternary attributes Anaphoric, Bridging, Familiar, Generic, Predicative, Referential, Specific, and Unique; these are inherited from supercategories, but otherwise default to 0. Thus, for example, the full attribute specification for UNIQUE_PHYSICAL_COPRESENCE is $[-A,-B,+F,-G,0P,+R,+S,+U]$. Counts for these attributes are shown in the table at bottom.

A cross-linguistic classification of communicative functions should be able to characterize the aspects of meaning that account for the different patterns of definiteness marking exhibited in (1–3): e.g., that (2) concerns a generic class of entities while (3) concerns a role filled by an individual. For more on communicative functions, see §2.

This paper develops supervised classifiers to predict communicative function labels for English NPs using lexical, morphological, and syntactic features. The contribution of our work is in both the output of the classifiers and the models themselves (features and weights). Each classifier predicts communicative function labels that capture aspects of discourse-newness, uniqueness, specificity, and so forth. Such functions are useful in a variety of language processing applications. For example, they should usually be preserved in translation, even when the grammatical mechanisms for expressing them are different. The communicative function labels also represent the discourse status of entities, making them relevant for entity tracking, knowledge base construction, and information extraction.

Our log-linear model is a form-meaning mapping that relates syntactic, lexical, and morphological features to properties of communicative functions. The learned weights of this model can, e.g., generate plausible hypotheses regarding the form-meaning relationship which can then be tested rigorously through controlled experiments. This hypothesis generation is linguistically significant as it indicates new grammatical mechanisms beyond the obvious *a* and *the* articles that are used for expressing definiteness in English.

To build our models, we leverage a cross-lingual definiteness annotation scheme (§2) and annotated English corpus (§3) developed in prior work (Bhatia et al., 2014). The classifiers, §4, are supervised models with features that combine lexical and morphosyntactic information and the prespecified attributes or groupings of the communicative function labels (such as Anaphoric, Bridging, Specific in fig. 1) to predict leaf labels (the non-bold faced labels in fig. 1); the evaluation measures (§5) include one that exploits these label groupings to award partial credit according to relatedness. §6 presents experiments comparing several models and discussing their strengths and weaknesses; computational work and applications related to definiteness are addressed in §7.

2 Annotation scheme

The literature on definiteness describes functions such as uniqueness, familiarity, identifiability, anaphoricity, specificity, and referentiality (Birner and Ward, 1994; Condoravdi, 1992; Evans, 1977, 1980; Gundel et al., 1988, 1993; Heim, 1990; Kadmon, 1987, 1990; Lyons, 1999; Prince, 1992; Roberts, 2003; Russell, 1905, *inter alia*) as being related to definiteness. Reductionist approaches to definiteness try to define it in terms of one or two of the aforementioned communicative functions. For example, Roberts (2003) proposes that the combination of uniqueness and a presupposition of familiarity underlie all definite descriptions. However, possessive definite descriptions (*John's daughter*) and the weak definites (*the son of Queen Juliana of the Netherlands*) are neither unique nor necessarily familiar to the listener before they are spoken. In contrast to the reductionist approaches are approaches to grammaticalization (Hopper and Traugott, 2003) in which grammar develops over time in such a way that each grammatical construction has some prototypical communicative functions, but may also have many non-prototypical communicative functions. The scheme we are adopting for this work—the annotation scheme for Communicative Functions of Definiteness (CFD) as described in Bhatia et al. (2014)—assumes that there may be multiple functions to definiteness. CFD is based on a combination of these functions and is summarized in fig. 1. It was developed by annotating texts in two languages (English and Hindi) for four different genres—namely TED talks, a presidential inaugural speech, news articles, and fictional narratives—keeping in mind the communicative functions that have been associated with definiteness in the linguistic literature.

CFD is hierarchically organized. This hierarchical organization serves to reduce the number of decisions that an annotator needs to make for speed and consistency. We now highlight some of the major distinctions in the hierarchy.

At the highest level, the distinction is made between **Anaphora**, **Nonanaphora**, and **Miscellaneous** functions of an NP (the annotatable unit). **Anaphora** and **Nonanaphora** respectively describe whether an entity is old or new in the discourse; the **Miscellaneous** function is mainly assigned to various kinds of nonreferential NPs.

The **Anaphora** category has two subcategories: **Basic_Anaphora** and **Extended_Anaphora**. **Basic_Anaphora** applies to NPs referring to entities that have been mentioned before. **Extended_Anaphora** applies to any NP whose referent has not been mentioned itself, but is evoked by a previously mentioned entity. For example, after mentioning a wedding, *the bride*, *the groom*, and *the cake* are considered to be **Extended_Anaphora**.

Within the **Nonanaphora** category, a first distinction is made between **Unique**, **Nonunique**, and **Generic**. The **Unique** function applies to NPs whose referent becomes unique in a context for any of several reasons. For example, *Obama* can safely be considered unique in contemporary political discourse in the United States. The function **Nonunique** applies to NPs that start out with multiple possible referents and that may or may not become identifiable in a speech situation. For example, *a little riding hood of red velvet* in fig. 2 could be annotated with the label **Nonunique**. Finally, **Generic** NPs refer to classes or types of entities rather than specific entities. For example, *Dinosaurs* in *Dinosaurs are extinct.* is a **Generic** NP.

Another important distinction CFD makes is between **Hearer_Old** for references to entities that are familiar to the hearer (e.g., if they are physically present in the speech situation), versus **Hearer_New** for nonfamiliar references. This distinction cuts across the two subparts of the hierarchy, **Anaphora** and **Nonanaphora**; thus, labels marking **Hearer_Old** or **Hearer_New** also encode other distinctions (e.g., **Unique_Hearer_Old**, **Unique_Hearer_New**, **Nonunique_Hearer_Old**). For further details on the annotation scheme, see fig. 1 and Bhatia et al. (2014).

Because the ordering of distinctions determines the tree structure of the hierarchy, the same communicative functions could have been organized in a superficially different way. In fact, Komen (2013) has proposed a hierarchy with similar leaf nodes, but different internal structure. Since it is possible that some natural groupings of labels are not reflected in the hierarchy we used, we also decompose each label into fundamental communicative functions, which we call *attributes*. Each label type is associated with values for attributes Anaphoric, Bridging, Familiar, Generic, Predicative, Referential, Specific, and Unique. These attributes can have values of +, −, or 0, as shown in fig. 1. For instance, with the Anaphoric

Once upon a time there was a dear little girl who was loved by everyone who looked at her, but most of all by her grandmother, and there was nothing that she would not have given to the child.

Once she (SAME_HEAD) gave her (DIFFERENT_HEAD) a little riding hood of red velvet (OTHER_NONREFERENTIAL), (NONUNIQUE_HEARER_NEW_SPEC) which suited her (SAME_HEAD) so well that she (SAME_HEAD) would never wear anything else (QUANTIFIED); so she (SAME_HEAD) was always called 'Little Red Riding Hood.' (UNIQUE_HEARER_NEW)

Figure 2: An annotated sentence from "Little Red Riding Hood." The previous sentence is shown for context.

attribute, a value of + applies to labels that can never mark NPs new to the discourse, − applies to labels that can *only* apply if the NP is new in the discourse, and 0 applies to labels such as **Pleonastic** (where anaphoricity is not applicable because there is no discourse referent).

3 Data

We use the English definiteness corpus of Bhatia et al. (2014), which consists of texts from multiple genres annotated with the scheme described in §2.[1] The 17 documents consist of prepared speeches (TED talks and a presidential address), published news articles, and fictional narratives. The TED data predominates (75% of the corpus);[2] the presidential speech represents about 16%, fictional narratives 5%, and news articles 4%. All told, the corpus contains 13,860 words (868 sentences), with 3,422 NPs (the annotatable units). Bhatia et al. (2014) report high inter-annotator agreement, estimating Cohen's $\kappa = 0.89$ within the TED genre as well as for all genres.

Figure 2 is an excerpt from the "Little Red Riding Hood" annotated with the CFD scheme.

4 Classification framework

To model the relationship between the grammar of definiteness and its communicative functions in a data-driven fashion, we work within the supervised framework of feature-rich discriminative classification, treating the functional categories from §2 as output labels y and various lexical, morphological, and syntactic characteristics of the language as features of the input x. Specifically, we learn two kinds of probabilistic models. The first is a log-linear model similar to multiclass logistic regression, but deviating in that logistic regression treats each output label (response) as atomic, whereas we decompose each into *attributes* based on their linguistic definitions, enabling commonalities between related labels to be recognized. Each weight in the model corresponds to a feature that mediates between *percepts* (characteristics of the input NP) and attributes (characteristics of the label). This is aimed at attaining better predictive accuracy as well as feature weights that better describe the form–function interactions we are interested in recovering. We also train a random forest model on the hypothesis that it would allow us to sacrifice interpretability of the learned parameters for predictive accuracy.

Our setup is formalized below, where we discuss the mathematical models and linguistically motivated features.

4.1 Models

We experiment with two classification methods: a log-linear model and a nonlinear tree-based ensemble model. Due to their consistency and interpretability, linear models are a valuable tool for quantifying and analyzing the effects of individual features. Non-linear models, while less interpretable, often outperform logistic regression (Perlich et al., 2003), and thus could be desirable when the predictions are needed for a downstream task.

[1] The data can be obtained from `http://www.cs.cmu.edu/~ytsvetko/definiteness_corpus`.

[2] The TED talks are from a large parallel corpus obtained from `http://www.ted.com/talks/`.

4.1.1 Log-linear model

At test time, we model the probability of communicative function label y conditional on an NP x as follows:

$$p_{\boldsymbol{\theta}}(y|x) = \log \frac{\exp \boldsymbol{\theta}^\top \mathbf{f}(x,y)}{\sum_{y' \in \mathcal{Y}} \exp \boldsymbol{\theta}^\top \mathbf{f}(x,y')} \tag{1}$$

where $\boldsymbol{\theta} \in \mathbb{R}^d$ is a vector of parameters (feature weights), and $\mathbf{f} : \mathcal{X} \times \mathcal{Y} \to \mathbb{R}^d$ is the feature function over input–label pairs. The feature function is defined as follows:

$$\mathbf{f}(x,y) = \boldsymbol{\phi}(x) \times \tilde{\boldsymbol{\omega}}(y) \tag{2}$$

where the percept function $\boldsymbol{\phi} : \mathcal{X} \to \mathbb{R}^c$ produces a vector of real-valued characteristics of the input, and the attribute function $\tilde{\boldsymbol{\omega}} : \mathcal{Y} \to \{0,1\}^a$ encodes characteristics of each label. There is a feature for every percept–attribute pairing: so $d = c \cdot a$ and $f_{(i-1)a+j}(x,y) = \phi_i(x)\tilde{\omega}_j(y), 1 \le i \le c, 1 \le j \le a$.[3] The contents of the percept and attribute functions are detailed in §4.2 and §4.3 respectively.

For prediction, having learned weights $\hat{\boldsymbol{\theta}}$ we use the Bayes-optimal decision rule for minimizing misclassification error, selecting the y that maximizes this probability:

$$\hat{y} \leftarrow \arg\max_{y \in \mathcal{Y}} p_{\hat{\boldsymbol{\theta}}}(y|x) \tag{3}$$

Training optimizes $\hat{\boldsymbol{\theta}}$ so as to maximize a convex L_2-regularized[4] learning objective over the training data $\mathcal{D}$:

$$\hat{\boldsymbol{\theta}} = \arg\max_{\boldsymbol{\theta}} -\lambda ||\boldsymbol{\theta}||_2^2 + \sum_{\langle x,y \rangle \in \mathcal{D}} \log \frac{\exp \boldsymbol{\theta}^\top \mathbf{f}(x,y)}{\sum_{y' \in \mathcal{Y}} \exp \left(\boldsymbol{\theta}^\top \mathbf{f}(x,y') \right)} \tag{4}$$

With $\tilde{\boldsymbol{\omega}}(y) =$ *the identity of the label*, this reduces to standard logistic regression.

4.1.2 Non-linear model

We employ a random forest classifier (Breiman, 2001), an ensemble of decision tree classifiers learned from many independent subsamples of the training data. Given an input, each tree classifier assigns a probability to each label; those probabilities are averaged to compute the probability distribution across the ensemble.

An important property of the random forests, in addition to being an effective tool in prediction, is their immunity to overfitting: as the number of trees increases, they produce a limiting value of the generalization error.[5] Thus, no hyperparameter tuning is required. Random forests are known to be robust to sparse data and to label imbalance (Chen et al., 2004), both of which are challenges with the definiteness dataset.

4.2 Percepts

The characteristics of the input that are incorporated in the model, which we call *percepts* to distinguish them from model features linking inputs to outputs, see §4.1, are intended to capture the aspects of English morphosyntax that may be relevant to the communicative functions of definiteness.

After preprocessing the text with a dependency parser and coreference resolver, which is described in §6.1, we extract several kinds of percepts for each NP.

4.2.1 Basic

Words of interest. These are the *head* within the NP, all of its *dependents*, and its *governor* (external to the NP). We are also interested in the *attached verb*, which is the first verb one encounters when traversing the dependency path upward from the head. For each of these words, we have separate percepts capturing: the token, the part-of-speech (POS) tag, the lemma, the dependency relation, and (for the head only) a

[3] Chahuneau et al. (2013) use a similar parametrization for their model of morphological inflection.

[4] As is standard practice with these models, bias parameters (which capture the overall frequency of percepts/attributes) are excluded from regularization.

[5] See Theorem 1.2 in Breiman (2001) for details.

binary indicator of plurality (determined from the POS tag). As there may be multiple dependents, we have additional features specific to the first and the last one. Moreover, to better capture tense, aspect and modality, we collect the attached verb's *auxiliaries*. We also make note of the negative particle (with dependency label *neg*) if it is a dependent of the verb.

Structural. The structural percepts are: the *path length* from the head up to the root, and to the attached verb. We also have percepts for the number of dependents, and the number of dependency relations that link non-neighbors. Integer values were binarized with thresholding.

Positional. These percepts are the *token length* of the NP, the NP's *location* in the sentence (first or second half), and the *attached verb's position* relative to the head (left or right). 12 additional percept templates record the POS and lemma of the left and right neighbors of the head, governor, and attached verb.

4.2.2 Contextual NPs

When extracting features for a given NP (call it the "target"), we also consider NPs in the following relationship with the target NP: its *immediate parent*, which is the smallest NP whose span fully subsumes that of the target; the *immediate child*, which is the largest NP subsumed within the target; the *immediate precedent* and *immediate successor* within the sentence; and the *nearest preceding coreferent mention*.

For each of these related NPs, we include all of their basic percepts conjoined with the nature of the relation to the target.

4.3 Attributes

As noted above, though CFD labels are organized into a tree hierarchy, there are actually several dimensions of commonality that suggest different groupings. These attributes are encoded as ternary characteristics; for each label (including internal labels), every one of the 8 attributes is assigned a value of +, −, or 0 (refer to fig. 1). In light of sparse data, we design features to exploit these similarities via the attribute vector function

$$\boldsymbol{\omega}(y) = [y, A(y), B(y), F(y), G(y), P(y), R(y), S(y), U(y)]^\top \tag{5}$$

where $A : \mathcal{Y} \to \{+, -, 0\}$ returns the value for Anaphoric, $B(y)$ for Bridging, etc. The identity of the label is also included in the vector so that different labels are always recognized as different by the attribute function. The categorical components of this vector are then binarized to form $\tilde{\boldsymbol{\omega}}(y)$; however, instead of a binary component that fires for the 0 value of each ternary attribute, there is a component that fires for *any* value of the attribute—a sort of bias term. The weights assigned to features incorporating + or − attribute values, then, are easily interpreted as deviations relative to the bias.

5 Evaluation

The following measures are used to evaluate our predictor against the gold standard for the held-out evaluation (dev or test) set $\mathcal{E}$:

- **Exact Match:** This accuracy measure gives credit only where the predicted and gold labels are identical.
- **By leaf label:** We also compute precision and recall of each leaf label to determine which categories are reliably predicted.
- **Soft Match:** This accuracy measure gives partial credit where the predicted and gold labels are related. It is computed as the proportion of attributes-plus-full-label whose (categorical) values match: $|\boldsymbol{\omega}(y) \cap \boldsymbol{\omega}(y')|/9$.

6 Experiments

6.1 Experimental Setup

Data splits. The annotated corpus of Bhatia et al. (2014) (§3) contains 17 documents in 3 genres: 13 prepared speeches (mostly TED talks),[6] 2 newspaper articles, and 2 fictional narratives. We arbitrarily choose some documents to hold out from each genre; the resulting test set consists of 2 TED talks

[6]We have combined the TED talks and presidential speech genres since both involved prepared speeches.

Condition	$\|\boldsymbol{\theta}\|$	λ	Exact Match Acc.	Soft Match Acc.
Majority baseline	—	—	12.1	47.8
Log-linear classifier, attributes only	473,064	100	38.7	77.1
Log-linear classifier, labels only	413,931	100	40.8	73.6
Full log-linear classifier (labels + attributes)	926,417	100	43.7	**78.2**
Random forest classifier	20,363	—	**49.7**	77.5

Table 1: Classifiers and baseline, as measured on the test set. The first two columns give the number of parameters and the tuned regularization hyperparameter, respectively; the third and fourth columns give accuracies as percentages. The best in each column is bolded.

("Alisa_News", "RobertHammond_park"), 1 newspaper article ("crime1_iPad_E"), and 1 narrative ("Little Red Riding Hood"). The test set then contains 19,28 tokens (111 sentences), in which there are 511 annotated NPs; while the training set contains 2,911 NPs among 11,932 tokens (757 sentences).

Preprocessing. Automatic dependency parses and coreference information were obtained with the parser and coreference resolution system in Stanford CoreNLP v. 3.3.0 (Socher et al., 2013; Recasens et al., 2013) for use in features (§4.2). Syntactic features were extracted from the Basic dependencies output by the parser. To evaluate the performance of Stanford system on our data, we manually inspected the dependencies and coreference information for a subset of sentences from our corpus (using texts from TED talks and fictional narratives genres) and recorded the errors. We found that about 70% of the sentences had all correct dependencies, and only about 0.04% of the total dependencies were incorrect for our data. However, only 62.5% of the coreference links were correctly identified by the coreference resolver. The rest of them were either missing or incorrectly identified. We believe this may have caused a portion of the classifier errors while predicting the Ananphoic labels.

Throughout our experiments (training as well as testing), we use the gold NP boundaries identified by the human annotators. The automatic dependency parses are used to extract percepts for each gold NP. If there is a conflict between the gold NP boundaries and the parsed NP boundaries, to avoid extracting misleading percepts, we assign a default value.

Learning. The log-linear model variants are trained with an in-house implementation of supervised learning with L_2-regularized AdaGrad (Duchi et al., 2011). Hyperparameters are tuned on a development set formed by holding out every tenth instance from the training set (test set experiments use the full training set): the power of 10 giving the highest Soft Match accuracy was chosen for λ.[7] The Python `scikit-learn` toolkit (Pedregosa et al., 2011) was used for the random forest classifier.[8]

6.2 Results

Measurements of overall classification performance appear in table 1. While far from perfect, our classifiers achieve promising accuracy levels given the small size of the training data and the number of labels in the annotation scheme. The random forest classifier is the most accurate in Exact Match, likely due to the robustness of that technique under conditions where the data are small and the frequencies of individual labels are imbalanced. By the Soft Match measure, our attribute-aware log-linear models perform very well. The most successful of the log-linear models is the richest model, which combines the fine-grained communicative function labels with higher-level attributes of those labels. But notably the attribute-only model, which decomposes the semantic labels into attributes without directly considering the full label, performs almost as well as the random forest classifier in Soft Match. This is encouraging because it suggests that the model has correctly exploited known linguistic generalizations to account for the grammaticalization of definiteness in English.

Table 2 reports the precision and recall of each leaf label predicted. Certain leaf labels are found to be easier for the classifier to predict: e.g., the communicative function label **Pleonastic** has a high F_1 score. This is expected as the **Ploenastic** CFD for English is quite regular and captured by the `EX`

[7] Preliminary experiments with cross-validation on the training data showed that the value of λ was stable across folds.

[8] Because it is a randomized algorithm, the results may vary slightly between runs; however, a cross-validation experiment on the training data found very little variance in accuracy.

Leaf label	N	P	R	F_1	Leaf label	N	P	R	F_1

part-of-speech tag. The classifier finds predictions of certain CFD labels, such as **Bridging_Event**, **Bridging_Nominal** and **Nonunique_Nonspecific**, to be more difficult due to data sparseness: it appears that there were not enough training instances for the classifier to learn the generalizations corresponding to these CFDs. **Bridging_Other_Context** was hard to predict as this was a category which referred not to the entities previously mentioned but to the whole speech event from the past. There seem to be no clear morphosyntactic cues associated with this CFD, so to train a classifier to predict this category label, we would need to model more complex semantic and discourse information. This also applies to the classifier confusion between the **Same_Head** and **Different_Head**, since both of these labels share all the semantic attributes used in this study.

An advantage of log-linear models is that inspecting the learned feature weights can provide useful insights into the model's behavior. Figure 3 lists 10 features that received the highest positive weights in the full model for the + and − values of the Specific attribute. These confirm some known properties of English definites and indefinites. The definite article, possessives (`PRP$`), proper nouns (`NNP`), and the second person pronoun are all associated with specific NPs, while the indefinite article is associated with nonspecific NPs. The model also seems to have picked up on the less obvious but well-attested tendency of objects to be nonspecific (Aissen, 2003).

In addition to confirming known grammaticalization patterns of definiteness, we can mine the highly-weighted features for new hypotheses: e.g., in figs. 3 and 4, the model thinks that objects of "from" are especially likely to be Specific, and that NPs with comparative adjectives (`JJR`) are especially likely to be nonspecific (fig. 3). From fig. 3, we also know that **Num. of dependents, dependent's POS: `1,PRP$`** has a higher weight than, say, **Num. of dependents, dependent's POS: `2,PRP$`**. This observation suggests a hypothesis that in English the NPs which have possessive pronouns immediately preceding the head are more likely to be specific than the NPs which have intervening words between the possessive pronoun and the head. Similarly, looking at another example in fig. 4, the following two percepts get high weights for the NP *the United States of America* to be Specific: **last dependent's POS: `NNP`** and **first dependent's lemma: `the`**. Since frequency and other factors affect the feature weights learned by the classifier, these differences in weights may or may not reflect an inherent association with Specificity. Whether these are general trends, or just an artifact of the sentences that happened to be in the training data and our statistical learning procedure, will require further investigation, ideally with additional datasets and more rigorous hypothesis testing.

Finally, we can remove features to test their impact on predictive performance. Notably, in experiments ablating features indicating articles—the most obvious exponents of definiteness in English—we see a decrease in performance, but not a drastic one. This suggests that the expression of communicative functions of definiteness is in fact much richer than morphological definiteness.

Errors. Several labels are unattested or virtually unattested in the training data, so the models unsurprisingly fail to predict them correctly at test time. **Same_Head** and **Different_Head**, though both common, are confused quite frequently. Whether the previous coreferent mention has the same or different head is a simple distinction for humans; low model accuracy is likely due to errors propagated from coreference resolution. This problem is so frequent that merging these two categories and retraining the random forest model improves Exact Match accuracy by 8% absolute and Soft Match accuracy by 5% absolute.

This is just for *the United States of America*.	**Last dependent's POS: NNP** **First dependent's lemma: the**	Unique_Larger_Situation
We were driving from *our home in Nashville* to a little farm we have 50 miles east of Nashville — driving ourselves.	**First dependent's POS: PRP$** **Head's left neighbor's POS: PRP$** **Governor's right neighbor's POS: PRP$** **Governor's lemma: from**	Bridging_Restrictive_Modifier

Figure 4: Sentences from our corpus illustrating percepts fired for gold NPs and their CFD annotations.

Another common confusion is between the highly frequent category **Unique_Larger_Situation** and the rarer category **Unique_Hearer_New**; the latter is supposed to occur only for the first occurrence of a proper name referring to a entity that is not already part of the knowledge of the larger community. In other words, this distinction requires world knowledge about well-known entities, which could perhaps be mined from the Web or other sources.

7 Related Work

Because semantic/pragmatic analysis of referring expressions is important for many NLP tasks, a computational model of the communicative functions of definiteness has the potential to leverage diverse lexical and grammatical cues to facilitate deeper inferences about the meaning of linguistic input. We have used a coreference resolution system to extract features for modeling definiteness, but an alternative would be to predict definiteness functions as input to (or jointly with) the coreference task. Applications such as information extraction and dialogue processing could be expected to benefit not only from coreference information, but also from some of the semantic distinctions made in our framework, including specificity and genericity.

Better computational processing of definiteness in different languages stands to help machine translation systems. It has been noted that machine translation systems face problems when the source and the target language use different grammatical strategies to express the same information (Stymne, 2009; Tsvetkov et al., 2013). Previous work on machine translation has attempted to deal with this in terms of either (a) preprocessing the source language to make it look more like the target language (Collins et al., 2005; Habash, 2007; Nießen and Ney, 2000; Stymne, 2009, *inter alia*); or (b) post-processing the machine translation output to match the target language, (e.g., Popović et al., 2006). Attempts have also been made to use syntax on the source and/or the target sides to capture the syntactic differences between languages (Liu et al., 2006; Yamada and Knight, 2002; Zhang et al., 2007). Automated prediction of (in)definite articles has been found beneficial in a variety of applications, including postediting of MT output (Knight and Chander, 1994), text generation (Elhadad, 1993; Minnen et al., 2000), and identification and correction of ESL errors (Han et al., 2006; Rozovskaya and Roth, 2010). More recently, Tsvetkov et al. (2013) trained a classifier to predict where English articles might plausibly be added or removed in a phrase, and used this classifier to improve the quality of statistical machine translation.

While definiteness morpheme prediction has been thoroughly studied in computational linguistics,

studies on additional, more complex aspects of definiteness are limited. Reiter and Frank (2010) exploit linguistically-motivated features in a supervised approach to distinguish between generic and specific NPs. Hendrickx et al. (2011) investigated the extent to which a coreference resolution system can resolve the bridging relations. Also in the context of coreference resolution, Ng and Cardie (2002) and Kong et al. (2010) have examined anaphoricity detection. To the best of our knowledge, no studies have been conducted on automatic prediction of semantic and pragmatic communicative functions of definiteness more broadly.

Our work is related to research in linguistics on the modeling of syntactic constructions such as dative shift and the expression of possession with "of" or "'s". Bresnan and Ford (2010) used logistic regression with semantic features to predict syntactic constructions. Although we are doing the opposite (using syntactic features to predict semantic categories), we share the assumption that reductionist approaches (as mentioned earlier) are not able to capture all the nuances of a linguistic phenomenon. Following Hopper and Traugott (2003) we observe that grammaticalization is accompanied by *function drift*, resulting in multiple communicative functions for each grammatical construction. Other attempts have also been made to capture, using classifiers, (propositional as well as non propositional) aspects of meaning that have been grammaticalized: see, for instance, Reichart and Rappoport (2010) for tense sense disambiguation, Prabhakaran et al. (2012) for modality tagging, and Srikumar and Roth (2013) for semantics expressed by prepositions.

8 Conclusion

We have presented a data-driven approach to modeling the relationship between universal communicative functions associated with (in)definiteness and their lexical/grammatical realization in a particular language. Our feature-rich classifiers can give insights into this relationship as well as predict communicative functions for the benefit of NLP systems. Exploiting the higher-level semantic attributes, our log-linear classifier compares favorably to the random forest classifier in Soft Match accuracy. Further improvements to the classifier may come from additional features or better preprocessing. This work has focused on English, but in future work we plan to build similar models for other languages—including languages without articles, under the hypothesis that such languages will rely on other, subtler devices to encode many of the functions of definiteness.

Argument structure of adverbial derivatives in Russian

Igor Boguslavsky

Abstract

Adverbial derivatives (AdvD) of nouns of the type *v jarosti* 'in a rage'*, s naslaždeniem* 'with pleasure'*, pod predlogom* 'under the pretext of' etc. often inherit the arguments (actants) of the noun they are derived from. However, as a rule, in case of AdvDs these arguments are realized in a way very different from the nouns. The main linguistic findings of the paper consist in the set of positions the arguments may take with respect to AdvD. In a general case, a actant slot of an AdvD can be either (a) blocked, or (b) filled by a dependent of the AdvD itself (e.g. *pod predlogom bolezni* 'under the pretext of illness', *v dokazatel'stvo svoej nevinovnosti* 'as a proof of his innocence'), or (c) filled by the dominating verb (*po privyčke prosnulsja rano* 'woke up early out of habit', *slushal pesnju s naslaždeniem* 'listened to the song with relish'), or (d) filled somewhere within the clause organized by the dominating verb; in this case the AdvD argument may be identified based on (d1) its syntactic position (*po privyčke* 'by habit'), or (d2) its semantic role with respect to its mother element (*v podarok* 'as a present'), or (d3) its communicative function (*v bol'šinstve* 'mostly'). A notation is proposed that permits to present the argument structure of AdvDs in a compact way.

1 Introduction

This paper is not about computation, it is about linguistics. It does not describe any electronic resource. It is not inspired by weaknesses of NLP applications that need to be fixed. We investigate certain heavily understudied and even largely unnoticed linguistic phenomena that deserve scientific study independently of whether their neglect causes serious errors in today's NLP applications or not. However, on the other hand, taking these phenomena into account is definitely useful for applications, such as semantic parsing, question answering, recognizing textual entailments, information extraction (e.g. Meyers et al. 1998), machine reading, machine translation, etc. Indeed, semantic parsers should represent the content of the text by means of elementary propositions independently of the syntactic status of the main predicate in these propositions, be it a verb, a noun, or an adverbial. They should be able to understand that such expressions as *I believe (that) he is wrong – My opinion is (that) he is wrong) – In my opinion <to my mind>, he is wrong* are different NL realizations of the same proposition. Question answering systems should be able to obtain an answer to the question *What habits does John have?* from the sentence *John woke up early out of habit*, although the argument frame of the noun *habit* does not cover this type of construction (it is the argument frame of the adverbial derivative *out of habit* that does). Similarly, textual entailment recognition systems should understand that *John woke up early out of habit* entails *John has a habit of waking up early*, which again requires correlating argument frames of three different expressions: the noun *habit,* the "support verb + noun" combination *to have a habit* and the adverbial *out of habit* .

Syntactic derivation is one of the most direct manifestations of the systemic character of the lexicon. As is well-known, language is capable of representing the same meaning (or several very close meanings) by means of words belonging to different grammatical classes. It is often possible to replace words of a certain grammatical category with those of another grammatical category without significant modification of their lexical meaning. For example, the concept 'believe' can be realised by means of a verb (*to believe*) or a noun (*opinion*) or an adverbial phrase (*in my opinion, to my mind*). This is one of the important ideas of Éléments de syntaxe structurale de Tesnière (1959). According to Tesnière, the ability to transfer one category to another at will in fluid speech is the primary tool that

Proceedings of COLING 2014, the 25th International Conference on Computational Linguistics: Technical Papers, pages 1071–1080, Dublin, Ireland, August 23-29 2014.

makes truly productive speech possible. This mechanism is an integral part of the linguistic capacity of humans and deserves in-depth study.

Lexical resources available to date are not sufficient for that. First, resources such as WordNet do not establish synonymy relations across category boundaries, and will not recognize these expressions as synonymous. Second, the task does not boil down to relating such expressions to the same concept. To reconstruct the proposition, one also needs to find the arguments of all the predicates and identify their roles. The latter task, also known as Semantic Role Labeling (SRL), is fairly well studied for the arguments of the verbs (cf. CoNLL-2004 and CoNLL-2005 shared tasks on semantic role labeling, Computational Linguistics Special Issue on Semantic Role Labeling, 2008). Much less is done in SRL of nouns and adjectives (Gerber 2011, Macleod 1997, 1998). Sometimes, adjectives and prepositions are included in (verbal and nominal) frames in FrameNet. However, we are not aware of any attempt to investigate arguments of adverbials. This category of words is largely understudied. It is not even represented in WordNet. In the introductory paper to the Special Issue on Semantic Role Labeling, the SRL task for adverbials is not even mentioned (Marquez et al. 2008).

Yet, adverbial derivatives are no less entitled to have arguments than the predicates they are derived from. If we want to find and identify the arguments of the verb *to cause* in (1), we would want to do the same in (2), where this concept is represented by means of the adverbial *due to:*

(1) *The minister's interview caused a dramatic fall of the market.*

(2) *The market fell dramatically due to the minister's interview.*

However, the problem is that, in a general case, it is more difficult to find these arguments in the sentence than it is for prototypical verbal or nominal predicates. The positions of these arguments in may differ greatly from the positions of «classical» arguments.

The goal of this research is to investigate these non-classical arguments with a view to their adequate representation in the dictionary and their automatic detection in the text. We intend to show (a) that the arguments of adverbials need to be found and identified, however non-trivial this task may be, (b) what their different types are and (c) how the argument structure of adverbial derivatives can be represented in the dictionary.

In this study, we will restrict ourselves to adverbial syntactic derivatives (AdvD) of Russian nouns and verbs. We will call a syntactic derivative of word *L* such a word, or phrase, *L´* that has the same (or very close) meaning as *L*, but belongs to a different syntactic category and hence displays a different behavior. We will denote the word *L* as the basic word, or keyword, of the derivation. *L´* may be a nominal derivative, or nominalization (*to construct - construction, to believe – opinion*), a verbal derivative (*revolution - revolutionize*), an adjectival derivative (*government – governmental*), or an adverbial derivative (*speed – at the speed of, cause – due to/because of*).

The plan of our presentation will be as follows. In Section 2 we will characterize briefly some properties of AdvD in Russian, then in Section 3 we will review related work on adverbial derivatives within the framework of the Meaning – Text theory. Section 4 will present different types of argument structures of adverbial derivatives. How these structures can be represented in the dictionary will be shown in Section 5. We will conclude in Section 6.

2 Adverbial derivatives in Russian

We will discuss two properties of AdvDs – their grammatical status and their semantic load. From the point of view of the grammatical status, there are two types of AdvD in Russian – grammatical and lexical ones. They will be explained in Sections 2.1 and 2.2. The semantic load of AdvD will be commented upon in Section 2.3.

2.1 Grammatical AdvDs (verbal adverbs)

Russian has a regular morphological way of constructing AdvDs of verbs – verbal adverbs (deeprichastija) that can be derived of virtually any verb. They serve to express a secondary predication attached to the main one.

(3) *On sprosil eto, gljadja ej v glaza.*

'He asked that, looking into her eyes'

Russian verbal adverbs are similar to participial constructions in adverbial usage (or gerunds) existing in a variety of languages. However, they also exhibit significant differences. An important peculiarity of the argument behaviour of Russian verbal adverbs is that their subject cannot be

expressed in the surface structure and should be co-referential with the subject of the main verb. Their other arguments do not have any characteristic properties and are attached to them just as they are attached to the finite form of the verb:
(4a) *Petr pokupaet odeždu v modnyx magazinax za ogromnye den'gi* 'Peter buys clothes in fashionable shops for a lot of money'.
(4b) *Pokupaja odeždu v modnyx magazinax za ogromnye den'gi, Petr večno po uši v dolgax* 'buying clothes in fashionable shops for a lot of money, Peter is always in debt up to his neck'.

Many languages have absolute constructions, absent in Russian, which allow the subject to be attached to the participle and to be non-coreferential with the subject of the main verb:
(5) *His wife buying clothes in fashionable shops, Peter is always in debt up to his neck.*
(6) Spanish: *Habiendo pasado más de una hora, las piernas comenzaron a flaquear* 'more than an hour having passed, his legs began to fail'.

Verbal adverbs may be active, as in (3), or passive, as in (7):
(7) *Buduči sorvannym, muxomor prodolžaet rasti* 'being plucked, the amanita continues to grow'.

It is to be noted that the implicit subject of the passive verbal adverb *buduči sorvannym* 'being plucked' is the second argument of the active form *sorvat'* 'pluck' and, according to the general rule, is co-referential with the subject of the main verb *muxomor* "amanita".

2.2 Lexical AdvDs

Besides verbal adverbs derived by means of inflection, there is a large number of AdvDs that are expressed by adverbs (*good – well, systematic – systematically, can - possibly*), prepositions (*cause – due to/because of*) or prepositional phrases (*love – with love*). The latter case is the most important, since a large number of AdvDs is formed in this way. It is to be noted that different AdvDs are formed with different prepositions. Semantically, lexical AdvDs are in many cases equivalent to verbal adverbs. Some examples: *otčajanie* 'dispair' – *v otčajanii* '(being) in dispair', *interes* 'interest' – *s interesom* 'with interest, feeling interest', *odežda* 'clothes' – *v odežde* 'being dressed', *bodrstvovat'* 'be awake' – *najavu* '(being) awake', *obed* 'dinner' – *za obedom* 'at dinner', *zaščita* 'protection' – *pod zaščitoj* 'under protection, being protected', *pomošč* 'help' – *s pomoščju* or *pri pomošči* 'with the help of, being helped by'.

2.3 Pure AdvDs vs. semantically loaded AdvDs

One has to distinguish between two types of AdvD: "pure" derivatives, which do not contain any additional meaning components absent in the meaning of the basic predicate, and semantically enriched derivatives, for which the reverse is true. As an example of the latter, let us consider the phrase *pod imenem X* 'under the name of X' as represented in
(8) *Napoleon exal pod imenem gerzoga Vičentskogo, to est' Kolenkura* 'Napoleon was travelling under the name of duke of Vicenza, that is of Colencour'.

The meaning of this sentence contains a component of replacing the true name with another one. *Pod imenem X* 'under the name of X' does not mean that the person in question has the name of X, but rather that this person or somebody else wants other people to refer to him/her as X while the speaker knows, believes or admits that this is not the true name. Obviously, the noun *imja* 'name' has no such component (as opposed to *pseudonym* or *nickname*). It cannot even be ascribed to the preposition *pod* 'under', either, since in (8) this preposition has obviously the same meaning as in phrases *pod nazvaniem <zagolovkom, rubrikoj>* 'under the title <heading>' to which the component of concealment is completely alien. Phrases like *pod imenem* (or its English counterpart *under the name*) that are to a certain extent idiomatic are lexical units in their own right and have their own entries in the dictionary.

As for "pure", non-idiomatic PP AdvDs, they hardly qualify for separate lexical units. However, irrespective of whether an AdvD is idiomatic or not, it should be supplied with the information about its arguments: if a sentence contains the phrase *at request*, e.g. *I called Mary at the request of my father,* we should be able to answer the question "Who asked whom to do what?" In this example, we are entitled to infer that speaker's father asked him/her to call Mary.

Note: strictly speaking, the content of father's request need not necessarily be "Make a call to Mary". He could have asked his son/daughter to invite Mary for dinner. However, the phrase *I called Mary at the request of my father* is still appropriate provided the act of inviting Mary contains calling

her as its essential part.

In order to be able to make such an inference, one needs to represent the argument structure of AdvDs fully and unambiguously and relate it to the argument structure of the basic word.

As an example of how the correlation between argument structures of different words can be established, we can recall the description of converse terms in the theory of Lexical Functions within the Meaning – Text approach (Melčuk et al. 1984a, 1984b, 1988, 1992). Conversives (the input and the output of the Lexical Function Conv) are a pair of words that denote the same situation but differ in the way their arguments are ordered, e.g. *buy – sell*. Like any verb, *buy* and *sell* are supplied with subcategorization frames (aka government patterns in the Meaning – Text approach) that list all their arguments and their means of expression. On the other hand, their being conversives implies that their lexical functional description should indicate the correlation between their argument structures. Namely, the first argument of *sell* ("who sells?") corresponds to the third argument of *buy* ("from whom buys?"), the third argument of *sell* ("to whom?") – to the first argument of *buy* ("who buys?"), while the second and the fourth arguments ("what?" and "for how much?") occupy the same positions within government patterns of both verbs. This correlation is rendered by the numerical index attached to the Conv symbol: $Conv_{3214}$(*sell*) = *buy*: the *j*-th position in the index is occupied by *i* if the *j*-th argument of the output corresponds to the *i*-th actant of the input.

For AdvDs the problem of the correlation of their argument structure with that of the basic predicate is particularly acute. While *sell* and *buy* are rightful lexical units entitled to have their own government patterns, adverbial collocations of the type *v jarosti* 'in anger', *po privyčke* 'by habit', *s akcentom* 'with an accent' or *pod predlogom* 'under the pretext of' are not usually treated as separate lexical units. It is assumed that all necessary information about their meaning and use should be formulated in the lexical entry of the noun. To what extent does an AdvD inherit the argument structure of the noun? If not in full, how should its argument structure be described in the dictionary?

Before answering this question, we will recall how syntactic derivatives, and AdvD in particular, are treated in the theory of lexical functions.

3 Syntactic derivatives in the theory of lexical functions

Two types of syntactic derivation are distinguished: "zero" and "actant" derivation. Zero syntactic derivatives (S_0, V_0, A_0 и Adv_0) have the same meaning as the keyword but belong to a different part of speech: S_0(*investigate*)=*investigation,* V_0(*investigation*)=*investigate,* A_0 (*government*)=*governmental,* Adv_0 (*good*)=*well*. Actant derivatives (S_i, A_i and Adv_i) are oriented towards one of the actants of the keyword in the following sense.

S_i is a standard name of the *i*-th actant of the keyword (S_1(*teach*) = *teacher*, S_2(*teach*) = (*subject*) *matter* [in high school], S_3(*teach*) = *pupil*).

A_i also has a bearing to the *i*-th actant, but in the adjectival syntactic status. This means that its typical syntactic function is to modify a noun that fills the *i*-th valence slot of the keyword. A grammatical way of expressing A_i is participles. A_1 is equivalent to an active participle, and A_2, to a passive participle. For example, adjectival derivatives of the verb *to control* are either an active participle *controlling* (A_1) or a prepositional phrase *under control* (A_2); cf. *controlling organizations* ('organizations that control something') – *operations under control* ('operations that are being controlled by someone').

Things are more complicated with adverbial actant derivatives (Adv_i). This function is defined as follows:

«Adv_i – determining property of the action by the *i*-th … actant of *L* according to its role in the situation denoted by *L*. Adv_1 is roughly equivalent to an active verbal adverb ('while L-ing') and Adv_2, to a passive verbal adverb ('while being L-ed').

Adv_2(*bombard*) = *under bombardment*

Adv_1(*speed*) = *at [a speed of...]*» (Mel'čuk 1996: 55).

As this definition shows, the only link between the actantial structures of the keyword and the adverbial derivative of the Adv_i type is the *i*-th actant of the keyword. Although it is not stated explicitly, one can presume that the *i*-th actant's position in the sentence is the position of the subject of the verb to which Adv_i is attached. In (9) the first actant of *anger* is obviously *Mary,* the first actant of the verb *reject,* and not *John* or anybody else.

(9) *Mary rejected John's proposal with anger.*

This is understandable, since lexical function Adv_i is intended to model the behaviour of verbal adverbs and, as mentioned above, they normally correlate strongly with the subject (first actant) of the main predicate (except for the absolute constructions). However, lexical function Adv_i provides no information as to the position of other actants of the keyword. The next section will show that this information is essential for text understanding and that different AdvDs significantly differ in this respect.

4 Argument structure of adverbial derivatives

If we compare adverbial derivation with other types of syntactic derivation, we will encounter an important difference. Argument structure of such derivatives as $Conv_{ij}$ or S_i can be easily characterized in terms of the argument structure of the keyword. When we pass from the keyword to such a derivative, we may find that an actant either stays in its initial position (*teach mathematics – teacher of mathematics*), or changes its number (*the verb dominates the preposition – the preposition depends on the verb*), or gets blocked altogether (*drive home - *driver home*). However, the syntactic position of the actant can only change in a very limited way. If a valence slot of the keyword is expressible in the sentence with its $Conv_{ij}$ or S_i at all, the actant should either be attached to the derivative directly, or through a copula or other lexical functional verb (*Peter teaches mathematics – Peter is a teacher of mathematics*) or by means of the apposition (*Peter, a teacher of mathematics*).

The matters stand differently with AdvDs. Their actant properties are much more diverse than those of $Conv_{ij}$ or S_i, or even of verbal adverbs. In some cases, the position of their actants in the sentence cannot be characterized in purely syntactic terms. In a general case, a valence slot of an AdvD can be either blocked, or:

- filled by a dependent of the AdvD itself;
- filled by the dominating verb;
- filled somewhere within the clause organized by the dominating verb; in this case the AdvD actant may be identified based on:
    - its syntactic position;
    - its semantic role;
    - its communicative function.

We will illustrate all these possibilities below.

4.1 Valence slots filled by a dependent of AdvD

In the canonical case, AdvD inherits most of the governing properties of the keyword.
(10a) *skorost' 800 km/čas* 'a speed of 800 km per hour',
(10b) *Samolet letel so skorostju 800 km/čas* 'the aircraft was flying at a speed of 800 km per hour',
(11a) *sovet Ivana* 'Ivan's advice',
(11b) *po sovetu Ivana* 'at Ivan's advice',
(12a) *Eto podarok ot Viktora* lit. 'this is a present from Victor',
(12b) *Ja polučil eto v podarok ot brata* lit. 'I got it as a present from my brother'.

In some cases, governing properties of AdvD are different from those of the keyword. Let us consider the pair *predlog* 'pretext' – *pod predlogom* 'on/under the pretext of' that manifests an interesting correlation of actant properties. The noun *predlog* 'pretext' has three valence slots: *P is a pretext for X for doing Q* = 'wishing to do Q, which violates norms of ethics, or politeness, X uses situation P to do Q; he thinks that P justifies Q' (Boguslavskaya 2003). When *predlog* is used without the preposition *pod,* it can attach actant Q (= the action carried out) but not P (= false motive). The latter can only be expressed outside the phrase containing *predlog*:
(13a) *Golovnaja bol'* [P] *– xorošij predlog, čtoby ostat'sja doma* [Q] 'headache [P] is a good pretext for staying at home [Q]'.
(13b) **predlog golovnoj boli* [P] 'the pretext of the headache [P]'

AdvD *pod predlogom* has opposite governing properties. Actant P (= false motive) can now be a dependent of AdvD while actant Q (= the action) loses this property and moves to the position of the dominating word:
(13c) *Ona ostalas' doma* [Q] *pod predlogom golovnoj boli* [P] 'she stayed at home [Q] on the pretext of the headache [P]'.

4.2 Valence slots filled by the dominating verb

Adverbial derivatives of many predicates which have a propositional valence slot fill it by means of the dominating verb. One example is (13c) above. In the following examples, the actant at issue is underlined in both the sentence with the basic predicate, and in the sentence with the AdvD.
(14a) *Ljusja dokazala polnuju sdaču svoix pozicij tem, čto pocelovala Marata v nos* 'Ljusja proved complete surrender by kissing Marat on the nose'.
(14b) *V konce koncov sama Ljusja priznala grubost' svoego zamečanija i v dokazatel'stvo polnoj sdači svoix pozicij pocelovala Marata v nos* 'after all, Ljusja herself acknowledged that her remark had been rude, and as a proof of complete surrender kissed Marat on the nose' (AdvD *v dokazatel'stvo* 'as a proof').
(15a) *On otvetil mnogoznačitel'nym myčaniem* 'he responded with a significant mumble'.
(15b) *V otvet on čto-to mnogoznačitel'no promyčal* 'in response he mumbled something in a significant manner' (AdvD *v otvet* 'in response').
(16a) *Ja sčitaju, čto ždat' bol'še nečego* 'I think there is nothing more to wait for'.
(16b) *Po-moemu, ždat' bol'še nečego* 'in my opinion, there is nothing more to wait for' (AdvD *po-moemy* 'in my opinion').

4.3 Valency slots filled by dependents of the dominating verb

If a valency slot of an AdvD is filled by a dependent of the dominating verb, the question arises as to how to specify its position among other dependents of the verb. We will show that this position can be identified based on the syntactic function (4.3.1), semantic role (4.3.2) or communicative function (4.3.3).

4.3.1 Syntactic function

As mentioned in section 2, in the prototypical case of adverbial derivation, that of verbal adverbs, one of the actants of the keyword (the first or the second) is necessarily co-referential with the first actant (subject) of the dominating verb. Since this actant is not expressible as a dependent of the AdvD, the subject of the dominating verb is its only manifestation in the sentence. In this sense, we can say that the valence slot is filled by the subject of the dominating verb. If it is the first actant of the keyword that is co-referential with the subject, we are dealing with the active verbal adverb (Adv_1, in Mel'čuk's terminology). If it is the second actant, the verbal adverb (Adv_2) is passive. If the co-reference requirement is not met, sentences with verbal adverbs are usually ungrammatical in Russian. Cf. a textbook example of a wrong use of a verbal adverb **Podjezžaja k stancii, u menja sletela šljapa* 'when approaching the station, my hat fell down'.

As for non-verbal AdvDs, this requirement holds for some of them and not for others. Let us discuss one example: the verb *privyknut'* 'have a habit of'. It has two valencies – 'who has the habit?' and 'what does the habit consist in?'. Its AdvD is *po privyčke* 'by habit'. Although it does not take any syntactic dependents, sentences with this AdvD provide unambiguous information on who has a habit and what it consists in/ hence, both valencies are filled:
(17) *Ivan po privyčke ostavil dver' otkrytoj* 'by habit, Ivan left the door open'
The identity of the first actant of *po privyčke* and the subject of the main verb can be easily demonstrated. Let's take the verbs *zanimat'* 'to borrow' and *odalživat'* 'to lend'. Being conversives, they denote the same situation and sentences (18a) and (18b) are synonymous:
(18a) *Ivan zanjal u soseda 1000 rublej* 'Ivan borrowed 1000 roubles from the neighbour'
(18b) *Sosed odolžil Ivanu 1000 rublej* 'the neighbour lent Ivan 1000 roubles'.

If AdvD *po privyčke* 'by habit' is introduced in (18a) and (18b) in the same position, the sentences will no longer be synonymous. (19a) refers to the habit of Ivan while (19b) – to the habit of the neighbour.
(19a) *Po privyčke Ivan zanjal u soseda 1000 rublej* 'by habit Ivan borrowed 1000 roubles from the neighbour'
(19b) *Po privyčke sosed odolžil Ivanu 1000 rublej* 'by habit the neighbour lent Ivan 1000 roubles'.

4.3.2 Semantic role

Another type of constraint is manifested by AdvDs *v podarok* 'as a present', *v dar* 'as a gift', *v nagradu* 'in reward'. Nouns of the *present / gift / reward* type have three valence slots: the agent of

presenting something (X), the theme (Y) and the recipient (Z). The AdvDs co-occur with a large set of verbs concentrated around the meaning of 'transfer': *polučat'* 'receive', *prinimat'* 'accept', *trebovat'* 'demand', *prosit'* 'request'; *prinosit'* 'bring (on foot)', *privozit'* 'bring (by transport)', *dostavljat'* 'deliver', *posylat'* 'send', *otpravljat'* 'dispatch', *prednaznačat'* 'intend for', *žalovat'* 'grant', *podnosit'* 'offer', *predlagat'* 'offer', *peredavat'* 'pass (to)', *vručat'* 'hand over', *davat'* 'give', *otdavat'* 'give back', etc. It is impossible to associate the subject of the main verb with any single actant of AdvD, since each of the three actants can perform the role of the subject:
(20a) *Otec* (X) *privez dočeri v podarok ožerelje* 'Father (X) brought a necklace as a present to his daughter'.
(20b) *Maria* (Z) *prinjala ožerelje v podarok* 'Mary (Z) accepted the necklace as a present'.
(20c) *Ožerelje* (Y) *dostalos' ej v podarok ot babuški* 'the necklace (Y) came to her as a present of her grandmother'.

It is not syntactic constraints that regulate the position of the actants of these AdvD with respect to the main verb but semantic ones. The correlation between the valence slots of AdvD and the main verb can be formulated IN TERMS OF SEMANTIC ROLES as follows: if a valence slot of AdvD which corresponds to semantic role R (Agent, Theme, Recipient) is instantiated, it is either filled by an AdvD dependent (as in *v podarok dočeri* 'as a present to one's daughter', *v podarok ot otca* 'as a present from one's father'), or by a dependent of the main verb which performs the role R with respect to the predicate of transfer within the meaning of the main verb. For example, in (20a-c) the subjects *otec* 'father', *Maria* 'Maria' and *ožerelje* 'necklace' all play different semantic roles with respect to the main verb: the father is the Agent of bringing, Maria is the Recipient of giving ('accept' ≈ 'agree to be given'), and the necklace is the Theme of coming. Accordingly, these words are the Agent, Recipient and Theme of the present, respectively.

It should be stressed that the semantic role of a noun phrase with respect to the dominating verb may be different from its semantic role with respect to an inner predicate of this verb. For example, in
(21a) *Ivan potreboval poltsarstva* 'Ivan demanded half of the kingdom' [= 'demanded that he were given half of the kingdom']
Ivan is the Agent of demanding and at the same time the Recipient of giving. What is important for AdvD of the *v podarok* type is the role of the actant with respect to giving. Therefore, in (21b) Ivan is the Recipient and not the Agent of reward:
(21b) *Ivan potreboval sebe v nagradu poltsarstva* 'Ivan demanded half of the kingdom as a reward'.

4.3.3 Communicative function

Boguslavsky (2005) discussed the argument frames of noun *bol'šinstvo* 'majority, most of' and *men'šinstvo* 'minority'. It was shown that these words have three arguments: the whole, a part of the whole and the property of the part that is shared by most of the elements of the whole. Here we will only be interested in one of these arguments – that of the whole, expressed prototypically by preposition *iz* 'of' as represented in phrases *the majority of cases, most of the students.* In sentences with AdvD *v bol'šinstve* 'mostly, for the most part' this valence slot is filled, as a rule, by the subject of the dominating verb:
(22) *Oni byli arestovany i podverglis' v bol'šinstve svoem ssylke v Gvianu i na Sejšel'skie ostrova* 'they were arrested and mostly exiled to Guiana or Seychelles' [= 'most of them were exiled…']

However, this is not the only possible syntactic role for this actant. In (23) it is the direct object *inostrannye knigi* 'foreign books' that fills the valence slot of the whole:
(23) *Russkie knigi byli sobrany pokojnym mužem knjagini…, inostrannye že – v bol'šinstve vyvezla sama Anna Arkadjevna iz Pariža* lit. 'Russian books were collected by the late husband of the princess…, while foreign books (dir. object) mostly Anna Arkadjevna brought from Paris herself' [= 'most of the foreign books'].

And even this is not all. What is essential here is not the syntactic role of the actant but the communicative organization of the clause. The valence slot of the whole should be filled by the Topic. Since the position of the Topic is most often held by the subject, it is clear why it is the subject that for the most part fills this valence slot. The claim that the valency of the whole of *v bol'šinstve* 'mostly' is Topic-oriented can be confirmed by a minimal pair of sentences below.

Due to the relatively free word order in Russian, the Topic-Focus distinction is rarely marked syntactically or lexically. The same syntactic structure may correspond to different Topic-Focus

articulations. In most cases it is the clause-initial phrase that is the Topic of the sentence[1]. In (24a) and (24b) the syntactic structures are the same but the word order and the Topic-Focus articulation s are different. Therefore, the valency slot of the whole is filled differently:
(24a) *Ženščiny* (Topic) *v bol'šinstve svoem sideli v zale*
lit. 'the women (Topic) in majority were sitting in the hall'
'most of the women were in the hall'
(24b) *V zale sideli* (Topic) *v bol'šinstve svoem ženščiny*
lit. 'in the hall were sitting (Topic) in majority the women'
'most of those in the hall were women'

5 Representation of adverbial derivatives in the lexicon

From the viewpoint of the theory of phraseology developed in Mel'čuk 1995, AdvDs belong to the class of collocations and should be represented in the dictionary within the entries of their nominal component – the keyword of the derivation (Mel'čuk 1995: 184). The entries of the keywords contain all the information on their argument frames. Based on this information, one can represent the argument frame of AdvD in a compact way.

AdvD are to be described in the dictionary entry of the keyword, as a value of the Adv Lexical Function. The argument structure of the derivative is described by means of an index attached to the Adv symbol. We showed above (in 2.3) how the correlation between the arguments of the conversives can be stated by means of the numerical index attached to the symbol of the Conv Lexical Function. We are going to describe AdvDs along similar lines, but the index should be somewhat more elaborated. Namely, the argument index of the Lexical Function Adv is constructed as follows:

- it consists of *n* positions, according to the number of valency slots of the keyword; the 1st position corresponds to the 1st slot of the keyword, the 2nd position corresponds to the 2nd slot etc.
- each position contains information on whether the corresponding valency can be filled if the keyword is represented by its adverbial derivative and, if so, how it should be filled. This information is one of the following:
  - 0, if the slot cannot be filled,
  - i, if the slot is filled as the *i*-th slot of the keyword,
  - G, if the slot is filled by the syntactic governor of the AdvD,
  - i(G), if the slot is filled by a phrase that is the *i*-th actant of the syntactic governor of AdvD or has semantic role *i* with respect to this governor,
  - Topic, if the slot is filled by the Topic of the clause to which belongs AdvD.

Let us show how the properties of AdvDs of different types can be represented using this notation. Each illustration consists of three parts: (a) the keyword and its argument frame, (b) an example containing AdvD, (c) representation of the argument frame of AdvD with a short comment.
(25a) *skorost'* 'speed' («what has the speed?», «the value of the speed»)
(25b) *Avtomobil' mčalsja so skorostju 200 km/čas* 'the car moved at the speed of 200 km/hour'
(25c) *so skorostju* 'at the speed of' = $Adv_{G,2}$ [the 1st argument is the syntactic governor of AdvD ('moved'), and the 2nd is the 2nd argument of the keyword]
(26a) *jarost'* 'rage' («who is in the state of rage?», «what was the cause of this state?»)
(26b) *On v jarosti razorval pis'mo na kločki* 'in a rage, he tore the letter to pieces'.
(26c) *v jarosti* 'in a rage' = $Adv_{1(G),0}$ [the 1st argument is the 1st argument ('he') of the syntactic governor ('tore'), the 2nd argument cannot be realized with AdvD]
(27a) *naslaždenie* 'relish, enjoyment'(«who enjoys? », «what does one enjoy?»)
(27b) *On s naslaždeniem vykuril sigaru* 'he smoked a cigar with relish'.
(27c) *s naslaždeniem* 'with relish' = $Adv_{1(G),G}$ [the 1st argument is the 1st argument ('he') of the syntactic governor ('smoked'), the 2nd argument is the syntactic governor itself. Note the important difference between (26c) and (27c): in case of 'with relish' the main predicate refers to the source of the emotional state: smoking a cigar is what made him feel relish; in (26b) the reason of feeling rage is not specified. This difference is reflected in different indices]
(28a) *somnenije* 'doubt' («who doubts?», «what does one doubt?»)

[1] Of course, this is a simplification, the reality is more complicated, but this is a general rule.

(28b) *Ona vrjad li pridet* ‘she will hardly come’
(28c) *vrjad li* ‘hardly, unlikely’ = $Adv_{0,G}$ [the 1st argument cannot be realized with AdvD, the 2nd is expressed by the syntactic governor]
(29a) *podarok* ‘a present’ (“who gives?”, “what is given?”, “to whom?”)
(29b) *Otec privjoz Marii v podarok ožerelje* ‘Father brought Maria a necklace as a present’.
(29c) *v podarok* ‘as a present’ = $Adv_{G(Agent),G(Theme),G(Recipient)}$ [in (29b) all the three argument slots of AdvD are filled by the corresponding arguments of the predicate of transfer – *prvjoz* ‘brought’]
(30a) *bol'šinstvo* ‘majority’ (“what constitutes the majority?”, “what is the whole?”)
(30b) *V zale sideli v bol’šinstve svoem ženščiny* lit. ‘in the hall were sitting (Topic) the women’
‘most of those in the hall were women’
(30c) *v bol’šinstve* ‘mostly’ = $Adv_{0,Topic}$ [this AdvD is topic-sensitive; in (30b) the Topic is ‘those who were in the hall’, therefore it is this meaning that fill the valency of the whole].

6 Conclusion

The data presented above show that the argument frames of the adverbial derivatives of predicates are much more diverse than it was believed before. The number of the arguments and their roles are motivated by the semantics of the predicate they are derived from, but their syntactic realization is largely different. We showed a variety of syntactic, semantic and communicative positions the arguments of adverbial derivatives may take and how these positions can be described in the dictionary in a compact way. This information is needed in many semantics-related tasks but is not available in any of the existing lexicographic resources. We proposed a way to represent this information in the lexicon in a compact way. Supplied with this information, the lexicon will be able to support the extraction of propositions for a variety of applications[2].

Abstract

Active learning has proved effective in many fields of natural language processing. However, in the field of spoken language understanding which is always dealing with noise, no complete comparison between different active learning methods has been done. This paper compares the best known active learning methods in noisy conditions for spoken language understanding. Additionally a new method based on Fisher information named as Weighted Gradient Uncertainty (WGU) is proposed. Furthermore, Strict Local Density (SLD) method is proposed based on a new concept of *local density* and a new technique of utilizing information density measures. Results demonstrate that both proposed methods outperform the best performance of the previous methods in noisy and noise-free conditions with SLD being superior to WGU slightly.

1 Introduction

Spoken language understanding (SLU) is currently an emerging field in the intersection of speech processing and natural language processing (Tur and De Mori, 2011). The task of an SLU system is to extract meaning from speech utterances. Example real-world applications are AT&T's How May I Help You? and BBN's Call Director. In the field of SLU, as well as other fields of natural language processing, gathering data is fairly cheap but labeling is quite expensive and time-consuming. Thus, active learning methods apply very well and can greatly reduce costs. This article evaluates different techniques of active learning in the context of statistical SLU to reduce the labeling effort as much as possible. Also, SLU deals with the most amount of noise, in comparison with other fields of NLP, making robustness one of its most important issues (Tur and De Mori, 2011). Therefore, in this article noisy conditions of SLU are explored too. In this paper, we concentrate on statistical approaches for modeling the SLU system. Specifically conditional random fields (Lafferty et al., 2001) are used with a flat semantic frame to represent meaning and to model the SLU system.

While there have been a couple of studies on active learning in the context of SLU, they have mostly used only methods in the frameworks of uncertainty sampling (Tur et al., 2003; Jars and Panaget, 2008) and query-by-committee (Gotab et al., 2009). In addition, noisy conditions which are an important aspect of SLU have not been addressed thoroughly.

In this paper, performance of various known active learning methods namely uncertainty sampling, query-by-committee, Fisher information ratio (Settles and Craven, 2008) and instability sampling (Zhu

Proceedings of COLING 2014, the 25th International Conference on Computational Linguistics: Technical Papers, pages 1081–1090, Dublin, Ireland, August 23-29 2014.

and Ma, 2012) are examined and analyzed in noise-free and noisy conditions of SLU. Also a new method for measuring informativeness of instances based on the Fisher information framework is developed and evaluated along with other methods. Besides, to deal with noisy conditions, the new concept of *local density* and a new technique to utilize density measures are introduced and described.

The rest of this paper is organized as follows: Section 2 briefly describes CRFs, pool-based active learning framework, and selected active learning methods applicable to CRFs. Section 3 describes the first proposed method: Weighted Gradient Uncertainty. Section 4 introduces the local density concept, describes its motives and the proposed method of SLD is described. In Section 5, the noise model is described and experiments are performed in both noisy and noise-free conditions. Finally in Section 6 conclusions are derived.

2 Active Learning and CRFs

CRFs (Lafferty et al., 2001) are statistical graphical models which have demonstrated state-of-the-art accuracy in many fields as well as in SLU. A linear-chain CRF with parameter vector $\vec{\theta}$, defines the probability of $\vec{y}$ being the true label sequence for observation sequence $\vec{x}$ (with length T) as:

$$P(\vec{y}|\vec{x};\vec{\theta}) = \frac{1}{Z_{\vec{\theta}}(\vec{x})} \cdot \exp\left(\sum_{j=1}^{T}\sum_{i=1}^{K}\theta_i f_i(y_{j-1}, y_j, \vec{x}, j)\right). \quad (1)$$

$Z_{\vec{\theta}}(\vec{x})$ is the normalization factor and ensures that sum of $P(\vec{y}|\vec{x};\vec{\theta})$ over all possible labelings equals 1. There are K feature functions $f_k(y_{j-1}, y_j, \vec{x}, j)$ in a linear-chain CRF along with their weights θ_k. Each feature f_k, is a function of the whole observation sequence, the position of current observation and the current and previous labels. Training is the process of finding the optimum weight vector $\vec{\theta}$ to maximize the conditional log-likelihood of training instances in the labeled data set $\mathcal{L}$:

$$\ell(\mathcal{L};\vec{\theta}) = \sum_{(\vec{x},\vec{y})\epsilon\mathcal{L}} \log P(\vec{y}|\vec{x};\vec{\theta}) - \sum_{k=1}^{K}\frac{\theta_k^2}{\sigma^2}. \quad (2)$$

The second term is a regularization penalty to prevent over-fitting. After training, the labels can be predicted using the Viterbi algorithm.

Given: Labeled set $\mathcal{L}$, unlabeled pool $\mathcal{U}$, query startegy $\phi(\cdot)$, query batch size $\mathcal{B}$
repeat
  // learn a model using the current $\mathcal{L}$
  $\theta = train(\mathcal{L})$;
  for $b = 1$ **to** $\mathcal{B}$ **do**
    // query the most informative instance
    $\mathbf{x}_b^* = \underset{x\epsilon\mathcal{U}}{\operatorname{argmax}}\, \phi(\boldsymbol{x})$;
    // move the labeled query from $\mathcal{U}$ *to* $\mathcal{L}$
    $\mathcal{L} = \mathcal{L} \cup \langle \mathbf{x}_b^*, label(\mathbf{x}_b^*)\rangle$;
    $\mathcal{U} = \mathcal{U} - \mathbf{x}_b^*$;
  end
until *some stopping criterion;*

Figure 1. Pool-based active learning (Settles and Craven, 2008).

The focus of this paper is on pool-based active learning in which a learner should select most informative instances for labeling from a pool of unlabeled ones. We adopt the same notation used by Settles and Craven (2008) for the generic pool-based algorithm, sketched in Figure 1. Query strategy

$\phi(\cdot)$ is a function which evaluates how informative an unlabeled instance is. Most methods of active learning are a definition for this function. In the following subsections the best known active learning methods are briefly described.

2.1 Uncertainty Sampling

In this very common framework the learner queries the instance that it is most uncertain how to label. Two methods in this framework proved effective according to Settles and Craven (2008) which are presented here. First is the **least confident (LC)** method:

$$\phi^{LC}(\vec{x}) = 1 - P(\vec{y}^*|\vec{x};\theta), \quad (3)$$

where $\vec{y}^*$ is the most likely label sequence. Second query strategy is the **sequence entropy (SE)** method which measures informativeness of an instance based on entropy in different labelings:

$$\phi^{SE}(\vec{x}) = -\sum_{\vec{y}\epsilon\mathcal{Y}} P(\vec{y}|\vec{x};\theta)\log P(\vec{y}|\vec{x};\theta), \quad (4)$$

where $\mathcal{Y}$ is the set of all possible labelings for $\vec{x}$.

2.2 Query-By-Committee

Query-by-committee (QBC) is another well-studied and common framework for active learning. There are many approaches in this framework, but we use the approach suggested by Settles and Craven (2008) which has performed best with CRFs: in each round of active learning, $\mathcal{L}$ is sampled $|\mathcal{L}|$ times (with replacement) to create a unique modified labeled set $\mathcal{L}^{(c)}$. This is done C times to create C unique labeled sets. Then a committee of C models is trained: Each model $\theta^{(c)}$ is trained using its corresponding labeled set $\mathcal{L}^{(c)}$. Then the disagreement among the committee members about labeling an instance is measured as its informativeness:

$$\phi^{QBC}(\vec{x}) = -\sum_{\vec{y}\epsilon\mathcal{N}^C} P(\vec{y}|\vec{x};C)\, log\, P(\vec{y}|\vec{x};C). \quad (5)$$

In this equation, $\mathcal{N}^C$ is the union of N-best labelings of all models in the committee, and $P(\vec{y}|\vec{x};C) = \frac{1}{C}\sum_{c=1}^{C} P(\vec{y}|\vec{x};\theta)$ is the consensus posterior probability for some label sequence $\vec{y}$.

2.3 Representativeness

It is suggested that considering representativeness of instances can reduce the chance of selecting outliers in the process of active learning (Roy and McCallum, 2001). Representativeness can be measured by density of each instance, defined as the average similarity of an instance to other instances. Because the computation of density can be quite time-consuming in large-scale data sets, it is suggested to compute density in clusters (Tang et al., 2002; Shen et al., 2004) or in a k-Nearest-Neighbor manner (Zhu et al., 2008). Representativeness is applied by multiplying density to any arbitrary uncertainty measure to prevent outliers. Settles and Craven (2008) define a query strategy based on density:

$$\phi^{ID}(\vec{x}) = \phi^{LC}(\vec{x}) \times [ID(\vec{x})]^{\beta}, \quad (6)$$

$$ID(\vec{x}) = \frac{1}{U}\sum_{u=1}^{U} Sim(\vec{x}, \vec{x}^{(u)}). \quad (7)$$

Parameter β controls the relative effect of density $ID(\vec{x})$. This density uses a similarity measure $Sim(\cdot,\cdot)$ to compute the average similarity of an instance with all other unlabeled instances. The similarity measure used by Settles and Craven (2008) is a cosine similarity between two instances after being transformed to a vector of fixed length using this relation:

$$\vec{x} = \left[\sum_{t=1}^{T} f_1(x_t), \ldots, \sum_{t=1}^{T} f_J(x_t)\right], \quad (8)$$

where $f_j(x_t)$ is the value of feature f_j for token x_t, and J is the number of features in input representation. These features can be generated using CRF feature templates. Please refer to Settles and Craven (2008) for more details.

2.4 Fisher Information

We also evaluate the FIR (Fisher Information Ratio) method proposed by Settles and Craven (2008). Two vectors based on Fisher information are defined:

$$\mathcal{I}_{\vec{x}}(\theta) = \sum_{\hat{y}\epsilon\mathcal{N}} P(\hat{y}|\vec{x};\theta)\left[\left(\frac{\partial \log P(\hat{y}|\vec{x};\theta)}{\partial\theta_1}\right)^2 + \delta, \dots, \left(\frac{\partial \log P(\hat{y}|\vec{x};\theta)}{\partial\theta_K}\right)^2 + \delta\right], \quad (9)$$

$$\mathcal{I}_{\mathcal{U}}(\theta) = \frac{1}{|\mathcal{U}|}\sum_{u=1}^{|\mathcal{U}|}\mathcal{I}_{\vec{x}(u)}(\theta), \quad (10)$$

where $\mathcal{I}_{\vec{x}}(\theta)$ and $\mathcal{I}_{\mathcal{U}}(\theta)$ are the Fisher information matrices for sequence $\vec{x}$ and unlabeled pool $\mathcal{U}$ respectively. These matrices are estimated using their diagonal due to performance issues. Also K is the total number of CRF features, $\mathcal{N}$ is the set of N-best label sequences for input $\vec{x}$ and constant δ<<1 is added to prevent division by zero. Finally, FIR measures the informativeness of instances using:

$$\phi^{FIR}(\vec{x}) = -trace\left(\mathcal{I}_x(\theta)^{-1}\mathcal{I}_{\mathcal{U}}(\theta)\right). \quad (11)$$

2.5 Instability Sampling

(Zhu and Ma, 2012) suggest selecting instances which are most unstable. They propose two new methods to select most unstable instances based on recent active learning cycles: label-insensitive instability sampling (LIIS) and label-sensitive instability sampling (LSIS). Given an unlabeled instance $\vec{x}$ at i[th] learning cycle, its instability value in LIIS is estimated by:

$$\phi^{LIIS}(\vec{x}) = \phi_i^{SE}(\vec{x}) + \sum_{i-l<k\leq i}\left(\phi_k^{SE}(\vec{x}) - \phi_{k-1}^{SE}(\vec{x})\right), \quad (12)$$

where $\phi_i^{SE}(\vec{x})$ is $\phi^{SE}(\vec{x})$ at i[th] learning cycle and l is the number of cycles considered for instability estimation. Likewise, the instability value of $\vec{x}$ in LSIS is estimated by:

$$\phi^{LSIS}(\vec{x}) = \phi_i^{SE}(\vec{x}) + \sum_{i-l<k\leq i}\delta\left(\vec{y}^{(k)},\vec{y}^{(k-1)}\right)\left(\phi_k^{SE}(\vec{x}) - \phi_{k-1}^{SE}(\vec{x})\right), \quad (13)$$

where $\delta\left(\vec{y}^{(k)},\vec{y}^{(k-1)}\right)$ is 0 if the predicted label sequences $\vec{y}^{(k)}$ and $\vec{y}^{(k-1)}$ are the same and 1 otherwise. It's worthwhile to point that none of the instability sampling methods have been evaluated in the context of sequence labeling and they have only been evaluated in the context of classification.

3 The First Proposed Method: Weighted Gradient Uncertainty (WGU)

The new method to be introduced in this article is an improvement over the FIR method (subsection 2.4). According to evaluations by Settles and Craven (2008), the FIR method didn't perform well in practice despite its sound theory. In this section, first we investigate the essence of each component of $\mathcal{I}_{\vec{x}}(\theta)$:

$$\mathcal{I}_{\vec{x}}(\theta)_k = \sum_{\hat{y}\epsilon\mathcal{N}} P(\hat{y}|\vec{x};\theta)\left(\frac{\partial\ log\ P(\hat{y}|\vec{x};\theta)}{\partial\theta_k}\right)^2. \quad (14)$$

According to this relation, the k[th] component of Fisher vector $\mathcal{I}_{\vec{x}}(\theta)$ is the weighted sum of squared gradients of log-probabilities for the N best labelings for instance $\vec{x}$ in k[th] dimension of CRF features. It can be seen intuitively that each component of the Fisher vector increases when there is a kind of entropy between the N-best probabilities. That's because when for example the best label sequence has probability 1 then its gradient will be zero in all dimensions (complete fit) and hence all the components will be zero. On the other hand, if N best label sequences have equal probabilities, none of them will have a zero gradient since none is a complete fit and $\mathcal{I}_{\vec{x}}(\theta)$ will be maximized.

To show this fact more rigidly, assume the N best label sequences as $\mathcal{N} = \{\vec{y}^{(1)}, \vec{y}^{(2)}, \dots, \vec{y}^{(N)}\}$, and also for simplicity, define: $P_n = P\left(\vec{y}^{(n)}\middle|\vec{x};\theta\right)$. Then we will have:

$$logP_n = \sum_{j=1}^{T}\sum_{i=1}^{K}\theta_i f_i\left(y_{j-1}^{(n)}, y_j^{(n)}, \vec{x}, j\right) - logZ_{\vec{\theta}}(\vec{x}), \quad (15)$$

and so, its partial derivative in k[th] dimension will be (assuming $\mathcal{N}$ contains all possible label sequences):

$$\frac{\partial log P_n}{\partial \theta_k} = \overbrace{\sum_{j=1}^{T} f_k\left(y_{j-1}^{(n)}, y_j^{(n)}, \vec{x}, j\right)}^{F_n^{(k)}} - \frac{1}{Z_{\vec{\theta}}(\vec{x})} \frac{\partial Z_{\vec{\theta}}(\vec{x})}{\partial \theta_k} = F_n^{(k)} - \sum_{m=1}^{N} P_m F_m^{(k)}, \quad (16)$$

where $F_n^{(k)}$ is the result of applying feature function f_k (from CRF model) on nth best label sequence. Now using (16) we can rewrite (14) as:

$$\mathcal{I}_{\vec{x}}(\theta)_k = \sum_{n=1}^{N} P_n \left(F_n^{(k)} - \sum_{m=1}^{N} P_m F_m^{(k)} \right)^2. \quad (17)$$

To fully understand each component, we further factorized the above relation and proved it to be equal to (the proof is omitted here for brevity):

$$\mathcal{I}_{\vec{x}}(\theta)_k = \sum_{i=1}^{N} \sum_{j=i+1}^{N} P_i P_j \left(F_i^{(k)} - F_j^{(k)} \right)^2. \quad (18)$$

This relation explains the meaning of components of the Fisher vector completely. Each component is a summation over N best label sequences. The expression under summation consists of two parts: $P_i P_j$ and $\left(F_i^{(k)} - F_j^{(k)}\right)^2$. It can be shown using Lagrange multipliers that the first part is maximized (independently) when $P_i = \frac{1}{N}, \forall i$; which means this part is maximized when maximum entropy between N best probabilities occurs. The second part is the squared difference of kth feature function applied to two label sequences. So this part is maximized when the dissimilarities between every two label sequences in N-best list are maximum, which in turn means the model has maximum uncertainty in choosing the N-best label sequences for the input. Notice that in this interpretation we have assumed the two parts to be independent while they are not actually. However since the number of features of CRF (i.e. K) is too large, the dependency is negligible and can be ignored. So we conclude that each component of the Fisher vector $\mathcal{I}_{\vec{x}}(\theta)$ is a measure of uncertainty of the model about the sequence $\vec{x}$ in the corresponding dimension. Accordingly, each component of the total Fisher information vector $\mathcal{I}_{\mathcal{U}}(\theta)$ is the average uncertainty of the model in the corresponding dimension.

Knowing the precise identity of Fisher vector $\mathcal{I}_{\vec{x}}(\theta)$, we propose a natural measure which we call Weighted Gradient Uncertainty (WGU) based on the facts explained in the previous paragraph:

$$\phi^{WGU}(\vec{x}) = \sqrt{\sum_j \mathcal{I}_{\mathcal{U}}(\theta)_j \left(\mathcal{I}_{\vec{x}}(\theta)_j\right)^2}. \quad (19)$$

This measure is the weighted norm of $\mathcal{I}_{\vec{x}}(\theta)$ with the total Fisher information vector $\mathcal{I}_{\mathcal{U}}(\theta)$ as the weight vector. This query strategy favors instances with high uncertainty in each dimension of CRF feature space, especially the dimensions where the average uncertainty is higher. In other terms, the WGU measure maximizes the components of the Fisher vector, while the FIR method minimizes the inversed components of the Fisher vector; and since many components of the Fisher vector are zero or near-zero, their inversed values are very large and block out the other larger components (with very small inverse values) leading to a measure which effectively just counts the number of zero components and chooses the instance with the maximum number of zero components.

4 Using Local Density for Noisy Conditions

As described in Introduction, a great issue in SLU systems is the presence of noise in utterances. To address this problem, all the ATIS[1] instances were converted to vectors according to (8) and were reduced to 2 dimensions using Principle Component Analysis (PCA). Then the global density $ID(\vec{x})$ for

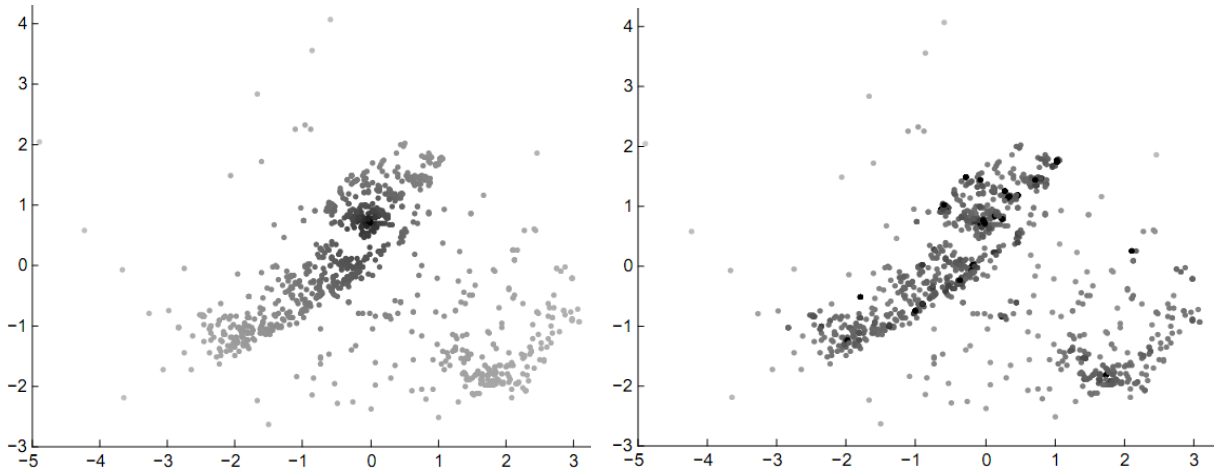
[1] ATIS is the dataset used in this article for evaluation; please read subsection 5.1.

each instance was computed using (7). Figure 2 shows the plot of all instances with darker points indicating instances with higher densities and lighter points showing the ones with lower densities.

As seen in Figure 2(a), the center of the distribution in terms of density is the darkest part. Also, the distribution of instances is not uniform at all, and excluding any part of the distribution especially parts further from the density center can lead to great decrease in performance of the model. The query strategy ϕ^{ID} (6) uses this density to reduce the chance of querying outliers. However, outliers as well as many other instances which are far from the density center are almost deprived of the chance of being selected. To address this problem and yet avoid outliers we choose to compute information density for each instance locally, i.e. using k nearest instances and not all instances. Thus, we define the local information density measure as follows:

$$LD(\vec{x}, k) = \frac{1}{k} \sum_{\vec{x}' \in \Gamma_k(\vec{x})} \text{Sim}(\vec{x}, \vec{x}'). \tag{20}$$

In which, $\Gamma_k(\vec{x})$ is the set of k most similar instances to $\vec{x}$, and k is the degree of locality.



(a) (b)

Figure 2. Plot of all ATIS instances. Darker points show higher densities and lighter ones show lower densities. (a) Using global density measure (b) Using local density measure (k=5).

The same procedure to plot Figure 2(a) is repeated again but with $LD(\vec{x}, k)$ computed as the density of each instance and the result is shown in Figure 2(b). The degree of locality is set to k=5. As seen in this plot, outliers are still completely grey which means they are avoided. Also, any small neighborhood with sufficient density is biased to black, which means the instances in the center of that neighborhood have almost the same chance of being queried as the instances in the center of global density (ID) in Figure 2(a).

Another advantage of local density is that it avoids noisy instances. Noisy instances in the SLU context are the utterances in which one or more words are erroneous due to ASR or user errors. Because of such errors, noisy instances take a small distance from their similar instances and reside alone in small neighborhoods.

Based on the LD measure (20), two active learning methods are considered: the first method applies local density measure to query strategy by multiplication (same as ϕ^{ID}):

$$\phi^{LD}(\vec{x}) = \phi^{LC}(\vec{x}) \times [LD(\vec{x}, k)]^{\beta}. \tag{21}$$

The second method which is proposed in this paper, strictly applies the local density measure by first filtering out instances with local densities lower than a threshold T, and then queries the most informative instance according to a certain query strategy (here we use ϕ^{LC}). This method is called Strict LD (SLD). We believe that this method of utilizing density measures is more effective than the traditional method (i.e. multiplying density measure by uncertainty measure (6)), since it does not affect all instances but

only very low-density ones. The threshold T is assumed to be in the form of $\alpha * \overline{LD}$, where $\overline{LD}$ is the average of local density over all unlabeled instances, and parameter α sets the intensity of filtering.

It is necessary to note that the k-Nearest-Neighbor density measure (Zhu et al., 2008) is identical to local density in definition but the motivation is different and in this article we look at the k-nearest-neighbor density from a completely different perspective: to avoid a shortcoming in the global density which is ignoring great parts of the input distribution and also to detect noisy instances.

5 Experiments

Experiments are all performed on the ATIS[1] data set (Hemphil et. al, 1990), both in noise-free and noisy conditions. In this section, the noise model used to generate noise is briefly described and then the evaluations are presented.

5.1 ATIS and Noise Model

ATIS is a relatively simple corpus which contains air travel information data. This corpus is the most commonly used data set for SLU research (Tur et. al, 2010). The data set contains questions (utterances) about flight, airport, and airline information. We specifically use the class-A (context independent) utterances from ATIS-3 corpus (Dahl et. al, 2004). These utterances are not semantically labelled, instead for each utterance there is an SQL command which queries the answer to the utterance from database. Thus a flat sematic representation was designed and semantic label sequences were generated semi-automatically from the SQL queries (as explained by He and Young (2006)). The flat semantic representation is listed in Table 1(a). A flat semantic representation is in fact a set of attributes (semantic labels) which are used to label an input utterance. Table 1(c) shows a typical utterance with sematic labels; note that IOB labeling scheme is used. Totally there are 1630 class-A instances (test + train) in ATIS-3 which are used in the experiments.

Attribute	Description	Attribute	Description
DCity	depart. city	ACity	arrival city
SCity	stop city	DAir	depart. airport

(c)

Table 1: (a) The flat semantic representation used to label utterances in the data set. (b) Some example pairs in noise model. Each pair is extracted from actual errors in ATIS-3 utterances. (c) A typical example from ATIS utterances.

Utterances in ATIS are de-noised by wizards[2]. There are two origins of noise: human (end-user) errors and ASR recognition errors. We design a simple noise-model based on actual errors and regenerate human and ASR errors. In ATIS-3, human errors are marked in SRO files and ASR errors are in N-best lists in log files. The noise model is a list of pairs of the form [correct-expression] → [erroneous-expression] which are applied to ATIS instances to add arbitrary percentage of noise. A few example pairs in the noise model are listed in Table 1(b). Each pair is extracted from an actual error; for example [phoenix] → [t x] is a result of an ASR error in ATIS-3 logs where "phoenix" in "Show me flights from phoenix …" was recognized as "t x" mistakenly. Obviously this pair is only applicable to an utterance which contains the word "phoenix".

[1] Air Travel Information System

[2] A wizard is a human expert who transcribes utterances or answers them (Hemphil et. al, 1990).

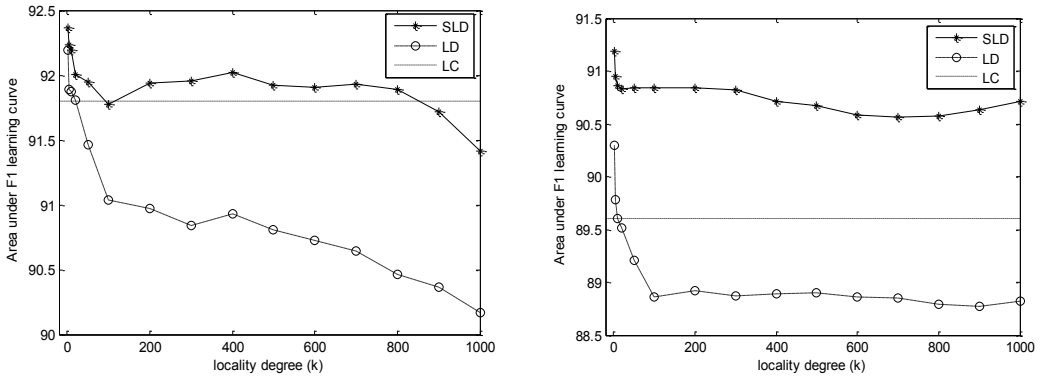
5.2 Parameter Settings

Using the noise model described, 3 levels of noise were generated: 7% of instances in level 1, 15% in level 2, and 25% in level 3 are noisy. In noisy conditions, when a noisy instance is selected by an active learning method, we assume that the instance is correctly detected as noisy by the annotator and is rejected (i.e. not added to $\mathcal{L}$); but the determination of an instance as noisy incurs a cost which we assume to be a quarter of cost of labeling one instance[1]. In all experiments, $\mathcal{L}$ is initialized with 5 random training instances. Batch size in all experiments is set to B=2 and new instances are added to $\mathcal{L}$ until the total labeling cost reaches 100. For query-by-committee method, we set C=4 and N=20 to balance between speed and accuracy. For LD and SLD, we set k=1 because it achieved best performance. For LIIS and LSIS, we set l=2 which achieved better results. Each method is evaluated as the average of 5 trials and each trial is performed using 5-fold cross validation. The reported performance for each method is the area under F1 learning curve (F1 score in SLU is computed as described by Tur and De Mori (2011)).

5.3 Effect of Locality

By initial evaluations, β=1 and α=0.6 were chosen for the LD and SLD method respectively. In Figure 3, the performances of LD and SLD for different degrees of locality (for k=1 to 1000) are shown. The performance of the LC method is also shown for comparison.

As seen in Figure 3, local density improves uncertainty measure (i.e. ϕ^{LC}, which is the base method in LD and SLD) and performs better than global density (i.e. local density with k=1000+). Note that LD has led to better performances than LC only for very local densities (i.e. k<5) while SLD has improved the performance of LC almost for all degrees of locality. It can also be seen that applying density strictly is more effective than the traditional way for all degrees of locality especially in noisy conditions.



(a) Noise-free condition (b) Noisy condition (average of all levels)

Figure 3. Effect of locality degree (in computation of information density) on performance of active learning methods. Plots (a) and (b) show the area under F1 learning curve for different values of k in LD and SLD methods, for noise-free and noisy conditions respectively. The area under F1 learning curve for LC is also shown for comparison.

5.4 Evaluations

The detailed results of the discussed active learning methods on different levels of noise are presented in Table 2. In each row, best performance is bolded and underlined, and second best performance is just bolded. Random refers to the random sampling of instances (passive learning). In noise-free condition, LD and SLD have improved a little over LC, but in average, SLD has performed remarkably better than LC, which shows the effectiveness of using local density to avoid noisy instances (note that LC is the base method used in LD and SLD). The instability sampling methods have improved over uncertainty

[1] The cost of labelling one instance is equal to 1 for any instance. In this paper, learning curves are depicted in terms of annotation cost which is equivalent to annotation time (please refer to Tomanek and Hahn (2010)).

sampling (i.e. SE) but not significantly. In the last row of Table 2 the running time of one cycle of active learning for each method is presented in seconds. QBC is the slowest method and LC is the fastest one. WGU is the second best in average performance but is rather slow in comparison to LC and this is a disadvantage of WGU. In fact all methods that iterate over best labelings are considerably slower that LC.

Learning curves cannot be shown for all active learning methods due to lack of space. Instead, learning curves are shown for selected methods. In Figure 4, learning curves for five methods of SLD, WGU, LIIS, FIR, and random are shown. It can be seen that the new WGU method has the best performance in early stages of active learning but soon declines and stays above the curve of LIIS. Also, the difference of SLD with other methods is more remarkable in the noisy conditions.

	Random	LC	SE	QBC	ID	FIR	LIIS	LSIS	WGU	LD	SLD
Noise-free	84.5	91.8	91.9	90.5	90.2	89.5	91.7	91.8	**92.1**	**92.1**	**92.4**
Noise level 1	84.1	**91.5**	90.7	90	89.6	89.1	91.1	90.8	**91.7**	91.2	**91.7**
Noise level 2	83.2	88.9	89	88.2	88.1	89.2	89.4	88.9	**90.4**	89.4	**91.1**
Noise level 3	83	88.4	88.4	87.5	87.7	**88.9**	88.7	87.8	**90**	89.3	**91**
Average	83.7	90.1	90	89	88.9	89.2	90.2	89.8	**91.1**	90.5	**91.6**
Runtime	**5**	**5**	8	20	**5.5**	8	8	8	8	**5.5**	**5.5**

Table 2. Area under F1 learning curves (max possible score is 100) and runtimes of various active learning methods on different levels of noise.

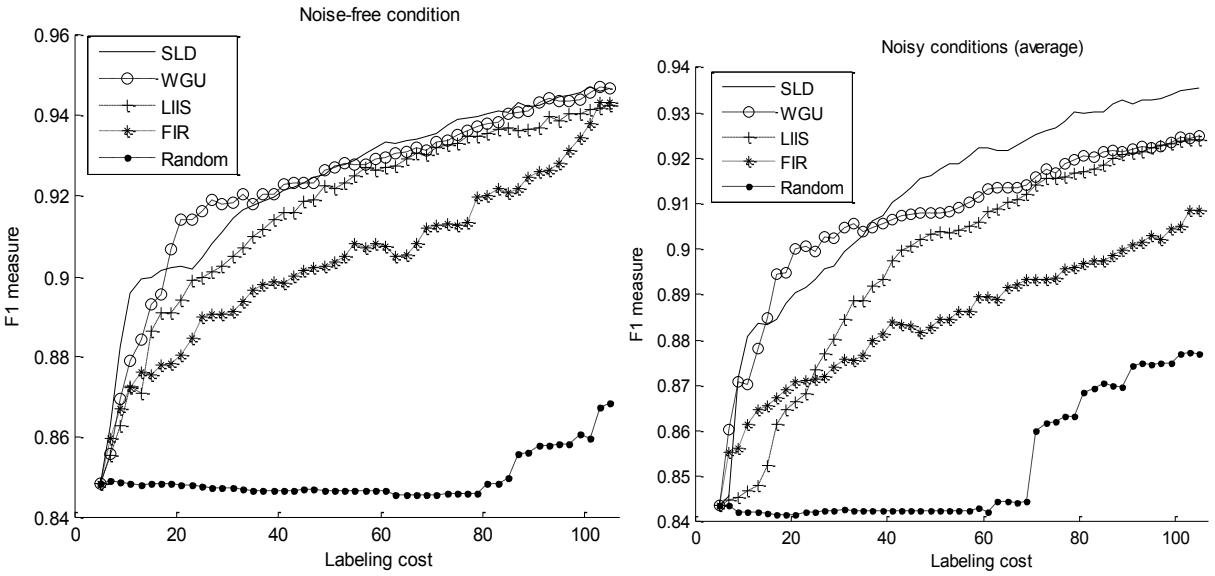


Figure 4. Learning curves for five selected methods: SLD, WGU, LIIS, FIR, and random for noise-free and noisy conditions (averaged across noise levels 1-3). Each learning curve shows the F1 measures achieved by the corresponding method for different labelling costs up to 100.

6 Conclusion

In this paper, best known active learning methods applicable to sequence labeling tasks were evaluated in the field of SLU (Spoken Language Understanding) in real conditions of noise. The new method of WGU (Weighted Gradient Uncertainty) with theoretical justification was proposed and performed well in the evaluations. Also, to deal directly with noisy instances, two methods of LD (Local Density) and SLD (Strict LD) were proposed based on the local density concept. It is possible to apply local density to WGU or other methods to achieve even better results but this could be the subject of future work.

Abstract

A self-adaptive classifier for efficient text-stream processing is proposed. The proposed classifier adaptively speeds up its classification while processing a given text stream for various NLP tasks. The key idea behind the classifier is to reuse results for past classification problems to solve forthcoming classification problems. A set of classification problems commonly seen in a text stream is stored to reuse the classification results, while the set size is controlled by removing the least-frequently-used or least-recently-used classification problems. Experimental results with Twitter streams confirmed that the proposed classifier applied to a state-of-the-art base-phrase chunker and dependency parser speeds up its classification by factors of 3.2 and 5.7, respectively.

1 Introduction

The rapid growth in popularity of microblogs (*e.g.*, Twitter) is enabling more and more people to instantly publish their experiences or thoughts any time they want from mobile devices. Since information in text posted by hundreds of millions of those people covers every space and time in the real world, analyzing such a text stream tells us what is going on in the real world and is therefore beneficial for reducing damage caused by natural disasters (Sakaki et al., 2010; Neubig et al., 2011a; Varga et al., 2013), monitoring political sentiment (Tumasjan et al., 2010) and disease epidemics (Aramaki et al., 2011), and predicting stock market (Gilbert and Karahalios, 2010) and criminal incident (Wang et al., 2012).

Text-stream processing, however, faces a new challenge; namely, the quality (content) and quantity (volume of flow) changes dramatically, reflecting a change in the real world. Current studies on processing microblogs have focused mainly on the difference between the quality of microblogs (or spoken languages) and news articles (or written languages) (Gimpel et al., 2011; Foster et al., 2011; Ritter et al., 2011; Han and Baldwin, 2011), and they have not addressed the issue of so-called "bursts" that increase the volume of text. Although it is desirable to use NLP analyzers with the highest possible accuracy for processing a text stream, high accuracy is generally attained by costly structured classification or classification with rich features, typically conjunctive features (Liang et al., 2008). It is therefore inevitable to trade accuracy for speed by using only a small fraction of features to assure real-time processing.

In this study, the aforementioned text-quantity issue concerning processing a text stream is addressed, and a self-adaptive algorithm that speeds up an NLP classifier trained with many conjunctive features (or with a polynomial kernel) for a given text stream is proposed and validated. Since globally-observable events such as natural disasters or sports events incur a rapid growth in the number of posts (Twitter, Inc., 2011), a text stream is expected to contain similar contents concerning these events when the volume of flow in a text stream increases. To adaptively speed up the NLP classifier, the proposed algorithm thus enumerates common classification problems from seen classification problems and keeps their classification results as partial results for use in solving forthcoming classification problems.

The proposed classifier was evaluated by applying it to streams of classification problems generated during the processing of the Twitter streams on the day of the 2011 Great East Japan Earthquake and on another day in March 2012 using a state-of-the-art base-phrase chunker (Sassano, 2008) and dependency parser (Sassano, 2004), and the obtained results confirm the effectiveness of the proposed algorithm.

2 Related work

A sentence is the processing unit used for fundamental NLP tasks such as word segmentation, part-of-speech tagging, phrase chunking, syntactic parsing, and semantic role labeling. Most efficient algorithms solving these tasks thus aim at speeding up the processing based on this unit (Kaji et al., 2010; Koo et al., 2010; Rush and Petrov, 2012), and few studies have attempted to speed up the processing of a given text (a set of sentences) as a whole. In the following, reported algorithms that adaptively speed up NLP analyzers for a given text are introduced.

A method of speeding up a classifier trained with many conjunctive features by using precomputed results for common classification problems was proposed by Yoshinaga and Kitsuregawa (2009; 2012). It solves classification problems that commonly appear in the processing of a large amount of text in advance and stores the results in a trie, so that they can be reused as partial results for solving new classification problems. This method was reported to achieve speed-up factors of 3.3 and 10.6 for base-phrase chunking and dependency parsing, respectively. An analogous algorithm for integer linear program (ILP) used to solve structured classification was proposed by Srikumar, Kundu, and Roth (2012; 2013). The algorithm was reported to achieve speed-up factors of 2.6 and 1.6 for semantic role labeling and entity-relation extraction, respectively. Although these two algorithms can be applied to various NLP tasks that can be solved by using a linear classifier or an ILP solver, how effective they are for processing a text stream is not clear.

A method of feature sharing for beam-search incremental parsers was proposed by Goldberg et al. (2013). Motivated by the observation that beam parsers solve similar classification problems in different parts of the beam, this method reuses partial results computed in the previous beam items. It reportedly achieved a speed-up factor of 1.2 for arc-standard and arc-eager dependency parsers. The key differences between the method proposed in this study and their feature-sharing method are twofold. First, the feature sharing in Goldberg et al. (2013) is performed in a token-wise manner in the sense that a key to retrieve a cached result is represented by a bag of tokens that invoke features, which manner prevents fine-grained caching. Second, the feature sharing is dynamically performed during parsing, but the cached results are cleared after processing each sentence.

An adaptive pruning method for fast HPSG parsing was proposed by van Noord (2009). This method preprocesses a large amount of text by using a target parser to collect derivation steps that are unlikely to contribute to the best parse, and it speeds up the parser by filtering out those unpromising derivation steps. Although this method was reported to attain a speed-up factor of four while keeping parsing accuracy, it needs to be tuned to trade parsing accuracy and speed for each domain. It is difficult to derive the true potential of their method in regard to processing a text stream whose domain shifts from time to time.

It has been demonstrated by Wachsmuth et al. (2011) that tuning a pipeline schedule of an information extraction (IE) system improves the efficiency of the system. Furthermore, the self-supervised learning algorithm devised by Wachsmuth et al. (2013) predicts the processing time for each possible pipeline schedule of an IE system, and the prediction is used to adaptively change the pipeline schedule for a given text stream. This method and the proposed method for speeding up an NLP classifier are complementary, and a combination of both methods is expected to synergistically speed up various NLP-systems.

In this study, based on the classifier proposed by Yoshinaga and Kitsuregawa (2009), a self-adaptive classifier that enumerates common classification problems from a given text stream and reuses their results is proposed. As a result, the proposed classifier adaptively speeds up the classification of forthcoming classification problems.

3 Preliminaries

As the basis of the proposed classifier, the previously-presented classifier that uses results of common classification problems (Yoshinaga and Kitsuregawa, 2009) is described as follows. This base classifier targets a linear classifier trained with many conjunctive features (including one converted from a classifier trained with polynomial kernel (Isozaki and Kazawa, 2002)) that are widely used for many NLP tasks. Although this classifier (and also the one proposed in this paper) can handle a multi-class classification problem, a binary classification problem is assumed here for brevity.

A binary classifier such as a perceptron and a support vector machine determines label $y \in \{+1, -1\}$ of input classification problem $\boldsymbol{x}$ by using the following equation (from which the bias term is omitted for brevity):

$$m(\boldsymbol{x}; \boldsymbol{\phi}, \boldsymbol{w}) = \boldsymbol{w}^{\mathrm{T}} \boldsymbol{\phi}(\boldsymbol{x}) = \sum_i w_i \phi_i(\boldsymbol{x}) \tag{1}$$

$$y = \begin{cases} +1 & (m(\boldsymbol{x}; \boldsymbol{\phi}, \boldsymbol{w}) \geq 0) \\ -1 & (m(\boldsymbol{x}; \boldsymbol{\phi}, \boldsymbol{w}) < 0). \end{cases} \tag{2}$$

Here, ϕ_i is a feature function, w_i is a weight for ϕ_i obtained as a result of training, and $m(\boldsymbol{x}; \boldsymbol{\phi}, \boldsymbol{w})$ is a margin between $\boldsymbol{x}$ and the separating hyperplane.

In most NLP tasks, feature functions are mostly indicator (or binary) functions that typically represent particular linguistic constraints. Here, feature functions are assumed to be indicator functions that return $\{0, 1\}$, and margin $m(\boldsymbol{x}; \boldsymbol{\phi}, \boldsymbol{w})$ is represented by the following equation:

$$m(\boldsymbol{x}; \boldsymbol{\phi}, \boldsymbol{w}) = \sum_i w_i \phi_i(\boldsymbol{x}) = \sum_{i, \phi_i(\boldsymbol{x})=1} w_i. \tag{3}$$

Feature function ϕ_i is hereafter referred to as feature ϕ_i; when $\phi_i(\boldsymbol{x}) = 1$ for given $\boldsymbol{x}$, $\boldsymbol{x}$ is said to "include" feature ϕ_i or feature ϕ_i is "active" in $\boldsymbol{x}$ (denoted as $\phi_i \in \boldsymbol{x}$). Having the number of active features, $|\boldsymbol{\phi}(\boldsymbol{x})| \equiv |\{\phi_i \mid \phi_i \in \boldsymbol{x}\}|$, Eq. 3 requires $\mathcal{O}(|\boldsymbol{\phi}(\boldsymbol{x})|)$ when the weights for the active features are summed up.

To speed up the summation in Eq. 3, classification results for some classification problems $\boldsymbol{x}_c$ are precomputed as $M_{\boldsymbol{x}_c} \equiv m(\boldsymbol{x}_c; \boldsymbol{\phi}, \boldsymbol{w})$ in advance, and then these precomputed results are reused as partial results for solving an input classification problem, $\boldsymbol{x}$:

$$m(\boldsymbol{x}; \boldsymbol{x}_c, \boldsymbol{\phi}, \boldsymbol{w}) = M_{\boldsymbol{x}_c} + \sum_{i, \phi_i \in \boldsymbol{x}, \phi_i \notin \boldsymbol{x}_c} w_i \tag{4}$$

$$\textit{where} \quad \forall \phi_j \in \boldsymbol{x}_c, \phi_j \in \boldsymbol{x}.$$

Note that for Eq. 4 to be computed faster than Eq. 3, $M_{\boldsymbol{x}_c}$ must be retrieved in time less than $\mathcal{O}(|\boldsymbol{\phi}(\boldsymbol{x}_c)|)$. It is actually possible when $\boldsymbol{x}_c$ includes conjunctive feature $\phi_{i,j}(\boldsymbol{x}_c) = \phi_i(\boldsymbol{x}_c)\phi_j(\boldsymbol{x}_c)$. If it is necessary to retrieve margin $M_{\boldsymbol{x}_c}$ precomputed for $\boldsymbol{x}_c$ including ϕ_i, ϕ_j, and $\phi_{i,j}$, it is necessary to check only non-conjunctive (or *primitive*) features ϕ_i and ϕ_j, since $\phi_{i,j}$ is active whenever ϕ_i and ϕ_j are active (so checking $\phi_{i,j}$ can be skipped). The second term of Eq. 4 sums up the weights of the remaining features that are not included in $\boldsymbol{x}_c$ but are included in $\boldsymbol{x}$. For example, under the assumption that $\boldsymbol{x}$ includes features ϕ_i, ϕ_j, ϕ_k, $\phi_{i,j}$, $\phi_{i,k}$, and $\phi_{j,k}$ and that margin $M_{\boldsymbol{x}_c}$ has been obtained for $\boldsymbol{x}_c$ (including ϕ_i, ϕ_j, and $\phi_{i,j}$), five features must be checked (two to retrieve $M_{\boldsymbol{x}_c}$ and three to sum up the weights of the remaining features ϕ_k, $\phi_{i,k}$ and $\phi_{j,k}$) by using Eq. 4. On the other hand, to compute $m(\boldsymbol{x}; \boldsymbol{\phi}, \boldsymbol{w})$ by Eq. 3, the weights for the six features must be checked.

To maximize the speed-up obtained by Eq. 4, reuse of margin $M_{\boldsymbol{x}_c}$ of common classification problem $\boldsymbol{x}_c$ should minimize the number of remaining features included only in $\boldsymbol{x}$. In other words, $\boldsymbol{x}_c$ should be as similar to $\boldsymbol{x}$ as possible (ideally, $\boldsymbol{x}_c = \boldsymbol{x}$). It is not, however, realistic to precompute margin $M_{\boldsymbol{x}} \equiv m(\boldsymbol{x}; \boldsymbol{\phi}, \boldsymbol{w})$ for every possible classification problem $\boldsymbol{x}$ since it requires $\mathcal{O}(2^{|\boldsymbol{\phi}'|})$ space where $|\boldsymbol{\phi}'|$ is the number of primitive features ($\boldsymbol{\phi}' \subset \boldsymbol{\phi}$) and $|\boldsymbol{\phi}'|$ is usually more than 10,000 in NLP tasks due to lexical features. Yoshinaga and Kitsuregawa (2009) therefore preprocess a large amount of text to enumerate possible classification problems, and select common classification problems, $\mathcal{X}_c \subset 2^{\boldsymbol{\phi}'}$, according to their probability and the reduction in the number of features to be checked by Eq 4.

Yoshinaga and Kitsuregawa (2009) then represent the common classification problems $\boldsymbol{x}_c \in \mathcal{X}_c$ by sequences of active primitive feature indices, and store those feature (index) sequences as keys in a prefix trie with precomputed margin $M(\boldsymbol{x}_c)$ as their values. To reuse a margin of common classification problem that is similar to input $\boldsymbol{x}$ in Eq. 4, features are ordered according to their frequency to form a feature sequence of $\boldsymbol{x}_c$. A longest-prefix search for the trie thereby retrieves a common classification problem similar to the input classification problem in linear time with respect to the number of primitive features in $\boldsymbol{x}_c$, $\mathcal{O}(|\boldsymbol{\phi}'(\boldsymbol{x}_c)|)$.

Algorithm 1 A self-adaptive classifier for enumerating common classification problems

INPUT: $\boldsymbol{x}$, $\boldsymbol{\phi}$, $\boldsymbol{\phi}' \subset \boldsymbol{\phi}$, $\boldsymbol{w} \in \mathbb{R}^{|\boldsymbol{\phi}|}$, $\mathcal{X}_c \subset 2^{\boldsymbol{\phi}'}$, $k > 0$
OUTPUT: $m(\boldsymbol{x}; \boldsymbol{\phi}, \boldsymbol{w}) \in \mathbb{R}$, $\mathcal{X}_c$
1: INITIALIZE: $\boldsymbol{x}_c$ s.t. $\boldsymbol{\phi}'(\boldsymbol{x}_c) = \mathbf{0}$, $M_{\boldsymbol{x}_c} \leftarrow 0$
2: **repeat**
3: $\quad \boldsymbol{x}_c^{old} \leftarrow \boldsymbol{x}_c$
4: $\quad \phi'_i = \underset{\phi'_i \in \boldsymbol{x}, \phi'_i \notin \boldsymbol{x}_c}{\text{argmax}}\ \text{FREQ}(\phi'_i)$ (extract a primitive feature according to its frequency)
5: $\quad \phi'_i(\boldsymbol{x}_c) \leftarrow 1$ (construct a new common-classification problem)
6: $\quad$ **if** $\boldsymbol{x}_c \notin \mathcal{X}_c$ **then**
7: $\quad\quad M_{\boldsymbol{x}_c} \leftarrow m(\boldsymbol{x}_c; \boldsymbol{x}_c^{old}, \boldsymbol{\phi}, \boldsymbol{w})$ (compute margin by using Eq. 4)
8: $\quad\quad$ **if** $|\mathcal{X}_c| = k$ **then**
9: $\quad\quad\quad \mathcal{X}_c \leftarrow \mathcal{X}_c - \{\text{USELESS}(\mathcal{X}_c)\}$
10: $\quad\quad \mathcal{X}_c \leftarrow \mathcal{X}_c \cup \{\boldsymbol{x}_c\}$
11: **until** $\boldsymbol{\phi}'(\boldsymbol{x}_c) \neq \boldsymbol{\phi}'(\boldsymbol{x})$
12: **return** $m(\boldsymbol{x}; \boldsymbol{\phi}, \boldsymbol{w}) = M_{\boldsymbol{x}_c}$, $\mathcal{X}_c$

4 Proposed method

The classifier described in Section 3 is extended so that it dynamically enumerates common classification problems from a given text stream[1] to adaptively speed up the classification. This classification "speed up" faces two challenges: which (partial) classification problems should be chosen to reuse their results from a given stream of classification problems, and how to efficiently maintain the extracted common classification problems. These two challenges are addressed in Sections 4.1 and 4.2, respectively.

4.1 Enumerating common classification problems dynamically from a text stream

Although Yoshinaga and Kitsuregawa (2009) select common classification problems according to their probability, such statistics cannot be known before a target text stream is entirely seen. A set of common classification problems was thus kept updated adaptively while processing a text stream; that is, classification problems are added when they will be useful, while they are removed when they will be useless, so that the number of common classification problems, $|\mathcal{X}_c|$, does not exceed a pre-defined threshold, k.

Algorithm 1 depicts the proposed self-adaptive classifier for enumerating common classification problems from an input classification problem, $\boldsymbol{x}$. To incrementally construct common classification problem $\boldsymbol{x}_c$ (Line 4-5), the algorithm extracts the primitive features (ϕ'_i) included in $\boldsymbol{x}$ one by one according to their probability of appearing in the training data of the classifier. When the resulting $\boldsymbol{x}_c$ is included in the current set of common classification problems, $\mathcal{X}_c$, stored margin $M_{\boldsymbol{x}_c}$ is reused. Otherwise, margin $M_{\boldsymbol{x}_c} = m(\boldsymbol{x}_c; \boldsymbol{x}_c^{old}, \boldsymbol{\phi}, \boldsymbol{w})$ is computed by using Eq. 4 (Line 7), and $\boldsymbol{x}_c$ is registered in $\mathcal{X}_c$ as a new common classification problem (Line 10).

An important issue is how to define function USELESS, which selects a common classification problem that will not contribute to speeding up the forthcoming classification, when the number of common classification problems, $|\mathcal{X}_c|$, reaches the pre-defined threshold k. To address this issue, the following two policies (designed originally for CPU caching) are proposed and compared in terms of the efficiency of the classifier in experiments:

Least Frequently Used (LFU) This policy counts frequency of common classification problems in a seen text stream, and it maintains only the top-k common classification problems by removing the least-common classification problem from $\mathcal{X}_c$:

$$\text{USELESS}_{\text{LFU}}(\mathcal{X}_c) = \underset{\boldsymbol{x}_c \in \mathcal{X}_c}{\text{argmin}}\ \text{FREQ}(\boldsymbol{x}_c) \tag{5}$$

[1] More precisely, a stream of classification problems generated during the analysis of a text stream.

A space-saving algorithm, (Metwally et al., 2005), is used to efficiently count the approximated frequency of k classification problems at most and to remove the common classification problem rejected by the space-saving algorithm.

Least Recently Used (LRU) When the volume of flow in a text stream rapidly increases, it is likely to relate to a burst of a certain topic. To exploit this characteristics, this policy preserves k common classification problems whose results are most recently reused:

$$\text{USELESS}_{\text{LRU}}(\mathcal{X}_c) = \operatorname*{argmin}_{\boldsymbol{x}_c \in \mathcal{X}_c} \text{TIME}(\boldsymbol{x}_c) \tag{6}$$

Common classification problems are associated with the last timing when their results are reused, and the least-recently-reused common classification problem is removed when $|\mathcal{X}_c| = k$. To realize this policy, a circular linked-list of size k is used to maintain precomputed results, and the oldest element is just overwritten while the corresponding classification problem is removed.

Fixed threshold k is used throughout the processing of a text stream, and its impact on classification speed was evaluated by experiments.

Since Algorithm 1 naively constructs common classification problems using all the active primitive features in input classification problem $\boldsymbol{x}$, it might repeatedly add and remove classification problems that include rare primitive features such as lexical features. This will incur serious overhead costs. To avoid this situation, the margin computation is terminated as soon as it is determined that the remaining computation does not change the sign of margin (namely, classification label y) of $\boldsymbol{x}$.

When $\boldsymbol{x}$ and $\boldsymbol{x}_c$ are given, lower- and upper-bounds of $m(\boldsymbol{x}; \boldsymbol{\phi}, \boldsymbol{w})$ can be computed by accumulating bounds of a partial margin computed by adding remaining active primitive features, $\{\phi'_j \in \boldsymbol{x} \mid \phi'_j \notin \boldsymbol{x}_c\}$, one by one to $\boldsymbol{x}_c$. It is assumed that primitive feature ϕ'_i is newly activated in $\boldsymbol{x}_c$ and $\boldsymbol{x}_c^{old}$ refers to $\boldsymbol{x}_c$ without ϕ'_i being activated. The partial margin, $m(\boldsymbol{x}_c; \boldsymbol{\phi}, \boldsymbol{w}) - m(\boldsymbol{x}_c^{old}; \boldsymbol{\phi}, \boldsymbol{w})$, is computed by summing up the weights of primitive feature ϕ'_i and conjunctive features that are composed of ϕ'_i and one or more primitive features $\phi'_j \in \boldsymbol{x}_c^{old}$. This partial margin is upper- and lower-bounded as follows:

$$m(\boldsymbol{x}_c; \boldsymbol{\phi}, \boldsymbol{w}) - m(\boldsymbol{x}_c^{old}; \boldsymbol{\phi}, \boldsymbol{w}) \geq \max(w_i^{min} | \{\phi_j \in \boldsymbol{x}_c \mid \phi_j \notin \boldsymbol{x}_c^{old}\}|, W_i^-) \tag{7}$$

$$m(\boldsymbol{x}_c; \boldsymbol{\phi}, \boldsymbol{w}) - m(\boldsymbol{x}_c^{old}; \boldsymbol{\phi}, \boldsymbol{w}) \leq \min(w_i^{max} | \{\phi_j \in \boldsymbol{x}_c \mid \phi_j \notin \boldsymbol{x}_c^{old}\}|, W_i^+), \tag{8}$$

where w_i^{min} and w_i^{max} refer to minimum and maximum weights among all the features regarding ϕ'_i, while W_i^+ and W_i^- refer to summations of all the features regarding ϕ'_i with positive and negative weights, respectively; that is, this upper or lower-bound is computed by assuming all the features regarding ϕ'_i to have a maximum or minimum weight (each bounded by W_i^+ or W_i^-). Accumulating these bounds for each remaining primitive feature makes it possible to obtain the bounds of $m(\boldsymbol{x}; \boldsymbol{\phi}, \boldsymbol{w})$ and thereby judge whether the sign of the margin can be changed by processing the remaining features.

4.2 Maintaining common classification problems with dynamic double-array trie

To maintain the enumerated common classification problems, a double-array trie (Aoe, 1989) is applied. The trie associates common classification problem $\boldsymbol{x}_c$ with unique index $i (1 \leq i \leq k)$, which is further associated with computed margin $M_{\boldsymbol{x}_c}$ and frequency or access time as described in Section 4.1. Although a double-array trie provides an extremely fast look-up, it had been considered that update operation (adding a new key to a double-array trie) is slow. However, in a recent study (Yata et al., 2009), the update speed of a double-array trie approaches that of a hash table. In the following section, a double-array trie similar to that of Yata et al. (2009) is used to maintain common classification problems.

Efficient dynamic double-array trie with deletion

A double-array trie (Aoe, 1989) and an algorithm that allows a fast update (Yata et al., 2009) are briefly introduced in the following. A double array is a data structure for a compact trie, which consists of two one-dimensional arrays called BASE and CHECK. In a double-array trie, each trie node occupies one element in BASE and CHECK, respectively.[2] For each node, p, BASE stores the offset address of its child

[2] Although the original double-array (Aoe, 1989) realizes a minimal-prefix trie by using another array (called TAIL) to store suffix nodes with only one child, TAIL is not adopted here since it is difficult to support space-efficient deletion with TAIL.

nodes, so a child node takes the address $c = \text{BASE}[p]$ XOR[3] l when the node is traversed from p by label l. For each node, c, CHECK stores the address of its parent node, p, and is used to confirm the validity of the traversal by checking whether $\text{CHECK}[c] = p$ is held after the node is reached by $c = \text{BASE}[p]$ XOR l.

Adding a new node to a trie could cause a conflict, meaning that the newly added node could be assigned to the address taken by an existing node in the trie. In such a case, it is necessary to collect all the sibling nodes of either the newly added node or the existing node that took the conflicting address, and then relocate either branching (with a lower number of child nodes) to empty addresses that are not taken by other nodes in the trie. This relocation is time-consuming, and is the reason for the slow update.

To perform this relocation quickly, Yata et al. (2009) introduced two additional one-dimensional arrays, called NLINK (node link) and BLOCK. For each node, NLINK stores the label needed to reach its first child and the label needed to reach from its parent the sibling node next to the node. It thereby makes it possible to quickly enumerate the sibling nodes for relocation. BLOCK stores information on empty addresses within each 256 consecutive addresses called a block[4] in BASE and CHECK. Each block is classified into three types, called "full," "closed" and "open." Full blocks have no empty addresses and are excluded from the target of relocation. Closed blocks have only one empty address or have failed to be relocated more times than a pre-specified threshold. Open blocks are other blocks, which have more than one empty address. The efficient update of the trie is enabled by choosing appropriate blocks to relocate a branching; a branching with one child node is relocated to a closed block, while a branching with multiple child nodes is relocated to an open block.

The above-described double-array trie was modified to support a deletion operation, which simply registers to each block empty addresses resulting from deletion. In consideration that a new key (common classification problem) will be stored immediately after the deletion (Line 10 in Algorithm 1), the double-array trie is not packed as in Yata et al. (2007) after a key is deleted.

Engineering a double-array trie to reduce trie size

To effectively maintain common classification problems in a trie, it is critical to reduce the number of trie nodes accessed in look-up, update, and deletion operations. The number of trie nodes was therefore reduced as much as possible by adopting a more compact representation of keys (common classification problems) and by elaborating the way to store values for the keys in the double-array trie.

Gap-based key representation To compress representations of common classification problems (feature sequences) in the trie, frequency-based indices are allocated to primitive features (Yoshinaga and Kitsuregawa, 2010). A gap representation (used to compress posting lists in information retrieval (Manning et al., 2008, Chapter 5)) is used to encode feature sequences. Each feature index is replaced with a gap from the preceding feature index (the first feature index is used as is). Each gap is then encoded by variable-byte coding (Williams and Zobel, 1999) to obtain shorter representations of feature sequences.

A reduced double-array trie The standard implementation of a double-array trie stores an (integer) index with a key at a child node (value node) traversed by a terminal symbol `'\0'` (or an alphabet not included in a key, *e.g.*, `'#'`) from the node reached after reading the entire key (Yoshinaga and Kitsuregawa, 2009; Yasuhara et al., 2013). However, when a key is not a prefix to the other keys, the value node has no sibling node, so a value can be directly embedded on the BASE of the node reached after reading the entire key instead of the offset address of the child (value) node. All the value nodes for the longest prefixes are thereby eliminated from the trie. The resulting double-array trie is referred to as a *reduced double-array trie*.

These two tricks reduce the number of trie nodes (memory usage), and make the trie operations faster. A reduced double-array trie is also used to compactly store the weights of conjunctive features, as described in Yoshinaga and Kitsuregawa (2010). Interested readers may refer to **cedar**,[5] open-source software of a dynamic double-array trie, for further implementation details of the reduced double-array trie.

[3]The original double-array (Aoe, 1989) uses addition instead of XOR operation to obtain a child address.

[4]Note that the XOR operation guarantees that all the child nodes are located within a certain block i (assuming 1 byte (0-255) for each label, l, child nodes of a node, p, are all located in addresses ($256i \leq c = \text{BASE}[p]$ XOR $l < 256(i+1)$).

Accuracy (complete)	94.16%	58.38%

Table 1: Model statistics for base-phrase chunking and dependency parsing.

5 Experiments

The proposed self-adaptive classifier was experimentally evaluated by applying it to streams of classification problems. The streams of classification problems were generated by processing Twitter streams using a state-of-the-art base-phrase chunker and dependency parser. All experiments were conducted with an Intel® Core™ i7-3720QM 2.6-GHz CPU server with 16-GB main memory.

5.1 Setup

Since March 11, 2011 (the day of the Great East Japan Earthquake; "3.11 earthquake" hereafter), Twitter streams were crawled by using Twitter API.[6] Tweets from famous Japanese users were crawled first. Next, timelines of those users were obtained. Then, the set of users were repeatedly expanded by tracing retweets and mentions in their timelines to collect as many tweets as possible. In the following experiments, two sets of 24-hour Twitter streams from the crawled tweets were used. The first Twitter stream was taken from the day of 3.11 earthquake (12:00 on Friday, March 11, 2011 to 12:00 on Saturday, March 12, 2011), and the second one was taken from the second weekend in March, 2012 (12:00 on Friday, March 9, 2012 to 12:00 on Saturday, March 10, 2012). The first Twitter stream is intended to evaluate the classifier performance on days with a significant, continuous burst, while the second one is to evaluate the performance on days without such a burst. No special events, other than a small earthquake (02:25 on March 10), occurred from March 9 to 10, 2012. Because the input to base-phrase chunking and dependency parsing is a sentence, each post was split by using punctuations as clues.

Although it might be better to evaluate the chunking and parsing speed with the proposed classifier for a text stream, the classification speed was evaluated for streams of classification problems generated in processing the Twitter streams by a deterministic base-phrase chunker (Sassano, 2008) and a shift-reduce dependency parser (Sassano, 2004), which are implemented in J.DepP.[12] Note that the chunker and parser are known to spend most of the time for classification (Yoshinaga and Kitsuregawa, 2012), and reducing the classification time leads to efficient processing of Twitter streams.

The base-phrase chunker processes each token in a sentence identified by a morphological analyzer, MeCab,[7] and judges whether the token is the beginning of a base-phrase chunk in Japanese (called a *bunsetsu*[8]) or not. The shift-reduce dependency parser processes each chunk in the chunked sentences and determines whether the head candidate chosen by the parser is correct head or not.

The classifiers for base-phrase chunking and dependency parsing were trained by using a variant of a passive-aggressive algorithm (PA-I) (Crammer et al., 2006) with a standard split[9] of the Kyoto-University Text Corpus (Kawahara et al., 2002) Version 4.0.[10] A third-order polynomial kernel was used to consider combinations of up-to three primitive features. The features used for training the classifiers were identical to those implemented in J.DepP. The polynomial kernel expanded (Kudo and Matsumoto, 2003) was used to make the number of resulting conjunctive features tractable without harming the accuracy.

Table 1 lists the statistics of the models trained for chunking and parsing. In Table 1, "accuracy (partial)" is the ratio of chunks (or dependency arcs) correctly identified by the chunker (or the parser), while "accuracy (complete)" is the exact-match accuracy of complete chunks (or dependency arcs) in a sentence. The accuracy of the resulting parser on the standard split was better than any published results

$k = 2^{24}$	399.17	**0.0070**	**3.16**	409.59	**0.0068**	**2.76**

Table 3: Experimental results obtained with the reduced double array trie: base phrase chunking.

for this dataset other than those reported for a parser based on "stacking" (Iwatate, 2012).[11]

Table 2 lists the detail of the Twitter streams used for evaluating the proposed classifier. Figures 1(a) and 1(b) show the change in the number of posts and classifications for parsing per minute, when the average number of posts and classifications per minute before the 3.11 earthquake is counted as one, respectively. The dataset shows a rapid growth in the number of posts after the 3.11 earthquake occurred (14:46:18). This event also incurs a rapid growth in the number of classifications for parsing. Although space limitations precluded the number of classifications for chunking, it had the same tendency as for parsing. It should be noted that the official retweets (reposts) occupied 25.8% (2,394,025) and 8.5% (542,726) of the entire posts from March 11 to 12, 2011 and from March 9 to 10, 2012, respectively.

5.2 Results

Tables 3 and 4 list the timings needed to solve the classification problems generated for each sentence by processing the Twitter streams listed in Table 2 using the base-phrase chunker and the dependency parser, respectively. In Table 3, "baseline" refers to the classifier using Eq. 3, while "Y&K '09" refers to Yoshinaga and Kitsuregawa (2009) who used Eq. 4, and enumerates common classification problems from the training corpus[9] of the classifier in advance. To highlight the performance gap caused by the algorithmic differences and make the memory consumptions comparable, the experiments were conducted using the same implementation of the reduced double-array trie, described in Section 4.2, for all the methods. The proposed classifier (with 65,536 ($k = 2^{16}$) common classification problems) achieved higher classifica-

[11] The best reported accuracy of a non-stacking parser is 91.96% (partial) and 57.44% (complete) for Kyoto-University Text Corpus Version 3.0 (Iwatate et al., 2008), and is better than that achieved by the MST algorithm (McDonald et al., 2005).

method	March 11-12, 2011 space [MiB]	speed [ms/sent.]	ratio	March 9-10, 2012 space [MiB]	speed [ms/sent.]	ratio

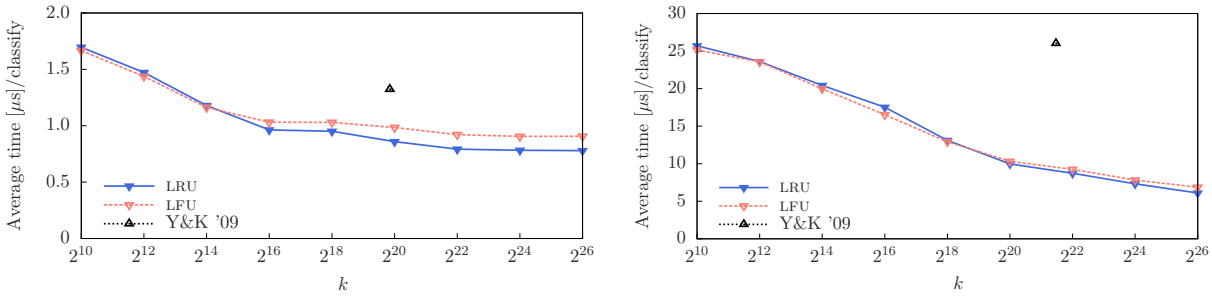
Table 4: Experimental results obtained with the reduced double array trie: dependency parsing.



(a) base-phrase chunking

(b) dependency parsing

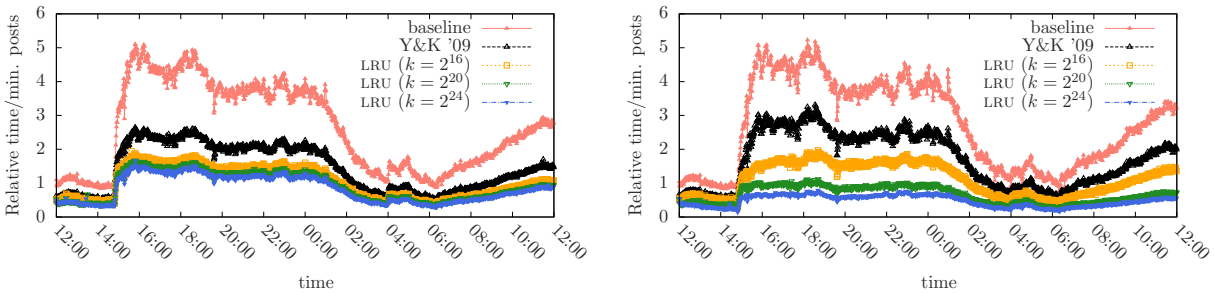
Figure 2: Average classification time per classification problem as a function of number of common classification problems k (2011 tweet stream).

tion speed than that achieved by Y&K '09 (with 943,864 (chunking) and 2,902,679 (parsing) common classification problems). Although the speed up is evident for both tweet datasets, the speed-up is more obvious in the case of the 2011 tweet stream. In the following experiments, in view of space limitations and redundancy, the 2011 tweet stream was used; however, note that the same conclusions are drawn from the results with the 2012 twitter stream.

Figure 2 shows the time needed for solving each classification problem for chunking and parsing of the 2011 tweet stream when the threshold to the number of common classification problems k is varied from 2^{10} to 2^{26}, respectively. In both tasks, the proposed classifier with the LRU policy outperforms the proposed classifier with the LFU policy when k was increased. This is not only because the LFU policy has higher overheads than the LRU policy but also because the LFU policy selects useless classification problems that include lexical features related to a burst in the past. The speed-up is saturated in the case of base-phrase chunking at $k = 2^{22}$ (Figure 2(a)). This is because the proposed classifier often terminates margin computation without seeing lexical features for base phrase chunking, so it rarely reuses results of common classification problems including lexical features that are preserved when k is increased. On the other hand in dependency parsing, the classifier relies on lexical features to resolve semantic ambiguities, so it cannot terminate margin computation without seeing lexical features and thus exploits common classification problems including lexical features.

Figure 3 shows the change in the time needed for solving classification problems generated from a one-minute text stream for chunking and parsing of the 2011 tweet stream. The y-axis shows the relative classification time, when the average classification time of the baseline method before the 3.11 earthquake is counted as one. The classification time of the baseline method and Yoshinaga and Kitsuregawa (2009)'s method rapidly increased in response to the increase of the number of classification problems, while the proposed classifier suppressed the increase in classification time. It is thus concluded that the proposed classifier is more robust in terms of real-time processing for a text stream.

Finally, the contributions of the three tricks of the proposed classifier to the classification performance for dependency parsing were evaluated. The three tricks are a gap-based key representation and a reduced double-array trie (Section 4.1), as well as the early termination of margin computation (Section 4.1).



(a) base-phrase chunking

(b) dependency parsing

Figure 3: Change in classification time of one-minute posts (2011 tweet stream).

method	plain (no tricks) space [MiB]	plain (no tricks) speed [ms/sent.]	plain (no tricks) ratio	+ gap-based key space [MiB]	+ gap-based key speed [ms/sent.]	+ gap-based key ratio	+ reduced double array space [MiB]	+ reduced double array speed [ms/sent.]	+ reduced double array ratio	+ early termination space [MiB]	+ early termination speed [ms/sent.]	+ early termination ratio
baseline	39.88	0.1413	0.84	n/a	n/a	n/a	31.50	0.1187	1.00	38.21	0.0745	1.59
Y&K '09	117.66	0.0922	1.29	110.52	0.0904	1.31	99.91	0.0738	1.61	106.61	0.0406	2.93
proposed $k = 2^{16}$	44.64	0.1037	1.14	44.50	0.1009	1.18	36.09	0.0845	1.41	42.68	0.0497	2.39
(LRU) $k = 2^{20}$	117.21	0.0590	2.01	114.57	0.0572	2.07	105.21	0.0492	2.41	108.88	0.0283	4.20
$k = 2^{24}$	969.48	0.0412	2.88	923.96	0.0398	2.98	897.70	0.0350	3.39	840.85	**0.0208**	**5.71**

Table 5: Contribution of each trick to classification performance; 2011 tweet dataset (underlined numbers are quoted from Table 4).

Table 5 lists the classification times per sentence in the case of dependency parsing, when each trick is cumulatively applied to plain classifiers without all the tricks. Classification is significantly speeded up by early termination of the margin computation and the reduced double-array trie. These tricks also contribute to speeding up the baseline method and Yoshinaga and Kitsuregawa (2009)'s method.

6 Conclusion

Aiming to efficiently process a real-world text stream (such as a Twitter stream) in real-time, a self-adaptive classifier that becomes faster for a given text stream is proposed. It enumerates common classification problems that are generated during the processing of a text stream, and reuses the results of those classification problems as partial results for solving forthcoming classification problems.

The proposed classifier was evaluated by applying it to the streams of classification problems generated by processing two sets of Twitter streams on the day of the 2011 Great East Japan Earthquake and the second weekend in March 2012 using a state-of-the-art base-phrase chunker and dependency parser. The proposed classifier speeds up the classification by factors of 3.2 (chunking) and 5.7 (parsing), which are significant factors in regard to processing a massive text stream.

It is planned to evaluate the classifier on other NLP tasks. A linear classifier with conjunctive features is widely used for NLP tasks such as word segmentation, part-of-speech tagging (Neubig et al., 2011b), and dependency parsing (Nivre and McDonald, 2008). Even for NLP tasks in which structured classification is effective (*e.g.*, named entity recognition), structure compilation (Liang et al., 2008) (or "uptraining" (Petrov et al., 2010)) gives state-of-the-art accuracy when a linear classifier with many conjunctive features is used. The proposed classifier is expected to be applied to a range of NLP tasks.

All the codes have been available for the research community as open-source software, including **pecco** (a self-adaptive classifier)[12] and **J.DepP** (a base-phrase chunker and dependency parser).[13]

Abstract

Previous models in syntax-based statistical machine translation usually resort to some kinds of synchronous procedures, few of these works are based on the analysis-transfer-generation methodology. In this paper, we present a statistical implementation of the analysis-transfer-generation methodology in rule-based translation. The procedures of syntax analysis, syntax transfer and language generation are modeled independently in order to break the synchronous constraint, resorting to dependency structures with dependency edges as atomic manipulating units. Large-scale experiments on Chinese to English translation show that our model exhibits state-of-the-art performance by significantly outperforming the phrase-based model. The statistical transfer-generation method results in significantly better performance with much smaller models.

1 Introduction

Researches in statistical machine translation have been flourishing in recent years. Statistical translation methods can be divided into word-based (Brown et al., 1993), phrase-based (Marcu and Wong, 2002; Koehn et al., 2003) and syntax-based models (Yamada and Knight, 2001; Graehl and Knight, 2004; Chiang, 2005; Liu et al., 2006; Mi et al., 2008; Huang et al., 2006; Lin, 2004; Ding and Palmer, 2004; Quirk et al., 2005; Shen et al., 2008; Xie et al., 2011; Meng et al., 2013). Compared with word-based and phrase-based methods, syntax-based models perform better in long distance reordering and enjoy higher generalization capability by leveraging the hierarchical structures in natural languages, and achieve the state-of-the-art performance in these years.

Most syntax-based models (except for Lin (2004)) utilize some kinds of synchronous generation procedures which directly model the structural correspondence between two languages. In contrast, the analysis-transfer-generation methodology in rule-based translation solves the machine translation problem in a more divided scheme, where the processing procedures of analysis, structural transfer and language generation are modeled separately. The analysis-transfer-generation strategy can tolerate higher non-isomorphism between languages if with a more general transformation unit and it can facilitate elaborating engineering of each processing procedure, however, there isn't a statistical transfer model that shows the comparable performance with the current state-of-the-art SMT model so far.

In this paper, we propose a novel statistical analysis-transfer-generation model for machine translation, to integrate the advantages of the transfer-generation scheme and the statistical modeling. The procedures of transfer and generation are modeled on dependency structures with dependency edges as atomic manipulating units. First, the source sentence is parsed by a dependency parser. Then, the source dependency structure is transferred into a target structure by translation rules, which composed of the source and target edges. Last, the target sentence is finally generated from the target edges which are used as intermediate syntactic structures. By directly modeling the edge, the most basic unit in the dependency tree, which definitely describe the modifying relationship and positional relation between words, our model alleviates the non-isomorphic problem and shows the flexibility of reordering.

Proceedings of COLING 2014, the 25th International Conference on Computational Linguistics: Technical Papers, pages 1103–1113, Dublin, Ireland, August 23-29 2014.

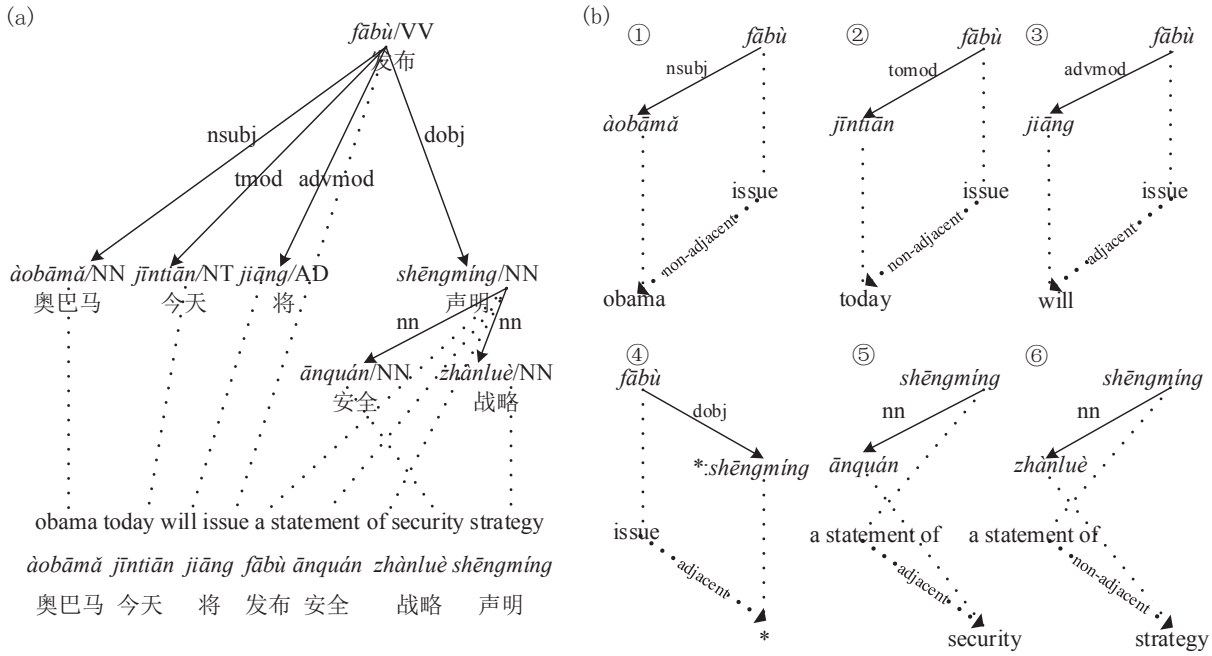

Figure 1: (a)An example of labeled Chinese dependency tree aligned with the corresponding English sentence. (b) Examples of the transfer rules extracted from the tree. "*" denotes a variable. All the inner nodes are treated as variables. The label on the target side of a rule denotes whether the head and the dependent are adjacent or not.

The rest of the paper is organized as follows, we first describe the dependency edge-based transfer model (Section 2). Then, we present our rule acquisition algorithm (Section 3), the decoding and target sentence generation process (Section 4). Finally, large-scale experiments (Section 5) on Chinese-to-English translation show that our edge-based transfer model gains state-of-the-art performance by significantly outperforming the phrase-based model (Koehn et al., 2003) by averaged +1.34 BLEU points on three test sets. To the best of our knowledge, this is the first transfer-generation-based statistical machine translation model that achieves the state-of-the-art performance.

2 Dependency Edge-based Transfer Model

2.1 Edges in Dependency Trees

Given a sentence, its dependency tree is a directed acyclic graph with words in the sentence as nodes. An example dependency tree is shown in Figure 1 (a). An edge in the tree represents a dependency relationship between a pair of words, a head and a dependent. When a nominal dependent acts as a subject and modifies a verbal head, they usually have a fixed relative position. In Figure 1 (a), "*àobāmǎ*" modifies "*fābù*". The grammatical relation label *nsubj* (Chang et al., 2009) between them denotes that a noun phrase acts as the subject of a clause. "*àobāmǎ*" is on the left of "*fābù*".

Based on the above observations, we take the edge as the elementary structure of a dependency tree and regard a dependency tree to be a set of edges.

Definition 1. *An source side* ***edge*** *is a 4-tuple $e = \langle H, D, P, R \rangle$, where H is the head, D is the dependent, P denotes the relative position between H and D, left or right, R is the grammatical relation label*
.

In Figure 1 (b), the upper sides of transfer rules are source side edges extracted from the dependency tree.

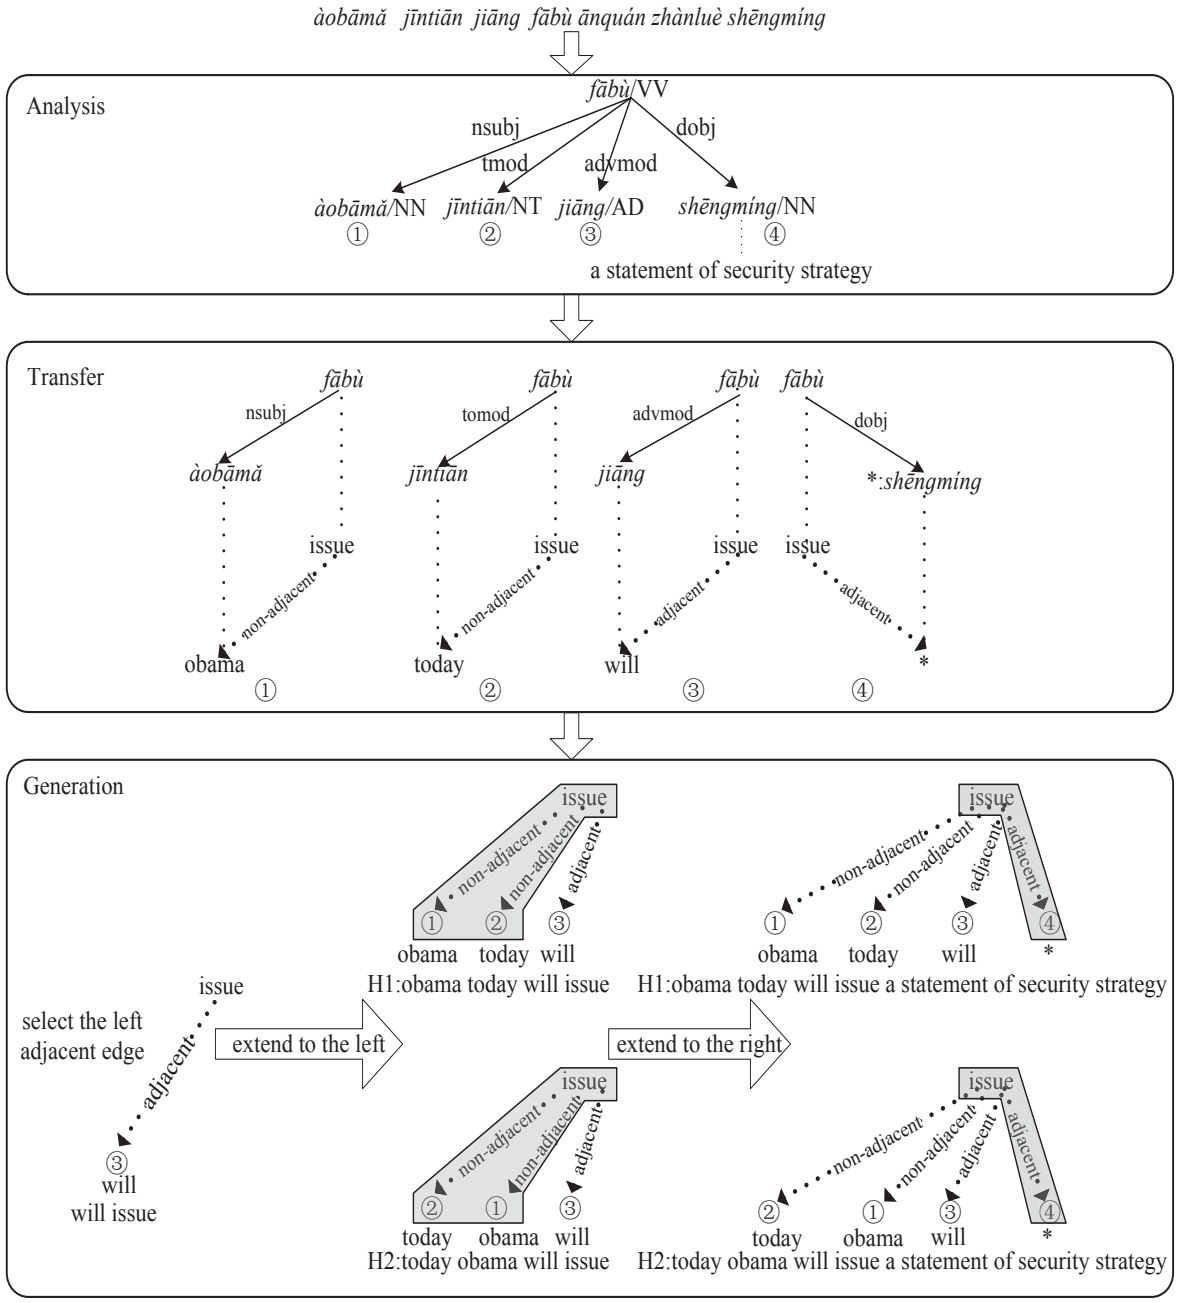

Figure 2: An example partial generation of translation. The same set of rules generate two target hypotheses with the same words and different word order. Assume the sub-tree rooted at "*shēngmíng*" has been translated to the corresponding target sentence fragment.

2.2 Transfer Rules

A transfer rule of our model represents the reordering and relative positions of edges between language pairs. For example, in Figure 1 (b), the first rule shows that when a nominal subject modifies a verb, the target side keeps the same position relations. "obama" is also on the left of "issue", the same with the source side relative position. The 5-th and 6-th rules show the inversion relations between the source and the target. Formally, a transfer rule can be defined as a triple $\langle e, f, \sim \rangle$, where e is an edge extracted from the source dependency tree, f is a target edge. $\sim$ denotes one-to-one correspondence between variables in e and f.

Figure 1 (b) are part of transfer rules extracted from the word aligned sentence in Figure 1 (a). The target edge denotes whether the target dependent is on the left or the right side of the target head, the

label on the edge indicates whether the target head and the target dependent are adjacent or not. If the dependent is an internal node(contrast with the leaf nodes in the dependency tree), then it will be regarded as a substitution node. The dependent in the 4-th transfer rule is an internal node and the its corresponding target side is a substitution variable.

Figure 2 shows a partial transfer-generation of our model which involves three phases. First, *analysis*. Given a source language sentence, we obtain its dependency tree using a dependency parser. We assume that the sub-tree of the substitution node has been translated. Second, *transfer*. For each internal node, we transfer the source side edges between the head and all its dependents into the target sides. In the second block of Figure 2, we transfer four edges into the target sides. Third, *generation*, corresponding to the third block of Figure 2. We generate the target sentence with the target side edges starting from the target head, "issue". We first try to concatenate the edges to the left. First, we select a target side edge that is on the left side of "issue" and adjacent to it to form a consecutive phrase. Edge 3 is selected and "to issue" is generated. Then, we enumerate all possible left concatenations of the other edges that are not adjacent to "issue". The two sequences(1,2,3 and 2,1,3) of the edges are generated, corresponding to the two hypotheses. After that, we extend the two hypotheses to the right. The internal node "*shēngmíng*" is a substitution node, so the candidate translation of the sub-tree rooted at "*shēngmíng*" is concatenated to the two hypotheses. Finally, we generate the two candidate translations of the input sentence.

3 Acquisition of Transfer Rules

Transfer rules can be extracted automatically from a word-aligned corpus, which is a set of triples $\langle T, S, A\rangle$, where T is a source dependency tree, S is a target side sentence and A is an alignment relation between T and S. Following the dependency-to-string model (Xie et al., 2011), we extract transfer rules from each triple $\langle T, S, A\rangle$ by three steps:

1. Tree Annotation: Label each node in the dependency tree with the alignment information
2. Edges Identification: Identify acceptable edges from the annotated dependency tree
3. Rule induction: Induce a set of lexicalized and un-lexicalized transfer rules from the acceptable edges.

3.1 Tree Annotation

Given a triple $\langle T, S, A\rangle$ as Figure 3 shows, we define two attributes for every node in T: node span and sub-tree span:

Definition 2. *Given a node n, its* ***node span*** $nsp(n)$ *is a set of consecutive indexes of the target words aligned with the node n.*

For example, nsp(*ānquán*)={7-8}, which corresponds to the target word "of" and "security".

Definition 3. *A node span $nsp(n)$ is* ***consistent*** *if for any other node n' in the dependency tree, $nsp(n)$ and $nsp(n')$ are not overlapping.*

For example, nsp(*zhànluè*) is consistent, while nsp(*ānquán*) is not consistent for it corresponds to the same word "of" with nsp(*shēngmíng*).

Definition 4. *Given a sub-tree T' rooted at n, the* ***sub-tree span*** $tsp(n)$ *of n is a consecutive target word indexes from the lower bound of the nsp of all the nodes in T' to the upper bound of those spans.*

For example, tsp(*shēngmíng*)={5-9},which corresponds to the target phrase "a statement of security strategy".

Definition 5. *A sub-tree span $tsp(n)$ is* ***consistent*** *if for any other node n' that is not in the sub-tree rooted at n in the dependency tree, $tsp(n)$ and $nsp(n')$ are not overlapping.*

For example, tsp(*shēngmíng*) is consistent, even though nsp(*shēngmíng*) is not consistent, while tsp(*ānquán*) is not consistent for "*shēngmíng*" is not a node in sub-tree rooted at "*ānquán*" and "*ānquán*" corresponds to the same word "*of*" with nsp(*shēngmíng*) .

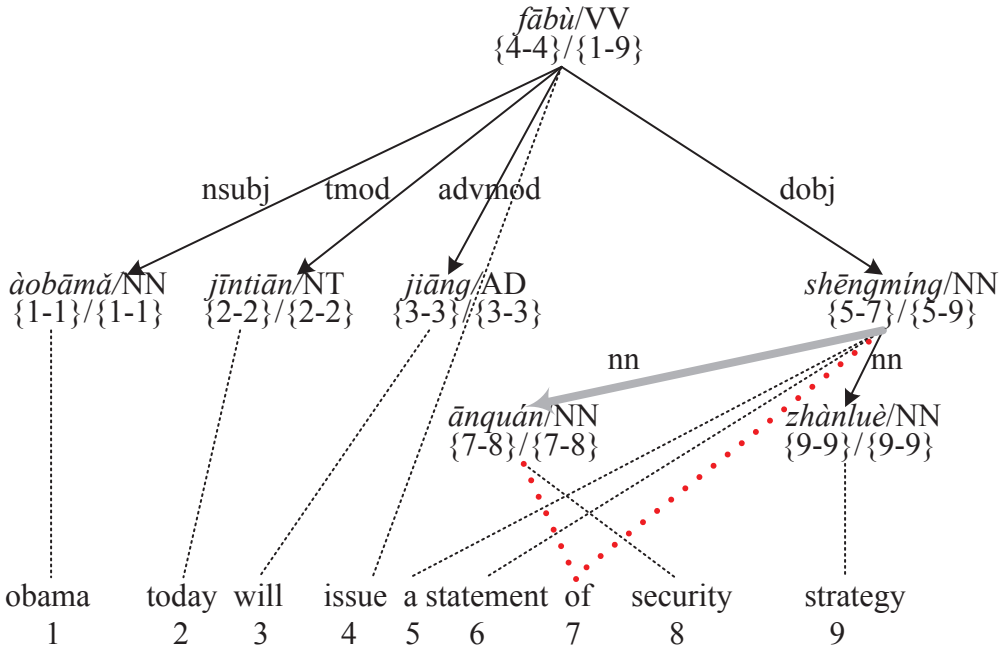

Figure 3: An example of annotated dependency tree. Each node is annotated with two spans, the former is node span and the latter is sub-tree span. The gray edge is not acceptable. It is different from Figure 1, because "ānquán" aligned with two words in Figure 3. "of" in the target side is aligned with both "ānquán" and "shēngmíng" which makes the gray edge un-acceptable.

3.2 Acceptable Edges Identification

We identify the edges from the annotated dependency tree that are **acceptable** for rule induction. For an acceptable edge, its *node span* of the head nsp(head) and the *sub-tree span* of the dependent tsp(dependent) satisfy the following properties:

1. nsp(head) and tsp(dependent) are consistent.
2. nsp(head) and tsp(dependent) are non-overlapping.

For example, tsp(*ānquán*) and nsp(*shēngmíng*) are neither consistent nor non-overlapping. So the gray edge between head "*shēngmíng*" and dependent "*ānquán*" is not an acceptable edge. nsp(*fābù*) and tsp(*shēngmíng*) are consistent and the two spans are non-overlapping. Thus, the edge between head "*fābù*" and dependent "*shēngmíng*" is an acceptable edge.

3.3 Transfer Rule Induction

From each acceptable source side edge, we induce a set of lexicalized and un-lexicalized transfer rules. We induce a lexicalized transfer rule from an acceptable edge by the following procedures:

1. extract the source side edge and mark the internal nodes as substitution sites. This form the input of a transfer rule.

2. extract the position information according to nsp(head) and tsp(dependent), whether they are adjacent or not and whether tsp(dependent) is on the left side or the right side of nsp(head).

In Figure 4, the first transfer rule is lexicalized rule, it is induced from the edge between "*fābù*" and "*àobāmǎ*".

In addition to the lexicalized rules described above, we also generalized the rules by replacing the word in an source side edge with a wild card and the part of speech of the word. For example, the rule in Figure 4 can be generalized in two ways. The generalized versions of the rule apply to "*àobāmǎ*" modifying any verb and "*fābù*" modifying any noun, respectively. The generalized rules are also called

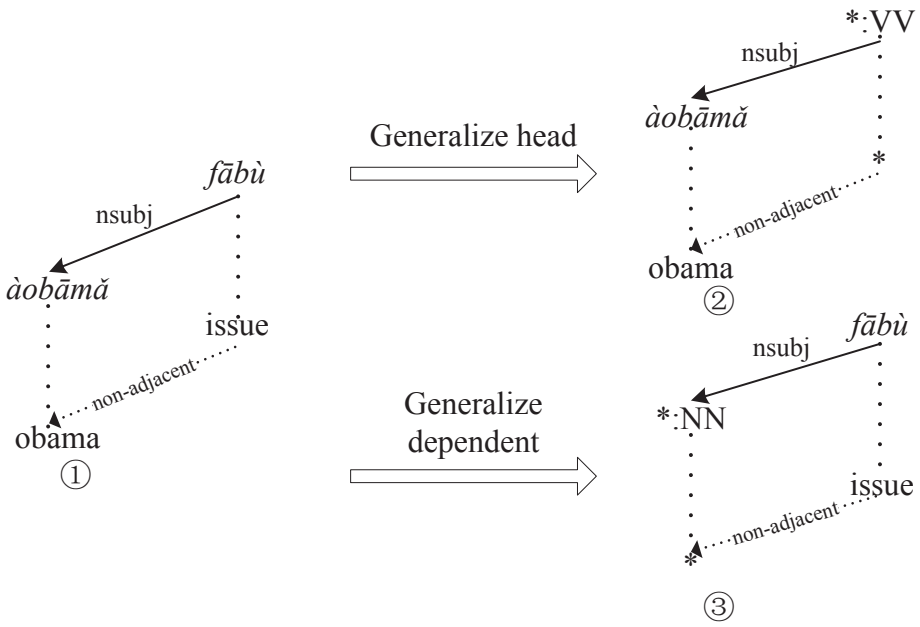

Figure 4: Generalization of transfer rule.

un-lexicalized rules for the loss of word information. The single node translations of the generalized words are also extracted.

The unaligned words of the target side is handled by extending nsp(head) and tsp(dependent) on both left and right directions. We do this process similar with the method of Och and Ney (2004). We might obtain $m(m \geq 1)$ extended rules from an acceptable edge. The frequency of each rule is divided by m. We take the extracted rule set as observed data and make use of relative frequency estimator to obtain the translation probabilities $P(t|s)$ and $P(s|t)$.

4 Decoding and Generation

We follow Och and Ney (2002), using a general log-linear model to score the sentence generated by each concatenation of the target edges. Let c be concatenations that concatenate the target edges to generate the target sentence e. The probability of e is defined as:

$$P(c) \propto \prod_i \phi_i(c)^{\lambda_i} \tag{1}$$

where $\phi_i(c)$ are features defined on concatenations and λ_i are feature weights. In our experiments of this paper, thirteen features are used as follows:

- Transfer rules translation probabilities $P(t|s)$ and $P(s|t)$, and lexical translation probabilities $P_{lex}(t|s)$ and $P_{lex}(s|t)$;
- Bilingual phrases probabilities $P_{bp}(t|s)$ and $P_{bp}(s|t)$, and bilingual phrases lexical translation probabilities $P_{bplex}(t|s)$ and $P_{bplex}(s|t)$;
- Transfer rule penalty $exp(-1)$;
- Bilingual phrase penalty $exp(-1)$;
- Pseudo translation rule penalty $exp(-1)$;
- Target word penalty $exp(|e|)$;
- Language model $P_{lm}(e)$.

Our decoder is based on a bottom-up chart-based beam-search algorithm. We regard the decoding process as the composition of the target side edges. For a given source language sentence, we obtain its

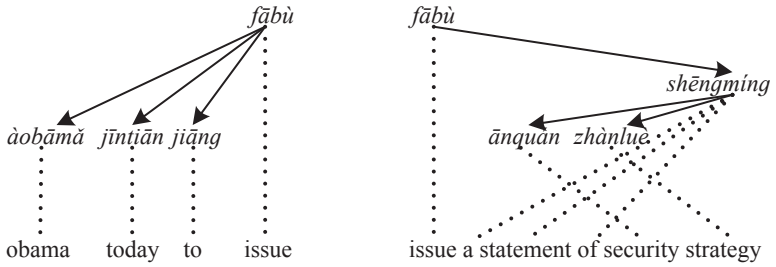

Figure 5: Two examples of the phrases incorporated in our model.

dependency tree T with an external dependency parser. Each node in T is traversed in post-order. For each internal node and root node n, we do the transfer-generation translation as the following procedures:

1. Extract all the source side edges including the lexicalized and generalized edges between n and all its dependents using the same way we extract the source side edges of the transfer rules.
2. *Transfer* the source side edges into target side edges. For a generalized rule, we restore it to a lexicalized rule by combining it with the single word translation. For no matched edges, we construct the pseudo translation rule according to the word order of the source head-dependent relation.
3. *Generate* the target sentence by bi-directional extension from an adjacent target edge. We first group all the target edges by their heads. For each group, we generate translation hypotheses with the following procedures:

   (a) Select an adjacent target edge as the starting position;

   (b) Extend to the left side and enumerate all possible permutations of the target edges directing left;

   (c) Extend to the right side and enumerate all possible permutations of the target edges directing right.

   Considering that in dependency trees, a head may relate to more than 4 edges which results in massive search space. We reduce the time complexity by using the maximum distortion limit. The distortion is defined as $(a_i - b_{i-1} - 1)$, where a_i denotes the start position of the source side edge that is translated into the ith target side edge and b_{i-1} denotes the end position of the source side edge translated into the $(i-1)$th target side edge.

When we reach the root node, the candidate translations of the input sentence are generated.

In our model, only the adjacent target edge of a transfer rule can be regarded as a consecutive phrase and its corresponding source side length is only 2. As we start extending the target sentence from the target head, it is quite natural to incorporate the bilingual phrases to make the target sentences be extended from the phrases as well as the single target head word. Due to the flexibility of our model, we can incorporate not only the syntactic phrases which are phrases covering a whole sub-tree, but also the non-syntactic phrases as the fixed dependency structures in Shen et al. (2008) which are consecutive phrases covering the head. Figure 5 shows two examples of the phrases incorporated in our model.

We prune the search space in several ways. First, beam threshold β, items with a score worse than β times of the best score in the same span will be discarded; second, beam size b, items with a score worse than the bth best item will be discarded. For our experiments, we set $\beta = 10^{-3}$ and $b = 300$; Third, we also prune rules for the same edge with a fixed rule limit ($r = 200$), which denotes the maximum number of rules we keep.

5 Experiments

In this section, the performance of our model is evaluated by comparing with phrase-based model (Koehn et al., 2003), on the NIST Chinese-to-English translation tasks. We also present the influence of the

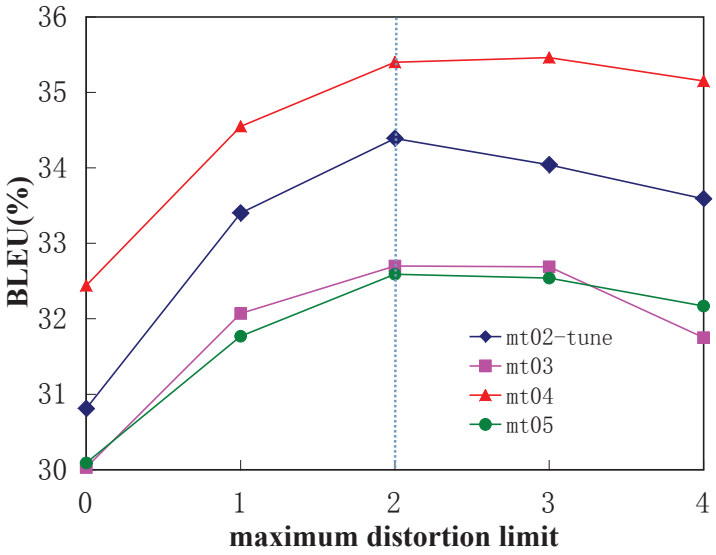

Figure 6: Effect of different maximum distortion limits on development set (mt02) and three tests(mt03,04,05). The performance of all the sets are consistent.

maximum distortion limit to our model. We take open source phrase-based system *Moses* (with default configuration)[1] as our baseline system.

5.1 Experimental Setting

Our training corpus consists of 1.25M sentence pairs from LDC data, including LDC2002E18, LDC2003E07, LDC2003E14, Hansards portion of LDC2004T07, LDC2004T08 and LDC2005T06.

To obtain the dependency trees of the source side, we parse the source sentences with Stanford Parser (Klein and Manning, 2003) into projective dependency structures with nodes annotated by POS tags and edges by dependency labels.

To obtain the word alignments, we run GIZA++ (Och and Ney, 2003) on the corpus in both directions and apply "grow-diag-and" refinement (Koehn et al., 2003). We extract the phrases covering no more than 10 nodes of the fixed structures.

We use SRILM (Stolcke, 2002) to train a 4-gram language model with modified Kneser-Ney smoothing on the Xinhua portion of the Gigaword corpus.

We use NIST MT Evaluation test set 2002 as our development set, 2003-2005 NIST datasets as testsets. The quality of translations is evaluated by the case insensitive NIST BLEU-4 metric[2].

We make use of the minimum error rate training algorithm (Och, 2003) in order to maximize the BLEU score of the development set.

The statistical significance test is performed by *sign-test* (Collins et al., 2005).

5.2 Influence of Maximum Distortion Limit

Figure 6 gives the performance of our system with different maximum distortion limits in terms of uncased BLEU of three NIST test sets. The performance of different distortion limit are consistent on both development set and three test sets. Maximum distortion limit 2 gets the best performances. A low distortion limit may cause the target sentence been translated more close to the sequence of the source, especially when the distortion limit equals to 0, none of the reordering is allowed, while a high distortion limit may lead the good translations be flooded by too many ambiguities when enumerating the possible sequences of the target non-adjacent dependents. We choose 2 as the maximum distortion limit in the next experiments.

System	Rule #	MT03	MT04	MT05	Average
Moses	44.49M	32.03	32.83	31.81	32.22
DEBT	30.7M	**32.7***	**35.4***	**32.59***	**33.56**

Table 1: Statistics of the extracted rules on training data and the BLEU scores (%) on the test sets. "DEBT" denotes our edge-based transfer model. The "*" denotes that the results are significantly better than the baseline system ($p<0.01$).

5.3 Performance of Our Model

Tabel 1 illustrates the translation results of our experiments. We (*DEBT*) surpass the baseline over +1.34 BLEU points on average. Our model significant outperforms the baseline phrase-based model, with $p < 0.01$ on statistical significance test *sign-test* (Collins et al., 2005).

We also list the statistical number of rules extracted from the training corpus. The number of our transfer rules is only 69.0% of the rules extracted by *Moses*, thus, the total rules in our model is 31% smaller than *Moses*.

6 Related Work

Transfer-based MT systems usually take a parse tree in the source language and translate it into a parse tree in the target language with transfer rules. Both our model and some of those previous works acquired transfer rules automatically from word-aligned corpus (Richardson et al., 2001; Carbonell et al., 2002; Lavoie et al., 2002; Lin, 2004). Gimpel and Smith (2009) and Gimpel and Smith (2014) used quasi-synchronous dependency grammar for MT and they are similar to our idea of doing transfer of dependency syntax in a non-synchronous setting. They do the translation as monolingual lattice parsing.

As dependency-based system, Lin (2004) used path as the transfer unit and regarded the translation problem with minimal path covering. Quirk et al. (2005) and Xiong et al. (2007) used treelets to model the source dependency tree using synchronous grammars. Quirk et al. (2005) projected the source dependency structure into target side by word alignment and faced the problem of non-isomorphism between languages. Xiong et al. (2007) directly modeled the treelet to the corresponding target string to alleviate the problem. Xie et al. (2011) directly specified the ordering information in head-dependents rules that represent the source side as head-dependents relations and the target side as string.

Differently, our model uses a much simpler elementary structure, edge, which consist of only a head and a dependent. As a transfer-generation model, we transfer an edge in the source dependency tree into target side and incorporate the position information on the target edge , which alleviate non-isomorphism problem and incorporate ordering among different target edges simultaneously. Moreover, our decoding method is quite different from previous dependency tree-based works. After parsing a given source language sentence, we transfer and generate the target sentence fragments recursively on each internal node of the dependency tree bottom-up.

7 Conclusions and Future Work

In this paper, we present a novel dependency edge-based transfer model using dependency trees on the source side for machine translation. We directly *transfer* the edges in source dependency tree into the target sides and then *generate* the target sentences by beam-search. With the concise transfer rules, our model is compatible with both the syntactic and non-syntactic phrases. Although the generation process of our model seems relatively simple, it still exhibits a good performance and outperforms the phrase-based model on large scale experiments. For the first time, a statistical transfer model shows a comparable performance with the state-of-the-art translation models.

Since the translation procedure is divided into three phases and each phase can be modeled independently, we would like to take further steps focusing on modeling the target language generation process specifically to ensure a better grammatical translation with the help of natural language generation methods.

Fast Domain Adaptation of SMT models without in-Domain Parallel Data

Abstract

We address a challenging problem frequently faced by MT service providers: creating a domain-specific system based on a purely source-monolingual sample of text from the domain. We solve this problem by introducing methods for domain adaptation requiring no in-domain parallel data. Our approach yields results comparable to state-of-the-art systems optimized on an in-domain parallel set with a drop of as little as 0.5 BLEU points across 4 domains.

1 Introduction

We consider the problem of creating the best possible statistical machine translation (SMT) system for a specific domain when no parallel sample or training data from such domain is available. We assume that we have access to a collection of phrase tables (PT) and other models independently created from now **unavailable** corpora, and we receive a monolingual source language sample from a text source we would like to optimize for.

For a MT provider to deliver a SMT system tailored to a customer's domain, a sample dataset is requested. In most cases, the customer is able to provide an in-domain mono-lingual sample from his operations. However, it is generally not feasible for the customer to provide the translations as well because the customer has to hire professional translators to do that. In such a scenario, the translations has to be generated by MT service provider itself by hiring human translators thus requiring an investment upfront. The methods proposed in this paper aim to avoid that by building a good quality pilot SMT system leveraging only sample mono-lingual source corpus, and previously trained library of models. This in turn postpones the task of generating in-domain parallel data to a later date when there is a commitment by the customer.

Unavailability of the raw parallel data could derive from a trading model where data owners share intermediate-level resources like PTs, Reordering Models (RM) and Language Models (LM), but can not, or do not want to, share the textual data such resources were derived from. This particular scenario has been explained in (Cancedda, 2012).

This scenario is similar to the multi-model framework studied in (Sennrich et al., 2013), with the additional challenge that no parallel development set is available. We build on the linear mixture model combination of the cited work, extending it to our more challenging environment:

1. We propose a new measure derived from the popular BLEU score (Papineni et al., 2002) to assess the fitness of a PT to cope with a given monolingual sample S. This measure is computed from n-gram statistics that can be easily extracted from a PT.

2. We propose a new method for tuning the parameters of a log linear model that does not require an in-domain parallel development set, and yet achieves results very close to traditional tuning on parallel in-domain data.

We present our proposed metric *BLEU-PT* and computation of multi-model in Section 2. The parameter estimation of log-linear parameters of the SMT system is described in Section 3. We present experiments and results in Sections 4 and 6 respectively.

*Major part of the work was performed when the authors were in Xerox Research Center Europe.

Proceedings of COLING 2014, the 25th International Conference on Computational Linguistics: Technical Papers, pages 1114–1123, Dublin, Ireland, August 23-29 2014.

2 Building Multi-Model

Given a library of phrase tables, the goal of this step is to generate a domain adapted multi-model. The challenging aspect in our scenario is the lack of in-domain parallel data, as well as absence of original parallel corpora corresponding to the library of models. This rules out the possibility of using metrics such as cross-entropy (Sennrich, 2012b) or LM-perplexity for computing the mixing coefficients. We present our proposed metric in section 2.1, and interpolation of the phrase tables in section 2.2.

2.1 BLEU-PT

Given a source corpus s, and a set of phrase tables $\{pt_1, pt_2,\ldots,pt_n\}$, the goal is to measure the similarity of each of these tables with s. For measuring the similarity, we use BLEU-PT which is an adaptation of the popular BLEU score for measuring the similarity between a corpus and a phrase table. The metric BLEU-PT is measured as described in Equation 1.

$$\text{BLEU-PT}(PT, S) = \left(\prod_{n=1}^{4} \frac{match(n|pt, s)}{total(n|s)} \right)^{1/4} \tag{1}$$

where $match(n|pt, s)$ is the count of n-grams of order n in the source corpus s that exist in the source side of the phrase table pt. $total(n|s)$ is the number of n-grams of order n in the source corpus.

2.2 Interpolating Models

A state-of-the-art approach for building multi-models is through linear interpolation of component models, exemplified in Equation 2 for the case of the forward conditional phrase translation model.

$$h_{phr}(s, t) = log \sum_{j=1}^{N} \phi_j P_{phr,j}(t|s) \tag{2}$$

Various approaches have been suggested for computing the coefficients ϕ of the interpolated model, the most recent being perplexity minimization described in (Sennrich, 2012b), where each translation model feature is optimized separately on the parallel development set. Our work is set in a scenario where no parallel development set is available for optimizing the interpolation coefficients. We have also observed that perplexity minimization is computationally intensive, requires aligned parallel development set, and the optimization time increases rapidly with increasing number of component models (for details, see Section 4.2).

We propose a simple approach for computation of the mixing coefficients that relies on the similarity of each model with respect to the test set. The mixing coefficients are obtained by normalizing similarity values. The similarity between a model (phrase table) and a corpus is computed using the BLEU-PT metric proposed in the previous section. Another similarity metric that can be used is *LM Perplexity*. However, in the current scenario we do not have resources (training data) to build a source side LM for computing the perplexity.

We empirically compare our method for computing mixing coefficients with the the perplexity minimization method. We also experiment with applying the mixing coefficients obtained by using our method for mixing features of a reordering and language model.

3 Parameter Estimation

The overall quality of translation is strongly impacted by how optimized the weights of the log-linear combination of various translation features are for a domain of interest. MERT (Och, 2003) and MIRA (Watanabe et al., 2007) are popular solution to compute an optimal weight vector by minimizing the error on a held-out parallel development set. BLEU and its approximations are commonly used error metrics. In this paper we assume lack of a parallel development set, therefore the above methods cannot be used.

Pecina et. al. (2012) showed that the optimized log-linear weight vector [1] of a SMT system does not depend as much on the actual domain of the development set (on which the system was optimized), as

[1] Not to be confused with the mixing coefficients in a linear combination of model components.

on how "distant" the relevant domain is from the domain of the training corpus used to build the SMT models. This is an important finding. It means that the weight vector can be modeled as a function of the **distance/similarity** between the in-domain development set and the model built from the training set. In this work, we learn this function from examples of previous parameter optimizations, using our BLEU-PT as a similarity metric. Once we have retrieved the most relevant PTs (translation and reordering models) from our library, and we have linearly interpolated them using normalized BLEU-PT, we use the learned model to estimate the optimal value of the log-linear weights, instead of optimizing them.

In order to learn this mapping, we create a dataset of examples (pairs of the form <BLEU-PT, log-linear weight vector>, where weight vectors are normalized to ensure comparability across models) by performing repeated optimizations for out-domain models on a number of parallel development sets (see section 4 for more details of this data) using a traditional optimization method (MIRA in this work). Based on this dataset, the function of our interest can therefore be learnt using a supervised approach. We explore two parametric methods and a non-parametric method. We present these in Section 3.1, and 3.2 respectively. For a mono-lingual source in a new domain, the BLEU-PT can be computed, and then mapped to the appropriate weight vector using the methods presented below.

3.1 Parametric Methods

We considered two distinct parametric methods for estimating the mapping from model/corpus similarity into weight vectors. The first one makes the assumption that parameters can be estimated independently of one another, given the similarity, whereas the second tries to leverage known covariance between distinct parameters in the vector.

3.1.1 Linear Regression

Motivated by initial experiments highlighting strong correlation between BLEU-PT and optimal feature weights (see Section 5.1 below), we assumed here a simple linear relation of the form:

$$\lambda_i^* = W_i \mathrm{X} + b_i \tag{3}$$

where λ_i^* is the optimal log-linear weight for feature i, X is the feature vector (BLEU-PT vector), W_i and b_i are coefficients to be estimated. While a drastic assumption, this has the advantage of limiting the risk of overfitting in a situation like ours where there is only relatively few datapoints to learn from. We estimate a_i and b_i by simple least squares regression. Once these are available for all features, we can predict the log linear weights of any model given its BLEU-PT similarity to a monolingual source sample using Eq. 3.

3.1.2 Multi-Task learning

Optimal log-linear parameters might not be fully independent given BLEU-PT, especially since it is known that model features can be highly correlated. To account for correlation between parameter weights, we explore the use of multi-task lasso[2] (Caruana, 1997) where several functions corresponding to each parameter are learned jointly considering the correlation between their values observed in the training data. Multi-task lasso consists of a least square loss model trained along with a regularizer and the objective is to minimize the following:

$$\arg\min_{w} \frac{1}{2N} ||\mathrm{X} \cdot W - \lambda||_2^2 + \alpha ||W||_{21} \quad where; \quad ||W||_{21} = \sum_{j}^{M} \sqrt{\sum_{i} w_{ij}^2} \tag{4}$$

Here, N is the number of training samples, X is the feature vector(BLEU-PT score vector) λ is the label vector(log linear weights). $||W||_{21}$ is the l_{21} regularizer (Yang et al., 2011). The problem of prediction of log linear weights is reduced to prediction of i interlinked tasks where each task has M features[3]. Coefficients are calculated using coordinate descent algorithm in Multi-Task lasso. Once the coefficients are calculated we use Eq. 3 to predict the log linear weights.

[2] `http://scikit-learn.org/`

[3] In our case we only have 1 feature i.e. BLEU-PT score.

3.2 Non Parametric: Nearest Neighbor

Finally, instead of building a parametric predictor for log linear weights, we experimented with a simple nearest-neighbor approach:

$$\lambda_i^* = \lambda_i(M_{j^*}) \tag{5}$$

where M_j ranges over the linearly interpolated phrase tables, and $\lambda_i(M)$ returns the stored optimal value for the i^{th} log-linear weight, and:

$$j^* = \arg\min_j \min_{s'}(|\text{BLEU-PT}(M, s) - \text{BLEU-PT}'(M_j, s')|) \tag{6}$$

where s is the monolingual sample on which we want to calculate the BLEU-PT and s' ranges over the source sides of our available parallel development sets. In other words, a BLEU-PT of a model is calculated on the source sample to be translated and the log-linear weight is chosen which corresponds to BLEU-PT′, where BLEU-PT′ is a training data point closest to BLEU-PT. This approach is close to the cross-domain tuning of Pecina et. al. (2012).

4 Experimental Program

We conducted a number of experiments for English-French language pair, comparing the methods proposed in the previous sections among one another and against state-of-the-art baselines and oracles.

4.1 Datasets

In this section, we present the datasets (EN-FR) that we have used for our experiments and the training data that was created for the purpose of supervised learning. We collected a set of 12 publicly available corpora and 1 proprietary corpus, statistics of datasets are provided in Table 1.

Corpus	Train	Development	Test
Commoncrawl	78M	12.4K	12.6K
ECB	4.7M	13.9K	14K
EMEA	13.8M	14K	15.7K
EUconst	133K	8K	8.4K
Europarl	52.8M	13.5K	13.5K
P1	5M	35K	14.5K
KDE4	1.5M	12.8K	5.8K
News Comm.	4M	12.7K	65K
OpenOffice	400K	5.4K	5.6K
OpenSubs	156M	16K	15.7K
PHP	314K	3.5K	4K
TED	2.65M	21K	14.6K
UN	1.92M	21K	21K

Table 1: Statistics of parallel sets (# of source tokens)

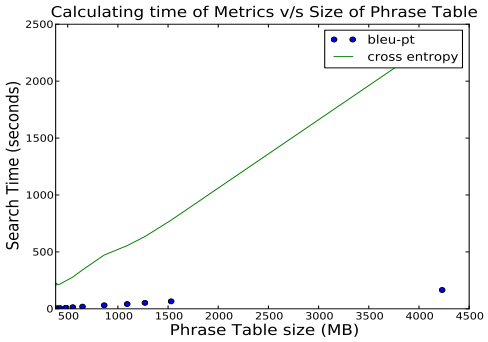

Figure 1: BLEU-PT v/s Cross-Entropy

Commoncrawl (CC) (Smith et al., 2013) and News Commentary (Bojar et al., 2013) corpora were provided in the 2013 shared translation task organized with workshop on machine translation. TED talks data was released as a part of IWSLT evaluation task (Cettolo et al., 2012). ECB, EMEA, EUconst, OpenOffice, OpenSubs 2011, PHP and UN corpora are provided as a part of OPUS parallel corpora (Tiedemann, 2012). The parallel corpora from OPUS were randomly split into training, development and testsets. Commoncrawl, News Commentary and TED datasets were used as they were provided in the evaluation task.

Out of 13 different domain datasets we selected 4 datasets randomly: Commoncrawl, KDE4, TED and UN (in bold in Table 1), to test our methods.

4.2 BLEU-PT v/s Cross-Entropy

We compared the overheads of calculating BLEU-PT and Cross-Entropy[4]. We are interested in estimating whether with increasing number of phrase tables the computation of both measures becomes slow or memory intensive.

[4]We used tmcombine.py script that comes along with the moses package to calculate the mixing coefficients.

Another advantage of using BLEU-PT apart from fast retrieval is that we can index the phrase tables using wFSA based indexing (explanation of indexing the phrase tables is not in the scope of this paper) and store the FSTs in binarised format on disk. When a source sample comes, we just load the indexed binaries and calculate the BLEU-PT while this cannot be achieved when we want to calculate cross entropy because we have to do one pass over all the phrase tables in question.

Experimental results depicted in Figure 1 shows that computation of BLEU-PT is fast (160 seconds) while computation of cross-entropy is slow (42 minutes) when we combine 12 phrase tables with total size of 4.2GB.

4.3 Training data for supervised learning and testing

As mentioned earlier, for estimating the parameters we require a training data containing the tuples of <BLEU-PT, log-linear-weight>. We perform parameter estimation on four of our datasets: Commoncrawl, KDE4, TED and UN. So, for obtaining evaluation results on say, UN, the rest of the resources are used for generating the training data. Our experimental setup can be explained well using the Venn diagram shown in Figure 2.

We set one of four domains as the test domain (in this case, UN) whose parallel set is not available to us and call it setup-UN. The training data tuples obtained from the rest of the 12 datasets are used to estimate parameters for the UN domain. From these 12 datasets we perform a round-robin experiment where one by one each dataset is considered as in-domain and the rest as out-domain. In-domain dataset provides the development set and the rest 11 out-domain models are linearly combined to build translation models. In figure 2, for example, the development set from the TED domain is taken as the development set of the multi-model build using the rest (i.e. excluding TED and UN). This multi-model is built by a weighted linear combination of the out-domain models (11 models). The parameters of this multi-model are tuned on the in-domain development set using MIRA. Simultaneously, we also calculate the BLEU-PT of the linear interpolated model on the source side of the in-domain development set (i.e. TED). This provides us the tuples of BLEU-PT and the log linear weights, which is our training data. So, four sets of experiments are conducted (one each for four datasets considered for testing), and for each set of experiments, there are 12 training data points. The final evaluation is done by measuring the BLEU score obtained on each test set using the predicted parameter estimates.

Reiterating, our optimizing method is fast, and hence, we are not not looking to learn the parameters apriori for all the domains based on a source side of the development set. The goal is to do a fast adaptation by predicting the parameters using statistical models for every new test in a particular domain even in the absence of a parallel development set.

4.4 Prediction

For prediction of parameters for a new domain, the BLEU-PT of the sample source corpus (UN in our example) is measured with the multi-model built on all the models (all the rest of 12 datasets including the TED model) and then the supervised predictor is applied. In our experiments, we test both parametric and non-parametric methods to estimate the parameters based on the training data obtained using the 12 domains.

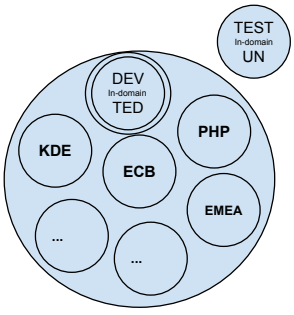

Figure 2: Cross domain tuning setup

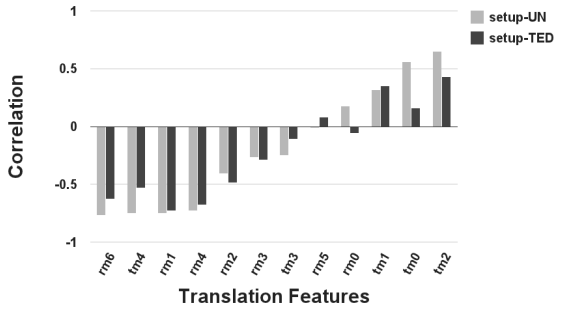

Figure 3: Correlation of log linear weights with BLEU-PT when indomain sets set to UN and TED

	Domain			Linear Interpolation

Table 2: System Description: Each system's training domain and development set domain along with the optimizer/predictor is mentioned. *def-bleupt-all* uses default weights from Moses decoder. Near.Neigh. shows that we used Nearest Neighbor predictor for optimizing weights. ✗ represent log linear interpolation of models while ✓ represents linear interpolation. The mixing coefficients for linear interpolation are calculated by normalizing bleu-pt scores unless mentioned otherwise.

5 Experiments and Results

5.1 Correlation analysis

Before embarking in the actual regression task, we examined the correlation between the similarity values (BLEU-PT) and the various weights in the training data. If there is good correlation between BLEU-PT and a particular parameter, then the linear regressor is expected to fit well and then predict an accurate parameter value for a new domain. For computing the correlation, we use Pearson correlation coefficient (PCC). Figure 3 shows the PCC between the feature weights and the BLEU-PT scores. The tm's are the translation model features, and rm's are the reordering model features.

We see that there is either a strong positive correlation or a strong negative correlation for most features in both the experimental setups shown in the figure 3. This validates our hypothesis that optimal parameters for a new test domain can indeed be estimated with good reliability. One can also observe that the correlation level also varies based on the mixture of training models. For example, the correlation is much higher in the training data that excluded UN (setup-UN) than the one that excluded TED (setup-TED).

In figure 3, one can also see that $tm0$ (forward phrase conditional probability) and $tm2$ (backward phrase conditional probability) which are shown in previous work to be the two most important features amongst all SMT features (Lopez and Resnik, 2006) in terms of their impact on translation quality, have a high correlation in setup-UN.

5.2 Systems

All SMT systems were built using the Moses toolkit (Koehn et al., 2007). To automatically align the parallel corpora we used MGIZA (Gao and Vogel, 2008). Aligned training data in each domain was then used to create the corresponding component translation models and lexical reordering models. We created 5-gram language models for every domain using SRILM (Stolcke, 2002) with improved Kneser-Ney smoothing (Chen and Goodman, 1999) on the target side of the training parallel corpora. Log linear weights for the systems were optimized using MIRA (Watanabe et al., 2007; Hasler et al., 2011) which is provided in the Moses toolkit. Performance of the systems are measured in terms of BLEU computed using the MultEval script (mteval-v13.pl).

We built one *in-dom-train* system where only in-domain training data is taken into account. This system shows the importance of in-domain training data in SMT (Haddow and Koehn, 2012). Three oracle systems are trained on out-domain training corpus and tuned on in-domain development data (in this case there are four domains we chose to test on: UN, TED, CommonCrawl and KDE4), thus 4 systems for each of the in-domain test sets.

We build another set of SMT systems in which language models are combined by linear interpolation[5].

[5]Linear interpolation of 12 LMs result in one single large LM, thus, one weight. So, a total of 14 weights have to be optimized or predicted

The systems using linear interpolated LM (mixing coefficients are normalized BLEU-PT scores) are *def-bleupt-all*, *mira-bleupt-all*, *gen-reg-bleupt-all*, *gen-mtl-bleupt-all* and *gen-nn-bleupt-all*. We compare *mira-bleupt-all* with *mira-bleupt-tm-rm-perp-lm* where mixing coefficients for LM interpolation are calculated by standard LM perplexity minimization method over target side of development set.

As mentioned earlier, ideally only a subset of all the models closer to the source sample should be taken into account for **quick** adaptation, so we select the top five domains related to the source sample and interpolate the respective models and address them as *top5-** systems. Adding more domains would unnecesary increase the size of the model and add more noise. Table 2 shows the configuration of different systems. In the next section we compare the performances of these systems and report the findings.

6 Results and Discussion

Table 3 presents results of the systems that use an in-domain parallel data. As expected, when an in-domain corpus is used both for training as well as for optimizing the log-linear parameters, the peformance is much higher than those systems that do not use in-domain parallel corpus for training (Koehn and Schroeder, 2007). We also observe that the use of normalized BLEU-PT for computing mixing coefficients gives comparable performance to using Cross-Entropy. The primary advantage in using BLEU-PT is that it can be compute much faster than Cross-Entropy (as shown in Figure 1). Evidently, normalized BLEU-PT scores as mixing coefficients performs at par with mixing coefficients retrieved by standard perplexity minimization method (Bertoldi and Federico, 2009). One can also use BLEU-PT for LM interpolation in cases where target side in-domain text is not available.

System	UN	TED	CC	KDE
in-dom-train	67.87	29.98	26.62	35.82
mira-bleupt-tm-rm	**44.14**	31.20	17.43	24.25
mira-perp-tm-bleupt-rm	43.56	31.36	17.54	**24.72**
mira-bleupt-tm-rm-perp-lm	43.96	31.85	**18.45**	23.39
mira-bleupt-all	43.66	**32.04**	18.44	23.09

Table 3: Comparison of In-Domain system versus the established Oracles in different setups.

System	UN	TED	CC	KDE
gen-reg-bleupt-all	43.27	32.18	17.95	21.05
gen-mtl-bleupt-all	43.35	32.61	18.26	20.67
gen-nn-bleupt-all	42.73	31.04	18.24	21.85

Table 4: Performance of generic systems (gen-*) in all setups.

Table 4 illustrates the impact of phrase table retrieval on the performance of multi-model. All the systems presented in this table use BLEU-PT for computing mixing coefficients, while the weights are computed using the three techniques that we explored in this paper. We see that in case of regression, the phrase table retrieval also results in a better MT performance. In the other two cases, the results are comparable. It shows that retrieval helps in building smaller sized multi-models while being more accurate on an average. Phrase table retrieval, thus, becomes particularly useful when a multi-model needs to be built from a library of dozens of pre-trained phrase tables of various domains.

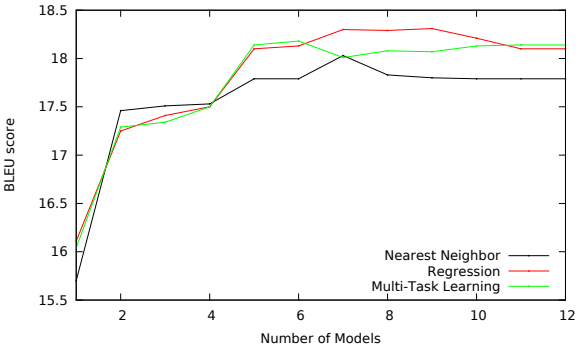

Figure 4: BLEU scores when top k models were used to evaluate commoncrawl test set where $k \in 1..12$.

System	UN	TED	CC	KDE
def-bleupt-all	42.03	30.82	17.97	19.66
mira-bleupt-all	43.66	32.04	18.44	23.09
top5-reg-bleupt-all	43.39$^{\blacktriangle}$	32.31$^{\blacktriangle}$	18.10	21.54$^{\blacktriangle}$
top5-mtl-bleupt-all	43.56$^{\blacktriangle}$	32.60$^{\blacktriangle}$	18.14	20.91$^{\blacktriangle}$
top5-nn-bleupt-all	42.96$^{\blacktriangle}$	30.89$^{\triangle}$	17.79	22.24$^{\blacktriangle}$

Table 5: Comparing the baseline system (def-bleupt-all) and Oracle (mira-bleupt-all) with domain specific multi-model systems trained on top5 domains. $^{\blacktriangle}$and $^{\triangle}$denotes significantly better results in comparison with def-bleupt-all system with p-value < 0.0001 and < 0.05 respectively.

Table 5 compares our approach of computing log-linear weights (in the absence of in-domain development set) to the state-of-art weight optimization technique MIRA (which requires an in-domain development set). As a baseline, we set default weights to all the parameters, which was shown to a strong

baseline in (Pecina et al., 2012). We see that the methods proposed by us perform significantly better than the default weights baseline (improvement of more than 1.5 BLEU score on an average across 4 domains). Among the three approaches for computing weights, the method that uses multi-task lasso performs best (except in setup-KDE where the non-parametric method performs best), along the expected lines as multi-task lasso considers the correlation between various features. In comparison to MIRA, our methods result in an average drop of as little as 0.5 BLEU points across 4 domains (see Table 5).

Figure 4 shows BLEU score curve when we vary the k in top-k systems. BLEU score curve is almost tangential zero when k is between 5 and 6 which essentially means that selection of $k = 5$ is a good choice. For CommonCrawl test set, the top five domains used were Europarl, OpenSubs, NewsCommentary, TED and ECB. This is a significant result which indicates that one can build a good system for a domain even in the absence of the parallel data in the domain of interest.

7 Related Work

Domain adaptation in statistical machine translation has been widely studied and leveraged through adding more training data (Koehn and Knight, 2001), filtering of out of domain training data (Axelrod et al., 2011; Koehn and Haddow, 2012), fillup technique (Bisazza et al., 2011), language model adaptation by perplexity minimization over in-domain data (Bertoldi and Federico, 2009) and various other approaches. However, all the above adaptation approaches require either parallel in-domain corpus or monolingual in-domain target side corpus, thus, not applicable in our scenario.

In this paper we studied mixture modelling of heterogeneous translation models which was first proposed in Foster et. al. (2007). They showed various ways of computing mixing coefficients for linear interpolation using several distance based metrics borrowed from information theory. However, to calculate any such metrics it was required that one has an access to the source/target training corpus and source/target development corpus. Other noteable works in mixture modelling in SMT are (Civera and Juan, 2007; Razmara et al., 2012; Duan et al., 2010).

More recently, Sennrich (2012b) designed an approach to calculate mixing coefficients by minimizing the perplexity of translation models over an **aligned** development set for mixture modelling via linear interpolation or by weighting the corpora. Sennrich et. al. (2012a) clustered of a large heterogeneous development corpus and tuned a translation system on different clusters. In the decoding phase each sentence was assigned to a cluster and the translation system tuned on that cluster was used to translate that sentence.

(Banerjee et al., 2010) build several domain specific translation systems, and trained a classifier to assign each incoming sentence to a domain and use the domain specific system to translate the corresponding sentence. They assume that each sentence in test set belongs to one of the already existing domains which means it would fail in the case where the sentence doesn't belong to any of the existing domains. In our case we do not make any such assumptions.

Academically, above approaches are well suited for solving the problem of domain adaptation, but during the deployment of SMT systems in industrial scenario where the client is unable to deliver the parallel in-domain data these approaches fail to provide a quick solution.

8 Conclusion

We present an approach to multi-model domain adaptation in a particularly challenging setting where there is no parallel in-domain data. Parameter estimation without in-domain development set is a problem that, to the best of our knowledge, has not been addressed before. We designed a method for tuning model parameters without parallel development set and validated it through an experimental program for which we compared performances against an array of Oracles and Baselines. The effectiveness of the proposed method empirically supports the findings of (Pecina et al., 2012), who discovered that the log linear weights largely depend on the **distance** of training domain from the domain on which the models are being optimized on. As a side result, we designed in the process a novel similarity metric between a phrase table and a source sample and implemented it effectively using wFSAs. We empirically showed the excellent computation speed of BLEU-PT scores as compared to standard Cross-Entropy measure using standard toolkits.

Abstract

In this paper, we propose a new method for effective error analysis of machine translation (MT) systems. In previous work on error analysis of MT, error trends are often shown by frequency. However, if we attempt to perform a more detailed analysis based on frequently erroneous word strings, the word strings also often occur in correct translations, and analyzing these correct sentences decreases the overall efficiency of error analysis. In this paper, we propose the use of regularized discriminative language models (LMs) to allow for more focused MT error analysis. In experiments, we demonstrate that our method is more efficient than frequency-based analysis, and examine differences across systems, language pairs, and evaluation measures. [1]

1 Introduction

Accuracy of Statistical Machine Translation (SMT) systems is continually increasing, but systems are now more complex than ever before. As a result, not all effects of making modifications to a system are known without actually making the modification and generating translations. Therefore, in the process of developing an SMT system, it is common to evaluate actual translations to identify problems to make improvements. This process is time consuming, as it is often necessary to analyze a large number of translations to get an overall grasp of the system's error trends. In addition, many sentences will contain no errors, or only errors from the long tail that are not representative of the system as a whole. On the other hand, if we are able to detect and rank important errors automatically, we will likely be able to find representative errors of the SMT system more efficiently.

Previous work has proposed methods for automatic error analysis of MT systems based on automatically separating errors into classes and sorting these classes by frequency (Vilar et al., 2006; Popovic and Ney, 2011). These classes cover common mistakes of MT systems, e.g. conjugation, reordering, word deletion, and insertion. This makes it possible to view overall error trends, but when the goal of analysis is to identify errors to make some concrete improvement to the system, it is often necessary to perform a more focused analysis, looking at actual errors made by a particular language pair or system. We show examples of errors types that are informative, but are language- or task-specific, and not covered by previous methods in Figure 1. In this example, the type given by more standard error typologies is indicated by "Traditional type," but we would prefer a more detailed analysis such as "Fine-grained type," would allows us to take specific steps to fix the machine translation system (such as ensuring that Wikipedia titles are not punctuated, or normalizing full-width characters to half-width). These fine-grained types are difficult to conceive without actually observing the MT system output, but if we are able to group actual errors into fine-grained classes based on, for example, lexical clues, this sort of analysis will become possible and more efficient.

Previous research on improving the efficiency of error analysis has generally focused on grouping error types by frequency, but try to apply such frequency-based techniques to individual errors, selected errors

Table 1: Frequently occurring erroneous n-grams

are often dominated by frequently occurring linguistic phenomena that are not necessarily indicative of translation errors. To show examples of this problem, in Table 1 we provide a list of erroneous n-grams that were produced by an MT system (described in Section 4.1) but not contained in the respective references. From this table, we can see that frequently occurring erroneous n-grams are simply n-grams that frequently occur in English, and because of this we cannot discover characteristic errors of the system for improvement just from this information.

In this paper, we propose a new method that uses regularized discriminative LMs to solve the above problem. Discriminative LMs are LMs trained to fix common output errors of a particular system. From the viewpoint of error analysis, if we train a discriminative LM using n-gram features and examine the weights learned by this model, n-grams with large negative or positive weights will be indicative of patterns that are over- or under-produced by the MT system. Because the weights are specifically trained to fix errors, it is likely that these patterns will be more informative than mistakes that are simply frequently occurring. We can also use a number of features of discriminative LMs to perform a more focused and efficient analysis. For example, if we perform training with L1 regularization, many features will be removed and only important patterns will remain in the model. Additionally, we can focus on specific varieties of errors by changing the evaluation measure used for training the LMs.

In our experiments, we validate the effectiveness of error analysis based on discriminative LMs. We perform a manual evaluation of the n-gram patterns discovered by random selection, by frequency-based analysis, and by the proposed method. As a result, the proposed method is more effective at identifying errors than other methods.

2 Discriminative Language Models

In this section, we first introduce the discriminative LM used in our method. As a target for our analysis, we have input sentences $\mathcal{F} = \{F_1, \ldots, F_K\}$, n-best outputs $\hat{\mathcal{E}} = \{\hat{\boldsymbol{E}}_1, \ldots, \hat{\boldsymbol{E}}_K\}$ of an MT system, and reference translations $\mathcal{R} = \{R_1, \ldots, R_K\}$. Discriminative LMs define feature vectors $\boldsymbol{\phi}(E_i)$ for each candidate in $\hat{\boldsymbol{E}}_k = \{E_1, E_2, \ldots, E_I\}$, and calculate inner products $\boldsymbol{w} \cdot \boldsymbol{\phi}(E_i)$ as scores.

To train the weight vector $\boldsymbol{w}$, we first calculate evaluation scores of all candidates using a sentence-level evaluation measure EV such as BLEU+1 (Lin and Och, 2004) given the reference sentence R_k.

We choose the sentence with the highest evaluation EV as an oracle E_k^*. Oracles are chosen for each n-best, and we train $\boldsymbol{w}$ so that the oracle's score becomes higher than the other candidates.

2.1 Structured Perceptron

While there are a number of methods for training discriminative LMs, we follow Roark et al. (2007) in using the structured perceptron as a simple and effective method for LM training. The structured perceptron is a widely used on-line learning method that examines one training instance and updates the weight vector using the difference between feature vectors generated from the oracle E^* and the hypothesis $\hat{E}$ calculated by the current model. For each iteration, $\boldsymbol{w}$ is updated using the difference between E^* and $\hat{E}$. If $\hat{E}$ is equal to E^*, the difference becomes $\mathbf{0}$, so no update is performed. This process is run for all $\mathcal{F}$ sequentially, and iterated until weights converge or we reach a fixed iteration limit N. We show the above procedure in Algorithm 1.

Algorithm 1 Structured perceptron training of the discriminative LM

for $n = 1$ **to** N **do**
  for all $\hat{\boldsymbol{E}} \in \hat{\mathcal{E}}$ **do**
    $E^* \leftarrow \arg\max_{E \in \hat{\boldsymbol{E}}} EV(E)$
    $\hat{E} \leftarrow \arg\max_{E \in \hat{\boldsymbol{E}}} \boldsymbol{w} \cdot \boldsymbol{\phi}(E)$
    $\boldsymbol{w} \leftarrow \boldsymbol{w} + \boldsymbol{\phi}(E^*) - \boldsymbol{\phi}(\hat{E})$
  end for
end for

2.2 Learning Sparse Discriminative LMs

While the structured perceptron is a simple and effective method for learning discriminative LMs, it also has no bias towards reducing the number of features used in the model. However, if we add a bias towards learning smaller models, we can keep only salient features (Tsuruoka et al., 2009).

In our work, we use L1 regularization to add this bias. L1 regularization gives a penalty to $\boldsymbol{w}$ proportional to the L1 norm $\|\boldsymbol{w}\|_1 = \sum_i |w_i|$, pushing a large number of elements in $\boldsymbol{w}$ to 0, so ineffective features are removed from the model.

To train L1 regularized discriminative LMs, we use the forward-backward splitting (FOBOS) algorithm proposed by Duchi and Singer (2009). FOBOS splits update and regularization, and lazily calculates the regularization upon using the weight to improve efficiency.

2.3 Features of Discriminative LMs

In the LM, we used the following three features:

1. System score feature ϕ_s: As our goal is fixing the output of the system, we add this feature to allow a default ordering of n-bests by score.
2. n-gram feature ϕ_n: We add a binary feature counting the frequency of each n-gram in the hypothesis. The weights of these features will be the main target of our analysis.
3. Hypothesis length feature ϕ_l: If the evaluation measure has a penalty for the number of words, this allows us to adjust it.

In this work, we do not use other features, but our method theoretically allows for addition of other features such as POS tags or syntactic information, which could also potentially be used as a target for analysis.

3 Discriminative LMs for Error Analysis

In this section, we describe how to incorporate information from discriminative LMs into manual error analysis.

Figure 2: Example of the evaluation sheet. Boxed words are chosen n-grams.

3.1 Focused Error Analysis of MT output

We first define the following general framework for focused analysis of errors in MT output. Using this, we can find error trends of chosen n-grams:

1. Automatically choose potentially erroneous n-grams in the MT output.
2. Select one or more 1-best translations that contain each chosen n-gram.
3. Show selected translations to an annotator with the selected n-gram highlighted.
4. The annotator looks at the indicated n-gram, and marks whether or not by examining the n-gram whether they were able to identify an error in the MT output. If the answer is “yes,” the annotator additionally indicates which variety of error was found according to Table 2.

A part of the actual evaluation sheet is shown in Fig. 2. The first four rows are the input, and the final row is the annotator’s evaluation.

3.2 Selection of Target n-grams

We can think of the following three methods for choosing potentially erroneous n-grams:

Random: n-grams that are selected randomly. This corresponds to the standard method of error analysis, where sentences are randomly sampled and analyzed.

	Sent	Words	
		English	Japanese
Train	330k	5.91M	6.09M
Dev	1166	24.3k	26.8k
Test	1160	26.7k	28.5k

Table 3: Data size of KFTT

Frequency: n-grams that are most frequently over-generated (occur in the hypothesis, but not in the references). This corresponds to a focused version of the frequency-based automatic error analysis methods of Vilar et al. (2006) and Popovic and Ney (2011).

LM: n-grams that have the lowest weight according to the discriminative LM. This is our proposed method.

In particular, for discriminative LMs, n-gram features that have large positive or negative weights indicate n-grams that are under-generated or over-generated by the system. Therefore, by examining high-weighted or low-weighted n-grams, it is likely that we will be able to get a grasp of the system mistakes. When performing actual evaluation, we want to analyze n-grams with 1-best translations. Almost high-weighted n-grams are only contained in oracle translations, and not contained in 1-best translation. Therefore, we use low-weighted n-grams for evaluation. If the discriminative LM is properly trained, low-weighted n-grams will often correspond to actual errors.

3.3 System Comparison

When developing MT systems, it is common to not only evaluate a single system, but also compare multiple systems, such as when comparing a new system with baselines.

To do this in the current work, we create discriminative LMs from n-bests generated by multiple translation systems, and choose representative n-grams using the proposed method. Then we examine the selected n-grams in context and then compare the result of this analysis.

4 Experiments

We evaluate the effectiveness of our method by performing a manual evaluation over three translation systems, two translation directions, and two evaluation measures.

4.1 Experiment Setup

For each MT system, we use Japanese-English data from the KFTT (Neubig, 2011) as a corpus. The size of the corpus is shown in Table 3. In our experiment, we use a forest-to-string (F2S) system trained using the Travatar toolkit (Neubig, 2013) for single system evaluation. For system comparison, we compare the above F2S system with a phrase based (PBMT) system and a hierarchical phrase based (HIERO) system built using Moses (Koehn et al., 2007).

The F2S system is built using Nile[2] for making word alignments, and syntax trees generated with Egret[3]. PBMT and HIERO are built using GIZA++ (Och and Ney, 2003) for word alignments. Each system is optimized using MERT (Och, 2003) with BLEU (Papineni et al., 2002) as an evaluation measure. For single system evaluation, we also use the reordering-oriented evaluation metric RIBES (Isozaki et al., 2010) as additional metric for training the discriminative LM.

For training discriminative LMs, our method uses the structured perceptron with 100 iterations and FOBOS for L1 regularization as described in Section 2.2. The regularization factor is chosen from the range 10^{-6}-10^{-2} to give the highest performance on the KFTT test data.

LMs are trained using 500-bests from each MT system and features described in Section 2.3. We use 1-grams to 3-grams as n-gram features.

Random	0.46	0.37
Frequency	0.30	0.31
LM	0.55	0.48

Table 5: Precision of top 30 n-grams that select errors in both directions

We show translation accuracies of each system before and after training in Table 4. From this table, we can see that the LM increases the accuracy of all dev data, but it does not necessarily have a large effect for the test data. The main reason for this is because the development set used to train the LM is relatively small, at only 1166 sentences. However, as our goal in this paper is to perform error analysis on set of data which we already have parallel references (in this case, the development set), the generalization ability of the model is not necessarily fundamental to our task at hand. We directly identify the ability to identify errors in the next section.

4.2 Evaluation of Error Identification Ability

This section evaluates the ability of our method to identify errors in MT output. As we are proposing our method as a tool for manual analysis of MT output, it is necessary to perform manual evaluation to ensure that our method is identifying locations that are actually erroneous according to human subjective evaluation. To measure the accuracy of each method, we perform an evaluation as described in Section 3.1 and use the precision of selected n-grams (the percentage of selected n-grams for which then annotator indicated that an error actually existed) as our evaluation measure. The annotator is an MT specialist who is proficient in English and Japanese. The order of the evaluation sentences is shuffled so the annotator can not determine which method was responsible for choosing each n-gram.

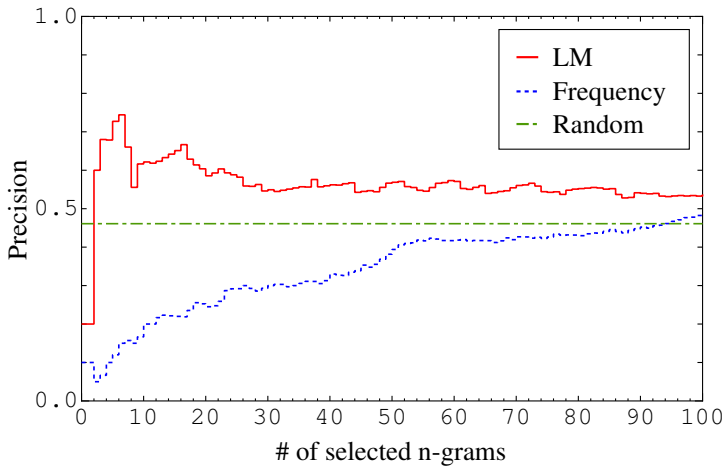

Figure 3: Precision of n-grams that select errors (Japanese to English)

We show the precision results for each number of selected n-grams over three methods for Japanese-English translation in Fig. 3, and the precision of the top 30 n-grams in both directions in Table 5. From

Table 6: Top 5 erroneous n-grams learned by the discriminative LM and examples. Boxes on MT indicates the selected n-gram, and boxes in Src and Ref indicate the corresponding words.

these results, we can see that each method is able to detect erroneous n-grams, but the proposed method achieves a precision that outperforms other methods.

To demonstrate why this is the case, in Table 6 we show examples, in context, of potentially erroneous n-grams chosen by our proposed method. Compared to the baseline n-grams in Table 1, we can see that these n-grams are not limited to frequently occurring n-grams in English, and are more likely to have a high probability of indicating actual errors.

In addition, to give a better idea of the prominence of the selected n-grams, in Table 7, we show the mean number of locations of the KFTT test data that contain the top 100 n-grams selected by each method. We can see that randomly selected n-grams are rarely contained in the separate test set, while the proposed method tends to select n-grams that are more frequent than random, and thus have a better chance of generalizing.

4.3 Effect of Evaluation Measure Choice

We can also hypothesize that by varying the evaluation measure used in training the LM, we can select different varieties of errors for analysis. To test this, we compare analysis results obtained using one

Method	Ja → En	En → Ja
Random	1.1	1.5
Frequency	381.0	432.6
LM	6.2	14.0

Table 7: Mean number of occurrences of selected n-grams in the test set

	(Context independent)	**0.15**	0
Insertion		0.17	**0.25**
Deletion		**0.18**	0.10
Reordering		0.14	**0.27**
Conjugation		0	**0.08**
Polarity		0	0
Unknown words		0	0

Table 8: Error statistics found when optimizing different metrics. Bold indicates the higher score.

LM optimized with BLEU and another with RIBES, which is a reordering-oriented evaluation metric. We show a breakdown of the identified errors in Table 8. From this table, we can see that the BLEU-optimized LM is able to detect more deletion errors than the RIBES-optimized LM. This is a natural result, as the BLEU metric puts a heavier weight on the brevity penalty assigned to shorter translations. On the other hand, the RIBES-optimized LM detects more reordering errors than the BLEU-optimized LM. The RIBES metric is sensitive to reordering errors, and thus reordering errors will cause larger decreases in RIBES. From this experiment, we can see that it is possible to focus on different error types by using different metrics in the optimization of the LM.

4.4 Result of System Comparison

Finally, we examine whether discriminative LMs allow us to grasp characteristic errors for system comparison. Similarly with single system analysis, we generated the top 30 potentially erroneous n-grams for PBMT, HIERO, and F2S in two directions, and evaluated them manually. The result is listed in Table 9. From this table, we can see that PBMT and HIERO count reordering errors as one of the three most frequent types, while F2S does not, especially for English to Japanese. This is consistent with common knowledge that syntactic information can be used to improve reordering accuracy. We can also see insertion is a problem when translating into English, and conjugation is a problem when translating into morphologically-rich Japanese. While these are only general trends, they largely match with intuition, even after analysis of only the top 30 n-grams.

5 Conclusion

In this paper, we proposed a new method for efficiently analyzing the output of MT systems using L1 regularized discriminative LMs, and evaluate its effectiveness. As a result, weights trained by discriminative LMs are more effective at identifying errors than n-grams chosen either randomly or by error frequency. This indicates that our method allows an MT system engineer to inspect fewer sentences in the course of identifying characteristic errors of the MT system.

The overall framework of using discriminative LMs in error analysis opens up a number of directions for future work, and there are a number of additional points we plan to analyze in the future. For example, while it is clear that the proposed method allows errors to be identified more efficiently, it is still necessary to quantify the overall benefit of having an MT expert use the result of this error analysis to improve

Abstract

Tree-to-string systems have gained significant popularity thanks to their simplicity and efficiency by exploring the source syntax information, but they lack in the target syntax to guarantee the grammaticality of the output. Instead of using complex tree-to-tree models, we integrate a structured language model, a left-to-right shift-reduce parser in specific, into an incremental tree-to-string model, and introduce an efficient grouping and pruning mechanism for this integration. Large-scale experiments on various Chinese-English test sets show that with a reasonable speed our method gains an average improvement of 0.7 points in terms of (T -B)/2 than a state-of-the-art tree-to-string system.

1 Introduction

Tree-to-string models (Liu et al., 2006; Huang et al., 2006) have made promising progress and gained significant popularity in recent years, as they run faster than string-to-tree counterparts (e.g. (Galley et al., 2006)), and do not need binarized grammars. Especially, Huang and Mi (2010) make it much faster by proposing an incremental tree-to-string model, which generates the target translation exactly in a left-to-right manner. Although, tree-to-string models have made those progresses, they can not utilize the target syntax information to guarantee the grammaticality of the output, as they only generate strings on the target side.

One direct approach to handle this problem is to extend tree-to-string models into complex tree-to-tree models (e.g. (Quirk et al., 2005; Liu et al., 2009; Mi and Liu, 2010)). However, tree-to-tree approaches still significantly under-perform than tree-to-string systems due to the poor rule coverage (Liu et al., 2009) and bi-parsing failures (Liu et al., 2009; Mi and Liu, 2010).

Another potential solution is to use structured language models (S) (Chelba and Jelinek, 2000; Charniak et al., 2003; Post and Gildea, 2008; Post and Gildea, 2009), as the monolingual S has achieved better perplexity than the traditional *n*-gram word sequence model. More importantly, the S is independent of any translation model. Thus, integrating a S into a tree-to-string model will not face the problems that tree-to-tree models have. However, integration is not easy, as the following two questions arise. First, the search space grows significantly, as a partial translation has a lot of syntax structures. Second, hypotheses in the same bin may not be comparable, since their syntactic structures may not be comparable, and the future costs are hard to estimate. Hassan et al. (2009) skip those problems by only keeping the best parsing structure for each hypothesis.

In this paper, we integrate a shift-reduce parser into an incremental tree-to-string model, and introduce an efficient grouping and pruning method to handle the growing search space and incomparable hypotheses problems. Large-scale experiments on various Chinese-English test sets show that with a rea-

Proceedings of COLING 2014, the 25th International Conference on Computational Linguistics: Technical Papers, pages 1133–1143, Dublin, Ireland, August 23-29 2014.

sonable speed our method gains an average improvement of 0.7 points in terms of (T -B)/2 than a state-of-the-art tree-to-string system.

2 Linear-time Shift-reduce Parsing

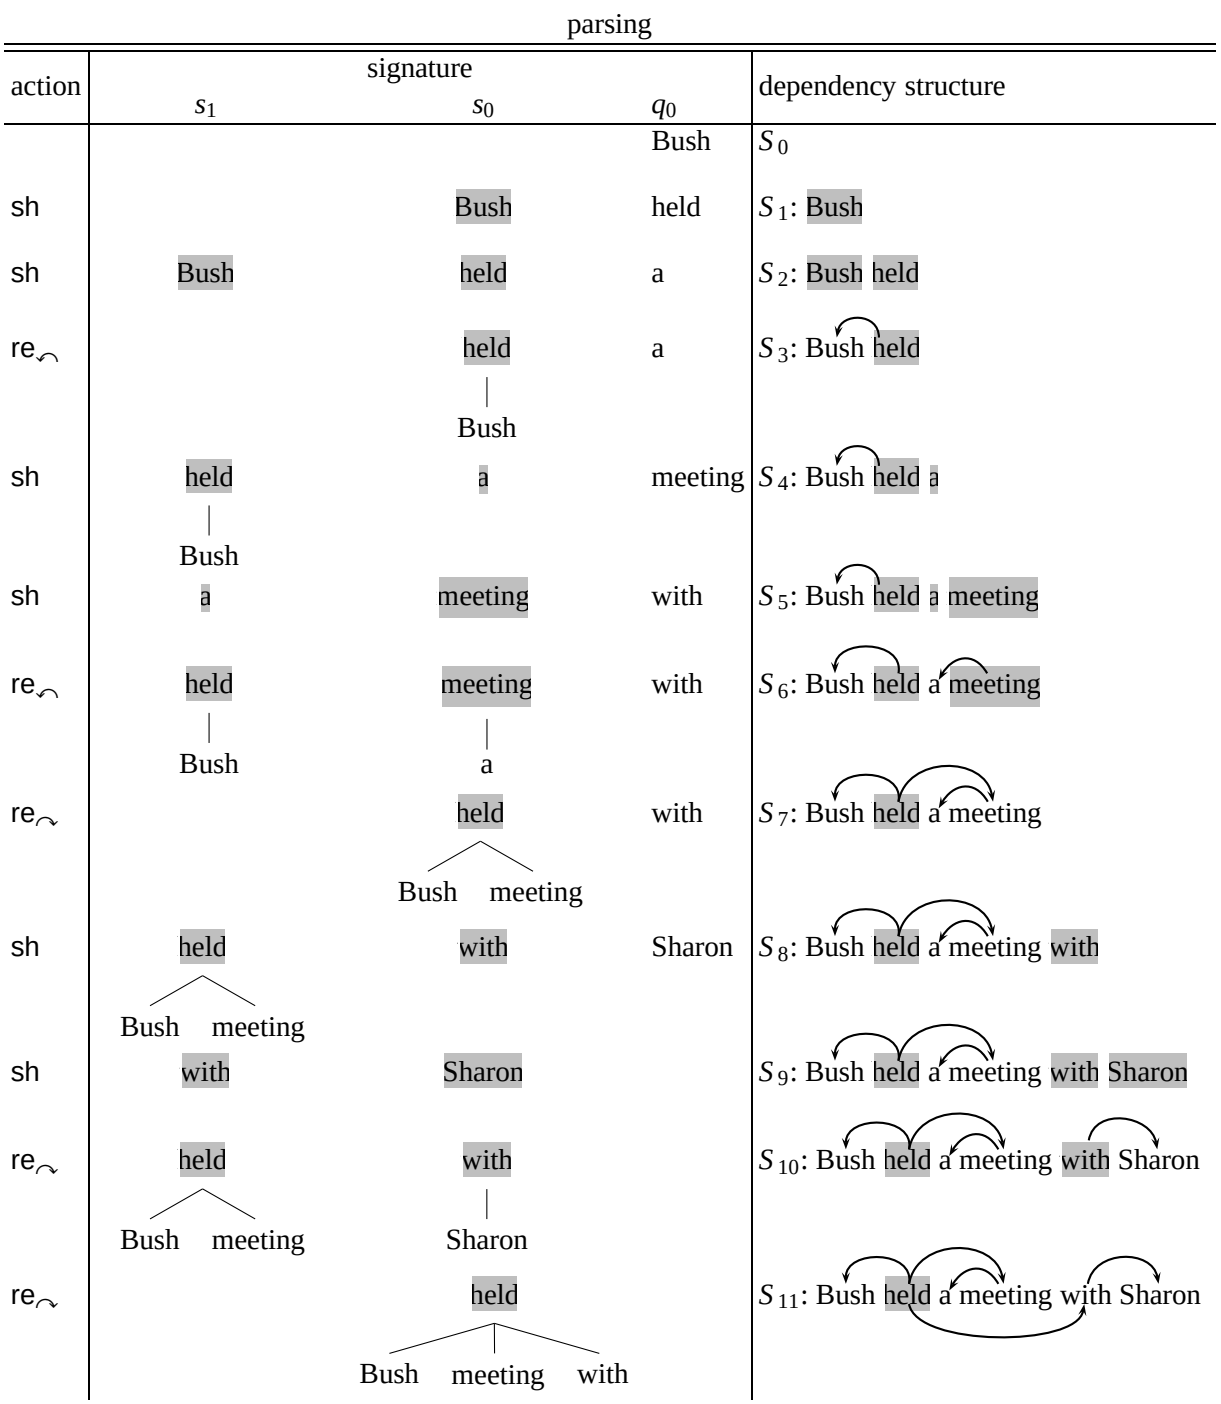

Figure 1: Linear-time left-to-right dependency parsing.

A shift-reduce parser performs a left-to-right scan of the input sentence, and at each *parsing step*, chooses one of two *parsing actions*: either **shift** (sh) the current word onto the stack, or **reduce** (re) the top two (or more) items at the end of the stack (Aho and Ullman, 1972). In the dependency parsing scenario, the reduce action is further divided into two cases: **left-reduce** (re$_\curvearrowleft$) and **right-reduce** (re$_\curvearrowright$), depending on which one of the two items becomes the head after reduction. Each parsing derivation can be represented by a sequence of parsing actions.

2.1 Shift-reduce Dependency Parsing

We will use the following sentence as the running example:

Bush held a meeting with Sharon

Given an input sentence **e**, where e_i is the ith token, $e_i...e_j$ is the substring of **e** from i to j, a shift-reduce parser searches for a dependency tree with a sequence of shift-reduce moves (see Figure 1). Starting from an initial structure S_0, we first shift (sh) a word e_1, "Bush", onto the parsing stack s_0, and form a structure S_1 with a singleton tree. Then e_2, "held", is shifted, and there are two or more structures in the parsing stack, we can use $\mathsf{re}_{\curvearrowleft}$ or $\mathsf{re}_{\curvearrowright}$ step to combine the top two trees on the stack, replace them with dependency structure $e_1 \curvearrowleft e_0$ or $e_1 \curvearrowright e_0$ (shown as S_3), and add one more dependency edge between e_0 and e_1.

Note that the shade nodes are exposed heads on which $\mathsf{re}_{\curvearrowleft}$ or $\mathsf{re}_{\curvearrowright}$ parsing actions can be performed. The middle columns in Figure 1 are the parsing signatures: q_0 (parsing queue), s_0 and s_1 (parsing stack), where s_0 and s_1 only have one level dependency. Take the line of S_{11} for example, "a" is not in the signature. As each action results in an update of cost, we can pick the best one (or few, with beam) after each action. Costs are accumulated in each step by extracting contextual features from the structure and the action. As the sentence gets longer, the number of partial structures generated at each steps grows exponentially, which makes it impossible to search all of the hypothesis. In practice, we usually use beam search instead.

Table 1: (a) atomic features, used for parsing signatures. (b): parsing feature templates, adapted from Huang and Sagae (2010). x.w and x.t denotes the root word and POS tag of the partial dependency tree, x.lc and x.rc denote x's leftmost and rightmost child respectively. (c) the feature window.

2.2 Features

We view features as "abstractions" or (partial) observations of the current structure. Feature templates f are functions that draw information from the feature window, consisting of current partial tree and first word to be processed. All Feature functions are listed in Table 1(b), which is a conjunction of atomic

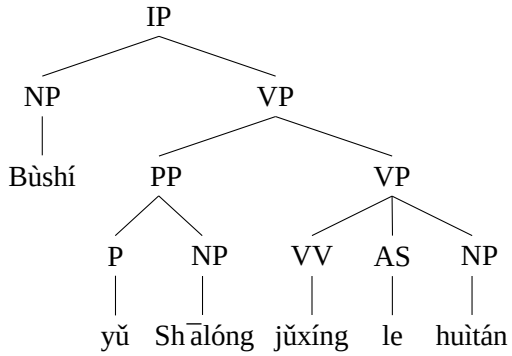

Figure 2: A parse tree

features in Table 1(a). To decide which action is the best of the current structure, we perform a three-way classification based on *f*, and conjoin these feature instances with each action:

$$[f \circ (\text{action=sh/re}_{\curvearrowright}/\text{re}_{\curvearrowleft})]$$

We extract all the feature templates from training data, and use the average perceptron algorithm and early-update strategy (Collins and Roark, 2004; Huang et al., 2012) to train the model.

3 Incremental Tree-to-string Translation with S

The incremental tree-to-string decoding (Huang and Mi, 2010) performs translation in two separate steps: parsing and decoding. A parser first parses the source language input into a 1-best tree in Figure 2, and the linear incremental decoder then searches for the best derivation that generates a target-language string in strictly left-to-right manner. Figure 3 works out the full running example, and we describe it in the following section.

3.1 Decoding with S

Since the incremental tree-to-string model generates translation in strictly left-to-right fashion, and the shift-reduce dependency parser also processes an input sentence in left-to-right order, it is intuitive to combine them together. The last two columns in Figure 3 show the dependency structures for the corresponding hypotheses. Start at the root *translation stack* with a dot **.** before the root node IP:

$$[\mathbf{.}\ \text{IP}\ ],$$

we first **predict** (pr) with rule r_1,

$$(r_1) \qquad \text{IP}\ (x_1\text{:NP}\ x_2\text{:VP}) \rightarrow\ x_1\ x_2,$$

and push its English-side to the translation stack, with variables replaced by matched tree nodes, here x_1 for NP and x_2 for VP. Since this *translation action* does not generate any translation string, we don't perform any dependency parsing actions. So we have the following translation stack

$$[\mathbf{.}\ \text{IP}\ ][\mathbf{.}\ \text{NP VP}],$$

where the dot **.** indicates the next symbol to process in the English word-order. Since node NP is the next symbol, we then predict with rule r_2,

$$(r_2) \qquad \text{NP(Bùshí)} \rightarrow \text{Bush},$$

and add it to the translation stack:

$$[\mathbf{.}\ \text{IP}\ ]\ [\mathbf{.}\ \text{NP VP}\ ]\ [\mathbf{.}\ \text{Bush}]$$

Since the symbol right after the dot in the top rule is a word, we **scan** (sc) it, and append it to the current translation, which results in the new translation stack

$$[\mathbf{.}\ \text{IP}\ ]\ [\mathbf{.}\ \text{NP VP}\ ]\ [\text{Bush}\ \mathbf{.}\ ]$$

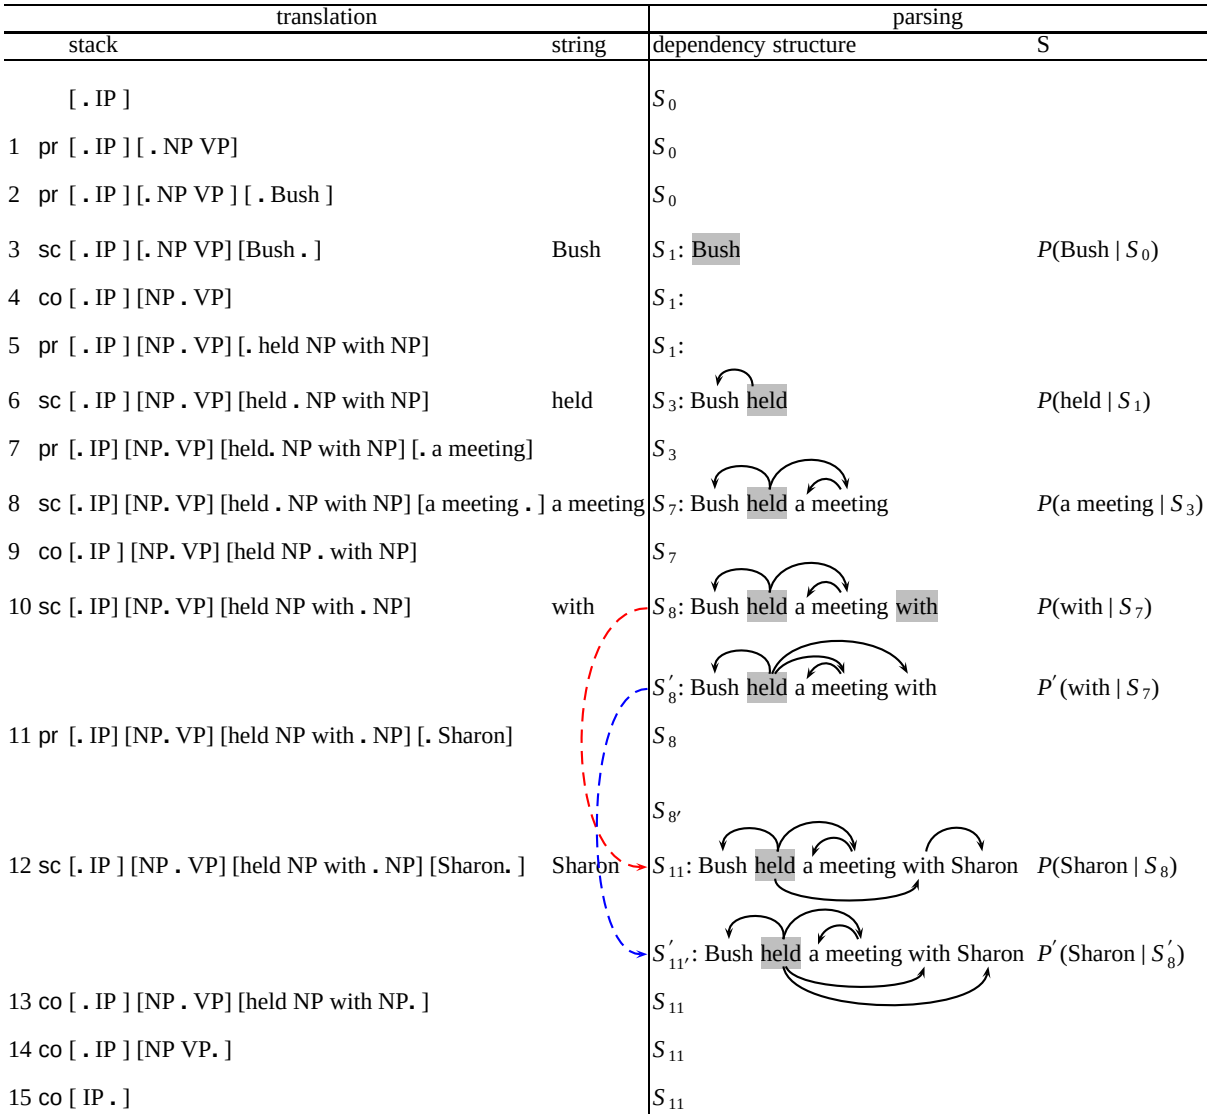

Figure 3: Simulation of the integraton of an S into an incremental tree-to-string decoding. The first column is the line number. The second column shows the translation actions: predict (pr), scan (sc), and complete (co). S_i denotes a dependency parsing structure. The shaded nodes are exposed roots of S_i.

Immediately after each sc translation action, our shift-reduce parser is triggered. Here, our parser applies the parsing action sh, and shift "Bush" into a partial dependency structure S_1 as a root "Bush" (shaded node) in Figure 3. Now the top rule on the translation stack has finished (dot is at the end), so we **complete** (co) it, pop the top rule and advance the dot in the second-to-top rule, denoting that NP is completed:

[. IP] [NP . VP].

Following this procedure, we have a dependency structure S_3 after we scan (sc) the word "held" and take a shift (sh) and a left reduce ($\text{re}_{\curvearrowleft}$) parsing actions. The shaded node "held" means exposed roots, that the shift-reduce parser takes actions on.

Following Huang and Mi (2010), the hypotheses with same *translation step*[1] fall into the same bin. Thus, only the prediction (pr) actions actually make a jump from a bin to another. Here line 2 to 4 fall into one bin (translation step = 4, as there are 4 nodes, IP, NP, VP and Bùshí, in the source tree are covered). Similarly, lines from 7 to 10 fall into another bin (translation step = 15).

[1]The step number is defined by the number of tree nodes covered in the source tree, and it is not equal to the number of translation actions taken so far.

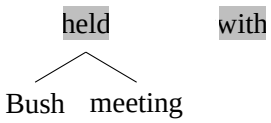
Noted that as we number the bins by the translation step, only pr actions make progress, the sc and co actions are treated as ”closure” operators in practice. Thus we always do as many sc/co actions as possible immediately after a pr step until the symbol after the dot is another non-terminal. The total number of bins is equal to the size of the parse tree, and each hypothesis has a constant number of outgoing hyper-edges to predict, so the time complexity is linear in the sentence length.

After adding our S to this translation, an interesting branch occurs after we scan the word “with”, we have two different partial dependency structures S_8 and S_8' for the same translation. If we denote $N(S_i)$ as the number of re actions that S_i takes, $N(S_8)$ is 3, while $N(S_8')$ is 4. Here $N(S_i)$ does not take into account the number of sh parsing actions, since all partial structures with same translations should shift the same number of translations. Thus, $N(S_i)$ determines the score of dependency structures, and only the hypotheses with same $N(S_i)$ are comparable to each other. In this case, we should distinguish S_8 with S_8', and if we make a prediction over the hypothesis of S_8, we can reach the correct parsing state S_{11} (shown in the red dashed line in Figure 3).

So the key problem of our integration is that, after each translation step, we will apply different sequences of parsing actions, which result in different and incomparable dependency structures with the same translation. In the following two Sections, we introduce three ways for this integration.

3.2 Naïve: Adding Parsing Signatures into Translation Signatures

One straightforward approach is to add the parsing signatures (in Figure 1) of each dependency structure (in Figure 1 and Figure 3) to translation signatures. Here, we only take into account of the s_0 and s_1 in the parsing stack, as the q_0 is the future word that is not available in translation strings. For example, the dependency structure S_8 has parsing signatures:



We add those information to its translation signature, and only the hypothesis that have same translation and parsing signatures can be recombined.

So, in each translation bin, different dependency structures with same translation strings are treated as different hypothesis, and all the hypothesis are sorted and ranked in the same way. For example, S_8 and S_8' are compared in the bin, and we only keep top b (the beam size) hypothesis for each bin.

Obviously, this simple approach suffers from the incomparable problem for those hypothesis that have different number of parsing actions (e.g. S_8 and S_8'). Moreover, it may result in very low translation variance in each beam.

3.3 Best-parse: Keeping the Best Dependency Structure for Each Translation

Following Hassan et al. (2009), we only keep the best parsing tree for each translation. That means after a consecutive translation sc actions, our shift-reduce parser applies all the possible parsing actions, and generates a set of new partial dependency structures. Then we only choose the best one with the highest S score, and only use this dependency structure for future predictions.

For example, for the translation in line 10 in Figure 3, we only keep S_8, if the parsing score of S_8 is higher than S_8', although they are not comparable. Another complicate example is shown in Figure 4, within the translation step 15, there are many alternatives with different parsing structures for the same translation (“a meeting with”) in the third column, but we can only choose the top one in the final.

3.4 Grouping: Regrouping Hypothesis by $N(S)$ in Each Bin

In order to do comparable sorting and pruning, our basic idea is to regroup those hypotheses in a same bin into small groups by $N(S)$. For each translation, we first apply all the possible parsing actions, and generate all dependency structures. Then we regroup all the hypothesis with different dependency structures based on the size of $N(S)$.

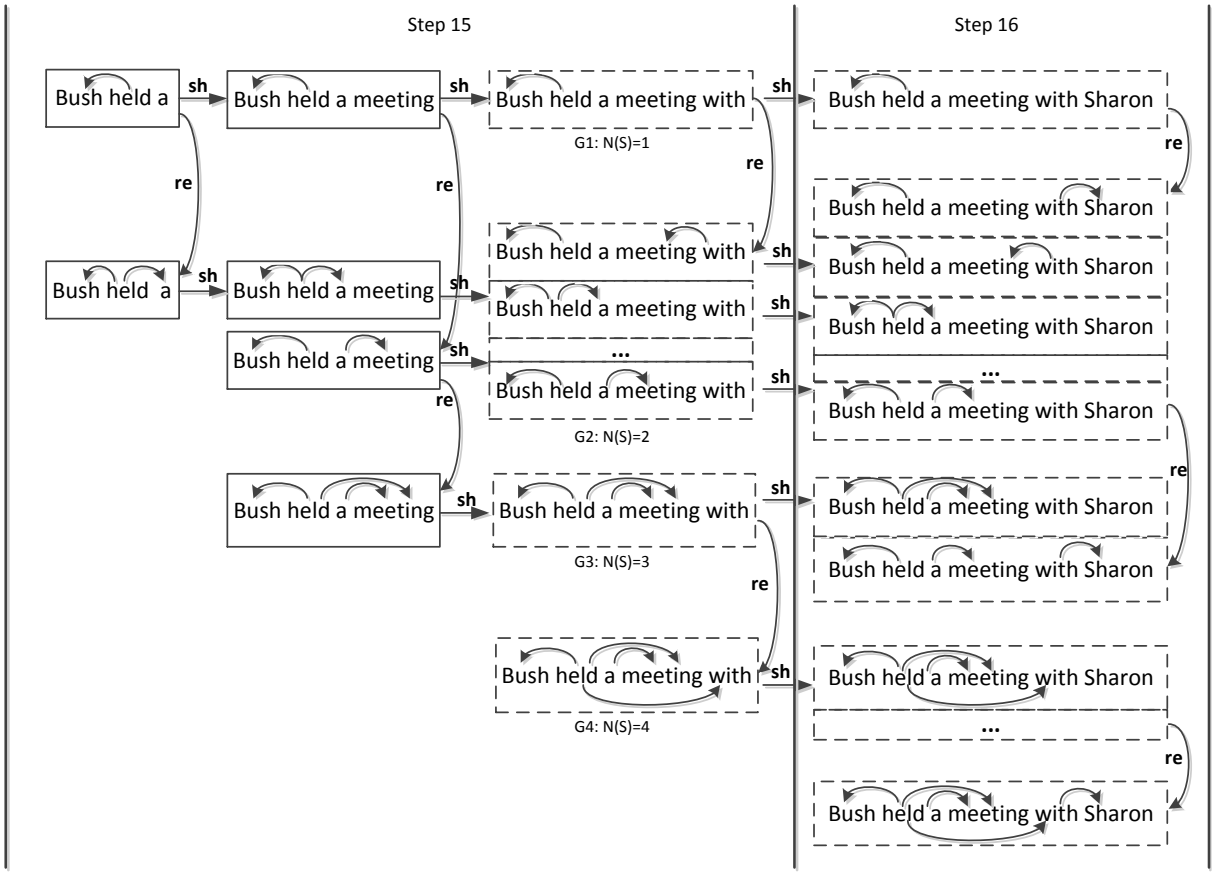


Figure 4: Multi-beam structures of two bins with different translation steps (15 and 16). The first three columns show the parsing movements in bin 15. Each dashed box is a group based on the number of reduce actions over the new translation strings ("a meeting with" for bin 15, and "Sharon" for bin 16). G_2 means two reduce actions have been applied. After this regrouping, we perform the pruning in two phases: 1) keep top b states in each group, and labeled each group with the state with the highest parsing score in this group; 2) sort the different groups, and keep top g groups.

For example, Figure 4 shows two bins with two different translation steps (15 and 16). In bin 15, the graph shows the parsing movements after we scan three new words ("a", "meeting", and "with"). The parsing sh action happens from a parsing state in one column to another state in the next column, while re happens from a state to another state in the same column. The third column in bin 15 lists some partial dependency structures that have all new words parsed. Here each dashed box is a group of hypothesis with a same $N(S)$, e.g. the G_2 contains all the dependency structures that have two reduce actions after parsed all the new words. Then, we sort and prune each group by the beam size b, and each group labeled as the highest hypothesis in this group. Finally, we sort those groups and only keep top g groups for the future predictions. Again, in Figure 4, we can keep the whole group G_3 and partial group of G_2 if $b = 2$. In our experiments, we set the group size g to 5.

3.5 Log-linear Model

We integrate our dependency parser into the log-linear model as an additional feature. So the decoder searches for the best translation $\mathbf{e}^*$ with a latent tree structure (evaluated by our S) according to the following equation:

$$\mathbf{e}^* = \underset{\mathbf{e} \in \mathbf{E}}{\operatorname{argmax}} \exp(\mathrm{S}(\mathbf{e}) \cdot w_s + \sum_i f_i \cdot w_i) \quad (1)$$

where S (**e**) is the dependency parsing score calculated by our parser, w_s is the weight of S (**e**), f_i are the features in the baseline model and w_i are the weights.

4 Experiments

4.1 Data Preparation

The training corpus consists of 1.5M sentence pairs with 38M/32M words of Chinese/English, respectively. We use the NIST evaluation sets of MT06 as our development set, and MT03, 04, 05, and 08 (newswire portion) as our test sets. We word-aligned the training data using GIZA++ with refinement option "grow-diag-and" (Koehn et al., 2003), and then parsed the Chinese sentences using the Berkeley parser (Petrov and Klein, 2007). we applied the algorithm of Galley et al. (2004) to extract tree-to-string translation rules. Our trigram word language model was trained on the target side of the training corpus using the SRILM toolkit (Stolcke, 2002) with modified Kneser-Ney smoothing. At decoding time, we again parse the input sentences using the Berkeley parser, and convert them into translation forests using rule pattern-matching (Mi et al., 2008).

Our baseline system is the incremental tree-to-string decoder of Huang and Mi (2010). We use the same feature set shown in Huang and Mi (2010), and tune all the weights using minimum error-rate training (Och, 2003) to maximize the B score on the development set.

Our dependency parser is an implementation of the "arc-standard" shift-reduce parser (Nivre, 2004), and it is trained on the standard split of English Penn Tree-bank (PTB): Sections 02-21 as the training set, Section 22 as the held-out set, and Section 23 as the test set. Using the same features as Huang and Sagae (2010), our dependency parser achieves a similar performance as Huang and Sagae (2010). We add the structured language model as an additional feature into the baseline system.

We evaluate translation quality using case-insensitive IBM B -4, calculated by the script `mteval-v13a.pl`. We also report the T scores.

4.2 Complete Comparisons on MT08

To explore the soundness of our approach, we carry out some experiments in Table 2. With a beam size 100, the baseline decoder achieves a B score of 21.06 with a speed of 1.7 seconds per sentence.

Since our dependency parser is trained on the English PTB, which is not included in the MT training set, there is a chance that the gain of B score is due to the increase of new *n*-grams in the PTB data. In order to rule out this possibility, we use the tool SRILM to train another tri-gram language model on English PTB and use it as a secondary language model for the decoder. The B score is 21.10, which is similar to the baseline result. Thus we can conclude that any gain of the following +S experiments is not because of the using of the additional English PTB.

Our second experiment re-ranks the 100-best translations of the baseline with our structured language model trained on PTB. The improvement is less than 0.2 B , which is not statistically significant, as the search space for re-ranking is relatively small compared with the decoding space.

As shown in Section 3, we have three different ways to integrate an S to the baseline system:

- **naïve**: adding the parsing signature to the translation signature;
- **best-parse**: keeping the best dependency structure for each translation;
- **grouping**: regrouping the hypothesis by $N(S)$ in each bin.

The naïve approach achieves a B score of 19.12, which is significantly lower than the baseline. The main reason is that adding parsing signatures leads to very restricted translation variance in each beam. We also tried to increase the beam size to 1000, but we do not see any improvement.

The fourth line in Table 2 shows the result of the best-parse (Hassan et al., 2009). This approach only slows the speed by a factor of two, but the improvement is not statistically significant. We manually looked into some dependency trees this approach generates, and found this approach always introduce local parsing errors.

The last line shows our efficient beam grouping scheme with a grouping size 5, it achieves a significant improvement with an acceptable speed, which is about 6 times slower than the baseline system.

System		B	Speed
baseline		21.06	1.7
+S	re-ranking	21.23	1.73
	naïve	19.12	2.6
	best-parse	21.30	3.4
	grouping (g=5)	**21.64**	10.6

Table 2: Results on MT08. The bold score is significantly better than the baseline result at level $p < 0.05$.

System	MT03		MT04		MT05		MT08		Avg.
	B	(T-B)/2	B	(T-B)/2	B	(T-B)/2	B	(T-B)/2	(T-B)/2
baseline	19.94	10.73	22.03	18.63	19.92	11.45	21.06	10.37	12.80
+S	**21.49**	**9.44**	22.33	18.38	**20.51**	**10.71**	**21.64**	**9.88**	**12.10**

Table 3: Results on all test sets. Bold scores are significantly better than the baseline system ($p < 0.5$).

4.3 Final Results on All Test Sets

Table 3 shows our main results on all test sets. Our method gains an average improvement of 0.7 points in terms of (T-B)/2. Results on NIST MT 03, 05, and 08 are statistically significant with $p < 0.05$, using bootstrap re-sampling with 1000 samples (Koehn, 2004). The average decoding speed is about 10 times slower than the baseline.

5 Related Work

The work of Schwartz et al. (2011) is similar in spirit to ours. We are different in the following ways. First, they integrate an S into a phrase-based system (Koehn et al., 2003), we pay more attention to a syntax-based system. Second, their approach slowdowns the speed at near 2000 times, thus, they can only tune their system on short sentences less than 20 words. Furthermore, their results are from a much bigger beam (10 times larger than their baseline), so it is not clear which factor contributes more, the larger beam size or the S . In contrast, our approach gains significant improvements over a state-of-the-art tree-to-string baseline at a reasonable speed, about 6 times slower. And we answer some questions beyond their work.

Hassan et al. (2009) incorporate a linear-time CCG parser into a DTM system, and achieve a significant improvement. Different from their work, we pay more attention to the dependency parser, and we also test this approach in our experiments. As they only keep 1-best parsing states during the decoding, they are suffering from the local parsing errors.

Galley and Manning (2009) adapt the maximum spanning tree (MST) parser of McDonald et al. (2005) to an incremental dependency parsing, and incorporate it into a phrase-based system. But this incremental parser remains in quadratic time.

Besides, there are also some other efforts that are less closely related to ours. Shen et al. (2008) and Mi and Liu (2010) develop a generative dependency language model for string-to-dependency and tree-to-tree models. But they need parse the target side first, and encode target syntactic structures in translation rules. Both papers integrate dependency structures into translation model, we instead model the dependency structures with a monolingual parsing model over translation strings.

6 Conclusion

In this paper, we presented an efficient algorithm to integrate a structured language model (an incremental shift-reduce parser in specific) into an incremental tree-to-string system. We calculate the structured language model scores incrementally at the decoding step, rather than re-scoring a complete translation. Our experiments suggest that it is important to design efficient pruning strategies, which have been

overlooked in previous work. Experimental results on large-scale data set show that our approach significantly improves the translation quality at a reasonable slower speed than a state-of-the-art tree-to-string system.

The structured language model introduced in our work only takes into account the target string, and ignores the reordering information in the source side. Thus, our future work seeks to incorporate more source side syntax information to guide the parsing of the target side, and tune a structured language model for both B and paring accuracy. Another potential work lies in the more efficient searching and pruning algorithms for integration.

Abstract

Lexicalized reordering model plays a central role in phrase-based statistical machine translation systems. The reordering model specifies the orientation for each phrase and calculates its probability conditioned on the phrase. In this paper, we describe the necessity and the challenge of introducing such a reordering model for hierarchical phrase-based translation. To deal with the challenge, we propose a novel lexicalized reordering model which is built directly on synchronous rules. For each target phrase contained in a rule, we calculate its orientation probability conditioned on the rule. We test our model on both small and large scale data. On NIST machine translation test sets, our reordering model achieved a 0.6-1.2 BLEU point improvements for Chinese-English translation over a strong baseline hierarchical phrase-based system.

1 Introduction

In statistical machine translation, the problem of reordering source language into the word order of the target language remains a central research topic. Statistical phrase-based translation models (Och and Ney, 2004; Koehn et al., 2003) are good at local reordering, or the reordering of words within the phrase, since the order is specified by phrasal translations. However, phrase-based models remain weak at long-distance reordering, or the reordering of the phrases. To improve the reordering of the phrases, two types of models have been developed.

The first one is lexicalized reordering models (Tillman, 2004; Huang et al., 2005; Al-Onaizan and Papineni, 2006; Nagata et al., 2006; Xiong et al., 2006; Zens and Ney, 2006; Koehn et al., 2007; Galley and Manning, 2008; Cherry et al., 2012) which predict reordering by taking advantage of lexical information. The model in (Koehn et al., 2007) distinguishes three orientations with respect to the previous and the next phrase—monotone (*M*), swap (*S*) and discontinuous (*D*). For example, we can extract a phrase pair "xiayou ||| the lower reach of" whose orientations with respect to the previous and the next phrase are *D* and *S* respectively, as shown in Figure 1. Such a model is simple and effective, and has become a standard component of phrase-based systems such as MOSES.

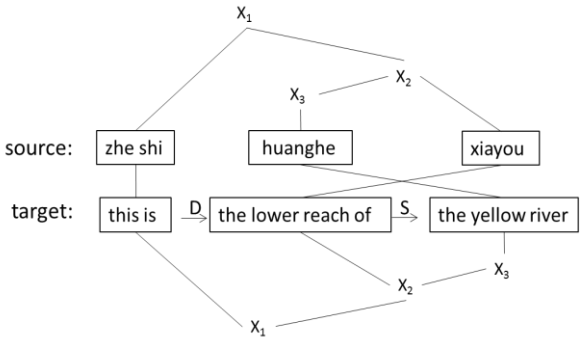

Figure 1. Phrase orientations for Chinese-English translation.

The other is a hierarchical phrase-based (HPB) translation model (Chiang, 2007) based on synchronous grammar. In the HPB model, a synchronous grammar rule may contain both terminals (words) and nonterminals (sub-phrases). The order of terminals and nonterminal are specified by the rule. For

Proceedings of COLING 2014, the 25th International Conference on Computational Linguistics: Technical Papers, pages 1144–1153, Dublin, Ireland, August 23-29 2014.

example, the translation rule <X xiayou, the lower reach of X > specifies that the translation of sub phrase X before "xiayou" should be put after "the lower reach of".

One problem with the HPB model is that the application of a rule is independent of the actual sub phrase. For example, the rule <X xiayou, the lower reach of X > will always swap the translation of X and "xiayou", no matter what is covered by X. This is an over-generalization problem. Much work has been done to solve this issue. For example, Zollmann and Venugopal (2006) annotate non-terminals by syntactic categories. He et al. (2008) proposes maximum entropy models which combine rich context information for selecting translation rules during decoding. Huang et al. (2010) automatically induce a set of latent syntactic categories to annotate nonterminals. These works alleviate the over-generalization problem by considering the content of X. In this paper, we try to solve it from an alternative view by modeling whether the phrases covered by X prefer the order specified by the rule. This has led us to borrow the lexicalized reordering model from the phrase-based model for the HPB model. We propose a novel lexicalized reordering model for hierarchical phrase-based translation and achieved a 0.6-1.2 BLEU point improvements for Chinese-English translation over a strong HPB baseline system.

2 Related work

In this section, we briefly review two types of related work which are a nonterminal-based lexicalized reordering models and a path-based lexicalized reordering model. Both of them calculate the orientation for HPB translation.

2.1 Nonterminal-based lexicalized reordering models

Xiao et al. (2011) proposed an orientation model for HPB translation. The orientation probability of a derivation is calculated as the product of orientation probabilities of all nonterminals except the root. In order to define the relative orders of nonterminals and their adjacent phrase, they expand the alignment in a rule to include both terminals and nonterminals. There may be multiple ways to segment a rule into phrases; they use the maximum adjacent phrase similar to Galley and Manning (2008). They significantly outperformed the HPB system on both Chinese-English and German-English translation.

Xiao et al. (2011) use the boundary word feature of nonterminals without considering their internal structure. For example, in Figure 1, suppose nonterminal X_1 is not the root node and the orientation probability of X_1 will condition on "zhe, xiayou, this, river".

In this paper, we will consider how the words covered by the nonterminal X_1 are reordered. Rather than using "xiayou" as a feature to determine the orientation of X_1 with respect to the next phrase, we think the immediately translated source word "huanghe" could be more informative through it is not on the boundary of X_1 , since "huanghe" is the exact starting point from where we search for the next phrase to translate.

Huck et al. (2013) proposed a very effective phrase orientation model for HPB translation. The model is also based on nonterminal. They extracted phrase orientation probabilities from word-aligned training data for use with hierarchical phrase inventories, and scored orientations in hierarchical decoding.

2.2 Path-based lexicalized reordering model

The most recent related work is Nguyen and Vogel (2013). They map a HPB derivation into a discontinuous phrase-based translation path in the following two steps:

1) Represent each rule as a sequence of phrase pairs and non-terminals.
2) The rules' sequences are used to find the corresponding phrase-based path of a HPB derivation and calculate the phrase-based reordering features.

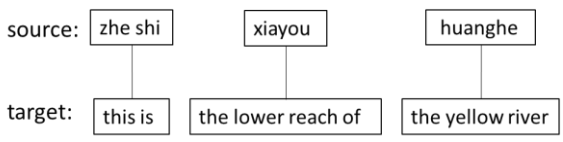

Figure 2. The phrase-based path of the derivation in Figure 1.

A phrase-based path is the sequence of phrase pairs, whose source sides covers the source sentences and whose target sides generated the target sentences from left to right. For example, the phrase-based path of the derivation in Figure 1 is shown in Figure 2.

The phrase-based reordering features for the above phrase-based path are:

$\log P_{next}(D \mid <\text{zheshi, this is}>)$, $\log P_{previous}(D \mid <\text{xiayou, the lower reach of}>)$,

$\log P_{next}(S \mid <\text{xiayou, the lower reach of}>)$, $\log P_{previous}(S \mid <\text{huanghe, the yellow river}>)$.

Nguyen and Vogel (2013) achieved significant improvement over both phrase-based and HPB models on three language pairs respectively.

One problem with the above work is that they did not use rules with unaligned source or target phrases. Though this can get faster and better Arabic-English translation, it leads to a 0.49 BLEU point loss for Chinese-English translation.

Another problem with path-based model is: there are many forms of HPB rules which we cannot map into a reasonable sequence of phrase pairs and non-terminals. We will show this with an example derivation shown in Figure 3. The main difference between Figure 3 and Figure 1 is there is such a rule <fangzhi X, prevent X from> that a source phrase "fangzhi" is aligned with a discontinuous target phrase "prevent…from". This makes it hard to find the corresponding phrase-based path because we do not know what is the right order of "fangzhi ||| prevent…from" and "daozei ||| the thieves" in the discontinuous phrase-based path. We face the following dilemmas:

- If "fangzhi ||| prevent…from" goes first, then the discontinuous phrase-based path is as shown in Figure 4(a). On such a path, we will consider the orientation of "the thieves" with respect to "breaking in". This is unreasonable because "the thieves" and "breaking in" are not adjacent in the target side. It does not satisfy the definition of the phrase-based reordering model which predicts the orientation with respect to previous or next adjacent target phrase.
- If "daozei ||| the thieves" goes first, then the discontinuous phrase-based path is as shown in Figure 4(b). This is unreasonable because "The policeman" and "the thieves" are not adjacent on the target side.

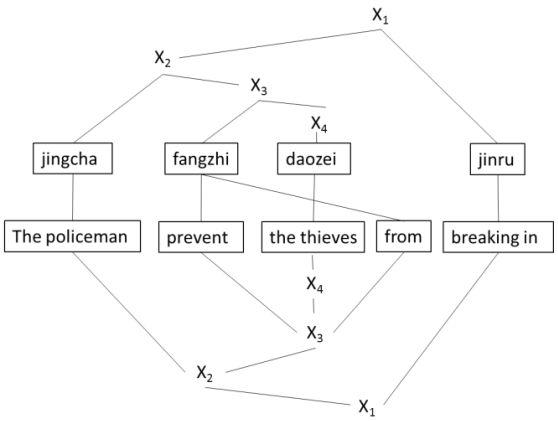

Figure 3. Example of Chinese-English translation and its derivation.

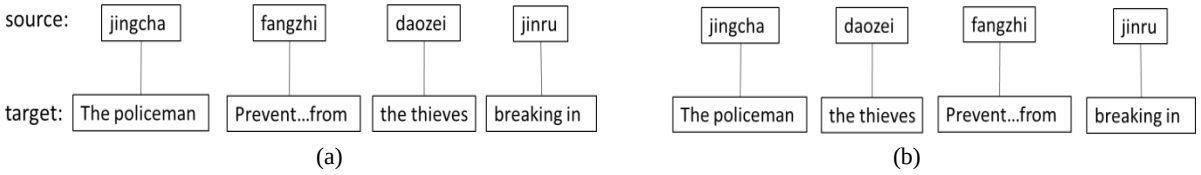

Figure 4. Two discontinuous phrase-based path candidates of the HPB derivation.

From the above example, we can see that if a target phrase is aligned to a discontinuous target phrase in a HPB rule, then it is hard to find a reasonable path whose target sides can generate the target sentence from left to right.

3 Our lexicalized reordering model

Rather than mapping a HPB derivation into a discontinuous phrase-based path and applying reordering model built on phrases, we propose a lexicalized reordering model which is built directly on HPB rules. For each target phrase contained in a HPB rule, we calculate its orientation probability conditioned on the rule. For the example derivation in Figure 3, we represent it by the structure shown in the following figure:

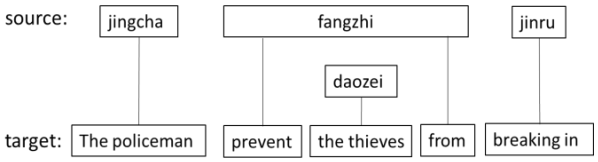

Figure 5. Our representation of the HPB derivation in Figure 3.

Different from Figure 4(a) and Figure 4(b) which contain a discontinuous phrase "prevent…from", we represent "prevent…from" as two individual target phrases: "prevent" and "from". Instead of considering the orientation of "prevent…from", we consider the orientation of "prevent" and "from" respectively. For example, we will consider the orientation of "prevent" with respect the previous phrase "the policeman" $O_{previous}(\text{prevent})$, and the orientation of "prevent" with respect the next phrase "the thieves" $O_{next}(\text{prevent})$. The probabilities of both $O_{previous}(\text{prevent})$ and $O_{next}(\text{prevent})$ are conditioned on the rule <fangzhi X, prevent X from>.

In Figure 5, every two neighboring target phrases are adjacent in the original target side. In this way, we can borrow the phrase-based reordering model which calculates the orientation with respect to previous and next adjacent phrase.

More formally, we represent a HPB rule in the general form of:

$$r = < s_0 \mathrm{X}_1 s_1 \mathrm{X}_2 s_2 ... \mathrm{X}_n s_n, t_0 \mathrm{X}_1 t_1 \mathrm{X}_2 t_2 ... \mathrm{X}_n t_n, \alpha >$$

where *n* is the number of nonterminals. $s_i, i = 1...n$, is the source phrase which is a continuous source word sequences. $t_i, i = 1...n$, is the target phrase which is a continuous target word sequences. We use α to represent the alignment of words and nonterminals in the rule. Note that s_i or t_i can be empty if there are adjacent nonterminals or there is nonterminal on the boundary. The lexicalized reordering probability of rule *r* is defined as the product of each target phrase's orientation probabilities conditioned on the rule *r*:

$$\prod_{i=0}^{n} P_{previous}(O_{previous}(t_i) \mid r, i) P_{next}(O_{next}(t_i) \mid r, i)$$

In the above equation, each probability is conditioned on the whole rule. In this way, we avoid the problem of mapping a HPB derivation into a discontinuous phrase-based path. There are two advantages for our reordering model:

- It is compatible with HPB rules which contain unaligned phrases.
- It is compatible with HPB rules in which a source phrase is aligned to a discontinuous target phrase.

Actually, our model is compatible with any kind of HPB rules since it is defined on the general form of rule.

Now we describe how to define $O_{previous}(t_i)$ and $O_{next}(t_i)$ in the model. Suppose t_i contains k_i target words and we write t_i as $t_i = w_{i(1)} w_{i(2)} ... w_{i(k_i\text{-}1)} w_{i(k_i)}$. Then we define:

$$O_{previous}(t_i) = O_{previous}(w_{i(1)}) = O(w_{i(1)\text{-}1}, w_{i(1)}), \qquad O_{next}(t_i) = O_{next}(w_{i(k_i)}) = O(w_{i(k_i)}, w_{i(k_i)+1})$$

where $O(w_j, w_{j+1})$ is the orientation of two adjacent target words and is determined as follows:

$$\begin{aligned}
&\text{If } (\ rm(w_j)+1 = lm(w_{j+1})\ ) && O(w_j, w_{j+1}) = M;\\
&\text{Else if } (\ rm(w_{j+1})+1 = lm(w_j)\ ) && O(w_j, w_{j+1}) = S;\\
&\text{Else} && O(w_j, w_{j+1}) = D;
\end{aligned}$$

$rm(w)$ is the position of the right most source word aligned to target word *w*; $lm(w)$ is the position of the left most source word aligned to target word *w*.

Above is our lexicalized reordering model which is built upon HPB rules. We complete its description using an example. For the rule <fangzhi X, prevent X from>, *n*=1, $t_0 = \text{“prevent”}$ and $t_1 = \text{“from”}$, the lexicalized reordering probability is:

$$P_{previous}(O_{previous}(\text{prevent})|\text{<fangzhi X, prevent X from>},0) \cdot P_{next}(O_{next}(\text{prevent})|\text{<fangzhi X, prevent X from>},0)$$
$$\cdot P_{previous}(O_{previous}(\text{from})|\text{<fangzhi X, prevent X from>},1) \cdot P_{next}(O_{next}(\text{from})|\text{<fangzhi X, prevent X from>},1)$$

Note that we calculate the orientation of plain phrase pairs in the same way as for HPB rules. We can represent a phrase pair in the form of $r = < s_0, t_0, \alpha >$, which is a rule that does not contain any nonterminal. Then we can apply our above model which is general enough to cover both HPB rules and plain phrase pairs.

4 Training and decoding

The training of our model is similar to the reordering model of Moses. During the standard phrase pair extraction and rule extraction, besides the nonterminal alignment in rules, we also keep the lexical alignments and orientations. If a phrase pair or a rule is observed with more than one set of alignment, we only keep the most frequent one and only count the orientations corresponding to the most frequent alignment.

Following Moses, we use relative frequency and add 0.5 smoothing technique to estimate the orientation probability based on all samples collected from the training corpus. Generally, given a rule *r* with *n* target phrases, we estimated the reordering probability for each t_i as follows:

$$P_{previous}(O_{previous}(t_i)|r,i) = \frac{0.5 + \#(O_{previous}(t_i),\ r)}{1.5 + \#(r)}, \qquad P_{next}(O_{next}(t_i)\,|\,r,i) = \frac{0.5 + \#(O_{next}(t_i), r)}{1.5 + \#(r)}$$

For each parallel sentences pair, we add a start and an end mark on both sides. They are aligned respectively.

Our phrase pairs and rules are extracted from word aligned parallel sentences. There are many phrase pairs and rules which contain unaligned target or source words. How to deal with them is quite important for our reordering model. We will describe how to process them in the following two subsections.

4.1 The processing of unaligned target words

Our main principle for processing an unaligned word is to: skip it and use the nearest aligned word. For example in Figure 3, the orientation of “prevent” with respect to the next phrase is determined by:

$$O_{next}(\text{prevent}) = O(\text{prevent}, \text{the})$$

If the target word “the” is unaligned and “thieves” is aligned with “daozei”, we will define:

$$O_{next}(\text{prevent}) = O(\text{prevent, the}) = O(\text{prevent, thieves}) = M$$

Similarly, in Figure 1, the orientation of “the lower reach of” with respect with “the yellow river” is determined by *O*(of, the). Suppose both “of” and “the” are unaligned and there are alignments for “reach-xiayou” and “yellow-huanghe”, we will have:

$$O(\text{of, the}) = O(\text{reach, yellow}) = S$$

We believe this orientation is consistent with our intuitions.

More formally, before we determine the orientation of two adjacent target words $O(w_p, w_q)$, we apply the following processing procedure:

While (target word w_p is unaligned) p--;

While (target word w_q is unaligned) q++;

If all words in a target phrase t_i are unaligned, we do not need to consider its orientation since t_i does not trigger any movement along the source words at all. Actually, it will be skipped when we determine the orientation of the previous and next aligned target phrases. (See also the decoding algorithm in Section 4.3)

4.2 The processing of unaligned source words

The processing of Section 4.1 can guarantee that the orientation is determined based on two aligned target words, namely w_p and w_q, which must be continuous or separated by unaligned target words.

Now we introduce the processing of unaligned source words. Before we determine the orientation of two target words $O(w_p, w_q)$, we apply the following procedure to modify the position index of the left most source word aligned to w_p and w_q respectively:

While (the $(lm(w_p)\text{-}1)^{\text{th}}$ source word is unaligned) $lm(w_p)$--;

While (the $(lm(w_q)\text{-}1)^{th}$ source word is unaligned) $lm(w_q)$--;

For the example shown in the Figure 6, initially we have $rm(w_1) = 1$ and $lm(w_4) = 4$. Since the source words w_3 and w_2 are unaligned, our procedure will modify the value of $lm(w_4)$ from 4 to 2. Finally, since $rm(w_1) + 1 = lm(w_4)$, the orientation of the two phrases marked by rectangular boxes in Figure 6 is:

$$O(w_2, w_3) = O(w_1, w_4) = M$$

Again, we believe this result is consistent with our intuition.

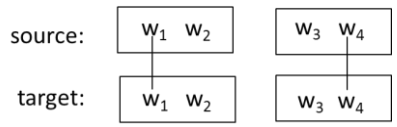

Figure 6. An example of phrases contain unaligned words

Note that during decoding, both the unaligned source and target words are also processed in the same way as in the training step. This makes our lexicalized reordering model consistent.

4.3 Decoding

Now we introduce how to integrate our reordering model into the HPB system during the standard CYK bottom-up decoding.

During decoding, if we just apply a plain phrase, we do not need to consider the orientation at once. It will be triggered when the phrase is used to compose a larger translation hypothesis together with other phrases or rules.

We need to calculate the reordering features whenever we apply a HPB rule or a glue rule during the CYK decoding. Generally, given a rule $r = < s_0 \mathrm{X}_1 s_1 \mathrm{X}_2 s_2 ... \mathrm{X}_n s_n, t_0 \mathrm{X}_1 t_1 \mathrm{X}_2 t_2 ... \mathrm{X}_n t_n, \alpha >$ defined in section 3, we calculate the reordering probability for the span covered by *r* with algorithm 1. In the algorithm, LL(X) represents the lowest rule which covers the left most word of X; LR(X) is the lowest

rule which covers the right most word of X; Both LL(X) and LR(X) can be found by traversing the derivation tree top to down recursively. LI(r) is the index of the last target phrase of rule *r*.

As in the example shown in Figure 3, for the rule $r_{2=}$<X_2 jinru, X_2 breaking in>, the orientation of X_2 and "breaking in" is:

$$O = O_{previous}(\text{breaking in}) = O(\text{from, breaking}) = D$$

The right most target word of X_2 is "from", the lowest rule covering "from" is $r_{3=}$<fangzhi X_4, prevent X_4 from> and the index of the last target phrase of r_3 is 1. So the reordering probability is:

$$prob = P_{previous}(D|r_1,0) \cdot P_{next}(D|r_3,1)$$

Note that, for readability, we use the product of probabilities to demonstrate the decoding process. Actually in practice, we use a linear model which sums the weighted log probabilities.

```
prob=1;
for (int i=1; i<=n; i++)
{
  if ( t_{i-1} is not empty and contains aligned words)
  {
      O = O_next(t_{i-1});
      prob* = P_next(O|r, i-1);
      prob* = P_previous(O|LL(X_i),0);
  }
  if ( t_i is not empty and contains aligned words)
  {
      O = O_previous(t_i);
      prob* = P_next(O|LR(X_i), LI(LR(X_i)));
      prob* = P_previous(O | r, i);
  }
  else if (i<n)
  {
      // X_i and X_{i+1} are continuous
      //or all words between them is unaligned
      rule r_p = LR(X_i);
      rule r_q = LL(X_{i+1});
      t = the first phrase of r_q;
      O = O_previous(t);
      prob* = P_next(O | r_p, LI(r_p))
      prob* = P_previous(O | r_q, 0);
      i++;
  }
}
```

Algorithm 1. Calculating the reordering probability for a span covered by a rule: $r = < s_0 X_1 s_1 X_2 s_2 ... X_n s_n, t_0 X_1 t_1 X_2 t_2 ... X_n t_n, \alpha >$.

As shown in Algorithm 1, the reordering probability depends on the lowest rules which cover the left/right most word. Therefore, we keep the lowest rules which cover the left/right most word for each partial translation. If two partial translations are same in everything but differ in the lowest rule, we need to keep both of them, rather than only keep the one with higher score. This will increase the complexity of the searching.

4.4 Discussion

Orientation can be determined based on word, phrase and hierarchical phrase (Galley and Manning, 2008). What we adopt in this paper is word based orientation. It is based on the following considerations:

- Our baseline is a HPB system, which can capture hierarchical orientation. We use word based orientation with the aim to complement the HPB system.
- Word based orientation is consistent during training and decoding; phrase based orientation is prone to inconsistent between training and decoding.

Galley and Manning (2008) has pointed out an inconsistency in Moses between training and decoding. Here we would like to note that phrase based orientation depends on phrase segmentation. For example, in Figure 1, the orientation of phrase "this is" with respect to next phrase could be either:

- D, if we think the next phrase is "the lower reach of " which is what Figure 1 shows.
- or S, if the next phrase is "the lower reach of the yellow river" which can compose a legal phrase pair with "huanghe xiayou" according to the standard phrase pair extraction algorithm.

The decision to adopt word-based orientation makes our work similar with Hayashi et al. (2010) who proposed a word-based reordering model for HPB system. The difference between our work and Hayashi et al. (2010) is: they adopt the reordering model proposed by Tromble and Eisner (2009) for the preprocessing approach, while we borrow the idea of lexicalized reordering models which are originally proposed for phrase-based machine translation.

5 Experiments

5.1 Experimental settings

Our baseline system is re-implementation of Hiero, a hierarchical phrase-based system (Chiang, 2007). Besides the standard features of a HPB model, there are six reordering features in our reordering model which are M, S and D with respect to the previous and next phrase respectively. They are integrated into the log-linear model of the HPB system. The Minimum Error Rate Training (MERT) (Och, 2003) algorithm is adopted to tune feature weights for translation systems.

We test our reordering model on a Chinese-English translation task. The NIST evaluation set MT06 was used as our development set to tune the feature weights, and the test data are MT04, MT 05 and MT08. We first conduct experiments by using the FBIS parallel training corpus, and then further test the effect of our method on a large scale parallel training corpus.

Word alignment is performed by GIZA++ (Och and Ney, 2000) in both directions with the default setting. The language model is a 4-gram model trained with the Xinhua portion of LDC English Gigaword Version 3.0 and the English part of the bilingual training data. Translation performances are measured with case-insensitive BLEU4 score (Papineni et al., 2002).

5.2 Experimental results on FBIS corpus

We first conduct experiments by using the FBIS parallel corpus to train the model of both the baseline and our lexicalized reordering model. After pre-processing, the statistics of FBIS corpus is shown in table 1.

	#sentences	#words
Chinese	128832	3016570
English	128832	3922816

Table 1. The statistics of FBIS corpus

Table 2 summarizes the translation performance. The first row shows the results of baseline HPB system, and the second row shows the results when we integrated our lexicalized reordering model (LRM). We get 1.2, 0.8 and 0.7 BLEU point improvements over the baseline HPB system on three test sets respectively.

	MT04	MT05	MT08
HPB	33.53	32.97	25.08
HPB+LRM	34.71	33.77	25.84

Table 2. Translation performance on the FBIS corpus.

5.3 Experimental results on large scale corpus

To further test the effect of our reordering model, we use a large scale corpus released by LDC. The catalog number of them is LDC2003E07, LDC2003E14, LDC2005T06, LDC2005T10, LDC2005E83, LDC2006E26, LDC2006E34, LDC2006E85 and LDC2006E92. There are 498K sentence pairs, 12.1M Chinese words and 13.8M English words. Table 3 summarizes the translation performance on the large scale of corpus.

	MT04	MT05	MT08
HPB	38.72	37.59	29.03
HPB+LRM	39.81	38.24	29.63

Table 3. Translation performance on a large scale parallel corpus.

Our model is still effective when we train the translation system on large scale data. We get 1.1, 0.7 and 0.6 BLEU point improvements over the baseline HPB system on three test sets respectively.

6 Conclusion and future work

We proposed a novel lexicalized reordering model for hierarchical phrase based machine translation. The model is compatible with any kind of HPB rules no matter how complex the alignments are. We tested our reordering model on both small and large scale data. On NIST machine translation test sets, our reordering model achieved a 0.6-1.2 BLEU point improvements for Chinese-English translation over a strong baseline hierarchical phrase-based system.

In future work, we will further test our model on other language pairs and compare it with other reordering models for HPB translation.

Abstract

Currently most of state-of-the-art methods for Chinese word segmentation (CWS) are based on supervised learning, which depend on large scale annotated corpus. However, these supervised methods do not work well when we deal with a new different domain without enough annotated corpus. In this paper, we propose a method to automatically expand the training corpus for the out-of-domain texts by exploiting the redundant information on Web. We break up a complex and uncertain segmentation by resorting to Web for an ample supply of relevant easy-to-segment sentences. Then we can pick out some reliable segmented sentences and add them to corpus. With the augmented corpus, we can re-train a better segmenter to resolve the original complex segmentation. The experimental results show that our approach can more effectively and stably improve the performance of CWS. Our method also provides a new viewpoint to enhance the performance of CWS by automatically expanding corpus rather than developing complicated algorithms or features.

1 Introduction

Word segmentation is a fundamental task for Chinese language processing. In recent years, Chinese word segmentation (CWS) has undergone great development. The popular method is to regard word segmentation as a sequence labeling problems (Xue, 2003; Peng et al., 2004). The goal of sequence labeling is to assign labels to all elements in a sequence, which can be handled with supervised learning algorithms, such as Maximum Entropy (ME) (Berger et al., 1996), Conditional Random Fields (CRF)(Lafferty et al., 2001).

After years of intensive researches, Chinese word segmentation achieves a quite high precision. However, the performance of segmentation is not so satisfying for the practical demands to analyze Chinese texts. The key reason is that most of annotated corpora are drawn from news texts. Therefore, the system trained on these corpora cannot work well with the out-of-domain texts.

Since these supervised approaches often has a high requirement on the quality and quantity of annotated corpus, which is always not easy to create. As a result, many methods were proposed to utilize the information of unlabeled data.

There are three kinds of methods for domain adaptation problem in CWS.

The first is to use unsupervised learning algorithm to segment texts, like branching entropy (BE) (Jin and Tanaka-Ishii, 2006), normalized variation of branching entropy (nVBE)(Magistry and Sagot, 2012).

Proceedings of COLING 2014, the 25th International Conference on Computational Linguistics: Technical Papers, pages 1154–1164, Dublin, Ireland, August 23-29 2014.

The second is to use unsupervised or domain-independent features in supervised learning for Chinese word segmentation, such as punctuation and mutual information(MI), word accessory variance (Feng et al., 2004; Zhao and Kit, 2008; Sun and Xu, 2011)

The third is to use semi-supervised learning (Zhu, 2005) in sequence labeling to address the difference in source and target distributions (Jiao et al., 2006; Altun et al., 2006; Suzuki and Isozaki, 2008).

Although these methods improve the performance of out-of-domain texts, the performance is still worse than that of in-domain texts obviously.

We firstly investigate the reasons of lower performance in new domain for state-of-the-art CWS systems and find that most of error segmentation were caused by out-of-vocabulary (OOV) words, also called new words or unknown words (see details in Section 3). It is difficult to devote efforts to building a corpus for out-of-domain texts, since new words are produced frequently as the development of the society, especially the Internet society. It is also impractical to manually maintain an up-to-date corpus to include all geographical names, person names, organization names, technical terms, etc.

In this paper, we propose a method to automatically expand the training corpus for the out-of-domain texts by exploiting the redundant information on Web. When we meet a complex and potentially difficult-to-segment sentence, we do not expect to solve it with more complicated learning algorithm or elaborate features. We assume that there are some relevant sentences that are relatively easy to process. These simple sentences can help to solve the complex one.

For example, the sentence “欧莱雅美宝莲 (L'Oreal, Maybelline)” is difficult to segment if both “欧莱雅 (L'Oreal)” and “美宝莲 (Maybelline)” are unknown words. However, we can always find some easy-to-segment sentences, such as “我使用美宝莲 (I use Maybelline)”, “欧莱雅的产品 (production of L'Oreal)”, and so on. When we use these simple sentences to re-train the segmenter, we can solve the previous complex sentence.

Our method relies on breaking up the complex problems into relevant smaller, simpler problems that can be solved easily. Fortunately, we can resort to the scale and redundancy of the web for an ample supply of simple sentences that are relatively easy to process.

Our method is very easy to implement upon a trainable base segmenter. Given the out-of-domain texts, we firstly choose some uncertain segmentations and select the candidate expansion seeds. Secondly, we use these seeds to get the relevant texts from Web search engine. Then we segment these texts and add the texts with high confidence to training corpus. Finally, we can get a better segmenter with the new corpus.

The rest of the paper is organized as follows: we review the related works in section 2. In section 3, we analyze the influence factor for CWS. Then we describe our method in section 4. Section 5 introduces the base segmenter. Section 6 gives the experimental results. Finally we conclude our work in section 7.

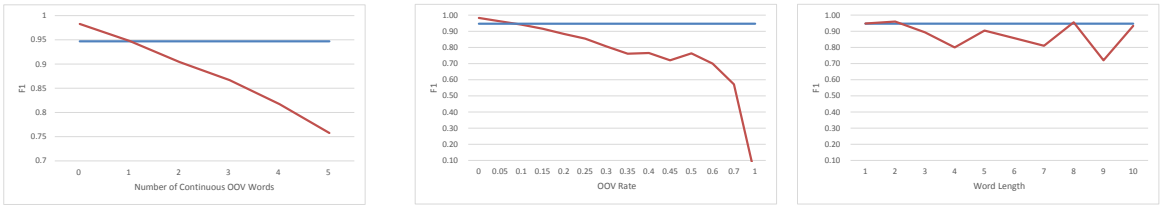
2 Related Works

The idea of exploring information redundancy on Web was introduced in question answering system (Kwok et al., 2001; Clarke et al., 2001; Banko et al., 2002) and the famous information extraction system KNOWITALL(Etzioni et al., 2004). However, this idea is rarely mentioned in Chinese word segmentation.

Nonetheless, there are three kinds of related methods on Chinese word segmentation.

One is active learning. Both (Li et al., 2012) and (Sassano, 2002) try to use active learning method to expand annotated corpus, but they still need to manually label some new raw texts in order to enlarge the training corpus. Different with these methods, our method do not require any manual oracle labeling at all.

Another is self-training, also called bootstrapping or self-teaching (Zhu, 2005). Self-training is a general semi-supervised learning approach. In self-training, a classifier is first trained with the small amount of labeled data. The classifier is then used to classify the unlabeled data.



(a) Number of continuous OOV words (b) OOV rate (c) Word Length

The blue horizontal line is the overall F1 score, and the red line is the F1 scores with different values of the factor.

Figure 1: Analysis of Influence Factors

Typically the most confident unlabeled points, together with their predicted labels, are added to the training set. The classifier is re-trained and the procedure repeated. Note that the classifier uses its own predictions to teach itself. Self-training has been applied to several natural language processing (NLP) tasks, such as word sense disambiguation (Yarowsky, 1995), POS-tagging (Clark et al., 2003; Jiang and Zhai, 2007; Liu and Zhang, 2012), parsing (Steedman et al., 2003; McClosky et al., 2006; Reichart and Rappoport, 2007; Sagae, 2010), information extraction(Etzioni et al., 2004)and so on. It has been proven that self-training can improve system performance on the target domain by simultaneously modeling annotated source-domain data and unannotated target domain data in the training process. However, the data on target domain cannot always help itself (Steedman et al., 2003).

The third is weakly supervised learning. (Li and Sun, 2009; Jiang et al., 2013) utilized the massive manual natural annotations or punctuation information on the Internet to improve the performance of CWS. However, these natural annotations are just partial annotations and their roles depend on the qualities of the selected resource, such as Wikipedia.

In this paper, we wish to propose a method to obtain new fully-annotated data in more aggressive way, which can combine the advantages of the above works.

3 Analysis of Influence Factors for CWS

Before describing our method, we give an analysis of the impact of out-of-vocabulary (OOV) words for segmentation. We first conduct experiments on the Chinese Treebank (CTB6.0) dataset (Xue et al., 2005) (The detailed information of dataset is shown in Section 6).

Table 1 shows the performance of base segmenter. The F1 score of OOV words is significantly lower than that of in-vocabulary (INV) words.

	Precision	Recall	F1
INV	95.86	96.58	96.21
OOV	74.12	66.77	70.25
Total	94.64	94.73	94.69

Table 1: Performances of INV and OOV words

We also investigate the impacts of three different factors: number of continuous OOV words, OOV rate and word length. Figure 1 shows the F1 scores with the changes of the different factors. We find that OOV words significantly improve the difficulty of segmentation, while the word length does not always harm the accuracy.

These findings also indicate that we can improve the performance of CWS if we have a dictionary or annotated corpus including these OOV words. With the redundancy of the Web information, it is not difficult to automatically obtain the expected dictionary or corpus.

4 Our Method

In this section, we describe our method to automatically expand the training corpus.

4.1 Framework of Automatic Corpus Expansion

Our framework of automatic corpus expansion is similar to standard process self-training or active learning for domain adaptation. Given a trainable base segmenter, the texts in out-of-domain, we firstly choose some uncertain segmentations and select the candidate expansion seeds. Secondly, we use these seeds to get the relevant texts from Web search engine. Then we segment these texts and add the texts with high confidence to training corpus. Finally, we can get a better segmenter with the new corpus.

Algorithm 1 illustrates the framework of automatic corpus expansion.

Algorithm 1 Framework of Automatic Corpus Expansion

Input:
Annotated Corpus C_A
Unannotated Corpus in Target domain C_T
Uncertainty Threshold T_u
Seed Extraction Threshold T_{se}
Acceptation Threshold T_a
Maximum Iteration Number: M

Output: Expanded Annotated Corpus C_A

1: **for** $i = 1$ to M **do**
2: Train a basic segmenter using current C_A with base learner
3: Use the basic segmenter to do segmentation for each sentence in C_T and calculate its confidence.
4: Choose out the sentences collection C_{TS}, in which the segmentation confidence of each sentence is less than T_u.
5: Extract the expansion seeds collection C_{seeds} from C_{TS} and use search engine to acquire relevant raw texts C_{RRT}.
6: Segment and calculate the confidence for each sentence in C_{RRT}.
7: Pick the reliable segmentations C_{new} with confidence more than T_a from C_{RRT}.
8: Add C_{new} into C_A.
9: **end for**
10: **return** C_A;

4.2 Uncertainty Sampling

The first key step in our method is to find the uncertain segmentations. There are many proposed uncertainty measures in the literature of active learning (Settles, 2010), such as entropy and query-by-committee (QBC) algorithm.

In our works, we investigate four following uncertainty measures for each sentence x. We use $S_1(x), S_2(x), \cdots, S_N(x)$ to represent the top N scores given by the segmenter.

Normalized Score U_{NS}

The first measures is normalized score by the length of x, the normalized score U_{NS} is calculated by

$$U_{NS} = \frac{S_1(x)}{L} \tag{1}$$

where L is the length of x.

Standard Deviation U_{SD}

The standard deviation is calculate with the top N scores.

$$U_{SD} = \sqrt{\frac{1}{N}\sum_{i=1}^{N}(S_i(x) - \mu)^2} \tag{2}$$

where $\mu = \frac{1}{N}\sum_{i=1}^{N} S_i(x)$ is the average or expected value of $S_i(x)$.

Entropy $U_{Entropy}$

Entropy is a measure of unpredictability or information content. Since we use character-based method for word segmentation, each character is labeled as one of {**B**, **M**, **E**, **S**} to indicate the segmentation. {**B**, **M**, **E**} represent *Begin*, *Middle*, *End* of a multi-character segmentation respectively, and **S** represents a *Single* character segmentation.

Given the top N labeled results for a sentence, each labeled sequence consists of the labels {**B**, **M**, **E**, **S**}. We define $l \in \{B, M, E, S\}$ to represent the label variable, and $\mathbf{count}_j(l)$ to be the number of occurrences of l on position j among the top N results. Thus, we can calculate the entropy for the labeling uncertainty of each character.

The entropy $H_j(l)$ for the character on position j is calculated by

$$H_j(l) = -\sum_{l} \frac{\mathbf{count}_j(l)}{N} \log \frac{\mathbf{count}_j(l)}{N}, \tag{3}$$

where $\sum_l \mathbf{count}_j(l) = N$.

The entropy of sentence $U_{Entropy}$ is the sum of the entropies of all the characters in the sentence.

$$U_{Entropy} = \sum_{j=1}^{L} H_j(l). \tag{4}$$

Margin U_{Margin}

Margin is the deviation of top 2 scores, which is often used in machine learning algorithms, such as support vector machine (Cristianini and Shawe-Taylor, 2000) and passive-aggressive algorithm (Crammer et al., 2006).

$$U_{Margin} = S_1(x) - S_2(x) \tag{5}$$

Among the above four measures, the larger the entropy is, the more uncertain the result is. For the rest three factors, the less the score is, the more uncertain the result is.

We test these four uncertainty measures on the development set in order to choose the best one as our confidence measure.

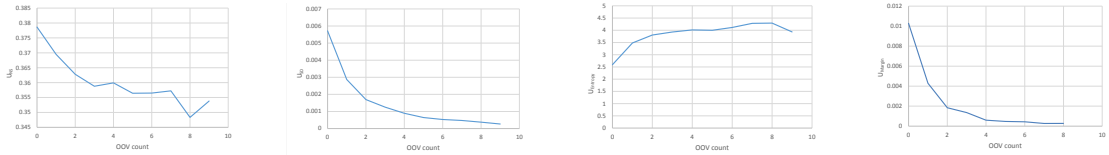
In figure 2, we illustrate the relationship between each uncertainty measure and the OOV count. We assume that the more OOV words are, the more uncertainty is. Meanwhile, a steep learning curve imply a good ability to distinguish whether the result is uncertain.

Obviously, the entropy is not helpful according to our assumption. The normalized score is okay but not good, and both the standard deviation and margin seem to be useful because they can give a better threshold to distinguish uncertain segmentation. Finally, we choose margin as our uncertainty measure.

4.3 Expansion Seeds Extraction

For the uncertain segmentation, not every word is unreliable. We just pick the suspicious fragments. Therefore, we need to extract some seed phrases to get the relevant texts. It is notable that these seed phrases do not need to be words. They can be the combinations of several words or only parts of words.

Take the following sentence for example.



(a) NScore (b) STDEV (c) Entropy (d) Margin

Figure 2: Different Uncertainty Measures

欧莱雅美宝莲兰蔻是很好的品牌
(L'Oreal, Maybelline, Lancome are good brands)

The first fragment "欧莱雅美宝莲兰蔻" is difficult to segment if these words does not appear in training corpus. Conversely, the second fragment is easy to segment since the containing words are very common.

We use base segmenter to get the top five results as follows:

	欧	莱	雅	美	宝	莲	兰	蔻	是	很	好	的	品	牌
1	B	M	M	M	E	B	M	E	S	B	E	S	B	E
2	B	M	M	E	B	E	B	E	S	B	E	S	B	E
3	B	M	E	B	E	B	M	E	S	B	E	S	B	E
4	S	B	M	M	E	B	E	S	S	B	E	S	B	E
5	S	B	M	M	M	E	B	E	S	B	E	S	B	E

(Li et al., 2012) proposed a good way to select the candidate words for active learning with diversity measurement to avoid duplicate annotation. However, their method is not suitable for our work. The reason is that they regarded CWS as a binary classification problem, while our base segmenter uses 1st-order sequence labeling.

In our work, we choose the expansion seeds by calculating the entropy of each character. If the entropy of the character is larger than threshold T_{se}, we say that this character may be in an uncertain context. Thus, we extract the consecutive uncertain characters and their contexts as the expansion seeds.

For the above example, we select the "欧莱雅美宝莲兰蔻 (L'Oreal, Maybelline, Lancome)" and its context "是 (is)" as a seed "欧莱雅美宝莲兰蔻是".

4.4 Collect relevance texts by using Web Search Engines

After obtaining the expansion seeds, we collect the relevant texts on multiple search engines including Google, Baidu and Bing.

For the seed "欧莱雅美宝莲兰蔻是", we can get the following relevance sentence, which is easy to segment.

欧莱雅拥有兰蔻、欧莱雅、美宝莲、薇姿等 500 多个品牌
(L'Oreal owns more than 500 brands, including Lancome, L'Oreal, Maybelline, Vichy, etc.)

In our work, we just get the top 100 relevant texts returned by each search engine without manual intervention. We do not use any search API and directly use the returned webpages by search engine, then extract the snippets and titles. Therefore, we just write a simple program to collect the webpages and clean them.

4.5 Expand Training Corpus

Since the qualities of these relevant texts are spotty, we just pick the reliable texts with high confidence scores. In contrast to uncertainty sampling, we find the certain segmentations from the collecting raw texts and add them to training corpus. Here, we also use a margin to find the reliable ones as new training data.

In our experiments, the number of selected sentence is $1 \sim 5$ for each seed.

Thus, we can re-train a new segmenter on the expanded corpus. After several iteration, we will get a segmenter with the best performance.

5 Base Segmenter

We use discriminative character-based sequence labeling for base word segmentation. Each character is labeled as one of {B, M, E, S} to indicate the segmentation.

We use online Passive-Aggressive (PA) algorithm (Crammer and Singer, 2003; Crammer et al., 2006) to train the model parameters. Following (Collins, 2002), the average strategy is used to avoid the overfitting problem.

6 Experiment

To evaluate our algorithm, we use both CTB6.0 and CTB7.0 datasets in our experiments. CTB is a segmented, part-of-speech tagged, and fully bracketed corpus in the constituency formalism. It is also a popular data set to evaluate word segmentation methods, such as (Sun and Xu, 2011). Since CTB dataset is collected from different sources, such as newswire, magazine, broadcast news and web blogs, it is suitable to evaluate the performance of CWS systems on different domains.

We conduct two experiments on different divisions of datasets.

1. The first experiment is performed on CTB6.0 for comparison with state-of-the-art systems which also utilize the unlabeled data for word segmentation.

2. The second experiment is performed on CTB7.0 for better evaluation on out-of-domain texts. CTB7.0 contains some newer news texts and web blogs texts, which is more suitable to evaluate our method for out-of-domain data.

In our experiments, we set $\mathcal{C} = 0.01$ for PA algorithm. We also try to use the different values of $\mathcal{C}$, and found that larger values of $\mathcal{C}$ imply a more aggressive update step and result to fast convergence, but it has little influence on the final accuracy. The maximum iteration number M' of PA algorithm is set to 50.

The feature templates are $C_iT_0, (i = -1, 0, 1)$,$C_{-1,0}T_0$, $C_{0,1}T_0, C_{-1,1}T_0$, $T_{-1,0}$. C represents a Chinese character, and the subscript of C indicates its position relative to the current character, whose subscript is 0. T represents the character-based tag.

The evaluation measure are reported are precision, recall, and an evenly-weighted F_1.

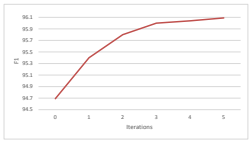
6.1 Experiments on CTB6.0

Train	Dev	Test
81-325, 400-454, 500-554, 590-596, 600-885, 900, 1001-1017, 1019, 1021-1035, 1037-1043, 1045-1059, 1062-1071, 1073-1078, 1100-1117, 1130-1131 1133-1140, 1143-1147, 1149-1151,2000-2139, 2160-2164, 2181-2279,2311-2549, 2603-2774, 2820-3079	41-80, 1120-1129, 2140-2159, 2280-2294, 2550-2569, 2775-2799, 3080-3109	(1-40,901-931 newswire) (1018, 1020, 1036, 1044,1060-1061, 1072, 1118-1119, 1132,1141-1142, 1148 magazine) (2165-2180, 2295-2310, 2570-2602, 2800-2819, 3110-3145 broadcast news)

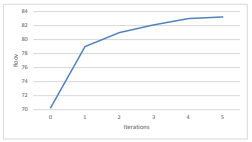
Table 2: CTB6.0 Dataset Division

On CTB 6.0, we divide the training, development and test sets according to (Yang and Xue, 2012). , which are shown in Table 2 The detailed statistical information is shown in Table 3.

Firstly, We use the development set to determine the parameters in Algorithm 1. For T_u, T_{se} and T_a, we have three rounds to determine the parameters. In first round, we find the best value $t1$ in the range to $0 \sim 1$ with the interval of 0.1. In second round, we find the best value $t2$ in range $t1 - 0.1 \sim t1 + 0.1$ with the interval of 0.01. In third round, we find the final best value $t3$

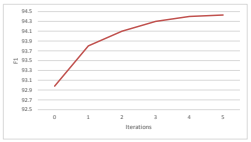


(a) F1 score

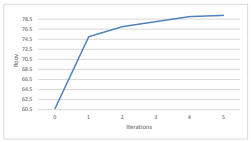


(b) OOV Recall

Figure 3: Iterative Learning Curve on CTB6.0



(a) F1 score



(b) OOV Recall

Figure 4: Iterative Learning Curve on CTB7.0

in the range to $t2 - 0.01 \sim t1 + 0.01$ with the interval of 0.001. The maximum iteration number M is just determined based on convergence with the range $1 \sim 10$.

Finally, we set these parameters as following: uncertainty threshold $T_u = 0.003$, seed extraction threshold $T_{se} = 0.65$, acceptation threshold $T_a = 0.004$ and maximum iteration number $M = 5$.

Figure 3 shows the changing curve of F1 and OOV recall in the process of corpus expansion. The performance of the baseline segmenter is shown at iteration 0. The curve shows that the F1 score and OOV recall have continuous improvement with the increasing of train corpus. The maximum performance is achieved at the $5th$ iteration. The detailed results are shown in Table 4. Compared with the baseline, the expanded corpus leads to a segmenter with significantly higher accuracy. The relative error reductions are 26.37% and 43.63% in terms of the balanced F-score and the recall of OOV words respectively.

Dataset	Sents	Words	Chars	OOV Rate
Train.	22757	639506	1053426	-
Dev.	2003	59764	100038	5.45%
Test	2694	81304	133798	5.58%

Table 3: Corpus Information of CTB 6.0

Test	P	R	F1	R_{oov}
Baseline	94.64	94.73	94.69	70.25
Final	95.66	96.51	96.09	83.23
(Sun and Xu, 2011)	95.86	95.62	95.74	79.28

Table 4: Performance on CTB6.0

6.2 Experiments on CTB7.0

CTB7.0 includes documents from newswire, magazine articles, broadcast news, broadcast conversations, newsgroups and weblogs. The newly added documents contains texts from web blogs, which is very different with news texts. Therefore, we use the documents (No. 4198 4411, weblogs) as test dataset, and the rest as training dataset. The detailed statistical information is shown in Table 5. We can see that the OOV rate is higher than the dataset in the first experiment.

Dataset	Sents	Words	Chars	OOV Rate
Train.	40425	987307	1601142	-
Test	10177	209827	342061	7.09%

Table 5: Corpus Information of CTB 7.0

Test	P	R	F1	R_{oov}
Baseline	93.58	92.40	92.98	60.72
Final	94.47	94.40	94.43	79.24

Table 6: Performance on CTB7.0

Figure 4 shows the changing curve of F1 and OOV recall in the process of corpus expansion. The performance of the baseline segmenter is shown at iteration 0. The curve shows that the F1 score and OOV recall have continuous improvement with the increasing of train corpus. The maximum performance is achieved at iteration 5. The detailed results are shown in Table 6. Compared with the baseline, the expanded corpus leads to a segmenter with significantly higher accuracy. The relative error reductions are 20.66% and 47.15% in terms of the balanced F-score and the recall of OOV words respectively.

6.3 Analysis

The experimental results show that our method is very effective to improve the performance of Chinese word segmentation. Especially, our method gives a significant boost on OOV words.

For the words such as "门兴格拉德巴赫 (Borussia Moenchengladbach)", "过氧化氢酶 (catalase)", "易中天 (Yi ZhongTian, a Chinese person name)" and "黄金档 (prime time)", it is still difficult to segment them correctly even if we can obtain useful features from unlabeled data. When we take advantage of the redundant information from Web, we can easily collect the relevant easy-to-segment sentences to expand the training corpus.

Our method can result to a segmenter significantly better than the systems which finds the informative features derived from unlabeled data, such as (Sun and Xu, 2011). This also suggests that expanding corpus is more effective than developing complicated algorithm or well-design features. Of course, our method is compatible with these technologies, which can further improve the performance of CWS by combining the Web redundancy.

7 Conclusion

In this paper, we propose a method to automatically expand the training corpus for the out-of-domain texts. Given the out-of-domain texts, we first choose some uncertain segmentations as candidate expansion seeds, and use these seeds to get the relevant texts from search engine. Then we segment the texts and add the texts with high confidence to training corpus. We can always obtain some easily-segmented texts due to the large amount of redundancy texts on Web, especially for new words. Our experimental results show that our proposed method can more effectively and stably utilize the unlabeled examples to improve the performance. Our method also provides a new viewpoint to enhance the performance of CWS by expanding corpus rather than developing complicated algorithms or features.

The long term goal of our method is to build an online and constant learning system, which can identify the difficult tasks and seek help from crowdsourcing. Search engines are special cases of crowdsourcing. In the future, we wish to investigate our method for other NLP tasks, such as POS tagging, Named Entity Recognition, and so on.

Fast High-Accuracy Part-of-Speech Tagging by Independent Classifiers

Robert C. Moore
Google Inc.
bobmoore@google.com

Abstract

Part-of-speech (POS) taggers can be quite accurate, but for practical use, accuracy often has to be sacrificed for speed. For example, the maintainers of the Stanford tagger (Toutanova et al., 2003; Manning, 2011) recommend tagging with a model whose per tag error rate is 17% higher, relatively, than their most accurate model, to gain a factor of 10 or more in speed. In this paper, we treat POS tagging as a single-token independent multiclass classification task. We show that by using a rich feature set we can obtain high tagging accuracy within this framework, and by employing some novel feature-weight-combination and hypothesis-pruning techniques we can also get very fast tagging with this model. A prototype tagger implemented in Perl is tested and found to be at least 8 times faster than any publicly available tagger reported to have comparable accuracy on the standard Penn Treebank Wall Street Journal test set.

1 Introduction

Part-of-speech (POS) tagging remains an important basic task in natural-language processing, often being used as an initial step in addressing more complex problems such as parsing (e.g., McDonald et al., 2005) or named-entity recognition (e.g., Florian et al., 2003). State-of-the-art-taggers typically employ discriminatively-trained models with hidden tag-sequence features. These models include features of the observable input sequence, plus hidden features consisting of tag sequences up to some fixed length.

With a tag-sequence model, the highest scoring tagging for an input sentence can be found by the Viterbi algorithm, but exact search can be slow with a large tag set. If tri-tag features are used, the full search space is $O(|T|^3 n)$, where $|T|$ is the size of the tag set and n is the length of the sentence. For the English Penn Treebank (Marcus et al., 1993) , $|T| = 45$, hence $|T|^3 = 91125$. For efficiency, some form of approximate search is normally used. For example, both Shen et al. (2007) and Huang et al. (2012) use approximate search in both training and tagging. Shen et al. use a specialized bi-directional beam search in which the search order is learned at training time and applied at tagging time, along with the model. Huang et al. use a more conventional left-to-right beam search, but they explore various special variants of the perceptron algorithm to cope with search errors during model training. These two taggers represent the current state of the art on the Penn Treebank Wall Street Journal (WSJ) corpus, for models trained using no additional resources, as measured on the standard training/development/test data split introduced by Collins (2002a): 2.67% per tag error for Shen et al., and 2.65% for Huang et al.

Alternatively, one may omit hidden tag-sequence features, enrich the set of observable features, and treat tagging each token as an independent multi-class classification problem. Toutanova et al. (2003) were the first to note that such models could achieve fairly high accuracy for POS tagging, reporting per-tag error of 3.43% on the standard WSJ development set. Liang et al. (2008) report 3.2% error on the standard WSJ test set (using a slightly smaller than standard training set), which as far as we know is the current state of the art for WSJ POS tagging by independent classifiers. The independent classifier approach has the advantage of a simple model structure with a search space for tagging of $O(|T|n)$. On the other hand, while Liang et al.'s result would have been state-of-the-art before Collins (2002a), today

Proceedings of COLING 2014, the 25th International Conference on Computational Linguistics: Technical Papers, pages 1165–1176, Dublin, Ireland, August 23-29 2014.

it represents an error rate about 20% higher than Huang et al.'s best result for tri-tag-based POS tagging, under similar training conditions.

In the first part of this paper, we introduce new features for tagging by independent classifiers. We introduce case-insensitive versions of several standard types of features, which enables our models to generalize over different casings of the same underlying word. We also cluster the vocabulary of the annotated training set, preserving as much information as possible about the tag probabilities for each word, and use sequences of the resulting classes to approximate the contextual information provided by hidden tri-tag features. With the further addition of another set of word-class features based on distributional similarity over a large corpus of unnanotated data, we obtain a model with a WSJ test set error of 2.66% (97.34% accuracy).

In the remainder of the paper, we show how to perform fast tagging with this model. Even with the simple structure of an independent multiclass classifer, tagging can be slow with a rich model and a large tag set, simply because feature extraction and model scoring take so much time. We address this in two ways. First we effectively reduce the number of features that have to be considered for a given token by combining the feature weights for more general features into those for more specific features. For example, if a word is in the training set vocabulary, none of its sublexical features need to be extracted or scored, if the weights of those features have already been combined into the weights for the corresponding "whole word" feature. Second, we limit the number of tags considered for each token by a pruning method that refines Ratnaparkhi's (1996) tag dictionary, employing a Kneser-Ney-smoothed probability distribution over the possible tags for each word, and applying a threshold tuned to reduce the number of tags considered while minimizing loss of accuracy. We have implemented a prototype tagger in Perl using these methods, which we find to be at least 8 times faster than any of the publicly available taggers reported to have comparable accuracy on the standard WSJ test set.

2 Models for Tagging by Independent Classifiers

We formulate the POS-tagging task as a linear multiclass classification problem defined by a set of tags $\mathcal{T}$ and a set of indicator features $\mathcal{F}$. Each training example consists of a set of features $\mathbf{f} \subseteq \mathcal{F}$ present in that example and a correct tag $t \in \mathcal{T}$. The feature set $\mathbf{f}$ for a particular example consists of observable properties of the token to be tagged and the tokens surrounding it. A model is a vector $\mathbf{w} \in \Re^{|\mathcal{T}|\times|\mathcal{F}|}$ indexed by feature-tag pairs. We refer to the coordinates $w_{(f,t)}$ of $\mathbf{w}$ as *feature weights*. A model $\mathbf{w}$ maximizes the sum of relevant feature weights to predict a tag $t(\mathbf{f}, \mathbf{w})$:

$$t(\mathbf{f}, \mathbf{w}) = \arg\max_{t \in \mathcal{T}} \sum_{f \in \mathbf{f}} w_{(f,t)} \tag{1}$$

In the remainder of this section we explain the feature sets we use and our method of training feature weights, and we evaluate the accuracy of the resulting models on the usual Wall Street Journal corpus from Penn Treebank III (Marcus et al., 1993).

2.1 Lexical Features

As noted above, the current state of the art for tagging by independent classifiers seems to be the results presented by Liang et al. (2008). Their best model uses the following set of base features for each word:

Whether the first character of the word is a capital letter
Prefixes of the word up to three characters
Suffixes of the word up to three characters
Two "shape" features described below
The full word

For each base feature, Liang et al. define three expanded features: whether the token being tagged has the base feature, whether the preceding token has the base feature, and whether the following token has the base feature. The shape features were first introduced by Collins (2002b) for named-entity recognition. What we will call the "Shape 1" feature is a generalization of the spelling of the word with all capital

letters treated as equivalent, all lower-case letters treated as equivalent, and all digits treated as equivalent. All other characters are treated as distinct. In the "Shape 2" feature, all sequences of capital letters, all sequences of lower case letters, and all sequences of digits are treated as equivalent, regardless of the length of the sequence or the identity of the upper case letters, lower case letters, or digits.

With this feature set as our starting point, and partially drawing from the feature sets of Ratnaparkhi (1996) and Collins (2002a), we settled on the following set of base features through experimentation on the WSJ development set:

Whether the word contains a capital letter
Whether the word contains a digit
Whether the word contains a hyphen
Lower-cased prefixes of the word up to four characters
Lower-cased suffixes of the word up to four characters
The Shape 1 feature for the word
The Shape 2 feature for the word
The full lower-cased word
The full word
A distributional-similarity-based class for the full word

In *all* these features we ignore distinctions among digits (rather than just in the shape features, as Liang et al. do). For the last feature, we used 256 word classes derived by unsupervised clustering for the most frequent 999996 distinct tokens (ignoring distinctions among digits) in 121.6 billion tokens of English-language newswire, using the method of Uszkoreit and Brants (2008). A 257th class was added for tokens not found in this set. We use Liang et al.'s mapping of all base features into expanded features for the token being tagged, the preceding token, and the following token. For the first token of a sentence we include a beginning-of-sentence feature in place of the preceding-token features, and for the last token of a sentence we include an end-of-sentence feature in place of the following-token features.

2.2 Word-Class-Sequence Features

In a hidden tri-tag model, the prediction for a particular tag t_i is linked to the predictions for the preceding tag t_{i-1}, the following tag t_{i+1}, the preceding tag pair $\langle t_{i-2}, t_{i-1} \rangle$, the following tag pair $\langle t_{i+1}, t_{i+2} \rangle$, and the surrounding tag pair $\langle t_{i-1}, t_{i+1} \rangle$. In tagging by independent classifiers, we do not have access to information regarding predictions for these nearby tags and tag combinations.

To substitute for these missing features, we carry out supervised clustering of the distinct words in the training set (again ignoring distinctions among digits) into 50 classes, attempting to maximize the information carried by each class regarding the tag probabilities for the words in the class. From these classes, we construct the features

$c(w_{i-1})$
$c(w_{i+1})$
$\langle c(w_{i-2}), c(w_{i-1}) \rangle$
$\langle c(w_{i+1}), c(w_{i+2}) \rangle$
$\langle c(w_{i-1}), c(w_{i+1}) \rangle$

The type of clustering we use here differs from the unsupervised clustering described previously. In assigning each word to a cluster, the unsupervised clustering algorithm looks only at adjacent words in unannoted data, while the supervised clustering algorithm looks only at the tags the word receives in the annotated data. The unsupervised clustering tells us what known words a large number of unknown words are simliar to, but the supervised clustering carries much more information about what tags the known words are likely to receive.

2.2.1 Clustering Algorithm

Our supervised clustering algorithm is based on the method presented by Dhillon et al. (2003). This is similar to the well-known Lloyd algorithm for k-means clustering, but uses KL-divergence between

probability distributions, instead of Euclidian distance, to assign items to clusters. In our application of this algorithm, we simply keep moving each word to the cluster that has the most similar probability distribution over tags, and then re-estimating the tag probability distributions for the clusters, until the clustering converges. At a high-level, our algorithm is:

- For each unique word w in the training set, estimate a smoothed probability distribution $p(T|w)$ over tags given w.
- Select k seed words, and initialize k clusters for clustering 0, with one seed word per cluster.[1]
- Set $i = 0$.
- Repeat until the assignment of words to clusters in clustering i is the same as in clustering $i-1$, returning clustering i:
  - For each cluster c in clustering i, compute a probability distribution $p(T|c)$ over tags given c, such that
$$p(t|c) = \sum_{w \in c} p(w|c)p(t|w)$$
  - For each word w, find the cluster c that minimizes the KL-divergence $D_{KL}(p(T|w)||p(T|c))$, and assign w to cluster c in clustering $i+1$.
  - Set $i = i + 1$.

As indicated, the probability distributions $p(T|c)$ over tags for a given cluster are computed as the word-frequency-weighted mean of probability distributions $p(T|w)$ over tags given the words in the cluster. The $p(T|w)$ distributions are estimated based on the relative frequencies of each tag for a given word, smoothed using the interpolated Kneser-Ney method (Chen and Goodman, 1999) widely used in statistical language modeling. (See Section 3.2 for more discussion of this smoothing method applied to POS tag prediction.)

2.2.2 Cluster Initialization

Our clustering algorithm is identical to that of Dhillon et al., except for the method of initializing the clusters. Their initialization method would assign all words with the same most likely tag to the same initial cluster. Instead, we initialize the clusters using a set of seed words with the property that conflating any two of them would result in a large loss of information about tag probabilities.

We define the distance between a pair of words (w_1, w_2) as the total decrease resulting from treating w_1 and w_2 as indistinguishable, in the estimated log probability, based on $p(T|W)$, of the reference tagging of the training data. Letting n_1 be the number of occurrences in the training data of w_1, and similarly for n_2 and w_2, we compute the distance between w_1 and w_2 as

$$n_1 D_{KL}(p(T|w_1)||p_{w_1 w_2}) + n_2 D_{KL}(p(T|w_2)||p_{w_1 w_2})$$

where $p_{w_1 w_2} = p(T|w_1 \vee w_2)$, computed as

$$p_{w_1 w_2}(t) = \frac{n_1}{n_1 + n_2} p(t|w_1) + \frac{n_2}{n_1 + n_2} p(t|w_2)$$

We select a set S of k seed words as follows:

- Choose a maximal subset V of the training data vocabulary, such that every word in V has a different distribution of observed POS tags.
- Choose a random ordering of V.
- Initialize S to contain the first k words of V.

[1] Note that most words in the training set are not assigned to any initial cluster.

- Find the minimum distance d between any two words in S.
- Taking each remaining word w of V in order:
  - Find the minimum distance d' between w and any word in S.
  - If $d' > d$,
    - Select from S a pair of words (w', w'') separated by d.
    - Find the minimum distance d'_2 between w' and any word in S other than w''.
    - Find the minimum distance d''_2 between w'' and any word in S other than w'.
    - If $d'_2 < d''_2$, remove w' from S, otherwise remove w'' from S.
    - Add w to S.
    - Recompute the minimum distance d between any two words in S.

2.2.3 Random restarts

The clustering we find depends on the set of seed words, which in turn depends on the order in which the words in V are enumerated to select the seed words. To ensure that we find a good clustering, we try multiple runs of the algorithm based on different random enumerations of V, returning the clustering yielding the lowest entropy for predicting the training set tags from the clusters.

We noticed in preliminary experiments that a poor clustering on the first iteration of the algorithm seldom leads to a good final clustering, so we save the training set tag entropy for the first iteration of the best clustering found so far, and we abandon a run of the algorithm if it results in higher training set tag entropy on its first iteration than the best previously observed final clustering had on its first iteration. We continue trying different random enumerations until a fixed number of runs has passed since the current best clustering was found.

2.2.4 Classes for unknown words

Note that this clustering method assigns classes only to words observed in the training data. All words (ignoring distinctions among digits) not seen in the training data are assigned to an additional class. In training the tagging model, however, we treat each word that has a single occurrence in the training data as a member of this unknown-word class, so that features based on that class will be seen in training; but at tagging time, we give all words seen in the training data the class they are assigned by the clustering algorithm, and apply the unknown-word class only to words not seen in the training data.

2.3 Feature Weight Training

Our models are trained by optimizing the multiclass SVM hinge loss objective (Crammer and Singer, 2001) using stochastic subgradient descent as described by Zhang (2004). We use a small, constant learning rate of 2^{-8}, which early in our experiments we found generally to be a good value, given the size of our training set and the sorts of feature sets we were using. We did not re-optimize the learning rate as we experimented with different feature sets. We do not use a numerical regularizer (such as L_1 or L_2), but we avoid over-fitting by using early stopping, and averaging as Collins (2002a) does with the averaged perceptron. To determine the stopping point, we evaluate the model on the development set after each pass through the training data. We continue iterating until we have made 10 consecutive passes through the training data without reducing the development set error, and we return the model from the iteration with the lowest error.

2.4 Evaluation of Tagging Accuracy

We evaluate the tagging accuracy of three models: our new model with all the features discussed above, our new model minus the unsupervised distributional clustering features (to give a "no additional resources" measurement), and the Liang et al. model that was our starting point. Our data is the ususal Wall Street Journal corpus from Penn Treebank III (Marcus et al., 1993), split into standard training (sections 0–18), development (sections 19–21), and test (sections 22-24) sets.

Table 1 shows WSJ development and test set error rates for all tokens and for unknown-word (OOV) tokens for all three models. Our full model has an overall test set tag error rate of 2.66%, or 97.34%

Tagging Model	Dev Set All Tag Error %	Dev Set OOV Tag Error %	Test Set All Tag Error %	Test Set OOV Tag Error %
Our full feature set	2.69	9.40	2.66	8.93
Our features minus unsupervised classes	2.83	10.45	2.77	10.14
Liang et al. feature set	3.23	12.47	3.17	11.92

Table 1: WSJ development and test set error rates for different feature sets

accuracy. Omitting unsupervised word-class features results in a relative increase in the error rate of 4.1% overall and 13.5% on unknown words. The model trained on the Liang et al. feature set gives results consistent with their reported 3.2% test set error, but the error is 19.2% higher than the model using our full feature set, and 14.4% higher than our model without unsupervised word-class features.

3 Efficient Tag Inference

Although the complexity of tag inference with our model is only $O(|T|n)$, with a rich feature set and many possible tags, the simple summation of feature weights and comparison of sums implied by Equation 1 can still be slow. With our full model, a given token occurrence can have up to 53 features present, and on the WSJ development set, we measured the average number of features present with a non-zero weight for at least one tag to be 38.0. Given 45 possible tags in the Penn Treebank tag set and our full model, the average number of relevant non-zero feature weights per token on the WSJ development set is 1215.0. We reduce computational costs in two ways. First, we introduce a method of combining feature weights that effectively reduces the number of features per token by a factor of 8. Then we introduce a refined version of a tag dictionary that reduces the number of tags considered per token by a factor of more than 12 without noticeably affecting tagging accuracy. The combination of these techniques reduces the number of non-zero feature weights used per token by a factor of 75, which, in our Perl implementation, speeds up tagging by a factor of 45.

3.1 Combining Feature Weights

The base lexical feature types in our model form a natural hierarchy as follows:

1. Original case tokens
   1.1. Unsupervised distributional word clusters
   1.2. Lower-cased tokens
      1.2.1. Lower-cased 4-character prefixes
         1.2.1.1. Lower-cased 3-character prefixes
            1.2.1.1.1. Lower-cased 2-character prefixes
               1.2.1.1.1.1. Lower-cased 1-character prefixes
      1.2.2. Lower-cased 4-character suffixes
         1.2.2.1. Lower-cased 3-character suffixes
            1.2.2.1.1. Lower-cased 2-character suffixes
               1.2.2.1.1.1. Lower-cased 1-character suffixes
   1.3. Shape 1 features
      1.3.1. Shape 2 features
         1.3.1.1. Contains upper case token
         1.3.1.2. Contains digit
         1.3.1.3. Contains hyphen

The significance of the hierarchy is that the occurrence of a base feature of any of these types fully determines which features of the types below it in the hierarchy also occur. For example, given a whole token with its original casing, the corresponding features of all the other feature types in the hierarchy are completely determined. Given just the lower-cased version of the token, the lower-cased prefixes

and suffixes are determined, but the distributional word cluster and the shape features are not completely determined, because they depend on capitalization.[2]

We use this hierarchy to perform a simple transformation on the trained tagging model. For every base lexical feature f found in the training data, we add to the value of each feature weight associated with that base feature, the value of all corresponding feature weights for base features below f in the hierarchy. For instance, to the feature weight for the 3-character suffix *ion*, the tag *NN*, and the position -1 (i.e, the word preceding the word being tagged), we add the value of feature weight for the 2-character suffix *on*, the tag *NN*, and the position -1, plus the value of the feature weight for the 1-character suffix *n*, the tag *NN*, and the position -1.

To use this transformed model, we make a corresponding modification to feature extraction in the tagger. We carry out feature extraction top-down with respect to the base feature hierarchy, and whenever we find a base feature f for which there are any corresponding feature weights in the model, we skip the extraction of all the base features below f in the hierarchy. We can do that because the model has been transformed to incorporate the weights for all the skipped features into the corresponding feature weights associated with f. The weights for the skipped features are still kept in the model, so that they can be used when we encounter an unknown feature of the same type as f, such as an unknown whole word, or an unknown 4-character suffix, when we have seen the corresponding 3-character suffix.

The word-class-sequence features are arranged into a similar hierarchy, which is used in a similar way.

1. $\langle c(w_{i-2}), c(w_{i-1}), c(w_{i+1}), c(w_{i+2})\rangle$
   - 1.1. $\langle c(w_{i-2}), c(w_{i-1})\rangle$
   - 1.2. $\langle c(w_{i+1}), c(w_{i+2})\rangle$
   - 1.3. $\langle c(w_{i-1}), c(w_{i+1})\rangle$
     - 1.3.1. $c(w_{i-1})$
     - 1.3.2. $c(w_{i+1})$

Note that in this hierarchy, we have introduced a new feature type that does not actually exist in the trained model, the combination of the word-class bigrams preceding and following the word being tagged. The weights for the features of this type are constructed from the sums of the weights of other features lower in the hierarchy. To keep the size of the transformed model from exploding, we limit the instances of this feature type to those seen at least twice in the training data. We found this covered about 80% of the tagging decisions for the WSJ development set. We also included in the transformed model all possible instances (including those not observed in the training data) of the feature type 1.3 for word-class bigrams surrounding the word being tagged, which allows us to drop the feature weights for the lowest two feature types 1.3.1 and 1.3.2 after their feature weights have been added to the weights for the word-class-bigram features.

Altogether, these transformations increase the size of our full model from 151,174 features with 861,111 non-zero feature weights to 392,318 features with 17,047,515 non-zero feature weights. While this may be a substantial relative increase in size, the resulting model is still not particularly large in absolute terms.

Feature Weight Combination	Features per Token	Weights per Token	Tokens per Second	All Tag Error %	OOV Tag Error %
No	38.0	1215.0	1100	2.69	9.40
Yes	4.7	194.0	6400	2.69	9.40

Table 2: WSJ development set speeds and error rates without and with feature weight combination

In Table 2, we show the effect of these transformations on the speed of tagging the WSJ development set while considering all possible labels for each token. As expected, feature weight combination has no effect on tagging error, since it results in the same tagging decisions as the original model and feature extraction method. The "Features per Token" column shows the average number of features used for

[2]Note that we could have placed the "contains digit" or "contains hyphen" features under "lower-cased tokens" instead of "Shape 2"; our choice here was arbitrary.

each tagging decision, without and with the model and feature extraction feature-weight-combination transformations. The transformations reduce this number by a factor of 8.13. The "Weights per Token" column is the corresponding number of non-zero feature weights used for each tagging decision. Feature weight combination reduces this number by a factor of 6.26.

The "Tokens per Second" measurements are rounded to two significant digits due to the limited precision of our observations. Time was measured to the nearest second, and for each tagger, the data set was replicated enough times for the total tagging time to fall in the range of 100 to 200 seconds. The times reported include only reading the sentence-split tokenized text, extracting features, and predicting tags; time to read in model parameters and initialize the corresponding data structures is not inlcuded. Times are for a single-threaded implementation in Perl on a Linux workstation equipped with Intel Xeon X5550 2.67 GHz processors. In this implementation, feature weight combination increases tagging throughput by a factor of 5.82.

3.2 Pruning Possible Tags

It has long been standard practice to prune the set of possible tags considered for each word, in order to speed up tagging. Ratnaparkhi (1996) may have been the first to use the common heuristic of defining a tag dictionary allowing any tag for unknown words, but restricting each known word to the tags it was observed with in the training data. In addition, the tag dictionary for known words is sometimes further pruned (e.g., Banko and Moore, 2004; Giménez and Màrquez, 2004, 2012) according to the relative frequency of tags for each word. Tags observed in the training data with less than some fixed proportion of the occurrences of a particular word are not considered as possible tags for that word in test data.

In our experiments, we find these heuristics produce fast tagging, but lead to a noticable loss of accuracy, because known words are never allowed to be labeled with tags they were not observed with in the training data. This is similar to the problem of unseen n-grams in statistical language modeling, so we apply methods developed in that field to the problem of dictionary pruning for POS tagging. We construct our tag dictionary based on a "bigram" model of the probability $p(t|w)$ of a tag t given a word w, estimated from the annotated training data. The probabilities for tags that have never been seen with a given word, as well as all the tag probabilities for unknown words, are estimated by interpolation with a "unigram" distribution over the tags.

To estimate the probabilities of tags given words, we use the same interpolated-Kneser-Ney-smoothed (Chen and Goodman, 1999) model that we used in Section 2.2.1 in our supervised word-clustering procedure. In this model, we estimate the probabilty $p(t|w)$ by interpolating a discounted relative frequency estimate with a lower-order estimate of $p(t)$. The lower-order estimates are based on "diversity counts", taking the count of a tag t to be the number of distinct words ever observed with that tag. This has the desirable property for POS tagging that closed-class tags receive a very low estimated probabilty of being assigned to a rare or unknown word, even though they occur very frequently with a small number of frequent words. We use a single value for the discount parameter in the Kneser-Ney formula, chosen to maximize the estimated probability of the reference tagging of the development set. These probabilities are estimated ignoring distinctions among digit characters, just as in the features of our tagging model.

We construct our tag dictionary by setting a threshold on the value of $p(t|w)$. Whenever $p(t|w)$ is less than or equal to the threshold, the tag t is considered not to be a possible POS tag for the word w. Our preferred threshold ($p(t|w) > 0.0005$) is set to prune as agressively as possible while maintaining tagging accuracy on the WSJ development set. This threshold is applied to both known and unknown words, which produces 24 possible tags for unknown words by applying the threshold to the lower-order probability estimate $p(t)$. Note that the probabilities we use for pruning can be viewed as posteriors of a very simple POS tagging model, which makes inferring a tag dictionary an instance of coarse-to-fine inference with posterior pruning (Charniak et al., 2006; Weiss and Taskar, 2010).

The standard tag dictionary pruning heuristics can be viewed as a application of the same approach, but with the $p(t|w)$ probabilities being unsmoothed relative-frequency estimates for known words and a uniform distribution for unknown words. The original Ratnaparkhi heuristic amounts to thresholding these probabilities at 0, with a higher threshold being applied when using additional pruning.

Pruning Method	Tags per Token	Weights per Token	Tokens per Second	All Tag Error %	OOV Tag Error %	Seen Tag Error %	Unseen Tag Error %	OOV Mean Tags	Seen Mean Tags	Unseen Mean Tags
None	45.0	194.0	6400	2.69	9.40	2.19	52.0	45.0	45.0	45.0
Ratnaparkhi	3.7	19.0	47000	2.81	9.40	2.07	100.0	45.0	2.3	1.3
Ratnaparkhi+	2.9	14.3	56000	2.81	9.40	2.07	100.0	45.0	1.4	1.2
Kneser-Ney	3.5	16.1	49000	2.69	9.45	2.18	55.5	21.3	2.8	10.2
Kneser-Ney+	1.8	6.1	67000	2.81	9.74	2.14	83.8	10.6	1.4	2.8

Table 3: WSJ development set speeds and error rates for different tag dictionary pruning methods

In Table 3 we compare these methods of tag dictionary pruning on the WSJ development set, when combined with our feature-weight-combination technique. The "Tags per Token" column shows the average number of tags considered for each tagging decision, depending on the tag pruning method used. "Weights per Token", "Tokens per Second", "All Tag Error %", and "OOV Tag Error %" are as in Table 2. The first line repeats the experiment with no tag dictionary pruning from Table 2. The next line gives results for Ratnaparkhi's dictionary pruning method, and the next line, "Ratnaparkhi+", gives results for the maximum additional pruning by thresholding based on unsmoothed relative frequencies that does not increase overall tagging error ($p(t|w) > 0.005$). We see that these taggers are much faster than the unpruned tagger, but noticeably less accurate.

The final two lines of Table 3 are for our tag dictionary pruning method, with different pruning thresholds. The "Kneser-Ney" line represents our preferred threshold, set to prune as agressively as possible without noticeably degrading the overall tagging error on the WSJ development set. This produces a lower error rate than either Ratnaparkhi or Ratnaparkhi+ pruning, but Ratnaparkhi+ pruning results in faster tagging. However, if we increase the pruning threshold until we match the Ratnaparkhi+ error rate, as shown in the final "Kneser-Ney+" line, our method is faster than Ratnaparkhi+.

The remaining columns of Table 3 provide some insight as to why Kneser-Ney-smoothed pruning with our preferred threshold results in lower error than Ratnaparkhi and Ratnaparkhi+ pruning. The column labeled "Seen Tag Error %" is the error rate for examples with word/tag pairs seen in training. The column labeled "Unseen Tag Error %" is the error rate for examples with word/tag pairs not seen in training, but with a word that was seen in training. There are 660 of the latter examples in the WSJ development set, which amounts to 0.5% of that data set. By construction, the error rate of the Ratnaparkhi and Ratnaparkhi+ pruning methods on this subset of the data is 100%, but both the unpruned tagger and the tagger with Kneser-Ney-smoothed pruning correctly tag nearly half of these examples.

The Ratnaparkhi and Ratnaparkhi+ pruning methods are somewhat more accurate than the Kneser-Ney-smoothed pruning method on the seen word/tag pairs and the unknown words, but not enough to overcome the losses on the unseen word/tag pairs with known words. In absolute numbers on the WSJ development set, both the Ratnaparkhi and Ratnaparkhi+ pruning methods make 131 fewer errors on the seen word/tag pairs and 2 fewer errors on the unknown words, but 294 more errors on the unseen word/tag pairs with known words, compared to Kneser-Ney-smoothed pruning method with our preferred threshold. The final three columns of Table 3 show the mean number of tags allowed by each dictionary for these three categories of examples. Compared to Ratnaparkhi and Ratnaparkhi+ pruning, our preferred threshold for Kneser-Ney-smoothed pruning slightly increases the number of tags considered for seen word/tag pairs, substantially reduces the number of tags considered for unknown words, and substantially increases the number of tags considered for unseen word/tag pairs with known words.

4 Comparison to Other Taggers

We compared our tagger to several publicly available taggers, on the standard WSJ POS tagging test set. As far as we know, six taggers have been reported to have an error rate of less than 2.7% (accuracy greater than 97.3%) on this test set. Three of these are publicly available: the Stanford tagger (Toutanova et al., 2003; Manning, 2011), the Prague COMPOST tagger (Spoustová, et al., 2009), and the UPenn

bidirectional tagger (Shen et al., 2007).[3] We tested two versions of the Stanford tagger, one based on their most accurate model "wsj-0-18-bidirectional-distsim", and one based on the much faster, but less accurate model "english-left3words-distsim" recommended for practical use on the Stanford tagger website. The UPenn tagger is run with a beam width of 3, which is the setting that gave their best reported results.

These taggers were all tested on on the same Linux workstation as our Perl tagger. To obtain comparable speed measurements omitting time for initialization, we performed two runs with each tagger. one on the first 1000 sentences of the test set, and another with those 1000 sentences followed by the entire test set replicated enough times to produce a difference in total time of at least 100 seconds. The tagging speed was inferred from the difference in these two times. The Stanford tagger reports tagging times directly, and these agreed with our measurements to two significant digits, which is the precision limit of our measurements.

We also report on the SVMTool tagger of Giménez and Màrquez (2004). Giménez recently provided us with benchmarks, which he obtained with a somewhat faster processor than ours, the Intel Xeon X5660 2.80 GHz. We give results for two versions of this tagger, one in Perl and one in C++, both with a combination of left-to-right and right-to-left tagging, which gives higher accuracy with this tagger than either direction by itself.

Tagger	Implementation Language	WSJ Tokens per Second	WSJ All Tag Error %	WSJ OOV Tag Error %	Brown Tokens per Second	Brown All Tag Error %	Brown OOV Tag Error %
This work	Perl	51000	2.66	9.02	40000	3.46	10.64
Stanford fast	Java	80000	3.13	10.31	50000	4.47	12.62
Stanford accurate	Java	5900	2.67	7.90	1600	3.86	11.21
COMPOST	C	2600	2.57	10.03	2700	3.36	12.16
UPenn	Java	270	2.67	10.39	290	3.90	12.96
SVMTool	Perl	1340	2.86	11.37			
SVMTool	C++	7700	2.86	11.37			

Table 4: WSJ test set and Brown corpus speeds and error rates compared to publicly available taggers

Results on the WSJ test set are shown in Table 4. We include a column giving the implementation language of each tagger to help interpret the results. Generally, we would expect an algorithm implemented in Perl to be slower than the same algorithm implemented in Java, which in turn would probably be slower than the same algorithm implemented in C/C++; although depending on the libraries used and the degree of optimization in the compilers, Java can sometimes be competitive with C/C++ (See, for example, `http://blog.famzah.net/2010/07/01/cpp-vs-python-vs-perl-vs-php-performance-benchmark/`).

"This work" refers to our tagger with feature weight combination and Kneser-Ney-smoothed dictionary pruning, with the pruning threshold set to maximize pruning without decreasing overall tagging accuracy on the WSJ development set. The fast Stanford tagger is the fastest overall by a wide margin, but it is also the least accurate. Our tagger is both the second fastest and the second most accurate, having an error rate relatively 3.9% higher (absolutely 0.09% higher) than the COMPOST tagger. But our tagger is almost 20 times faster than COMPOST, and more than 8 times faster than the accurate Stanford tagger, the second fastest tagger of equivalent or better accuracy. This is despite the fact that our tagger is written in Perl, while the other high-accuracy taggers are written either in Java or C.

As a final, out-of-domain evaluation, we ran the five taggers that we had direct access to on the Brown Corpus subset (3279 sentences, 83769 tokens) from the Penn Treebank. As might be expected, tagging was in general both slower and less accurate than on in-domain data. Our tagger maintained its relative position with respect to both speed and accuracy compared to all the other taggers. The only qualitative change in position of any tagger is that on the Brown Corpus data, the accurate Stanford tagger is slower than COMPOST, which actually runs faster than it does on the WSJ test set.

[3] A fourth tagger, the semi-supervised condensed nearest neighbor tagger of Søgaard (2011), has some released source code, but not a complete tagger nor detailed instructions on how to build the tagger Søgaard evaluates.

5 Conclusions

We have shown that a feature-rich model for POS tagging by independent classifiers can reach tagging accuracies comparable to several state-of-the art taggers, and we have introduced implementation strategies that result in much faster tagging than any other high-accuracy tagger we are aware of, despite these other taggers being implemented in faster programming languages.

A number of the techniques introduced here may have applications to other tasks. The sort of word-class-sequence models derived by supervised clustering described in Section 2.2 may be useful for other sequence labeling tasks, such as named-entity recognition. Our method of pruning the tag dictionary with smoothed probability distributions could also be used for label pruning for other problems with large label sets. Finally, the feature-weight-combination technique of Section 3.1 can be applied to any rich feature space in which the features have the kind of hierarchical structure we see in POS tagging. Such feature spaces are common in NLP, since we are almost always dealing with lexical items and their sublexical features.

Abstract

Morfessor is a family of methods for learning morphological segmentations of words based on unannotated data. We introduce a new variant of Morfessor, FlatCat, that applies a hidden Markov model structure. It builds on previous work on Morfessor, sharing model components with the popular Morfessor Baseline and Categories-MAP variants. Our experiments show that while unsupervised FlatCat does not reach the accuracy of Categories-MAP, with semi-supervised learning it provides state-of-the-art results in the Morpho Challenge 2010 tasks for English, Finnish, and Turkish.

1 Introduction

Morphological analysis is essential for automatic processing of compounding and highly-inflecting languages, for which the number of unique word forms may be very large. Apart from rule-based analyzers, the task has been approached by machine learning methodology. Especially unsupervised methods that require no linguistic resources have been studied widely (Hammarström and Borin, 2011). Typically these methods focus on morphological segmentation, i.e., finding *morphs*, the surface forms of the morphemes.

For language processing applications, unsupervised learning of morphology can provide decent-quality analyses without resources produced by human experts. However, while morphological analyzers and large annotated corpora may be expensive to obtain, a small amount of linguistic expertise is more easily available. A well-informed native speaker of a language can often identify the different prefixes, stems, and suffixes of words. Then the question is how many annotated words makes a difference. One answer was provided by Kohonen et al. (2010), who showed that already one hundred manually segmented words provide significant improvements to the quality of the output when comparing to a linguistic gold standard.

The semi-supervised approach by Kohonen et al. (2010) was based on Morfessor Baseline, the simplest of the Morfessor methods by Creutz and Lagus (2002; 2007). The statistical model of Morfessor Baseline is simply a categorical distribution of morphs—a unigram model in the terms of statistical language modeling. As the semi-supervised Morfessor Baseline outperformed all unsupervised and semi-supervised methods evaluated in the Morpho Challenge competitions (Kurimo et al., 2010a) so far, the next question is how the approach works for more complex models.

Another popular variant of Morfessor, Categories-MAP (CatMAP) (Creutz and Lagus, 2005), models word formation using a hidden Markov model (HMM). The context-sensitivity of the model improves the precision of the segmentation. For example, it can prevent splitting a single *s*, a common English suffix, from the beginning of a word. Moreover, it can disambiguate between identical morphs that are actually surface forms of different morphemes. Finally, separation of stems and affixes in the output makes it simple to use the method as a stemmer.

In contrast to Morfessor Baseline, the lexicon of CatMAP is *hierarchical*: a morph that is already in the lexicon may be used to encode the forms of other morphs. This has both advantages and drawbacks.

Proceedings of COLING 2014, the 25th International Conference on Computational Linguistics: Technical Papers, pages 1177–1185, Dublin, Ireland, August 23-29 2014.

One downside is that it mixes the prior and likelihood components of the cost function, so that the semi-supervised approach presented by Kohonen et al. (2010) is not usable.

1.1 Hierarchical versus flat lexicons

From the viewpoint of data compression and following the two-part Minimum Description Length principle (Rissanen, 1978), Morfessor tries to minimize the number of bits needed to encode both the model parameters and the training data. Equivalently, the cost function L can be derived from the Maximum a Posteriori (MAP) estimate:

$$\hat{\theta} = \arg\max_{\theta} \mathrm{P}(\theta \mid \boldsymbol{D}) = \arg\min_{\theta} \big(-\log \mathrm{P}(\theta) - \log \mathrm{P}(\boldsymbol{D} \mid \theta) \big) = \arg\min_{\theta} L(\theta, \boldsymbol{D}), \qquad (1)$$

where θ are the model parameters, $\boldsymbol{D}$ is the training corpus, $\mathrm{P}(\theta)$ is the prior of the parameters and $\mathrm{P}(\boldsymbol{D} \mid \theta)$ is the data likelihood.

In context-independent models such as Morfessor Baseline, the parameters include only the forms and probabilities of the morphs in the lexicon of the model. Morfessor Baseline and Categories-ML (CatML) (Creutz and Lagus, 2004) use a flat lexicon, in which the forms of the morphs are encoded directly as strings: each letter requires a certain number of bits to encode. Thus longer morphs are more expensive. Encoding a long morph is worthwhile only if the morph is referred to frequently enough from the words in the training data. If a certain string, let us say *segmentation*, is common enough in the training data, it is cost-effective to have it as a whole in the lexicon. Splitting it into two items, *segment* and *ation*, would double the number of pointers from the data, even if those morphs were already in the lexicon. The undersegmentation of frequent words becomes evident especially if the training data is a corpus instead of a list of unique word forms.

In contrast, Morfessor CatMAP applies a hierarchical lexicon, which makes use of the morphs that are already in the lexicon. Instead of encoding the form of *segmentation* by its 12 letters, we could just encode the form with two references to the forms of the morphs *segment* and *ation*. This may also cause errors, for example encoding *station* with *st* and *ation*.

The lexicon of Morfessor CatMAP allows but does not force hierarchical encoding for the forms: each morph has an extra parameter that indicates whether it has a hierarchical representation or not. The problem of oversegmentation, as in *st* + *ation*, is solved using the morph categories. The categories, which are states of the HMM, include stem, prefix, suffix, and a special non-morpheme category. The non-morpheme category is intended to catch segments that do not fit well into the three proper morph categories because they are fragments of a larger morph. In our example, the morph *st* cannot be a suffix as it starts the word, it is unlikely to be a prefix as it directly precedes a common suffix *ation*, and it is unlikely to be a stem as it is very short. Thus the algorithm is likely to use the non-morpheme state. The hierarchy is expanded only up to the level in which there are no non-morphemes, so the final analysis is still *station*. Without the hierarchy, the non-morphemes have to be removed heuristically, as in CatML (Creutz and Lagus, 2004).

A hierarchical lexicon presents some challenges to model training. For a standard unigram or HMM model, if you know the state and emission sequence of the training data, you can directly derive the maximum likelihood (ML) parameters of the model: a probability of a morph is proportional to the number of times it is referred to, conditional on the state in the HMM. But if the lexicon is partly hierarchical, also the references *within* the lexicon add to the reference counts, and there is no direct way to find the ML parameters even if the encoding of the training data is known. Similarly, semi-supervised learning cannot be accomplished simply by adding the counts from an annotated data set, as it is not clear when to use hierarchy instead of segmenting a word directly in the data.

Moreover, for a flat lexicon, the cost function divides into two parts that have opposing optima: the cost of the data (likelihood) is optimal when there is minimal splitting and the lexicon consists of the words in the training data, whereas the cost of the model (prior) is optimal when the lexicon is minimal and consists only of the letters. In consequence, the balance of precision and recall of the segmentation boundaries can be directly controlled by setting a weight for the data likelihood. Tuning this hyperparameter is a very simple form of supervision, but it has drastic effects on the segmentation results

(Kohonen et al., 2010). A direct control of the balance may also be useful for some applications: Virpioja et al. (2011) found that the performance of the segmentation algorithms in machine translation correlates more with the precision than the recall. The weighting approach does not work for hierarchical lexicons, for which changing the weight does not directly affect the decision whether to encode the morph with hierarchy or not.

1.2 Morfessor FlatCat

In this paper, we introduce a new member to the Morfessor family, Morfessor FlatCat. As indicated by its name, FlatCat uses a flat lexicon. Our hypothesis is that enabling semi-supervised learning is effective in compensating for the undersegmentation caused by the lack of hierarchy. In particular, semi-supervised learning can improve modeling of suffixation. In the examined languages, suffixes tend to serve syntactic purposes, such as marking case, tense, person or number. Examples are the suffix *s* marking tense and person in *she writes* and number in *stations*. Thus the suffix class is closed and has only a small number of morphemes compared to the prefix and stem categories. As a consequence, a large coverage of suffixes can be achieved already with a relatively small annotated data set.

The basic model of morphotactics in FlatCat is the same as in the CatML and CatMAP variants: a hidden Markov model with states that correspond to a word boundary and four morph categories: stem, prefix, suffix, and non-morpheme. As in CatML, we apply heuristics for removal of non-morphemes from the final segmentation. However, because FlatCat uses MAP estimation of the parameters, these heuristics are not necessary during the training for controlling the model complexity, but merely used as a post-processing step to get meaningful categories.

Modeling of morphotactics improves the segmentation of compound words, by allowing the overall level of segmentation to be increased without increasing the number of correct morphs used in incorrect positions. As the benefits of semi-supervised learning and improved morphotactics are likely to complement each other, we can expect improved performance over the semi-supervised Morfessor Baseline method. By experimental comparison to the previous Morfessor variants, we are able to shed more light on the effects of using an HMM versus unigram model for morphotactics, using a hierarchical versus flat lexicon, and exploiting small amounts of annotated training data.

2 FlatCat model and algorithms

Morfessor FlatCat uses components from the older Morfessor variants. Instead of going through all the details, we refer to the previous work and highlight only the differences. Common components between Morfessor methods are summarized in Table 1.

As a generative model, Morfessor FlatCat describes the joint distribution $\mathrm{P}(\boldsymbol{A}, \boldsymbol{W} \mid \theta)$ of words and their analyses. The words $\boldsymbol{W}$ are observed, but their analyses, $\boldsymbol{A}$, is a latent variable in the model. An analysis of a word contains its morphs and morph categories: prefix, stem, suffix, and non-morpheme.

As marginalizing over all possible analyses is generally infeasible, point estimates are used during the training. The likelihood conditioned on the current analyses is

$$\mathrm{P}(\boldsymbol{D} \mid \boldsymbol{A}, \theta) = \prod_{j=1}^{|\boldsymbol{D}|} \mathrm{P}(\boldsymbol{A}_j \mid \theta). \tag{2}$$

If m_i are the morphs in $\boldsymbol{A}_j$, c_i are the hidden states of the HMM corresponding to the categories of the morphs, and $\#$ is the word boundary, $\mathrm{P}(\boldsymbol{A}_j \mid \theta)$ is

$$\mathrm{P}(c_1 \mid \#) \prod_{i=1}^{|\boldsymbol{A}_j|} \left[\mathrm{P}(m_i \mid c_i)\, \mathrm{P}(c_{i+1} \mid c_i) \right] \mathrm{P}(\# \mid c_{|\boldsymbol{A}_j|}). \tag{3}$$

Morfessor FlatCat applies an MDL-derived prior designed to control the number of non-zero parameters. The prior is otherwise the same as in Morfessor Baseline, but it includes the usage properties from Morfessor CatMAP: the length of the morph and its right and left perplexity. The perplexity measures describe the predictability of the contexts in which the morph occurs. The emission probability of

a morph conditioned on the morph category, $\mathrm{P}(m \mid c)$, is calculated from the properties of the morphs similarly as in CatMAP.

2.1 Training algorithms

The parameters are optimized using a local search. Only a part of the parameters are optimized in each step: the parameters that are used in calculating the likelihood of a certain part, *unit*, of the corpus. Units vary in complexity, from all occurrences of a certain morph to the occurrences of a morph bigram whose context fits to certain criteria.

The algorithm tries to simultaneously find the optimal segmentation for the unit and the optimal parameters consistent with that segmentation:

$$(\boldsymbol{A}, \theta) = \underset{\textsc{Op}(\boldsymbol{A},\theta)}{\arg\min} \big\{ L(\theta, \boldsymbol{A}, \boldsymbol{D}) \big\}. \tag{4}$$

The training operators OP define the units changed by the local search and the alternative segmentations tried for each unit. There are three training operators: *split, join* and *resegment*, analogous to the similarly named stages in CatMAP.

The split operator is applied first. It targets all occurrences of a specific morph in the corpus simultaneously, attempting to split it into two parts. The whole corpus is processed by sorting the current morphs by length from shortest to longest.

The second operator attempts to join morph bigrams, grouped by the position of the bigram in the word. The position grouped bigram counts are sorted by frequency, from most to least common.

Finally, resegmenting uses the generalized Viterbi algorithm to find the currently optimal segmentation for one whole word at a time. This operator targets each corpus word in increasing order of frequency.

The heuristics used in FlatCat to remove non-morphemes from the final segmentation are the following: All consequent non-morphemes are joined together. If the resulting morph is longer than 4 characters, it is accepted as a stem. All non-morphemes preceded by a suffix and followed by only suffixes or other non-morphemes are recategorized as suffixes without joining with their neighbors. If any short non-morphemes remain, they are joined either to the preceding or following morphs (the latter only for those in the initial position).

2.2 Semi-supervised learning

Kohonen et al. (2010) found that semi-supervised learning of Morfessor models was not effective by only fixing the values of the analysis $\boldsymbol{A}$ for the annotated samples $\boldsymbol{D}_A$. Their solution was to introduce corpus likelihood weights α and β, one for the unannotated data set and one for the annotated data set. Thus, instead of optimizing the MAP estimate, Kohonen et al. (2010) minimize the cost

$$L(\theta, \boldsymbol{A}, \boldsymbol{D}, \boldsymbol{D}_A) = -\log \mathrm{P}(\theta) - \alpha \log \mathrm{P}(\boldsymbol{D} \mid \boldsymbol{A}, \theta) - \beta \log \mathrm{P}(\boldsymbol{D}_A \mid \boldsymbol{A}, \theta). \tag{5}$$

The weights can be tuned on a development set. We use the same scheme for FlatCat.

The likelihood of the annotated data is calculated using the same HMM that is used for the unannotated data. The morph properties are estimated only from the unannotated data. To ensure that the morphs required for the annotated data can be emitted, a copy of each word in the annotations is added to the

unannotated data. This unannotated copy is loosely linked to the annotated word: operations that would result in the removal of a morph required for the annotations from the lexicon cannot be selected, as such an operation would have infinite cost.

3 Experiments

We compare Morfessor FlatCat[1] to two previous Morfessor methods and a fully supervised discriminative segmentation method. The Morfessor methods used as references are the CatMAP[2] and Baseline[3] implementations by Creutz and Lagus (2005) and Virpioja et al. (2013), respectively. Virpioja et al. (2013) implements the semi-supervised method described by Kohonen et al. (2010). For a supervised discriminative model, we use a character-level conditional random field (CRF) implementation by Ruokolainen et al. (2013)[4].

We use the English, Finnish and Turkish data sets from Morpho Challenge 2010 (Kurimo et al., 2010b). They include large unannotated word lists, one thousand annotated words for training, 700–800 annotated words for parameter tuning, and 10×1000 annotated words for testing.

For evalution, we use the BPR score by Virpioja et al. (2011). The score calculates the precision (Pre), recall (Rec), and F_1-score (F) of the predicted morph boundaries compared to a linguistic gold standard. In the presence of alternative gold standard analyses, we weight each alternative equally.

We also report the mean average precision from the English and Finnish information retrieval (IR) tasks of the Morpho Challenge. The Lemur Toolkit (Ogilvie and Callan, 2001) with Okapi BM25 ranking was used. The Finnish data consists of 55K documents, 50 test queries and 23K binary relevance assessments. The English data consists of 170K documents, 50 test queries and 20K binary relevance assessments. The domain of both data sets is short newspaper articles. All word forms in both the corpora and the queries were replaced by the morphological segmentation to be evaluated.

Morfessor FlatCat is a pipeline method that refines an initial segmentation given as input. We try two different initializations for the semi-supervised setting: initializing with the segmentation produced by semi-supervised Morfessor Baseline, and initializing with the CRF segmentation. All unsupervised and likelihood-weighted results are initialized with the corresponding Baseline output.

All methods were trained using word types. The weight and perplexity threshold parameters were optimized separately for each method, using a grid search with the held-out data set. The supervised CRF method was trained using the one thousand word annotated training data set.

Abbreviations have been used for Unsupervised (U), likelihood weighted (W), semi-supervised (SS) and fully supervised (S) methods. Best results for each measure have been hilighted using boldface.

3.1 Comparison to linguistic gold standards

The results of the BPR evaluations are shown in Tables 2 (English, Finnish) and 3 (Turkish). Semi-supervised FlatCat initialized using CRF achieves the highest F-score for both the English and Turkish data sets. The difference between the highest and second-highest scoring methods is statistically significant for Finnish and Turkish, but not for English (Wilcoxon signed-rank test, $p < 0.01$).

Table 4 shows BPR for subsets of words consisting of different morph category patterns. Each subset consists of 500 words from the English or Finnish gold standard, with one of five selected morph patterns as the only valid analysis. The subsets consist of words with the following morph patterns: words that should not be segmented (STM), compound words consisting of exactly two stems (STM + STM), a prefix followed by a stem (PRE + STM), a stem followed by a single suffix (STM + SUF) and a stem and exactly two suffixes (STM + SUF + SUF). For the STM pattern only precision is reported, as recall is not defined for an empty set of true boundaries.

The fact that semi-supervised FlatCat compares well against CatMAP in recall, for all morph patterns and for the test set as a whole, indicates that supervision indeed is effective in compensating for the undersegmentation caused by the lack of hierarchy in the lexicon. The benefit of modeling morphotactics can be seen in improved precision for the STM + STM (for English and Finnish) and PRE + STM (for Finnish) patterns when comparing against semi-supervised Baseline. The more aggressive segmentation of Baseline gives better results for the English PRE + STM subset than for Finnish due to the shortness of the English prefixes (on average 3.6 letters for the English and 5.3 for the Finnish subset). While not directly observable in Table 4, a large part of the improvement over semi-supervised Baseline is explained by that FlatCat does not use suffix-like morphs in incorrect positions.

Initializing the FlatCat model with CRF segmentation improves the F-scores in all subsets compared to the initialization with Morfessor Baseline. While FlatCat cannot keep the accuracy of the suffix boundaries at as high level as CRF, it clearly improves the stem splitting.

3.2 Information retrieval

Stemming has been shown to improve IR results (Kurimo et al., 2009), by removing inflection that is often not relevant to the query. The morph categories make it possible to simulate stemming by removing morphs categorized as prefixes or suffixes. As longer affixes are more likely to be meaningful, we limited the affix removal to morphs of at most 3 letters. For methods that use morph categories, we report two IR results: the first using all the data and the second with short affix removal (SAR) applied.

In the IR results, we include the topline methods from Morpho Challenge: Snowball Porter stemmer (Porter, 1980) for English and "TWOL first" for Finnish. The latter selects the lemma from the first of the possible analyses given by the morphological analyzer FINTWOL (Lingsoft, Inc.) based on the

two-level model by Koskenniemi (1983). As baseline results we also include unsegmented word forms and truncating each word after the first five letters (First 5).

The results of the IR experiment are shown in Table 5. FlatCat provides the highest score for Finnish. The English scores are similar to those of the semi-supervised Baseline. FlatCat performs better than CRF for both languages. This is explained by the higher level of consistency in the segmentations produced by FlatCat, which makes the resulting morphs more useful as query terms. The number of morphs in the lexicons of FlatCat initialized using CRF are 108 391 (English), 46 123 (Finnish) and 74 193 (Turkish), which is much smaller than the respective morph lexicon sizes counted from the CRF segmentation: 339 682 (English), 396 869 (Finnish) and 182 356 (Turkish). This decrease in lexicon size indicates a more structured segmentation.

The IR performance of semi-supervised FlatCat benefits from the removal of short affixes for English when initialized by CRF, and Finnish for both initializations. It also improves the results of unsupervised FlatCat and CatMAP for Finnish, but lowers the precision for English. A possible explanation is that the unsupervised methods do not analyze the suffixes with a high enough accuracy.

4 Conclusions

We have introduced a new variant of the Morfessor method, Morfessor FlatCat. It predicts both morphs and their categories based on unannotated data, but also annotated training data can be provided. It was shown to outperform earlier Morfessor methods in the semi-supervised learning task for English, Finnish and Turkish.

The purely supervised CRF-based segmentation method proposed by Ruokolainen et al. (2013) outperforms FlatCat for Finnish and reaches the same level for English. However, we show that a discriminative model such as CRF gives inconsistent segmentations that do not work as well in a practical application: In English and Finnish information retrieval tasks, FlatCat clearly outperformed the CRF-based segmentation.

We see two major directions for future work. Currently Morfessor FlatCat, like most Morfessor methods, assumes that words in a sentence occur independently. Making use of the sentence context in which words occur would, however, allow making Part-Of-Speech -like distinctions. These distinctions could

help disambiguate inflections of different lexemes that have the same surface form but should be analyzed differently (Can and Manandhar, 2013).

The second direction is removal of the assumption that a morphology consists only of concatenative processes. Introducing transformations to model allomorphy in a similar manner as Kohonen et al. (2009) would allow finding the shared abstract morphemes underlying different allomorphs. This could be especially beneficial in information retrieval and machine translation applications.

Abstract

Although Japanese has relatively free word order, Japanese word order is not completely arbitrary and has some sort of preference. Since such preference is incompletely understood, even native Japanese writers often write Japanese sentences which are grammatically well-formed but not easy to read. This paper proposes a method for reordering words in a Japanese sentence so that the sentence becomes more readable. Our method can identify more suitable word order than conventional word reordering methods by concurrently performing dependency parsing and word reordering instead of sequentially performing the two processing steps. As the result of an experiment on word reordering using newspaper articles, we confirmed the effectiveness of our method.

1 Introduction

Japanese has relatively free word order, and thus Japanese sentences which make sense can be written without having a strong awareness of word order. However, Japanese word order is not completely arbitrary and has some sort of preference. Since such preference is incompletely understood, even native Japanese writers often write Japanese sentences which are grammatically well-formed but not easy to read. The word reordering of such sentences enables the readability to be improved.

There have been proposed some methods for reordering words in a Japanese sentence so that the sentence becomes easier to read (Uchimoto et al., 2000; Yokobayashi et al., 2004). In addition, there exist a lot of researches for estimating appropriate word order in various languages (Filippova and Strube, 2007; Harbusch et al., 2006; Kruijff et al., 2001; Ringger et al., 2004; Shaw and Hatzivassiloglou, 1999). Although most of these previous researches used syntactic information, the sentences they used there were what had been previously parsed. It is a problem that word reordering suffers the influence of parsing errors. Furthermore, as the related works, there are various researches on word reordering for improving the performance of statistical machine translation (Goto et al., 2012; Elming, 2008; Ge, 2010; Christoph and Hermann, 2003; Nizar, 2007). These researches consider information as to both a source language and a target language to handle word order differences between them. Therefore, their problem setting is different from that for improving the readability of a single language.

This paper proposes a method for reordering words in a Japanese sentence so that the sentence becomes easier to read for revision support. Our proposed method concurrently performs dependency parsing and word reordering for an input sentence of which the dependency structure is still unknown. Our method can identify more suitable word order than conventional word reordering methods because it can concurrently consider the preference of both word order and dependency. An experiment using newspaper articles showed the effectiveness of our method.

2 Word Order and Dependency in Japanese Sentences

There have been a lot of researches on Japanese word order in linguistics (for example, Nihongo Kijutsu Bunpo Kenkyukai, 2009; Saeki, 1998), which have marshalled fundamental contributing factors which

Proceedings of COLING 2014, the 25th International Conference on Computational Linguistics: Technical Papers, pages 1186–1196, Dublin, Ireland, August 23-29 2014.

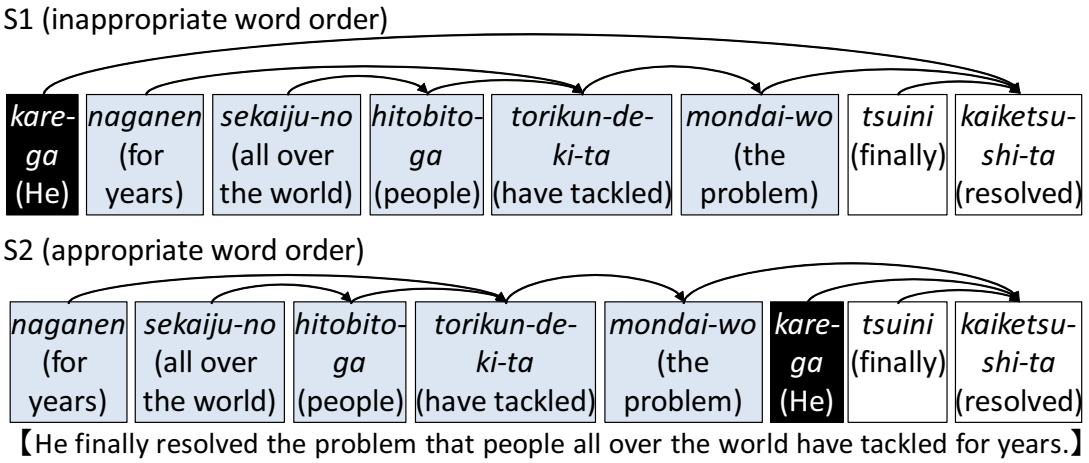

Figure 1: Example of inappropriate/appropriate word order

decide the appropriate word order in detail. In a Japanese sentence, a predicate of the main clause is fundamentally placed in last position, and thus, case elements, adverbial elements, or subordinate clauses are located before it. In addition, case elements are basically placed in the order of a nominative, a dative and an accusative. However, the basic order of case elements is often changed by being influenced from grammatical and discourse factors. For example, it is pointed out that a long case element has strong preference to be located at the beginning of a sentence even if the element is not nominative, as shown in Figure 1.

In Figure 1, a box and an arrow express a *bunsetsu*[1] and a dependency relation respectively. Both the sentences S1 and S2 have the same meaning which is translated as "He finally resolved the problem that people all over the world have tackled for years" in English. The difference between S1 and S2 is just in their word orders in Japanese.

The word order of S1 is more difficult to read than that of S2 because the distance between the bunsetsu "*kare-ga* (He)" and its modified bunsetsu "*kaiketsu-shi-ta* (resolved)" is large and thus the loads on working memory become large. This example suggests that if the dependency structure of S1 is identified, that information is useful to reorder the word order of S1 to that of S2 so that it becomes easier to read. In fact, most of the conventional word reordering methods have reordered words using the previously parsed dependency structure. However, the word order of S1 is thought to be more difficult to parse than that of S2 because dependency parsers are usually trained on syntactically annotated corpora in which sentences have the appropriate word order such as that in S2. This is why it is highly possible that dependency parsing can achieve a higher accuracy by changing the word order of S1 to that of S2 in advance.

The above observations indicate that word reordering and dependency parsing depend on each other. Therefore, we consider it is more desirable to concurrently perform the two processings than to sequentially perform them.

3 Word Reordering Method

In our method, a sentence, on which morphological analysis and bunsetsu segmentation have been performed, is considered as the input[2]. We assume that the input sentence might have unsuitable word order,

[1] *Bunsetsu* is a linguistic unit in Japanese that roughly corresponds to a basic phrase in English. A bunsetsu consists of one independent word and zero or more ancillary words. A dependency relation in Japanese is a modification relation in which a modifier bunsetsu depends on a modified bunsetsu. That is, the modifier bunsetsu and the modified bunsetsu work as modifier and modifyee, respectively.

[2] In order to focus attention on the comparison between our method and the conventional method, we assumed the input on which the lower layer processings than dependency parsing have been performed. Even if morphological analysis and bunsetsu segmentation are automatically performed on input sentences which have unsuitable word order, we can expect the accuracies

which is not easy to read but grammatically well-formed. Our method identifies the suitable word order which is easy to read by concurrently performing dependency parsing.

The simultaneous performing of dependency parsing and word reordering is realized by searching for the maximum-likelihood pattern of word order and dependency structure for the input sentence. Note our method reorders bunsetsus in a sentence without paraphrasing and does not reorder morphemes within a bunsetsu.

3.1 Probabilistic Model for Word Reordering

When a sequence of bunsetsus in an input sentence $B = b_1 \cdots b_n$ is provided, our method identifies the structure S which maximizes $P(S|B)$. The structure S is defined as a tuple $S = \langle O, D \rangle$ where $O = \{o_{1,2}, o_{1,3}, \cdots, o_{1,n}, \cdots, o_{i,j}, \cdots, o_{n-2,n-1}, o_{n-2,n}, o_{n-1,n}\}$ is the word order pattern after reordering and $D = \{d_1, \cdots, d_{n-1}\}$ is dependency structure. Here, $o_{i,j}$ $(1 \leq i < j \leq n)$ expresses the order between b_i and b_j after reordering. $o_{i,j}$ is 1 if b_i is located before b_j, and is 0 otherwise. In addition, d_i expresses the dependency relation whose modifier bunsetsu is b_i.

$P(S|B)$ for a $S = \langle O, D \rangle$ is calculated as follows.

$$\begin{aligned} P(S|B) &= P(O, D|B) \\ &= \sqrt{P(O|B) \times P(D|O, B) \times P(D|B) \times P(O|D, B)} \end{aligned} \quad (1)$$

Formula (1) is obtained for the product of the following two formulas. According to the probability theory, the calculated result of Formula (1) is equal to those of Formulas (2) and (3). However, in practice, since each factor in the formulas is estimated based on the corpus used for training, the calculated results of these formulas are different from each other. We use Formula (1) to estimate $P(S|B)$ by using both values of $P(D|O, B)$ and $P(O|D, B)$. In fact, we pre-experimentally confirmed that the calculated result of Formula (1) was better than those of the others.

$$P(O, D|B) = P(O|B) \times P(D|O, B) \quad (2)$$

$$P(O, D|B) = P(D|B) \times P(O|D, B) \quad (3)$$

Assuming that order $o_{i,j}$ between two bunsetsus is independent of that between other two bunsetsus and that each dependency relation d_i is independent of the others, each factor in Formula (1) can be approximated as follows:

$$P(O|B) \cong \prod_{i=1}^{n-1} \prod_{j=i+1}^{n} P(o_{i,j}|B) \quad (4)$$

$$P(D|O, B) \cong \prod_{i=1}^{n-1} P(d_i|O, B) \quad (5)$$

$$P(D|B) \cong \prod_{i=1}^{n-1} P(d_i|B) \quad (6)$$

$$P(O|D, B) \cong \prod_{i=1}^{n-1} \prod_{j=i+1}^{n} P(o_{i,j}|D, B) \quad (7)$$

where $P(o_{i,j}|B)$ is the probability that the order between b_i and b_j is $o_{i,j}$ when B is provided, $P(d_i|O, B)$ is the probability that the dependency relation whose modifier bunsetsu is b_i is d_i when the sentence generated by reordering B according to O is provided, $P(d_i|B)$ is the probability that the dependency relation whose modifier bunsetsu is b_i is d_i when B is provided, and $P(o_{i,j}|D, B)$ is the probability that the order between b_i and b_j is $o_{i,j}$ when B where the dependency relation is D is provided. These probabilities are estimated by the maximum entropy method.

remain comparatively high. This is because their processings use mainly local information.

To estimate $P(d_i|O, B)$, we used the features used in Uchimoto et al. (1999) except when eliminating features about Japanese commas (called *toten*, which is a kind of punctuation) and quotation marks. To estimate $P(d_i|B)$, we used the features which can be obtained without information about the order of input bunsetsus among the features used in estimating $P(d_i|O, B)$. To estimate $P(o_{i,j}|D, B)$, if b_i and b_j modifies the same bunsetsu, we used the features used in Uchimoto et al. (2000), except when eliminating features about parallel relations and semantic features. Otherwise, we used the features left after eliminating features about modified bunsetsus from those used in the above-mentioned case. To estimate $P(o_{i,j}|B)$, we used the features which can be obtained without dependency information among the features used to estimate $P(O_{i,j}|D, B)$.

3.2 Search Algorithm

Since there are a huge number of the structures $S = \langle O, D\rangle$ which are theoretically possible for an input sentence B, an efficient algorithm is desired. However, since O and D are dependent on each other, it is difficult to find the optimal structure efficiently. In our research, we extend CYK algorithm used in conventional dependency parsing to efficiently find the suboptimal $S = \langle O, D\rangle$ which maximizes $P(S|B)$ efficiently.

Our research assumes that an input sentence, which is grammatically well-formed, is reordered without changing the meaning so that the sentence becomes much easier to read. From this assumption, we can use following conditions for efficient search:

1. The dependency structure of an input sentence should satisfy the following Japanese syntactic constraints under the input word order:
   - No dependency is directed from right to left.
   - Dependencies don't cross each other.
   - Each bunsetsu, except the last one, depends on only one bunsetsu.
2. Even after the words are reordered, the dependency structure should satisfy the above-mentioned Japanese syntactic constraints under the changed word order.
3. The dependency structures of a sentence before and after reordering should be identical.

Using the condition 1 and the condition 3, we can narrow down the search space of D to dependency structures that satisfy Japanese syntactic constraints under the input word order. Furthermore, the search space of O can be narrowed down to the word order patterns derived from the above narrowed dependency structures based on the conditions 2 and 3. That is, after dependency structures possible for an input sentence are narrowed down, we just have to find the word order patterns after reordering so that each of the dependency structures is maintained and satisfies the Japanese syntactic constraints even under the changed word order.

On the other hand, it is well known that CYK algorithm can efficiently find the optimal dependency structure which satisfies Japanese syntactic constraints. Therefore, in our research, we have extended the CYK algorithm for the conventional dependency parsing so that it can find the suboptimal D and O from among the dependency structures and word order patterns which satisfy the conditions 1, 2 and 3.

3.2.1 Word Reordering Algorithm

Algorithm 1 shows our word reordering algorithm. In our algorithm, the $n \times n$ triangular matrix $M_{i,j}(1 \leq i \leq j \leq n)$ such as the left-side figure in Figure 2 is prepared for an input sentence consisting of n numbers of bunsetsus. $M_{i,j}$, the element of the triangular matrix M in the i-th row and j-th column, is filled by $argmax_{S_{i,j}} P(S_{i,j}|B_{i,j})$, which is the maximum-likelihood structure for an input subsequence $B_{i,j} = b_i \cdots b_j$. In this section, for convenience of explanation, we represent $S_{i,j}$ as a sequence of dependency relations $d_x(i \leq x \leq j)$. For example, $S_{i,j} = d_i d_{i+1} \cdots d_j^0$ means that the first bunsetsu is b_i, the second is b_{i+1}, $\cdots$, the last is b_j, and the dependency structure is $\{d_i, d_{i+1}, \cdots, d_{j-1}\}$. Here, if we need to clearly specify the modified bunsetsu, we represent the dependency relation that bunsetsu

Algorithm 1 word reordering algorithm

15: **end for**
16: **return** $M_{1,n}$

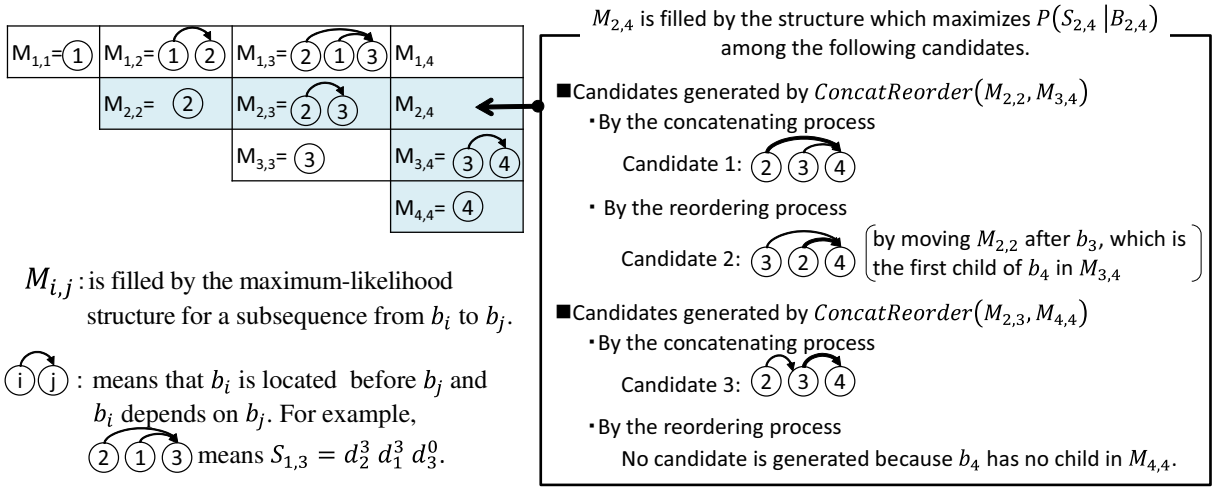

Figure 2: Execution example of our search algorithm

b_x modifies b_y as d_x^y. In addition, d_j^0 means that the last bunsetsu of the subsequence don't modify any bunsetsu.

First, the statements of the lines 4 to 6 fill each of diagonal elements $M_{i,i}$ $(1 \leq i \leq n)$ with d_i^0. Next, the statements of the lines 7 to 15 fill $M_{i,j}$ in turn toward the upper right $M_{1,n}$ along the diagonal line, starting from the diagonal elements $M_{i,i}$. The maximum-likelihood structure which should fill an $M_{i,j}$ is found as follows:

The statements of the lines 10 to 12 repeat the process of generating candidates of the maximum-likelihood structure from $M_{i,k}$ and $M_{k+1,j}$ by the function $ConcatReorder$, and adding them to the set of structure candidates $C_{i,j}$. The function $ConcatReorder$ takes two arguments of $M_{i,k}$ and $M_{k+1,j}$ and returns the set of candidates of the maximum-likelihood structure which should fill $M_{i,j}$. The function $ConcatReorder$ is composed of two processes: concatenating process and reordering process. First, the concatenating process generates a candidate by simply concatenating $M_{i,k}$ and $M_{k+1,j}$ in turn about the word order and connecting $M_{i,k}$ and $M_{k+1,j}$ by the dependency relation between the last bunsetsus of them about the dependency structure, without changing the internal structure of each of them. For example, when $M_{i,k} = d_i d_{i+1} \cdots d_{k-1} d_k^0$ and $M_{k+1,j} = d_{k+1} d_{k+2} \cdots d_{j-1} d_j^0$ are given as the argument, the concatenating process generates "$d_i d_{i+1} \cdots d_{k-1} d_k^j d_{k+1} d_{k+2} \cdots d_{j-1} d_j^0$."

Second, the reordering process generates candidates by reordering words in the candidate generated by the concatenating process. The reordering is executed on the following conditions. The first condition is that the dependency structure is maintained and satisfies the Japanese syntactic constraints even under the changed word order. The second condition is that the order of any two words within each of $M_{i,k}$ and $M_{k+1,j}$ is maintained. Concretely, the first reordered candidate is generated by moving $M_{i,k}$ after the first (leftmost) child[3] of the last bunsetsu of $M_{k+1,j}$ among the children in $M_{k+1,j}$. Then, the second reordered candidate is generated by moving $M_{i,k}$ after the second child. The reordering process is continued until the last reordered candidate is generated by moving $M_{i,k}$ after the last child. That is, the number of candidates generated by the reordering process is equal to the number of children of the last bunsetsu in $M_{k+1,j}$. For example, when $M_{i,k} = d_i d_{i+1} \cdots d_{k-1} d_k^0$ and $M_{k+1,j} = d_{k+1}^j d_{k+2}^j \cdots d_{j-1}^j d_j^0$, which means all bunsetsus except the last one depend on the last one, are given, the reordering process generates the following $j-k-1$ candidates: "$d_{k+1}^j d_i d_{i+1} \cdots d_{k-1} d_k^j d_{k+2}^j d_{k+3}^j \cdots d_{j-1}^j d_j^0$," "$d_{k+1}^j d_{k+2}^j d_i d_{i+1} \cdots d_{k-1} d_k^j d_{k+3}^j d_{k+4}^j \cdots d_{j-1}^j d_j^0$," ..., and "$d_{k+1}^j d_{k+2}^j \cdots d_{j-1}^j d_i d_{i+1} \cdots d_{k-1} d_k^j d_j^0$." Therefore, in this case, the function $ConcatReorder$ finally returns the set of candidates of which size is $j-k$, which includes the candidates generated by the reordering process and a candidate generated by the concatenating process. Next, in the line 13, our algorithm fills in $argmax_{S_{i,j} \in C_{i,j}} P(S_{i,j}|B_{i,j})$ which is the maximum-likelihood structure for a subsequence $B_{i,j}$ on $M_{i,j}$.

Finally, our algorithm outputs $M_{1,n}$ as the maximum-likelihood structure of word order and dependency structure for the input sentence.

Note that if the function *ConcatReorder* is changed to the function *Concat* in the line 11, our algorithm becomes the same as CYK algorithm used in the conventional dependency parsing. The function $Concat$ takes two arguments of $M_{i,k}$ and $M_{k+1,j}$ and generates a candidate of the maximum-likelihood structure which should fill $M_{i,j}$ by the same way as the concatenating process in the function $ConcatReorder$. Then, the function $Concat$ returns the set which has the generated candidate as a element, of which size is 1.

3.2.2 Execution Example of Word Reordering Algorithm

Figure 2 represents an example of execution of our word reordering algorithm in $n = 4$. The left side of Figure 2 represents the triangle diagram which has 4×4 dimensions. The elements of the triangle diagram $M_{1,1}, M_{2,2}, M_{3,3}, M_{4,4}, M_{1,2}, M_{2,3}, M_{3,4}$, and $M_{1,3}$ have already been filled in turn, and $M_{2,4}$ is being filled. The right side of Figure 2 shows the process of calculating the maximum-likelihood structure which should fill $M_{2,4}$. First, in the loop from the line 10 to the line 12 in Algorithm 1, two structure candidates are generated by $ConcatReorder(M_{2,2}, M_{3,4})$. The candidate 1 is generated by the concatenating process, that is, by simply concatenating $M_{2,2}$ and $M_{3,4}$ and connecting the last bunsetsu of $M_{2,2}$ and that of $M_{3,4}$. The candidate 2 is generated by the reordering process, that is, by moving $M_{2,2}$ after b_3, which is the first child of b_4 in $M_{3,4}$. Second, the candidate 3 is generated by the concatenating process in $ConcatReorder(M_{2,3}, M_{4,4})$. On the other hand, the reordering process in $ConcatReorder(M_{2,3}, M_{4,4})$ generates no candidates because b_4 has no child in $M_{4,4}$. Among the three structures generated in the above way, the structure which maximizes $P(S_{2,4}|B) = P(O_{2,4}, D_{2,4}|B_{2,4})$ fills $M_{2,4}$.

4 Experiment

To evaluate the effectiveness of our method, we conducted an experiment on word reordering by using Japanese newspaper articles.

4.1 Outline of Experiment

In the experiment, as the test data, we used sentences generated by only changing the word order of newspaper article sentences in Kyoto Text Corpus (Kurohashi and Nagao, 1998), maintaining the dependency structure. That is, we artificially generated sentences which made sense but were not easy to read,

[3]When b_i depends on b_j, we call b_i as a child of b_j. Furthermore, if b_j has more than or equal to one child, the children are numbered from left to right based on their positions.

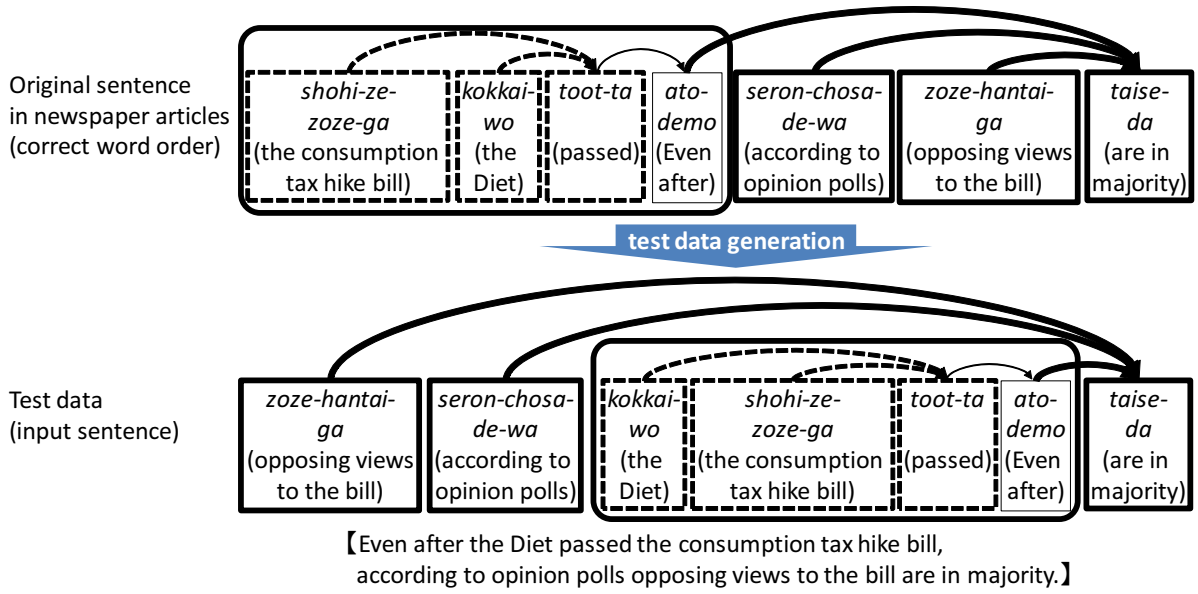

Figure 3: Example of test data generation

in order to focus solely on problems caused by unsuitable word order. Figure 3 shows an example of the test data generation. The generation procedure is as follows:

1. Find a bunsetsu modified by multiple bunsetsus from the sentence end.
2. Change randomly the order of the sub-trees which modify such bunsetsu.
3. Iterate 1 and 2 until reaching the beginning of the sentence.

In Figure 3, the bunsetsus "*taise-da* (are in the majority)" and "*toot-ta* (passed)" are found as bunsetsus modified by multiple bunsetsus. For example, when "*toot-ta* (passed)" is found, the order of "*shohi-ze-zoze-ga* (the consumption tax hike bill)" and "*kokkai-wo* (the Diet)" is randomly changed. In this experiment, all Japanese commas (*toten*) in a sentence, and sentences which have quotation marks were removed.

In this way, we artificially generated 865 sentences (7,620 bunsetsus) from newspaper articles of Jan. 9 in Kyoto Text Corpus and used them as the test data. As the training data, we used 7,976 sentences in 7 days' newspaper articles (Jan. 1, 3-8). Here, we used the maximum entropy method tool (Zhang, 2008) with the default options except "-i 1000."

In the evaluation of word reordering, we obtained the following two measurements, which are defined by Uchimoto et al. (2000):

- **complete agreement:** the percentage of the sentences in which all words' order completely agrees with that of the original sentence.
- **pair agreement:** the percentage of the pairs of bunsetsus whose word order agrees with that in the original sentence. (For example, in Figure 3, if the word order of the input sentence is not changed after reordering, the pair agreement is 52.4% ($= 11/{}_7C_2$) because the 11 pairs out of the ${}_7C_2$ pairs are the same as those in the original sentence.)

In the evaluation of dependency parsing, we obtained the **dependency accuracy** (the percentage of correctly analyzed dependencies out of all dependencies) and **sentence accuracy** (the percentage of the sentences in which all the dependencies are analyzed correctly), which are defined by Sekine et al. (2000).

For comparison, we established two baselines. Both of the baselines execute the dependency parsing primarily, and then, perform the word reordering by using the conventional word reordering method

Table 1: Experimental results (word reordering)

	pair agreement	complete agreement
our method	77.3% (30,190/38,838)	25.7% (222/865)
baseline 1	75.4% (29,279/38,838)*	23.8% (206/865)
baseline 2	74.8% (29,067/38,838)*	23.5% (203/865)
no reordering	61.5% (23,886/38,838)*	8.0% (69/865)*

Note that the agreements followed by * differ significantly from those of our method ($p < 0.05$).

Table 2: Experimental results (dependency parsing)

	dependency accuracy	sentence accuracy
our method	78.4% (5,293/6,755)	35.3% (305/865)
baseline 1	79.2% (5,350/6,755)	31.6% (273/865)*
baseline 2	81.2% (5,487/6,755)*	32.1% (278/865)*

Note that the accuracies followed by * differ significantly from those of our method ($p < 0.05$).

(Uchimoto et al., 1999). The difference between the two is the method of dependency parsing. The baselines 1 and 2 use the dependency parsing method proposed by Uchimoto et al. (2000) and the dependency parsing tool CaboCha (Kudo and Matsumoto, 2002), respectively. The features used for the word reordering in both the baselines are the same as those used to estimate $P(o_{i,j}|D, B)$ in our method. Additionally, the features used for the dependency parsing in the baseline 1 are the same as those used to estimate $P(d_i|O, B)$ in our method.

4.2 Experimental Results

Table 1 shows the experimental results on word reordering of our method and the baselines. Here, the last row shows the agreements measured by comparing the input word order with the correct word order. The agreements mean the values which can be achieved with no reordering[4]. The pair and complete agreements of our method were highest among all. The pair agreement of our method is significantly different from those of both the baselines ($p < 0.05$) although there is no significant difference between the complete agreements of them.

Next, Table 2 shows the experimental results on dependency parsing. The sentence accuracy of our method is significantly higher than those of both the baselines ($p < 0.05$). On the other hand, the dependency accuracy of our method is significantly lower than that of the baseline 2 although there is no significant difference between the dependency accuracies of our method and the baseline 1 ($p > 0.05$). Here, if the input sentences had the correct word order, the dependency accuracies of the baselines 1 and 2 were 86.4% (5,835/6,755) and 88.1% (5,950/6,755), respectively. We can see that the unsuitable word order caused a large decrease of the accuracies of the conventional dependency parsing methods. This is why the word order agreements of the baselines were decreased.

Figure 4 shows an example of sentences of which all bunsetsus were correctly reordered and the dependency structure was correctly parsed only by our method. We can see that our method can achieve the complicated word reordering. On the other hand, Figure 5 shows an example of sentences incorrectly reordered and parsed by our method. In this example, our method could not identify the correct modified bunsetsu and the appropriate position of the bunsetsu "*arikata-wo* (whole concept)." This is because the dependency probability between the bunsetsu "*arikata-wo* (whole concept)" and the bunsetsu "*fukume*

[4]Some input sentences were in complete agreement with the original ordering. There were some cases that the randomly reordered sentences accidentally have the same word order as the original ones. In addition, there were some sentences in which all bunsetsus except the last one depend on the next bunsetsu. The word order of such sentences is not changed by the test data generation procedure because the procedure is executed on condition of maintaining the dependency structure.

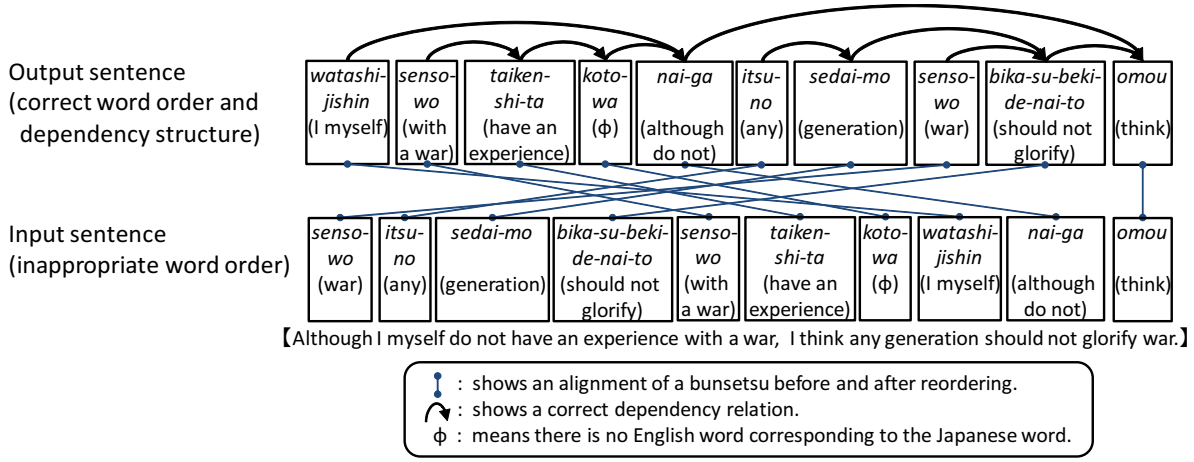

Figure 4: Example of sentences correctly reordered and parsed by our method

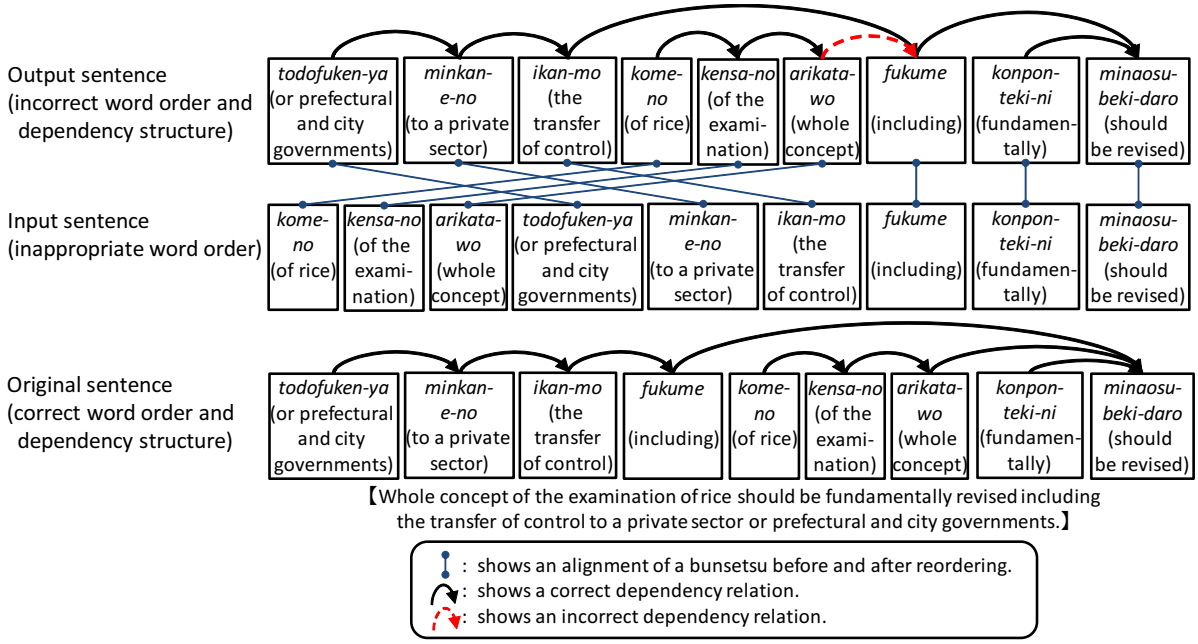

Figure 5: Example of sentences incorrectly reordered and parsed by our method

(including)" is higher than the one between the bunsetsu "*arikata-wo* (whole concept)" and the bunsetsu "*minaosu-beki-daro* (should be revised)", and the probability that the bunsetsu "*arikata-wo* (whole concept)" is located at the left side of "*fukume* (including)" is higher than that of the right side. Since the word order of the output sentence has a strong probability of causing a wrong interpretation like "The transfer of control to a private sector or prefectural and city governments should be fundamentally revised including whole concept of the examination of rice.", this reordering has a harmful influence on the comprehension. We need to study techniques for avoiding the word order which causes the change of meanings in an input sentence.

From the above, we confirmed the effectiveness of our method on word reordering and dependency parsing of a sentence of which the word order is not easy to read.

5 Conclusion

This paper proposed the method for reordering bunsetsus in a Japanese sentence. Our method can identify suitable word order by concurrently performing word reordering and dependency parsing. Based on the

idea of limiting the search space using the Japanese syntactic constraints, we made the search algorithm by extending the CYK algorithm used in the conventional dependency parsing, and found the optimal structure efficiently. The result of the experiment using newspaper articles showed the effectiveness of our method.

In our future works, we would like to collect sentences written by Japanese subjects who do not have much writing skills, to conduct an experiment using those sentences. In addition, we would like to conduct a subjective evaluation to investigate whether the output sentences are indeed more readable than the input ones.

Query-focused Multi-Document Summarization: Combining a Topic Model with Graph-based Semi-supervised Learning

Yanran Li and **Sujian Li***
Key Laboratory of Computational Linguistics,
Peking University, MOE, China
{liyanran,lisujian}@pku.edu.cn

Abstract

Graph-based learning algorithms have been shown to be an effective approach for query-focused multi-document summarization (MDS). In this paper, we extend the standard graph ranking algorithm by proposing a two-layer (i.e. sentence layer and topic layer) graph-based semi-supervised learning approach based on topic modeling techniques. Experimental results on TAC datasets show that by considering topic information, we can effectively improve the summary performance.

1 Introduction

Query-focused multi-document summarization (MDS) can facilitate users to grasp the main idea of the documents according to the users' concern. In query-focused summarization, one query is firstly proposed at the beginning of the documents. Then according to the given query and its influence on sentences, a ranking score is assigned to each of the sentences and higher ranked sentences are picked into a summary.

Among existing approaches, graph-based semi-supervised learning algorithms have been shown to be an effective way to impose a query's influence on sentences (Zhou et al, 2003; Zhou et al, 2004; Wan et al, 2007). Specifically, a weighted network is constructed where each sentence is modeled as a node and relationships between sentences are modeled as directed or undirected edges. With the assumption that a query is the most important node, initially, a positive score is assigned to the query and zero to the remaining nodes. All nodes then spread their ranking scores to their nearby neighbors via the weighted network. This spreading process is repeated until a global stable state is achieved, and all nodes obtain their final ranking scores.

The primary disadvantage of existing learning method is that sentences are ranked without considering topic level information. As we know, a collection of related documents usually covers a few different topics. For example, the specific event "Quebec independence" may involve the topics such as "leader in independence movement", "referendum", "related efforts in independence movement" and so on. It is important to discover the latent topics when summarizing a document collection, because sentences in an important topic would be more important than those talking about trivial topics (Hardy et al, 2002; Harabagiu and Lacatusu, 2005; Otterbacher et al, 2005; Wan and Yang, 2008).

The topic models (Blei et al, 2003) offer a good opportunity for the topic-level information modeling by offering clear and rigorous probabilistic interpretations over other existing clustering techniques. So far, LDA has been widely used in summarization task by discovering topics latent in the document collections (Daume and Marcu, 2006; Haghighi and Vanderwende, 2009; Jin et al, 2010; Mason and Charniak, 2011; Delort and Alfonseca, 2012). However, as far as we know, how to combine topic information and semi-supervised learning into a unified framework has seldom been exploited.

In this paper, inspired by the graph-based semi-supervised strategy and topic models, we propose a two-layer (i.e. sentence layer and topic layer) graph-based semi-supervised learning approach for

Proceedings of COLING 2014, the 25th International Conference on Computational Linguistics: Technical Papers, pages 1197–1207, Dublin, Ireland, August 23-29 2014.

query-focused MDS. By using two revised versions of LDA topic model (See Section 2), our approach naturally models the relations between topics and sentences, and further use these relations to construct the two-layer graph. Experiments on the TAC datasets demonstrate that we can improve summarization performance under the framework of two-layer graph-based semi-supervised learning.

The rest of this paper is organized as follows: Section 2 describes our LDA based topic models, W-LDA and S-LDA. Section 3 presents the construction of the two-layer graph and the semi-supervised learning and the experimental results are provided in Section 4. Then, Section 5 describes related work on query-focused multi-document summarization and topic modeling techniques and we conclude this paper in Section 6.

2 Topic Modeling

2.1 Model Description

As discussed in Section 1, a collection of documents often involves different topics related to a specific event. The basic idea of our summarization approach is to discover the latent topics and cluster sentences according to the topics. Inspired by (Chemudugunta et al, 2006) and (Li et al, 2011), we find 4 types of words in the text: (1) Stop words that occur frequently in the text. (2) Background words that describe the general information about an event, such as "Quebec" and "independence". (3) Aspect words talking about topics across the corpus. (4) Document-specific words that are local to a single document and do not appear across different corpus. Similar ideas can also be found in many LDA based summarization techniques (Haghighi and Vanderwende, 2009; Li et al, 2011; Delort and Alfonseca, 2012).

Stop words can easily be filtered out by a standard list of stopwords. We use a background word distribution ϕ_B to model vocabularies commonly used in the document collection. We assume that there are K aspect topics shared across corpus and each topic is associated with a topic-word distribution $\phi_k,\ k \in [1, K]$. For each document m, there is a document-specific word distribution $\phi_m,\ m \in [K + 1, K + M]$. Each word w is modeled as a mixture of background topics, document-specific topics or aspect topics. We use a latent parameter y_w to denote whether it is a background word, a document-specific word or an aspect word. y_w is sampled from a multinomial distribution with parameter π.

2.2 W-LDA and S-LDA

We describe two models: a word level model W-LDA and a sentence level S-LDA. Their difference only lies in whether the words within a sentence are generated from the same topic.

W-LDA: Figure 1 and Figure 3 show the graphical model and generation process of W-LDA, which is based on Chemudugunta et al's work (2007). Using the Gibbs sampling technique, in each iteration two latent parameters y_w and z_w are sampled simultaneously as follows:

$$P(y_w = 0) \propto \frac{N_{m0,-w} + \gamma}{N_{m,-w} + 3\gamma} \frac{E_B^w + \lambda}{\sum_{w'} E_B^{w'} + V\lambda} \tag{1}$$

$$P(y_w = 1) \propto \frac{N_{m1,-w} + \gamma}{N_{m,-w} + 3\gamma} \frac{E_m^w + \lambda}{\sum_{w'} E_m^{w'} + V\lambda} \tag{2}$$

$$P(y_w = 2, z_w = k) \propto \frac{N_{m2,-w} + \gamma}{N_{m,-w} + 3\gamma} \times \frac{C_m^k + \alpha}{\sum_{k'} C_m^k + K\alpha} \frac{E_k^w + \lambda}{\sum_{w'} E_k^{w'} + V\lambda} \tag{3}$$

where $N_{m0,-w}, N_{m1,-w}$ and $N_{m2,-w}$ denote the number of words assigned to background, document-specific and aspect topic in current document. $N_{m,-w}$ denotes the total number of words in current document. E_B^w, E_m^w and E_k^w are the number of times that word w appears in background topic, document-specific topic and aspect topic k. C_m^k denotes the number of words assigned to topic k in current document.

With one Gibbs sampling, we can make the following estimation:

$$\phi_k^w = \frac{E_k^w + \lambda}{\sum_{w'} E_k^{w'} + V\lambda} \tag{4}$$

Then, the probability that a sentence s is generated from topic k is computed based on the probability that each of its aspect words is generated from topic k:

$$P(s|z_s = k) = \prod_{w \in s, y_w = 2} \phi_k^w \tag{5}$$

   (b) if $y_w = 0$: draw $w \sim \phi_B$
   if $y_w = 1$: draw $w \sim \phi_m$
   if $y_w = 2$: draw $w \sim Multi(\phi_{z_w})$

Figure 4: Generation process of S-LDA

S-LDA: In S-LDA, each sentence is treated as a whole and words within a sentence are generated from the same topic (Gruber et al., 2007). Its graphical model and generated process are shown in Figure 2 and Figure 4. In S-LDA, we firstly sample the topic z_s for each sentence as follows:

$$\begin{aligned} P(z_s = k|z_{-s}, y, w) &\propto \frac{\Gamma(\sum_{w'} E_k^{w'} + V\lambda)}{\Gamma(\sum_{w'} E_k^{w'} + N_s^A + V\lambda)} \\ &\times \prod_{w \in s, y_w = 2} \frac{\Gamma(E_k^w + N_s^w + \lambda)}{\Gamma(E_k^w + \lambda)} \cdot \frac{C_m^k + \alpha}{\sum_{k'} C_m^{k'} + K\alpha} \end{aligned} \tag{6}$$

C_m^k denotes the number of sentences in document m assigned to topic k. N_s^A denotes the number of aspect words in current sentence. Then y_w is sampled.

In our experiments, we set hyperparameters $\alpha = 1,\ \beta = 0.5,\ \lambda = 0.01$. We run 500 burn-in iterations through all documents in the collection to stabilize the distribution of z and y before collecting samples.

3 Graph-based Semi-supervised Learning

As stated before, the consideration of higher level information (i.e. topics) would be helpful for sentence ranking in summarization. In our two-layer graph, the upper layer is composed of topic nodes and the lower layer is composed of sentences nodes, among which there is one node representing the query.

Formally, given a document set D, let $G =< V_s, V_t, E >$ be the two-layer graph, where $V_s = \{s_1, s_2, ..., s_N\}$ denotes the set of all the sentence nodes and s_1 is the query. $V_t = \{z_1, z_2, ..., z_K\}$ corresponds to all the topic nodes. The collection of edges E in the graph consists of the relations within layers and between layers. And the edge weights are measured according to the similarities between nodes, which are computed based on the topic distribution from our two topic model extensions. Specifically, we introduce four edge weight matrices $\hat{W}_{N*K}$, $\bar{W}_{K*N}$, U and P to describe the sentence-to-topic relations, the topic-to-sentence relations, the sentence-to-sentence relations and the topic-to-topic relations respectively.

Firstly, the row-normalized edge weight matrices $\hat{W}_{N*K}$ and $\bar{W}_{K*N}$ denotes the similarity matrix between sentences and topics,

$$\hat{W}_{i,j} = \frac{sim(s_i, z_k)}{\sum_{k'} sim(s_i, z_{k'})} \quad \bar{W}_{i,j} = \frac{sim(s_i, z_k)}{\sum_j sim(s_j, z_k)} \tag{7}$$

where $sim(s_i, z_k) = p(s_i|z_{s_i} = z_k)$ is the probability that the sentence is generated from that topic calculated in Equation (5).

The edge weight matrix U describe the sentence-to-sentence relations. In the same way, the similarity between two sentences is the cosine similarity between their topic distributions, $sim(s_i, s_j) = \frac{1}{C_1} \sum_k p(s_i|z_{s_i} = k) \cdot p(s_j|z_{s_j} = z_k)$, where $C_1 = \sqrt{\sum_k p^2(s_i|z_{s_i} = k)} \sqrt{\sum_k p^2(s_j|z_{s_j} = k)}$ is the normalized factor. Since the row-normalization process will make the sentence-to-sentence relation matrix asymmetric, we adopt the following strategy: let $Sim(s)$ denote the similarity matrix between sentences, where $Sim(s)(i, j) = sim(s_i, s_j)$ and D denotes the diagonal matrix with (i, i)-element equal to the sum of the i^{th} row of $Sim(s)$. Edge weight matrix between sentences U is calculated as follows:

$$U = D^{-\frac{1}{2}} Sim(s) D^{-\frac{1}{2}} \tag{8}$$

Then, the edge weight matrix between topics P is the normalized symmetric matrix of the similairty matrix between two topics. The cosine similarity between two topics is calculated according to word-topic distribution.

$$sim(z_i, z_j) = \frac{1}{C_2} \sum_w p(w|z_i) p(w|z_j) = \frac{1}{C_2} \sum_w \phi_{z_i}^w \phi_{z_j}^w \tag{9}$$

where $C_2 = \sqrt{\sum_w p^2(w|z_i)} \cdot \sqrt{\sum_w p^2(w|z_j)}$ is the normalized factor.

We further transform the task to an optimizing problem based on the assumption that closely related nodes (sentences and topics) tend to have similar scores. So we would give more penalty for the difference between closely related nodes with regard to edge weight matrices $\hat{W}_{N*K}$, $\bar{W}_{K*N}$, U and P. This motivates the following optimization function $\Omega(f, g)$ in Equation (10) similar to the graph harmonic function(Zhu et al, 2003). f denotes the sentence score vector and g denotes the topic score vector. Intuitively, $\Omega(f, g)$ measures the sum of difference between graph nodes; the more they differ, the larger $\Omega(f, g)$ would be.

$$\begin{aligned} \Omega(f, g) = & \, a \sum_{0 \le i,j \le N} U_{i,j} (f_i - f_j)^2 + a \sum_{0 \le i,j \le K} P_{i,j} (g_i - g_j)^2 \\ & + (1 - a) \sum_{0 \le i \le N} \sum_{0 \le j \le K} \hat{W}_{ij} (f_i - g_j)^2 \\ & + (1 - a) \sum_{0 \le i \le N} \sum_{0 \le j \le K} \bar{W}_{ij} (g_i - f_j)^2 \end{aligned} \tag{10}$$

The score vectors can be achieved by minimizing the function in Equation (10). That is, (f, g)=argmin$_{f,g} \Omega(f, g)$. We can get the following equations (details are shown in Appendix).

$$\begin{aligned} f &= aUf + \frac{1}{2}(1 - a)(\hat{W} + \bar{W}^T) g \\ g &= aPg + \frac{1}{2}(1 - a)(\hat{W}^T + \bar{W}) f \end{aligned} \tag{11}$$

Equation (11) conforms to our intuition: (1) A sentence would be important if it is heavily connected with many important sentences and a topic would be important if it is closely related to other important topics. (2) A sentence would be important if it is expressing an important topic, and in turn a topic would be important if it is referred by an important sentence. Based on Equation (11), the ranking algorithm is designed in a semi-supervised way, where the score of the labeled query is fixed to the largest score of 1 during each iteration, as shown in Figure 5. Then, our algorithm iteratively calculates the score of topics and sentences until convergence[1].

Input: The sentence set $\{s_1, s_2, ..., s_N\}$, topic set $\{z_1, z_2, ..., z_K\}$, edge weight matrix $\hat{W}$, $\bar{W}$, U and P. s_1 is the query.
Output: Sentence score vector f and topic score vector g.
BEGIN
1. Initialization, k=0:
$f^0 = (1, 0, 0, ..., 0)^T$, $g^0 = (0, 0, ..., 0)^T$
2. Update sentence score vector
$f^{k+1} = aUf^k + \frac{1}{2}(1-a)(\hat{W} + \bar{W}^T)g^k$
3. Update topic score vector
$g^{k+1} = aPg^k + \frac{1}{2}(1-a)(\hat{W}^T + \bar{W})f^k$
4. fix the score of query in f^{k+1} to 1.
5. k=k+1 Go to Step 2 until convergence.
END

Figure 5: Sentence Ranking Algorithm

Input: The sentence set $S = \{s_1, s_2, ..., s_N\}$, sentence score vector f
Output: Summary Y.

$Y = Y + \{s_m\}$
(c) $X = x - \{s_m\}$
END

Figure 6: Sentence Selection Algorithm

3.1 Summary Generation

Sentence compression can largely improve summarization quality (Zajic et al, 2007; Peng et al, 2011). Since sentence compression is not the main task in this paper, we just use the revised sentence compression techniques in (Li et al, 2011).Here, we remove the redundant modifiers such as adverbials, relative clause modifiers, abbreviations, participials and infinitive modifiers for each sentence.

As for the sentence selection process, sentences with higher ranking score are selected into the summary. Then Maximum Marginal Relevance (MMR)(Goldstein et al, 1999) is further used for redundancy removal. We just apply a simple greedy algorithm for sentence selection as shown in Figure 6. We use Y to denote the summary set which contains the selected summary sentences. The algorithm first initializes Y to Φ and X as the set $\{S - s_1\}$. During each iteration, we select the highest ranked sentence s_j from the sentence set X. We need to assure that the value of semantic similarity between two sentences is less than Th_{sem}. Th_{sem} denotes the threshold for the cosine similarity between two sentences and is set to 0.5 in our model.

4 Experiments

The query-focused MDS task defined in TAC (Text Analysis Conference) evaluations requires generating a concise and well organized summary for a collection of related documents according to a given query. The query usually consists of a narrative/question sentence. Our experiment data is composed of TAC (2008-2009) data[2], which contain 48 and 44 document collections respectively. We use docset-A data sets in TAC which has 10 documents per collection. The average numbers of sentences per document in TAC2008 and TAC2009 are 252 and 243 respectively, and the system-generated summary is limited to 100 words. It is noted that the corpus of TAC2008 and TAC2009 are similar. In our experiment, we apply the optimal topic number trained on TAC2008 dataset to TAC2009 dataset.

[1]In our experiments, if $|f_i^k - f_1^{k+1}| \leq 0.0001 (1 \leq i \leq N)$ and $|g_i^k - g_1^{k+1}| \leq 0.0001 (1 \leq i \leq T)$, iteration stops.

[2]TAC data sets are for the update summarization tasks, where the summarization for docset-A can be seen the query-focused summarization task referred in this paper.

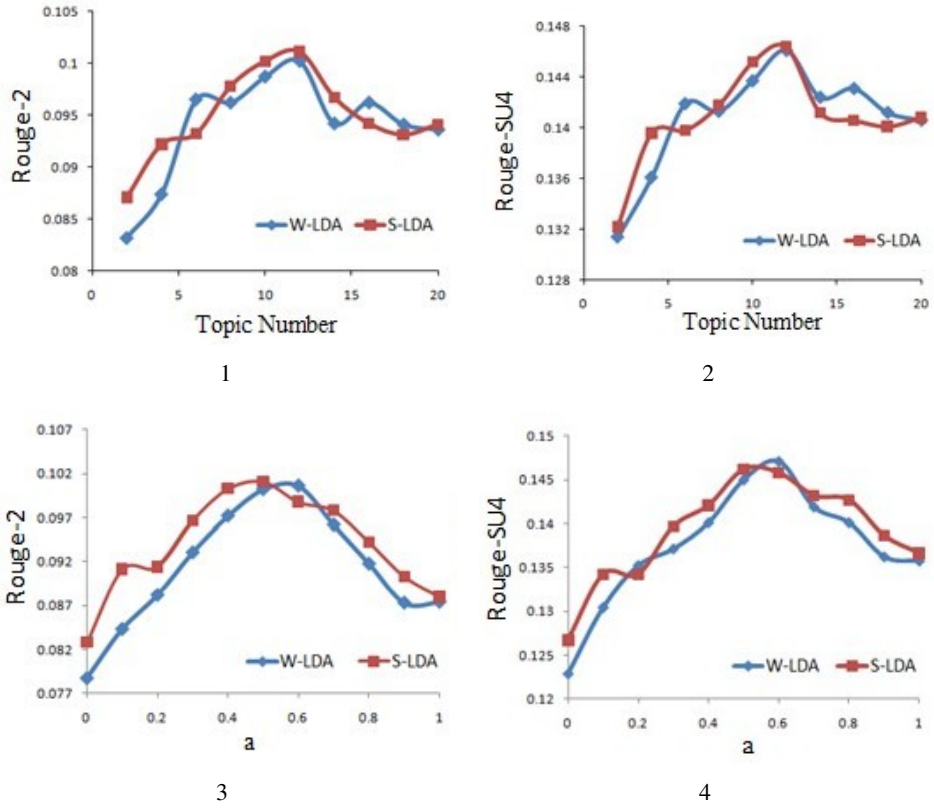

Figure 7: ROUGE score via (1)(2) topic number and (3)(4) parameter a on TAC2008.

As for evaluation metrics, we use ROUGE (Recall-Oriented Understudy for Gisting Evaluation) (Lin, 2004) measures. ROUGE measures summary quality by counting overlapping units such as the n-gram, word sequences and word pairs between the candidate summary and the reference summary. We report ROUGE-1, ROUGE-2, and ROUGE-SU4[3] scores and their corresponding 95% confidential intervals, to evaluate the performance of the system-generated summaries. As a preprocessing step, stopwords are firstly removed with a list of 598 stop words and the remaining words are then stemmed using PorterStemmer.[4].

4.1 Parameter Tuning

There are two parameters to tune in our model. The first parameter is a in Equation (11) that controls the tradeoff between influence from topics and from sentences. The second one is the topic number K in LDA topic model. The combination of the two factors makes it hard to find a global optimized solution. So we apply a gradient search strategy. At first, parameter a is fixed to a given value. Then the performance of using different topic numbers is evaluated. After that, we fix the topic number to the value which has achieved the best performance, and conduct experiments to find an appropriate value for a. Here, we use TAC2008 as training data and test our model on TAC2009.

First, a is set to 0.5, then we change topic number K from 2 to 20 at the interval of 2. The ROUGE score reaches their peaks when the topic number is around 12, as shown in Figure 7(1) and Figure 7(2). Then we fix the number of K to 12 and change the value of parameter a from 0 to 1 with the interval of 0.1. When the value of a is set to 0, the model degenerates into a one-layer graph ranking algorithm where topic clustering information is neglected. As we can see from Figure 7(3) and Figure 7(4) , the ROUGE scores reach their peaks around 0.6 and then drop afterwards. Thus, the topic number is set to 12 and a is set to 0.6 in the test dataset.

[3]Jackknife scoring for ROUGE is used in order to compare with the human summaries.
[4]http://tartarus.org/martin/PorterStemmer/

4.2 Baseline Comparison

We firstly compare W-LDA and S-LDA with other clustering approaches. To be fair, we use the identical sentence compression techniques and preprocessing methods for all baselines. Summaries are truncated to the same length of 100 words.

Standard-LDA: A simplified version of W-LDA without considering the background or document-specific information.

K-means: Using the K-means clustering algorithm for graph construction. We firstly randomly select K sentences as initial centroid for clusters and then iteratively assign a sentence to each cluster. The centroid is recomputed until convergence. The similarity between nodes in the graph (sentence or cluster) is computed using the standard cosine measure based on the tf-idf information. K is set to 12, the same as topic number in LDA.

Agglomerative: a bottom-up hierarchical clustering algorithm and starts with the sentences as individual clusters and, at each step, merges the most similar or closest pair of clusters, until the number of the clusters reduces to the desired number $K = 12$.

Divisive: a top-down hierarchical clustering algorithm and starts with one, all-inclusive cluster and, at each step, splits the largest cluster until the number of clusters increases to the desired number K, $K = 12$.

Approach	Rouge-1	Rouge-2	Rouge-SU4
W-LDA	0.3791 (0.3702-0.3880)	0.1092 (0.1047-0.1135)	0.1382 (0.1350-0.1414)
S-LDA	**0.3802 (0.3721-0.3883)**	**0.1109 (0.1061-0.1157)**	**0.1398 (0.1342-0.1454)**
Standard LDA	0.3702 (0.3614-0.3790)	0.1012 (0.0960-0.1064)	0.1292 (0.1242-0.1344)
K-means	0.3658 (0.3582-0.3734)	0.1046 (0.0992-0.1080)	0.1327 (0.1263-0.1391)
Agglomerative	0.3681 (0.3612-0.3750)	0.1042 (0.091-0.1093)	0.1319 (0.1266-0.1272)
Divisive	0.3676 (0.3610-0.3742)	0.1021 (0.0981-0.1061)	0.1320 (0.1275-0.1365)

Table 1: Comparison with other clustering baselines.

Table 1 presents the performance of different clustering algorithms for summarization. Traditional clustering algorithms such as K-means, Agglomerative and Divisive clustering achieve comparative results. Compared with traditional clustering algorithms, LDA based models (W-LDA, S-LDA, Standard-LDA) achieve better results. This can be explained by the clear and rigorous probabilistic interpretation of topic models. Background information and document-specific information would influence the performance of topic modeling (Chemudugunta et al, 2006), that is why S-LDA and W-LDA achieve better ROUGE performance than the standard LDA. We can also see that S-LDA is slightly better than W-LDA in regard with ROUGE performance. The reason can be explained as follows: The aim of topic modeling in this task is to cluster sentences according to their topics. So treating sentence as a unit in topic modeling would be better than treating it as a set of independent words. In addition, forcing the words in one sentence to share the same aspect topic can ensure semantic cohesion of the mined topics.

Next, we compare our model with the following widely used summarization approaches.

Manifold: One-layer graph-based semi-supervised approach developed by Wan et al.(2008). Sentence relations are calculated according to $tf - idf$ and topic information is neglected.

LexRank: An unsupervised graph-based summarization approach(Erkan and Radev, 2004), which is a revised version of the famous web ranking algorithm PageRank.

KL-Divergence: The approach developed by (Lin et al, 2006) by using a KL-divergence based sentence selection strategy.

$$KL(P_s||Q_d) = \sum_w P(w) log \frac{P(w)}{Q(w)} \tag{12}$$

where P_s is the unigram distribution of candidate summary and Q_d denotes the unigram distribution of document collection. Since this approach is designed for general summarization, query influence is not considered.

Hiersum: A LDA based approach proposed by (Haghighi and Vanderwende, 2009), where unigram distribution is calculated from LDA topic model in Equation (12).

MEAD: A centroid based summary algorithm by (Radev et al, 2004). Cluster centroids in MEAD consists of words which are central not only to one article in a cluster, but to all the articles. Similarity is measured by using $tf - idf$.

Approach	Rouge-1	Rouge-2	Rouge-SU4
W-LDA	0.3891 (0.3802-0.3980)	0.1192 (0.1147-0.1235)	0.1482 (0.1450-0.1514)
S-LDA	**0.3902 (0.3821-0.3983)**	**0.1209 (0.1161-0.1257)**	**0.1498 (0.1442-0.1554)**
Manifold	0.3581 (0.3508-0.3656)	0.1007 (0.0952-0.1062)	0.1267 (0.1214-0.1320)
LexRank	0.3442 (0.3381-0.3502)	0.0817 (0.0782-0.0852)	0.1106 (0.1064-0.1148)
KL-divergence	0.3468 (0.3410-0.3526)	0.0820 (0.0782-0.0858)	0.1117 (0.1073-0.1161)
Hiersum	0.3599 (0.3526-0.3672)	0.1004 (0.0956-0.1052)	0.1280 (0.1221-0.1339)
MEAD	0.3451 (0.3390-0.3512)	0.0862 (0.0817-0.0907)	0.1131 (0.1080-0.1182)

Table 2: Performance comparison with baselines

Performance is presented at Table 2. We can find that ROUGE performance of one-layer graph ranking algorithms such as Manifold and LexRank, where topic information is neglected, achieve worse results than all two-layer models where topic information is considered (See Table 1). This verifies our previous claim (Hardy et at., 2002; Harabagiu and Lacatusu, 2005; Wan and Yang, 2008) that the consideration of topic information will improve summarization performance. S-LDA and W-LDA achieve better performance than KL-divergence and Hiersum. This is because the sentence selection strategy for KL-divergence and Hiersum tries to select sentence best representing the document as shown in Equation (12), but do not consider the influence of query.

4.3 Manual Evaluation

W-LDA and S-LDA get comparative ROUGE scores. To obtain a more accurate measure to decide which approach is better, we perform a simple user study concerning the following aspects on 40 randomly selected topics in TAC2009: (1) Overall quality. (2) Focus: Whether the summary contains less irrelevant content? (3) Responsiveness: Whether the summary is responsive to the query. (4) Non-Redundancy: Whether the summary is non-redundant. Each respect is rated from 1 (very poor) to 5 (very good). Four native speakers who are Ph.D. students in computer science (none are authors) performed the task.

The average score and standard deviation for W-LDA and S-LDA are displayed in Table 3. We can see that the two models almost tie in foucs and non-redundancy. This is because two models use the same sentence selection strategy based on MMR for redundancy removal and propagation model to impose the query's influence on sentences. S-LDA outperforms W-LDA in overall ranking and responsiveness ranking. This implies that treating sentence as a unit in topic modeling would be preferable to just treating it as a series of independent words.

	S-LDA	W-LDA
Overall	3.98 ± 0.52	3.58 ± 0.55
Focus	3.65 ± 0.54	3.35 ± 0.61
Responsiveness	3.73 ± 0.43	3.38 ± 0.46
Non-Redundancy	3.48 ± 0.51	3.45 ± 0.48

Table 3: Manual evaluation for S-LDA and W-LDA.

5 Related Work

Graph-based ranking approaches have been hot these days for both generic and query-focused summarization (Zhou et al, 2003; Zhou et al, 2004; Erkan and Radev, 2004; Wan et al, 2007; Wei et al, 2008). Commonly used graph-based ranking algorithms are mainly inspired by the link analysis algorithm in web research such as PageRank (Page et al, 1999). (Wan et al, 2007) proposed the approach that treated

the task of query-focused MDS as a semi-supervised learning task, in which the query is treated as a labeled node, and sentences as unlabeled nodes. Then the scores of sentences are determined from the manifold learning algorithm proposed by (Zhou et al, 2003) or the harmonic approach proposed by (Zhu et al, 2003).

It is worthy of noting that researchers have found that by considering topic level information, the summarization performance can be effectively improved (Hardy et al, 2002; Wan and Yang, 2008; Harabagiu and Lacatusu, 2005). For example, (Otterbacher et al, 2005) models documents as a stochastic graph and calculates sentence ranking scores with a topic-sensitive version of PageRank. (Wan and Yang, 2008) developed a two-layer graph by clustering sentences by using standard clustering algorithms such as K-means or agglomerate clustering. However, his algorithm is for general summarization where the influence of query is not considered.

A significant portion of recent work incorporates LDA topic models (Blei et al, 2008) in summarization tasks for their clear and rigorous probabilistic topic interpretations (Daume and Marcu, 2006; Titov and McDonald, 2008; Haghighi and Vanderwende, 2009; Mason and Charniak, 2011; Li et al, 2013a; Li et al, 2013b). (Haghighi and Vanderwende, 2009) introduced a LDA based model called Hiersum to find the subtopics or aspects by combining KL-divergence criterion for selecting relevant sentences. AYESSUM (Daume and Marcu, 2006) and the Special Words and Background model (Chemudugunta et al, 2006) are very similar to Hiersum. In the same way, (Delort and Alfonseca, 2012) tried to use LDA to model different levels of information for novelty detection in update summarization. Furthermore, (Paul and Dredze, 2013) extends their f-LDA to jointly model combinations of drug, aspect and route of administration as an exploratory tool for extractive summarization.

6 Conclusions and Future Work

In this paper, we propose a two-layer graph-based semi-supervised algorithm for query-focused MDS. Topic modeling techniques are used for sentence clustering and further graph construction. By considering different kinds of information such as background or document-specific information, our two LDA topic model extensions achieve better results than traditional clustering algorithms.

One primary disadvantage of our models is that it is hard to decide the topic number K in LDA models and how to define topic number is still a open problem in LDA topic models. From Figure 7, we can see that summarization performance is sensitive to topic number. We train the value of topic number on TAC2008 dataset and test the model on TAC2009. Such process makes sense because the corpus sizes and contents of two datasets are similar. But it would be hard to extend optimal topic number in TAC2008 to other datasets. Using non-parametric topic modeling techniques where topic number does not have to be predefined is one of our future works.

APPENDIX

To optimize $\Omega(f, g)$, shown in Equation (10), we set the partial derivative with respect to f_m to 0, for $m \in [1, N]$. Let δ_{mn} denote the index function as follows:

$$\delta_{mn} = \begin{cases} 1 & if\ m = n \\ 0 & if\ m \neq n \end{cases}$$

$$\begin{aligned}
0 &= \frac{\partial \Omega(f,g)}{f_t} \\
&= 2a \sum_{i,j} U_{i,j}(f_i - f_j)(\delta_{it} - \delta_{jt}) + 2(1-a) \\
&\times \sum_{i,j} \hat{W}_{ij}(f_i - g_j)\delta_{it} - 2(1-a) \sum_{i,j} \bar{W}_{ij}(g_i - f_j)\delta_{jt} \\
&= 2(1-a) \sum_j \hat{W}_{tj}(f_t - g_j) + 2(1-a) \sum_i \bar{W}_{it}(g_i - f_t) \\
&+ 2a \sum_j U_{tj}(f_t - f_j) + 2a \sum_i U_{it}(f_i - f_t) \\
&= f_t[4a \sum_j U_{tj} + 2(1-a) \sum_j \hat{W}_{tj} + 2(1-a) \sum_j \bar{W}_{jt}] \\
&- 4a \sum_j U_{tj} f_j - 2(1-a) \sum_j \hat{W}_{tj} g_j - 2(1-a) \sum_j \bar{W}_{jt} g_j \\
&\sum_j U_{tj} = 1 \qquad \sum_j \hat{W}_{tj} = 1 \qquad \sum_j \bar{W}_{jt} = 1 \\
f_t &= a \sum_j U_{tj} f_j + \frac{1}{2}(1-a)[\sum_j (\hat{W}_{tj} + \bar{W}_{jt}) g_j]
\end{aligned}$$

So we have:

$$f = aUf + \frac{1}{2}(1-a)(\hat{W} + \bar{W}^T)g$$

A similar approach is used to obtain the second part of Equation (11).

Ranking Multidocument Event Descriptions for Building Thematic Timelines

Abstract

This paper tackles the problem of timeline generation from traditional news sources. Our system builds thematic timelines for a general-domain topic defined by a user query. The system selects and ranks events relevant to the input query. Each event is represented by a one-sentence description in the output timeline.

We present an inter-cluster ranking algorithm that takes events from multiple clusters as input and that selects the most salient and relevant events. A cluster, in our work, contains all the events happening in a specific date. Our algorithm utilizes the temporal information derived from a large collection of extensively temporal analyzed texts. Such temporal information is combined with textual contents into an event scoring model in order to rank events based on their salience and query-relevance.

1 Introduction

We aim at building thematic timelines from multiple documents relevant to a specific, user-generated query. For instance, for the query "*Libya conflict*", our system will return important events related to the Libya conflict in 2011 involving Kadhafi forces, rebels, NATO intervention, etc. (Figure 1). Such a timeline can then be visualized as a textual, event-based summary, or through any existing graphical timeline visualization tool.

The main contribution of this paper is a two-step inter-cluster ranking algorithm aimed at selecting salient and non-redundant events from temporal clusters, which are sets of sentences describing events related to the query and that occurred at the same day. In the first step, a scoring model is proposed to rank sentences describing events, according to their relevance and salience to the topic. In the second step, the ranked events are iteratively reranked based on their content in order to reduce information redundancy. We finally obtain an extendable, chronological summary of important events concerning the query.

This paper is organized as follows: §2 introduces related work. §3 presents the resources used and gives an overview of the system. The salient date algorithm proposed by Kessler et al. (2012), that we used to build our temporal clusters, is briefly summarized in §4. §5 and §6 describe our ranking approach to event selection and a content-based reranking algorithm, respectively. The evaluations are presented in §7. §8 is dedicated to the conclusion and future work.

2 Related Work

Our work is closely related to event detection and tracking (EDT) and multidocument summarization (MDS). This section introduces some important work in these fields.

2.1 Event Detection and Tracking

EDT on news streams has been intensively studied. Early work concentrates on detecting events from article texts using vector-based techniques (Allan et al., 1998; Petrović et al., 2010) or graphical models

Figure 1: A chronology about "*Libya conflict*" written by journalists.

(Sayyadi et al., 2009). These papers do not consider time, which is an essential dimension of event timelines.

Attempts to use temporal information for EDT are significant in the literature. To name but a few, Alonso et al. (2009) apply time-based clustering on search results. Yan et al. (2011) use document timestamps to calculate temporal proximity for timeline generation from web documents. Similarly, Zhao et al. (2007) use text similarity and time intensity for event clustering on social streams. Kessler et al. (2012) exploit temporal analysis to detect salient dates of an event from raw text. Following this direction, Battistelli et al. (2013) apply sequential pattern mining to select a one-sentence description for each salient date of an event.

2.2 Multidocument Summarization

Sentence extraction is essential in extractive text summarization. In the unsupervised approach, sentences are scored using term weight and term proximity induced from a document collection (Goldstein et al., 2000). In the supervised approach, training data generated from reference summaries are used to learn classification or ranking models. New sentences are selected based on their confidence value on learned models (Wan et al., 2007). As information comes from documents on the same topic, it should be noticed that it is also important to reduce redundancy in MDS (Carbonell and Goldstein, 1998).

Filippova (2010) builds a co-occurrence word graph from a collection of related sentences and generates a generic summary from the graph based on shortest path finding. Her algorithm is a hybrid method between extractive and abstractive approaches to MDS.

3 Resources and System Overview

3.1 Corpus and Chronologies

For this work, we use a corpus of newswire texts provided by the AFP French news agency. The English AFP corpus is composed of 1.3 million texts that span the 2004-2011 period (511 documents/day in average and 426 millions words). Each document is an XML file containing title, document creation time (DCT), set of keywords, and textual content split into paragraphs.

AFP "chronologies" (textual event timelines) are a specific type of articles written by AFP journalists in order to contextualize current events. These chronologies may concern any topic discussed in the media, and consist in a list of dates (typically between 10 and 20) associated with a text describing the related event(s). Figure 1 shows an example of such a chronology. Note that several important events can occur at the same date.

3.2 System Overview

Figure 2 shows the general architecture of the system. When the user submits a query, sentences are retrieved by the Lucene search engine and are clustered by the dates appearing in those sentences (step ①

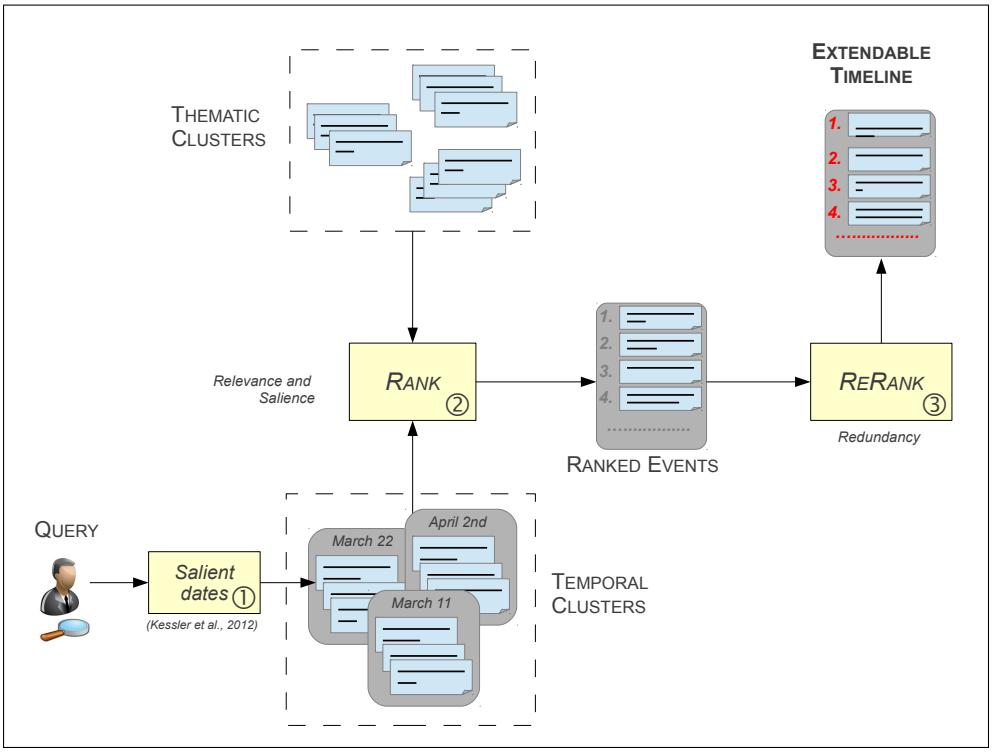

Figure 2: System overview.

in the Figure (Kessler et al., 2012)).

Then, all sentences are ranked by the relevance and salience of described events. This is done by modeling event relevance and salience as a scoring function (step ②). *Thematic* clusters are created by applying clustering on the set of events on the same date. Finally, sentences are reranked by an iterative algorithm aiming at reducing redundancy from the initial list (step ③) to achieve an extendable timeline.

4 Temporal Clusters

As stated in the introduction, our main contribution in this paper is to rank and select salient and non-redundant sentences from clusters, in order to build query-based timelines. We rely on the algorithm proposed by Kessler et al. (2012) for building temporal clusters. This section is a quick overview of their approach.

4.1 Preprocessing

A temporal analysis is performed on all documents from the AFP corpus (see §3.1) with the Heideltime (Strötgen and Gertz, 2013) parser. The main purpose is to collect as much temporal information as possible. Absolute dates and DCT-relative dates are extracted and normalized (full dates represented in a common format). DCT-relative dates are those which are relative to the date on which the document is published, such as "*Yesterday*" (day before DCT), "*next Friday*" (first Friday following the DCT) or "*on Friday*" (can be first Friday preceding or following the DCT, depending on the tense of the verb that governs the temporal expression).

In a corpus containing 426 millions words, 845,000 absolute dates and 4.6 millions relative dates were detected and normalized.

4.2 Temporal Cluster Building

At query time, temporal clusters (or "salient date sets") are then built with the help of a search engine (Lucene in that case[1]). Articles are indexed by Lucene at sentence-level (a document = a sentence).

[1] `http://lucene.apache.org`

...launched the first air strike on	March 19	*, has deployed around 20 Rafale and Mirage...*
...last week, said they were arrested on	Saturday	*along with Getty photographer Joe Raedle...*
...since coalition air strikes began	Saturday	*, a figure that could not be confirmed...*
...United State to launch air raids on	March 19	*, are in a hurry to get out of whether NATO...*

Figure 3: All the temporal expressions in the following sentences were normalized at date level as 'Mar 19 2011'.

Given the query, a number of sentences are retrieved by search engine. Dates are extracted from these sentences. These dates are then ranked by their "salience" in the set of documents. The idea behind the notion of salient date is that if a date is important in a sub-corpus (Lucene output), then we can say that important events occurred at this date, and then that these events must appear in a timeline.

In practice, salience is mostly defined by the number of occurrences of the date in the documents from the search engine, as well as some other features that are used to feed a machine learning classifier.

The output of this salient date algorithm is then a ranked list of dates, where each date comes together with a set of sentences that contain this date and that are relevant to the query. We call *temporal clusters* these sets of sentences linked to a specific date (see Figures 2 and 3).

5 Event Ranking

Our ranking mechanism relies on the mutual relation between relevance and salience. It aims at ranking events based on these two factors. The problem of information redundancy will be addressed by a reranking step in §6. Our principal motivation is that an event has more chance to be selected into a timeline if it is both relevant to the topic and important, or in other words, salient w.r.t other related events. The concepts of relevance and salience are realized in our ranking function by considering term proximity and date frequency, respectively.

Previous works in event detection normally formalize events as individual terms or syntactic patterns, which facilitates the use of text content. Instead, as our method utilizes both time and text content, we come to a formalization of an event as a pair of its mentioned date and its one-sentence description.

Given an input query, the aim of ranking is to select the most relevant and salient events. The relevance of an event is calculated by vector-based query similarity, and augmented by the average relevance of its containing thematic cluster. Salience is contributed by date frequency and averaged term weight. As a result, the overall score of an event e given a query q is the multiplication of the following four factors:

$$\begin{aligned} score(e|q) = & rel_e(e|q) \\ & * rel_{cl}(cl|q) \\ & * salience_e(e|d,q) \\ & * salience_d(d|q), \end{aligned} \tag{1}$$

where:

- $rel_e(e|q)$ is the relevance of e to q (see §5.1).
- $rel_{cl}(cl|q)$ is the relevance of a thematic cluster cl to q, which is the averaged relevance of its members (see §5.2).
- $salience_e(e|d,q)$ is the salience of e w.r.t the date d that the event happens. It is calculated as the average salience of the terms in its one-sentence description. Term salience, in turn, is calculated based on term frequency in the date cluster (see §5.3).
- $salience_d(d|q)$ is the salience of d w.r.t to q. Date salience is the averaged salience of all the events in that date (see §5.4).

5.1 Event Relevance: $rel_e(e|q)$

The motivation behind considering relevance is that if an event is relevant to the query then it is an important event. We use the conventional TFIDF vector space model with bag-of-word assumption to represent document and query vectors. For relevance, the similarity between document and query vectors is the built-in Lucene score formula[2],

$$rel_e(e|q) = cosine(\vec{e}, \vec{q}) * norm_L(\vec{e}, \vec{q}). \tag{2}$$

5.2 Thematic Cluster Relevance: $rel_{cl}(cl|q)$

Date salience does not always correctly reflect the importance of event. For instance, the date of Haiti earthquake considers the earthquake itself as the main event. However, related events such as the sorrow expression of UN Secretary General also happen immediately after the earthquake but still in the same date. Such satellite events will have the same date salience as the central event. In another case, a date when there is no central event but there are many "consequent" events will also have a high salience value. E.g., on the day after the earthquake, international aids are planned; number of victims is estimated; aftermath events are invoked, etc.

Those examples show that the "one event per date" assumption is weak in reality. To overcome this weakness, we apply an hierarchical clustering technique, in which two clusters are merged if their normalized Manhattan distance is lower than a threshold θ, to generate thematic sub-clusters inside a date cluster [3]. In in-house experiments, we observed that different values of θ did not significantly vary performance. We hence selected $\theta = 0.5$ for our system.The score of each thematic cluster is then calculated as averaged document relevance,

$$rel_{cl}(cl|q) = \frac{\sum_e rel_e(e|q)}{|cl|}. \tag{3}$$

5.3 Event Salience: $salience_e(e|d, q)$

An important event tends to contain salient terms. Those terms, in turn, tend to occur frequently on a date. We hence come to measure term salience as its frequency of occurrence on the date $f(t|d, q)$, and event salience as the averaged salience of its terms. For term normalization, stopwords are removed and tokens are normalized by the Porter stemming algorithm (Porter, 1997).

$$salience_e(e|d, q) = \frac{\sum_{t \in e} f(t|d, q)}{|e| \sum_{t' \in d} f(t'|d, q)} \tag{4}$$

5.4 Date Salience: $salience_d(d|q)$

The use of temporal clusters, i.e. date clusters, is motivated by the observation that an important event happens on a salient date. Date salience is the total relevance of all events happening on that date (the numerator):

$$salience_d(d|q) = \frac{\sum_e rel_e(e|q)}{\sum_d \sum_e rel_e(e|q)}. \tag{5}$$

The denominator is used to normalize date salience so that it is comparable to other factors in (1).

6 Event Reranking

The score described in previous section leads to a ranked list of salient and relevant events. However, it does not consider the fact that some information can be redundant between events. The reranking algorithm presented in this section strives to reduce such redundancy. In principal, information redundancy is

[2] `https://lucene.apache.org/core/3_6_2/api/core/org/apache/lucene/search/Similarity.html`

[3] In our implementation, for each one-sentence document, we used the whole texts of its containing article to create its document vector. Manhattan distance is the sum of the absolute difference of term weight between two clusters

11: **end for**
12: **end while**

estimated by the distinction between *used* and *unused* terms. The algorithm iteratively recomputes event salience (hence the overall event score) based on used/unused terms as follows:

$$salience^*_e(e|d,q) = \frac{\sum_{t^* \in e} f(t^*|d,q)}{|e| \sum_{t' \in d} f(t'|d,q)}, \tag{6}$$

where t^* is an unused term on the date d. A used term is the one that already occurred in better-ranked sentences. This formula is different from (4) in the distinction between used and unused terms. Each time a new event is selected, its appropriate list of used terms is updated with the terms in the one-sentence description of the selected event. Each date has its own list of used/unused terms.

The algorithm for reranking is provided in Algorithm 1. At first, the score of all sentences related to the query $S(q)$ is calculated using the formula (1) with event salience defined in (6) (lines 3-5). Then, the highest scored sentence is selected into the output (lines 6-7) and is removed from the pool. In line 8, d^* is the date when the event e happens: $d^* = date(e^*)$. The list of used terms on its date is updated with the terms from that selected sentence (lines 9-11). A new iteration restarts by recalculating score of unselected sentences according to new lists of used terms. The algorithm terminates after K iterations, i.e. when K events have been selected into timeline.

Figure 4 illustrates the effect of reranking on the order of events in a timeline. The upper shows the top events ranked by score without reranking. The date 'Mar 31 2011' appears three times in 1^{st}, 2^{nd}, and 3^{rd} events. The lower shows the ranking of events after the highest scored event has been selected. As an effect of reranking, the two events previously ranked 2^{nd} and 3^{rd} now fall down the list.

Figure 5: Timeline for the query "*Libya conflict*" created by the Rank-Rerank method. Events are shown in chronological order, each accompanied with its rank starting from 1, displayed as a number between ().

7 Evaluations

Our system for building timelines is named as RaRE, as short for "*Rank and RErank*". We use a set of 91 chronologies manually written by expert journalists from the AFP news agency (Figure 1) as golden reference summaries for evaluation. As our generated timelines are extendable, we need to define its length for evaluation. Considering the characteristics of reference summaries, we decide that if a reference summary of a timeline contains k events, we appropriately use only the k highest ranked events in the timeline for evaluation (Figure 5). The evaluations of the date selection and summary generation are presented in §7.1 and §7.2, respectively.

7.1 Evaluate Date Selection

We evaluate the dates selected by timelines returned by our system. The purposes of this evaluation are two-fold: *i)* Since time (as date in our case) is an essential dimension of chronological timeline, it is necessary to evaluate the time selected by timelines; *ii)* The novelty of this work w.r.t Kessler et al. (2012) is the mixture of content and temporal information. We need to show empirical evidences that at least, this mixture does not break the performance of date selection.

The dates occurring in a timeline are compared with the dates occurring in its reference timeline using Mean Average Precision (MAP) metric. It should be noted that by using MAP@k as evaluation metric, a date with higher rank has more impact than another date with lower rank. We use two systems presented in Kessler et al. (2012), named as DFIDF and ML in Table 1, for comparison as follows:

- DFIDF is an unsupervised system solely relying on date frequency with a tfidf-like scoring function. This method uses the AFP corpus, the same as the one used in our work. As the AFP corpus is temporally analyzed, the method indexes all the occurrences of dates in the corpus. Dates are then scored and ranked with so-called DFIDF, a tfidf-like scoring mechanism.

- ML is a supervised system that learns a classifier and ranks unseen dates based on classification

System	MAP
DFIDF	71.46
ML	79.18
RaRE	77.83

Table 1: Comparison of salient date detection using MAP.

System	P	R
DFIDF*	27.24	25.50
ML*	29.93	27.54
RaRE-no-rerank	28.82	24.47
RaRE	31.23	26.63

Table 2: Comparison of MDS using ROUGE at 95% confidence interval.

confidence. The method leverages the dates in reference summaries to create training data with salient/non-salient examples. Temporal features such as date frequency, DCT, novelty, etc., are extracted to learn an adaptive boosting classifier.

As shown in Table 1, our method is close to ML. This result is encouraging as ML requires training data; and on the other hand, our system is not designed to directly solve the task of date selection. As expected, our system beats the unsupervised system DFIDF by a large margin. This superiority shows that the mixture of temporal information and content leads to an improvement on date selection over using only the former.

7.2 Evaluate Summary Generation

In order to evaluate timelines as text summaries, we ignore dates and consider all the entries in a timeline as one summary. We use ROUGE metric (Lin, 2004) to evaluate generated timelines against reference summaries.

The following baselines are implemented (Table 2): In DFIDF*, salient dates are taken from the outputs of the DFIDF system described in previous section. Each salient date is equivalent to a cluster containing all the events happening in that date. We then select the event the most relevant to the query, i.e. the event with the highest Lucene score, as representative of that salient date. Note that consequently, DFIDF* makes an assumption, which is not assumed in RaRE, that there is only one event happens in a particular date. The same assumption is presumed in Battistelli et al. (2013). However, because their system is particularly designed for French and is intended to parse small corpora, we could not conduct a direct comparison with their method. ML* is built similarly to DFIDF*, except that salient dates are instead taken from the ML system. The RaRE-no-rerank system is identical to RaRE in the ranking step, but the reranking step is omitted.

Our system is superior to DFIDF* as expected. Moreover, it outperforms ML*, even though ML* performs better on the task of date selection. Among these three systems that combine temporal information and textual contents for summary generation, our system is the most successful. Furthermore, RaRE outperforms RaRE-no-rerank, which shows that reducing redundancy by reranking improves the performance of summary generation.

8 Conclusion and Future Work

We presented a two-step inter-cluster ranking algorithm for event selection. The *rank* step sorts events based on their salience and query relevance. The event scoring function is based on both date frequency induced from temporal analyzed texts and term weighting induced from contents to reflect these two factors. The *rerank* step allows to reduce information redundancy by using inter-sentence dependency between the descriptions of events happening in the same time period (i.e. the same date in this work).

Ranking based on sentences may be sensitive to sparsity. In the future, we will expand local contexts, for instance, to neighboring sentences, to acquire richer textual representation of events. One remaining issue is that reference chronologies, written by the journalists, are very subjective, and that we have only one example of chronology per topic. In the future, we will conduct a manual evaluation in order to complete results from this automatic evaluation. With the help of a validation interface, journalists will be provided ranked list of events w.r.t. their queries. They will then be able to select and edit the events that they wish to validate for their future timelines. Such an interface will both help journalists to produce new timelines, and bring a new evaluation methodology for our system.

Acknowledgements

This work has been partially funded by French National Research Agency (ANR) under project Chronolines (ANR-10-CORD-010). We would like to thank the French News Agency (AFP) for providing us with the corpus. We would like to thank anonymous reviewers for comments and suggestions on the paper.

Abstract

This paper integrates techniques in natural language processing and computer vision to improve recognition and description of entities and activities in real-world videos. We propose a strategy for generating textual descriptions of videos by using a factor graph to combine visual detections with language statistics. We use state-of-the-art visual recognition systems to obtain confidences on entities, activities, and scenes present in the video. Our factor graph model combines these detection confidences with probabilistic knowledge mined from text corpora to estimate the most likely subject, verb, object, and place. Results on YouTube videos show that our approach improves both the joint detection of these latent, diverse sentence components and the detection of some individual components when compared to using the vision system alone, as well as over a previous n-gram language-modeling approach. The joint detection allows us to automatically generate more accurate, richer sentential descriptions of videos with a wide array of possible content.

1 Introduction

Integrating language and vision is a topic that is attracting increasing attention in computational linguistics (Berg and Hockenmaier, 2013). Although there is a fair bit of research on generating natural-language descriptions of images (Feng and Lapata, 2013; Yang et al., 2011; Li et al., 2011; Ordonez et al., 2011), there is significantly less work on describing videos (Barbu et al., 2012; Guadarrama et al., 2013; Das et al., 2013; Rohrbach et al., 2013; Senina et al., 2014). In particular, much of the research on videos utilizes artificially constructed videos with prescribed sets of objects and actions (Barbu et al., 2012; Yu and Siskind, 2013). Generating natural-language descriptions of videos *in the wild*, such as those posted on YouTube, is a very challenging task.

In this paper, we focus on selecting content for generating sentences to describe videos. Due to the large numbers of video actions and objects and scarcity of training data, we introduce a graphical model for integrating statistical linguistic knowledge mined from large text corpora with noisy computer vision detections. This integration allows us to infer which vision detections to trust given prior linguistic knowledge. Using a large, realistic collection of YouTube videos, we demonstrate that this model effectively exploits linguistic knowledge to improve visual interpretation, producing more accurate descriptions compared to relying solely on visual information. For example, consider the frames of the video in Figure 1. Instead of generating the inaccurate description "A person is playing on the keyboard in the kitchen" using purely visual information, our system generates the more correct "A person is playing the piano in the house" by using statistics mined from parsed corpora to improve the interpretation of the uncertain visual detections, such as the presence of both a computer keyboard and a piano in the video.

2 Background and Related Work

Several recent projects have integrated linguistic and visual information to aid description of images and videos. The most related work on image description is Baby Talk (Kulkarni et al., 2011), which uses

*Indicates equal contribution

Proceedings of COLING 2014, the 25th International Conference on Computational Linguistics: Technical Papers, pages 1218–1227, Dublin, Ireland, August 23-29 2014.

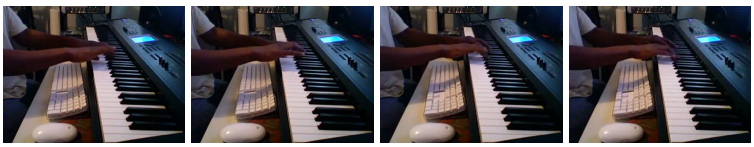

Figure 1: Frames which depict a person playing a piano in front of a keyboard from one of the videos in our dataset. Purely visual information is more confident in the computer keyboard's presence than the piano's, while our model can correctly determine that the person is more likely to be playing the piano than the computer keyboard.

a Conditional Random Field (CRF) to integrate visual detections with statistical linguistic knowledge mined from parsed image descriptions and Google queries, and the work of Yang et al. (2011) which uses corpus statistics to aid the description of objects and scenes. We go beyond the scope of these previous works by also selecting verbs through the integration of activity recognition from video and statistics from parsed corpora.

With regard to video description, the work of Barbu et al. (2012) uses a small, hand-coded grammar to describe a sparse set of prescribed activities. In contrast, we utilize corpus statistics to aid the description of a wide range of naturally-occurring videos. The most similar work is (Krishnamoorthy et al., 2013; Guadarrama et al., 2013) which uses an n-gram language model to help determine the best subject-verb-object for describing a video. Krishnamoorthy et al. (2013) used a limited set of videos containing a small set of 20 entities, and the work of Guadarrama et al. (2013) showed an advantage of using linguistic knowledge only for the case of "zero shot activity recognition," in which the appropriate verb for describing the activity was never seen during training. Compared to this prior work, we explore a much larger set of entities and activities (see Section 3.2) and add scene recognition (see Section 3.3) to further enrich the descriptions. Our experiments demonstrate that our graphical model produces a more accurate subject-verb-object-place description than these simpler n-gram language modeling approaches.

Our Contributions:

- We present a new method, a *Factor Graph Model* (FGM), to perform content selection by integrating visual and linguistic information to select the best subject-verb-object-place description of a video.
- Our model includes scene (location) information which has not been addressed by previous video description works (Barbu et al., 2012; Krishnamoorthy et al., 2013; Guadarrama et al., 2013).
- We demonstrate the scalability of our model by evaluating it on a large dataset of naturally occurring videos (1297 training, 670 testing), recognizing sentential subjects out of 45 candidate entities, objects out of 218 candidate objects, verbs out of 218 candidate activities, and places out of 12 candidate scenes.

3 Approach

Our overall approach uses a probabilistic graphical model to integrate the visual detection of entities, activities, and scenes with language statistics to determine the best subject, verb, object, and place to describe a given video. A descriptive English sentence is generated from the selected sentential components.

3.1 Video Dataset

We use the video dataset collected by Chen and Dolan (2011). The dataset contains 1,967 short YouTube video clips paired with multiple human-generated natural-language descriptions. The video clips are 10 to 25 seconds in duration and typically consist of a single activity. Portions of this dataset have been used in previous work on video description (Motwani and Mooney, 2012; Krishnamoorthy et al., 2013; Guadarrama et al., 2013). We use 1,297 randomly selected videos for training and evaluate predictions on the remaining 670 test videos.

3.2 Visual Recognition of Subject, Verb, and Object

We utilize the visual recognition techniques employed by Guadarrama et al. (2013) to process the videos and produce probabilistic detections of grammatical subjects, verbs, and objects. In our data-set there are 45 candidate entities for the grammatical subject (such as *animal, baby, cat, chef*, and *person*) and 241 for the grammatical object (such as *flute, motorbike, shrimp, person*, and *tv*). There are 218 candidate activities for the grammatical verb, including *climb, cut, play, ride*, and *walk*.

Entity Related Features From each video two frames per second are extracted and passed to pre-trained visual object classifiers and detectors. As in Guadarrama et al. (2013), we compute representations based on detected objects using ObjectBank (Li et al., 2010) and the 20 PASCAL (Everingham et al., 2010) object classes for each frame. We use the PASCAL scores and ObjectBank scores with max pooling over the set of frames as the entity descriptors for the video clip. Additionally, to be able to recognize more objects, we use the LLC-10k proposed by Deng et al. (2012) which was trained on ImageNet 2011 object dataset with 10k categories. LLC-10K uses a bank of linear SVM classifiers over pooled local vector-quantized features learned from the 7K bottom level synsets of the 10K ImageNet database. We aggregate the 10K classifier scores obtained for each frame by doing max pooling across frames.

Activity Related Features We use the activity recognizers described in Guadarrama et al. (2013) to produce probabilistic verb detections. They extract Dense Trajectories developed by Wang et al. (2011) and compute HoG (Histogram of Gradients), HoF (Histograms of Optical Flow) and MBH (Motion Boundary Histogram) features over space time volumes around the trajectories. We used the default parameters proposed in Wang et al. (2011) ($N = 32$, $n_\sigma = 2$, $n_r = 3$) and adopted a standard bag-of-features representation. We construct a codebook for each descriptor (Trajectory, HoG, HoF, MBH) separately. For each descriptor we randomly sampled 100K points and clustered them using K-means into a codebook of 4000 words. Descriptors are assigned to their closest vocabulary word using Euclidean distance. Each video is then represented as a histogram over these clusters.

Multi-channel SVM To allow object and activity features inform one another, we combine all the features extracted using a multi-channel approach inspired by Zhang et al. (2007) to build three non-linear SVM (Chang and Lin, 2011) classifiers for the subject, verb, and object, as described in Guadarrama et al. (2013). Note that we do not employ the hierarchical semantic model of Guadarrama et al. (2013) to augment our object or activity recognition. In addition, each SVM learns a Platt scaling (Platt, 1999) to predict the label and a visual confidence value, $C(t) \in [0, 1]$, for each entity or activity t. The output of the SVMs constitute the visual confidences on subject, verb, and object in all the models described henceforth.

3.3 Visual Scene Recognition

In addition to the techniques employed by Guadarrama et al. (2013) used to obtain probabilistic detections of grammatical subjects, verbs, and objects, we developed a novel scene detector based on state-of-the-art computer vision methods.

We examined the description of all the 1,967 videos in the YouTube dataset and extracted scene words from the dependency parses as described in Section 3.4. With the help of WordNet[1] we grouped the list of scene words and their synonyms into distinct scene classes. Based on the frequency of mentions and the coverage of scenes in the dataset, we shortlisted a set of 12 final scenes (*mountain, pool, beach, road, kitchen, field, snow, forest, house, stage, track*, and *sky*).

For the detection itself, we follow Xiao et al. (2010) and select several state-of-the-art features that are potentially useful for scene recognition. We extract GIST, HOG2x2, SSIM (self-similarity) and Dense SIFT descriptors. We also extract LBP (Local Binary Patterns), Sparse SIFT Histograms, Line features, Color Histograms, Texton Histograms, Tiny Images, Geometric Probability Map and Geometric specific histograms. The code for extracting the features and computing kernels for the features is taken from

[1] `http://wordnet.princeton.edu`

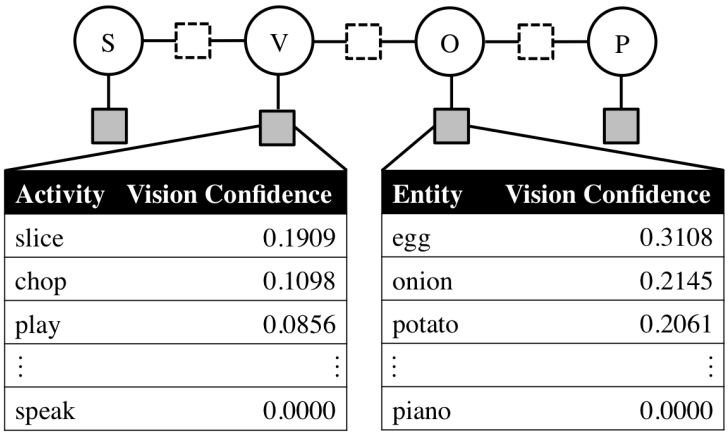
the original papers as described in Xiao et al. (2010). Using the features and kernels, we train one-vs-all SVMs (Chang and Lin, 2011) to classify images into scene categories. As in Xiao et al. (2010), this gave us 51 different SVM classifiers with different feature and kernel choices. We use the images from the UIUC 15 scene dataset (Lazebnik et al., 2006) and the SUN 397 scene dataset (Xiao et al., 2010) for training the scene classifiers for all scenes except *kitchen*. The training images for *kitchen* were obtained by selecting 100 frames from about 15 training videos, since the classifier trained on images from the existing scene datasets performed extremely poorly on the videos. We use all the classifiers to detect scenes for each frame. We then average the scene detection scores over all the classifiers across all the frames of the video. This gives us visual confidence values, $C(t)$, over all scene categories t for the video.

3.4 Language Statistics

A key aspect of our approach is the use of language statistics mined from English text corpora to bias visual interpretation. Like Krishnamoorthy et al. (2013), we use dependency-parsed text from four large "out of domain" corpora: English Gigaword, British National Corpus (BNC), ukWac and WaCkypedia_EN. We also use a small, specialized "in domain" corpus: dependency parsed sentences from the human-generated, English descriptions for the YouTube training videos mentioned in Section 3.1. We extract SVOP (subject, verb, object, place) tuples from the dependency parses. The subject-verb relationships are identified using *nsubj* dependencies, the verb-object relationships using *dobj* and *prep* dependencies. Object-place relationships are identified using the *prep* dependency, checking that the noun modified by the preposition is one of our recognizable places (or synonyms of the recognizable scenes as indicated by WordNet). We then extract co-occuring SV, VO, and OP bigram statistics from the resulting SVOP tuples to inform our factor-graph model, which uses both the out-of-domain (p_o) and in-domain (p_i) bigram probabilities.

3.5 Content Selection Using Factor Graphs

In order to combine visual and linguistic evidence, we use the probabilistic factor-graph model shown in Figure 2. This model integrates the uncertain visual detections described in Sections 3.2 and 3.3 with the language statistics described in Section 3.4 to predict the best words for describing the subject (S), verb (V), object (O), and place (P) for each test video. After instantiating the potential functions for this model, we perform a maximum a posteriori (MAP) estimation (via the max-product algorithm) to determine the most probable joint set of values for these latent variables.



Activity	Vision Confidence
slice	0.1909
chop	0.1098
play	0.0856
⋮	⋮
speak	0.0000

Entity	Vision Confidence
egg	0.3108
onion	0.2145
potato	0.2061
⋮	⋮
piano	0.0000

Figure 2: The factor graph model used for content selection (right), and sample frames from a video to be described (left). Visual confidence values are observed (gray potentials) and inform sentence components. Language potentials (dashed) connect latent words between sentence components. Samples of the vision confidence values used as observations for the verb and object are shown for the example test video.

Observation Potentials. The observations in our model take the form of confidence scores from the visual detectors described in Sections 3.2 and 3.3. That is, the potential for each sentence component $k \in \{S, V, O, P\}$, $\phi_k(t) = C_k(t)$ is the detection confidence that the classifier for component k (C_k) gives to the word t.

Language Potentials. Language statistics were gathered as described in Section 3.4 and used to determine the language potentials as follows:

$$\phi_{k,l}(t, s) := p(l = s|k = t) := \alpha p_o(l = s|k = t) + (1 - \alpha)p_i(l = s|k = t)$$

Where k and l are two contiguous components in the SVOP sequence and t and s are words that are possible values for these two components, respectively. We would expect

$$\phi_{V,O}(\text{ride}, \text{motorbike}) := p(\text{O=motorbike}|\text{V=ride})$$

to be relatively high, since *motorbike* is a likely object of the verb *ride*. The potential between two sequential components k and l in the SVOP sequence is computed by linearly interpolating the bigram probability observed in the out-of-domain corpus of general text (p_o) and the in-domain corpus of video descriptions (p_i). The interpolation parameter α adjusts the importance of these two corpora in determining the bigram probability. We optimized performance by fixing $\alpha = 0.25$ when cross-validating on the training data. This weighting effectively allows general text corpora to be used to smooth the probability estimates for video descriptions. We note that meaningful information would likely be captured by non-contiguous language potentials such as $\phi_{V,P}$, but that the resulting factor graphs would contain cycles, preventing us from performing exact inference tractably.

3.6 Sentence Generation

Finally, we use the SVOP tuple chosen by our model to generate an English sentence using the following template: *"Determiner (A,The) - Subject - Verb (Present, Present Continuous) - Preposition (optional) - Determiner (A,The) - Object (optional) - Preposition - Determiner (A,The) - Place (optional)"* The most probable prepositions are identified using preposition-object and preposition-place bigram statistics mined from the dependency parsed corpora described in Section 3.4. Given an SVOP tuple, our objective is to generate a rich sentence using the subject, verb, object, and place information. However, it is not prudent to add the object and place to the description of all videos since some verbs may be intransitive and the place information may be redundant. In order to achieve the best set of components to include, we use the above template to first generate a set of candidate sentences based on the SVO triple, SVP triple and the SVOP quadruple. Then, each sentence type (SVO, SVP, and SVOP) is ranked using the BerkeleyLM language model (Pauls and Klein, 2011) trained on the GoogleNgram corpus. Finally, we output the sentence with the highest average 5-gram probability in order to normalize for sentence length.

4 Experimental Results

We compared using the vision system alone to our model, which augments that system with linguistic knowledge. Specifically, we consider the *Highest Vision Confidence* (HVC) model, which takes for each sentence component the word with the highest confidence from the state-of-the-art vision detectors described in Sections 3.2 and 3.3. We compare the results of this model on the 670 test videos to those of our *Factor Graph Model* (FGM), as discussed in Section 3.5.

4.1 N-gram Baseline

Additionally, we compare both models against the existing, baseline *n-gram* model of Krishnamoorthy et al. (2013) by extending their best n-gram model to support places. To be specific, we build a quadragram model, similar to the trigram model of Krishnamoorthy et al. (2013). We first extract SVOP tuples from the dependency parses as described in Section 3.4. We then train a backoff language model with Kneyser-Ney smoothing (Chen and Goodman, 1996) for estimating the likelihood of the SVOP quadruple. On quadruples that are not seen during training, this quadragram language model backs off to SVO

Most	S%	V%	O%	[P]%	SVO%	SVO[P]%
n-gram	76.57	11.04	11.19	18.30	2.39	1.86
HVC	76.57	$^{+}$22.24	11.94	17.24	$^{+}$4.33	$^{+}$2.92
FGM	76.42	$^{+}$21.34	12.39	19.89	$^{+}$**5.67**	$^{+}$3.71
Any						
n-gram	86.87	19.25	21.94	21.75	5.67	2.65
HVC	86.57	$^{+}$38.66	22.09	21.22	$^{+}$10.15	$^{+}$4.24
FGM	86.27	$^{+}$37.16	$^{+}$**24.63**	**24.67**	$^{+}$10.45	$^{+}$6.10

Table 1: Average binary accuracy of predicting the **most** common word (top) and of predicting **any** given word (bottom). **Bold** entries are statistically significantly ($p < 0.05$) greater than the HVC model, while $^{+}$ entries are significantly greater than the n-gram model. No model scored significantly higher than FGM on any metric. [P] indicates that the score ranges only over the subset of videos for which any annotator provided a place.

triple and subject-verb, verb-object, object-place bigrams to estimate the probability of the quadruple. As in the case of the factor graph model, we consider the effect of learning from a domain specific text corpus. We build quadragram language models for both out-of-domain and in-domain text-corpora described in Section 3.4. The probability of a quadragram in the language model is computed by linearly interpolating the probabilities from the in-domain and out-of-domain corpus. We experiment with different number of top subjects, objects, verbs, and places to estimate the most likely SVOP quadruple from the quadragram language model. We report the results for the best performing n-gram model that considers the top 5 subjects, 5 objects, 10 verbs, and 3 places based on the vision confidences and an out-of-domain corpus weight of 1. This model also incorporates *verb expansion* as described in the original work (Krishnamoorthy et al., 2013).

4.2 Content Evaluation

Table 1 shows the accuracy of the models when their prediction for each sentence component is considered correct only if it is the word *most commonly* used by human annotators to describe the video, as well as the accuracy of the models when the prediction is considered correct if used by *any* of the annotators to describe the video. We evaluate the accuracy of each component (S,V,O,P) individually, and for complete SVO and SVOP tuples, where *all* components must be correct in order for a complete tuple to be judged correct. Because only about half (56.3%) of test videos were described with a place by some annotator, accuracies involving places ("[P]") are averaged only over the subset of videos for which any annotator provided a place. Significance was determined using a paired t-test which compared the distributions of the binary correctness of each model's prediction on each video for the specified component(s).

We also use the WUP metric from Wordnet::Similarity[2] to measure the quality of the predicted words to account for semantically similar words. For example, where the binary metric would mark "slice" as an incorrect substitute for "cut", the WUP metric will provide "partial credit" for such predictions. The results using WUP similarity metrics for the most common word and any valid word (maximum WUP similarity is chosen from among valid words) are presented in Table 2. Since WUP provides scores are in the range [0,1], we view the scores as "percent relevance," and we obtain tuple scores for each sentence by taking the product of the component WUP scores.

5 Discussion

It is clear from the results in Table 1 that both the HVC and the FGM outperform the n-gram language model approach used in the most-similar previous work (Krishnamoorthy et al., 2013; Guadarrama et al., 2013). Note that while Krishnamoorthy et al. (2013) showed an improvement with an n-gram model considering only the top few vision detections, the FGM considers vision confidences over the entire set

[2] `http://wn-similarity.sourceforge.net/`

Most	S%	V%	O%	[P]%	SVO%	SVO[P]%
n-gram	89.00	41.56	44.01	**57.62**	17.53	10.83
HVC	89.09	$^{+*}$48.85	43.99	56.00	$^{+}$20.82	$^{+}$12.95
FGM	89.01	$^{+}$47.05	$^{+}$**45.29**	$^{+}$**59.64**	$^{+}$21.54	$^{+}$**14.50**
Any						
n-gram	96.60	55.08	65.52	**61.98**	35.70	22.84
HVC	96.54	$^{+*}$65.61	65.32	60.67	$^{+}$42.53	$^{+}$27.75
FGM	96.32	$^{+}$63.49	$^{+}$**67.52**	$^{+}$**64.68**	$^{+}$42.43	$^{+}$29.34

Table 2: Average WUP score of the predicted word against the **most** common word (top) and the maximum score against **any** given word (bottom). **Bold** entries are statistically significantly ($p < 0.05$) greater than the HVC model; $^{+}$ entries are significantly greater than the n-gram model; * entries are significantly greater than the FGM. [P] indicates that the score ranges only over the subset of videos for which any annotator provided a place.

of grammatical objects. Additionally, our models are evaluated on a much more diverse set of videos while Krishnamoorthy et al. (2013) evaluate the n-gram model on 185 videos (a small subset of the 1,967 videos containing the 20 grammatical objects that their system recognized).

The performance differences between the vision system (HVC) and our integrated model (FGM) are modest but significant in important places. Specifically, the FGM makes improvements to SVO (Table 1, top) and SVOP (Table 2, top) tuple accuracies. FGM also significantly improves both the O and [P] (Table 1, bottom, and Table 2) component accuracies, suggesting that it can help clean up some noise from the vision systems even at the component level by considering related bigram probabilities. FGM causes no significant losses under the binary metric, but performs worse than the HVC model on predicting a verb component semantically similar to the correct verb under the WUP metric (Table 2). This loss on the verb component is worth the gains in tuple accuracy, since tuple prediction is the more difficult and most central part of the content selection task. Additionally, experiments by the authors of Guadarrama et al. (2013) on Amazon Mechanical Turk have shown that humans tend to heavily penalize tuples and descriptions even if they have most of the components correct.

Table 3 shows frames from some test videos and the sentence components chosen by the models to describe them. In the top four videos we see the FGM improving raw vision results. For example, it determines that a person is more likely slicing an onion than an egg. Some specific confidence values for the HVC can be seen for this video in Figure 2. In the bottom two videos of Table 3 we see the HVC performing better without linguistic information. For example, the FGM intuits that a person is more likely to be driving a car than lifting it, and steers the prediction away from the correct verb. This may be part of a larger phenomenon in which YouTube videos often depict unusual actions, and consequently general language knowledge can sometimes hurt performance by selecting more common activities.

6 Future Work

Compared to the human gold standard descriptions, there appears to be room for improvement in detecting activities, objects, and scenes with high precision. Visual recognition of entities and activities in diverse real-world videos is extremely challenging, partially due to lack of training data. As a result our current model is faced with large amounts of noise in the vision potentials, especially for objects. Going forward, we believe that improving visual recognition will allow the language statistics to be even more useful. We are currently exploring deep image feature representations (Donahue et al., 2013) to improve object and verb recognition, as well as model transfer from large labeled object ontologies (Deng et al., 2009).

From the generation perspective, there is scope to move beyond the template based sentence generation. This becomes particularly relevant if we detect multiple grammatical objects such as adjectives or adverbs. We need to decide whether additional grammatical objects would enrich the sentence de-

FGM improves over HVC	
"A person is slicing the onion in the kitchen" 	Gold: person, slice, onion, *(none)* HVC: person, slice, egg, kitchen FGM: person, slice, onion, kitchen
"A person is running a race on the road" 	Gold: person, run, race, *(none)* HVC: person, ride, race, ground FGM: person, run, race, road
"A person is playing the guitar on the stage" 	Gold: person, play, guitar, tree HVC: person, play, water, kitchen FGM: person, play, guitar, stage
"A person is playing a guitar in the house" 	Gold: person, play, guitar, *(none)* HVC: person, pour, chili, kitchen FGM: person, play, guitar, house
HVC better alone	
"A person is lifting a car on the road" 	Gold: person, lift, car, ground HVC: person, lift, car, road FGM: person, drive, car, road
"A person is pouring the egg in the kitchen" 	Gold: person, pour, mushroom, kitchen HVC: person, pour, egg, kitchen FGM: person, play, egg, kitchen

Table 3: Example videos and: (Gold) the most common SVOP provided by annotators; (HVC) the highest vision confidence selections; (FGM) the selections from our factor graph model. The top section shows videos where the FGM improved over HVC; the bottom shows videos where the HVC did better alone. For each video, the sentence generated from the components chosen from the more successful system is shown.

scription and identify when to add them appropriately. With increasing applications for such systems in automatic video surveillance and video retrieval, generating richer and more diverse sentences for longer videos is an area for future research. In comparison to previous approaches (Krishnamoorthy et al., 2013; Yang et al., 2011) the factor graph model can be easily extended to support this. Additional nodes can be attached suitably to the graph to enable the prediction of adjectives and adverbs to enrich the base SVOP tuple.

7 Conclusions

This work introduces a new framework to generate simple descriptions of short videos by integrating visual detection confidences with language statistics obtained from large textual corpora. Experimental results show that our approach achieves modest improvements over a pure vision system and significantly improves over previous methods in predicting the complete subject-verb-object and subject-verb-object-place tuples. Our work has a broad coverage of objects and verbs and extends previous works by predicting place information.

There are instances where our model fails to predict the correct verb when compared to the HVC model. This could partially be because the SVM classifiers that detect activity already leverage entity information during training, and adding external language does not appear to improve verb prediction significantly. Further detracting from performance, our model occasionally propagates, rather than correcting, errors from the HVC. For example, when the HVC predicts the correct verb and incorrect object, such as in "person ride car" when the video truly depicts a person riding a motorbike, our model selects the more likely verb pairing "person drive car", extending the error from the object to the verb as well.

Despite these drawbacks, our approach predicts complete subject-verb-object-place tuples more closely related to the most commonly used human descriptions than vision alone (Table 2), and in general improves both object and place recognition accuracies (Tables 1, 2).

Abstract

Most previous research on authorship attribution (AA) assumes that the training and test data are drawn from same distribution. But in real scenarios, this assumption is too strong. The goal of this study is to improve the prediction results in cross-topic AA (CTAA), where the training data comes from one topic but the test data comes from another. Our proposed idea is to build a predictive model for one topic using documents from all other available topics. In addition to improving the performance of CTAA, we also make a thorough analysis of the sensitivity to changes in topic of four most commonly used feature types in AA. We empirically illustrate that our proposed framework is significantly better than the one trained on a single out-of-domain topic and is as effective, in some cases, as same-topic setting.

1 Introduction

Authorship Attribution is the problem of identifying who, from a number of given candidate authors, wrote the given piece of text. The authorship attribution task can be viewed as a multi-class single-label text classification task where each author indicates a class. However, the purpose of AA is to model each author's writing style. AA methods have a wide range of applications, including Forensic Linguistics (spam filtering (de Vel et al., 2001), verifying the authorship of threatening emails), cybercrimes (identifying authors of malicious code and defending against pedophiles), and plagiarism detection (Stamatatos, 2011).

The AA methods can be useful in applied areas such as law and journalism where the identification of the true author of a piece of text (such as a ransom note) may be able to save lives or help prosecute offenders. One of the outstanding problems in AA studies is the unrealistic assumption that the samples of both known and unknown authorship are drawn from the same distribution. This assumption considerably simplifies the AA task but also limits the practical usability of the methods. In practical scenarios usually the documents under investigation are from a different domain than that of the training documents. We feel the need to advance the way AA methods are designed so that the bridge between domains will be minimized to obtain the optimum performance. Therefore, we try to improve the performance of cross-topic AA (CTAA), one of the dimensions of cross-domain AA (CDAA) where training and test data come from different topics.

In this paper, we focus on one of the outstanding research questions on AA: *Can we reliably predict the author of a document written in one topic with a predictive model developed using documents from other topics?* We hypothesize that the addition of training data even if it comes from a topic different than that of the test data improves cross-topic AA performance. To test the hypothesis, we compare the performance of our proposed model trained on documents from all available out-of-topic data with two models, one trained on single out-of-topic data and another trained on the same topic (intra-topic)

Proceedings of COLING 2014, the 25th International Conference on Computational Linguistics: Technical Papers, pages 1228–1237, Dublin, Ireland, August 23-29 2014.

data. We also compare the performance of using four widely used features in AA to demonstrate their discriminative power in intra-topic and cross-topic AA. The contributions of this study are as follows:

- We propose a new method to identify the author of a document on a topic using a predictive model trained on examples from different topics. The successful results attained indicate that authors maintain a consistent style across topics.
- This is the first comprehensive study showing empirically which widely used features in AA are effective for cross-topic AA. We demonstrate that character n-grams are a strong discriminator among authors in CTAA and that lexical features are less effective in CTAA than they are for intra-topic AA.
- We empirically illustrate that having the same amount of training documents from multiple topics is significantly better than having documents from a single topic. It shows that topic variety in training documents improves the performance of CTAA.
- We also demonstrate that across all genres, adding an extra topic to the training data gives a character n-gram model a greater boost in performance than to a stop-word, a stylistic or a lexical model. This is true regardless of the topics on which the model is trained.
- Our proposed methodology is simple to implement suggesting that our findings on cross-topic AA will be generalizable to other classification problems too.

The paper is organized as follows. Section 2 describes two cross-topic datasets while Section 3 describes the methodology for our experiments. Section 4 describes different features while Section 5 presents the experimental setup. We present the evaluation and analysis in Sections 6 and 7. In Section 8, we describe previous studies on cross-topic AA. Finally, Section 9 presents our conclusions and some future directions.

2 Cross-Topic Datasets

Although several corpora are available for traditional AA, we need datasets containing documents from a number of authors from different domains (different topics, different genres). We need many topics to be able to test cross-topic performance, and many genres to ensure that our findings are robust across different styles of text. Obtaining such corpora is a challenging task since most authorship attribution studies focus on a single domain. We have found two datasets that meet our criteria, one having both cross-topic and cross-genre flavor, and the other having only cross-topic flavor. The first corpus contains communication samples from 21 authors in six genres (Email, Essay, Blog, Chat, Phone Interview, and Discussion) on six topics (Catholic Church, Gay Marriage, War in Iraq, Legalization of Marijuana, Privacy Rights, and Sex Discrimination), which we call dataset 1. This dataset was obtained from Goldstein-Stewart *et al.* (2009). Using this dataset, it is possible to see how the performance of cross-topic AA changes across different genres.

Another corpus is composed of texts published in The Guardian daily newspaper written by 13 authors in one genre on four topics (dataset 2) due Stamatatos *et al.* (2013). It contains opinion articles (comments) about World, U.K., Culture, and Politics. Table 1 shows some statistics about the datasets.

Corpus	#authors	#genres	#topics	avg #docs/author	avg #sentences/doc	avg #words/doc
Dataset 1	21	6	6	36	31.7	600
Dataset 2	13	1	4	64	53	1034

Table 1: Some statistics about dataset 1 and dataset 2.

In dataset 1, the average document length is almost half the average document length in dataset 2, while the number of authors is almost twice as that in dataset 2. Also, in dataset 1, there is only one document written by an author on each topic on each genre. However, there are, on average, 16 documents per author per topic on each genre in dataset 2. Overall, dataset 1 seems more challenging and resembles more a realistic scenario of forensic investigations where very few short documents per author might be available.

3 Methodology

To answer our research question and test our hypothesis, we designed three training scenarios. First of all, to demonstrate the complexity of cross-topic tasks, we compare the performance between two training conditions: Intra-Topic (IT), and Single Cross-Topic (SCT). Once we show that it is important to solve this CTAA problem, we design one more training condition based on our proposed idea, Multiple Cross-Topics (MCT) and compare its performance with the IT and the SCT scenarios.

Intra-Topic (IT) In this scenario, all the documents in both the training and test data belong to the same topic. Although this is a strong assumption that does not hold true in most of the realistic scenarios, we examine AA under such conditions in order to be able to compare it with our proposed methods.

Single Cross-Topic (SCT) In this setting, the test data consists of documents from a single topic while the AA model is trained using documents belonging to another topic different than the topic of the test data, but from the same genre. For example, in dataset 1, for 'Chat' genre, a model could be trained on a topic 'Gay Marriage' and tested on the topic 'Legalization of Marijuana'. We experiment on all combinations of test/train topics, i.e., for each test topic, we train separately on each of the remaining topics.

Multiple Cross-Topics (MCT) Unlike in SCT and IT scenarios, here for each test topic, we train on documents from all available topics other than the one used for testing. Our assumption is that authors somehow maintain their unique writeprints across different topics. Therefore, even though the additional data comes from a topic different than that of the test data, we expect to see improvements in the performance of cross-topic AA.

In the SCT scenario, since there is a mismatch between the training and test topic, we expect to obtain experimental results worst than that of the IT scenario. However, we expect that the performance of cross-topic AA using our proposed MCT scenario will be better than SCT in all the cases.

4 Features

The choice of features depends greatly on the type of classification problem. Previous research has explored various types of features that can discriminate among the candidate authors. Stylistic features, character-level and word-level n-grams are the most frequently and successfully used features (Houvardas and Stamatatos, 2006; Zheng et al., 2006; Frantzeskou et al., 2007; Abbasi and Chen, 2008; Luyckx and Daelemans, 2011; Koppel et al., 2011). We consider four of the most widely used features. Our goal behind exploring four different types of features is to understand which features are the best for cross-topic AA.

Lexical Features. Bag-of-words is one of the commonly used document representations that uses single-content words as document features. Authorship attribution approaches using a bag-of-words representation have been found to be effective (Diederich et al., 2003; Kaster et al., 2005; Zhao and Zobel, 2005; Coyotl-Morales et al., 2006). We call bag-of-words the lexical features since we exclude stop-words.

Stop-Words. Stop-words carry no or very little semantic meaning of the texts, however, their use indicates the presence of certain syntactic structures. Although, these words are excluded in the topic-based text classification tasks due to lack of any semantic information in them, we believe these features will be effective in cross-domain AA as hinted by previous work (Goldstein-Stewart et al., 2009). Typically, words such as articles, prepositions, and conjunctions are considered as stop-words. We use a list of stop words publicly available for download (`www.webconfs.com/stop-words.php`).

Stylistic Features. Previous research has shown stylistic features to be effective in AA (Stamatatos, 2006; Bhargava et al., 2013). We use 13 stylistic features: number of sentences, number of tokens per sentence, number of punctuations per sentence, number of emoticons per document, percentage of words without vowel, percentage of contractions, percentage of total alphabetic characters, percentage of two consecutive punctuations, percentage of three consecutive punctuations, percentage of upper case words,

total parenthesis count, percentage of sentence initial words with first letter capitalized, and percentage of words without vowel.

Character n-grams. An n-gram is a sequence of n-contiguous characters. These features capture both the thematic as well as stylistic information of the texts, and hence have been proven to be very effective in previous AA studies (Keselj et al., 2003; Peng et al., 2003; Escalante et al., 2011). Since these features carry stylistic choices of the authors, we believe they will be stable across domains.

5 Experimental Settings

Following the training scenarios discussed previously in Section 3, we performed a set of experiments. We used 643 predefined stop-words. We considered as lexical features all words that were not stop words, and were among the 3,500 most frequent words occurring at least twice in the training data. We used 3,500 most frequent character 3-grams occurring at least six times in the training data.

Since dataset 1 is already balanced across authors, we used all the documents from this dataset. However, dataset 2 was originally imbalanced, therefore we chose at most ten documents per author to avoid a highly skewed distribution. In order to create a corpus like in the realistic scenarios of forensic investigations such as tweets, SMS, and emails, we chunked each selected document by sentence boundaries into five new short documents. This shortening of the documents increases the complexity of the task but enhances the practical applicability of our methods. We use these chunked versions for evaluating our proposed method. Splitting the documents in this way has been used in the past to deal with the lack of more documents per author(Luyckx and Daelemans, 2011; Koppel and Winter, 2014).

We obtained the performance measures using support vector machines (SVMs) implemented in Weka (Witten and Frank, 2005) with default parameters. We considered using SVMs because preliminary results showed this algorithm outperformed other reasonable alternatives. We used prediction accuracy as the performance measure to evaluate different training scenarios. Rather than just comparing the accuracies, we make most of the decisions based on statistical significance computed using two-tailed t-tests with 95% confidence interval.

All the experiments for cross-topic settings are carried out by controlling the genre. In the IT scenario, we computed the accuracy on each test topic using stratified 10-fold cross-validation. In the SCT scenario, for each test topic, prediction accuracy was computed by training separately on each remaining topic and averaging performances. We computed the accuracy on each test topic in the MCT scenario by withholding one topic as test topic and training on all other topics. For each training scenario, we computed one single score for each genre by averaging the accuracies across all test topics belonging to that genre.

6 Experimental Results and Evaluation

In this section, we report results and analysis on different experiments we carried out. We will start by showing empirically the challenge of cross-topic AA. Then, we will show results of our proposed approach.

6.1 Is Cross-Topic AA More Difficult than Intra-Topic AA?

Table 2: Comparison of AA performance on IT and SCT scenarios on dataset 1. For each feature type, the IT and SCT columns indicate the accuracy (%) while the IT-SCT column is the relative gain of IT over SCT. For each genre, bold figures represent the best accuracy. Statistical significance is indicated by * in positive direction and by $^\flat$ in negative direction.

First of all, we want to understand if the cross-topic problem is more difficult than the intra-topic problem of AA. We compared the performance of the IT and the SCT scenarios using four types of features on various genres of dataset 1 as shown in Table 2. We clearly observed that for each genre, and for each feature type, the performance of the IT scenario is better than the SCT scenario and the difference is statistically significant. The only exceptions are 'Email' and 'Essay' genres for stylistic features. This is a strong indication that irrespective of the type of domain as well as the features considered, cross-topic AA is much more difficult than intra-topic AA.

6.2 Does Our Proposed Method Improve CTAA Performance?

We target to answer: *Can we reliably predict the author of a document written in one topic with a predictive model developed using documents from multiple other topics?* We carry out various experiments and compare the performance of our proposed MCT scenario with that of IT and SCT scenarios separately. Although, comparing MCT with only SCT would be enough to answer our research question and test our hypothesis, we are also interested in gaining more insights about cross-topic AA and understanding how it compares to IT, the simplest case of AA.

(d) Character n-grams

Table 3: Performance of lexical, stop-words, stylistic, and character $n-$gram features on dataset 1. The SCT, IT and MCT columns indicate the accuracy (%) while the MCT-SCT and MCT-IT columns present the relative gain of MCT over the other scenario. Statistical significance is indicated by * in positive direction and by $^{\flat}$ in negative direction.

MCT-SCT columns on Table 3 illustrate the statistical significance of MCT over SCT in a positive direction for all the genres. Using any type of feature in any genre, it is possible to significantly improve the performance of CTAA by training a machine learning algorithm using documents from all available out-of-domain topics. This serves as evidence to confirm our hypothesis and answer our research question that documents written in one topic can be reliably predicted with a model developed using documents from multiple other topics. This indicates that authors maintain a consistent writing style across topics.

In the MCT-IT column in Table 3(a), we can seen that the IT is significantly better than the MCT in three genres, while the MCT is better than the IT in only one. This is because lexical features directly capture the choices of authors in a certain thematic area, and hence they yield a good performance in the intra-topic setting. However, we observed contrasting and interesting patterns using stop-words, stylistic features, and character n-grams (MCT-IT column of Tables 3(b), 3(c), and 3(d)). MCT was better than IT, and the difference was significantly better, in 10 genres, while IT performance was significantly better than MCT in none of the genres. This is a very interesting finding as we observed that the cross-topic AA problem can be solved as effectively as the intra-topic AA problem using these features and a variety of topics.

Also using dataset 2, we found that for each type of feature, MCT is better than SCT, and the difference is statistically significant as shown in Table 4. This is another supporting evidence to our hypothesis. The small gain of IT over MCT suggests that our proposed approach is competitive even with the IT scenario.

Feature Type	IT	SCT	MCT	MCT-IT	MCT-SCT
Lexical Features	63.98	21.46	38.62	-39.64$^\flat$	79.96*
Stop-words	45.01	31.66	41.21	-8.44	30.16*

Character n-grams	75.08	45.87	64.54	-14.04$^\flat$	40.7*

Table 4: Performance of four types of features on three different training scenarios on dataset 2. For each feature type, the SCT, IT and MCT columns indicate the accuracy (%) while the MCT-SCT and MCT-IT columns present the relative gain of MCT over the other scenario. Statistical significance is indicated by * in positive direction and by $^\flat$ in negative direction.

6.3 Sensitivity of Features to Changes in Topic

We also want to demonstrate the behavior of four different feature types to changes in topic. We want to test if lexical features favor intra-topic AA and character n-grams favor cross-topic AA. Unlike lexical features, character n-grams carry stylistic choices of authors, and hence are expected to be robust across topics. In Table 2, for each genre, the relative gain of IT over SCT using lexical features is highest compared to that of stop-words, stylistic features, and character n-grams, thereby indicating that lexical features are more effective for ITAA than for CTAA. It is also apparent in Table 2 that the gain of characters n-grams is always better than that of stop-words and stylistic features. While looking at the performance on the SCT scenario using four features, it is observed that character n-grams give the best performance, while stop-words and stylistic features give the second best performance, which leaves lexical features at the bottom. This is because the first three features are topic-independent and hence were able to better discriminate among authors in cross-topic scenarios than lexical features. However, overall, character n-grams have the highest discriminative power in both IT and SCT, which confirms findings of earlier research (Stamatatos, 2013).

In Table 3, character n-grams, when compared to lexical features, stop-words, and stylistic features, yield the highest average relative gain on MCT over the SCT scenario (138.77%, vs 114.15% for lexical features, 97.41% for stop-words, 46.55% for stylistic features). Also, comparing the prediction accuracies of all four features separately in SCT, IT, and MCT scenarios, it is observed that character n-grams score best in most of the genres on each training scenario. This confirms that character n-grams have higher discriminative power in cross-topic AA than stop-words, stylistic features and lexical features.

For cross-topic AA, we observed that the accuracy across the board is not high. It is because the CTAA task is harder than other single domain classification tasks since the topics of the test data are fully disjoint with the topics of the training data. On top of that, the shorter document length makes it more challenging. The current system might not be production quality, but our findings will enable better models in the future that hopefully will be accurate enough to solve CTAA problems more effectively.

6.4 Cross-Topic AA with Varying Number of Training Topics

For traditional AA, it has been shown that around 10,000 word-tokens per author suffice as a 'reliable minimum for an authorial set' (Burrows, 2007). In our study, we have as few as 600 word-tokens per author, much less than the minimum size requirement stated by previous research. In this section, we look at how performance improves with increase in amount of training data by adding additional topics.

To explore this, we experimented by training on documents from all possible combinations of topics. In dataset 1, there are a total of six topics. Therefore, for each test topic, we experiment separately using one, two, three, four, and five topics for training. When measuring performance on k training topics, we gather all possible combinations of training on k of the five topics and then average the performance across all these combinations. For example, if we use two topics for training, then for each test topic, there are $\binom{5}{2} = 10$ possible training combinations that we then average to get a final score. We illustrate the results in Figure 1 for four genres using four types of features. Irrespective of the genres, topics, and types of features used, CTAA performance improves gradually with addition of more data. In most genres, this improvement seems to be almost linear with the number of topics trained on, suggesting that gathering more out-of-topic data should continue to improve the performance. We also observed that the character

(d) Genre = Blog

Figure 1: Effect of training on varying number of topics in CTAA using lexical, stop-words, stylistic, and character n-gram features on dataset 1.

n-grams are the most effective author discriminator in cross-topic AA.

We performed a deeper analysis of the effect of individual topics, which is shown in Table 5. We took an initial topic as training data and then paired it with each of the other topics as additional training data and measured the average performance gain from the addition of the second topic. It is shown that across all genres, adding a second topic to the training data gives a character n-gram model greatest boost in performance than to a stop word or a stylistic or a lexical model. This is true regardless of the topics on which the model is trained. We do not observe negative transfer as in transfer learning (Pan and Yang, 2010) because in cross topic AA authors maintain styles across topics.

Initial Topic	**Genre = Chat**				**Genre = Email**			
	Lexical	**Stop-words**	**Stylistic**	**Character n-grams**	**Lexical**	**Stop-words**	**Stylistic**	**Character n-grams**

Table 5: Average performance gain from adding an additional topic as training data across different initial topics on dataset 1. Each value is the average accuracy gain after adding the second topic.

7 Is it Just 'More Data' that is Helping or is 'Diversity' Relevant?

The quantity of training data was not controlled in the experiments presented in Section 6, therefore, we performed some additional experiments where we did control for this. In Table 6, we present the comparison of SCT and MCT scenarios using the same amount of training data to understand whether the performance improvement in the MCT scenario is due to diversity or due to the fact of adding more data. We use dataset 1 to make this comparison. For the SCT scenario, for each test topic, we averaged

performance over three random samplings, where in each sampling we randomly selected four documents per author in each training topic. For the MCT scenario, for each test topic, we averaged performance

Table 6: Comparison of MCT and SCT scenarios on controlled training data using four types of features on dataset 1. For each feature type, the SCT and MCT columns indicate the accuracy (%) while the MCT-SCT columns present the relative gain of MCT over the SCT. Statistical significance is indicated by * in positive direction and by $^{\flat}$ in negative direction.

over three random samplings, where in each sampling we randomly selected four training topics. For each selection of four training topics, we averaged performance over three random samplings where in each sampling we randomly selected one document per author in each training topic. Thus, we ended up with the same number of documents for training both models. Even with the same amount of training data, training on documents from different topics is better than training on documents from a single topic, with statistically significant performance gains ranging from 3.2% to 39.86% as shown in Table 6. This demonstrates that data from a diverse set of topics will still give a boost in performance and is always significantly better than using data from the same topic.

8 Related Work

The majority of the work in authorship attribution deals with single-domain datasets. However, there have been a handful of studies that add some cross-topic flavor in the AA task (Mikros and Argiri, 2007; Goldstein-Stewart et al., 2009; Schein et al., 2010; Stamatatos, 2013). Mikros *et al.* (2007) concluded that many stylometric variables are actually discriminating topic rather than author and their use in AA should be done carefully. However, the study was performed on a single corpus containing only two authors in two topics that raises questions on reliability of their conclusions. Stamatatos (2013) illustrated the effectiveness of character n-grams in cross-topic AA. It was also shown in that study that avoiding rare features is effective in both intra-topic and cross-topic AA. However, all these conclusions came from training an SVM classifier in only one fixed topic. In contrast, in our paper, we draw our conclusions from all possible training/testing combinations rather than fixing in advance the training topic.

Goldstein-Stewart *et al.* (2009) also carried out some cross-topic experiments by concatenating the texts of an author from different genres. This experimental setting results in a corpus where each test document contains a mix of genres, which is not representative of real world AA problems. Still, to provide some comparisons to the work of Goldstein-Stewart *et al.* (2009), we concatenated all the texts in dataset 1 produced by an individual on a single topic, across all genres to produce one document per author on each topic. We compare our results with those reported in the paper under same training/testing conditions. We withheld one topic and trained on documents from the other five topics.

Test Topic	**Lexical**	**Stop-words**	**Stylistic**	**Character n-grams**	**Stop-words + Character n-grams**	**Previous Work**
Sex Discrimination	66.67	76.19	33.33	95.24	**95.24**	95
Catholic Church	76.19	95.24	38.10	95.24	**100**	95
Gay Marriage	80.95	80.95	42.86	90.48	90.48	**95**
Legalization of Marijuana	52.38	66.67	33.33	95.24	**100**	100
Privacy Rights	42.86	52.38	28.57	95.24	90.48	**100**
War in Iraq	57.14	71.43	38.10	100	**100**	81
Average	62.7	73.81	35.72	95.24	**96.03**	94.33

Table 7: Comparing performance of our work with previous work in the same training/testing setting. The results in the last column were obtained from Goldstein-Stewart *et al.*(2009). For each test topic, the bold figure represents the best performance.

The last column of Table 7 presents the results obtained by using the combination of stop-words and 88 Linguistic Inquiry and Word Count (LIWC) features as reported in Goldstein-Stewart *et al.* (2009). We observed that the combination of character n-grams and stop-words, on average, performs better than those reported in the paper. On this fixed training/testing scenario, we see better accuracies, as high as 100%, across the board. This is because, in this experiment, each training sample on average was ≈ 25 times longer than the training sample in our chunked versions. This illustrates that authorship attribution of short documents, as in our chunked versions, is a challenging task, but we believe it resembles a more realistic scenario of forensic investigations.

9 Conclusions and Future Work

In this research, we presented the first comprehensive study with rigorous analysis on cross-topic AA. Although previous work had hinted some of our findings, it was based on very limited experiments (using only one fixed topic for training). We investigated CTAA using all possible combinations of topics to draw more robust and stable conclusions. We first illustrated the difficulty of cross-topic AA by comparing its performance with intra-topic AA using different types of features. We demonstrated that a framework trained on documents belonging to thematic areas different than that of the documents under investigation statistically improves the performance of cross-topic AA. This improves the ability of the model to find the authors of documents belonging to a new topic not present during the training of the model. By controlling the training data, we demonstrated that training on diverse topics is better than training on a single topic confirming that MCT not only benefits from more data but also from a thematic variety. We also showed a statistical analysis that lexical features are closer to the thematic area and hence were an effective author discriminator in intra-topic attribution. Similarly, character n-grams prove to be a very powerful feature especially in a condition where training and test documents come from different thematic areas. Although intra-topic AA is easier than cross-topic AA, our proposed model for CTAA achieves performance close or in some cases, better than that of an intra-topic AA model. Another interesting conclusion of our study is that addition of more training data from any topic, no matter how distant or close it is with the topic of documents under investigation, improves the performance of CTAA for all types of features. We believe that our contribution to cross-topic AA will be generalizable to other classification problems too.

In the future, we plan to explore the cross-genre problem of AA that is critical for tasks like linking user accounts across emails, blogs, and other social media. Our proposed CTAA approach can be directly applied to the cross-genre problem but we may discover different feature behavior in this scenario. We also plan to explore domain adaptation and transfer learning techniques to solve CDAA problems.

Abstract

We propose the use of a game with a purpose (GWAP) to facilitate crowd-sourcing of phrase-equivalents, as an alternative to expert or paid crowd-sourcing. Doodling is an online multi-player game, in which one player (*drawer*), draws pictures on a shared board to get the other players (*guessers*) to guess the meaning behind an assigned phrase. In this paper we describe the system and results from several experiments intended to improve the quality of information generated by the play. In addition, we describe the mechanism by which we take candidate phrases generated during the games and filter out true phrase equivalents. We expect that, at scale, this game will be more cost-efficient than paid mechanisms for a similar task, and demonstrate this by comparing the productivity of an hour of game play to an equivalent crowd-sourced Amazon Mechanical Turk task to produce phrase-equivalents over one week.

1 Introduction

While it is fairly well known when individual words have the same meaning, it is far more difficult to determine when phrases or even sentences carry the same basic idea. While it might be possible to address this task with machine learning techniques, building a corpus of sentences from which to seed a database requires human intelligence. We suggest a *game with a purpose* (GWAP) that will serve to generate phrases with similar meanings, while simultaneously providing meta-information about the quality of the match. In this drawing game, called *Doodling*, individuals compete in groups to guess the meaning behind a given drawing that is being drawn by one designated *drawer* trying to convey a given phrase or a short sentence. The designated drawer decides when a guessed phrase matches the source phrase. For example "*How far is the airport*?" might match semantically "W*hat is the distance to the airport*?" In addition, the drawer can indicate for each partial guess how close it is on a scale of 1-3 to help the guessers converge on phrases that will match the given phrase or sentence. We then pass all of the guesses and annotations through an SVM classifier to automatically identify potential phrase-equivalents. In this study we examine several techniques for using this system to generate high quality data while also making the game more enjoyable. We measure the efficacy of each technique by comparing our results to a gold standard: using human evaluators to rate the phrase matches generated through the game manually. We also compare Doodling to a paid crowdsourcing paradigm – Amazon's Mechanical Turk – to source phrase equivalents for the same set of phrases, and we show that our approach might be cost effective for large scale sourcing of paraphrases of equivalent quality.

2 Background

In this section we define the problem we are trying to address, and discuss the various ways it has been approached in the past.

2.1 Phrase-equivalents & Evaluation of Quality

In this paper, we define phrase equivalents (PEs) as text elements – phrases or short sentences – that have same or similar semantic content, but with surface structure different from each other. PEs are similar to *paraphrases*, but broader in scope, inclusive of partial matches in meaning as well as complete

Proceedings of COLING 2014, the 25th International Conference on Computational Linguistics: Technical Papers, pages 1238–1247, Dublin, Ireland, August 23-29 2014.

paraphrases. PEs are useful for many NLP systems from simple language modelling and smoothing, to complex Machine Translation technology for generation of a surface form in the target language. Most existing corpora are hand-created, and hence they tend to be small in size, and available only in limited languages and domains. Other data driven approaches – such as, creation of paraphrases using monolingual machine translation (Quirk et al., 2004), mining inference rules from text corpora (Lin & Pantel, 2001), or paraphrase extraction from parallel corpora (Dolan et al., 2004) (Barzilay & McKeown, 2001) – were shown to be effective, but such approaches require significant seed corpora which are available only in limited domains and languages. In addition, the (Lin & Pantel, 2001) approach can generate equivalents using user defined patterns, and may not be appropriate for generating loosely related conceptual paraphrases like the human generated ones that Doodling may generate.

The criteria used for evaluating phrase equivalents differ vastly in research literature, ranging from conceptual equivalence (Barzilay & McKeown, 2001), to interchangeability (Ibrahim et al, 2003), to preservation of grammatical correctness and semantic equivalence (Callison-Burch, 2005), and the standard metric of BLEU score (Callison-Burch, 2005; Papineni et al., 2002). In general, there is no accepted standard model for measuring quality, hence we adopted manual annotation by experts.

2.2 Crowdsourcing & Games with a Purpose (GWAP) for Computational Linguistics

Many flavors of crowdsourcing paradigms exist for the creation of language data. From the *for-pay* model where the contribution is for monetary rewards (Callison-Burch, 2009; Irvine & Klementiev, 2010; Chen & Dolan, 2011), to the *for-recognition* model, where the contribution is made for individuals' visibility in a community (e.g., SourceForge), and the *common-good* model, value is produced for the benefit of some community (Kumaran et al., 2009). In this paper, we explore the *for-fun* model (Cooper et al., 2010; Law et al., 2007; Von Ahn & Dabbish, 2004; Von Ahn et al., 2006), in which data is a by-product of some gameplay, often referred to as "Games with a Purpose" (Von Ahn & Dabbish, 2008), which have been shown to be very successful in many domains.

Specifically with respect to generation of paraphrases or phrase equivalents, (Chen & Dolan, 2011) present their paraphrase collection using video annotations, focusing primarily on viability of establishing Mechanical Turk for providing paraphrases in a productive way. (Barzilay & McKeown, 2003) posited that multiple translations of a foreign text may be a naturally occurring source for paraphrases as each is authored by a different translator; our approach is analogous to this approach, though our source phrases/sentences are not from a foreign language. (Chklovski, 2005) presents an online paraphrase collection tool and studies the incentive model for responsible contributions by volunteers. Paraphrases generated by Doodling would be similar to paraphrases labelled under class "Phrasal" and to a lesser extent class "Elaboration" in (Chen & Dolan, 2011). In our earlier work (Kumaran et al., 2012) we focused on a proof-of-concept methodology using a Pictionary-based approach for generation of paraphrases. In this paper, we expand our concept for generating phrase equivalents in scale inexpensively, using several game and UI/UX features, and also compare it with a realistic for-pay baseline using Mechanical Turk. The power of our methodology is its self-verification mechanisms (by drawer annotating the response for convergence, and the final acceptance) that validates the generated paraphrases.

3 Doodling as a Game

In this section, we present the design elements and the game flow of the Doodling game.

3.1 Game Design

In the Doodling game, the games are played in rooms with one player (designated as the *Drawer*) sketches an assigned concept - as phrase or sentence - while other players in the game room (*Guessers*) attempt to guess the assigned concept from the drawing that is being replicated to all screens. The Guessers typically start guessing the words first (based on the concept that the Drawer starts sketching on the screen); while the game will automatically indicate exact partial matches (for example, "Taxi" as a guess for the given phrase, "Taxi Driver"), the drawer also has the ability to provide feedback using annotations. The Drawer may annotate partial guesses as incorrect (red), on the right track (orange), or partially correct (green), to guide the convergence. All the guessers' guesses and the drawer's annotation are broadcast to all the players in the room. Such broadcasting provides a mechanism in which players

can build on the top of other's guesses, gradually building up the phrase or the sentence. At some point, if one of the guessers guess the right phrase exactly, the game is closed automatically. In addition, if the drawer judges the guess as having the same meaning as the assigned concept (for example, "Cabbie" for "Taxi Driver"), he/she can end the round by marking the guess as correct, rewarding the guesser with game points. If the timer runs out before a correct guess happens, then the game times out. Figure 1 shows the UI during the progress of a game (the given text element being "*taxi driver*").

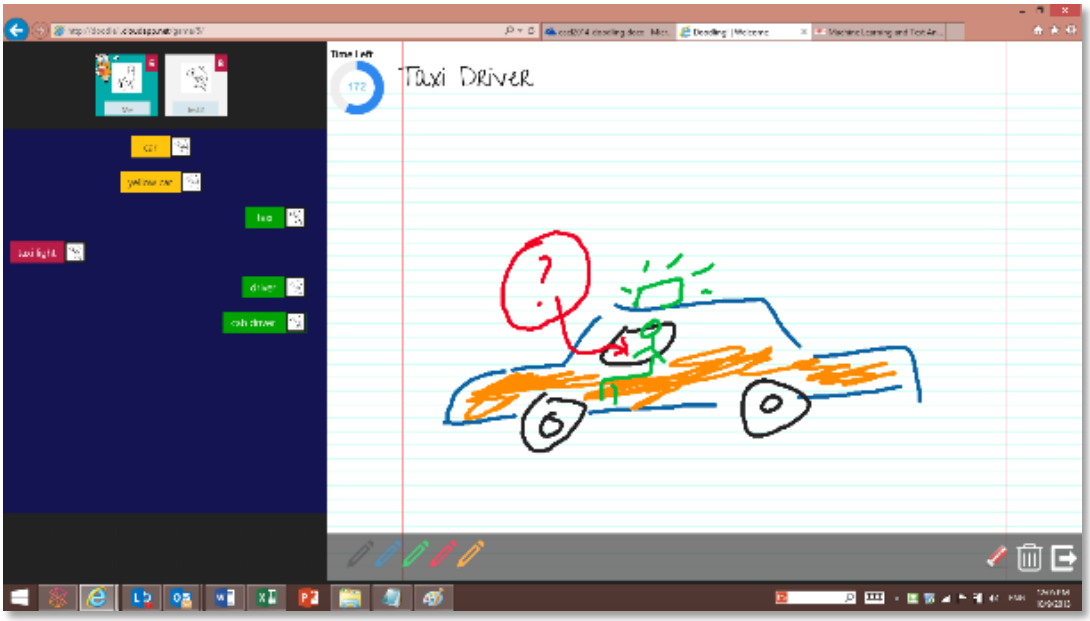

Figure 1: Doodling Game

Our primary intuition is that the sketches provide a language-independent means of communication of concepts that is effectively employed for the generation of phrase equivalents. Thus, we leverage a fun drawing-guessing game to fulfill the linguistic purpose of generating phrase-equivalents. An important aspect of making Doodling effective was to make it engaging to play. We underwent multiple user studies followed by changes to the game's UI/UX. Earlier trials had revealed the need for additional feedback from the drawer, leading to the introduction of 3-stage annotations of guessed phrases. From a usability standpoint, the UI and gestures were optimized for use with touchscreen capable devices, including of the use of swipe gestures for annotating incoming guesses.

The Doodling game subscribes to the Inversion Problem (Von Ahn & Dabbish, 2008), where one of the players produces an output in the form of a sketch for a given input phrase. The other players attempt to guess the given input. The game may produce multiple surface forms of a single semantic intent that have a relationship similar to that of the input-output pair in the "noisy-channel" model.

3.2 Game Elements

While the game dynamics promote the resolution of the underlying computational problem (i.e., the generation of phrase equivalents), we made certain modifications to the basic *sketch-and-convey* metaphor – in the formation and constitution of the game rooms, in the assignment of roles to players in a round-robin fashion, and the drawer's feedback using annotation, in exposing every player's guess to the entire game room, and the winning strategy that encourages building on each other's guesses – in order to help the rounds finish successfully, converge faster, and be more competitive. Above all, the game dynamics and the UI were designed to make Doodling enjoyable as a game.

Roles: Users may join existing game rooms, or can create a new private game room after logging in to the Doodling portal. In a game room, one of the users is assigned – randomly – the role of Drawer (D), and the others the role of Guessers (G). At the end of a given game round, the role of drawer cycles among the game room participants. All G's both compete (the first guesser to guess right – either fully or partially – is rewarded), as well as collaborate (each builds on other's guesses to build longer phrases for bigger rewards) in guessing the text element being conveyed by the D.

Game Round: Like the sketches, the individual guesses of a given G are broadcast to the entire room, along with any annotation from D on each of the guesses (red/orange/green). While the right guesses (either lexicographic match, or as judged by D) gives the game point to the specific G, the broadcast of guesses and feedbacks from D to the entire game room provides a transparent mechanism to help each player build on the guesses of the others. The game round closes with exact reproduction of the source phrase by one of the G's, or by D accepting a full semantic equivalent by double tapping a tile. As an incentive for the role of the drawer, the D is also rewarded with some game points.

Data: In our current experiments, we used standard phrases from a generic WikiTravel (http://wikitravel.org/en/wikitravel:phrasebook template) tourism phrase book as input elements. The authors subjectively classified each text element as Easy or Hard, depending on the potential difficulty to express it as a sketch; though such annotation implies additional preparatory work, it may be well worth the investment as such tagged corpora forms the seed for many variations. We plan to add text elements in many domains (Celebrities, Movies and Idioms), to provide diversity to the players.

Text Element	Diff.	Granularity
Cheese Omelette	Easy	Phrase
Museum of Modern Art	Hard	Phrase
I would like a bowl of soup.	Easy	Sentence
I am not feeling well!	Hard	Sentence

Table 1: Sample of text elements used in the initial seed corpus

In order to understand the dynamics of the game, and to improve the quality and quantity of the phrase equivalents generated in Doodling, we incorporated many features.

Number of Players: The application supports 2-4 players per game room, to measure the effect of room size on convergence rate and the player enjoyment. We hypothesize that those game rooms with more players will lead to better completion primarily due to higher productivity in phrase generation.

Hints & Reminders: we provided hints to all guessers at the beginning of the game to prime then on what to expect about the guess phrase. Hints are simple text elements, such as "Short Phrase" or "Hard Sentence", etc. In addition, we also provided some reminders periodically for improving the game dynamics, especially for the new players, including a reminder to the drawer that they can accept non-exact phrases with the same meaning by double-tapping on the guess tile. Reminders appear on the screen, and fade away unobtrusively. Some game rooms were provided the hints, while others are not, in order to measure how helpful the hints are for game completion.

Soft Matches: Exact lexicographic guesses (full or partial) are automatically rewarded by the game engine. However, as the primary mechanism for gathering paraphrases, soft matches were allowed and rewarded at the discretion of the drawer (either by the double-tap action that accepts a guess as a correct phrase equivalent, or by the swipe-right action that which indicates a potential partial match). Yet, to discourage collusion or cheating, a reporting mechanism is provided: The final accepted guess along with the input text element are shown to all participants, to report any unsatisfactory acceptance.

Metrics: For measuring the effectiveness of the Doodling game, we define many metrics ranging from completion statistics (completion rate and completion time), to quality by comparison with gold data (true positives as compared with user-annotated data, precision and accuracy of automatically classified data), to qualitative user feedback (fun factor).

4 Doodling: Experimental Evaluation

Doodling is an HTML5 app that is accessible from most devices - touchscreen laptop or tablets - and deployed in the cloud (http://doodle1.cloudapp.net/). After deployment, we recruited volunteers (primarily graduate students) to log in and play the game for one hour. As the volunteers entered the game server, they were assigned to different game rooms; each room was instrumented for a specific configuration (game room size - between 2 and 4 players, and availability of hints and reminders). Each room was given the same set of 38 phrases in the same sequence, to keep the variability to a minimum. After an hour, the games were closed and the players asked to fill in an online questionnaire.

In these trials, the 14 volunteers played a total of 112 games, in different game rooms. Most players had previously been exposed to the *sketch-and-convey* metaphor through Pictionary-type games.

4.1 Quality of the Generated Data

Basis for evaluation: We first extracted all of the text elements annotated as a potential match (green, orange, or winning) by the Drawer. Each of the three authors then independently classified according to the relevance of the match. The following five classes were used for annotating every annotated text element: EF (Exact Full Match), EP (Exact Partial Match), TF (True Full Match), TP (True Partial Match) or NM (Not a Match). Partial matches entailed guesses which captured some sub-element of the seed text, but not the entire meaning. We then measured inter-annotator agreement of author's annotations using a Fleiss Kappa measure (Fleiss, 1971), which stood at 0.7424, indicating substantial agreement among our annotations. Hence, we used our annotation (using majority voting for resolving any conflicts) as the gold data set for validating automatically the user generated paraphrases, in subsequent sections.

Quality of the generated data: Of the 112 games played, 98 of them completed successfully. Games were considered incomplete if the timer expired before successful completion. Of the 98 completed games, 15 of the final guesses were false positives (i.e. NM, wrong answers accepted erroneously), 42 games closed with guessers reproducing the exact text element given to the drawer (i.e. EF), and 19 games closed with Drawer correctly accepting a guess that is semantically equivalent to the given text element (i.e. TF, a true phrase-equivalent), and the remaining producing various degrees partial semantic matches (i.e. TP, true partial phrase-equivalents). The average time of completion for successfully completed games was 160 seconds.

In addition, most of the games, irrespective of whether closed correctly or not, produced partial equivalents to the given text element as intermediate guesses, thus providing valuable data for research. These include all the potential matches which were not accepted as the final answer for a game, but were marked as green or orange via the drawers' swipe-based annotation. Table 3 shows the breakdown of the gold classification of all of the potential matches.

4.2 From Game to Corpus

Once assured the quality of the generated data, we devised a methodology for automatically detecting phrase equivalents (full or partial) from the user generated data, so that the game would be able to scale without the need for human annotators to verify individual guesses. We designed a classifier for automatically validating phrase equivalents (partial or full), based only on the game meta data, and very shallow text level features, and not based on any linguistic (such as, dictionaries, thesauri, etc.) or other specialized corpora (such as, parallel or paraphrase corpora). Our basic premise is that if such a classifier can identify good paraphrases with simple features, then we will be able to identify the phrase equivalents automatically, in new domains or languages.

Our classifier uses only simple game and text-level features: hardness of the input text element (easy/medium/hard), status of completion flag and cheating flag at completion, order and time of the guess, drawer's annotation (green/orange/red), cross-game evidence, substring similarities to the input text element and orthographic overlap with the input text. First, we extracted any exact matches (EF or EP) by removing any text elements that were a substring of the original guess, leaving us with a training corpus of 122 potential phrase-equivalents. We trained the classifier using a 5-fold cross-validation this corpus. Some paraphrases thus extracted are shown in Table 2.

Source phrase	**Paraphrases extracted**
Police Officer	Policeman, Police Inspector, Police Superintend
I lost my luggage.	I need to find my bag at the lost-and-found counter, Lost-and-found luggage counter.
School Teacher	Class Teacher, Teacher teaching in school.
Railway Station	Railroad Station, Railway Platform

Table 2: Automatically Extracted Paraphrases

	Doodling	Doodling + SVM			MTurk
	Raw Corpus	Training Corpus	SVM = NM	SVM = TF|TP	Corpus
Size	234	122	73	49	92
Exact Full (EF)	42	EF and EP Data automatically removed from Corpus using String and Substring Match			0
Exact Partial (EP)	71				21

True Full (TF)	30	30	2	28	53
True Partial (TP)	11	11	5	6	13
Not a Match (NM)	81	81	66	15	5
Precision (TF+TP/Size)	17%	34%	10%	69%	72%

Table 3: Comparison of corpora produced by Doodling and MTurk to gold data. SVM numbers are an average of the results generated during the 5-fold cross-validation.

The classifier reduces the burden on expert hand-annotators, by automatically filtering out text elements that are likely to not be a match. As can be seen in Table 3, only 17% of the raw corpus constitutes useful data. Removing exact and substring matches (EF and EP) increases the precision to 34%. The usable corpus produced by the classifier (SVM=TF|TP) has a precision of 69%, with only 10% of the remaining corpus (SVM=NM) constituting false negative, or "lost" data. The overall accuracy of the classifier (% of true positives + true negatives) is 82%.

This methodology provides a viable means of generating paraphrase corpora, with a small amount of hand-crafted corpus in a new domain. The classifier can be fine-tuned either for accuracy of prediction (precision) or productivity (recall); in our experiments we fine-tuned it for precision. Also, we believe that given that these features used are devoid of linguistic or domain information, our results may provide a lower bound on the quality of automatic identification of phrase equivalents; this may be improved substantially by use of appropriate linguistic resources or specialized corpora.

In addition to phrase-equivalent data, many of the guesses relate semantically to the input text element, in varying degrees. Using similar features as used in the classifier, the annotation data can be used for identifying sets of related words for given input text elements, creating valuable resources for search query expansion.

5 Mechanical Turk Experiments

To understand the quantitative difference between Doodling and a paid crowdsourcing model for generating paraphrases we designed a "Data Collection" Mechanical Turk task using the same phrases that were used in our user experiments. Based on previous work relating to designing of Turk experiments and accepted best practices, we kept the task description simple: Each task asked a respondent to generate five unique and semantically equivalent phrases for a given source phrase. The respondents were chosen based on their familiarity with English as their first language, and each phrase was to be annotated by 20 respondents over one week duration; this duration was chosen to keep the respondent population size roughly equal to that of our user experiment. Reward for completing the generation of five phrase-equivalents for a single given phrase was fixed at $0.10USD, in line with the rewards given out for tasks with similar levels of difficulty as cited in published literature (Callison-Burch et al. 2009; Dolan et al, 2011). Though the time frame was a larger than the duration of our experiments (one hour) significantly, the overall time taken for task is comparable to the time spent in gameplay.

At the end of the one-week duration of the experiment, 14 out of 38 phrases got at least one set of valid paraphrases, leading to a completion percentage of 37%. Most of the submitted phrases were annotated only by one respondent; the average number of respondents per phrase was 1.23. The annotation data was judged by the authors in the same scale as outlined in Section 5.1, and the Fleiss Kappa measure for the annotation was 0.74, signifying significant agreement between their judgments. Overall, 72% of the MTurker generated paraphrases were accepted as full or partial alternatives (See Table 3). While the quality of data is very good, any misunderstanding of the task generated results that are significantly off the mark: For example, "*How do I get to the nearest international airport?*" was generated for "*International Airport*" as the source phrase. Since the participation and completion was low, we extended the duration of the task by another week, but the second week yielded only 2 additional completed tasks indicating that the duration of the experiment was not the sole factor in the relative low rate of task completion; perhaps it is the nature of the task that did not attract significant participation.

6 Discussions

6.1 Viability of Doodling as a Game

The 85% successful completion (98 out of 112) of the games is encouraging, and indicates the viability of the game to complete successfully. At the end of the experimental session (wherein 30 rounds of the game had been completed by each player on an average), the players were asked to fill in an online survey to measure various qualitative metrics on effectiveness of Doodling as a game. A wide variety of questions were asked, ranging from specific input (*How did [a specific feature] affect your ability to guess the right phrase?*) to generic qualitative measures (*Would you play this game again?*). Among the questions were three specific questions on how much the players enjoyed the game as a drawer, as a guesser and overall, in a scale of 1 (*Hated it*.) to 5 (*Loved it*!). From the 10 respondents, the enjoyment factor averaged at 4.7 overall. Such high score validates the game design and UX as a viable mechanism for an enjoyable game. Further, 9 out of 10 respondents said that they would *definitely* play the game again, with comments such as "It was very interesting and fun" and "This game is kind of addictive", indicating attraction of the game for subsequent engagement

6.2 Use of Hints & Reminders

We find no evidence for the hints or reminders to be valuable either in improving the quality of the result, or helping the time for convergence/completion. We note that several gamers resorted to other means of indicating the structure of the guess phrases, such as drawing out a number of dashes to indicate the size of the guess phrase, with some of them requesting us to do the same.

6.3 Scaling Up: Comparison with Mechanical Turk for crowd-sourcing phrase equivalents

GWAPs have been criticized for their complexity, long time-to-market, and hidden running costs (Wang et al., 2012). Paid crowd-sourcing methods, by comparison, are simpler to set up, and have lower initial costs. While a concrete, direct comparison is not possible, Table 3 lays out some of the differences between the two methods, especially with reference to our metrics.

	Mechanical Turk (MT)	Doodling
Experimental Operating Costs	US$82	US$90
Ongoing Costs	US$0.10/source phrase	US$90/month
Setup Costs	Minimal	3 man-months
Players/Workers	9	14
Time	2 weeks	1 hour
Completion (Games with ≥ 1 TF generated)	14/38 (37%)	38/38 (100%)
Quantity (# of Unique TFs)	53	28
Precision (% of usable data)	72%	69% (with Classifier)

Table 4: Comparison of MTurk and Doodling experiments for generation of phrase-equivalents

In the case of the Doodling game, the development of the game took 3 man-months, while Mechanical Turk's (MT) setup time was minimal. Both the Doodling and MT experiments had similar operational costs, at US$90 and US$82 respectively. This cost of $90 for Doodling consists of hosting and bandwidth charges incurred for two virtual servers running on a commercial cloud platform. However, once we scale Doodling up to permit more users and higher productivity, we expect the costs to remain fixed, whereas MT costs will scale proportionally to the productivity at US$0.10 per source. In addition, even with approximately equal investment, one hour of Doodling game play is more productive than the two weeks of MT task. As discussed in Section 5, we encountered a significant limitation of paid crowd-sourcing: workers may not choose to do tasks they consider uninteresting. While it is possible to increase the pay rate to increase the completion rate, this entails additional costs, with deteriorating completion rates. While we expect the productivity of Doodling to scale with the number of users, MT's productivity is low even for our limited experiment, and may not scale at all.

To put this in perspective, the time taken to generate useful data using Mechanical Turk varies highly depending on the task: (Chen and Dolan, 2011) reported a duration of 2 months, whereas (Callison-Burch et al., 2009) reported 2 days for their experiments. In our Doodling experiment, the task completion rate for the game (one hour, 14 players) is faster than the equivalent Mechanical Turk task (two weeks, 9 workers). We argue that for scalable data collection, a fixed recurring cost for a reliable completion rate may be preferable over a variable recurring cost. Furthermore, the Doodling game setup is easily scalable to large user base with little marginal cost, and hence we hypothesize that the economy of scale will make Doodling cheaper than MT for diverse domains. Finally, while MT workers tend to be transient, gamers tend to be loyal, particularly if the game is perceived to be interesting. Such a user base may be likely to participate and be productive in other (perhaps related) GWAPs for the generation of useful language data.

6.4 Cheating

Doodling depends on fair gameplay in order to generate reliable phrase-equivalent. Although we did not have many cases of cheating during the trials, cases of cheating will be unavoidable as the game scales to more users. The drawer scribbling answers to the canvas is a most obvious form of cheating, which may require sophisticated image recognition algorithms to weed out automatically. However, we opted for a low-cost approach of allowing any guesser to mark a certain game round as cheating, if they find the drawer scribbling on the canvas. Any guesser can also mark a game round as cheating, if he/she finds the drawer concluding a game round with guesses that are not equivalent phrases. All guessers in a room other than the guesser who provided the accepted guess, are given three seconds to report cheating in case the guess was not found as a suitable equivalent phrase. While this methodology may not work in a two player room, we expect that in larger rooms the competitive nature of the players will keep a game honest. Frequent offenders may be penalized. Proposed penalties would be banning from game rooms, disabling certain roles or introducing harder authentication protocol to prune out offending players.

Along the same lines, we intend to introduce an "inappropriate or offending" flag, to be flagged for a drawing or a guess, by any of the players in the room. Such flags, once set, may need to be investigated offline, and the players penalized in order to discourage misuse or abuse of the game environment.

7 Conclusions and Future Work

In this paper, we explored gaming as a methodology for generating paraphrase data that is useful for NLP or IR research and development of practical systems. Specifically, we outlined a *game-with-a-purpose* – Doodling – that is based on *sketch-and-convey* metaphor, where a sketch by a Drawer was used as a mechanism for abstracting a concept (the source phrase) which was then surfaced by different guessers in the game room, potentially producing paraphrases. We showed that our online multiplayer game was effective in generating paraphrase data, by mining user guesses in the familiar *sketch-and-convey* paradigm, and rewarding phrase-equivalents in addition to exact phrase guesses. Our experiments for just one hour with volunteers have shown that this game can generate high quality data in scale. Most importantly, our volunteers rated the game "very enjoyable", even after an hour of continual play. In addition, we presented a classification mechanism to automatically identify good partial or full phrase-equivalents from the user guesses, using only the meta-level features of the game and shallow text features, opening an avenue for data generation in diverse domains, with a small seed corpora. We believe the quality of such identification may be improved significantly with addition of linguistic resources, such as, dictionaries or thesauri. Finally, our experiments with Amazon's Mechanical Turk indicated that our game is comparable to and potentially more scalable than paid crowd-sourcing. We believe such a game may be a viable mechanism for generating paraphrase data in diverse domains and languages, cheaply.

7.1 Future Work

Currently, we are in the process of developing and releasing Doodling as a multiplayer game app, providing a potential opportunity to study its uptake in the Internet, and the quality of data generated. In our experiments we measured, through a post-game survey, the potential for Doodling being a fun game, and we obtained a score of 4.7 out of 5 for "fun-factor", in addition to many verbal comments on

how enjoyable the game was. Such user feedback amply indicate Doodling's potential for scaling well as a game in diverse domains, such as sports, entertainment and idioms. Also, while the current implementation of Doodling game works well for phrases, we have ample evidence that it works for short sentences (such as, "My luggage is lost", "Where is the nearest post office?" etc.). We hope to extend it to complex sentences as future work.

One of our goals long term is to explore the game's potential for generating parallel data – perhaps through a game being played between two players conversant in two different languages. While this multi- and cross-lingual game poses significant challenges, it provides for an interesting exploration into generation of parallel data through games. Significantly, it may also provide opportunities for language learning and/or cross-cultural awareness, as many of the idioms and culture-specific phrases are not readily conveyed by the surface forms in one language or another. If successful, this may pave way for cost-effective generation of parallel data between many languages of the world.

Abstract

Inference about whether a word in one text has similar meaning to another word in the other text is an essential task in order to understand whether two texts have similar meaning. However, this inference becomes difficult especially when two words do not share a lexical root, do not have the same argument structure, or do not have the same part-of-speech. This paper presents an unsupervised approach for inferring verbs from nouns along with a new online resource PreDic (PREdicate DICtionary) that contains verbs inferred from nouns sharing similar concepts but not the root. The verbs in PreDic are categorized into three groups, enabling applications to target precision-oriented, recall-oriented, or harmony-oriented results as needed. The experiment results show that the proposed unsupervised approach performs similar to or better than WordNet and NOMLEX. Furthermore, a new domain-verb association measure is presented to show the association relationships between inferred verbs and domains to which the verbs are possibly applied.

1 Introduction

The variability of expression is an underlying phenomenon in natural language, and the recognition of the variability serves as the foundation of understanding natural language. Recognizing textual entailment is a research area that seeks to understand this variability, and thus to identify, generate, or extract textual entailment relations from texts. Textual entailment describes a relation of texts where the meaning of one text can be inferred plausibly from another text (Dagan et al., 2010). As a related term, paraphrases refer to expressions that deliver almost the same information using different words (Androutsopoulos and Malakasiotis, 2009). As a lighter form of textual entailment, inference rules refer to expressions that carry not only the same meanings but also similar meanings and could be useful to question answering (Lin and Pantel, 2001).

Much research in recent years has focused on recognizing textual entailment pairs in natural language texts. For example, consider the following sentences:

(1) Emily Bronte *wrote* Wuthering Heights.

(2) Emily Bronte *authored* Wuthering Heights.

Given that these two sentences deliver the same meaning, the verbs *wrote* and *authored* are in a textual entailment relation.

Textual entailment plays a very important role in many areas. For example, in question answering, paraphrases from bilingual parallel corpus were used to expand the original questions (Lin and Pantel, 2001; Duboue and Chu-Carroll, 2006; Riezler et al., 2007); in information extraction, paraphrases were extracted and then used to find entities to fill the slots of binary relations (Shinyama and Sekine, 2003); in machine translation, paraphrases were captured and used as part of reference translations (Madnani et al., 2007; Marton et al., 2009).

Proceedings of COLING 2014, the 25th International Conference on Computational Linguistics: Technical Papers, pages 1248–1259, Dublin, Ireland, August 23-29 2014.

Among textual entailment relations, recognizing the textual entailment of the *predicate* part of a sentence is a hard task, especially when two sentences use different words of different parts-of-speech and different argument structures. This difficulty becomes worse if the predicates of two sentences share neither any lexical root nor have proper chains from thesauri. For example, consider the following sentences:

(3) The *ingredients* of pasta are flour, eggs, and a little bit of water.

(4) Pasta is *made from* flour, eggs, and a little bit of water.

(5) What is the main *ingredient* of pasta?

As example (3) and (4) deliver the same meaning, the words *ingredients* and *made from* have a textual entailment relation. Moreover, example (4) can be an answer to example (5). However, those text pieces share neither any lexical root (*make* vs. *ingredient*) nor any syntactic structure (*X predicate Y* vs. *predicate preposition (of) X linking-verb (is) Y*) nor part-of-speech (*verb* vs. *noun*), so recognizing them as a textual entailment relation is harder than between examples (1) and (2). These inferences from nouns to verbs crossing root boundary remain unclear, and no resources have been published so far, to the best of our knowledge.

This paper presents a new unsupervised approach of inferring verbs from nouns, which share concepts but do not share roots, from glosses of multiple dictionaries. Unsupervised verb inference from nouns crossing root boundary, which covers the variable expressions between nouns and verbs, can be used to help recognize textual entailment relations. PreDic implemented the new approach and can be accessed online at *http://lod.kaist.ac.kr/predic*. PreDic only works for English nouns.

2 Related Work

Collecting similar words from a text is largely based on the *Distributional Hypothesis* (Harris, 1981). The basic idea is that words that occur in the same contexts tend to have similar meanings. Many studies in the literature acquired inference rules or paraphrases based on this hypothesis (Lin, 1998; Lin and Pantel, 2001; Bhagat and Ravichandran, 2008). If we apply that idea to the glosses of dictionaries, then we obtain many similar or relevant words in the glosses for entry words in the dictionaries.

Using dictionary glosses to understand natural language has been a popular approach. Lesk (1986) tried to identify the correct sense of each of two adjacent words, each of which having more than one gloss in the dictionary, by counting overlaps among the combinations of each gloss of each word. Glosses also have been used for extending the functionalities of another resource. Extended WordNet was built by analyzing glosses and extracting extra relations for WordNet synsets (Harabagiu et al., 1999).

Nominalization is a way of inferring nouns mainly from verbs or adjectives, especially when they share the same root. Macleod et al. (1998) built a dictionary of nominalization, NOMLEX (NOMinalization LEXicon). NOMLEX contains the nominalizations of verbs with additional information to relate the complements of nouns to the arguments of the corresponding verbs. This dictionary can be used to capture the following textual entailment relation (Bedaride and Gardent, 2009).

(6) Rome's *destruction of* Carthage.

(7) Rome *destroy(ed)* Carthage.

Argument-Mapped WordNet (Szpektor and Dagan, 2009) provides explicit mappings of arguments between verbs to alleviate the difficulty of tracking argument changes. They manually built or automatically captured rules to augment WordNet's inference capability, which permits inference over predicates only on substitution relations, such as synonyms and hypernyms, e.g. *buy* $\Rightarrow$ *acquire*. The Argument-Mapped WordNet defined only unary rules for verb-nominalization relations and verb-verb relations (e.g., X_{obj}*'s employment* $\Leftrightarrow$ *employ* X_{obj} as a nominalization-verb relation or X_{subj} $break_{\{intrans\}} \Rightarrow damage_{\{trans\}}$ X_{obj} as a verb-verb relation).

However, neither the resources of nominalization nor the mappings of argument changes can recognize examples (3) and (4) as textual entailment relations. Nonetheless, we may find a clue by chaining in WordNet. WordNet (Miller, 1995) and Extended WordNet (Harabagiu et al., 1999) contain links among synsets, so paraphrases that cross lexical root boundaries can be captured by chaining (i.e., *noun A → verb form B of noun A → verb synonym C of verb B*). We adopted this approach to compare PreDic to WordNet in the experiment.

3 Methodology

Among many entailment relations, our methodology has focused on the relations between nouns and verbs that represent similar concepts without sharing their roots. Specifically, verbs for nouns that do not share the same root are collected and then used to recognize textual entailment relations, such as the examples (3) and (4) above. The following sections describe how we collect noun-verb entailment relations crossing roots and how we categorize them for applications.

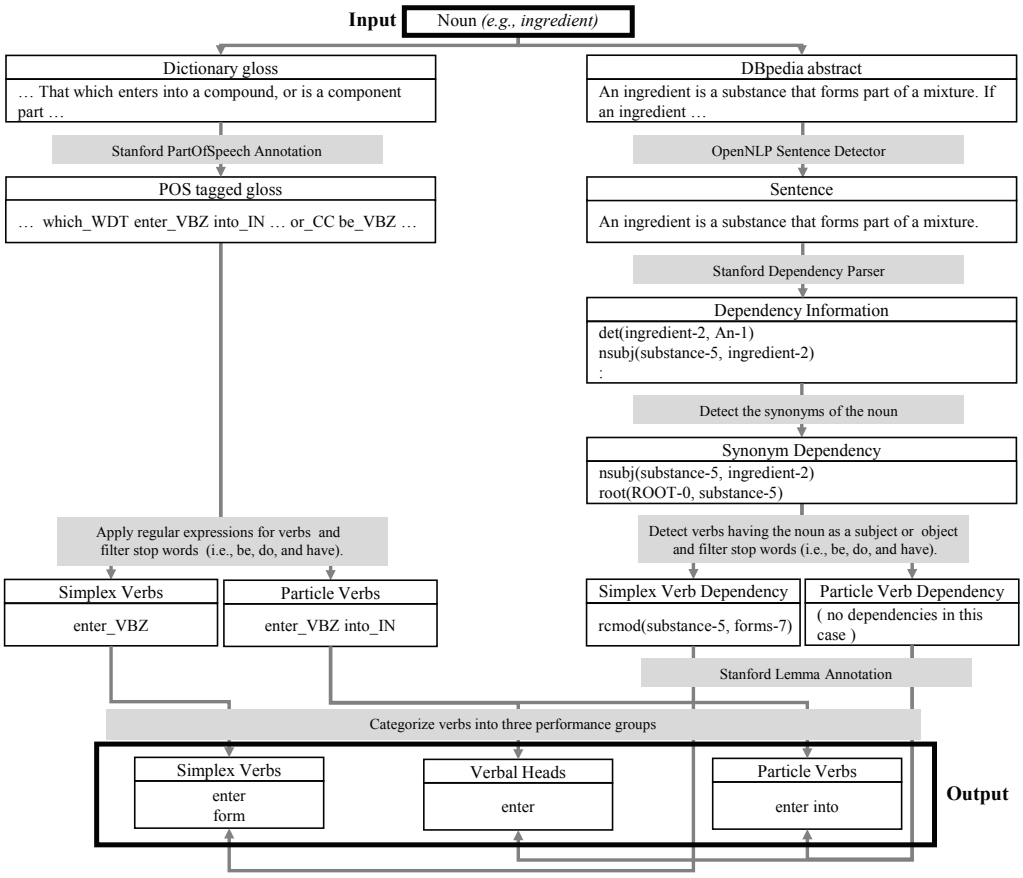

Figure 1: Algorithm consists of two major steps for generating verbs from nouns: acquisition and categorization. Verbs are detected by matching regular expression patterns against POS tagged glosses and by analyzing dependency information, and then categorized into three verb groups (Simplex, Particle, and Verbal Head).

3.1 Acquisition

Verbs that can express a similar concept of a noun can be extracted by analyzing the dictionary glosses of the noun. For example, *The Collaborative International Dictionary of English* describes *ingredient* as "...That which *enters into* a compound, or is a component part of any combination, recipe, or mixture; an element; a constituent..." This example shows that verbs used in the dictionary glosses for a noun can be regarded as having entailment relationships with the noun. Encyclopedias, such as Wikipedia[1], can

[1]http://www.wikipedia.org

also be used as a source for collecting such verbs. Here is an excerpt from Wikipedia article on the word *ingredient*: "An ingredient ... *forms...used ... purported ... required ... listed ... consists of* ..." Table 1 shows sample collected verbs that have entailment relationship with the noun *ingredient*.

Noun	Dictionary Gloss	Collected Verb
ingredient	An ingredient is a substance that *forms* part of a mixture (in a general sense)... If an ingredient itself *consists of* more than one... (Wikipedia)	*form, consist of, enter into*
	... which *enters into* a compound, or is a component part of any combination, recipe, or mixture; an element; a constituent... (The Collaborative International Dictionary of English)	

Table 1: An example of how verbs are collected from glosses. Simplex verbs and particle verbs are collected from the glosses.

Our approach uses five freely available online resources to infer verbs: The Collaborative International Dictionary of English Version 0.48 (which is also referred to as GCIDE), WordNet 3.0, DBpedia version 3.8[2] (which is a structured version of Wikipedia), dictionary.cambridge.org (especially, Cambridge Learners Dictionary and Cambridge Advanced Learners Dictionary), and www.merriam-webster.com (especially, Merriam-Webster's Collegiate Dictionary and Merriam-Webster's Learners Dictionary).

Fig. 1 shows the algorithm for generating and categorizing verbs. Dictionary glosses and texts from DBpedia are processed in different ways in the algorithm. As most of the dictionary glosses are phrases rather than sentences, they have simple syntax and few numbers of verbs. Therefore, after tagging parts-of-speech to every word in the glosses, regular expressions are used to capture verbs. However, texts from DBpedia are composed of several sentences and contain comparatively large numbers of verbs. Thus, dependency parsing is used to capture the verbs that have "close" relations to the noun.

The detailed procedures for generating verbs from dictionary glosses are described here. At the beginning, Stanford CoreNLP[3] adds a part-of-speech tag to each word in the gloss. Then, a regular expression captures simplex verbs of which part-of-speech tag is either one of the "VB", "VBD", "VBG", "VBN", "VBP", or "VBZ". Another regular expression captures particle verbs of which verb's part-of-speech tag is one of the listed above and particle's part-of-speech tag is either "RP" or "IN". Then, verbs that are too commonly used such as *have*, *be*, and *do* are filtered out. At the end, the captured verbs are categorized into three verb groups. A detailed explanation of the categorization is described at section 3.2.

The detailed procedures for generating verbs from DBpedia texts are described here. At the beginning, OpenNLP Sentence Detector[4] splits the text into sentences. Next, Stanford Dependency Parser[5] generates dependency information about the words in each sentence. Then, a list of noun synonyms are gathered from *nsubj* and *root* tags (for more information about the tags or relation names, see de Marneffe et al. (2008)). Next, simplex verbs are captured. That is, if the noun or any of the noun synonyms appears at the head position with any of *rcmod, ccomp, parataxis, vmod, partmod,* and *infmod* tag, then the word in the dependent position is captured. Similarly, if any of the noun synonyms appears at the dependent position with any of *nsubj, nsubjpass, xsubj*, and *dobj*, then the word at the head position is captured. In case of *pobj* that has "preposition" as a head and "object" as a dependent, the verb located at a different dependency relation is extracted by recursively tracing dependency relations. Afterwards, particle verbs are captured by finding particles for each of the simplex verb. That is, if a dependency relation has a *prep* tag and has any one of the simplex verbs at the head position, then the word at the dependent position is regarded as a particle candidate. When the part-of-speech tag for the particle candidate is either "RP" or "IN", then the particle candidate is regarded as a particle of interest. Consequently, the combination of the simplex verb and the particle is generated as a particle verb. Finally, the captured

[2]http://wiki.dbpedia.org/Downloads38?v=6c5

[3]http://nlp.stanford.edu/software/corenlp.shtml

[4]https://opennlp.apache.org

[5]http://nlp.stanford.edu/software/stanford-dependencies.shtml

verbs are categorized into three verb groups.

3.2 Categorization

We pay special attention to particle verbs. Particle verbs are a combination of a verb usually with an adverb or a preposition (Blaheta and Johnson, 2001). The adverbs or prepositions, when combined with simplex verbs, generate another concept that simplex verbs alone do not carry. For example, by adding the second word to *shoot*, various concepts can be produced: *shoot up, shoot off*, etc (Meyer, 1975). Hence, the definition of particle verb we use here is, to a certain degree, similar to the definition of multi-word verbs that, at the least way, carry extra meaning, or some of the words have a restricted or modified meaning when they go together.

Thus, we assume that particle verbs in text play more important roles than simplex verbs by delivering the author's intention more specifically. Based on this assumption, we built a performance group model that categorizes each verb into up to three groups. Fig. 2 shows how collected verbs are assigned to three different performance groups: (1) group of simplex verbs and verbal heads from particle verbs, (2) group of particle verbs, and (3) group of verbal heads from particle verbs. A simplex verb can be assigned to only simplex group while a particle verb, as a whole or only as a verbal head, can be assigned up to three groups. Fig. 2 formalizes the concept of categorization.

Performance Group Model: $\{v1, v2p\} \rightarrow \{\{v1, v2\}, \{v2p\}, \{v2\}\}$

- input : *v1* (simplex verb), *v2p* (particle verb)
- output : $\{v1, v2\}$ (group of simplex verbs and verbal heads of particle verbs), $\{v2p\}$ (group of particle verbs), $\{v2\}$ (group of verbal heads of particle verbs)

Figure 2: Performance group model that assigns collected verbs into three verb groups (v1: simplex verb, v2: verbal head of particle verb, v2p: particle verb). A simplex verb can be assigned to only simplex group while a particle verb, as a whole or only as a verb part, can be assigned up to three groups.

For example, when *form, consist of*, and *enter into* are collected for *ingredient*, they are categorized as follows: *form, consist*, and *enter* are assigned to the simplex group; *consist of* and *enter into* are assigned to the particle group; *consist* and *enter* are assigned to the verbal head group. Table 2 shows an example of categorization in detail.

Collected Verb	**Verb Group**		
	Simplex	**Particle**	**Verbal Head**
form, consist of, enter into	form, consist, enter	consist of, enter into	consist, enter

Table 2: Examples of how verbs are categorized into up to three verb groups (Simplex: group of simplex verbs, Particle: group of particle verbs, Verbal Head: group of verbal heads of particle verbs).

3.2.1 Simplex Verb Group

Only simplex verbs among collected verbs are assigned to the simplex group. For example, if the following verbs are collected from the glosses on the word ingredient (*form, consist of, enter into*), then *form*, *"consist"* of *consists of*, and *"enter"* of *enter into* are assigned to the simplex group. As the number of verbs in the simplex group is the largest among the three verb groups, chances are that the number of recognized texts in entailment relations using verbs in this group would be the largest among the three groups. Therefore, verbs in this group should be used to recognize as much relevant information as possible in spite of low precision. In other words, this group is suitable for recall-oriented tasks.

3.2.2 Particle Verb Group

Only particle verbs composed of two words are assigned to the particle group. For example, *consists of* and *enter into* from the collected verbs in Table 2 are assigned to the particle group. As the verbs in

this group are all particle verbs, chances are that the number of recognized texts in entailment relations using verbs in this group would be the smallest among the three groups. Therefore, verbs in this group should be used to recognize as much accurate information as possible at the expense of low recall. In other words, this group is suitable for precision-oriented tasks.

3.2.3 Verbal Head Group

The verbal head of a particle verb is the word that determines the syntactic type or the nature of that particle verb. Only verbal heads of particle verbs are assigned to the verbal head group. For example, *"consist"* of *consist of* and *"enter"* of *enter into* from the collected verbs in Table 2 are assigned to the verbal head group. This group comes between the simplex group and the particle group in terms of both precision and recall. For example, if one searched for *consist* in a text, then texts with *consist of* and *consist in* would be retrieved. It is not clear whether *consist in* fits the search needs, but it is reasonable to think that the word *consist* is common in both of the two types of search results, and therefore, all of the results would share some meaning to a certain extent. Consequently, verbs in this group should be used as a compromise between precision and recall. In other words, this group is suitable for harmony-oriented tasks.

4 Experiment

The experiment aimed at proving three things: the application performance of PreDic compared to NOMLEX that is regarded as a baseline system, the application performance of PreDic compared to WordNet, and the efficiency of the performance group model in real use. We will discuss the application performance at sections 5.1 and the efficiency of performance group model at section 5.2, respectively. In this section, we describe how the experiment was designed and performed.

4.1 Task: Textual Entailment for Relation Extraction

Relation extraction is one of the application areas that uses textual entailment as a core function. PreDic was used to extract binary relations that have textual entailment. Binary relation, *relation(X,Y)*, is one of the typical relation types, and extracting binary relation can be classified into three tasks: given two instances of *X* and *Y* (e.g., *pizza* and *dough*), find relations (e.g., *ingredient*); given one instance of *X* (e.g., *pizza*) and a relation (e.g., *ingredient*), find the other instances of *Y* (e.g., *dough*); and given a relation (e.g., *ingredient*), find instances of *X* and *Y* (e.g., *pizza* and *dough*) (Sarawagi, 2008).

As the second type (i.e., given one instance of *X* and a relation, find the other instances of *Y*) can have predefined noun relations, an experiment with this type can show how noun relations and verb relations are used interchangeably. Therefore, the experiment was performed with a predefined list of subject instances and noun relations.

4.2 Test Data

A PASCAL RTE (Recognizing Textual Entailment) dataset would be the best choice for experiment. However, as a PASCAL RTE dataset for information extraction is composed of pairs of texts, rather than a text and a structured template like the second type mentioned above (Dagan et al., 2009) , it was difficult to validate the proposed approach's capability of inferring verbs from nouns.

Therefore, we decided to use pairs of templates and texts from Wikipedia because they are easily found in Wikipedia. Article names were used as subject instances, and the property names of the infobox were used as noun relations (Wikipedia's infobox is a fixed-format table provided by the system, and people populate the table to present a summary of an article text). However, we used DBpedia instead of Wikipedia in the experiment. This is because DBpedia is easier to access from application viewpoint. That is, it already captured infobox property names from Wikipedia's article. Furthermore, DBpedia provides first few sentences as abstracts from Wikipedia's article rather than full text that is sometime too long and complex to process.

Templates were built for *Cuisine* and *Country* domains. For the *Cuisine* domain, 1,029 cuisine instance names were prepared based on the top 10 countries that have the largest number of cuisine related pages in Wikipedia's cuisine category. For the *Country* domain, 206 country instance names were prepared.

Domain	Relation	Definition
Cuisine	ingredient	Substance of the cuisine
	origin	The country or period of origin
	serving	Temperature or dishes served with
Country	border	Geographical units such as countries, rivers, or mountain, etc.
	language	Official or unofficial spoken languages
	population	The number of people living in the borders of the country

Table 3: Noun relations and definitions about relations used for the experiment.

Each domain had three noun relations (*ingredient, origin*, and *serving* for *Cuisine*, and *border, language*, and *population* for *Country*). These relations were chosen according to the frequencies of infobox property names. Thus, a total of 3,087 (1,029 instances multiplied by three noun relations) templates were prepared for the *Cuisine* domain, and a total of 618 (206 instances multiplied by three noun relations) templates were prepared for the *Country* domain. Table 3 shows the noun relations and their descriptions used in this experiment.

Total 7,996 sentences were prepared as texts from DBpedia for the *Cuisine* domain, and 3,062 sentences were prepared as texts from DBpedia for the *Country* domain. Three human raters read these sentences and marked whether each sentence expressed a similar concept to the prepared templates. For example, if a rater read "Typically pasta is made from an unleavened dough of a durum wheat flour ...", then the rater was supposed to mark the sentence as "relevant" to the template of *ingredient (X, Y)*. The agreement could be subjective, so we adopted a majority vote from three raters for each sentence. Hence, the sentences upon which the two raters agreed were annotated as relevant and put into the answer set. Each rater worked independently and was not aware of how our proposed algorithm worked.

4.3 Execution

For a given template (e.g., *ingredient (Pasta, Y)*, a number of patterns were generated by substituting the noun relation with verbs from PreDic (e.g., *made from (Pasta, Y)*, *contain (Pasta, Y)*, etc.). When the subject and predicate of each sentence matched the subject instance and verb of each pattern, the sentence was marked as "retrieved". If the retrieved sentence exists in the answer set, then it is marked as "retrieved and relevant".

The performances of PreDic was compared to the performances of NOMLEX. The verbs from NOMLEX were manually collected for the experiment. We also compared the performances of PreDic to the performances of WordNet. However, getting similar verbs of PreDic from WordNet was hard because WordNet does not directly provide verbs for a noun unless the noun itself also has a verb form. Hence, we adopted to collect verbs chaining words by navigating relations in WordNet (Szpektor and Dagan, 2009). We performed chaining up to a certain level until we could collect a similar number of verbs to PreDic. For example, when a similar number of verbs were extracted in the first search for the noun, then all verbs were collected and stopped (level 1). If a similar number of verbs were not extracted, then the extracted noun synonyms were searched again for verbs, and so on. MIT Java WordNet Interface (Finlayson, 2013) was used to collect verbs for the six noun relations from locally installed WordNet 3.1 (see Appendix for the complete list of the acquired verbs from PreDic and WordNet for the experiment. Simplex verbs are omitted if they can be generated by particle verbs).

5 Result and Discussion

5.1 Comparison to NOMLEX and WordNet

As NOMLEX provides verbs as long as nouns have their verbal forms, the performances of the two nouns (i.e., *ingredient* and *language*) could not be measured. Moreover, NOMLEX provides only simplex verbs, so only the performances using simplex verbs could be measured. Table 4 shows that PreDic is better at recall for all relations. In terms of F1, PreDic is better for four relations (i.e., *ingredient,*

origin, language, and *population*) while NOMLEX is better for two relations (i.e., *serving* and *border*). However, PreDic is better at precision for only two relations (i.e., *ingredient* and *language*) while NOMLEX is better at precision for four relations (i.e., *origin, serving, border*, and *population*). Although NOMLEX performs more precisely, its limited coverage degraded the overall performance of the resource.

Relation (R.S.)	**Verb Group**	**PreDic**					**NOMLEX**				
		Ret	**R.R.**	**Pre**	**Rec**	**F1**	**Ret**	**R.R.**	**Pre**	**Rec**	**F1**
ingredient (1413)	simplex	1104	571	**0.52**	**0.40**	**0.45**	-	-	-	-	-
origin (636)	simplex	1298	242	0.19	**0.38**	**0.25**	97	81	**0.84**	0.13	0.22
serving (505)	simplex	1124	344	0.31	**0.68**	0.42	407	285	**0.70**	0.56	**0.63**
border (233)	simplex	259	112	0.43	**0.48**	0.45	105	105	**1.00**	0.45	**0.62**
language (80)	simplex	245	9	**0.04**	**0.11**	**0.06**	-	-	-	-	-
population (133)	simplex	216	7	0.03	**0.05**	**0.04**	3	1	**0.33**	0.01	0.01

Table 4: Application Performance of PreDic and NOMLEX. The coverage of NOMLEX is limited to the nouns that have verbal forms. R.S.: number of relevant sentences, Ret: number of retrieved sentences, R.R.: number of retrieved & relevant sentences, Pre: precision (%), Rec: recall (%), F1: F1 score (%). The best scores for each relation are printed in **bold**.

Table 5 shows the performance comparison between PreDic and WordNet. According to Table 5, PreDic is better at recall for all relations except *border*. PreDic is better at precision for three relations (*ingredient, origin*, and *population*) and WordNet is better for three relations (*serving, border*, and *language*). In terms of F1, PreDic is better for four relations (*ingredient, origin, border*, and *population*), and WordNet is better for two relations (*serving* and *language*).

Table 5: Application Performance of PreDic and WordNet. PreDic shows better or similar performances than WordNet (refer to Table 4 for the acronyms in the table header). The best scores for each relation are printed in **bold**.

If we compile all counts and scores of each relation into verb groups by micro average and macro average, we can get more straightforward comparisons. Micro-averaging assigns equal weight to each instance (e.g., each retrieval) regardless of classes, whereas macro-averaging assigns equal weight to each class (e.g., each predicate). Table 6 shows that PreDic is the best at recall for both micro average (i.e., 0.43) and macro average (i.e., 0.42), while NOMLEX is best at precision for both micro average (i.e., 0.77) and macro average (i.e., 0.48). However, the large difference in precision for NOMLEX between micro and macro average (i.e., 29 percent) shows that NOMLEX performs well on some nouns but not on other nouns. In contrast, PreDic provides not only the better recall and broader coverage than NOMLEX and WordNet, but also competitive macro average precision (i.e., 0.39 vs. 0.41) compared to NOMLEX or even better micro average precision (i.e., 0.60 vs. 0.52) compared to WordNet.

	Verb Group	**Precision**			**Recall**		
		PreDic	**WordNet**	**NOMLEX**	**PreDic**	**WordNet**	**NOMLEX**
Micro Average	simplex	0.30	0.52	**0.77****	**0.43**	0.28	0.16**
	particle	0.60	0.00*	N/A	0.11	0.00	N/A
	verbal head	0.42	0.49	N/A	0.35	0.10	N/A
Macro Average	simplex	0.25	0.41	**0.48****	**0.42**	0.25	0.19**
	particle	0.39	0.00*	N/A	0.07	0.00	N/A
	verbal head	0.37	0.18	N/A	0.28	0.10	N/A

Table 6: Micro and Macro Average Performances of PreDic, WordNet, and NOMLEX. Scores for WordNet (*) were calculated by using only two relations (*origin* and *serving*) and scores for NOMLEX (**) were calculated by using only four relations. The best scores at precision and recall for each average are printed in **bold**.

The results imply that an unsupervised approach can outperform over hand-crafted resources. This also implies that unsupervised approaches can contribute to building diverse lexical resources and cover more variability of expressions in natural language as well.

5.2 Efficiency of Performance Group Model for PreDic

If we narrow the scope of performance to PreDic, we can see from the performances of PreDic in Table 5 that the verbs from the simplex group are best at recall for all relations as expected, the verbs from the particle group are best at precision for four relations (i.e., *ingredient, origin, language*, and *population*), and the verbs from the verbal head group are best at F1 for four relations (i.e., *origin, border, language*, and *population*). These results are consistent with the results in Table 6. The performances of PreDic in Table 6 show that the particle group is best at precision for micro and macro averages (i.e., 0.60 and 0.39, respectively) and the simplex group is best at recall (i.e., 0.43 and 0.42, respectively).

These results assure that our assumption for performance group model is convincing. This implies that performance group model can be adopted for implementing tasks as a precision-oriented, recall-oriented, or even harmony-oriented as needed. That is, as the variability of natural language is hard to predict, this performance group model plays a very important role in guiding applications on whether to focus on getting high-quality information at the expense of large quantities of information, large quantities at the expense of high quality, or a compromise between these two extremes given limited available time and cost. For example, when acquiring more verbs from another source, particle verb group can be used since it provides few but accurate seed verbs, whereas simplex verb group can be preferable when extracting information from texts because it offers more verbs.

6 Domain Verb Association

The relationship between nouns and inferred verbs can be measured by counting co-occurrences using web search engines (Soderland et al., 2004), and in this paper we used Google to collect the frequencies of the co-occurrences. According to Table 7, *prepare, contain, make from, form*, and *consist of* show

Verb	Hits w/ *ingredient*
prepare	56,100,000
contain	46,400,000
make from	37,800,000
form	33,700,000
consist of	15,500,000
attract	3,440,000
occupy with	3,420,000
display in	3,260,000
list by	2,050,000
use with	839,000
enter into	661,000

Table 7: Noun-Verb co-occurrence counts. These numbers provide conceptual relationships between the noun *ingredient* and the inferred verbs.

Verb	Hits w/ Cuisine	DVA
make from	7,452,978	**1.00**
consist of	1,454,047	**0.20**
prepare	718,686	**0.10**
form	406,778	**0.05**
use with	191,220	**0.03**
contain	101,411	**0.01**
enter into	22,749	0.00
display in	8,714	0.00
attract	4,298	0.00
list by	4,605	0.00
occupy with	9	0.00

Table 8: Domain Verb Associations (DVA) for *Cuisine* domain and the inferred verbs. The verbs with DVA above 0.00 (printed in **bold**) seem to be more associated with the *Cuisine* domain.

Verb	Hits w/ Drug	DVA
contain	1,651,933	**1.00**
make from	594,561	**0.36**
use with	490,588	**0.30**
consist of	54,163	**0.03**
form	42,963	**0.03**
prepare	30,366	**0.02**
attract	121	0.00
display in	51	0.00
enter into	12	0.00
list by	9	0.00
occupy with	0	0.00

Table 9: Domain Verb Associations (DVA) for *Drug* domain and the inferred verbs. The verbs with DVA above 0.00 (printed in **bold**) seem to be more associated with *Drug* domain.

much more co-occurrences with *ingredient* than with the other verbs (with a threshold of 10 million, for example). Although the co-occurrences do not consider the distance between two words, they must reveal the degree of relationships between the concept of nouns and their actual verbal forms in texts.

However, what matters more is how much inferred verbs are used with the words of interest rather than a noun itself. Furthermore, if we can rank preferred verbs by domains, inferred verbs can be more useful to applications that focus on specific domains. Hence we defined Domain Verb Association (DVA) to measure how frequently inferred verbs are used with domain instances that can be used as subjects or objects for the verbs. Let D denote a set of domain instances, V a set of verbs inferred from a predicate P, v_f a verb form of a (base form) verb v. Domain Verb Association measures a normalized association score for an ordered combination of a domain and a verb by summing the co-occurrences of each domain instance in the domain and each verb form of the base form of the verb:

$$DVA\,(D, v|P) = \frac{\sum_{d_i \in D} \sum_{v_f \in v} hits\,(d_i \,||\, v_f)}{\max_{v \in V} DVA\,(D, v|P)} \quad (1)$$

where *hits* is the number of search engine hits for query and $d_i \,||\, v_f$ is a concatenation of two words enclosed by " and ".

For the experiment, we defined present simple, past simple, and simple present passive voice as a set of verb forms, without taking the argument structures of the verbs into account for simplicity. We chose *hamburger, pasta*, and *sandwich* as a set of sample representative instances of the domain *Cuisine*. We also selected *Advil, Aspirin*, and *Benadryl* as a set of sample representative instances of the domain *Drug*. Consequently, queries $d_i \,||\, v_f$ were built like *"pasta makes from", "pasta made from"* or *"pasta is made from"* for each combination of a domain instance and an inferred verb. *DVA* scores for the association of the inferred verbs from *ingredient* and the two domains (*Cuisine* and *Drug*) using Eq. (1) are shown in Table 8 and Table 9, respectively. The results show that each domain prefers some verbs to other verbs in that *make from* is the most frequent in *Cuisine* domain but *contain* is the most frequent in *Drug* domain. *Make from* is used about 70 times more often than *contain* in *Cuisine* domain, while *contain* is used about two and a half times more often than *make from* in *Drug* domain. Certainly we believe that this measure will help to improve the application performance of using PreDic.

7 Conclusion

We have presented an unsupervised approach for inferring verbs from nouns crossing root boundary and introduced a new lexical resource, *PreDic*, which is an implementation of the approach and contains verbs inferred from nouns that share neither a root nor argument structure nor a part-of-speech. We have also demonstrated a performance group model that arranges verbs into three groups is practical enough to guide applications to pursue recall-oriented, precision-oriented, or harmony-oriented results. Furthermore, the Domain Verb Association measure was introduced to show the relationships between inferred verbs and domains to which the inferred verbs are possibly applied.

Many researchers have suggested effective approaches for verb entailment acquisition and built valuable lexical resources with which the variability of natural language expression can be understood more systematically. However, unsupervised verb inference from nouns that can deliver similar meaning without shared roots has not been explicitly addressed so far. This research presents compelling evidence that the proposed approach can be a stepping stone for such applications as information extraction or natural language question answering in understanding the variability of natural language expression and recognizing such relations in text. Our future research needs to incorporate more syntactic and external knowledge, and to learn more verbs using some of the inferred verbs as seeds. Moreover, the inference over composite nouns and other parts of speech will also be investigated. Notwithstanding these future research issues, the present research findings provide clear evidence that utilizing verb inference from nouns is a fruitful textual inference approach.

Enriching Wikipedia's Intra-language Links by their Cross-language Transfer

Abstract

Although hyperlinks enhance the utility of Wikipedia, embedding them in articles imposes a burden on contributors. To alleviate this burden as well as enrich hyperlinks in Wikipedia articles, we propose a method for transferring intra-language links between different-language articles linked via an inter-language link. The method avoids anchor selection and disambiguation problems by which usual wikification methods are affected, by exploiting the analogy between different language editions of Wikipedia. The effectiveness of the method was demonstrated through an experiment of transferring intra-language links from English to Japanese. It increased the number of intra-language links in Japanese articles by 40.9%, and the accuracy of anchors selected was estimated to be 96.3%.

1 Introduction

Wikipedia is a Web-based encyclopedia constructed collaboratively by many contributors and continues to enlarge and improve daily. Because of its overwhelming scale, improved quality, and multilingual nature, it has acquired a huge number of readers worldwide. One of the distinguishing features of Wikipedia is that it is a hypertext, which greatly enhances its usefulness and usability. That is, an article is linked to its related articles in the same language via intra-language links as well as to its counterpart articles in different languages via inter-language links (ILLs), and readers can navigate within millions of articles.

Editing Wikipedia articles naturally includes linking them to their related articles, which imposes an additional burden on contributors. As a result, Wikipedia articles may remain incomplete; they sometimes lack important links as well as contain incorrect links. Thus, it is desirable to automate link-related editorial tasks such as embedding links in new articles and verifying links in existing articles. Linking a plain text, usually non-Wikipedia articles, to Wikipedia articles is called wikification, and much effort has been devoted to developing a variety of wikification methods over the past decade (Mihalcea and Csomai, 2007; Milne and Witten, 2008a; Fogarolli, 2009; Ratinov et al., 2011). However, wikification methods are still immature and affected by two hard problems; anchor selection, which involves keyword extraction or term recognition, and destination-article determination, which is a kind of word sense disambiguation (WSD).

We focused on the comparability of intra-language links between different language editions of Wikipedia, and developed a method for transferring intra-language links in one language edition to another language edition. Although the method is not applicable to texts other than Wikipedia articles, it avoids the problems of anchor selection and destination-article disambiguation by using analogy with different language editions. It does not require any language resources other than Wikipedia itself. When the target language is a morphologically rich one, a morphological analyzer is also required. Although the method is applicable to any language pairs, we evaluated its effectiveness through an

Proceedings of COLING 2014, the 25th International Conference on Computational Linguistics: Technical Papers, pages 1260–1268, Dublin, Ireland, August 23-29 2014.

experiment of transferring intra-language links from English to Japanese.

2 Basic Idea

In Wikipedia, an article in one language is often linked to another article in another language via an ILL. These two articles, which describe the same entity, concept or topic, are comparable. Note that this comparability holds not only for texts in articles but also for intra-language links, each of which links an anchor or an important term within an article to another same-language article describing the entity, concept, or topic denoted by the anchor term. Figure 1 gives an example pair of ILL-linked articles; an English article "Tata Motors" and a Japanese article "タタ・モーターズ." The former has an intra-language link from an anchor "Jaguar" to the English article "Jaguar Cars," while the latter has an intra-language link from an anchor "ジャガー" to the Japanese article "ジャガー (自動車)." These two intra-language links are comparable: namely, the anchors are translations of one another and the destination articles are linked via an ILL.

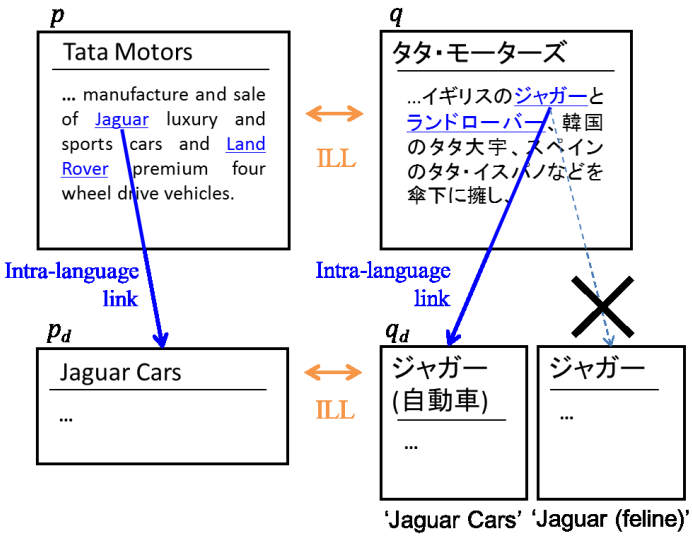

Figure 1. Transferring intra-language link.

The above fact inspired us to develop a method for transferring intra-language links between ILL-linked articles to enrich the intra-language links in each article. Suppose an extreme case in which an article q in one language, which is linked to its counterpart p in another language via an ILL, has no intra-language links. An intra-language link can be transferred from p to q as follows. First, following an intra-language link (p to p_d) and then the ILL (p_d to q_d), the final destination article q_d is identified as that to be linked from q. Second, the text of q is searched for possible anchors for the destination article q_d, which are learned from the entire Wikipedia beforehand. If two or more possible anchors are found, the most appropriate one will be selected according to a certain criterion. For example, suppose all intra-language links are missing from the Japanese article "タタ・モーターズ" in Figure 1. The intra-language link from the English article "Tata Motors" to "Jaguar Cars" and the ILL from "Jaguar Cars" to "ジャガー (自動車)" suggest that the Japanese article "タタ・モーターズ" should have an intra-language link to "ジャガー (自動車)." The possible anchors for "ジャガー (自動車)," which have been learned from all the Wikipedia articles linked to it, include "ジャガー (自動車)," "ジャガー," and others. Since the text of "タタ・モーターズ" contains "ジャガー," it is selected as the anchor for the destination article "ジャガー (自動車)."

It should be noted that our proposed method avoids the two hard problems in wikification, anchor selection and disambiguation, by exploiting the intra-language links provided by Wikipedia in another language. Resulting anchors are certainly important terms within q, since their counterparts have been selected as anchors by the author of counterpart p in another language. Even if an anchor were an ambiguous term, i.e., had two or more possible destination articles, it would be certainly linked to the appropriate one due to the "one sense per discourse" hypothesis (Gale et al., 1992). The hypothesis is extended to a pair of ILL-linked articles, p and q, as follows. A pair of corresponding anchors should be regarded as a single term and express the same sense in a discourse shared by p and q. In other words, they should be linked to articles that are linked via an ILL. Since the proposed method relies on this extended hypothesis, it will select correct destination articles for anchors in q as long as anchors in p have been linked to their correct destination articles.

It should also be noted that the proposed method first determines the destination articles then the anchors for them, while usual wikification methods first select anchors then determine their destination articles. The main reason for this is convenience of implementation; cross-language mapping of

destination articles is one-to-one (or one-to-zero), while that of anchors can be one-to-many. Determining destination articles prior to anchors, however, results in an additional advantage that allows a destination article to be proposed without an anchor for it. Since the pair p and q is not parallel but just comparable, the counterpart of an anchor in p is not always found in q. This is often the case when q is incomplete, under construction, or written in a different style from that of p. In such a case, our method proposes a destination article q_d without an anchor, and q will be linked to q_d once q is enlarged to contain a term appropriate as the anchor for q_d.

3 Proposed Method

The proposed method is divided into two steps; the preprocessing step for collecting possible anchors for all Wikipedia articles in a target language as well as estimating probabilities required in the succeeding step and the main step for transferring intra-language links in a source-language article p to the target-language article q linked to p via an ILL. In this section, a triplet (p, a, p_d) denotes an intra-language link from anchor a in article p to destination article p_d and, likewise, a triplet (q, b, q_d) does. Note that although an article can have two or more intra-language links from the same anchor at different positions in the text to the same destination article, they are treated as a single link.

3.1 Preprocessing Step

Collecting Possible Anchors for Wikipedia Articles

The title of a Wikipedia article can be used as an anchor for the article. However, a title is often accompanied by a parenthesized note indicating the domain of the article to discriminate from other articles with the same title. The title "ジャガー (自動車)" of an article that describes a car named Jaguar is an example; the parenthesized note "(自動車)" discriminates the article from another article "ジャガー", which describes an animal belonging to the cat family. Such a title accompanied by a parenthesized note rarely occurs in usual texts, and the title with the parenthesized note deleted is often marked as an anchor. Accordingly, we also regard a title with a parenthesized note deleted (e.g., "ジャガー") as a possible anchor. Other terms, typically synonyms of the article title, are often used as anchors. Therefore, we collect terms that are actually used as anchors for each article from the entire Wikipedia. Finally, we threshold possible anchors by their keyphraseness to eliminate general words. The keyphraseness $\kappa(b)$ of a term b is defined as the probability that b is used as an anchor in Wikipedia articles (Mihalcea and Csomai, 2007), i.e.,

$$\kappa(b) = \frac{|\{q|\exists q_d.\,(q, b, q_d) \in L_t\}|}{\mathrm{df}(b)},$$

where L_t is a set consisting of all intra-language links in the target-language Wikipedia and $\mathrm{df}(b)$ is the number of Wikipedia articles in which b occurs.

In summary, a set of possible anchors $\mathrm{A}(q_d)$ are constructed for a target-language destination article q_d as follows:

$$\mathrm{A}(q_d) = (\{title(q_d), title'(q_d)\} \cup \{b|\exists q.\,(q, b, q_d) \in L_t\}) \cap \{b|\kappa(b) \geq \theta\},$$

where $title(q_d)$ and $title'(q_d)$ are q_d's title with and without the parenthesized note, respectively, and θ is the threshold for the keyphraseness.

Estimating Probabilities

The following probabilities, which will be used to select one from among possible anchors for a destination article, are estimated from the entire Wikipedia.

- The probability that the target-language anchor is b on the condition that its source-language counterpart is a, i.e.,

$$\mathrm{P}(b|a) = \frac{\mathrm{count}(a, b)}{\sum_{b'} \mathrm{count}(a, b')},$$

$$\mathrm{count}(a,b) = \left|\left\{\left((p,a),(q,b)\right)\right| \begin{array}{c}\exists p_d.\,\exists q_d.\,(p,a,p_d) \in L_s \wedge (q,b,q_d) \in L_t \\ \wedge\, (p,q) \in ILL \wedge (p_d,q_d) \in ILL\end{array}\right\}\right|,$$

where L_s is a set consisting of all intra-language links in the source-language Wikipedia, and ILL is a set of all pairs of ILL-linked articles.

- The probability that the anchor is b on condition that the destination article is q_d, i.e.,

$$\mathrm{P}(b|q_d) = \frac{|\{q|(q,b,q_d) \in L_t\}|}{|\{q|\exists b'.(q,b',q_d) \in L_t\}|}$$

- The probability that the destination article is q_d on condition that the anchor is b, i.e.,

$$\mathrm{P}(q_d|b) = \frac{|\{q|\ (q,b,q_d) \in L_t\}|}{|\{q|\exists q'_d.(q,b,q'_d) \in L_t\}|}$$

3.2 Main Step

Let p and q be source-language and target-language articles that are linked via an ILL, respectively. Intra-language links in p are transferred to q as follows:

(i) For each source-language intra-language link (p,a,p_d), do (ii) to (v).

(ii) If p_d has an ILL to an article in the target language, let q_d be the destination article of the ILL from p_d. Otherwise, output "NOT TRANSFERRED" and move to the next intra-language link.

(iii) If $\mathrm{A}(q_d)$ is empty, output the transferred intra-language link (q, NULL, q_d), which means that q should be linked to q_d but does not contain a term appropriate as the anchor, and move to the next intra-language link.

(iv) For each possible anchor $b \in \mathrm{A}(q_d)$, search the text of q for b. If found, let $\mathrm{pos}(b,q)$ denote the position of its first occurrence in the text; otherwise, let $\mathrm{pos}(b,q) = -1$.

(v) If at least one possible anchor is found, choose the most appropriate one $\hat{b}$ according to an anchor priority score $\mathrm{Score}(b)$, i.e.,

$$\hat{b} = \underset{b \text{ s.t. } b \in \mathrm{A}(q_d) \wedge \mathrm{pos}(b,q) \geq 0}{\mathrm{argmax}} \mathrm{Score}(b).$$

and output the transferred intra-language link $(q, \hat{b}, q_d)$. Otherwise, output the transferred intra-language link (q, NULL, q_d).

We have the following five alternative anchor priority scores in step (v) above.

- Anchor translation probability: $\mathrm{Score}_1(b) = \mathrm{P}(b|a)$.
  This score favors the anchor that occurs most frequently as counterpart to the source-language anchor.

- Anchor probability: $\mathrm{Score}_2(b) = \mathrm{P}(b|q_d)$.
  This score favors the anchor by which the destination article is pointed most frequently.

- Destination article likelihood: $\mathrm{Score}_3(b) = \mathrm{P}(q_d|b)$.
  This score favors the anchor that is most likely to point the destination article.

- Spelling: $\mathrm{Score}_4(b) = 1 - \mathrm{dist}\big(b, title'(q_d)\big)/\max\{\mathrm{len}(b), \mathrm{len}(title'(q_d))\}$,
  where $\mathrm{dist}(s,s')$ is the Levenshtein distance between character strings s and s' (Levenshtein, 1966), and $\mathrm{len}(s)$ is the length of character string s.

  This score favors the anchor with the highest similarity to the article's title without a parenthesized note, which is the most representative term denoting the entity, concept, or topic described in the article.

- Position: $\mathrm{Score}_5(b) = 1/\mathrm{pos}(b,q)$.
  Note that in a Wikipedia article, among two or more occurrences of an important term, the first one tends to be marked as an anchor.

4 Experiment

4.1 Experimental Settings

We conducted an experiment on transferring intra-language links from the English edition to the Japanese edition of Wikipedia.

Input Data

The English edition of Wikipedia (2013-04-03 dump), consisting of 4,241,324 articles, and the Japanese edition of Wikipedia (2013-03-28 dump), consisting of 951,411 articles[1], were used for the experiment. Intra-language links were extracted from each dump file, and ILLs were obtained from Wikidata (2013-03-28 dump). Redirect pages were resolved preliminarily, i.e., if the destination of an intra-language link or ILL was a redirect page, the destination was replaced with an article pointed by the redirect page.

Anchor	English translation	Keyphraseness
ベイジアン・ネットワーク	Bayesian network	1
地獄の辞典	Dictionnaire Infernal	0.810
悪魔学	demonology	0.678
パリ	Paris	0.574
オカルト	occult	0.304
悪魔	devil	0.135
ニコラス	Nicholas	0.039
対立	conflict	0.001
半分	half	7.8×10^{-5}
より	Yori (kana)	4.4×10^{-6}

Table 1. Example of keyphraseness values.

From among a total of 366,358 pairs of English and Japanese articles linked by ILLs, 3,595 pairs were randomly selected as a test set. The remaining pairs were used as training data for constructing English and Japanese intra-language link sets, L_s and L_t. The English articles in the test set contained 179,963 intra-language links in total; these were input to the algorithm of the proposed method.

Keyphraseness Threshold

Limiting possible anchors to meaningful ones and gaining many links are in a trade-off relation adjustable by the keyphraseness threshold θ. In the experiment, θ was set to 0, 0.01, 0.05, and 0.1.

Keyphraseness values of several anchors are listed in Table 1. Technical words (e.g., "ベイジアン・ネットワーク" – Bayesian network) and uncommon proper names (e.g., "地獄の辞典" – Dictionnaire Infernal) tend to have high keyphraseness values. Common words (e.g., "悪魔" – devil and "対立" – conflict) and proper names (e.g., "パリ" – Paris and "ニコラス" – Nicholas), especially identical to a general noun, have middle or low values according to their commonness. Although some functional words (e.g., "より" – from) may be included in possible anchors for the Wikipedia articles of their homographic content words (e.g., "より" – Yori (kana)), they naturally have extremely low values. By setting θ to a value slightly greater than zero, functional words could be removed from possible anchors.

Comparison of Anchor Priority Scores

To determine the most effective anchor priority score, the accuracy of anchors selected according to each score was evaluated, assuming the existing intra-language links in the original Japanese articles as gold standard. That is, anchor accuracy Acc is defined as the percentage of originally pointed destination articles for which correct anchors were selected, i.e.,

$$\mathrm{Acc} = \frac{|Result \cap GoldSTD|}{|\{(q, b, q_d) \in Result | \exists b'.(q, b', q_d) \in GoldSTD\}|},$$

where $Result$ is a set consisting of all transferred intra-language links and $GoldSTD$ is the gold standard intra-language link set. Table 2 lists the anchor accuracies for each anchor priority score and each θ. Anchor translation probability exhibited the best results and, therefore, we adopted anchor translation probability as the anchor priority score.

[1] Redirect pages and articles with no intra-language links were not included in these counts.

Anchor priority score	Anchor accuracy (%)			
	$\theta = 0$	$\theta = 0.01$	$\theta = 0.05$	$\theta = 0.1$
Anchor translation probability	**96.3**	**93.9**	**93.0**	**92.0**
Anchor probability	95.6	93.3	92.4	91.4
Destination article likelihood	90.7	90.8	91.5	91.3
Spelling	95.1	93.1	92.5	91.8
Position	88.2	87.3	87.9	87.6

Table 2. Anchor accuracy.

4.2 Experimental Results

We inputted 179,963 English intra-language links to the algorithm of the proposed method and classified them into the following five classes. Examples of each class, except class B, are given in Figure 2, which is an excerpt from the results for the pair of English article "Jacques Collin de Plancy" and Japanese article "コラン・ド・プランシー."

A. Transferred to a Japanese intra-language link in the gold standard (bold underline in Figure 2)

B. Transferred to a Japanese intra-language link whose anchor is not the same as the gold standard link to the same destination article

C. Transferred to a Japanese intra-language link not in the gold standard (double underline in Figure 2)

D. Transferred to a Japanese intra-language link without anchor (wavy underline in Figure 2)

E. Not transferred to a Japanese intra-language link (dashed underline in Figure 2)

Table 3 lists the numbers of English intra-language links per class. The proposed method added many new intra-language links to Wikipedia articles. Since the total number of existing Japanese intra-language links in the test-set articles was $T = 161{,}940$, the increase rate of Japanese intra-language links was $100(C + D)/T = 100(13{,}916 + 52{,}275)/161{,}940 = 40.9\%$ ($\theta = 0$). When new links without anchors were excluded, the increase rate was $100C/T = 100 \cdot 13{,}916/161{,}940 = 8.6\%$ ($\theta = 0$).

The anchor accuracy of existing links was $100A/(A + B) = 100 \cdot 31{,}770/(31{,}770 + 1{,}219) = 96.3\%$ ($\theta = 0$). Anchor accuracy of new intra-language links could not be calculated because of the unavailability of gold standard data. However, the proposed method specifies the anchor b for destination article q_d only when possible anchors for it is found in the target-language article q. The specified anchor b is likely to be the counterpart of source-language anchor a pointing to p_d that is the source-language counterpart of q_d, regardless of whether b already points to q_d or not. Thus, the anchor accuracy of new links should be similar to that of existing links.

Among the $S = 179{,}963$ input English intra-language links, $100D/S = 100 \cdot 52{,}275/179{,}963 = 29.0\%$ ($\theta = 0$) were transferred to Japanese intra-language links with the anchor unspecified. This was because different language articles contain different contents even though they are linked via an ILL. The anchor-unspecified links are put in the "関連項目" sections ("See also" sections) of target-language articles, and Wikipedia authors are expected to enlarge or revise the articles so that these anchor-unspecified links can be converted to anchor-specified links. Additionally, among the $S = 179{,}963$ input English intra-language links, $100E/S = 100 \cdot 80{,}783/179{,}963 = 44.9\%$ were not transferred to Japanese intra-language links. We assumed this was mainly due to missing Japanese articles. Note that the total number of Japanese articles is less than one-fourth that of English articles. The percentage of not-transferred links will decrease with the growing number of Japanese articles.

Jacques Collin de Plancy

Jacques Albin Simon Collin de Plancy (Plancy-l'Abbaye, 28 January 1793 –Paris, 1881) was a French occultist, demonologist and writer; he published several works on occultism and demonology.[1][2]

He was born **Jacques Albin Simon Collin** on 28 (in some sources 30) January 1793 in Plancy (presently Plancy-l'Abbaye) son of Edme-Aubin Collin and Marie-Anne Danton, sister of Georges-Jacques Danton who was executed the year after Jacques was born.[3] He later added the aristocratic "de Plancy" himself - an addition which would later cause accusations against his son in his career as a diplomat. He was a free-thinker influenced by Voltaire. He worked as a printer and publisher in Plancy-l'Abbaye and Paris. Between 1830 and 1837, he resided in Brussels, and then in the Netherlands, before he returned to France after having converted to the Catholic religion.

E	Not transferred		80,783 (44.9%)			

Table 3. English intra-language links classified according to results.

4.3 Additional Comments on Experimental Results

Among alternative anchor priority scores, anchor translation probability seems most effective because this is a posterior probability of the target-language counterpart to the source-language anchor. Anchor probability is also useful because this is a posterior probability of the anchor for the destination. Higher accuracy with spelling score indicates that Wikipedia editors tend to use the title of the destination as an anchor. This may be caused by manually specifying the anchor and destination independently. Contrary to expectations that the first occurrence likely becomes an anchor, position score exhibited the worst results. More detailed analysis of the context in which a term tends to be selected as an anchor is necessary.

Table 2 shows that the anchor probability, unexpectedly, decreases with a rise of the keyphraseness threshold. It was caused by articles that have only one possible anchor with keyphraseness value be-

low the threshold (e.g., "駅" – station). When the threshold was set high, the possible anchor set for such an article became empty and, as a results, the algorithm failed to reproduce the existing links to it.

In this experiment, we transferred English links onto Japanese articles. Since the English edition of Wikipedia is richer than Japanese, it has been assumed that an English-to-Japanese direction is more effective than the inverse. However, among the 179,963 links in English and 161,940 links in Japanese extracted from the test set of English-Japanese article pairs, only 32,989 links are paired with their counterparts and others do not have counterparts. This fact indicates that a Japanese-to-English transfer of links is also useful for enriching English articles. It also leads a low anchor recall, which is the percentage of correct links among existing links: $100A/T = 100 \cdot 31{,}770/161{,}940 = 19.6\%$ ($\theta = 0$). Combining usual wikification techniques should help improve the anchor recall.

5 Discussion

We now discuss two future directions, an extension to multiple language combination and a variation for inappropriate intra-language link detection.

The proposed method can be straightforwardly extended to three or more language combinations: Even if two source articles in two different languages are handled separately, the target article would be more enriched with the union of two transferred link sets. While this contributes to increasing the coverage of links, the reliability of links can also be improved by taking the intersection of the two transferred link sets. A more sophisticated combination of multiple source languages is a further problem.

In the experiment, existing links were used as the gold standard for evaluation, despite the fact that they are not always appropriate because they are manually created by unspecified contributors. For example, there is a biology-related article containing an anchor "translation" linking to an article "Translation" describing language translation, not to another article "Translation (biology)." Such an incorrect intra-language link may be detected using a similar method as the proposed one. In the above example, suppose the Japanese counterpart article contains an anchor "翻訳" linking to an article "翻訳 (生物学)." Two anchors "translation" and "翻訳" correspond to each other but their destination articles are not linked via an ILL. This inconsistency may be evidence for an inappropriate intra-language link. Note that which of the English and Japanese links is inappropriate cannot be easily determined. How to estimate the appropriateness of intra-language links is a problem to be solved.

6 Related Work

Wikification, which aims at linking mainly non-Wikipedia articles to Wikipedia articles, can be naturally applied to linking between Wikipedia articles. There has been much research on wikification, most of which focused on disambiguation of destination articles (Milne and Witten, 2008a; Fogarolli, 2009; Ratinov et al., 2011). Determining an appropriate destination article for an anchor term is a special case of WSD. Although a variety of ideas for WSD have been adapted to wikification, their performance is not satisfactory and there is room for further improvement. Another important issue with wikification is anchor selection, although most literature on wikification avoids the issue by selecting every term that is used as an anchor in any Wikipedia article. Anchor selection is a keyword extraction problem, which has been tackled using syntactic, statistical, and/or machine learning techniques but remains room for further improvement (Jacquemin and Bourigault, 2003). It should be added that our proposed method avoids both disambiguation and anchor selection problems by exploiting link information in another language edition of Wikipedia.

Adafre and de Rijke (2005) proposed a method for finding "missing intra-language links" in a Wikipedia article by assuming that an intra-language link represents the relatedness between concepts described by the linked articles. Their method adds intra-language links to an article by using articles with similar link structures as that of the article in question. Similar methods that use the Wikipedia's link structures as a semantic network have been proposed for entity linking (Milne and Witten, 2008b; Fogarolli, 2009; Ratinov et al., 2011). These still remain monolingual methods; the availability of other language editions cannot be assumed.

A bilingual approach to improving quality of Wikipedia articles has also been studied. Sorg and Cimiano (2008) proposed a method for finding new ILLs by using a classifier whose features include

the number of ILLs between articles pointed by an article in one language and those pointed by an article in another language. Wang et al. (2013) improved the classifier by extending the intra-language links to increase the number of features. Both methods and our proposed method exploit the comparability between intra-language links in different language editions. However, while the former find new ILLs, the latter finds new intra-language links.

7 Conclusion

We proposed a method for enriching intra-language links in Wikipedia articles. It transfers intra-language links between a pair of different language articles linked by an inter-language link through the following two steps: first, determine destination articles to which the target-language article should be linked by following a source-language intra-language link and an ILL successively from each of the anchors in the source-language article; second, determine an anchor for each of the destination articles by searching the target-language article for possible anchors and selecting the most appropriate one according to the anchor translation probability criterion if two or more possible anchors are found. Unlike usual wikification methods, our method avoids anchor selection and disambiguation problems by exploiting the comparability of intra-language links between different language editions of Wikipedia.

We conducted an experiment of transferring intra-language links from the English edition to the Japanese edition to evaluate the effectiveness of our method. The method increased the number of intra-language links in Japanese articles by 40.9%, and the accuracy of anchors selected was estimated to be 96.3%. Future work includes an extension to multiple language combination and a variation for inappropriate intra-language link detection.

Abstract

Non-literal expression recognition is a challenging task in natural language processing. An ironic expression implies the opposite of the literal meaning, causing problems in opinion mining and sentiment analysis. In this paper, ironic messages are collected from microblogs to form an irony corpus based on the use of emoticons, linguistic forms, and sentiment polarity. Five linguistic patterns are mined by using the proposed bootstrapping approach. We also analyze the linguistic structure and elements used to convey irony. Based on our observations, ironic words/phrases and contextual information are the necessary elements in irony, while the contextual information can be hidden in linguistic forms. A rhetorical element, which is optional in irony, can also be used to help strengthen the effects and understandability of an ironic expression. The ironic elements in each instance of our irony corpus are labelled based on this structure. This corpus can be used to study the usage of ironic expressions and the identification of ironic elements, and thus improve the performance of irony recognition.

1 Introduction

Dealing with non-literal meaning is a challenging task in natural language processing. Linguistic context and background knowledge are required to interpret non-literal utterances properly. An ironic expression, where the meaning is the opposite of what is literally expressed, is one of the indirect and non-literal linguistic forms that cannot be easily processed and detected. One cannot capture the real meanings of opinions and sentiments expressed in a document or conversation if irony is not taken into account.

The challenges of irony processing involve the following issues: (1) No comprehensive irony corpus is available. (2) Irony analysis is related to semantics, pragmatics and discourse studies, which are the most challenging in natural language processing. (3) Contextual information and background knowledge are necessary, but they are hard to obtain and process. (4) Non-linguistic or non-verbal factors, e.g., intonations, gestures and talking speed in speech, and spaces, punctuations and typography in writing, have to be considered.

This paper focuses on irony corpus construction, ironic pattern mining, and ironic structure analysis. Messages were collected from a microblogging platform based on emoticons, and ironic messages and patterns were extracted to build an irony corpus. The structure of ironic expressions and the clarification of the uses of ironic elements were also analyzed. Labels representing the ironic elements are added to each message in the irony corpus. To the best of our knowledge, this is the first Chinese irony corpus available for research.

This paper is organized as follows. Section 2 surveys the related work. Section 3 proposes a methodology to construct an irony corpus. Section 4 presents the patterns mined from the corpus. Section 5 discusses the results of ironic expressions collected from a different type of corpus. Section 6 makes the error analysis. Section 7 analyzes linguistic structure of Chinese irony. Section 8 concludes the remarks.

2 Related Work

Sarcasm and irony have been studied by linguistics and cognitive scientists (Giora and Fein, 1999; Gibbs and Colston, 2007) for years, but there has been no concrete claim on the linguistic structure of irony. Some studies have started focusing on the processing of sarcasm and irony recently, but it is still not clear whether sarcasm and irony differ significantly or represent the same concept.

The research of non-literal expression identification has drawn attention in recent years. Katz and Giesbrecht (2006) use meaning vectors for literal and non-literal expression classification. Li and Sporleder (2010) focus on distinguishing literal and non-literal usages of idioms.

Filatova (2012) uses crowdsourcing to generate an irony and sarcasm corpus. Veale and Hao (2010) construct a corpus of ironic similes using the wildcarded query "as * as a *" on a search engine. Davidov et al. (2010) collect messages from Twitter and product reviews from Amazon.com using the Mechanical Turk service. The #sarcasm hashtag is used as ground truth, and a k-nearest neighbor strategy is used for classification. González-Ibáñez et al. (2011) also make use of hashtags in Twitter as labels to build a sarcasm corpus. In their study, both human classification and automatic classification achieve low accuracy in sarcasm detection. Reyes et al. (2012) analyze humor and irony based on the user-generated tags, such as "#humor" and "#irony", in twitter. Lukin and Walker (2013) use a bootstrapping method to improve the performance of the classifiers for identifying sarcastic and nasty utterances in online dialogues.

The hashtag-based approaches are not always suitable for irony corpus construction for all the languages. As of March 9, 2014, only 113 messages are found to contain the hashtag #反諷 (#irony) in Weibo, the largest Chinese language microblogging platform. This paper differs from the previous work in that we employ negative emoticons and positive words as clues to capture the irony. The linguistic patterns mined from the irony corpus can be used to detect if a sentence is ironic.

3 Irony Corpus Generation from Microblogs

This section introduces a bootstrapping methodology to construct an irony corpus and mine irony patterns. While Lukin and Walker (2013) also used a bootstrapping method to improve sarcasm and nastiness classifiers, this paper, in contrast, focuses on irony pattern mining and corpus construction.

3.1 An Emotion-Tagged Corpus

The traditional definition of verbal irony is adopted, where the speaker says something that seems to be the opposite of what they mean (Gibbs and Colston, 2007). Under this definition, texts annotated with polarity information that expresses the actual meaning should be collected, and the literal meanings of words in the texts should be identified. If any disagreement exists between the actual meaning and literal meaning, then we say the text contains irony.

Nowadays, emoticons are used quite often in social media to express the feelings of the posters. The tagged emoticons specify their actual meanings in some sense. Based on this idea, messages were collected from Plurk[1], a microblogging platform similar to Twitter. It lets users post messages limited to 140 characters, and allows them to use graphical emoticons in their messages.

It was assumed that these emoticons can represent the poster's sentiments, and, therefore, be regarded as sentiment labels of the messages. Among 35 emoticons, 23 are categorized into positive, and 12 are categorized into negative. Collected messages are dated from Jun 21, 2008 to Nov 7, 2009, and all of them are in Traditional Chinese.

On the other hand, the literal meanings of the posted messages need to be known. Many sentiment analysis algorithms (Liu, 2012) can be explored. A lexicon-based approach was adopted. The NTU Sentiment Dictionary, or NTUSD (Ku and Chen, 2007), was employed to determine the sentiment of a word. This dictionary provides 21,056 positive and 22,751 negative words. Most of these words are in Traditional Chinese.

[1] http://www.plurk.com

3.2 Candidates Extraction

Possible irony messages were extracted from the Plurk corpus by using NTUSD. Since the typical social function of irony is expressing negative meaning with positive words, as mentioned in Gibbs and Colston (2007), focus was directed on those messages with negative emoticons and positive words. A total of 3,178,372 messages was found containing at least one negative emoticon. Among them, 304,754 messages with at least one positive word are found and form an irony candidate dataset.

Discourse relation determines how two discourse units cohere to each other. Sentiment transition of two clausal arguments is identified based on their discourse relation (Zhou et al., 2011; Wang et al., 2012; Huang et al., 2013). In the sentence "he is nice but not attractive," positive opinion in the beginning is transformed to a negative one by the discourse connective "but." Both the positive word "nice" and the negative phrase "not attractive" are used literally. Thus, it was necessary to filter out messages containing such connectives.

Messages are removed only when the positive word occurs earlier than the discourse connectives with a comparison function, due to Chinese grammatical structure. The Chinese discourse connectives used here include "但", "但是", "可是", "只是", "不過" (all the above are equivalent to the English word *but*), "然而" (however), "卻" (comparatively), "可惜" (unfortunately), "偏偏" (contrarily), "反而" (oppositely), and "倒是" (on the contrary). A total of 254,836 messages remains after this process.

3.3 Pattern Mining

Although irony can be used without any customary linguistic patterns, some ironic expressions do exhibit specific forms of language use. Colston and O'Brien (2000) suggest that both irony and hyperbole create contrasts between expected and ensuing events. It was assumed that exaggerated expressions could be used with irony to strengthen the effects of the speech act. In the expression 我真是太幸運啦！ (I am really and extremely lucky!), the adverbs *really* and *extremely* are used to strengthen the ironic effect. Thus, combinations of degree adverb phrases and a positive adjective are used as patterns to find possible irony expressions automatically in the candidate dataset.

Not all degree adverbs in Chinese are used because some of them are mostly used in formal texts and not frequently present in microblogs. The degree adverb phrases used here include the combinations of the adverbs "還" (*hái*), "也" (*yě*), "未免" (*wèimiǎn*), "可" (*kě*) and "實在" (truly) and the degree adverbs "真" (really), "太" (extremely) and "非常" (very).

The following bootstrapping procedure was used to find more patterns.

(1) Which patterns should be used is decided. At the very beginning of the bootstrapping procedure, the [degree adverb + positive adjective] pattern mentioned above is used.

(2) Messages containing the patterns in step (1) are automatically retrieved from the candidates. NTUSD is used to determine sentiment polarity, and CKIP parser is used to get parts of speech[2].

(3) Messages retrieved in step (2) were reviewed by the annotator to decide which of them are actually ironic.

(4) If the annotator finds new irony patterns in the reviewed messages, then the procedure starts again from step (1) and uses the patterns to repeat the process.

This process was repeated for four times. After the fourth iteration, no more new patterns were found by the annotator. Finally, 2,825 messages are found to have any of the patterns, and 1,005 of them are confirmed to be ironic and make up the NTU Irony Corpus.[3] Examples of these patterns and ironic messages are shown in Section 4.

4 Irony Patterns

All the patterns mined by the approach used in Section 3 are categorized into the following five groups.

4.1 Degree Adverbs + Positive Adjective

In this pattern, the following two components must exist:

[2] http://ckipsvr.iis.sinica.edu.tw.

[3] The NTU Irony Corpus is available at http://nlg.csie.ntu.edu.tw/nlpresource/irony_corpus/.

(a) Degree adverb phrase + positive adjective phrase
(b) Negative context

The negative context can occur either before or after the component (a). For example, the following expression is used when someone has to wait for a long time to start ordering in a restaurant. In total, 13.03% of all the messages in the corpus contain this pattern.

(s1) 點餐都要等半小時，服務還真是好阿
I have to wait for half an hour to order. The service is definitely really good.

The underlined expression is the contextual information described in (b), and the double-underlined expression is the linguistic form described in (a). In the second clause the adverbs "還" (*hái*) and "真" (really) are combined to form a degree adverb phrase for intensification or hyperbole. Although the positive word *good* is used, the speaker means the opposite. The first clause indicates why they think the service is not good, and, therefore, provides the contextual information.

4.2 The Use of Positive Adjective with High Intensity

In this pattern, the following two components must exist:

(a) Positive adjective with high intensity
(b) Negative context

Specific positive adjectives with high intensity are used to form ironic expressions with or without other rhetorical elements. Since the context is negative, the positive adjective is used to express non-literal meanings. The adjectives we found in the corpus include "偉大" (*great*), "了不起" (r*emarkable*) and "天才" (*genius*). Only 2.09% of the messages in the corpus contain this pattern. For example, the word *great* is used in the following message:

(s2) 我的 plurk「又」發生不明錯誤了...這真是這世紀最偉大的發明啊
My Plurk account encountered an unknown error 'again'... This is indeed the greatest invention in the century.

4.3 The Use of Positive Noun with High Intensity

In this pattern, the following two components must exist:

(a) Positive noun with high intensity
(b) Negative context

Specific nouns that represent highly positive meanings are also used to express irony. These nouns include "巨星" (*superstar*), "大禮" (*big gift*) and "境界" (*wonderful state*). When they are used with a negative context, an ironic expression is formed. This is pattern is not found frequently in the corpus. Only 2.00% of the messages in the corpus contain this pattern. An example is listed below:

(s3) 中秋節收到的大禮是.....長了一堆肉
The big gift I received in the Mid Autumn Festival was…… a lot of fat in my body.

4.4 The Use of "很好" (very good)

In this pattern, the following two components must exist:

(a) Sentence boundary + 很好 + punctuation
(b) Negative context

A sentence boundary occurs before the word "很好" (very good) because there is no subject. Multiple punctuations, and particularly exclamation marks and ellipses, can be used after "很好" to increase the intensity. In the following example, exclamation marks are used:

(s4)感冒... 很好!! 我的假期飛了
I caught a cold... Very good!! My vacation is gone.

Sometimes this pattern is followed by an exclamation word, such as "啊" (*a*), "呀" (*ya*), and "嘛" (*ma*). These exclamations, like punctuations, can help strengthen the level of the speaker's feelings. In our irony corpus, this pattern is used in 50.84% of all ironic messages. Obviously, this is a common way when people want to express their negative feelings with an ironic expression.

4.5 "可以再…一點" (It's okay to be worse)

In this pattern, the following expression must exist:

可以再 + negative adjective + 一點
(It is okay to be more + negative adjective)

This pattern literally states that it is okay for something to become worse and is a commonly used pattern to express irony in our corpus. It can be found in 33.53% of the messages in the corpus. In most cases, even when no proper contextual information is present, the listener can tell the literal meaning is not meant because it violates most people's inclinations. Thus, the use of this pattern is usually non-literal and ironic. An example is shown below.

(s5)零下十一度...你可以再冷一點
It's -11°C...It is okay to be colder

A message can contain more than one pattern, causing the sum of the percentages of the above five patterns to be greater than 100%. For example, both patterns 4.4 and 4.5 are used in the following message:

(s6)很好!!!!我可以再笨一點 再笨一點阿...
Very Good!!!! It is okay for me to be more idiotic…

The patterns in Sections 4.4 and 4.5 are mainly based on their linguistic forms and frequently used in ironic expressions. We argue that these patterns are more static than the others, and we call them the *customary patterns*. On the other hand, the patterns in Sections 4.1, 4.2 and 4.3 are called *non-customary patterns*.

5 Collecting Ironic Expressions from Blogs

In order to understand how irony is conveyed in different types of media, we use the methodology and mined patterns described in Sections 3 and 4 to collect irony expressions from the Yahoo Kimo Blogs corpus.

5.1 The Yahoo Blog Corpus

The Yahoo Kimo Blog corpus, referred to the Yahoo corpus in the following sections, contains blog articles from November 1, 2005 to August 20, 2007 (Yang, Lin and Chen, 2009). Out of all the posts in the dataset, 2,764,202 posts have at least one emoticon. The articles posted in July 2006 are used here, and they are divided into 341,932 smaller units by the full stop symbol. All articles are in Traditional Chinese.

Since the Plurk platform can be used as an instant messaging system, and readers of the message are usually on the author's friend list, these messages are usually conversational. On the other hand, Ya-

hoo blogs are not limited in length and a blog article itself is not part of the conversation. Thus, the blog articles are usually more formal compared to microblog messages.

Although the articles are separated by a full stop into shorter units, these units are not necessarily identical to sentences due to the conventional usage of the Chinese period symbol. They can consist of multiple sentences and thus contain a discourse structure, which makes them suitable for this corpus study.

5.2 Extract Ironic Expressions

A similar approach to the steps described in Section 3.3, is used to collect ironic expressions from the Yahoo corpus, but four patterns of irony found in Plurk are used to perform step (1). These patterns, as listed below, are adopted because they are the most frequently used ones in our Plurk irony corpus. They can also reflect the uses of customary and non-customary irony patterns as the first two patterns are customary, and the last two are non-customary. Pattern 1 and Pattern 2 are the same patterns as mentioned in Section 4.4 and Section 4.5, respectively. Pattern 3 and Pattern 4 are two forms from the pattern described in Section 4.1. Only step (1) to step (3) are performed, and step (4) is bypassed; that is, the process is not repeated.

Pattern 1:
(a) Sentence boundary + 很好 + punctuation
(b) Negative context
Pattern 2:
可以再 + negative adjective + 一點
Pattern 3:
(a) 還真 + positive adjective
(b) Negative context
Pattern 4:
(a) 真是 + positive expression
(b) Negative context

5.3 Results and Discussion

A total of 36 ironic texts is obtained. All the four irony patterns seen in Plurk can be found in Yahoo. The final results are shown in Table 1.

	Number of Ironic Expressions	Percentage
Pattern 1	14	38.89%
Pattern 2	10	27.78%
Pattern 3	5	13.89%
Pattern 4	7	19.44%

Table 1: Ironic texts found for the four Patterns in Yahoo.

The proportions of the four patterns in Plurk and Yahoo are also compared. The percentages are calculated by dividing the occurrence of each pattern by the occurrence of all four patterns in the same datasets. As can be seen in Figure 1, the proportions of patterns (1) and (2) in Plurk are significantly higher than in Yahoo, and the proportions of patterns (3) and (4) in Plurk are significantly lower than in Yahoo ($p<0.05$ according to the t-test). This suggests that patterns (1) and (2) tend to be used in informal and conversational texts while patterns (3) and (4) tend to be used in formal articles to convey irony. Also, this may suggest that customary patterns are more likely to be used in conversations, and authors of formal articles prefer an indirect way to express irony, although more data are required for further studies in the future.

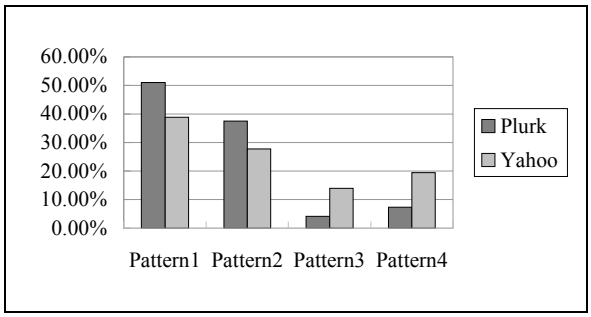

Figure 1: Comparison of the proportion of the four patterns in Plurk and Yahoo.

6 Error Analysis

In this section, we analyze why non-ironic messages were retrieved by the automatic processes. The 1,820 wrong messages specified in Section 3.3 are classified into the following two categories.

(1) Sentiment identification

Using the patterns to find possible ironic messages involves the correct sentiment identification. NTUSD does not cover some new words used on Internet informal conversations. The sentiment of a word can also be changed depending on its context. For example, "太強" (so strong) is listed as a positive term in NTUSD. However, it is used to indicate a negative condition in the example (s7).

(s7) 止痛藥的副作用也太強了吧，昏睡一整晚
The *side effect of the pain reliever was so strong, making me sleep through the whole night.*

(2) Opinion targets

In a Plurk message, even though the message poster is talking about the same topic, more than one entity with associated opinions can be present. For example:

(s8) 最近公司生意很好，好累ㄛ
The business of our company is running so well. I am so tired.

The poster expresses negative sentiment by using the word "tired." Although the positive word "很好" (very good) is also used, it modifies the word "business" rather than the poster's condition. That is, the opinion targets of the two words are different, and this causes problems when automatically retrieving ironic messages.

7 Linguistic Structure of Irony

In this section, the linguistic structure of irony is analyzed based on our observations on the corpus.

7.1 Ironic Word

As described, the literal meaning of an ironic word or phrase is opposite to the actual meaning. An ironic word/phrase is necessary to separate irony from regular utterances. If the ironic word of an utterance is reverted, the speaker's actual sentiment or intention is reconstructed.

However, it is not easy to identify the ironic word in an utterance. Sometimes more than one word can be an ironic word. In our corpus, 94.93% of the ironic words are adjectives, while others are used as adverbs, verbs or nouns. The recognition of ironic word/phrase is a challenging task, but other ironic elements described in Sections 7.2 and 7.3 can be analyzed side by side to help improve the performance.

7.2 Contextual Information

Contextual information is usually provided as part of ironic utterances to help convey irony. For example, the underlined sentence in the following utterance is crucial for irony interpretation:

(s9) 我掛彩了，真是太好運了
I was injured. I was really lucky.

Without the first sentence, it is hard to tell if *lucky* is actually meant. Although a speaker can still use ironic words/phrases without providing contextual information, this can be an ineffective way to communicate the actual meanings of irony. According to the cooperative principle proposed by Grice (1975), the speaker must give enough information in order to enable successful communication and implicatures. The four maxims of the cooperative principle include:

(1) **Maxim of Quantity**: The speaker should make their contribution as informative as is required. Do not make the contribution more informative than is required.
(2) **Maxim of Quality**: The speaker should not say what they believe to be false, and should not say that for which they lack adequate evidence.
(3) **Maxim of Relation**: The speaker should be relevant.
(4) **Maxim of Manner**: The speaker should avoid obscurity of expression, avoid ambiguity, be brief and be orderly.

Based on Grice's maxims, it is assumed *enough, correct, relevant,* and *understandable* contextual information should be provided with ironic expressions. However, the speaker sometimes assumes the listener already knows about the conditions where the irony takes place and has the required background knowledge; thus the contextual information is hidden in the ironic utterance.

Four types of context can be used to interpret irony:

(1) **Linguistic context**: The linguistic context refers to the words that are expressed before and/or after the irony words in a sentence or discourse. It is easier to obtain and analyze than the other three types of context.
(2) **Physical context**: Physical context refers to what is actually present and/or happening in the environment or circumstance where the conversation is taking place. It is also related to the timing. In online conversations, participants are not usually in the same location, but they can be aware of the same ongoing events and situations. It is not necessary for the speaker to provide physical context information if they assume the objects or situations are noticeable to the listeners.
(3) **Epistemic context**: The background knowledge shared by the participants in a conversion can also be used to interpret the irony. This type of context does not change over time. For example, people know rocks are hard, so they can understand the expression *the bed is as soft as a rock* is not literal.
(4) **Social context**: Social relationship can be important for expressing and interpreting irony, especially in online messages.

We argue that at least one type of contextual information must exist, but it can be hidden if the speaker thinks the listener is already aware of it. Physical, epistemic and social context can be hidden, while linguistic contextual information must be present.

7.3 Rhetoric

As shown in Section 4, degree adverbs, punctuations and exclamations can be used to convey irony. Some of them can even be repeated to intensify the effects. These elements increase contradiction and strengthen the degree of negative opinions. Unlike ironic words and context, rhetoric elements are not necessary to convey irony.

Liebrecht et al. (2013) call the words used to strengthen evaluative utterances *intensifiers*. In their experiments, non-hyperbolic sarcastic messages often contain an explicit marker on Twitter. They argue that sarcasm is often signaled by hyperbolic words, including intensifiers and exclamations, and sarcastic utterances with hyperbolic words are easier to identify by listeners/readers than sarcastic utterances without hyperbolic words. It can be seen that adverbs, adjectives, punctuations and exclamations with high intensity observed in our irony patterns have very similar effects.

Among the 113 messages containing the #反諷 (#irony) hashtag in Weibo, which was mentioned in Section 2, 83.19% do not exhibit hyperbole or uses of intensifiers. This observation is similar to the argument suggested in Liebrecht et al. (2013) and is one of the reasons why the hashtag is not suitable

for the irony pattern mining task in this study. In comparison, this methodology helps find more clues of irony that can be seen from their linguistic forms.

7.4 Corpus Labeling

To increase the usefulness of the corpus, ironic element tags are added to each message. An example is shown in Figure 2.

<context sentiment="pos">才剛買的書，竟然掉頁了，</context>這品質<rhetoric>也太</rhetoric><ironic sentiment="neg">好</ ironic>了<rhetoric>吧</rhetoric>.

English translation:
<context sentiment="pos">The book I just bought has fallen apart.</context> The quality is <rhetoric>just extremely</rhetoric> <ironic sentiment="neg">good</ ironic>*le*<rhetoric>*ba*</rhetoric>.

Figure 2: An example message with ironic element tags.

As can be seen in the example, "好" (good) is the word that is used in the opposite way, so it is marked with the ironic word/phrase label <ironic>. The preceding sentence states what actually happened, and is marked with the label <context>. The message poster also uses the degree adverb "太" (extremely) and used the exclamation "吧" (*ba,* a sentence-final partical). These two words are marked with the <rhetoric> label. The sentiment polarity marks of the ironic word and contextual information, shown as either *pos* or *neg*, are also added.

8 Conclusion

In this paper, five types of irony patterns are mined, and an irony corpus is constructed based on linguistic forms and sentiment classification. Four verbal forms in Plurk and Yahoo were further examined. The former platform restricts short text conversation, and the latter platform allows for the long text description. The experimental results show that the customary forms tend to be used in informal and conversational texts while the non-customary forms tend to be used in formal articles to convey irony. The three basic elements that form a successful ironic speech act were also analyzed. These elements, including the words/phrases with reversed meanings, contextual information and rhetorical words, should be identified first in order to properly process ironic expressions and perform linguistic analysis. In the mined patterns, it was found that hyperbole was frequently present. In future work, we will explore other opinion mining and sentiment analysis algorithms, and focus on automatic recognition of hyperbole and the ironic elements.

Abstract

We address the problem of transferring semantic annotations to new languages using parallel corpora. Previous work has transferred these annotations on a token-to-token basis, an approach that is sensitive to alignment errors and translation shifts. We present a global approach to transfer that aggregates information across the whole parallel corpus and leads to more robust labellers. We build two global models, one for predicate labelling and one for role labelling, each tailored to the task at hand. We show that the combination of direct and global methods outperforms previous results.

1 Introduction

With the proliferation of the Internet in non-English speaking countries, the need for multilingual processing becomes more and more pressing. Various efforts have focused on developing language-independent NLP tools and extending to other languages tools that had been exclusive to English. Furthermore, several annotation efforts have been devoted to developing resources for different languages, needed for supervised learning (Hajič et al., 2009). However, there is still a large number of languages for which corpora with semantic annotations do not exist. Since manual annotation is a costly and time-consuming approach to resource development, cross-lingual annotation transfer offers an alternative.

Semantic parsing or semantic role labelling (SRL) is the task of automatically labelling predicates and arguments with predicate-argument structure. This level of analysis provides a more stable semantic representation across syntactically different sentences. The example sentences (1a) and (1b) illustrate how the semantic annotation remains stable across the locative alternation of the verb *load*.

(1) a. [AGENT Jessica] [REL-LOAD.01 loaded] [THEME boxes] [DESTINATION into the wagon].
b. [AGENT Jessica] [REL-LOAD.01 loaded] [DESTINATION the wagon] [THEME with boxes].

Also in the cross-lingual setting, the predicate-argument structure of a sentence is considered to be more stable than its syntactic form as the English sentence in (2a) and its French translation in (2b) show:

(2) a. [EXPERIENCER Mary] [REL-LIKE.01 liked] [CONTENT the idea]. (English)
b. [CONTENT L'idée] a [REL-LIKE.01 plu] [EXPERIENCER à Marie]. (French)

This is why several pieces of work have transferred semantic annotations from a source language, for which semantic annotations exist, to a target language using parallel corpora (Padó, 2007; Basili et al., 2009; Annesi and Basili, 2010). These transfer methods rely on the assumption of semantic equivalence of the original and the translated sentences, but also on correct and complete alignments between words

Proceedings of COLING 2014, the 25th International Conference on Computational Linguistics: Technical Papers, pages 1279–1290, Dublin, Ireland, August 23-29 2014.

or constituents in those sentences. We will refer to these traditional methods as direct transfer because the semantic annotations are transferred directly from token to token. Although direct transfer methods are straightforward and easy to implement, they are vulnerable to missing or incorrect alignments which lead to missing and erroneous annotations in the target language. Consequently, non-literal translations and translation shifts present major problems for these methods.

In this paper we propose a global approach to the cross-lingual transfer of PropBank (Palmer et al., 2005) semantic annotations that aggregates information at the corpus level and, as a consequence, is more robust to non-literal translations and alignment errors. Our global approach involves two steps: in the learning step, two global models are learned on the basis of role and predicate annotations in the source language (English). In the labelling step, these models assign labels to verbs and their arguments in the target language (French) without consulting any parallel data. Contrary to previous work, we build separate models for the transfer of semantic role and predicate annotation because predictors for the two models are different in nature. We model cross-lingual transfer of predicate labels as a cross-lingual word sense disambiguation (WSD) task because this fits well with the lexical nature of the task: annotating French verbs with English predicate labels. Our approach to predicate labelling needs word alignments but instead of relying on local (token-to-token) correspondences like the direct method, it exploits alignment information gathered from the whole corpus thus avoiding transfer errors caused by local misalignments. Our model for cross-lingual semantic role labelling[1] is based on syntactic-semantic mappings learned from a gold annotated monolingual corpus. The SRL method does not need aligned data. Our methods are knowledge-lean as our predicate labelling method only needs a part of speech (PoS) tagger in the two languages and no syntactic information on either side, in contrast to previous work. For SRL, a syntactic parser for the target language is needed, but no joint semantic-syntactic parsing framework as was the case in previous work (van der Plas et al., 2011). The requirements of the global annotation transfer methods in terms of data and annotations, and their differences from direct transfer, are illustrated in Figure 1.

Our contribution is three-fold. First, we present a global approach to semantic annotation transfer that corrects token-level mistakes found in traditional direct transfer methods. We show the strengths and limitations of global vs. direct transfer and explain how the two can be combined. Second, in contrast to previous work, we address the two tasks of cross-lingual predicate labelling and cross-lingual semantic role labelling by building two separate models tailored to the task at hand. We show how the predicate labels produced by our high-coverage and knowledge-lean model for cross-lingual predicate labelling are successfully used as predictors for semantic role labelling. Third, due to its knowledge-lean and flexible character, our method adapts relatively easily to other language pairs without requiring semantic lexicons in the target language.

In the next section, we present related work on cross-lingual annotation transfer. In Section 3 we present the data used in our experiments and in Section 4 we briefly discuss direct transfer. The two global methods proposed in this paper are presented in Section 5. We report and discuss our results in Section 6, before concluding.

2 Related work

Transferring annotation from one language to another in order to train monolingual tools for new languages was first introduced by Yarowsky and Ngai (2001). In their approach, token-level part-of-speech (PoS) and noun phrase bracketing information was projected across word-aligned bitext and this partial annotation served to estimate the parameters of a model that generalized from the noisy projection in a robust way. In more recent work, Das and Petrov (2011) propose a graph-based framework for projecting syntactic information across languages. They create type-level tag dictionaries by aggregating over projected token-level information extracted from bi-text and use label propagation on a similarity graph to smooth and expand the label distributions. A different approach to cross-lingual PoS tagging is proposed

[1]Most unsupervised approaches consider argument identification as a separate task that is omitted (Lang and Lapata, 2010) or performed heuristically (Lang and Lapata, 2011). We focus on semantic role labelling in this paper and consider argument identification as given.

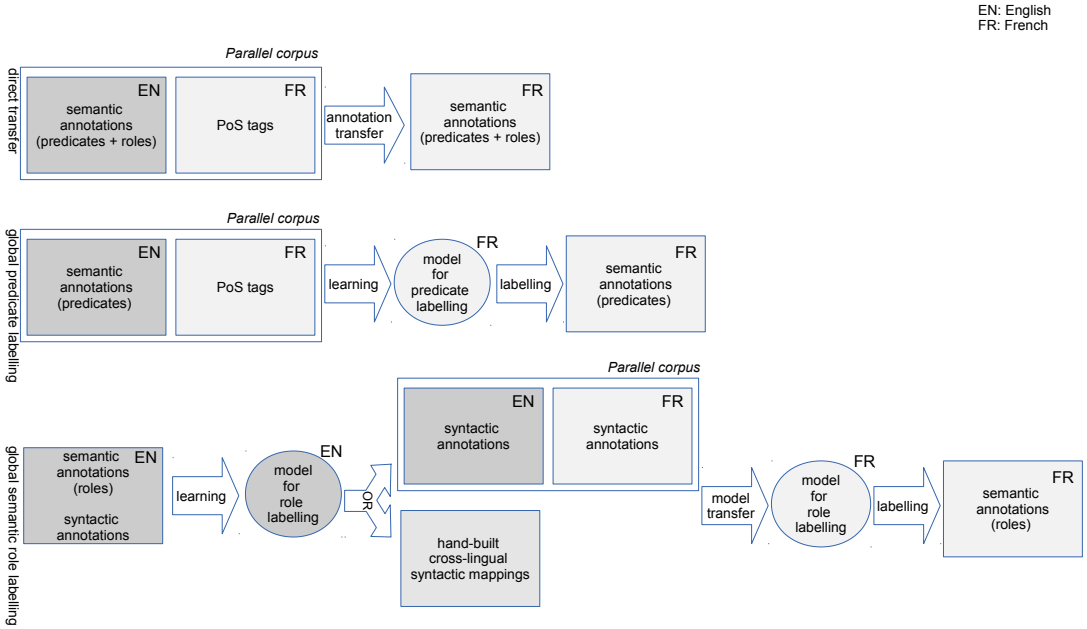

Figure 1: Direct vs. global cross-lingual transfer of semantic annotations.

by Täckström et al. (2013) who couple token and type constraints to guide learning. Our approach to cross-lingual semantic role labelling follows this vein. Instead of solely relying on token-level information acquired from word-alignments, we combine this with type-level information captured by our global methods which are trained on the entire corpus. We however are concerned with semantic annotations and not PoS.

Transfer of semantic annotation has started off with direct transfer of FrameNet semantic annotations (Padó, 2007; Basili et al., 2009; Annesi and Basili, 2010). With the addition of a learning step and the use of PropBank data, Van der Plas et al. (2011) have scaled up previous efforts. They show that a joint semantic-syntactic parser trained on the output of direct transfer produces better parses than the input it received by aggregating information across multiple examples. In their work, transfer of predicate labels and semantic role labels is done in one step. The model needs an aggressive filter to compensate for missing annotations on the predicate level after direct transfer. This filter successively leads to drops in performance for the role labellings. Here, we build two separate global models that complement direct transfer instead of relying on it.

The same emphasis on learning is found in cross-lingual model transfer where source language models are adapted to work on the target language directly. For semantic role labelling, Kozhevnikov and Titov (2013) use shared feature representations (syntactic and lexical) to adapt a source model to a target-language model. The ideas behind their cross-lingual model adaptation resemble the ideas behind our global method for semantic role labelling. However, in contrast to their work we do not consider the predicate labelling as given because, as manual annotations show (van der Plas et al., 2010), this task is not trivial. We first build a tailored global model for cross-lingual predicate labelling and then use the predicted predicate labels for semantic role labelling.

3 Data

In our experiments, we use the English-French part of the Europarl corpus (Koehn, 2005). The dataset is tokenised and lowercased and only sentence pairs corresponding to a one-to-one sentence alignment with lengths ranging from one to 40 tokens on both French and English sides are considered. Furthermore, because translation shifts are known to pose problems for the automatic projection of semantic roles across languages (Padó, 2007), we select only those parallel sentences in Europarl that are direct

translations from English to French or vice versa. In the end, we have a parallel corpus of 276-thousand sentence pairs.

The English part of the parallel corpus is annotated by a freely-available syntactic-semantic parser (Henderson et al., 2008; Titov et al., 2009) trained on the CoNLL 2009 training set (the Penn Treebank corpus (Marcus et al., 1993) merged with PropBank labels (Palmer et al., 2005) and NomBank labels (Meyers, 2007)). The probabilistic model is a joint generative model of syntactic and semantic dependencies that maximises the joint probability of the dependencies while building two separate structures.

The WSD classifier used for predicate labelling is trained on the parallel training corpus tagged with semantic roles on the English side. The candidate predicate labels that are considered by the classifier for each French verb are the labels of its English translations in the training corpus. Verbs on the English side are replaced by the corresponding predicate label where available. Then both parts of the corpus are lemmatized and tagged by part of speech (Schmid, 1994) and the parallel files are rebuilt (one sentence per line) by replacing words on both sides by the corresponding 'lemma_PoS tag' pair. The corpus is then word aligned in both directions using GIZA++ (Och and Ney, 2003) and a lexicon is built from intersecting alignments. Lexicon entries for French verbs contain the English predicate labels to which they were aligned in the training corpus. The entry for the verb *encourager*, for instance, contains seven predicate labels: {urge.01, foster.01, stimulate.01, promote.02, encourage.01, encourage.02, renew.01}, two of which correspond to the same English verb (*encourage*). We keep labels with an alignment confidence score above 0.01 according to GIZA++.

Contrary to our predicate labelling model, the role labelling model needs syntactic information in the target language. For parsing French, we use the dependency parser described in Titov and Henderson (2007). We train the parser on the dependency version of the French Paris 7 treebank (Candito et al., 2009), achieving 87.2% labelled accuracy on this data set. The French Treebank (Abeillé et al., 2003) is a treebank of 21,564 sentences annotated with constituency annotation. We use the automatic dependency conversion of the French Treebank into dependency format (Candito et al., 2009) to train the French syntactic parser that is used to annotate the French part of the parallel corpus.

For testing, we use the hand-annotated data described in Van der Plas et al. (2010). We randomly split those 1000 sentences into test and development set containing 500 sentences each. We use the development set for the current experiments, which contains 1,917 core roles in total. We limit our experiments to verbal predicates because the semantic annotations on French test sentences are limited to verbal predicates.

4 Direct cross-lingual transfer

Before explaining the global methods, we present the direct semantic transfer (DST) method proposed by Van der Plas et al. (2011) that we use for comparisons and combinations throughout this paper. The method is based on the Direct Correspondence Assumption for syntactic dependency trees proposed by Hwa et al. (2005). The transfer proceeds as follows: For any pair of sentences E and F that are translations of each other in the parallel corpus, we transfer the semantic relationship $R(x_E, y_E)$ to $R(x_F, y_F)$ if and only if there exists a word-alignment between x_E and x_F and between y_E and y_F, and we transfer the semantic property $P(x_E)$ to $P(x_F)$ if and only if there exists a word-alignment between x_E and x_F.

The relationships that are transferred are semantic role dependencies and the properties are predicate senses. These are transferred from the English part of the parallel training corpus that is automatically annotated with syntactic-semantic analyses, as explained in the previous section.

5 Global cross-lingual transfer of semantic annotations

In contrast to direct transfer where annotations are transferred on a token-to-token basis in word-aligned sentences, we propose two global methods for cross-lingual transfer, one for predicates and one for semantic roles, that both consist of a learning and a labelling step. Our methods are globally defined and as a consequence rely less on local translation correspondences than previous methods, which makes them less vulnerable to missing and incorrect alignment links.

5.1 Global cross-lingual predicate labelling

In cross-lingual predicate labelling, our aim is to put predicate labels that originate from the English side of the parallel corpus on the French verbs in the other side of the corpus. The predicate labels contain the English verb and its sense. For example, "give.01" stands for the first sense of the verb *give*. As the predicate label contains a lot of lexical information, putting the correct English predicate label on a French verb is very close to Word Sense Disambiguation (WSD), the task of automatically identifying the meaning of words in context (Navigli, 2009). In the cross-lingual variant of this task, the candidate senses are the words' translations in other languages and WSD aims at predicting semantically correct translations for words in context (Resnik and Yarowsky, 2000; Ng et al., 2003; Carpuat and Wu, 2007; Apidianaki, 2009). The main difference between cross-lingual WSD and our cross-lingual transfer of predicate labels is that we do not search for correct translations of French words but for the most appropriate predicate labels in context (i.e. verbs disambiguated with a predicate sense).

The global predicate labelling method consists of a learning step and a labelling step. During learning, we compute estimates for annotation transfer on the basis of the word alignments between English and French predicates over the entire parallel training corpus. At labelling time, we label French verbs with English predicate labels without the need for parallel data or alignments. The method is language-independent and only requires minimal linguistic resources (PoS information).

In terms of coverage, a predicate label is provided for all French verbs in the test set for which information was retained during training and not only for aligned ones, in contrast to direct transfer. We expect to augment the recall when using global estimates and hope that the effect on precision is not too negative.

Learning

For each French verb (v) in the lexicon built as described in Section 3, we want to be able to identify its correct predicate label in a new context by choosing one among its candidate labels (L) retained from the training corpus. A feature vector is built for each candidate label L_i ($1 \leq i \leq |L|$) found for the verb v in the lexicon, following the procedure described in Apidianaki et al. (2012). For each candidate label, we extract the content word co-occurrences of the verb v in the French sentences where it translates an English verb tagged with this label in the training corpus. The retained French words constitute the features of the vector built for that label. Let N be the number of features retained for each label L_i of the verb v from the corresponding French contexts. Each feature F_j ($1 \leq j \leq N$) receives a total weight with the label ($\text{tw}(F_j, L_i)$) which is learned from the data and defined as the product of the feature's global weight ($\text{gw}(F_j)$) and its local weight with that label ($\text{lw}(F_j, L_i)$). The global weight of a feature F_j is a function of the number n of candidate labels of v to which F_j is related, and of the probabilities (p_{ij}) that F_j co-occurs with instances of the verb v corresponding to each of the labels:

$$\text{gw}(F_j) = 1 - \frac{\sum_{i=1}^{n} p_{ij} \log(p_{ij})}{n} \tag{1}$$

Each p_{ij} is computed as the ratio of the co-occurrence counts of F_j with v when it is aligned to a label L_i to the total number of features (N) seen with this candidate label:

$$p_{ij} = \frac{cooc\_count(F_j, L_i)}{N} \tag{2}$$

The local weight between feature F_j and label L_i ($\text{lw}(F_j, L_i)$) directly depends on the number of times they occur together:

$$\text{lw}(F_j, L_i) = \log(\text{cooc\_count}(F_j, L_i)) \tag{3}$$

The intuition underlying this weighting scheme is that if an interesting semantic relation exists between a feature F_j and a specific predicate label L_i of a verb v, then we expect the probability (p_{ij}) of the feature F_j occurring in the contexts where v is translated by this label to be larger than if they were independent. In other words, a feature gets a high total weight (tw) with a label when it appears frequently in the corresponding French contexts and rarely in the contexts of the other labels.

Labelling

Predicate identification on the French side is done by selecting verbs based on the PoS labels provided by the tagger and subsequently filtering out modals and instances of the verb *être* (*be*).[2] The most suitable predicate labels are then assigned to the retained French verbs by the disambiguation classifier. The context of a new instance of a French verb is compared to the weighted feature vectors (V_i's) built for its candidate labels as described above, and an association score is assigned to each label. To facilitate comparison with the vectors, the new contexts (sentences) are lemmatised and PoS tagged on the fly (with TreeTagger) and the content word co-occurrences of the French verb are gathered in a bag of words. If common features (CFs) are found between the new context and the vector of a label (L_i), their association score corresponds to the mean of the weights of their shared features with L_i found in the corresponding vector. In Equation 4, $(CF_j)_{j=1}^{|CF|}$ is the set of common features between a label vector V_i and the new context C and tw is the total weight of a CF with label L_i, computed as explained in the previous section.

$$\text{assoc\_score}(V_i, C) = \frac{\sum_{j=1}^{|CF|} \text{tw}(CF_j, L_i)}{|CF|} \quad (4)$$

The label that receives the highest association score with the new context is returned and serves to annotate the corresponding French verb.

5.2 Global cross-lingual role labelling

For role labelling, we adopt a different strategy. Whereas predicate labels include a lot of lexical information, role labels do not. However, for role labels there is another source of information that helps to define global estimates: the correlation between syntax and semantics.

Previous work in monolingual unsupervised semantic role induction (Grenager and Manning, 2006; Lang and Lapata, 2010; Lang and Lapata, 2011) showed that mapping rules that assign semantic roles to arguments of a verb based on the syntactic functions of these arguments, represent a baseline that is very hard to beat. This strong correlation between syntactic labels and semantic role labels in the PropBank annotation has been shown in detail by Merlo and Van der Plas (2009). In contrast to previous work on monolingual unsupervised semantic role induction, we add the predicate label as a predictor. The core arguments of the verb, that are the numbered labels in PropBank, are known to be verb-specific. We have access to predicate labels assigned by the cross-lingual predicate labelling method described in the previous section and exploit them for role labelling.

For a given predicate, diathesis alternations are the major source of variation in propositions. They give rise to different syntactic structures, while the semantic roles remain stable. For example, the sentence "I gave the book to Jean" is syntactically different from "I gave Jean the book", but semantic roles on the three arguments stay the same. We will show in a feasibility study that the effect of diathesis alternations on the correlation between syntax and semantics is limited. In a cross-lingual setting, structural divergences (Dorr, 1994) are expected to reduce the correlation between syntax and semantics. An example is the difference in syntactic structure between the sentences "Tu me manques" vs. "I miss you", which are translations of each other, however the semantic roles are the same across languages.

As our global method is not restricted to alignments at labelling time, we are able to classify all given arguments[3] and not just those that are aligned in a parallel corpus. In this way, we believe that the negative effect of structural divergences and diathesis alternations is limited. Moreover, we show how mild supervision from the partial annotations that result from the direct transfer can potentially remedy these difficulties.

Learning syntactic-semantic mappings

The syntactic-semantic mapping rules that are exploited by our model for role labelling are extracted from gold-annotated monolingual data. As a consequence, the extracted rules are of high quality which

[2] We exclude the verb *être* because its English counterpart (*be*) is not annotated in the CoNLL-2009 data used in our experiments.

[3] We focus on the classification of core semantic roles because diathesis alternations and cross-lingual divergences mainly involve these roles.

would not be the case if parallel data was used. Manually annotated parallel corpora are very sparse and automatic parsing introduces errors which might be propagated by the direct transfer methods and result in noisy annotations. Using gold-standard monolingual data thus ensures the quality of the mappings exploited by our global model.

We build a model that determines the most suitable semantic role label r for a given argument of a given predicate p, based on its syntactic dependency label d.[4] We simply compute the maximum likelihood estimates (MLE) and count occurrences of the following triples $< p, d, r >$ in a large body of English gold semantically and syntactically annotated data.

$$P_{MLE}(r|p,d) = \frac{count(p,d,r)}{count(p,d)} \tag{5}$$

In the cross-lingual setting, the mapping rules extracted from the English training data are applied to French. We learn the correspondences between English and French syntactic labels in a data-driven way by syntactically annotating both sides of our parallel training corpus. We base the cross-lingual syntactic mapping on alignment counts between syntactic labels in the parallel corpus parsed syntactically both on the English and the French side (cf. Section 3). An alternative that needs no parallel data is to study the annotation guidelines for the two languages and determine the cross-lingual correspondences between syntactic labels by hand.

The syntactic label set used for French (Candito et al., 2009) is less fine-grained than the English labels (20 versus 36). As a consequence, the mapping from English syntactic labels to French treebank labels is for the most part a many-to-one mapping, which leads to information loss but suffices for our purpose as will be shown in the next section.

Once the correspondences between the syntactic labels of the two syntactic annotation frameworks are discovered, the cross-lingual transfer of syntactic-semantic mappings consists in substituting the English syntactic labels with their French counterparts to adapt the model described above.

Labelling

For role labelling, we use estimates derived from the training data (see Equation 5) to determine the most suitable role of a given argument. Because a particular triple in the test set might not have been seen during training, we backoff to 2-tuples that discard the predicate label, and backoff to A1 if neither the dependency label nor the predicate has been seen in training.

To treat the R-suffix, which takes care of anaphoric arguments, we use the following simple rule: for the monolingual setting all arguments with PoS-tags "WDT", "WP", and "WRB" receive the R-suffix. In the cross-lingual setting, we translate the PoS tags to the single French PoS tag "PROREL". We do not treat the C-prefix, which takes care of discontinuous arguments, because there were only a few examples.

We do not accept duplicate semantic roles, a constraint that leads to valid role configurations in general (Punyakanok et al., 2008). We expect the more prominent semantic roles, such as A0 and A1, to appear earlier in the sentence than semantic roles with higher numbers. We therefore attribute semantic roles of a predicate from left to right.

5.3 Combining direct and global cross-lingual transfer

Direct transfer methods generally have low recall, we however expect them to be more precise than the global methods. In our combined method, we use the annotations assigned by direct transfer as the backbone and fill missing labels by the global methods. The annotations from direct transfer restrict the possible roles the global method adds. We expect, as an additional benefit of this combination, that the partial annotations from direct transfer together with the no-duplicate-role constraint described above will remedy problems related to diathesis alternations. Although the probabilities computed will favour the canonical alternation in general, the partial annotations may prevent a canonical analysis in a particular proposition. Consider the following alternation example: *Mary presented the flowers to John* vs. the less canonical alternation *Mary presented John with the flowers*. Although the most probable role

[4] We chose not to include the complete dependency path from predicate to argument because of data sparseness. We select the dependency label on the arc that points to the argument under discussion.

Predicate identification and labelling							
		Labelled			Unlabelled		
		Prec	Rec	F	Prec	Rec	F

for the *prep* relation would be A2, based on the canonical alternation, partial annotations on *Mary* (A0) and *John* (A2) in combination with the no-duplicate-role constraint would rule that out and the next most probable label would be put on *with*: A1.

6 Results and discussion

We ran experiments using the two global methods described in Section 5 separately and combined with direct transfer. In this section, we present the results and compare to several baselines and upper bounds from manual annotations and previous work.

6.1 Cross-lingual predicate labelling

Table 1 shows the results of cross-lingual predicate labelling (Labelled) and identification (Unlabelled). The first row shows the results from using the traditional direct transfer method. The second row presents results from the global method where we use cross-lingual WSD to label predicates. The third row combines direct and global transfer, as explained in Section 5.3. For comparison, we present results when using the parser from Van der Plas et al. (2011) on our test data: the fourth row contains results when using all (unfiltered) data, the fifth row when using data filtered for incomplete predicate labellings. We show an upper bound in the last row which corresponds to the inter-annotator agreement for manual annotation on a random set of 100 sentences (van der Plas et al., 2010).

Overall the figures, including the upper bound from manual annotations, are not very high. Annotating French verbs with English predicate labels is a hard task. When we look at the differences between the three automatic methods, we see that recall is very low (29%) for the direct method. From the recall figures for unlabelled predicates, we see that the direct method leaves many predicates without a label.

The global method has a much better recall, 39%, and a slightly lower precision. The best results are however attained when the two methods are combined, that is, when global transfer is used to fill in missing predicates from direct transfer. We get an F-measure of 45% which is a big improvement over the baseline of direct transfer, which attained 37%. These results show that the global method for predicate labelling improves recall without sacrificing precision too much.

We compare these results also to the results obtained by Van der Plas et al. (2011)'s three step model, where a parser trained on transferred annotations annotates in turn the test sentences. We see that the current method gives better results (recall and F-measure) when the parser is trained on unfiltered data. An aggressive filter, that removes more than half of the data and leads to a big drop in performance for argument labelling (recall that argument and predicate labelling is done in parallel in this model) finally leads to a result that outperforms ours. This result is not surprising because the parser has access to much more expressive syntax. Note that our global method only needs a PoS tagger in the source language and no syntactic information nor joint semantic-syntactic parsing frameworks. It is thus knowledge-lean and easier to apply to languages without a parser, a difference that should be taken into account in the interpretation of the results. However, we can learn from these results that structural information is beneficial. In future work, we plan to include word position information in our cross-lingual WSD method. This will give the method access to structural information while keeping it knowledge-lean.

In Figure 2, we give an example that illustrates the contribution of the global method. In this example,

English (automatic): There is in particular one amendment, let [let.01] me point [point.02] out, concerning [concern.01] the energy sector, which, in my capacity as rapporteur, I see [see.01] as particularly important.
Transfer: Il y a notamment un amendement, je le souligne, concernant [concern.01] le secteur de l'énergie, qui me paraît en tant que rapporteur particulièrement important.
CLWSD: Il y a notamment un amendement, je le souligne [stress.01], concernant [concern.01] le secteur de l'énergie, qui me paraît [seem.01] en tant que rapporteur particulièrement important.

Figure 2: Predicate label addition and correction using CLWSD.

the cross-lingual WSD method annotates more verbs than the direct transfer approach: labels [stress.01] and [seem.01] assigned during disambiguation, are missing from the first sentence after transfer. Even with a high quality word alignment, it would not be possible to get these labels from the English source sentence through direct transfer because they are simply not there, due to the non-literal translation. This example shows the limitations of token-to token direct transfer and how the global method compensates for that by using information aggregated across the whole parallel corpus.

6.2 Global cross-lingual role labelling

Though already supported by previous work (Grenager and Manning, 2006; Lang and Lapata, 2010; Lang and Lapata, 2011), we tested the hypothesis that syntactic-semantic mappings provide good approximations for semantic role labelling, especially when adding predicate information. We therefore first ran a monolingual feasibility study by collecting counts from the CoNLL 2009 training set and testing on the CoNLL 2009 test set. The accuracy attained with this simple method is 79%. This shows that in a monolingual setting, the predicate label combined with the syntactic label of the argument are good predictors for the semantic role of the argument. This number can serve as a baseline for semantic role labelling given the correct predicate label.

In previous sections, we discussed diathesis alternations as problematic for using syntactic-semantic mapping rules. To measure the importance of diathesis alternations we need to measure the variation in a large corpus. By applying the mapping rules learned from the training data on the same data we get an idea of the amount of variation. We get an accuracy of 86%. Although the 14% probably contains the most interesting examples from a linguistic point of view, these results on monolingual data show that predicate-centered syntactic-semantic mapping rules are a promising direction for improving recall in direct transfer methods.

Table 2 shows the results[5] for semantic role labelling for the three cross-lingual transfer methods and the baseline of applying the most frequent semantic role label 'A1'. For the global and the combined methods we use the predicate labels provided by the cross-lingual WSD method. The numbers in Table 2 provide performance numbers given the predicate from the cross-lingual WSD method. We discussed in Subsection 5.2 that, when applying syntactic-semantic mapping rules cross-lingually, differences in annotation framework and cross-lingual divergences are at play. We see indeed that when applying syntactic-semantic mapping rules cross-lingually the accuracy drops from 79 to 68%. This drop in performance when applying to French the syntactic-semantic mappings that were learned on English data is not too important. This accuracy number is, in any case, much better than the results from direct transfer. This is mainly due to the low recall of direct transfer which results in very few but rather precise (87%) semantic roles. It is therefore very useful to use the direct transfer method as a backbone that restricts the labels we get from global transfer by imposing consistency with the available annotation (no-duplicate-argument-constraint). By combining the two methods, we get 73% accuracy that is not far from the 79% in the monolingual setting. In future work, we would like to investigate whether the drop in performance between the monolingual and cross-lingual setting is larger for languages that are less related.

We also compare our results to previous work on cross-lingual transfer of semantic roles. Kozhevnikov and Titov (2013) evaluate on the full test set described in Subsection 3 (1000 sentences), they use gold predicates instead of predicted predicates and evaluate on both core roles and adjuncts. The authors shared with us their results for core roles only: 74% and 77%, when using original and transferred

[5] As we focus on argument labelling (and not identification) we provide accuracy scores.

syntax, respectively. We use original syntax and should therefore compare to the 74%. When we use gold predicate annotations as Kozhevnikov and Titov (2013) did, instead of the predicate labels obtained through cross-lingual WSD, and test on all 1000 sentences, we attain 75% for the combined method and 71% for the global method. These results compare favourably with their results. This is encouraging because their model uses a larger feature set that includes (cross-lingual) lexical features, the unlabelled dependency graph and PoS information. Interestingly, they attain better scores when they use a transferred syntactic model instead of the original syntax. This result seems in line with our discussion on the loss of information when trying to map the English syntactic label inventory to the French inventory. We keep syntactic model transfer in mind for future work.

Because we consider the arguments as given, while Van der Plas et al. (2011) do both argument identification and labelling for all core roles and adjuncts, and provide precision and recall given the predicate only, we cannot directly compare to their results. We however include their results for the sake of completeness. Their parser results in 65% F-score.

Applying A1 (the most frequent semantic role) to the entire data set gives us 48% accuracy. That is much higher than results from transfer, again due to the low recall of the direct transfer method, but much lower than the results of the combined and global methods.

7 Conclusion

We have introduced a global approach to transfer that aggregates information at the corpus level thereby correcting and complementing the annotations from traditional direct transfer methods that suffer from token-level mistakes. We show that the combination of direct transfer (a high-precision method) and global methods (high in recall) outperforms previous results.

In contrast to previous work, we transfer predicate annotations and semantic role annotations by building two separate models tailored to the task at hand. We show how the predicate labels produced by our high-coverage model for cross-lingual predicate labelling are successfully used as predictors for semantic role labelling.

In future work, we would like to feed structural information to the cross-lingual WSD method such as information about word position, which would preserve its knowledge-lean character without need for syntactic parsing. Furthermore, we intend to use cross-lingual WSD for labelling adjuncts (non-core semantic roles) since this task is also rather lexical in nature. Last but not least, we want to add argument identification which will allow to propose a complete SRL annotation framework based on global information.

Abstract

We consider *multilingual semantic parsing* – the task of simultaneously parsing semantically equivalent sentences from multiple different languages into their corresponding formal semantic representations. Our model is built on top of the *hybrid tree* semantic parsing framework, where natural language sentences and their corresponding semantics are assumed to be generated jointly from an underlying generative process. We first introduce a variant of the joint generative process, which essentially gives us a new semantic parsing model within the framework. Based on the different models that can be developed within the framework, we then investigate several approaches for performing the multilingual semantic parsing task. We present our evaluations on a standard dataset annotated with sentences in multiple languages coming from different language families.

1 Introduction

Semantic parsing, the task of parsing natural language sentences into their formal semantic representations (Mooney, 2007) is one of the most important tasks in the field of natural language processing and artificial intelligence. This area of research recently has received a significant amount of attention (Zettlemoyer and Collins, 2005; Kate and Mooney, 2006; Wong and Mooney, 2006; Lu et al., 2008; Jones et al., 2012b). Consider these example sentence-semantics pairs:

English:	Which states have points that are higher than the highest point in Texas ?
Semantics:	$answer(state(loc_1(place(higher_2(highest(place(loc_2(stateid('TX'))))))))$
English:	What rivers do not run through Tennessee ?
Semantics:	$answer(exclude(river(all), traverse_2(stateid('TN'))))$

In the typical setting, the semantic parser learns from a collection of such sentence-semantics pairs a model that can parse novel input sentences into their respective semantic representations. Such semantic representations can then be used to interact with certain downstream components to perform interesting tasks. For example, retrieving of answers from an underlying database, or performing certain actions based on the generated executable semantic instructions.

Note that in the training data, although complete sentence-semantics pairs are given, specific word-level semantic information is not explicitly provided. The model therefore needs to automatically learn such latent mappings between natural language words/phrases and semantic units.

One natural assumption is that the semantics exhibit certain restricted structures, such as the recursive tree structures. Under such an assumption, one can convert the second semantics appeared above as the tree structure illustrated in Figure 1. More details about such tree structured representations will be given in Section 2.1.

Currently, researchers only focused on the semantic parsing task under a single language setting where the input is a sentence from one particular language. However, natural language is highly ambiguous, and identifying the correct semantics associated with words with limited background information is a

Proceedings of COLING 2014, the 25th International Conference on Computational Linguistics: Technical Papers, pages 1291–1301, Dublin, Ireland, August 23-29 2014.

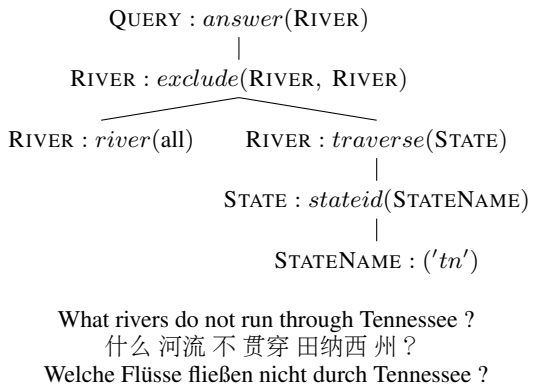

Figure 1: An example tree-structured semantic representation (above) and its corresponding natural language sentences (in English, Chinese and German).

challenging task. Researchers resorted to performing context-dependent semantic parsing to alleviate such an issue (Zettlemoyer and Collins, 2009).

On the other hand, researchers have successfully exploited parallel texts for improved word-level semantic processing (Chan and Ng, 2005). This is because words from different languages that convey the same semantics can be used to disambiguate each other's semantics. In fact, texts from different languages that convey the same semantic information becomes increasingly available nowadays. Web crawlers such as Google and Yahoo! are able to rapidly aggregate a large volume of news stories every day. One crucial fact is that many such news articles written in different languages are actually all discussing the same underlying story and therefore convey similar or identical semantic information. To build better automatic systems for improved natural language understanding, it is therefore helpful to develop algorithms that can simultaneously process the underlying semantic information associated with all these documents coming from different language sources together. For example, consider the following example taken from the multilingual version of the dataset, which shows semantically equivalent sentences from three different languages and their corresponding semantics:

English:	What rivers do not run through Tennessee ?
Chinese:	什么 河流 不 贯穿 田纳西？
German:	Welche Flüsse fließen nicht durch Tennessee ?
Semantics:	$answer(exclude(river(all), traverse_2(stateid('TN'))))$

As a step towards the above-mentioned goal, this work focuses on the development of an automated system that is capable of simultaneously parsing semantically equivalent natural language texts in different languages into their underlying semantics.

Specifically, in this work, we first introduce a new variant of a semantic parsing model under an existing framework. This new variant can be used together with other models for jointly making semantic parsing predictions, leading to an improved multilingual semantic parsing system. We demonstrate the effectiveness of this new variant through experiments. Although bilingual parsing has been extensively studied in fields such as statistical machine translation (Wu, 1997; Chiang, 2007), to the best of our knowledge, bilingual or multilingual semantic parsing that focuses on parsing sentences from multiple different languages into their formal semantic representations has not yet been studied. We present the very first work on performing multilingual semantic parsing that simultaneously parses semantically equivalent sentences from multiple different languages into their semantics. We believe this line of work can potentially lead to further developments and advancements in areas such as multilingual semantic processing and semantics-based machine translations (Jones et al., 2012a).

2 Background

2.1 Semantics

Researchers have focused on various semantic formalisms for semantic parsing. Popular examples include the tree-structured semantic representations (Wong and Mooney, 2006; Kate and Mooney,

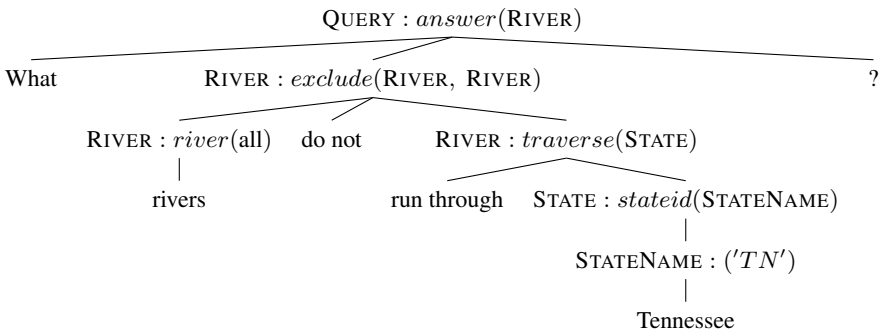

Figure 2: An example hybrid tree. Such a hybrid tree is generated from the generative process, and captures the correspondences between natural language words and semantic units.

2006), the lambda calculus expressions (Zettlemoyer and Collins, 2005; Wong and Mooney, 2007), and dependency-based semantic representations (DCS) (Liang et al., 2013). In this work, we specifically focus on the tree-structured representations for semantics.

Each semantic representation consists of semantic units as its tree nodes, where each semantic unit is of the following form:

$$m_a \equiv \tau_a : p_\alpha(\tau_b*) \tag{1}$$

Here m_a is used to denote a complete semantic unit, which consists of its semantic type τ_a, its function symbol p_α, as well as a list of types for argument semantic units τ_b* (here $*$ means 0, 1, or 2; we assume there are at most two arguments for each semantic unit). In other words, each semantic unit can be regarded as a function which takes in other semantic representations of specific types as arguments, and returns a new semantic representation of a particular type. For example, in Figure 1, the semantic unit at the root has a type QUERY, a function name $answer$, and a single argument type RIVER.

2.2 Related Work

Substantial research efforts have focused on building monolingual semantic parsing systems. We survey in this section several of them.

WASP (Wong and Mooney, 2006) is a model motivated by statistical synchronous parsing-based machine translation (Chiang, 2007), which essentially casts the semantic parsing problem as a phrase-based translation problem (Koehn et al., 2003). KRISP (Kate and Mooney, 2006) makes use of Support Vector Machines with string kernels (Lodhi et al., 2002) to recursively map contiguous word sequences into semantic units to construct a tree structure. The SCISSOR model (Ge and Mooney, 2005) performs integrated semantic and syntactic parsing. The model parses natural language sentences into semantically augmented parse trees whose nodes consist of both semantic and syntactic labels and then builds semantic representations based on such augmented trees. The *hybrid tree* model (Lu et al., 2008; Lu et al., 2009), whose code is publicly available, makes the assumption that there exists an underlying generative process for jointly producing both the language and semantics. The model employs efficient dynamic programming algorithms for learning a distribution over the latent *hybrid trees* which jointly encode both language and semantics. An example hybrid tree representation is shown in Figure 2. Jones et al. (2012b) recently proposed a framework that performs semantic parsing with tree transducers. The model learns representations that are similar to the hybrid tree structures using a generative process under a Bayesian framework.

Besides these approaches, recently there are also several works that take alternative learning approaches for semantic parsing which do not require annotated semantic representations (Poon and Domingos, 2009; Clarke et al., 2010; Goldwasser et al., 2011; Liang et al., 2013; Artzi and Zettlemoyer, 2013). Most of such approaches rely on either weak supervision or certain forms of indirect supervision. Some of these works also focus on optimizing specific downstream tasks rather than the semantic parsing task itself.

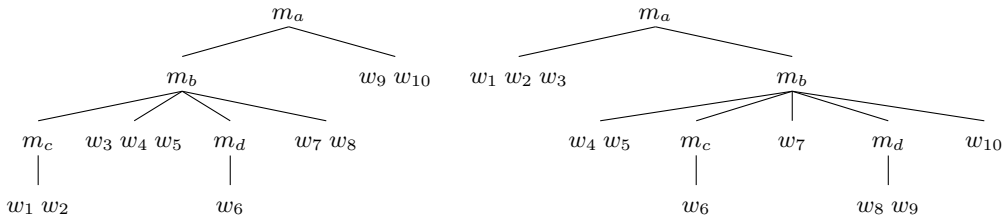

Figure 3: Two example hybrid trees. Their leaves are natural language words, and the internal nodes are semantic units. Both hybrid trees correspond to the same $\mathbf{n}$-$\mathbf{m}$ pair $\langle \overline{w_1\ w_2\ w_3\ w_4\ w_5\ w_6\ w_7\ w_8\ w_9\ w_{10}}, m_a(m_b(m_c, m_d))\rangle$. Thus they can be viewed as two different ways of generating such a pair from the joint generative process.

We note there also exist various multilingual or cross-lingual semantic processing works. Most of such works focus on semantic role labeling(SRL), the task of recovery of shallow meaning. Examples include multilingual semantic role labeling (Björkelund et al., 2009), multilingual joint syntactic and semantic dependency parsing (Henderson et al., 2013), and cross-lingual transfer of semantic role labeling models (Kozhevnikov and Titov, 2013). Researchers also looked into exploiting semantic information for bilingual processing such as machine translations (Chan et al., 2007; Carpuat and Wu, 2007; Jones et al., 2012a).

In this work, we focus on the task of multilingual semantic parsing under the setting where the input consists of semantically equivalent sentences from multiple different languages, and the outputs are formal semantic representations. We specifically focus on the hybrid tree model, a state-of-the-art framework for semantic parsing. We first make an extension to the model, and investigate methods for performing such a multilingual semantic parsing task by aggregating a few variants of the models under such a framework.

3 Approach

In this section, we first discuss the hybrid tree model of Lu et al. (2008), and introduce a novel extension. Next we discuss the approach used for multilingual semantic parsing.

3.1 The Hybrid Tree Model

For a given $\mathbf{n}$-$\mathbf{m}$ pair (where $\mathbf{n}$ is a complete natural language sentence, and $\mathbf{m}$ is a complete semantic representation), the hybrid tree model assumes that both $\mathbf{n}$ and $\mathbf{m}$ are generated from an underlying generative process in a top-down, left-to-right, level-by-level, recursive manner. The joint generative process for the pair results in a new tree-structured representation called a *hybrid tree*, which consists of natural language words as leaves, and semantic units as internal nodes.

There are three types of model parameters involved in the generative process. The meaning representation model parameters (ρ) are used for generating one semantic unit from its parent semantic unit. The hybrid pattern parameters (ϕ) are used for deciding how natural language words and semantic units are organized together to form the next level of the nodes of the hybrid tree structure. The emission parameters (θ) are used for generating natural language words from its corresponding semantic unit.

For a given $\mathbf{n}$-$\mathbf{m}$ pair, there are multiple possible hybrid trees that can jointly represent such a pair. See Figure 3 for two possible hybrid trees that contain the same $\mathbf{n}$-$\mathbf{m}$ pair. Consider the first example hybrid tree illustrated there. The probability of generating such a hybrid tree $\mathbf{h}$ (i.e., jointly generating both the natural language sentence $\mathbf{n}$ and the semantics $\mathbf{m}$) is:

$$\begin{aligned} P(\mathbf{n}, \mathbf{m}, \mathbf{h}) = {} & \rho(m_a) \times \phi(\overline{\mathbf{X}\mathbf{w}}|m_a) \times \theta(\mathbf{X}|m_a, \Lambda) \times \theta(w_9|m_a, \Lambda) \times \theta(w_{10}|m_a, \Lambda) \\ & \times \rho(m_b|m_a, \arg = 1) \times \phi(\overline{\mathbf{X}\mathbf{w}\mathbf{Y}\mathbf{w}}|m_b) \times \theta(\mathbf{X}|m_b, \Lambda) \times \theta(w_3|m_b, \Lambda) \\ & \times \theta(w_4|m_b, \Lambda) \times \theta(w_5|m_b, \Lambda) \times \theta(\mathbf{Y}|m_b, \Lambda) \times \theta(w_7|m_b, \Lambda) \times \theta(w_8|m_b, \Lambda) \\ & \times \rho(m_c|m_b, \arg = 1) \times \phi(\overline{\mathbf{w}}|m_c) \times \theta(w_1|m_c, \Lambda) \times \theta(w_2|m_c, \Lambda) \\ & \times \rho(m_d|m_b, \arg = 2) \times \phi(\overline{\mathbf{w}}|m_d) \times \theta(w_6|m_d, \Lambda) \end{aligned} \quad (2)$$

Note that $\overline{\mathbf{Xw}}$ refers to a pattern which says the next level of the hybrid tree is expected to consist of the first child semantic unit, followed by a contiguous sequence of natural language words. Similar definitions can be given to the patterns $\overline{\mathbf{XwYw}}$ and $\overline{\mathbf{w}}$, where $\mathbf{X}$ and $\mathbf{Y}$ refer to the first and second child semantic unit, respectively. The symbols $\mathbf{X}$ and $\mathbf{Y}$ appear in emission parameters are used to denote placeholders for the first and second child semantic unit, respectively.

The hybrid tree model then focuses on the learning of these model parameters from the training data using maximum likelihood estimation. In other words, the model tries to maximize:

$$\sum_i \log P(\mathbf{n}_i, \mathbf{m}_i; \rho, \phi, \theta) = \sum_i \log \sum_{\mathbf{h}} P(\mathbf{n}_i, \mathbf{m}_i, \mathbf{h}; \rho, \phi, \theta) \tag{3}$$

Since the correct hybrid tree associated with $\mathbf{n}$-$\mathbf{m}$ pair is unknown, we marginalize over the hidden variable $\mathbf{h}$. The model parameters will then be estimated using the Expectation-Maximization (EM) algorithm (Dempster et al., 1977). Specifically, an inside-outside style algorithm (Baker, 2005) is used where an additional layer of dynamic programming algorithms are used for efficient inference (Lu et al., 2008). The complexity of the inference algorithm is $O(mn^3)$, where m is the size of the semantic representation (number of semantic units), and n is the number of words in the input sentence.

Note that the generation of natural language words involves the context Λ. Specifically, if the context is empty, the model is regarded as the *unigram model*. If the context is the previously generated word, the model is called a *bigram model*. For example, consider the generation of the natural language word w_4 in the left hybrid tree in Figure 2. The probability for generating this word is $\theta(w_4|m_b)$ and $\theta(w_4|m_b, w_3)$, under the unigram and the bigram model, respectively. In Lu et al. (2008), the mixgram model (an interpolation between the unigram model and the bigram model) was also considered when parsing novel sentences, which yielded a better performance.

Once the model parameters are learned, we will be able to use them to parse novel sentences. Specifically, for each novel input sentence, we first find the most probable hybrid tree that contains the sentence $\mathbf{n}$, and then extract its internal nodes to form the semantic representation. Efficient dynamic programming algorithms similar to the ones used for training can also be employed here. In addition, the algorithm can also be extended to support exact top-k decoding, which will be useful later for combining multiple lists of outputs with rank aggregation (to be discussed in Sec. 3.3).

3.2 The Backward Bigram Model

One assumption associated with the original hybrid tree model is that nodes at each level of the hybrid tree are generated from the left to the right. An alternative assumption would be that the nodes at each level are generated in the reverse order – from the right to the left. While this alternative assumption will not introduce any difference in the unigram model (since each node is generated from its respective parent semantic unit only, regardless of its context), such a new assumption will lead to a completely new generative process under the bigram assumption.

To see this, again consider the emission probability for generating the word w_4 in the hybrid tree on the left of Figure 3. Under the assumption of our new model, the probability of generating this word is $\theta(w_4|m_b, w_5)$, since now the context Λ becomes the word to the right of the current word. The parameter estimation and parsing (decoding) procedures are largely similar to those of the original bigram model, where similar efficient dynamic programming algorithms can be employed.

3.3 Multilingual Semantic Parsing

In multilingual semantic parsing, the input consists of multiple semantically equivalent sentences, each of which is from a different language. One approach for building such a multilingual semantic parsing system is to develop a joint generative process from which both the semantic representations and the sentences in different languages are generated simultaneously. However, building such a joint model is non-trivial. Typically, sentences from different languages exhibit very different syntactic structures and word orderings. It is also non-trivial to design efficient dynamic programming algorithms for this case where multiple languages are involved in the joint generative process. Furthermore, the difficulty of building such a joint generative model becomes higher as the number of input languages increases.

Previous research efforts show that it can be beneficial to learn individual models independently, and then combine the learned models only during the inference stage (Punyakanok et al., 2005; Chang et al., 2012). Motivated by this, we take the approach that learns a separate semantic parser for each different language first. Next, we combine these semantic parsers for different languages into a single multilingual semantic parser only during the inference stage.

One common approach for combining different outputs from different systems is to perform *majority voting* based on optimal predictions from each parser. We first obtain the best output semantic representation from each individual semantic parser, and then count the number of occurrences for each possible output. The most frequent output semantic representation is returned as the final output of our system. Naturally, this approach is only applicable when there are at least three systems/models.

An alternative approach is to allow each system to produce a ranked list of k most probable outputs, each is associated with a score. Our system then aggregates these ranked lists to select the best output. This problem is known as *rank aggregation* and has been extensively studied in fields such as data mining and information retrieval (Dwork et al., 2001; Gleich and Lim, 2011; Li, 2011). For our task, we first let each semantic parser (for each language) generate a ranked list of the top-k most probable outputs (hybrid trees) for the given input. Next, based these hybrid trees we find a ranked list of most probable semantic representations. Each such semantic representation is also associated with a score, which is the log-likelihood of the hybrid tree, i.e., $\log P(\mathbf{n}, \mathbf{m}, \mathbf{h})$. Note that for each semantic representation, we only consider the score associated with the most probable hybrid tree that contains such a semantic representation. We use the standard approach for combining two ranked lists with scores. Consider a ranked list from the j-th model/system that consists of n distinct items. Let's use $s_i^{(j)}$ to denote the original score associated with the i-th semantic representation in the j-th ranked list. We normalize the score $s_i^{(j)}$ in the following way to obtain the new score $\tilde{s}_i^{(j)}$ (normalized score, divided by the standard deviation associated with the sample):

$$\tilde{s}_i^{(j)} = \frac{s_i^{(j)}}{n\mu^{(j)}\delta^{(j)}} \quad \text{where} \quad \mu^{(j)} = \frac{1}{n}\sum_{k=1}^{n} s_k^{(j)}, \quad \delta^{(j)} = \sqrt{\frac{1}{n-1}\sum_{k=1}^{n}(s_k^{(j)} - \mu^{(j)})^2}$$

Such new scores will then be used for aggregating the results to form a new ranked list. How do we find the best output from multiple lists? Two useful sources of information that we may use include: 1) the number of times each output appears in these lists; 2) the combined score $\sum_j \tilde{s}^{(j)}$ for each output s. We believe the more frequent an output appears in these lists (i.e., more systems/models predict such an output in their top-k lists), the more likely it can be a good candidate. Therefore we first find the set of most frequent outputs, next from such a set we select the output with the highest overall score $\sum_j \tilde{s}^{(j)}$ as the final output of our system.

4 Experiments

4.1 Data and Setup

We conducted our experiments on the multilingual GEOQUERY dataset released by Jones et al. (2012b). This dataset consists of 880 instances of natural language queries related to US geography facts. Each query is coupled with its corresponding semantic representation originally written in Prolog. The original GEOQUERY dataset (Wong and Mooney, 2006; Kate and Mooney, 2006) contains natural language queries in English only. Additional Chinese annotations were provided by Lu and Ng (2011) when performing a natural language generation task. Jones et al. (2012b) further provided the following three additional language annotations to this dataset: German, Greek and Thai. Thus, this dataset is now fully annotated with five different languages, two of which (Chinese, Thai) are Sino-Tibetan languages, and the rest are all Indo-European languages.

Following previous works on semantic parsing (Kwiatkowski et al., 2010; Jones et al., 2012b), we split the dataset into two portions. The training set consists of 600 instances, and we report evaluation results on the portion consisting of the remaining 280 instances. We used the identical split provided by Jones et al. (2012b) for all the experiments. Following previous works, we used the standard approach for

Table 2: Semantic parsing results when two different input languages are considered (for example, the column ENDE gives the results when each input to our system consists of a pair of semantically equivalent sentences written in English and German.). Scores are accuracy percentages.

evaluation on the multilingual GEOQUERY dataset. Specifically, we first let our semantic parsers produce semantic representations from multilingual input sentences. The resulting semantic representations are then converted into Prolog queries in a deterministic manner, which can be used to interact with the underlying knowledge base to retrieve answers. A predicted semantic representation is considered correct if and only if it retrieves identical results as the correct reference semantic representation when both are used for retrieving answers from the underlying database.

4.2 Results and Discussions

We performed experiments on the conventional monolingual semantic parsing task first. We report accuracy scores, which are defined as the number of correctly parsed inputs (i.e., the total number of correct semantic representations) divided by the total number of input sentences. Baseline results for unigram, bigram, and mixgram models, which are originally introduced in Lu et al. (2008) are reported under "Unigram", "Bigram", and "Mixgram" respectively in Table 1. The results for backward bigram models are reported under "Bigram(inv)".

To assess the effectiveness of our methods for combining different outputs, we first conducted experiments on voting over the outputs from the three models originally introduced in the work of Lu et al. (2008) (Voting(u,b,m)). Next we performed voting over outputs from unigram model, bigram model, as well as the backward bigram model introduced in this paper (Voting(u,b,bi)). These voting-based approaches yielded better results over the first voting-based approach. Specifically, we compared this new voting-based approach against the previous best model reported in Lu et al. (2008) – mixgram model, which was also based on a combination of unigram and bigram models. We used the paired t-test to assess the significance of the overall improvements across different languages when using our new method. When comparing the approach "Voting(u,b,m)" over "Mixgram", we obtained a one-tailed p-value of 0.40. When comparing the approach "Voting(u,b,bi)" over "Mixgram", we obtained a one-tailed p-value of 0.11. We also investigated the effectiveness of the aggregation-based approach. This approach is based on aggregating the two top-100 lists generated by unigram, bigram and backward bigram models. When comparing this approach over "Mixgram", we obtained a one-tailed p-value of

	EnDe El	EnDe Th	EnDe Cn	EnEl Th	EnEl Cn	EnTh Cn	DeEl Th	DeEl Cn	DeTh Cn	ElTh Cn

Voting (u,b)	87.5	86.1	86.4	89.6	**86.4**	89.3
Voting (u,b,bi)	**88.6**	86.8	**87.1**	**90.0**	85.7	**89.6**
Aggregation	87.1	**87.1**	86.1	88.9	86.1	88.6

Table 4: Semantic parsing results when four or five different input languages are considered (for example, the column EnDeElTh gives the results when each input to our system consists of four semantically equivalent sentences, which are written in English, German, Greek, and Thai respectively.). Scores are accuracy percentages.

0.29 under the paired t-test. These results indicate that the approach based on voting over the unigram, bigram and backward bigram models gives the most promising results for monolingual semantic parsing, demonstrating the usefulness of our proposed backward bigram model.

Next we move to the multilingual setting where we would like to simultaneously process more than two languages. Specifically, we considered multilingual semantic parsing where there are two, three, four and five input languages. Table 2, Table 3, and Table 4 summarize these results. Table 2 shows the results for bilingual semantic parsing where we have two different input languages. The results reported under "Unigram" are based on the aggregation approach over unigram models. Similarly for "Bigram", "Bigram(inv)", and "Mixgram" (we also tried the voting-based approach for combining such baseline systems, which yielded slightly worse results). From this table we can see that generally speaking by considering two different languages as the input, our system is able to do better semantic parsing. We compared the voting-based approaches against the baseline approaches. For the approach "Voting(u,b)" (we excluded mixgram models in voting since now we have four models, two from each language, which are sufficient for voting, and preliminary results show that the inclusion of the mixgram models is not helpful), it does not outperform the bigram baseline approach (which is the most competitive amongst all baseline approaches) significantly ($p = 0.19$). When comparing the aggregation approach against the bigram baseline approach, we obtain $p = 0.04$. In contrast, the approach "Voting(u,b,bi)" outperforms all the baseline systems significantly ($p < 0.005$). These results again demonstrate the effectiveness of our newly proposed backward bigram model.

We can see from the results presented in Table 3 and Table 4 that, in general, the performance of the multilingual semantic parser tends to improve as the number of input languages increases. However this is not always the case. For example, consider the final system where we use all five languages as the input (refer to the results in the column of EnDeElThCn in Table 4); interestingly, when we remove German (De) from the inputs, we are able to build a better system in terms of accuracy (refer to the results in the column of EnElThCn). We believe this is partly due to the fact that the monolingual semantic parsing

task with German as the input language (see DE in Table 1) is relatively more challenging. Nevertheless, when all the languages are considered, the overall system is able to obtain an accuracy of 89.6% with the voting-based approach where our proposed backward bigram model is incorporated. This is significantly higher than any other monolingual system's performance reported in the literature. According to Jones et al. (2012b), the results of state-of-the-art monolingual semantic parsing systems on four of these five languages considered here are: 82.1%(EN), 75.0%(DE), 75.4%(EL), and 78.2%(TH). Note that to date, no single system reported in the literature can dominate all other systems across all these languages on this dataset in terms of accuracy performance. We hypothesize that this is because semantic information conveyed by the sentences from a single language tends to be highly ambiguous, and various linguistic phenomenons can be difficult to capture under a monolingual setting for any existing monolingual semantic parsing system. The multilingual semantic parsing system introduced in this work, in contrast, can exploit richer information from multiple languages to successfully disambiguate the semantics associated with the inputs for improved semantic parsing.

5 Conclusions

In this work, we focused on *multilingual semantic parsing*, the task of simultaneously parsing sentences from various different languages into their corresponding formal semantic representations. Our work is built on top of the *hybrid tree* framework where different generative process can be developed for jointly modelling the generation of both language and semantics. We first introduced a variant of the generative process, leading to a new semantic parsing model. Next we presented methods for combining and aggregating outputs from different models within the framework to build our multilingual semantic parsing system. Our results demonstrate the effectiveness of our approaches for such a task. To the best of our knowledge, this is the first work that tackles such a multilingual semantic parsing task which simultaneously parses sentences from multiple languages into formal semantic representations. Future work include explorations on applications of our system in areas such as multilingual semantic processing, cross-lingual semantic processing, and semantics-based machine translations (Jones et al., 2012a).

Unsupervised Word Sense Induction using Distributional Statistics

Abstract

Word sense induction is an unsupervised task to find and characterize different senses of polysemous words. This work investigates two unsupervised approaches that focus on using distributional word statistics to cluster the contextual information of the target words using two different algorithms involving latent dirichlet allocation and spectral clustering. Using a large corpus for achieving this task, we quantitatively analyze our clusters on the Semeval-2010 dataset and also perform a qualitative analysis of our induced senses. Our results indicate that our methods successfully characterized the senses of the target words and were also able to find unconventional senses for those words.

1 Introduction

Word Sense Induction (WSI) involves automatically determining the number of senses of a given word or a phrase and identifying the features which differentiate those senses. This task, although similar to the Word Sense Disambiguation (WSD) task, is fundamentally different because it does not involve any supervision or explicit human knowledge about senses of words. WSI has potential to be extremely useful in downstream applications because, apart from the savings on annotation costs, it also mitigates several theoretical conflicts associated with supervised WSD tasks, which generally involve deciding on the granularity of senses. Ideally, a WSI algorithm would be able to adapt to different tasks requiring different sense granularities. WSI algorithms can also be used to model the evolution of the senses of a word with time and hence can be much easier to maintain than existing fixed sense inventories like WordNet(Miller, 1995), Ontonotes(Hovy et al., 2006) etc. Automatic sense identification systems also have the potential to generalize well to large amounts of diverse data and hence be useful in various difficult domain independent tasks such as machine translation and information retrieval.

Several factors make the problem of word sense induction very challenging. Most importantly, it is not clear what should be the 'true' senses of a word. The semantic continuum makes it always possible to break a sense into finer grained subsenses. Thus, the problem is one of finding the optimal granularity for any given task. Even in a semi-supervised setting, it is unknown which sense inventories are most suited as starting points in a sense bootstrapping procedure.

Our unsupervised approach relies heavily on the distributional statistics of words which occur in the proximity of the target words. Hence, we first obtain the distributional statistics from a very large corpus to facilitate generalization and reliable estimation of different possible senses. Then we use these statistics in a novel manner to obtain a representation for the senses of the target word. In this paper, we discus the performance of induced senses on the Semeval 2010 WSD/WSI(Manandhar et al., 2010) task.

2 Related Work

Much of the work on word sense induction has been quite recent following the Semeval tasks on WSI in 2007(Agirre and Soroa, 2007) and 2010, but the task was recognized much earlier and various semi-supervised and unsupervised efforts were directed towards the problem.Yarowsky (1995) proposed a

Proceedings of COLING 2014, the 25th International Conference on Computational Linguistics: Technical Papers, pages 1302–1310, Dublin, Ireland, August 23-29 2014.

semi-supervised approach, which required humans to specify seed words for every ambiguous word and assumed one sense per discourse for an ambiguous word. The unsupervised approaches mainly focus on clustering the instances of the target words in a corpus, using first-order vectors, second-order vectors (Purandare and Pedersen, 2004)(Schütze, 1998) etc. Pantel and Lin (2002) used various syntactic and surface features for clustering the various occurences of a target word. Co-occurence graph-based approaches(Véronis, 2004) have also been used, which represent the words co-occuring with the target words as nodes and then identify the highly dense subgraphs or 'hubs' within this co-occurence graph. Brody and Lapata (2009) and Lau et al. (2012) proposed bayesian WSI systems which cluster the instances by applying Latent Dirichlet Allocation (LDA)(Blei et al., 2003), Hierarchical Dirichlet Processes (HDP)(Teh et al., 2006) etc. wherein each occurence of a target word is represented as a 'document' and its surrounding context as the 'observable content'. Choe and Charniak (2013) propose a 'naive bayes' model for WSI which assumes one sense per discourse and uses Expectation Maximization(EM) to estimate model parameters like the probability of generating an instance feature like a word in the context, given the sense of the target word in a particular instance. Reisinger and Mooney (2010) and Huang et al. (2012) have proposed sense dependent multiple prototypes for a word instead of the conventional one vector representation per word and have shown that this sense differentiation improves semantic similarity measurements between words.

3 Basic Motivation: Co-occurence graphs

Conventionally, each word is represented as a co-occurence vector which may contain frequency, point wise mutual information or some lower dimensional representation of context and this representation conflates all the senses of a word. These vectors can be viewed as a graph where words are nodes which have an edge between them if a word occurs in the distributional vector of another. Given a target ambiguous word w, we refer to those words as the 'first order' words(referred to by 'neighbors') which are directly connected to w. The 'second order' words are the words directly connected to the first order words and so on. This graph is cyclic and each node might have multiple senses conflated into it. In this work, we only consider the first and second order words, eg. a target word like 'bank' will have words like 'river' ,'money' etc in it's first order and the second order vectors will be the words from the context of the first order words like 'river':'flood','plains' etc, 'money': 'currency', 'economy' etc. Essentially, these second order words characterize the first order words and hence are very informative for clustering the first order words into different senses. Essentially, we use the second order words as features of the first order words and use them to cluster the first order words into different senses.It must be noted that the first order words themselves might have multiple senses and ideally, those words should also be disambiguated but in the current work we only focus on disambiguating the 'target' words.

4 Methodology

For clustering the neighbors of the target words, we implement and compare two methods which differ significantly in their technical details and employ distribtutional statistics of the neighbors differently, which we describe in the sections below. For obtaining the distributional statistics on a large scale, we used the 5-gram data of Google N-gram corpus(Michel et al., 2011) which effectively lets us use as 10 word window. No lemmatization or case normalization was performed because the large corpus size ameliorated the problem of sparseness. Only nouns, verbs, adjectives and adverbs were employed for the statistical estimation because our pilot studies suggested that these words were most informative.

4.1 Latent Dirichlet Allocation

LDA(Blei et al., 2003) is a well known bayesian generative topic model which models every 'document' as a mixture of latent 'topics' and all its 'words' as multinomial draws from those latent topics. In topic model parlance, a 'corpus' consists of various 'documents'. Each 'document' has a collection of tokens which is treated like a bag of words, where each word is drawn from a latent 'topic'. The topics are shared across documents thus giving each document a topic proportion based upon the topic assignment of the tokens in a document. The priors on topic proportions and the topic multimonial paramers are

dirichlet parameters. An important characteristic of LDA is its clustering property which makes the model inclined to enforce sparseness with small dirichlet priors.
It is important to note that we employ LDA in a significantly different manner than the previous approaches which have used LDA or other related topic models for word sense induction. Other topic modelling based approaches for WSI represent each instance of the target word as a 'document' and the immediate context as the 'bag of words' for that 'document'. Unlike these approaches, we represented a target ambiguous word as the 'corpus' in the topic modelling parlance. Then we found out all the 'first order' words co-occuring with the target word within a 10 word window. Each 'first order' word/type is considered a 'document' in our LDA based approach. The latent 'topics' for each 'document' are the latent 'senses' and each first order type comprises of a 'sense distribution' which is indicative of its tendency to induce a particular sense in the target word. The 'second order' types are all the words occuring in a 10 word window of every 'first order' word. These types along with their frequency, form the 'bag of words' for the 'first order' type(LDA document). Hence, in our model, the latent senses are shared across all the first order neighbors of the target word and the second order tokens play the role of 'words' in our LDA based model. After getting the sense distributions for each first order type, we perform k-means over all the sense distribution vectors such that every first order neighbor gets assigned a cluster.
We posit that the distributional statistics of a large corpus helps in improving the coverage of second or-

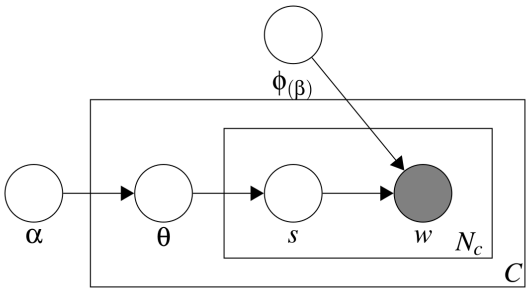

Figure 1: Figure1: s is the latent sense variable. θ is the sense distribution of a first order neighbor. w is a second order neighbor of a first order word. ϕ is the sense multinomial with a dirichlet prior β. α is a dirichlet prior on the sense proportion of a first order type.

der words which are essential for reliable clustering of the first order words. However, the large number of occurences and a large vocabulary make it intractable to run LDA using the original frequency of the second order words. To overcome this computational hurdle, we posit that with a diverse representation of the second order words, LDA based parameter estimation relies more upon the relative distribution of the these words across all the first order words rather than their actual distributions. Hence, we decided to scale down the actual counts for each word so that we could run LDA with the finite resources available. An important parameter in this model is the number of latent topics/senses to use, which is specified to be the actual number of senses specified in the Ontonotes sense inventory. This is an idealized case in which the number of senses are known. The α hyperparameter is chosen to be small with respect to the average 'document lengths' we encounter. This has the effect of pushing most of the probabilistic weight to one topics instead of diluting it among many topics. We also decided to analyze the effect of part of speech tags of the second order words in clustering the first order words. The various configurations we experimented with were:

- All: Considered nouns,verbs,adjectives and adverbs in second order bag of words.
- Nouns: Only considered second order words which were nouns to study the effect of Nouns on clustering.
- Verbs: Only considered second order words which were verbs.

- Nadj: Considered both nouns and adjectives to study the effect of Noun phrases over clustering.

- Vadv: Considered both verbs and adjectives for second order bag of words.

4.2 Spectral Clustering

Spectral Clustering(Ng et al., 2002) is a clustering technique which uses a pairwise similarity matrix, L, to find out clusters such that the seperation between the entities in two seperate clusters is maximum while implicitly taking into account the distances between groups of points instead of considering them individually. The aim is to find the eigenvectors of $D^{-1}L$ corresponding to smallest eigenvalues to minimize the similarity across two clusters. Here D is a diagonal matrix with degree of node i on entry D_{ii}. For k clusters, k eigenvectors ordered by their eigenvalues are found out. These k eigenvectors are used to form a $n \times k$ matrix where n is the number of datapoints. Each row of this matrix is considered a datapoint with a vector of length k, thus effectively reducing the dimension of the datapoints to k most prominent dimensions according to the similarity matrix decomposition. Finally, k-means is performed on the n vectors to assign a cluster to each datapoint.
We cluster the first order neighbors for each target word using spectral clustering. The crux of this algorithm lies in using appropriate pairwise distance matrices. For constructing the pairwise distance matrices of first order types, we used two vectorial representations of the first order words:

- **Senna embeddings**: The word embeddings trained by a neural network by (Weston et al., 2012)

- **Distributional vectors** comprised of the frequencies of the second order words.

Then we used these vectors to calculate mutual pairwise distance matrices(we experimented with Euclidean and Cosine distances), which were converted into similarity matrices by using Gaussian kernels. These matrices were used as input to the spectral clustering algorithm.
We chose to ignore very low frequency words for making word vectors. This cutoff was decided by analyzing the distributional frequency vs. rank curves of the words, which were heavy tailed. Again, we use the same number of clusters as the number of senses in Ontonotes sense inventory, so that we can study the correspondence between our clusters and the Ontonotes senses.

5 Quantitative Analysis

In this paper, we discus our systems' performances on the Semeval-2010 word sense induction/disambiguation dataset, which contains 100 target words: 50 nouns and 50 verbs. The test data is a part of OntoNotes (Hovy et al., 2006) and contains around 9000 instances of usage of the target words. For annotating a particular test instance, we first filtered the surrounding context to retain only salient Nouns, Verbs, Adverbs, and Adjectives. We report a mixture of senses for each instance, where the weight for each sense was proportional to the number of filtered surrounding words belonging to that sense/cluster. As mentioned earlier, we experimented with a variety of settings for spectral clustering and LDA based methods. The performance with different settings was generally similar and hence, we report our best results here. For a better insight into how our models in different settings performed, we also report the full tables for paired F-score. The performance trend of various systems is similar for other measures. We compare our results to three baselines:

- Most Frequent Sense (MFS) baseline: assigns all the test instances to the most frequent sense of the target word.

- Brown University's system results (Choe and Charniak, 2013).

- Lau (LDA) (Lau et al., 2012), who provide only the results for one of the three measures. In particular, we compare our system to their results obtained by a model that was based on LDA and used the gold standard number of senses as the number of topics to be used.

System	V-measure			Paired F-score			Supervised F-score			#cl
	all	nouns	verbs	all	nouns	verbs	all	nouns	verbs	
LDA	4.4	5.2	3.2	60.7	53.2	71.7	60.9	55.2	69.2	2.45
Spectral	4.5	4.6	4.2	61.5	54.5	71.6	60.7	55.1	68.8	1.87
MFS	0.0	0.0	0.0	63.5	57.0	72.7	58.7	53.2	66.6	1.00
Brown	18.0	23.7	9.9	52.9	52.5	53.5	65.4	62.6	69.5	3.42
Lau	-	-	-	-	-	-	64.0	60.0	69.0	-

Table 1: Performance on Paired F-score and supervised F-score. LDA and Spectral are the two methods proposed in this paper. Lau is the baseline in which LDA system of (Lau et al., 2012) is considered. It should be noted that in their paper, (Lau et al., 2012) did not report their performance on Paired F-score.

The Semeval-2010 task provides us with 3 evaluation metrics: V-measure, Paired F-score and Supervised F-score. It was noticed (Manandhar and Klapaftis, 2009) that V-measure tends to favour systems that produce a higher number of clusters than the gold standard and hence is not a reliable estimate of the performance of WSI systems. But, we report our results on V-measure too as it gives useful insight about the nature of data and the WSI algorithms.
It is important to note that all the measures treat Ontonotes sense annotations as the gold standard, which makes this task unfit for our evaluation purposes. As mentioned earlier, our argument is that several decisions related to the granularity of senses and definition of senses are a topic of dispute, and hence we believe that instead of relying upon a pre-annotated sense inventory, it should be more effective to induce senses automatically in an unsupervised manner using a large and unbiased corpus, and tune the granularity governing parameters for different downstream tasks which require sense disambiguation. But our performance on these annotations still provides us with valuable information about the agreement between Ontonotes senses and our systems' senses. In our experiments, we have not tried to tune the hyperparameters or perform agglomerative clustering to better fit our clusters to the gold standard clusters by using training/development set at all, because we wanted to analyze the performance of our algorithms in the most general setting.

5.1 V-Measure

The V-measure defines the quality of a cluster to be the harmonic mean of homogeneity and coverage. These can be viewed as precision and recall of the element-wise assignment to clusters, where homogeneity measures the 'pureness' of the clusters and coverage measures the 'cohesiveness'. It was noticed (Manandhar and Klapaftis, 2009) that V-measure tends to favour systems producing a higher number of clusters than the gold standard and hence is not a reliable estimate of the performance of WSI systems. In addition, the number of induced clusters in our systems is bounded at the top by the Gold Standard number of senses because of our choice of hyperparameters in both spectral clustering and LDA based approaches.

From the results, we realized that the number of senses induced in the test set by our system is quite low compared to the baselines and other systems that participated in Semeval-2010. This hurts our V-measure. Our systems perform better on nouns than verbs generally according to this measure. Also, LDA-based approaches with the number of topics equal to the number of gold-standard senses perform the best. For spectral clustering, euclidean distances seem to perform better.

5.2 Paired F-score

The paired F-score is the harmonic mean of precision and recall on the task of classifying whether the instances in a pair belong to the same cluster or not. This measure also penalizes the systems if the number of induced senses is not equal to the number of senses in the gold standard. It must be noted that in our approach, the induced number of senses on the test dataset is not equal to the original number of senses although we clustered with the number of clusters specified by Ontonotes, because our clusters are different from Ontonotes senses. MFS has a recall of 100% which makes it a very hard baseline to

P F-score(%)	all	nouns	verbs	#cl

Brown	52.9	52.5	53.5	3.42

Table 2: General trend for the various settings: Paired F-Score Evaluation: Spectral Clustering: 'C':cosine distance, 'E': Euclidean Distance, 'D': Second order Distributinal counts, 'S':Senna embeddings and the adjacent numbers are the number of nearest neighbors(in 1000s) considered for the distance matrix.

P F-score(%)	all	nouns	verbs	#cl
all	60.7	53.2	71.7	2.47
noun	59.6	52.1	70.7	2.32
verb	60.0	52.4	71.0	2.25
nadj	59.7	52.6	70.1	2.3
vadv	59.3	52.27	69.6	2.25
MFS	63.5	57.0	72.7	1.00
Brown	52.9	52.5	53.5	3.42

Table 3: General trend for the various settings: Paired F-Score Evaluation: LDA: 'all': All POS tags considered in the first order neighborhood, 'noun': Only nouns considere, 'verbs': Only verbs considered, 'nadj': nouns and adjectives considered, 'vadv':verbs and adverbs considered

beat. Semeval-2010 results show that none of the systems outperform the MFS baseline. Both of our systems perform better than other systems on this measure and are comparable to the performance of the MFS baseline.

5.3 Supervised F-score

For the supervised task, the test data is split into two parts: one for mapping the system senses to the gold standard senses, and the other for evaluation based upon the mapped senses. We report our performance on the 80% mapping and 20% evaluation split. The mapping is done automatically by the program provided by the organizers which is based upon representing the gold standard clusters as a mixture of the system senses.

Our different systems perform similarly on the supervised evaluation. We outperform the tough MFS baseline and perform competitively against other systems. We observe that other systems outperform us on the target nouns whereas our performance on verbs is similar to that of other systems. This can be attributed to the fact that our methods induce a small number of senses in general over the test set but according to the test data based upon Ontonotes, the senses of nouns have a much higher resolution than verbs.

5.4 Discussion on Quantitative Results

In general, we found our performance to be competetive with the other systems. Also, we perform significantly better than other Semeval-2010 systems on the paired F-score metric. In our experiments,

Sense	Cluster Words
1	Engineers,Presbyterian,Service,Jewish,Police,Ethnicity,Independent,Movements
2	membrane,complicated,surgical,hypothalamic,potassium,lymphatic,electron,tumor
3	Cynthia,Armstrong,Tracy,Marilyn,Stella,Abbot,Gustavus,Clark,Stewart,Monica
4	heels,noses,haze,hand,drooping,galloped,nakedness,pallid,anguish,palms
5	night,burdens,gut,assassins,witness,results,celestial,visual,deep,Hell
6	lifted,hastily,hovering,guiding,sinner,tendency,developing,sacrificed,condemned

Table 4: Example words in the clusters of 'body.n'

we found that for spectral clustering, Euclidean distances tend to perform better than Cosine distances. Also, the distributional counts of the second order words tend to perform better than Senna vectors which is not surprising because the Senna vectors are trained with the philosophy of a language model, which results in words often being clustered according to their POS tags rather than their semantic closeness. Spectral methods, yield slightly better results on two metrics than LDA based clustering which suggests that similarity matrices give us a better idea about interactions between groups of words than simple occurence frequencies of the words. But a bigger advantage of spectral clustering techniques is the speed of computing SVD which is much better than that of slow inference algorithms of LDA based models.

For LDA based models, we also note that different settings focusing on different POS tags, performed very similarly and did not indicate any strong preference for any POS tag for the task of WSI using LDA. Finally, both our methods tend to induce a small number of senses in the test data, which suggests that the induced senses are relatively coarse-grained. Further splitting of coarse clusters using hierarchical clustering methods might be helpful if a task requires finer-grained senses.

6 Qualitative Analysis

In this section, we present some deductions drawn from the qualitative analysis of clusters generated by our methods which support our hypothesis. In particular, we discus the nature of clusters generated by the spectral clustering algorithm using the second order distributional vectors for obtaining the similarity matrix based on Euclidean distance.

A preliminary analysis of cluster sizes revealed that in almost all the cases, one of the clusters was very large(about 3 times larger than the second largest cluster) and this largest cluster seemed to conflate a lot of senses. Other clusters were generally similar sized and most of them represented a sense of the target word on their own. The results in general look very promising and many clusters can be easily interpreted as different senses of the target word.

In Table 4, we show the top few words for the word 'body.n'. Some senses very clearly represent themselves : 1. Body as in organization, 2. Biological terms related to body, 4. Body in a more informal sense. Sense 5 seems like a mixture of two senses of body, one related to celestial bodies and other related to dead bodies/murder. Interestingly, sense 3 comprises proper nouns i.e. people whose bodies have been mentioned in the corpus. This is not a conventional sense listed in any of the sense inventories but based upon the requirements of a task, one might be interested in differentiating between general mentions of 'bodies' and mentions of 'bodies' which appear when mentioning famous people or celebrities. This sort of clustering can be incredibly useful in tasks like Machine Translation and Information Retreival which require us to model semantics of rare words such as important proper nouns.

7 Discussion and Future Work

We used a large corpus and its distributional statistics to perform word sense induction for a set of 100 target words. We proposed two algorithms which cluster the salient words surrounding the target word by using the distributions of surrounding words. Both LDA based algorithm and the spectral clustering algorithm yielded similar clusters. We believe that these clusters can be employed in downstream tasks and can be further broken into smaller fine grained clusters automatically if needed by the application.

We also evaluated our clusters arising from the distributional statistics, in the Semeval-2010 tasks without any tuning and showed that they perform competetively with other approaches.
We argue that treating existing sense inventories as gold standards for WSI tasks is not an appropriate measure for WSI systems because these inventories would not be able to measure two very important characteristics of WSI systems which make them more advantageous than supervised WSD systems:a) coverage and b) discovery of new senses.
Hence, the Semeval-2010 experiments are not an accurate reflection of the capabilities of WSI systems because they rely on the Ontonotes sense inventory for the Gold Standard judgements, which are admitted even by the OntoNotes builders to be only 85% reliable on average (Hovy et al., 2006). Our competetive performance on these tasks show that our methods can be compliant with standard word sense disambiguation tasks but more importantly, our qualitative analysis showed that our techniques can discover new unconventional senses too, which might not be present in the sense inventories but could be very useful in tasks requiring differentiations. Unfortunately, no metrics exist that can help us quantify the coverage of senses and their novelty. An ideal metric to evaluate the WSI systems in a better manner, would be their performance on extrinsic tasks like Machine Translation, Information Retreival, Machine Reading etc., which require differentiation of senses at different granular levels. WSI techniques have a potential of eliminating sense annotation costs hence enabling wider use of sense differentiation in a more generalized setting.
Our techniques resulted in coarse-grained senses. A major challenge in this task is to determine the appropriate number of senses to induce. To overcome this problem, non-parametric methods could be conceived to identify the ideal number of clusters automatically. In future, the WSI systems like ours can also be used to analyze the evolution of senses over a period of time or geographical variation of senses. As mentioned earlier, the co-occurence graph consists of many canonical representation of words which must be split according to their different senses. In our experiments, we considered a small number of target words and did not take into account the multiplicity of senses in the representation of 'first' and 'second' order neighbors. A more sophisticated iterative approach involving making several passes over a co-occurence graph and refining senses of different words in each pass can ameliorate the problem associated with a single canonical representation of neighboring words. Finally, designing extrinsic tasks to measure the efficacy of WSI systems will be extremely helpful in development of more robust and useful WSI systems.

Abstract

In this paper, we study the task of product record linkage across multiple e-commerce websites. We solve this task via a semi-supervised approach and adopt the self-training algorithm for learning with little labeled data. In previous self-training algorithms, the learner tries to convert the most confidently predicted unlabeled examples of each class into labeled training examples. However, they evaluate the confidence of an instance only based on the individual evidence from the instance. The correlation among data instances is rarely considered.

To address it, we develop a novel variant of the self-training algorithm by leveraging the data characteristics for the task of product record linkage. We joint consider a candidate linked pair and its corresponding correlated pairs as a group at the selection of pseudo labeled data. We propose a novel confidence evaluation method for a group of instances, and incorporate it as a re-ranking step in the self-training algorithm. We evaluate the novel self-training algorithm on two large datasets constructed based on real e-commerce Websites. We adopt several competitive methods as comparisons and perform extensive experiments. The results show that our method outperforms these baselines that do not consider data correlation.

1 Introduction

Recent years have witnessed the rapid development of online e-commerce business, e.g. Amazon and eBay, which raises the need for better storing, organizing and analyzing the large amount of product records. An important task is how to effectively link product records across multiple databases or websites. This task serves as a fundamental step for many applications. For example, it will be useful to provide entity-oriented search and product comparison analysis in eBay, where record linkage can help to unify the corresponding records (i.e. records from different sellers) given a product. Record linkage has been shown to be important in many fields, including biology (Needleman and Wunsch, 1970), database (Neiling, 2006) and text mining (Goiser and Christen, 2006; Bilenko and Mooney, 2003). In this paper, we mainly focus on the task of product record linkage for online e-commerce websites, but our method is easy to be extended to other data sources and tasks.

Early studies on record linkage were mainly based on the classical probabilistic approach developed by Fellegi and Sunter (1969), furthermore it was improved by the application of the expectation-maximization (EM) algorithm (Winkler, 1988) and the use of approximate string comparison algorithms (Christen, 2006; Winkler, 2006). The early work was not flexible to incorporate rich information. The development of machine learning techniques in the late $1990s$ provides a new approach for record linkage, and it has become the mainstream methodology for this task. The task of record linkage is usually re-casted as the record pair classification problem, i.e. whether a record pair refers to the same entity or not (Elfeky et al., 2002; Neiling, 2006; Tejada et al., 2002; Nahm et al., 2002). Supervised methods can also be used to learn distance measures for approximate string comparisons (Bilenko and Mooney, 2003;

Proceedings of COLING 2014, the 25th International Conference on Computational Linguistics: Technical Papers, pages 1311–1321, Dublin, Ireland, August 23-29 2014.

Cohen et al., 2003). Although supervised techniques often achieve good linkage quality, they are largely limited by the availability of the training data.

To address this problem, semi-supervised learning approaches aim to make good use of a small portion of labeled and a large amount of unlabeled data to build a better classifier (Yarowsky, 1995). Self-training is a commonly used algorithm for semi-supervised learning, where in each iteration the learner converts the most confidently predicted unlabeled examples of each class into labeled training examples. It has been successfully applied to many tasks, such as sentiment analysis (He and Zhou, 2011; Riloff et al., 2003) and object detection from images (Rosenberg et al., 2005).

In this paper, we solve the task of product record linkage via a semi-supervised approach and adopt the flexible self-training framework for learning with little labeled data. We propose a novel variant of the self-training algorithm by incorporating the correlation existing in the data instances, which is rarely studied in previous studies. To introduce our idea, we first present an illustrative example in Figure 1. There are two databases $\mathcal{D}$ and $\mathcal{D}'$, and we have three records $r_1, r_2, r_3 \in \mathcal{D}$ and another three records $r'_1, r'_2, r'_3 \in \mathcal{D}'$. Furthermore, we assume r_1 and r'_1 refer to the same product. We can see that r_1 is involved in three candidate pairs, i.e. (r_1, r'_1), (r_1, r'_2) and (r_1, r'_3). Similarly, r'_1 is involved in three candidate pairs, i.e. (r'_1, r_1), (r'_1, r_2) and (r'_1, r_3). Usually, each individual database does not contain duplicate records, once we know r_1 is linked to r'_1, we can infer the rest candidate pairs should not be linked. In other words, only if we are confident that no pair in the set $\{(r_1, r'_2), (r_1, r'_3), (r_2, r'_1), (r_3, r'_1)\}$ is not linked, r_1 is likely to be linked with r'_1.

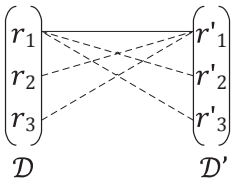

Figure 1: An illustrative example for correlation among record pairs. The real line denotes the real linkage relation and the dash line denotes the candidate linkage relation.

For the task of record linkage, the number of positive instances (i.e. linked record pairs) are usually much less than that of negative instances. We mainly consider the confidence evaluation of the candidate positive instance. By following the above idea, given a *candidate* linked pair, we treat all the correlated record pairs together as a group and evaluate the linkage confidence based on the evidence of all record pairs in this group, i.e. *group confidence evaluation*. We incorporate the group confidence evaluation into the self-training algorithm as a re-ranking step. Interestingly, once we have identified a linked pair, the rest correlated record pairs can be naturally judged as negative instances. We evaluate the novel self-training algorithm on two large datasets constructed based on real e-commerce Websites. We adopt several competitive methods as comparisons and perform extensive experiments. The results show that our method outperforms these baselines that do not consider data correlation.

2 Related Work

We have briefly described the supervised approaches for record linkage in the introduction. Now we discuss other related studies, including unsupervised clustering techniques, genetic programming based approaches and linking based on more complex constraints.

Unsupervised clustering techniques have been investigated both for improved blocking (Cohen and Richman, 2002; McCallum et al., 2000) and for automatic record pair classification (Elfeky et al., 2002). Usually, such techniques do not perform not as well as supervised approaches.

Most recently, genetic programming (GP) (Koza et al., 1999) has also been utilized to the task of record linkage. GenLink (Isele and Bizer, 2012) is a GP-based supervised learning algorithm in order to learn linkage rules from a set of existing reference links, which also suffers from the problem of lack of labeled data. Ngomo and Lyko (2013) evaluated linear and boolean classifiers against classifiers

computed by using genetic programming for the record linkage problem. Their experiments showed that both approaches did not perform well on real data.

Some other studies exploit more complex constraints that include relationships between different entity types to link all types of entities in coordination (Bhattacharya and Getoor, 2007; Dong et al., 2005; On et al., 2007). The usage of such constraints can indeed help to get better linkage results, but is in many cases domain-dependent. We try to develop an approach which can be applicable across domains.

In order to address the problem of limited labeled data, we mainly consider the semi-supervised approaches. There are rarely semi-supervised approaches specially for the record linkage problem. Some studies on improving self-training algorithms are related to our work. Self-training with editing (Li and Zhou, 2005) can help to reduce mislabeled pseudo training examples, and reserved self-training (Guan and Yang, 2013) is designed for handling imbalanced data. We have very different focus with theirs, i.e. incorporating the instance correlations into learning algorithms, which can applied to other self-training variants.

3 Problem Definition

In this section, we first introduce the preliminary related to our task. Then we formally define our studied task.

Product record. A product record r is characterized by a referred product entity e and a set of attribute values $\mathcal{V} = \{(v_i)\}_i$, where v_i denotes the value of the ith attribute in r. We use $r.e$ and $r.\mathcal{V}$ to index the product entity and attribute value set of the record r respectively. A product record corresponds to a unique product entity but a product entity can map to multiple product records across multiple databases. Attribute values are represented as strings, i.e. a sequence of characters. An attribute of a product might correspond to different descriptive text across websites.

Product record linkage. The task of product record linkage is to judge whether two product records refer to the same product entity. Given two product records r and r', we aim to judge whether $r.e$ is the same to $r'.e$. Usually, r and r' come from different product databases. Although different product databases can have different attributes for the same product and different attribute names for the same attribute, we make an assumption about the task: *candidate record pairs share the same set of attributes*. It is relatively easy to automatically identify common attributes and align attributes (Härder et al., 1999; Rundensteiner, 1999; Hassanzadeh et al., 2013), which is not our focus in this paper. We mainly study product record linkage under the same set of attributes, and this assumption makes our study more focused. If r and r' refer to the same product entity, denoted by $r \sim r'$; otherwise, we denote it by $r \not\sim r'$.

4 A General Machine Learning based Approach

Given a product type, as we mentioned above, we assume that it corresponds to a specific set of attributes, and all the product records share the same set of attributes but possibly with different descriptive text for attribute values. In this section, we further present a general supervised approach with similarity features.

4.1 Defining the similarity function

Given two product records r and r', we can obtain the similarity between their descriptive text of an attribute by using a similarity function. The major intuition is that if two records refer to the same product, they should have similar text for the same attribute, i.e. the similarity function should return a large similarity value. Let $f(\cdot, \cdot)$ denote a similarity function, which takes two text strings and returns a similarity value within the interval $[0, 1]$ for these two strings. As revealed in (Bilenko and Mooney, 2003), different attributes or fields may need different similarity functions to achieve best similarity evaluation. Thus, instead of fixing a single similarity function, we consider using the following widely used similarity functions: 1) Exact match; 2) Cosine similarity; 3) Jaccard coefficient; 4) K-Gram similarity (Kondrak, 2005); 5) Levenshtein similarity (Levenshtein, 1966); 6) Affine Gap similarity (Needleman and Wunsch, 1970).

4.2 The learning framework

Based on these similarity functions, we propose a general learning framework for product record linkage by using similarity values of different fields as features.

Given a product type, we assume that there are A attributes and K similarity functions. For two records r and r', we can obtain a similarity feature vector $\mathbf{x} = [x_{a,k}]_{i=1,k=1}^{A,K}$, which is indexed by an attribute and a similarity function: $x_{a,k}$ denotes the similarity of the ath attribute between r and r' by using the kth similarity function. Furthermore, each feature vector $\mathbf{x}$ will correspond to a unique binary label y which indicates that r and r' refer to the same product entity. Given a set of record pairs and their linkage labels $\{(\mathbf{x}, y)\}$, we can learn a classifier which is able to predict the linkage label given the similarity feature vector of two records. To this end, we have reformulated the task of product record linkage as a binary classification problem. Any classifiers can be used for this task. In what follows, we will use *instances* and *candidate pairs* alternatively.

5 Group based Self-Training

In the above, we have presented a supervised learning approach for product record linkage. The approach is easy to apply in practice, however, the performance is largely limited by the availability of training data. For our current task, i.e. product record linkage, the generation of labeled data becomes even much harder: there are usually many product types and it is infeasible to create a large amount of labeled data for each type. Although it is difficult to obtain labeled data, we can easily obtain sufficient unlabeled data. Thus, in this paper, we study the task of product record linkage in a semi-supervised setting by leveraging both the learning ability of the classifiers and the usefulness of the large amount of unlabeled data. We propose a novel group based self-training algorithm for product record linkage. Before introducing our method, we first introduce the general self-training algorithm.

5.1 The general self-training algorithm

Self-training is a semi-supervised learning algorithm. It starts training on labeled data only, after each iteration, the most confidently predicted unlabeled samples would be incorporated as new labeled data, i.e. pseudo labeled data, decided by confidence scores from the classifier. After several iterations, it is expected to get a better classifier trained with both labeled data and pseudo labeled data. The general procedure of self-training algorithm is summarized in Algorithm 1.

Algorithm 1: The general procedure of the self-training algorithm.

```
Input: labeled dataset L, unlabeled dataset U, the classifier C.
U' ← S randomly selected examples from U, S is usually set to 0.5 × |U|;
repeat
    Training the classifier: Use L to train C, and label the examples in U';
    Selecting pseudo labeled data: Select T most confidently classified examples from U' and add them to L;
    Filling unlabeled data: Refill U' with examples from U, to keep U' at a constant size of S examples.
until I iterations or U = ∅;
return The extended labeled dataset L and the trained classifier C.
```

We can see that self-training is a wrapper algorithm by taking a classifier as the learning component, and it has three major steps in an iteration: 1) training classifier; 2) selecting pseudo labeled data; and 3) filling unlabeled data. Among the three steps, the most important step is the pseudo labeled data selection. Previously, the most commonly used method is to select the top confident instances of the classifier, and it is easy to see that the performance of self-training relies on the learning ability of the embedded classifier.

5.2 Group confidence evaluation

Recall that each instance is a pair of product records (r, r') and their label indicates whether they should be linked or not. Let $P^L(r, r')$ denote the confidence that r and r' refer to the same product entity (linked

confidence), and $P^N(r, r')$ denote the confidence that r and r' refer to different product entities (non-linked confidence). $P^L(r, r')$ and $P^N(r, r')$ can be estimated by the confidence scores from the classifier. In the task of product record linkage, there are usually more negative instances, i.e. the number of non-linked pairs is much more than that of linked pairs. Thus, we mainly study the confidence of a candidate positive instance. The standard self-training algorithm selects top ranked positive instances according to the confidence scores estimated by the classifier, i.e. we select the instances with large linked confidence $P^L(\cdot, \cdot)$. However, when applied to product record linkage, it ignores important characteristics underlying the data, which will be potentially helpful to the task.

Let us examine the illustrative example in Figure 1. Recall that r_1 and r'_1 refer to the same product, i.e. $r_1 \sim r'_1$. We can see that r_1 is involved in three candidate pairs, i.e. (r_1, r'_1), (r_1, r'_2) and (r_1, r'_3). Similarly, r'_1 is involved in three candidate pairs, i.e. (r'_1, r_1), (r'_1, r_2) and (r'_1, r_3). We totally have a set of five candidate pairs, i.e. $\{(r_1, r'_1), (r_1, r'_2), (r_1, r'_3), (r_2, r'_1), (r_3, r'_1)\}$. Here we follow the assumption of the one-to-one mapping, i.e. given two databases, a product record can link to at most one record in the other database. By leveraging the correlation among candidate pairs, with $r_1 \sim r'_1$, we can infer the rest four candidate pairs must not be linked, i.e. $r_1 \not\sim r'_2, r_1 \not\sim r'_3, r_2 \not\sim r'_1, r_3 \not\sim r'_1$. Next, we formally characterize the above idea and present the algorithm. Given two databases $\mathcal{D}$ and $\mathcal{D}'$, let $\mathcal{C} \subset \mathcal{D} \times \mathcal{D}'$ denote the candidate pair set where two product records in a pair come from $\mathcal{D}$ and $\mathcal{D}'$ respectively. Consider a candidate pair $(r, r') \in \mathcal{C}$, where $r \in \mathcal{D}, r' \in \mathcal{D}'$. We consider the following two sets: $\mathcal{S}_r = \{(r, b)|(r, b) \in \mathcal{C}, b \in \mathcal{D}' \text{ and } b \neq r'\}$ and $\mathcal{S}_{r'} = \{(a, r')|(a, r') \in \mathcal{C}, a \in \mathcal{D} \text{ and } a \neq r\}$. Intuitively, if we know $r \sim r'$, then all the pairs in both $\mathcal{S}_r$ and $\mathcal{S}_{r'}$ must not be linked. Thus, we define **the conflicting set** of pair (r, r') as $\mathcal{S}_{cfl}^{r,r'} = \mathcal{S}_r \cup \mathcal{S}_{r'}$.

With the definition of the conflicting set, let us reconsider the pseudo labeled data selection. The straightforward way is to evaluate each instance with their linked confidence $P^L()$ from the classifier. However, it oversimplifies the data dependence and does not make use of the correlated characteristics. Consider an instance, which is a record pair (r, r'), we can have the following two properties:

- If $r \sim r'$, then $\forall (a, b) \in \mathcal{S}_{cfl}^{r,r'}$, we have $a \not\sim b$;
- If $\exists (a, b) \in \mathcal{S}_{cfl}^{r,r'}$ and $a \sim b$, then we have $r \not\sim r'$.

The above properties suggest that it should be helpful to consider the correlation among instances when evaluating the confidence of a positive instance, i.e. a candidate linked record pair. Intuitively, if two records refer to the same product entity, they should have large linked confidence and their conflicting pairs should have large non-linked confidence. We propose to use the following method to evaluate the linkage confidence between r and r'

$$\text{Conf}(r, r') = P^L(r, r') \Big(\prod_{(a,b) \in \mathcal{S}_{cfl}^{r,r'}} P^N(a, b) \Big)^{1/M}, \tag{1}$$

where $M = |\mathcal{S}_{cfl}^{r,r'}|$, $P^L(\cdot, \cdot)$ and $P^N(\cdot, \cdot)$ are positive and negative confidence scores estimated by the classifier respectively. Note that we take the geometric mean of the non-linked confidence of these conflicting pairs, which is to reduce the affect of large outlier values and the varying size of the conflict sets. We treat a candidate linked pair and all the candidate pairs in its conflicting set as a group. The group confidence evaluation consists of two intuitions: 1) the confidence that two records should be linked; 2) the confidence that any pair of records in the conflicting set must not be linked. We have taken these two aspects into a unified evaluation score.

5.3 The proposed self-training algorithm

In this part, we present the novel self-training algorithm based on the group confidence evaluation. We have the similar steps with the general self-training algorithm in Algorithm 1. The major focus is to modify the step of *pseudo labeled data selection*. As mentioned above, we mainly consider the confidence evaluation of positive instances. Our method for pseudo labeled data selection is three-step process:

- Select top T' most confidently classified positive examples by the classifier;
- Rerank these T' examples by the group confidence scores defined in Equation 1;
- Select top T examples from the reranked T' examples ($T \leq T'$) as pseudo positive instances and their corresponding conflicting instances in the conflicting sets as pseudo negative instances.

We select positive instances not only based on the instance itself but also their corresponding conflicting instances: if we have high confidence about a positive instance, then the confidence of their conflicting instances being negative should be high, too. Next, we present the detailed group based self-training algorithm in Algorithm 2.

Algorithm 2: The procedure of the group based self-training algorithm.

Input: labeled dataset $\mathcal{L}$, unlabeled dataset $\mathcal{U}$, the classifier $\mathcal{C}$.
$\mathcal{U}' \leftarrow S$ randomly selected examples from $\mathcal{U}$;
repeat
  Training the classifier: Use $\mathcal{L}$ to train $\mathcal{C}$, and label the examples in $\mathcal{U}'$;
  Selecting pseudo labeled data selection:
  - Select T' most confident positive examples from $\mathcal{U}'$ and add them to $\mathcal{L}$;
  - Calculate the group confidence scores for the T' examples according to Equation 1.
  - Rerank these T' examples by their group confidence scores and add top T examples to $\mathcal{L}$ as the pseudo positive instances.
  - For each of the T examples, add their conflicting instances to $\mathcal{L}$ into as the pseudo negative instances.

  Filling unlabeled data: Refill $\mathcal{U}'$ with examples from $\mathcal{U}$, to keep $\mathcal{U}'$ at a constant size of S examples.
until *I iterations or $\mathcal{U} = \emptyset$*;
return *The extended labeled dataset $\mathcal{L}$ and the trained classifier $\mathcal{C}$.*

On one hand, our group based self-training algorithm naturally exploits the correlation among data instances and evaluate the confidence scores in a broader view, which avoids the decision conflicts caused by the data dependence. On the other hand, we focus on evaluating the confidence of being a positive instance, which further reduces the bias from imbalanced data distribution. Thus, it is expected to achieve better performance in the task of product record linkage.

Most classifiers can provide the estimated confidence scores $P^L()$ (i.e. for a positive instance) and $P^N()$ (i.e. for a negative instance): Maximum-Entropy models output the conditional probabilities of an instance for each class (Berger et al., 1996); the Decision Tree C4.5 algorithm is also able to compute the probability distribution over different classes for each instance (Quinlan, 1993).

6 Experiments

6.1 Construction of the test collection

We test our method on two real e-commerce datasets respectively from Jingdong[1] and eTao[2]. Jingdong is the largest B2C e-commerce company and eTao is one of the largest product search portals in China. Due to the extremely large product databases, it is infeasible to generate training data on each product type for these two product databases. We consider two popular kinds of products: laptop and camera. These two kinds of products cover a considerable amount of brands and models, especially suitable for the test of record linkage. Both Jindong and eTao have set up specific categories for these two kinds of products respectively, thus we can easily crawl the product records under the corresponding category label. To generate linked record datasets, we first manually align attributes (i.e. fields) for these two kinds between Jindong and eTao. We summarize the numbers of aligned fields and some example fields in Table 1. Not all the records contain the information for all the fields, we set the value of the empty field to a "*NULL*" string.

[1] http://www.jd.com
[2] http://www.etao.com

We adopt a blocking approach (Baxter et al., 2003) to automatically generate a set of candidate pairs, i.e. a record in Jindong is to be linked with a record in eTao. This approach consider all pairwise links between Jindong records and eTao records for the same kind of product. If there exists at least one common word in the field of *brand* or *model* between a record pair, we consider it to be a candidate pair. The automatic method generates 20,094 candidate pairs and 12,157 candidate pairs respectively for *LAPTOP* and *CAMERA*. Then we invite professional workers from an e-commerce company to link records across these two product databases. Instead of examining all the candidate pairs, the labeling process adopts a product-oriented way to generate the gold standard. Given a product record of a database, the annotator first identifies the product entity that the record refers to, then she looks for the corresponding record in another database. In the annotation process, Web access is available all the time. Annotators can make use of the search engines of Jindong and eTao to accelerate the product lookup. A linked record pair is treated as a positive instance. Finally, we identify 501 linkable products (i.e. 501 positive instances) in LAPTOP dataset, and 478 linkable products (i.e. 478 positive instances) in CAMERA dataset. All the other candidate pairs are automatically labeled as *negative*. We present the the data statistics in Table 1.

Dataset	# positive instances	# negative instances	# fields	Example fields
LAPTOP	501	19593	10	OS, screen size, CPU type, ram size
CAMERA	478	11679	11	lens type, sensor type, focal length, aperture size

Table 1: Basic statistics of datasets.

6.2 Experimental setup

For each kind of product, we divide the dataset into two parts, i.e. a training set and a test set. In order to examine different methods in a semi-supervised setting, we keep a small amount of instances in the training set, and we assume all the methods can use of the data (without labels) in the test set. There are more negative instances, we mainly consider the amount of positive instances, and the number of positive instances is called as *the number of seeds*. We randomly generate the training set with the given number of seeds. Once we add one positive instance into the training set, we add all the its conflicting instances into the training set. This is to reduce the correlation between training instances and testing instances for a fair comparison. In later experiments, given the seed number, we will generate ten random training sets and take the average of ten runs as the final performance. In later experiments, we do not explicitly report the number of negative instances unless needed.

We adopt three widely used evaluation metrics for the classification task: Precision, Recall and the F-measure [3].

We compare the following methods for the task of product record linkage:

- *Supervised Classifier* (**SC**): the standard supervised classifier, which does not consider the unlabeled data at all.
- *Traditional Self-Training* (**t-ST**): the traditional self-training method in Algorithm 1 which adds an equal amount of samples of each class in pseudo labeled selection at each iteration.
- *Proportional Self-Training* (**p-ST**): the traditional self-training method in Algorithm 1 but add samples according to the class distribution at each iteration.
- *Simple Group Based Self-Training* (**s-ST**): a simplified version of our approach without the group confidence valuation, which directly selects samples of high confidence scores estimated from the classifier together with their conflicting pairs as negative samples at each iteration.
- *Group Based Self-Training* (**g-ST**): the proposed group based self-training algorithm in Algorithm 2, which uses the group confidence evaluation method to select pseudo positive instances.

[3] http:/en.wikipedia.org/wiki/Precision_and_recall

Recall all the methods rely on the wrapped classifier. We select two classic but very different classifiers: the Maximum Entropy model (***MaxEnt***) and the Decision Tree $C4.5$ (***Tree***). We implement these two classifiers using the machine learning toolkit Weka[4]. We use the six similarity functions to obtain similarity values between two records on each field as features. All the self-training based methods run ten iterations and at each iteration they add the same number of positive instances, i.e. 30. Different methods select pseudo *negative instances* differently. *t-ST* does not consider the correlation between data instances, and it adds top 30 confident negative instances. *p-ST* adds top $30 \times \frac{\#\text{negative instances}}{\#\text{positive instances}}$ confident negative instances. Both *p-ST* and *g-ST* take all the conflicting instances of the selected pseudo positive instances as the negative instances. We present the average numbers of pseudo negative instances at an iteration in Table 2. As will be revealed later, although *p-ST* adds more negative instances, *g-ST* performs much better than *p-ST*, which indicates simply adding more negative instances might not lead to better performance. We do not perform specific preprocessing steps to make the data balanced (e.g. under-sampling or over-sampling), and we find the data distribution does not significantly affect the performance of the classifiers on our dataset.

Dataset	t-ST	p-ST	s-ST	g-ST
LAPTOP	30	950	845	854
CAMERA	30	655	569	584

Table 2: Average numbers of pseudo negative instances selected at each iteration.

6.3 Results and analysis

Overall performance comparison. To test the performance under weak supervision, we first set the seed number to 30, which nearly takes up a proportion of 5% of the labeled data. We present the results of different methods in Table 3 and Table 4. We first examine the performance of the baselines. We can see that semi-supervised learning is very effective to improve over the the supervised classifier when the amount of training data is small. It is interesting to see that *s-ST* performs best among all the baselines. Recall that the major difference between *s-ST* and other baselines is that it select the conflicting pairs of the pseudo positive instances as the negative instances. It indicates that it is important to consider the correlation among the data instances. In addition, Decision Tree seems to be more competitive than Maximum Entropy Model for product record linkage. Then we take our group based self-training algorithm into comparison. In terms of F1 measure, we can see that it is consistently better than all the baselines on two datasets respectively by using two different classifiers. It is worth looking into the performance comparison on precision and recall. We can see that (1) *s-ST* and *g-ST* yield better results in terms of precision while the other baselines yield better results in terms of recall; (2) our method *g-ST* largely improves over the best baseline *s-ST*. It is not surprising to have these observations since that our group evaluation method is more careful at the selection of pseudo positive instance: it considers the evidence from the conflicting instances.

amine how it affects the performance of these methods. By varying the number of seeds from 10 to 50 with a step of 10, we present the F1 results in Figure 2 on two datasets by using two classifiers. We can see that our method is consistently better than baselines with the varying of the seed number. Especially, our method still works well when there is little labeled data, i.e. $\#seeds = 10$. With a weaker classifier, i.e. *MaxEnt*, our method yields more improvement than that with *Tree*. Besides the seed number, there are another two factors which potentially affect the performance: (1) the iteration number and (2) the number of pseudo positive instances selected at each iteration. We also examine the tuning results of these two parameters and find our method is consistently better than *s-ST* with the varying of these two factors. These results show that our method is very effective and it is of high stability and practicability.

7 Conclusion

In this paper, we develop a novel variant of the self-training algorithm by leveraging the data characteristic for the task of product record linkage. We joint consider a candidate linked pair and its corresponding correlated pairs as a group, at the selection of pseudo labeled data. We propose a confidence evaluation method for a group of instances, and incorporate it as a re-ranking step in the self-training algorithm. We evaluate the novel self-training algorithm on two large datasets constructed based on real e-commerce Websites. We adopt several competitive methods as comparisons and perform extensive experiments. The results show that our method outperforms these baselines that do not consider data correlation. We also carefully examine the affects of various parameters, and the tuning results indicate the stability and robustness of our method.

The major contribution and novelty of this paper is the novel group confidence evaluation to model the correlation existing in data. Although we develop the idea in the setting of self-training algorithms, it will be promising to be applied in other learning algorithms, i.e. active learning.

Abstract

Recently the research on supervised term weighting has attracted growing attention in the field of Traditional Text Categorization (TTC) and Sentiment Analysis (SA). Despite their impressive achievements, we show that existing methods more or less suffer from the problem of *over-weighting*. Overlooked by prior studies, over-weighting is a new concept proposed in this paper. To address this problem, two regularization techniques, *singular term cutting* and *bias term*, are integrated into our framework of supervised term weighting schemes. Using the concepts of over-weighting and regularization, we provide new insights into existing methods and present their regularized versions. Moreover, under the guidance of our framework, we develop a novel supervised term weighting scheme, regularized entropy (*re*). The proposed framework is evaluated on three datasets widely used in SA. The experimental results indicate that our *re* enjoys the best results in comparisons with existing methods, and regularization techniques can significantly improve the performances of existing supervised weighting methods.

1 Introduction

Sentiment Analysis (SA), also known as opinion mining, has enjoyed a burst of research interest with growing avenues (e.g., social networks and e-commerce websites) for people to express their sentiments on the Internet. A typical sentiment-analysis application mainly involves three key subtasks, namely holder detection, target extraction and sentiment classification (Liu, 2012; Hu and Liu, 2004). A simple and most extensively studied case of sentiment classification is sentiment polarity classification, which is the binary classification task of labelling the polarity of a sentiment-oriented document as positive or negative. Sentiment classification can be performed at the document, sentence, phase or word level. In this paper, we focus on sentiment polarity classification at document level.

Just like Information Retrieval (IR) and TTC, in sentiment classification, the content of an opinion-orientated document can be represented as a vector of terms in light of Vector Space Model (VSM). In VSM, each dimension of the vector corresponds to a term and different terms have different weights, thus the term weight represents the contribution of the term to the sentiment of a document in sentiment classification. Term weighting is the task of assigning appropriate weights to terms according to their correlations with the category concept. Term weighting schemes fall into two categories (Lan et al., 2009; Debole and Sebastiani, 2003). The first one, known as *unsupervised* term weighting method, does not take category information into account. The second one referred to as *supervised* term weighting method embraces the category label information of training documents in the categorization tasks. Although most term weighting approaches to text categorization, including sentiment classification, are borrowed from IR, recently several new supervised term weighting schemes have been studied and achieved significant successes in TTC and SA (Lan et al., 2009; Martineau and Finin, 2009; Paltoglou and Thelwall, 2010).

Despite the impressive achievements in the current field of supervised term weighting for TTC and SA, we indentify that existing supervised methods, more or less, suffer from over-weighting problem and thus develop a robust framework to address this problem. Over-weighting, overlooked by prior studies, is a new concept introduced in this paper. It would occur due to the presence of many noisy

Proceedings of COLING 2014, the 25th International Conference on Computational Linguistics: Technical Papers, pages 1322–1330, Dublin, Ireland, August 23-29 2014.

words and the unreasonably too large ratios between weights of different terms. Thus, it could result in poor representations of sentiments containing in documents. In order to reduce over-weighting problem for supervised term weighting, two regularization techniques called *singular term cutting* and *bias term* are proposed and integrated into our framework of supervised term weighting schemes. Singular term cutting is introduced to cut down the weights of noisy or unusual terms, and bias term is added to shrink the ratios between weights of different terms.

Using the concepts of over-weighting and regularization, we provide new insights into existing supervised weighting methods and then present their regularized versions. We also propose a novel term weighting scheme called *regularized entropy* (*re*) under the guidance of our framework. The formulation of *re* bases on entropy, which is used to measure the distribution of terms over different categories, and the terms with smaller entropy value have larger weights.

After presenting our framework, the regularized versions of existing methods and *re* in detail, experiments are conducted on three publicly available datasets widely used in SA. In our experiments, *re* is compared against many existing methods appearing in IR, TTC and SA. We also compare the performances of existing supervised weighting methods against their regularized versions. The results of comparative experiments indicate that *re* clearly outperform existing methods, the introduction of regularization techniques significantly improves the performances of existing supervised weighting methods.

2 Review of Term Weighting Schemes in IR, TTC and SA

In IR, TTC and SA, one of the main issues is the representation of documents. VSM provides a simplifying representation by representing documents as vector of terms. Term weighting aims to evaluate the relative importance of different terms in VSM. There are three components in a term weighting scheme, namely local weight, global weight and normalization factor (Salton and Buckley, 1988; Lan et al., 2009). Final term weight is the product of the three components:

$$t_{ij} = l_{ij} \times g_i \times n_j \,, \tag{1}$$

where t_{ij} is the final weight of i_{th} term in the j_{th} document, l_{ij} is the local weight of i_{th} term in the j_{th} document, g_i is the global weight of the i_{th} term, and n_j is the normalization factor for the j_{th} document.

2.1 Local Term Weighting Schemes

Local weight component is derived only from frequencies within the document. Table 1 lists three common local weighting methods, namely raw term frequency (*tf*), term presence (*tp*) and augmented term frequency (*atf*). In IR and TTC, the most widely used local weight is *tf* , but pioneering research

Local weight	Notation	Description
tf	tf	Raw term frequency.
$\begin{cases} 1, & \text{if } tf > 0 \\ 0, & \text{otherwise} \end{cases}$	tp	Term presence, 1 for presence and 0 for absence.
$k + (1-k)\dfrac{tf}{\max_t(tf)}$	atf	Augmented term frequency, $\max_t(tf)$ is the maximum frequency of any term in the document, k is set to 0.5 for short documents (Salton and Buckley, 1988).

Table 1: Local term weighting schemes.

Notation	Description
a	Positive document frequency, i.e., number of documents in positive category containing term t_i.
b	Number of documents in positive category which do not contain term t_i.
c	Negative document frequency, i.e., number of documents in negative category containing term t_i.
d	Number of documents in negative category which do not contain term t_i.
N	Total number of documents in document collection, $N = a + b + c + d$.
N^+, N^-	N^+ is number of documents in positive category, and N^- is number of documents in negative category. $N^+ = a+b$, $N^- = c+d$.

Table 2: Notations used to formulate global term weighting schemes.

Global weight	Notation	Description
$\log_2 \frac{N}{a+c}$	*idf*	Inverse document frequency (Jones, 1972)
$\log_2\left(\frac{N}{a+c}-1\right)$	*pidf*	Probabilistic *idf* (Wu and Salton, 1981)
$\log_2 \frac{b+d+0.5}{a+c+0.5}$	*bidf*	BM 25 *idf* (Jones et al., 2000)
$\frac{a}{N}\log_2 \frac{aN}{(a+b)(a+c)}+\frac{b}{N}\log_2 \frac{bN}{(a+b)(b+d)}+$ $\frac{c}{N}\log_2 \frac{cN}{(a+c)(c+d)}+\frac{d}{N}\log_2 \frac{dN}{(b+d)(c+d)}$	*ig*	Information gain
$\log_2\left(\max(\frac{aN}{(a+c)N^+},\frac{cN}{(a+c)N^-})\right)$	*mi*	Mutual information
$\log_2 \frac{N^-a}{N^+c}$	*didf*	Delta *idf* (Martineau and Finin, 2009)
$\log_2 \frac{N^-a+0.5}{N^+c+0.5}$	*dsidf*	Delta smoothed *idf* (Paltoglou and Thelwall, 2010)
$\log_2 \frac{N^-(a+0.5)}{N^+(c+0.5)}$	*dsidf'*	Another version of *dsidf*
$\log_2 \frac{(N^- -c+0.5)a+0.5}{(N^+ -a+0.5)c+0.5}$	*dbidf*	Delta BM25 *idf* (Paltoglou and Thelwall, 2010)
$\log_2 \frac{(N^- -c+0.5)(a+0.5)}{(N^+ -a+0.5)(c+0.5)}$	*dbidf'*	Another version of *dbidf*
$\log_2\left(2+\frac{a}{\max(1,c)}\right)$	*rf*	Relevance frequency (Lan et al., 2009)

Table 3: Global term weighting schemes.

on SA by Pang et al. (2002) showed that much better performance was achieved by using *tp*, not *tf*. This conclusion for SA was opposite to TTC, so *tp* was preferred in subsequent SA research.

2.2 Global Term Weighting Schemes

In contrast to local weight, global weight depends on the whole document collection. To formulate different global weighting schemes, some notations are first introduced in table 2. By using these notations, table 3 presents several representative global weighting schemes in IR, TTC and SA, including inverse document frequency (*idf*), probabilistic *idf* (*pidf*), BM25 *idf* (*bidf*), information gain (*ig*), delta *idf* (*didf*), *dsidf'*, delta BM25 *idf* (*dbidf*), *dbidf'* and relevance frequency (*rf*). Among these global weighting methods, *idf*, *pidf* and *bidf* are unsupervised methods because they do not utilize the category label information of document collection. The common idea behind them is that a term that occurs rarely is good at discriminating between documents.

Other global weighting schemes in table 3 are supervised term weighting methods. Among these supervised factors, feature selection methods, *ig* and *mi* are studied earliest. In TTC field, Debole and Sebastiani (2003) replaced *idf* with *ig* and other feature selection methods, *gr* and *chi*, for global term weighting. They concluded that these feature selection methods did not give a consistent superiority over the standard *idf*. In SA field, Deng et al. (2013) also employed several feature selection methods, including *ig* and *mi*, to learn the global weight of each term from training documents with category labels. The experimental results showed that compared with *bidf*, *mi* produced better accuracy on two of three datasets but *ig* provided very poor results.

For the rest of supervised term weighting schemes in table 3, *rf* is published in TTC literature, *didf* and *dbidf* are published in SA literature. The intuitive consideration of *rf* is that the more concentrated a high frequency term is in the positive category than in the negative category, the more contributions

it makes in selecting the positive samples from the negative samples. Driven by this intuition, *rf* was proposed to capture this basic idea. The experimental results showed that when combined with the local component *tf*, *rf* consistently and significantly outperformed other term weighting methods, including *idf* and *ig*. Due to the asymmetry of *rf*, it only boosts the weights of terms that appear more frequently in the positive category. In other words, *rf* discriminates against terms appearing more frequently in negative category. The asymmetry of *rf* is reasonable for TTC because it only cares whether a document belongs to a topic or not and a single document can concentrate on different topics. However, it is not the case for binary sentiment classification since terms appear in positive or negative reviews are of the same importance.

In SA field, The first published supervised term weighing scheme, introduced by Martineau and Finin (2009), is called delta *idf*. Instead of only using *tf* as term weights, the authors assigned term weights for a document by calculating the difference of that term's *idf* values in the positive and negative training documents. Obviously, *didf* boosts the importance of terms that are unevenly distributed between the positive and negative categories and discounts evenly distributed words. It is known that the distribution of sentimental words is more uneven than stop words, as a result, *didf* assign much greater weights to sentimental words than stop words. The produced results showed that *didf* provided higher classification accuracy than the simple *tf* or the binary weighting scheme *tp*. Nonetheless, *didf* is susceptible to the errors caused by the case that $a = 0$ or $c = 0$, and the authors did not provide any detail that how they deal with this problem. Following the idea of *didf* and to rectify the problem of *didf*, Paltoglou and Thelwall (2010) presented a smoothed version of *didf*, delta smoothed *idf* (*dsidf*), and explored other more sophisticated global term weighting methods originated from IR including BM25 *idf* (*bidf*) and delta BM25 *idf* (*dbidf*). The formulas of these schemes are also presented in table 3. They showed that these variants of the classic *tf-idf* scheme provided significant increases over the best term weighting methods for SA in terms of accuracy. The idea of introducing smoothness technique is wonderful and can indeed avoid the computational errors in *didf*, but due to the unsuitable implementation, the smoothed version of *didf* provided by Paltoglou and Thelwall (2010) severely encounters the problem of over-weighting. We provide another version of *dsidf*, namely *dsidf'*. Besides *dsidf*, over-weighting is also severely encountered by *dbidf*, and our versions of it is denoted as *dbidf'*.

3 Research Design

Based on our review of term weighting schemes above, we believe that supervised term weighting can, but not always, boost the performances of text categorization. Actually, the somewhat successful ones, such as *rf*, *didf* and *dsidf*, follow the same intuition that the more imbalanced a term's distribution is across different categories, the more contribution it makes in discriminating between the positive and negative documents. The only difference between them lies in the quantification of the imbalance of a term's distribution. However, existing methods more or less suffer from the problem of over-weighting. We argue that a successful supervised weighting method should satisfy the following two criteria and develop a robust framework of supervised term weighting schemes.

Criterion 1: Assign large weights to terms that unevenly distribute across different categories.
Criterion 2: Avoid the over-weighting problem.

3.1 Our Framework

Over-weighting is somewhat like over-fitting in statistical machine learning, so we name it over-weighting. It is known that over-fitting occurs when a statistical model describes random error or noise instead of the underlying relationship. Similarly, over-weighting could occur in supervised term weighting. In practice we indentify that over-weighting is caused by the presence of noisy terms and the unsuitable quantification of the degree of the imbalance of a term's distribution.

The presence of noisy terms would lead to the problem of over-weighting. To illustrate this phenomenon, suppose that the training document collection contains 10,000 documents and evenly distributes over the positive and negative category, the number of documents containing the strange term "leoni" belonging to positive category is 5, i.e., $a = 5$, and no document belonging to negative category contains "leoni", i.e., $c = 0$, according to the formulation of most existing supervised methods such as dsidf, the weight of "leoni" should be large since "leoni" unevenly distributes over different categories. However, since the total number of documents containing "leoni" is so trivial compared to the size of

training collection, "leoni" could be an unusual word. We call the terms like "leoni" singular terms. Statistically, singular terms account for a great part of the whole terms in the dictionary constructed based on the training documents even if we filter out low frequency words. As singular terms do not embody any sentiment and the weights of them are supposed to be small, we formulate the global weight of term t_i as

$$g_i = \begin{cases} 0, \text{if } a = 0 \,(\text{or } c = 0) \text{ and } (a+c)/N < \alpha \\ r, \text{otherwise} \end{cases} \tag{2}$$

where r is a variable quantifying the imbalance of a term's distribution across different categories and its value ranges from 0 to 1, α is a very small number, here we set α to 0.005. As formula (2) cuts down the weights of singular terms, we name the first regularization technique *singular term cutting*.

Also, an unsuitable quantification of a term's distribution would lead to unreasonably too large ratios between different weights and thus results in over-weighting, although the term weight calculated by (2) is no more than 1. This finding leads us to introduce the second regularization technique, bias term, to the weight of term t_i, so our framework of supervised term weighting schemes is modified as

$$g_i = \begin{cases} b_0, \text{if } a = 0 \,(\text{or } c = 0) \text{ and } (a+c)/N < \alpha \\ b_0 + r, \text{otherwise} \end{cases} \tag{3}$$

where b_0 is the bias term, it shrinks the ratios between different weights of terms, the value of it controls the trade-off between weighting the terms freely and preventing over-weighting. If b_0 is too large, supervised term weighting would make no difference and under-weighting would occur. If b_0 is too small, over-weighting would occur. The optimal value of b_0 can be obtained via cross-validation, a model selection technique widely used in machine learning.

3.2 Regularized Versions of Existing Methods

As mentioned before, the somewhat successful ones of existing supervised weighting methods try to quantify the imbalance of a term's distribution. Recall that in our framework, r is just right a variable sharing this purpose, so we can make improvement on existing supervised weighting methods by replacing r with them. Ahead of the improvement of existing methods, we first provide new insights into existing methods using the concepts of over-weighting and regularization.

Because r quantifies the degree of the imbalance of a term's distribution across different categories, existing methods are required to satisfy Criterion 1. It has been clear that *didf*, *dsidf*, *dsidf'*, *dbidf*, *dbidf'*, *mi* and *rf* satisfy Criterion 1 via the review of existing methods in section 2. Another property shared by them is that the formulations of them base on logarithmic function. It is known that logarithmic function plays the role of shrinking the ratios between different term weights, so they implicitly satisfy Criterion 2 and in some degree reduce the over-weighting problem. In actuality, *dsidf*, *dsidf'* and *rf* can be treated as the further regularized versions of *didf* since the constant 2+ in *rf* and the smoothness in *dsidf* and *dsidf'* can be treated as regularization techniques. We have pointed out in section 2 that due to the unreasonable implementation of smoothness, *dsidf* and *dbidf* do not reduce, but aggravate over-weighting. As to *dsidf'* and *dbidf'*, they limit over-weighting in a very great degree via the introduction of smoothness technique and logarithmic function, but over-weighting is still not overcome completely, experimental results in section 4 will show that the performances of them can be further enhanced by cutting the weights of singular terms and adding a bias term.

Method	Regularized version
didf *dsidf* *dsidf'* *rf*	$\begin{cases} b_0, \text{if } a = 0 \,(\text{or } c = 0) \text{ and } (a+c)/N < \alpha \\ b_0 + \dfrac{\log_2 \max(a,c)/\min(a,c)}{\max_t\{\log_2 \max(a,c)/\min(a,c)\}}, \text{otherwise} \end{cases}$
dbidf *dbidf'*	$\begin{cases} b_0, \text{if } a = 0 \,(\text{or } c = 0) \text{ and } (a+c)/N < \alpha \\ b_0 + \dfrac{\log_2 (N^- - \min(a,c))/\max(a,c)}{\max_t\{\log_2 (N^- - \max(a,c))/\min(a,c)\}}, \text{otherwise} \end{cases}$
mi	$\begin{cases} b_0, \text{if } a = 0 \,(\text{or } c = 0) \text{ and } (a+c)/N < \alpha \\ b_0 + \log_2 \dfrac{mi}{\max_t\{mi\}}, \text{otherwise} \end{cases}$

Table 4: Regularized versions of existing supervised term weighting schemes.

Up to present we have known that existing supervised methods encounter over-weighting in different degree. In order to make improvements on existing methods and under the guidance of our framework, we present the regularized versions of *didf*, *dsidf*, *dsidf'*, *dbidf*, *dbidf'* and *mi* in table 4. These methods are selected to improve due to their typical representations and diversities.
Note that the regularized versions of *didf*, *dsidf*, *dsidf'* and *rf* and are the same one due to the fact that *dsidf*, *dsidf'* and *rf* are same as *didf* if there is no smoothness or constant in them. For the same reason, *dbidf* and *dbidf'* are grouped together.

3.3 Regularized Entropy

Inspired by the derivation of our framework for supervised term weighting, we propose a novel supervised term weighting scheme called regularized entropy (*re*). For *re*, entropy is exploited to measure the degree of the imbalance of a term's distribution across different categories. According to information theory (Shannon, 1948), for a random variable X with m outcomes $\{x_1,\ldots, x_m\}$, the entropy, a measure of uncertainty and denoted by $H(X)$, is defined as

$$H(X) = -\sum_{i=1}^{m} p(x_i)\log_2 p(x_i), \tag{4}$$

where $p(x_i)$ is the probability that X equals to x_i. Let p^+ and p^- denote the probability of documents where term t_i occurs and belonging to positive and negative category respectively, then p^+ and p^- can be estimated as

$$p^+ \approx \frac{a}{a+c}, p^- \approx \frac{c}{a+c}. \tag{5}$$

According to formula (4), if term t_i occurs in a document, the degree of uncertainty of this document belonging to a category is

$$h = -p^+\log_2 p^+ - p^-\log_2 p^- = -\frac{a}{a+c}\log_2\frac{a}{a+c} - \frac{c}{a+c}\log_2\frac{c}{a+c}. \tag{6}$$

Obviously, if the documents containing term t_i distribute evenly over different categories, the entropy h will be large. In contrast, if the documents containing term t_i distribute unevenly over different categories, the entropy h will be relatively small. However, we hope that the more uneven the distribution of documents where term t_i occurs, the larger the weight of t_i is. And that the entropy h is between 0 and 1, so the original formula of the weight of term t_i is

$$g_i = 1 - h. \tag{7}$$

We call the scheme formulated by the (7) *nature entropy* (*ne*). It seems that *ne* can be used as the weights of terms directly and will perform well. Unfortunately, *ne* suffers from the same problem with existing methods. Under the guidance of our framework, the regularized version of *ne* is formulated as

$$g_i = \begin{cases} b_0, \text{if } a = 0\ (\text{or } c = 0) \text{ and } (a+c)/N < \alpha \\ b_0 + (1-h), \text{otherwise} \end{cases}. \tag{8}$$

We name the proposed method formulated by (8) *regularized entropy* (*re*), which literally indicates the idea behind the scheme.

4 Experimental Results

We conduct sentiment classification experiments on three document-level datasets. The first one is Cornell movie review dataset introduced by Pang and Lee (2004). This sentiment polarity dataset consists of 1,000 positive and 1,000 negative movie reviews. The second dataset is taken from Multi-Domain Sentiment Dataset (MDSD) of product reviews (Blitzer et al., 2007). MDSD is initially released for the research on sentiment domain adaption but can also be used for sentiment polarity classification. It contains Amazon product reviews for different product types, we select camera reviews and thus refer the second corpus as Amazon camera review dataset. Also, it consists of 1,000 positive and 1,000 negative camera reviews.

For the above two datasets, the results are based on the standard 10-fold cross validation. Term weighting is performed on the 1,800 training reviews for each fold and the remaining 200 are used to evaluate the predicting accuracy. The overall classification accuracy is the average accuracy across 10 folds.

We also use the Stanford large movie review dataset developed by Mass et al. (2011). It contains 50,000 movie reviews, split equally into 25,000 training and 25,000 testing set. For this dataset, due to the original

split, no cross validation is used. Term weighting is only implemented on the training set, and the classification accuracy is reported based on the testing set.

We only use unigrams as the features. Support Vector Machine (SVM) is used as the classifier. Specially, we adopt the L2-regularized L2-loss linear SVM and the implementation software is LIBLINEAR (Fan et al., 2008). In all our experiments, cross-validation is performed on training document collection to obtain optimal value of b_0. On Cornell and Stanford movie review dataset, b_0 is set to 0.1 for *re*, 0.05 for the improved versions of *didf*, *dsidf*, *dsidf'* and *rf*, 0.02 for that of *mi*, and 0.01 for those of *dbidf* and *dbidf'*. On Amazon camera review dataset, b_0 is set to 0.05 for *re* 0.03 for the improved versions of *didf*, *dsidf*, *dsidf'* and *rf*, 0.02 for that of *mi*, and 0.01 for those of *dbidf* and *dbidf'*.

4.1 Experiment 1: Comparisons of *re* Against Existing Methods

Table 5 reports the classification accuracies of *re* and other term weighting schemes. On the Cornell movie review dataset, the local weighting method *tp* outperforms *tf* significantly in general except the case that *dbidf* and *dsidf* are used as the global weighting methods. There is no distinct difference between *tp* and *atf*, neither of them consistently performs better than each other when combined with various global weighting methods.

Compared to the change of local weighting methods, global weighting methods lead to more significant difference on classification accuracy. Combined with different local weighting schemes, the proposed global weighting method, *re*, has always been shown to clearly perform better than other global weighting methods. Specially, the highest classification accuracy, 89.65%, is achieved by the combination of *re* and *atf*, i.e., *atf-re*. Compared to *no*, *re* shows apparent superiorities, the increases of accuracy are +1.55% (from 88.05% to 89.60%) and +1.50% (from 88.15% to 89.65%) respectively when the local methods are *tp* and *atf*. The most popular *idf* in IR field is not a good choice for sentiment classification. For the methods originated from TTC field, the feature selection approaches, *mi* performs well and the classification accuracies produced by it is higher than the others except *re* in apparent advantages. Unlike *mi*, *ig* is instead a disappointing performer, the accuracy 87.65%, provided by *ig* when combined with *tp*, is far lower than that of *mi*, this observation is entirely predictable due to the fact that *ig* does not follow Criterion 1 and suffers over-weighting. As for *rf*, it do not perform well, the highest accuracy provided by them is only 88.00% respectively. It is not surprising that *rf* does not even outperform no since its discrimination against the terms that appear more frequently in the negative reviews. When it comes to the approaches that recently appeared in SA literature, both *dsidf* and *dbidf* performs very poorly because of over-weighting problem caused by the unreasonable implementation. But both *dsidf'* and *dbidf'* are shown to give slightly better results than *no*.

On the Amazon camera review dataset, the performances of local weighting methods agree with those on Cornell movie review dataset. Again, *tp* and *atf* yield comparable classification accuracy and both of them outperform *tf*. The performances on this dataset produced by global weighting methods are, generally, in accordance to those on the previous dataset, but some differences deserve our attention. First, *re* outperforms *no* with greater superiorities compared to the previous dataset, the increase of accuracy is +2.20% (from 87.25% to 89.45%) and +2.00% (from 87.50% to 89.50%) respectively when the local methods are *tp* and *atf* . Another one is that *dsidf'* provides more apparent advantages over *no* compared to the previous dataset but differences between *re* and *dsidf'* become smaller.

Cornell movie review				Amazon camera review				Stanford movie review			
Method	Original version	Regularized version	Difference to original version	Method	Original version	Regularized version	Difference to original version	Method	Original version	Regularized version	Difference to original version
didf	N/A	89.50	N/A	*didf*	N/A	89.60	N/A	*didf*	N/A	89.71	N/A
dsidf	80.20	89.50	+9.30	*dsidf*	82.80	89.60	+6.80	*dsidf*	86.89	89.71	+2.82
dsidf'	88.20	89.50	+1.30	*dsidf'*	88.95	89.60	+0.65	*dsidf'*	89.25	89.71	+0.46
rf	88.00	89.50	+1.50	*rf*	87.35	89.60	+2.25	*rf*	88.36	89.71	+1.35
dbidf	81.10	89.25	+8.15	*dbidf*	87.00	89.65	+2.65	*dbidf*	86.83	89.49	+2.66
dbidf'	88.30	89.25	+0.95	*dbidf'*	89.10	89.65	+0.55	*dbidf'*	89.39	89.49	+0.10
mi	88.85	89.10	+0.25	*mi*	89.05	89.55	+0.50	*mi*	89.45	89.59	+0.14
ne	83.45	89.60	+6.15	*ne*	87.85	89.45	+1.60	*ne*	87.32	89.81	+2.49

Table 6: Classification accuracies of original versions of *ne* and some existing supervised term weighting schemes and their regularized versions under our framework.

On the Stanford large movie review dataset, differences in accuracy are smaller than those on the previous ones, but the testing set contains 25,000 documents, the variance of the performance estimate is quite low (Maas et al., 2011). Interestingly, unlike the conclusion on the Cornell movie review dataset, *tp* does not show significant advantages over *tf* and even slightly underperforms *tf* when the global methods are *idf*, *ig*, *dbidf*, and *dbidf'*. The performances of *tp* and *atf* are still comparable but *atf* reveals a slight superiority over *tp*. In spite of the smaller differences, among the global weighting methods, *re* still embraces the highest classification accuracy, 89.81%, when combined with *tp*. In accordance to the observations on the previous two datasets, *mi*, *dsidf'* and *dbidf'* yield higher classification accuracies than *no*. Again, the other global methods, *idf*, *ig*, *rf*, *dsidf* and *dbidf* still produce comparable or lower accuracies in comparison with *no*.

4.2 Experiment 2: Comparisons Existing Methods Against Their Regularized Versions

We also compare the performances of some representative supervised methods, i.e., *didf*, *dsidf*, *dsidf'*, *dbidf*, *dbidf'*, *rf*, and *mi* against their regularized versions. In this experiment, we only use *tp* as the local weighting method. Table 6 records the classification accuracies of original versions of these methods and their improved versions. We can observe that the regularized versions of existing methods consistently have much better accuracy. Regularized version of *dsidf* yields the most significant improvements, the accuracy difference to original version is +9.30%, +6.80% and +2.82% on three datasets respectively. The accuracy difference between *dbidf* and its regularized version is also remarkable and significant. These observations validate our analysis in section 2 that *dsidf* and *dbidf* severely encounters over-weighting problem. Note that the improvements of the regularized versions of *dsidf'*, *dbidf'* and *mi* over their originals are trivial as they are much less subjected to over-weighting. Significance test will be included for these methods to test if the improvements are statistically reliable.

5 Conclusion and Future Work

In this study we have proposed a robust framework of supervised term weighting schemes. This framework is developed based on the techniques introduced to reduce over-weighting problem commonly suffered by existing supervised weighting methods.

Over-weighting is a new concept proposed in this paper, which is caused by the presence of many noisy words and the unreasonably too large ratios between weights of different terms. To reduce over-weighting, we have introduced two regularization techniques, singular term cutting and bias term. Singular term cutting cuts down the weights of noisy or strange words, and bias term shrinks the ratios between weights of different terms. Comparative experiments have shown that regularization techniques significantly enhance the performances of existing supervised methods.

More over, a novel supervised term weighting scheme, *re*, is proposed under our framework. The formulation of *re* bases on entropy, which is used to measure a term's distribution across different categories. The experimental results have shown that *re* not only outperforms its original version, *ne*, with great advantage but also consistently outperforms existing methods appearing in IR, TTC and SA. In the future, we would like to extend our work to other tasks such as multi-class classification and traditional text categorization.

Abstract

Sentiment classification aims to automatically predict sentiment polarity (e.g., positive or negative) of user-generated sentiment data (e.g., reviews, blogs). To obtain sentiment classification with high accuracy, supervised techniques require a large amount of manually labeled data. The labeling work can be time-consuming and expensive, which makes unsupervised (or semi-supervised) sentiment analysis essential for this application. In this paper, we propose a novel algorithm, called graph co-regularized non-negative matrix tri-factorization (GNMTF), from the geometric perspective. GNMTF assumes that if two words (or documents) are sufficiently close to each other, they tend to share the same sentiment polarity. To achieve this, we encode the geometric information by constructing the nearest neighbor graphs, in conjunction with a non-negative matrix tri-factorization framework. We derive an efficient algorithm for learning the factorization, analyze its complexity, and provide proof of convergence. Our empirical study on two open data sets validates that GNMTF can consistently improve the sentiment classification accuracy in comparison to the state-of-the-art methods.

1 Introduction

Recently, sentiment classification has gained a wide interest in natural language processing (NLP) community. Methods for automatically classifying sentiments expressed in products and movie reviews can roughly be divided into supervised and unsupervised (or semi-supervised) sentiment analysis. Supervised techniques have been proved promising and widely used in sentiment classification (Pang et al., 2002; Pang and Lee, 2008; Liu, 2012). However, the performance of these methods relies on manually labeled training data. In some cases, the labeling work may be time-consuming and expensive. This motivates the problem of learning robust sentiment classification via unsupervised (or semi-supervised) paradigm.

A traditional way to perform unsupervised sentiment analysis is the lexicon-based method (Turney, 2002; Taboada et al., 2011). Lexicon-based methods employ a sentiment lexicon to determine overall sentiment orientation of a document. However, it is difficult to define a universally optimal sentiment lexicon to cover all words from different domains (Lu et al., 2011a). Besides, most semi-automated lexicon-based methods yield unsatisfactory lexicons, with either high coverage and low precision or vice versa (Ng et al., 2006). Thus it is challenging for lexicon-based methods to accurately identify the overall sentiment polarity of users generated sentiment data. Recently, Li et al. (2009) proposed a constrained non-negative matrix tri-factorization (CNMTF) approach to sentiment classification, with a domain-independent sentiment lexicon as prior knowledge. Experimental results show that CNMTF achieves state-of-the-art performance.

From the geometric perspective, the data points (words or documents) may be sampled from a distribution supported by a low-dimensional manifold embedded in a high-dimensional space (Cai et al., 2011). This geometric structure, meaning that two words (or documents) sufficiently close to each other tend to share the same sentiment polarity, should be preserved during the matrix factorization. Research studies

Proceedings of COLING 2014, the 25th International Conference on Computational Linguistics: Technical Papers, pages 1331–1340, Dublin, Ireland, August 23-29 2014.

have shown that learning performance can be significantly enhanced in many real applications (e.g., text mining, computer vision, etc.) if the geometric structure is exploited (Roweis and Saul, 2000; Tenenbaum et al., 2000). However, CNMTF fails to exploit the geometric structure, it is not clear whether this geometric information is useful for sentiment classification, which remains an under-explored area. This paper is thus designed to fill the gap.

In this paper, we propose a novel algorithm, called graph co-regularized non-negative matrix tri-factorization (GNMTF). We construct two affinity graphs to encode the geometric information underlying the word space and the document space, respectively. Intuitively, if two words or documents are sufficiently close to each other, they tend to share the same sentiment polarity. Taking these two graphs as co-regularization for the non-negative matrix tri-factorization, leading to the better sentiment polarity prediction which respects to the geometric structures of the word space and document space. We also derive an efficient algorithm for learning the tri-factorization, analyze its complexity, and provide proof of convergence. Empirical study on two open data sets shows encouraging results of the proposed method in comparison to state-of-the-art methods.

The remainder of this paper is organized as follows. Section 2 introduces the basic concept of matrix tri-factorization. Section 3 describes our graph co-regularized non-negative matrix tri-factorization (GNMTF) for sentiment classification. Section 4 presents the experimental results. Section 5 introduces the related work. In section 6, we conclude the paper and discuss future research directions.

2 Preliminaries

2.1 Non-negative Matrix Tri-factorization

Li et al. (2009) proposed a matrix factorization based framework for unsupervised (or semi-supervised) sentiment analysis. The proposed framework is built on the orthogonal non-negative matrix tri-factorization (NMTF) (Ding et al., 2006). In these models, a term-document matrix $\mathbf{X} = [\mathbf{x}_1, \cdots, \mathbf{x}_n] \in \mathbb{R}^{m \times n}$ is approximated by three factor matrices that specify cluster labels for words and documents by solving the following optimization problem:

$$\min_{\mathbf{U},\mathbf{H},\mathbf{V} \geq 0} \mathcal{O} = \left\|\mathbf{X} - \mathbf{U}\mathbf{H}\mathbf{V}^T\right\|_F^2 + \sigma_1 \left\|\mathbf{U}^T\mathbf{U} - \mathbf{I}\right\|_F^2 + \sigma_2 \left\|\mathbf{V}^T\mathbf{V} - \mathbf{I}\right\|_F^2 \tag{1}$$

where σ_1 and σ_2 are the shrinkage regularization parameters, $\mathbf{U} = [\mathbf{u}_1, \cdots, \mathbf{u}_k] \in \mathbb{R}_+^{m \times k}$ is the word-sentiment matrix, $\mathbf{V} = [\mathbf{v}_1, \cdots, \mathbf{v}_n] \in \mathbb{R}_+^{n \times k}$ is the document-sentiment matrix, and k is the number of sentiment classes for documents. Our task is polarity sentiment classification (positive or negative), i.e., $k = 2$. For example, $\mathbf{V}_{i1} = 1$ (or $\mathbf{U}_{i1} = 1$) represents that the sentiment polarity of document i (or word i) is positive, and $\mathbf{V}_{i2} = 1$ (or $\mathbf{U}_{i2} = 1$) represents that the sentiment polarity of document i (or word i) is negative. $\mathbf{V}_{i*} = 0$ (or $\mathbf{U}_{i*} = 0$) represents unknown, i.e., the document i (or word i) is neither positive or negative. $\mathbf{H} \in \mathbb{R}_+^{k \times k}$ provides a condensed view of $\mathbf{X}$; $\|\cdot\|_F$ is the Frobenius norm and $\mathbf{I}$ is a $k \times k$ identity matrix with all entries equal to 1. Based on the shrinkage methodology, we can approximately satisfy the orthogonality constraints for $\mathbf{U}$ and $\mathbf{V}$ by preventing the second and third terms from getting too large.

2.2 Constrained NMTF

Lexical knowledge in the form of the polarity of words in the lexicon can be introduced in matrix tri-factorization. By partially specifying word polarity via $\mathbf{U}$, the lexicon influences the sentiment prediction $\mathbf{V}$ over documents. Following the literature (Li et al., 2009), let $\mathbf{U}_0$ represent lexical prior knowledge about sentiment words in the lexicon, e.g., if word i is positive $(\mathbf{U}_0)_{i1} = 1$ while if it is negative $(\mathbf{U}_0)_{i2} = 1$, and if it does not exist in the lexicon $(\mathbf{U}_0)_{i*} = 0$. Li et al. (2009) also investigated that we had a few documents manually labeled for the purpose of capturing some domain-specific connotations. Let $\mathbf{V}_0$ denote the manually labeled documents, if the document expresses positive sentiment $(\mathbf{V}_0)_{ii} = 1$, and $(\mathbf{V}_0)_{i2} = 1$ for negative sentiment. Therefore, the semi-supervised learning with lexical knowledge can be written as:

$$\min_{\mathbf{U},\mathbf{H},\mathbf{V} \geq 0} \mathcal{O} + \alpha \mathrm{Tr}\big[(\mathbf{U} - \mathbf{U}_0)^T \mathbf{C}^u (\mathbf{U} - \mathbf{U}_0)\big] + \beta \mathrm{Tr}\big[(\mathbf{V} - \mathbf{V}_0)^T \mathbf{C}^v (\mathbf{V} - \mathbf{V}_0)\big] \tag{2}$$

where $\mathrm{Tr}(\cdot)$ denotes the trace of a matrix, $\alpha > 0$ and $\beta > 0$ are the parameters which control the contribution of lexical prior knowledge and manually labeled documents. $\mathbf{C}^u \in \{0,1\}^{m\times m}$ is a diagonal matrix whose entry $\mathbf{C}^u_{ii} = 1$ if the category of the i-th word is known and $\mathbf{C}^u_{ii} = 0$ otherwise. $\mathbf{C}^v \in \{0,1\}^{n\times n}$ is a diagonal matrix whose entry $\mathbf{C}^v_{ii} = 1$ if the category of the i-th document is labeled and $\mathbf{C}^v_{ii} = 0$ otherwise.

3 Graph Co-regularized Non-negative Matrix Tri-factorization

In this section, we introduce our proposed graph co-regularized non-negative matrix tri-factorization (GNMTF) algorithm which avoids this limitation by incorporating the geometrically based co-regularization.

3.1 Model Formulation

Based on the manifold assumption (Belkin and Niyogi, 2001), if two documents $\mathbf{x}_i$ and $\mathbf{x}_j$ are sufficiently close to each other in the intrinsic geometric of the documents distribution, then their sentiment polarity $\mathbf{v}_i$ and $\mathbf{v}_j$ should be close. In order to model the geometric structure, we construct a document-document graph G^v. In the graph, nodes represent documents in the corpus and edges represent the affinity between the documents. The affinity matrix $\mathbf{W}^v \in \mathbb{R}^{n\times n}$ of the graph G^v is defined as

$$\mathbf{W}^v_{ij} = \begin{cases} \cos(\mathbf{x}_i, \mathbf{x}_j) & \text{if } \mathbf{x}_i \in \mathcal{N}_p(\mathbf{x}_j) \text{ or } \mathbf{x}_j \in \mathcal{N}_p(\mathbf{x}_i) \\ 0 & \text{otherwise} \end{cases} \tag{3}$$

where $\mathcal{N}_p(\mathbf{x}_i)$ represents the p-nearest neighbors of document $\mathbf{x}_i$. Many matrices, e.g., 0-1 weighting, textual similarity and heat kernel weighting (Belkin and Niyogi, 2001), can be used to obtain nearest neighbors of a document, and further define the affinity matrix. Since $\mathbf{W}^v_{ij}$ in our paper is only for measuring the closeness, we only use the simple textual similarity and do not treat the different weighting schemes separately due to the limited space. For further information, please refer to (Cai et al., 2011).

Preserving the geometric structure in the document space is reduced to minimizing the following loss function:

$$\begin{aligned} \mathcal{R}^v &= \frac{1}{2}\sum_{i,j=1}^{n} \left\|\mathbf{v}_i - \mathbf{v}_j\right\|_2^2 \mathbf{W}^v_{ij} = \sum_{i=1}^{n} \mathbf{v}_i^T \mathbf{v}_i \mathbf{D}^v_{ii} - \sum_{i,j=1}^{n} \mathbf{v}_i^T \mathbf{v}_j \mathbf{W}^v_{ij} \\ &= \mathrm{Tr}(\mathbf{V}^T \mathbf{D}^v \mathbf{V}) - \mathrm{Tr}(\mathbf{V}^T \mathbf{W}^v \mathbf{V}) = \mathrm{Tr}(\mathbf{V}^T \mathbf{L}^v \mathbf{V}) \end{aligned} \tag{4}$$

where $\mathbf{D}^v \in \mathbb{R}^{n\times n}$ is a diagonal matrix whose entries are column (or row, since $\mathbf{D}^v$ is symmetric) sums of $\mathbf{W}^v$, $\mathbf{D}^v_{ii} = \sum_{j=1}^{n} \mathbf{W}^v_{ij}$, and $\mathbf{L}^v = \mathbf{D}^v - \mathbf{W}^v$ is the Laplacian matrix (Chung, 1997) of the constructed graph G^v.

Similarly to document-document geometric structure, if two words $\mathbf{w}_i = [\mathbf{x}_{i1}, \cdots, \mathbf{x}_{in}]$ and $\mathbf{w}_j = [\mathbf{x}_{j1}, \cdots, \mathbf{x}_{jn}]$ are sufficiently close to each other in the intrinsic geometric of the words distribution, then their sentiment polarity $\mathbf{u}_i$ and $\mathbf{u}_j$ should be close. In order to model the geometric structure in the word space, we construct a word-word graph G^u. In the graph, nodes represent distinct words and edges represent the affinity between words. The affinity matrix $\mathbf{W}^u \in \mathbb{R}^{m\times m}$ of the graph G^u is defined as

$$\mathbf{W}^u_{ij} = \begin{cases} \cos(\mathbf{w}_i, \mathbf{w}_j) & \text{if } \mathbf{w}_i \in \mathcal{N}_p(\mathbf{w}_j) \text{ or } \mathbf{w}_j \in \mathcal{N}_p(\mathbf{w}_i) \\ 0 & \text{otherwise} \end{cases} \tag{5}$$

where $\mathcal{N}_p(\mathbf{w}_j)$ represents the p-nearest neighbor of word $\mathbf{w}_j$. Here, we represent a term $\mathbf{w}_j$ as a document vector $[\mathbf{x}_{j1}, \cdots, \mathbf{x}_{jn}]$. To measure the closeness of two words, a common way is to calculate the similarity of their vector representations. Although there are several ways (e.g., co-occurrence information, semantic similarity computed by WordNet, Wikipedia, or search engine have been empirically studied in NLP literature (Hu et al., 2009)) to define the affinity matrix $\mathbf{W}^u$, we do not treat the different ways separately and leave this investigation for future work.

Preserving the geometric structure in the word space is reduced to minimizing the following loss function:

$$\mathcal{R}^u = \frac{1}{2}\sum_{i,j=1}^{m} \left\|\mathbf{u}_i - \mathbf{u}_j\right\|_2^2 \mathbf{W}^u_{ij} = \mathrm{Tr}(\mathbf{U}^T \mathbf{L}^u \mathbf{U}) \tag{6}$$

where $\mathbf{L}^u = \mathbf{D}^u - \mathbf{W}^u$ is the Laplacian matrix of the constructed graph G^u, and $\mathbf{D}^u \in \mathbb{R}^{m\times m}$ is a diagonal matrix whose entries are $\mathbf{D}^u_{ii} = \sum_{j=1}^{m} \mathbf{W}^u_{ij}$.

Finally, we treat unsupervised (or semi-supervised) sentiment classification as a clustering problem, employing lexical prior knowledge and partial manually labeled data to guide the learning process. Moreover, we introduce the geometric structures from both document and word sides as co-regularization. Therefore, our proposed unsupervised (or semi-supervised) sentiment classification framework can be mathematically formulated as solving the following optimization problem:

$$\begin{aligned}\min_{\mathbf{U},\mathbf{H},\mathbf{V}\geq 0} \mathcal{L} = &\left\|\mathbf{X} - \mathbf{U}\mathbf{H}\mathbf{V}^T\right\|_F^2 + \sigma_1\left\|\mathbf{U}^T\mathbf{U} - \mathbf{I}\right\|_F^2 + \sigma_2\left\|\mathbf{V}^T\mathbf{V} - \mathbf{I}\right\|_F^2 \\ &+ \alpha\mathrm{Tr}\big[(\mathbf{U}-\mathbf{U}_0)^T\mathbf{C}^u(\mathbf{U}-\mathbf{U}_0)\big] + \gamma\mathrm{Tr}(\mathbf{U}^T\mathbf{L}^u\mathbf{U}) \\ &+ \beta\mathrm{Tr}\big[(\mathbf{V}-\mathbf{V}_0)^T\mathbf{C}^v(\mathbf{V}-\mathbf{V}_0)\big] + \delta\mathrm{Tr}(\mathbf{V}^T\mathbf{L}^v\mathbf{V})\end{aligned} \tag{7}$$

where $\delta > 0$ and $\gamma > 0$ are parameters which control the contributions of document space and word space geometric information, respectively. With the optimization results, the sentiment polarity of a new document $\mathbf{x}_i$ can be easily inferred by $f(\mathbf{x}_i) = \arg\max_{j\in\{p,\, n\}} \mathbf{V}_{ij}$.

3.2 Learning Algorithm

We present the solution to the GNMTF optimization problem in equation (7) as the following theorem. The theoretical aspects of the optimization are presented in the next subsection.

Theorem 3.1. *Updating* $\mathbf{U}$*,* $\mathbf{H}$ *and* $\mathbf{V}$ *using equations (8)∼(10) will monotonically decrease the objective function in equation (7) until convergence.*

$$\mathbf{U} \leftarrow \mathbf{U} \circ \frac{\left[\mathbf{X}\mathbf{V}\mathbf{H}^T + \sigma_1\mathbf{U} + \alpha\mathbf{C}^u\mathbf{U}_0 + \gamma\mathbf{W}^u\mathbf{U}\right]}{\left[\mathbf{U}\mathbf{H}\mathbf{V}^T\mathbf{V}\mathbf{H}^T + \sigma_1\mathbf{U}\mathbf{U}^T\mathbf{U} + \alpha\mathbf{C}^u\mathbf{U} + \gamma\mathbf{D}^u\mathbf{U}\right]} \tag{8}$$

$$\mathbf{H} \leftarrow \mathbf{H} \circ \frac{\left[\mathbf{U}^T\mathbf{X}\mathbf{V}\right]}{\left[\mathbf{U}^T\mathbf{U}\mathbf{H}\mathbf{V}^T\mathbf{V}\right]} \tag{9}$$

$$\mathbf{V} \leftarrow \mathbf{V} \circ \frac{\left[\mathbf{X}^T\mathbf{U}\mathbf{H} + \sigma_2\mathbf{V} + \beta\mathbf{C}^v\mathbf{V}_0 + \delta\mathbf{W}^v\mathbf{V}\right]}{\left[\mathbf{V}\mathbf{H}^T\mathbf{U}^T\mathbf{U}\mathbf{H} + \sigma_2\mathbf{V}\mathbf{V}^T\mathbf{V} + \beta\mathbf{C}^v\mathbf{V} + \delta\mathbf{D}^v\mathbf{V}\right]} \tag{10}$$

where operator $\circ$ *is element-wise product and* $\frac{[\cdot]}{[\cdot]}$ *is element-wise division.*

Based on Theorem 3.1, we note that the multiplicative update rules given by equations (8)∼(10) are obtained by extending the updates of standard NMTF (Ding et al., 2006). A number of techniques can be used here to optimize the objective function in equation (7), such as alternating least squares (Kim and Park, 2008), the active set method (Kim and Park, 2008), and the projected gradients approach (Lin, 2007). Nonetheless, the multiplicative updates derived in this paper has reasonably fast convergence behavior as shown empirically in the experiments.

3.3 Theoretical Analysis

In this subsection, we give the theoretical analysis of the optimization, convergence and computational complexity. Without loss of generality, we only show the optimization of $\mathbf{U}$ and formulate the Lagrange function with constraints as follows:

$$\mathcal{L}(\mathbf{U}) = \left\|\mathbf{X} - \mathbf{U}\mathbf{H}\mathbf{V}^T\right\|_F^2 + \sigma_1\left\|\mathbf{U}^T\mathbf{U} - \mathbf{I}\right\|_F^2 + \alpha\mathrm{Tr}\big[(\mathbf{U}-\mathbf{U}_0)^T\mathbf{C}^u(\mathbf{U}-\mathbf{U}_0)\big] + \mathrm{Tr}(\Psi\mathbf{U}^T) \tag{11}$$

where Ψ is the Lagrange multiplier for the nonnegative constraint $\mathbf{U} \geq \mathbf{0}$.

The partial derivative of $\mathcal{L}(\mathbf{U})$ w.r.t. $\mathbf{U}$ is

$$\begin{aligned}\bigtriangledown_{\mathbf{U}}\mathcal{L}(\mathbf{U}) = &-2\mathbf{X}\mathbf{V}\mathbf{H}^T + 2\mathbf{U}\mathbf{H}\mathbf{V}^T\mathbf{V}\mathbf{H}^T + 2\sigma_1\mathbf{U}\mathbf{U}^T\mathbf{U} - 2\sigma_1\mathbf{U} \\ &+ 2\alpha\mathbf{C}^u\mathbf{U} - 2\alpha\mathbf{C}^u\mathbf{U}_0 + 2\gamma\mathbf{D}^u\mathbf{U} - 2\gamma\mathbf{W}^u\mathbf{U} + \Psi\end{aligned}$$

Using the Karush-Kuhn-Tucker (KKT) (Boyd and Vandenberghe, 2004) condition $\Psi \circ \mathbf{U} = \mathbf{0}$, we can obtain

$$\begin{aligned}\nabla_{\mathbf{U}}\mathcal{L}(\mathbf{U}) \circ \mathbf{U} = &\left[\mathbf{U}\mathbf{H}\mathbf{V}^T\mathbf{V}\mathbf{H}^T + \sigma_1\mathbf{U}\mathbf{U}^T\mathbf{U} + \alpha\mathbf{C}^u\mathbf{U} + \gamma\mathbf{D}^u\mathbf{U}\right] \circ \mathbf{U} \\ &- \left[\mathbf{X}\mathbf{V}\mathbf{H}^T + \sigma_1\mathbf{U} + \alpha\mathbf{C}^u\mathbf{U}_0 + \gamma\mathbf{W}^u\mathbf{U}\right] \circ \mathbf{U} = \mathbf{0}\end{aligned}$$

This leads to the update rule in equation (8). Following the similar derivations as shown above, we can obtain the updating rules for all the other variables $\mathbf{H}$ and $\mathbf{V}$ in GNMTF optimization, as shown in equations (9) and (10).

3.3.1 Convergence Analysis

In this subsection, we prove the convergence of multiplicative updates given by equations (8)$\sim$(10). We first introduce the definition of auxiliary function as follows.

Definition 3.1. *$\mathcal{F}(\mathbf{Y}, \mathbf{Y}')$ is an auxiliary function for $\mathcal{L}(\mathbf{Y})$ if $\mathcal{L}(\mathbf{Y}) \leq \mathcal{F}(\mathbf{Y}, \mathbf{Y}')$ and equality holds if and only if $\mathcal{L}(\mathbf{Y}) = \mathcal{F}(\mathbf{Y}, \mathbf{Y})$.*

Lemma 3.1. *(Lee and Seung, 2001) If $\mathcal{F}$ is an auxiliary function for $\mathcal{L}$, $\mathcal{L}$ is non-increasing under the update $\mathbf{Y}^{(t+1)} = \arg\min_{\mathbf{Y}} \mathcal{F}(\mathbf{Y}, \mathbf{Y}^{(t)})$*

Proof. By Definition 3.1, $\mathcal{L}(\mathbf{Y}^{(t+1)}) \leq \mathcal{F}(\mathbf{Y}^{(t+1)}, \mathbf{Y}^{(t)}) \leq \mathcal{F}(\mathbf{Y}^{(t)}, \mathbf{Y}^{(t)}) = \mathcal{L}(\mathbf{Y}^{(t)})$ □

Theorem 3.2. *Let function*

$$\begin{aligned}\mathcal{F}(\mathbf{U}_{ij}, \mathbf{U}_{ij}^{(t)}) = &\mathcal{L}(\mathbf{U}_{ij}^{(t)}) + \mathcal{L}'(\mathbf{U}_{ij}^{(t)})(\mathbf{U}_{ij} - \mathbf{U}_{ij}^{(t)}) \\ &+ \frac{\left[\mathbf{U}\mathbf{H}\mathbf{V}^T\mathbf{V}\mathbf{H}^T + \sigma_1\mathbf{U}\mathbf{U}^T\mathbf{U} + \alpha\mathbf{C}^u\mathbf{U} + \gamma\mathbf{D}^u\mathbf{U}\right]_{ij}}{\mathbf{U}_{ij}}(\mathbf{U}_{ij} - \mathbf{U}_{ij}^{(t)})\end{aligned} \tag{12}$$

be a proper auxiliary function for $\mathcal{L}(\mathbf{U}_{ij})$, where $\mathcal{L}'(\mathbf{U}_{ij}) = [\nabla_{\mathbf{U}}\mathcal{L}(\mathbf{U})]_{ij}$ is the first-order derivatives of $\mathcal{L}(\mathbf{U}_{ij})$ with respect to $\mathbf{U}_{ij}$.

Theorem 3.2 can be proved similarly to (Ding et al., 2006). Due to limited space, we omit the details of the validation. Based on Lemmas 3.1 and Theorem 3.2, the update rule for $\mathbf{U}$ can be obtained by minimizing $\mathcal{F}(\mathbf{U}_{ij}^{(t+1)}, \mathbf{U}_{ij}^{(t)})$. When setting $\nabla_{\mathbf{U}_{ij}^{(t+1)}}\mathcal{F}(\mathbf{U}_{ij}^{(t+1)}, \mathbf{U}_{ij}^{(t)})$, we can obtain

$$\mathbf{U}_{ij}^{(t+1)} = \mathbf{U}_{ij}^{(t)} \frac{\left[\mathbf{X}\mathbf{V}\mathbf{H}^T + \sigma_1\mathbf{U} + \alpha\mathbf{C}^u\mathbf{U}_0 + \gamma\mathbf{W}^u\mathbf{U}\right]_{ij}}{\left[\mathbf{U}\mathbf{H}\mathbf{V}^T\mathbf{V}\mathbf{H}^T + \sigma_1\mathbf{U}\mathbf{U}^T\mathbf{U} + \alpha\mathbf{C}^u\mathbf{U} + \gamma\mathbf{D}^u\mathbf{U}\right]_{ij}}$$

By Lemma 3.1 and Theorem 3.2, we have $\mathcal{L}(\mathbf{U}^{(0)}) = \mathcal{F}(\mathbf{U}^{(0)}, \mathbf{U}^{(0)}) \geq \mathcal{F}(\mathbf{U}^{(1)}, \mathbf{U}^{(0)}) \geq \mathcal{F}(\mathbf{U}^{(1)}, \mathbf{U}^{(1)}) = \mathcal{L}(\mathbf{U}^{(1)}) \geq \cdots \geq \mathcal{L}(\mathbf{U}^{(Iter)})$, where $Iter$ denotes the number of iteration number. Therefore, $\mathbf{U}$ is monotonically decreasing. Since the objective function $\mathcal{L}$ is lower bounded by 0, the correctness and convergence of Theorem 3.1 is validated.

3.3.2 Time Complexity Analysis

In this subsection, we discuss the time computational complexity of the proposed algorithm GNMTF. Besides expressing the complexity of the algorithm using big O notation, we also count the number of arithmetic operations to provide more details about running time. We show the results in Table 1, where $m \gg k$ and $n \gg k$.

Based on the updating rules summarized in Theorem 3.1, it it not hard to count the arithmetic operators of each iteration in GNMTF. It is important to note that $\mathbf{C}^u$ is a diagonal matrix, the nonzero elements on each row of $\mathbf{C}^u$ is 1. Thus, we only need zero addition and mk multiplications to compute $\mathbf{C}^u\mathbf{U}$. Similarly, for $\mathbf{C}^u\mathbf{U}_0$, $\mathbf{C}^v\mathbf{V}$, $\mathbf{C}^v\mathbf{V}_0$, $\mathbf{D}^u\mathbf{U}$ and $\mathbf{D}^v\mathbf{V}$, we also only need zero addition and mk multiplications for each of them. Besides, we also note that $\mathbf{W}^u$ is a sparse matrix, if we use a p-nearest neighbor graph, the average nonzero elements on each row of $\mathbf{W}^u$ is p. Thus, we only need mpk additions and mpk multiplications to compute $\mathbf{W}^u\mathbf{U}$. Similarly, for $\mathbf{W}^v\mathbf{V}$, we need the same operation counts as $\mathbf{W}^u\mathbf{U}$. Suppose the multiplicative updates stop after $Iter$ iterations, the time cost of multiplicative updates then becomes $O(Iter \times mnk)$. Therefore, the overall running time of GNMTF is similar to the standard NMTF and CNMTF.

	addition	multiplication	division	overall
GNMTF: $\mathbf{U}$	$2k^3 + (2m+n)k^2 + m(n+p)k$	$2k^3 + (2m+n)k^2 + m(n+p+7)k$	mk	$O(mnk)$
GNMTF: $\mathbf{H}$	$2k^3 + (m+n+2)k^2 + mnk$	$2k^3 + (m+n+1)k^2 + mnk$	k^2	$O(mnk)$
GNMTF: $\mathbf{V}$	$2k^3 + (2n+m)k^2 + n(m+p)k$	$2k^3 + (2n+m)k^2 + n(m+p+7)k$	nk	$O(mnk)$

Table 1: Computational operation counts for each iteration in GNMTF.

4 Experiments

4.1 Data Sets

Sentiment classification has been extensively studied in the literature. Among these, a large majority proposed experiments performed on the benchmarks made of Movies Reviews (Pang et al., 2002) and Amazon products (Blitzer et al., 2007).

Movies data This data set has been widely used for sentiment analysis in the literature (Pang et al., 2002), which consists of 1000 positive and 1000 negative reviews drawn from the IMDB archive of rec.arts.movies.reviews.newsgroups.

Amazon data This data set is heterogeneous, heavily unbalanced and large-scale, a smaller version has been released. The reduced data set contains 4 product types: Kitchen, Books, DVDs, and Electronics (Blitzer et al., 2007). There are 4000 positive and 4000 negative reviews.[1]

For these two data sets, we select 8000 words with highest document-frequency to generate the vocabulary. Stopwords[2] are removed and a normalized term-frequency representation is used. In order to construct the lexical prior knowledge matrix $\mathbf{U}_0$, we use the sentiment lexicon generated by (Hu and Liu, 2004). It contains 2,006 positive words (e.g., "beautiful") and 4,783 negative words (e.g., "upset").

4.2 Unsupervised Sentiment Classification

Our first experiment is to explore the benefits of incorporating the geometric information in the unsupervised paradigm (that is $\mathbf{C}^v = \mathbf{0}$). Therefore, the third part in equation (7) will be ignored. For this unsupervised paradigm of GNMTF, we empirically set $\alpha = \delta = \gamma = 1$, $\sigma_1 = \sigma_2 = 1$, $Iter = 100$ and run GNMTF 10 repeated times to remove any randomness caused by the random initialization. Due to limited space, we do not present the impacts of the parameters on the learning model. Now we compare our proposed GNMTF with the following four categories of methods:

(1) Lexicon-Based Methods (LBM in short): Taboada et al. (2011) proposed to incorporate intensification and negation to refine the sentiment score for each document. This is the state-of-the-art lexicon-based method for unsupervised sentiment classification.

(2) Document Clustering Methods: We choose the most representative cluster methods, K-means, NMTF, Information-Theoretic Co-clustering (ITCC) (Dhillon et al., 2003), and Euclidean Co-clustering method (ECC) (Cho et al., 2004). We set the number of clusters as two in these methods. Note that all these methods do not make use of the sentiment lexicon.

(3) Constrained NMTF (CNMTF in short): Li et al. (2009) incorporated the sentiment lexicon into NMTF as a domain-independent prior constraint.

(4) Graph co-regularized Non-negative Matrix Tri-factorization (GNMTF in short): It is a new algorithm proposed in this paper. We use cosine similarity for constructing the p-nearest neighbor graph for its simplicity. The number of nearest neighbor p is set to 10 empirically both on document and word spaces.

4.2.1 Sentiment Classification Results

The experimental results are reported in Table 2. We perform a significant test, i.e., a t-test with a default significant level of 0.05. From Table 2, we can see that (1) Both CNMTF and GNMTF consider the lexical prior knowledge from off-the-shelf sentiment lexicon and achieve better performance than NMTF. This suggests the importance of the lexical prior knowledge in learning the sentiment classification (row

#	Methods	Movies	Amazon
1	LBM	0.632	0.580
2	K-means	0.543 (-8.9%)	0.535 (-4.5%)
3	NMTF	0.561 (-7.1%)	0.547 (-3.3%)
4	ECC	0.678 (+4.6%)	0.642 (+6.2%)
5	ITCC	0.714 (+8.2%)	0.655 (+7.5%)
6	CNMTF	0.695 (+6.3%)	0.658 (+7.8%)
7	**GNMTF**	**0.736 (+10.4%)**	**0.705 (+12.5%)**

Table 2: Sentiment classification accuracy of unsupervised paradigm on the data sets. Improvements of K-means, NMTF, ITCC, ECC, CNMTF and GNMTF over baseline LBM are shown in parentheses.

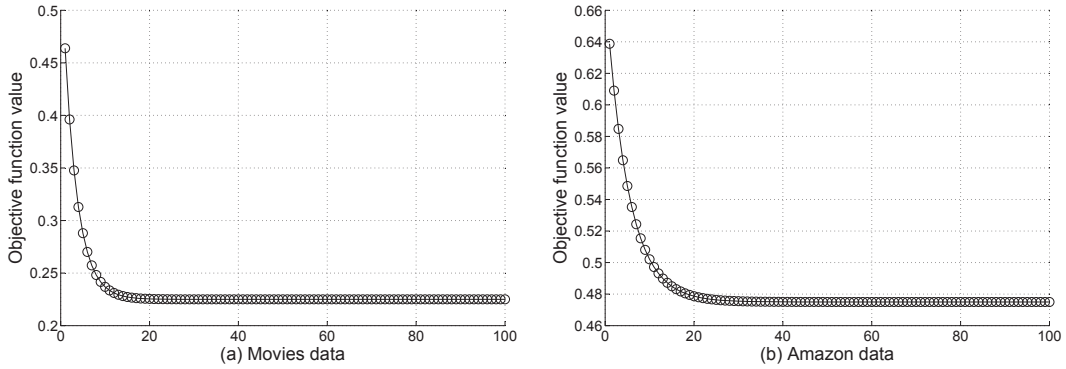

Figure 1: Convergence curves of GNMTF on both data sets.

3 vs. row 6 and row 7); (2) Regardless of the data sets, our GNMTF significantly outperforms state-of-the-art CNMTF and achieves the best performance. This shows the superiority of geometric information and graph co-regularization framework (row 4 vs. row 5, the improvements are statistically significant at $p < 0.05$).

4.2.2 Convergence Behavior

In subsection 3.3.1, we have shown that the multiplicative updates given by equations (8)$\sim$(10) are convergent. Here, we empirically show the convergence behavior of GNMTF.

Figure 1 shows the convergence curves of GNMTF on Movies and Amazon data sets. From the figure, y-axis is the value of objective function and x-axis denotes the iteration number. We can see that the multiplicative updates for GNMTF converge very fast, usually within 50 iterations.

4.3 Semi-supervised Sentiment Classification

In this subsection, we describe our proposed GNMTF with a few labeled documents. For this semi-supervised paradigm of GNMTF, we empirically set $Iter = 100$, $\sigma_1 = \sigma_2 = 2$, $\alpha = \beta = \delta = \gamma = 1$ and $p = 10$ on document and word spaces and also run 10 repeated times to remove any randomness caused by the random initialization. Due to limited space, we do not give an in-depth parameter analysis. For CNMTF, we set $\alpha = \beta = 1$ for fair comparison. We also compare our proposed GNMTF with some representative semi-supervised approaches described in (Li et al., 2009): (1) Semi-supervised learning with local and global consistency (Consistency Method in short) (Zhou et al., 2004); (2) Semi-supervised learning using gaussian fields and harmonic functions (GFHF in short) (Zhu et al., 2003). Besides, we also compare the results of our proposed GNMTF with the representative supervised classification method: support vector machine (SVM), which has been widely used in sentiment classification (Pang et al., 2002).

The results are presented in Figure 2. From the figure, we can see that GNMTF outperforms other methods over the entire range of number of labeled documents on both data sets. By this observation, we can conclude that taking the geometric information can still improve the sentiment classification accuracy in semi-supervised paradigm.

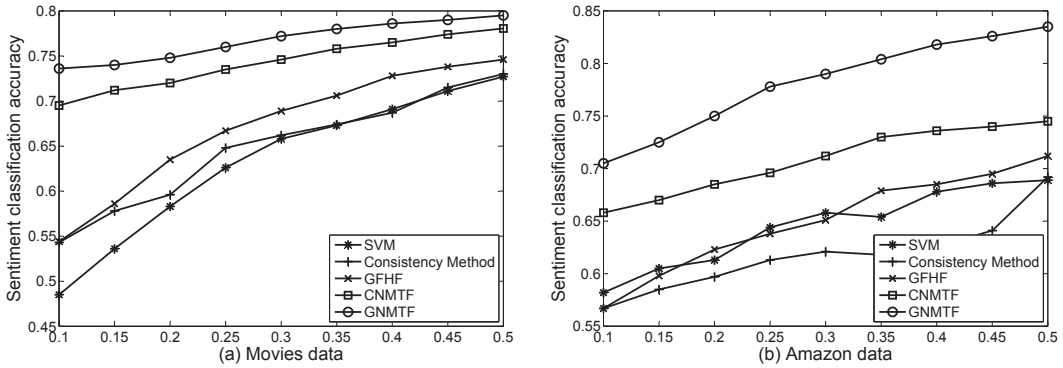

Figure 2: Sentiment classification accuracy vs. different percentage of labeled documents, where x-axis denotes the number of documents labeled as a fraction of the original labeled documents.

5 Related Work

Sentiment classification has gained widely interest in NLP community, we point the readers to recent books (Pang and Lee, 2008; Liu, 2012) for an in-depth survey of literature on sentiment analysis.

Methods for automatically classifying sentiments expressed in products and movie reviews can roughly be divided into supervised and unsupervised (or semi-supervised) sentiment analysis. Supervised techniques have been proved promising and widely used in sentiment classification (Pang et al., 2002; Pang and Lee, 2008; Liu, 2012). However, the performance of these methods relies on manually labeled training data. In some cases, the labeling work may be time-consuming and expensive. This motivates the problem of learning robust sentiment classification via unsupervised (or semi-supervised) paradigm.

The most representative way to perform semi-supervised paradigm is to employ partial labeled data to guide the sentiment classification (Goldberg and Zhu, 2006; Sindhwani and Melville, 2008; Wan, 2009; Li et al., 2011). However, we do not have any labeled data at hand in many situations, which makes the unsupervised paradigm possible. The most representative way to perform unsupervised paradigm is to use a sentiment lexicon to guide the sentiment classification (Turney, 2002; Taboada et al., 2011) or learn sentiment orientation via a matrix factorization clustering framework (Li et al., 2009; **?**; Hu et al., 2013). In contrast, we perform sentiment classification with the different model formulation and learning algorithm, which considers both word-level and document-level sentiment-related contextual information (e.g., the neighboring words or documents tend to share the same sentiment polarity) into a unified framework. The proposed framework makes use of the valuable geometric information to compensate the problem of lack of labeled data for sentiment classification. In addition, some researchers also explored the matrix factorization techniques for other NLP tasks, such as relation extraction (Peng and Park, 2013) and question answering (Zhou et al., 2013)

Besides, many studies address some other aspects of sentiment analysis, such as cross-domain sentiment classification (Blitzer et al., 2007; Pan et al., 2010; Hu et al., 2011; Bollegala et al., 2011; Glorot et al., 2011), cross-lingual sentiment classification (Wan, 2009; Lu et al., 2011b; Meng et al., 2012) and imbalanced sentiment classification (Li et al., 2011), which are out of scope of this paper.

6 Conclusion and Future Work

In this paper, we propose a novel algorithm, called graph co-regularized non-negative matrix tri-factorization (GNMTF), from a geometric perspective. GNMTF assumes that if two words (or documents) are sufficiently close to each other, they tend to share the same sentiment polarity. To achieve this, we encode the geometric information by constructing the nearest neighbor graphs, in conjunction with a non-negative matrix tri-factorization framework. We derive an efficient algorithm for learning the factorization, analyze its complexity, and provide proof of convergence. Our empirical study on two open data sets validates that GNMTF can consistently improve the sentiment classification accuracy in comparison to state-of-the-art methods.

There are some ways in which this research could be continued. First, some other ways should be considered to construct the graphs (e.g., hyperlinks between documents, synonyms or co-occurrences between words). Second, we will try to extend the proposed framework for other aspects of sentiment analysis, such as cross-domain or cross-lingual settings.

Abstract

In this paper, we develop a novel semi-supervised learning algorithm called hybrid deep belief networks (HDBN), to address the semi-supervised sentiment classification problem with deep learning. First, we construct the previous several hidden layers using restricted Boltzmann machines (RBM), which can reduce the dimension and abstract the information of the reviews quickly. Second, we construct the following hidden layers using convolutional restricted Boltzmann machines (CRBM), which can abstract the information of reviews effectively. Third, the constructed deep architecture is fine-tuned by gradient-descent based supervised learning with an exponential loss function. We did several experiments on five sentiment classification datasets, and show that HDBN is competitive with previous semi-supervised learning algorithm. Experiments are also conducted to verify the effectiveness of our proposed method with different number of unlabeled reviews.

1 Introduction

Recently, more and more people write reviews and share opinions on the World Wide Web, which present a wealth of information on products and services (Liu et al., 2010). These reviews will not only help other users make better judgements but they are also useful resources for manufacturers of products to keep track and manage customer opinions (Wei and Gulla, 2010). However, there are large amount of reviews for every topic, it is difficult for a user to manually learn the opinions of an interesting topic. Sentiment classification, which aims to classify a text according to the expressed sentimental polarities of opinions such as '*positive*' or '*negtive*', '*thumb up*' or '*thumb down*', '*favorable*' or '*unfavorable*' (Li et al., 2010), can facilitate the investigation of corresponding products or services.

In order to learn a good text classifier, a large number of labeled reviews are often needed for training (Zhen and Yeung, 2010). However, labeling reviews is often difficult, expensive or time consuming (Chapelle et al., 2006). On the other hand, it is much easier to obtain a large number of unlabeled reviews, such as the growing availability and popularity of online review sites and personal blogs (Pang and Lee, 2008). In recent years, a new approach called semi-supervised learning, which uses large amount of unlabeled data together with labeled data to build better learners (Zhu, 2007), has been developed in the machine learning community.

There are several works have been done in semi-supervised learning for sentiment classification, and get competitive performance (Li et al., 2010; Dasgupta and Ng, 2009; Zhou et al., 2010). However, most of the existing semi-supervised learning methods are still far from satisfactory. As shown by several researchers (Salakhutdinov and Hinton, 2007; Hinton et al., 2006), deep architecture, which composed of multiple levels of non-linear operations, is expected to perform well in semi-supervised learning because of its capability of modeling hard artificial intelligent tasks. Deep belief networks (DBN) is a representative deep learning algorithm achieving notable success for text classification, which is a directed belief nets with many hidden layers constructed by restricted Boltzmann machines (RBM), and refined by a gradient-descent based supervised learning (Hinton et al., 2006). Ranzato and Szummer (Ranzato and

Proceedings of COLING 2014, the 25th International Conference on Computational Linguistics: Technical Papers, pages 1341–1349, Dublin, Ireland, August 23-29 2014.

Szummer, 2008) propose an algorithm to learn text document representations based on semi-supervised auto-encoders that are combined to form a deep network. Zhou et al. (Zhou et al., 2010) propose a novel semi-supervised learning algorithm to address the semi-supervised sentiment classification problem with active learning. The key issue of traditional DBN is the efficiency of RBM training. Convolutional neural networks (CNN), which are specifically designed to deal with the variability of two dimensional shapes, have had great success in machine learning tasks and represent one of the early successes of deep learning (LeCun et al., 1998). Desjardins and Bengio (Desjardins and Bengio, 2008) adapt RBM to operate in a convolutional manner, and show that the convolutional RBM (CRBM) are more efficient than standard RBM.

CRBM has been applied successfully to a wide range of visual and audio recognition tasks (Lee et al., 2009a; Lee et al., 2009b). Though the success of CRBM in addressing two dimensional issues, there is still no published research on the using of CRBM in textual information processing. In this paper, we propose a novel semi-supervised learning algorithm called hybrid deep belief networks (HDBN), to address the semi-supervised sentiment classification problem with deep learning. HDBN is a hybrid of RBM and CRBM deep architecture, the bottom layers are constructed by RBM, and the upper layers are constructed by CRBM, then the whole constructed deep architecture is fine tuned by a gradient-descent based supervised learning based on an exponential loss function.

The remainder of this paper is organized as follows. In Section 2, we introduce our semi-supervised learning method HDBN in details. Extensive empirical studies conducted on five real-world sentiment datasets are presented in Section 3. Section 4 concludes our paper.

2 Hybrid deep belief networks

2.1 Problem formulation

The sentiment classification dataset composed of many review documents, each review document composed of a bag of words. To classify these review documents using corpus-based approaches, we need to preprocess them in advance. The preprocess method for these reviews is similar with (Zhou et al., 2010). We tokenize and downcase each review and represent it as a vector of unigrams, using binary weight equal to 1 for terms present in a vector. Moreover, the punctuations, numbers, and words of length one are removed from the vector. Finally, we combine all the words in the dataset, sort the vocabulary by document frequency and remove the top 1.5%, because many of these high document frequency words are stopwords or domain specific general-purpose words.

After preprocess, each review can be represented as a vector of binary weight $\mathbf{x}^i$. If the j^{th} word of the vocabulary is in the i^{th} review, $\mathbf{x}_j^i = 1$; otherwise, $\mathbf{x}_j^i = 0$. Then the dataset can be represented as a matrix:

$$\mathbf{X} = \left[\mathbf{x}^1, \mathbf{x}^2, \ldots, \mathbf{x}^{R+T}\right] = \begin{bmatrix} x_1^1, x_1^2, \ldots, x_1^{R+T} \\ x_2^1, x_2^2, \ldots, x_2^{R+T} \\ \vdots, \vdots, \ldots, \vdots \\ x_D^1, x_D^2, \ldots, x_D^{R+T} \end{bmatrix} \tag{1}$$

where R is the number of training reviews, T is the number of test reviews, D is the number of feature words in the dataset. Every column of $\mathbf{X}$ corresponds to a sample $\mathbf{x}$, which is a representation of a review. A sample that has all features is viewed as a vector in $\mathbb{R}^D$, where the i^{th} coordinate corresponds to the i^{th} feature.

The L labeled reviews are chosen randomly from R training reviews, or chosen actively by active learning, which can be seen as:

$$\mathbf{X}^L = \mathbf{X}^R(\mathbf{S}),\ \mathbf{S} = [s_1,\ ...,\ s_L],\ 1 \le s_i \le R \tag{2}$$

where $\mathbf{S}$ is the index of selected training reviews to be labeled manually.

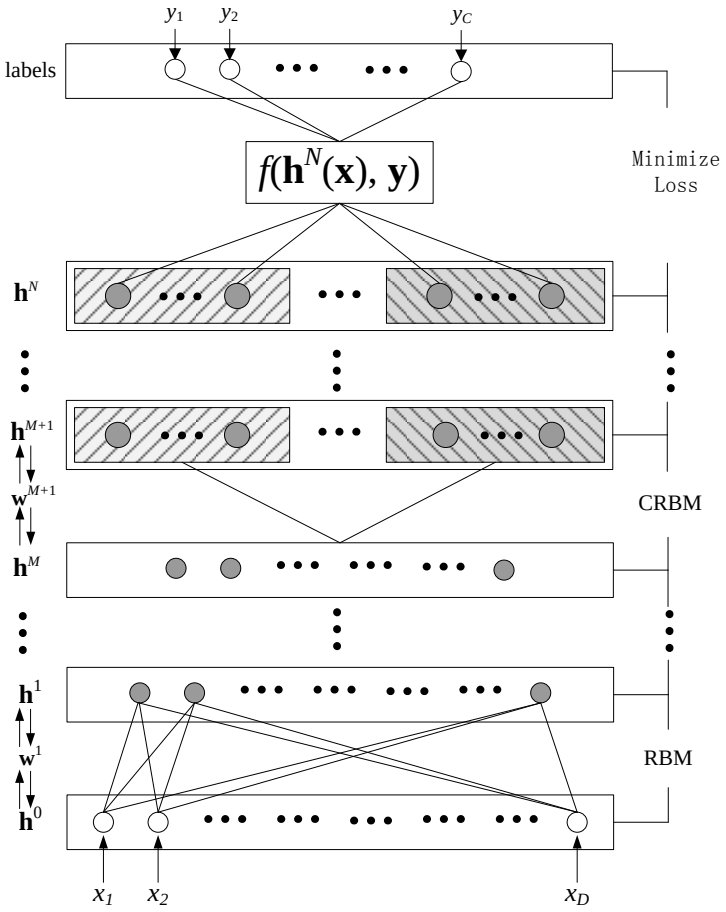

Figure 1: Architecture of HDBN.

The L labels correspond to L labeled training reviews is denoted as:

$$\mathbf{Y}^L = \left[\mathbf{y}^1, \mathbf{y}^2, \ldots, \mathbf{y}^L\right] = \begin{bmatrix} y_1^1, y_1^2, \ldots, y_1^L \\ y_2^1, y_2^2, \ldots, y_2^L \\ \vdots, \vdots, \ldots, \vdots \\ y_C^1, y_C^2, \ldots, y_C^L \end{bmatrix} \tag{3}$$

where C is the number of classes. Every column of $\mathbf{Y}$ is a vector in $\mathbb{R}^C$, where the j^{th} coordinate corresponds to the j^{th} class.

$$y_j^i = \begin{cases} 1 & \text{if } \mathbf{x}^i \in j^{\text{th}} \text{ class} \\ -1 & \text{if } \mathbf{x}^i \notin j^{\text{th}} \text{ class} \end{cases} \tag{4}$$

For example, if a review $\mathbf{x}^i$ is positive, $\mathbf{y}^i = [1, -1]'$; otherwise, $\mathbf{y}^i = [-1, 1]'$.

We intend to seek the mapping function $\mathbf{X} \rightarrow \mathbf{Y}$ using the L labeled data and all unlabeled data. After training, we can determine $\mathbf{y}$ using the mapping function when a new sample $\mathbf{x}$ comes.

2.2 Architecture of HDBN

In this part, we propose a novel semi-supervised learning method HDBN to address the problem formulated in Section 2.1. The sentiment datasets have high dimension (about 10,000), and computation complexity of convolutional calculation is relatively high, so we use RBM to reduce the dimension of review with normal calculation firstly. Fig. 1 shows the deep architecture of HDBN, a fully interconnected directed belief nets with one input layer $\mathbf{h}^0$, N hidden layers $\mathbf{h}^1, \mathbf{h}^2, ..., \mathbf{h}^N$, and one label layer at the top. The input layer $\mathbf{h}^0$ has D units, equal to the number of features of sample review $\mathbf{x}$. The hidden

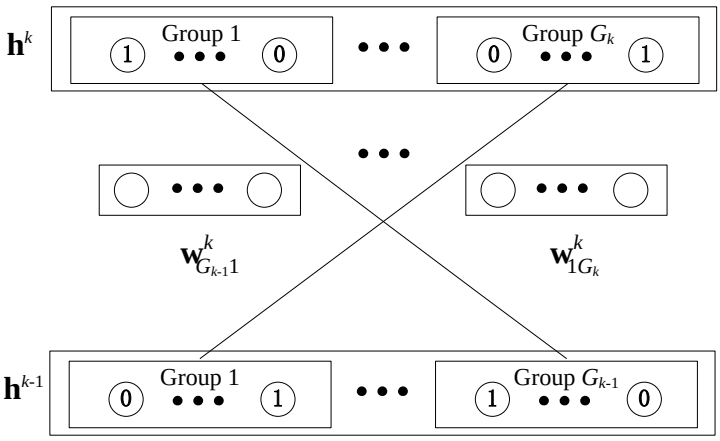

Figure 2: Architecture of CRBM.

layer has M layers constructed by RBM and $N-M$ layers constructed by CRBM. The label layer has C units, equal to the number of classes of label vector $\mathbf{y}$. The numbers of hidden layers and the number of units for hidden layers, currently, are pre-defined according to the experience or intuition. The seeking of the mapping function $\mathbf{X} \rightarrow \mathbf{Y}$, here, is transformed to the problem of finding the parameter space $\mathbf{W} = \{\mathbf{w}^1, \mathbf{w}^2, \ldots, \mathbf{w}^N\}$ for the deep architecture.

The training of the HDBN can be divided into two stages:

1. HDBN is constructed by greedy layer-wise unsupervised learning using RBMs and CRBMs as building blocks. L labeled data and all unlabeled data are utilized to find the parameter space $\mathbf{W}$ with N layers.

2. HDBN is trained according to the exponential loss function using gradient descent based supervised learning. The parameter space $\mathbf{W}$ is refined using L labeled data.

2.3 Unsupervised learning

As show in Fig. 1, we construct HDBN layer by layer using RBMs and CRBMs, the details of RBM can be seen in (Hinton et al., 2006), and CRBM is introduced below.

The architecture of CRBM can be seen in Fig. 2, which is similar to RBM, a two-layer recurrent neural network in which stochastic binary input groups are connected to stochastic binary output groups using symmetrically weighted connections. The top layer represents a vector of stochastic binary hidden feature $\mathbf{h}^k$ and the bottom layer represents a vector of binary visible data $\mathbf{h}^{k-1}$, $k = M+1, ..., N$. The k^{th} layer consists of G_k groups, where each group consists of D_k units, resulting in $G_k \times D_k$ hidden units. The layer $\mathbf{h}^M$ is consist of 1 group and D_M units. $\mathbf{w}^k$ is the symmetric interaction term connecting corresponding groups between data $\mathbf{h}^{k-1}$ and feature $\mathbf{h}^k$. However, comparing with RBM, the weights of CRBM between the hidden and visible groups are shared among all locations (Lee et al., 2009a), and the calculation is operated in a convolutional manner (Desjardins and Bengio, 2008).

We define the energy of the state $(\mathbf{h}^{k-1}, \mathbf{h}^k)$ as:

$$E\left(\mathbf{h}^{k-1}, \mathbf{h}^k; \theta\right) = -\sum_{s=1}^{G_{k-1}} \sum_{t=1}^{G_k} (\tilde{w}^k_{st} * h^{k-1}_s) \bullet h^k_t - \sum_{s=1}^{G_{k-1}} b^{k-1}_s \sum_{u=1}^{D_{k-1}} h^{k-1}_s - \sum_{t=1}^{G_k} c^k_t \sum_{v=1}^{D_k} h^k_t \qquad (5)$$

where $\theta = (\mathbf{w}, \mathbf{b}, \mathbf{c})$ are the model parameters: w^k_{st} is a filter between unit s in the layer $\mathbf{h}^{k-1}$ and unit t in the layer $\mathbf{h}^k$, $k = M+1, ..., N$. The dimension of the filter w^k_{st} is equal to $D_{k-1} - D_k + 1$. b^{k-1}_s is the s^{th} bias of layer $\mathbf{h}^{k-1}$ and c^k_t is the t^{th} bias of layer $\mathbf{h}^k$. A tilde above an array ($\tilde{w}$) denote flipping the array, $*$ denote valid convolution, and $\bullet$ denote element-wise product followed by summation, i.e., $A \bullet B = trA^T B$ (Lee et al., 2009a).

Similar to RBM, Gibbs sampler can be performed based on the following conditional distribution.

The probability of turning on unit v in group t is a logistic function of the states of $\mathbf{h}^{k-1}$ and w_{st}^k:

$$p\left(h_{t,v}^k = 1|\mathbf{h}^{k-1}\right) = \text{sigm}\left(c_t^k + (\sum_s \tilde{w}_{st}^k * h_s^{k-1})_v\right) \tag{6}$$

The probability of turning on unit u in group s is a logistic function of the states of $\mathbf{h}^k$ and w_{st}^k:

$$p\left(h_{s,u}^{k-1} = 1|\mathbf{h}^k\right) = \text{sigm}\left(b_s^{k-1} + (\sum_t w_{st}^k \star h_t^k)_u\right) \tag{7}$$

A star $\star$ denote full convolution.

2.4 Supervised learning

In HDBN, we construct the deep architecture using all labeled reviews with unlabeled reviews by inputting them one by one from layer $\mathbf{h}^0$. The deep architecture is constructed layer by layer from bottom to top, and each time, the parameter space $\mathbf{w}^k$ is trained by the calculated data in the $k-1^{th}$ layer.

Algorithm 1: Algorithm of HDBN

Input: data $\mathbf{X}$, $\mathbf{Y}^L$
number of training data R; number of test data T;
number of layers N; number of epochs Q;
number of units in every hidden layer $D_1 ... D_N$;
number of groups in every convolutional hidden layer $G_M ... G_N$;
hidden layer $\mathbf{h}^1, \ldots, \mathbf{h}^M$;
convolutional hidden layer $\mathbf{h}^{M+1}, \ldots, \mathbf{h}^{N-1}$;
parameter space $\mathbf{W} = \{\mathbf{w}^1, \ldots, \mathbf{w}^N\}$;
biases $\mathbf{b}$, $\mathbf{c}$; momentum ϑ and learning rate η;
Output: deep architecture with parameter space $\mathbf{W}$
1. Greedy layer-wise unsupervised learning
for $k = 1; k \leq N-1$ **do**
  for $q = 1; q \leq Q$ **do**
    for $r = 1; r \leq R+T$ **do**
      Calculate the non-linear positive and negative phase:
      if $k \leq M$ **then**
        Normal calculation.
      else
        Convolutional calculation according to Eq. 6 and Eq. 7.
      end
      Update the weights and biases:
      $w_{st}^k = \vartheta w_{st}^k + \eta\left(\left\langle h_{s,r}^{k-1} h_{t,r}^k \right\rangle_{P_0} - \left\langle h_{s,r}^{k-1} h_{t,r}^k \right\rangle_{P_1}\right)$
    end
  end
end
2. Supervised learning based on gradient descent
$\arg\min_W \sum_{i=1}^{L}\sum_{j=1}^{C} \exp(-h^N(x_j^i) y_j^i)$

According to the $\mathbf{w}^k$ calculated by RBM and CRBM, the layer $\mathbf{h}^k, k = 1, \ldots, M$ can be computed as following when a sample $\mathbf{x}$ inputs from layer $\mathbf{h}^0$:

$$h_t^k(\mathbf{x}) = \text{sigm}\left(c_t^k + \sum_{s=1}^{D_{k-1}} w_{st}^k h_s^{k-1}(\mathbf{x})\right), t = 1, \ldots, D_k \tag{8}$$

When $k = M+1, \ldots, N-1$, the layer $\mathbf{h}^k$ can be represented as:

$$h_t^k(\mathbf{x}) = \mathrm{sigm}\left(c_t^k + \sum_{s=1}^{G_{k-1}} \tilde{w}_{st}^k * h_s^{k-1}(\mathbf{x})\right), t = 1, \ldots, G_k \tag{9}$$

The parameter space $\mathbf{w}^N$ is initialized randomly, just as backpropagation algorithm.

$$h_t^N(\mathbf{x}) = c_t^N + \sum_{s=1}^{G_{N-1} \times D_{N-1}} w_{st}^N h_s^{N-1}(\mathbf{x}),\ t = 1, \ldots, D_N \tag{10}$$

After greedy layer-wise unsupervised learning, $\mathbf{h}^N(\mathbf{x})$ is the representation of $\mathbf{x}$. Then we use L labeled reviews to refine the parameter space $\mathbf{W}$ for better discriminative ability. This task can be formulated as an optimization problem:

$$\arg\min_{\mathbf{W}} \quad \mathrm{f}\left(h^N\left(\mathbf{X}^L\right), \mathbf{Y}^L\right) \tag{11}$$

where

$$\mathrm{f}\left(h^N\left(\mathbf{X}^L\right), \mathbf{Y}^L\right) = \sum_{i=1}^{L}\sum_{j=1}^{C} \mathrm{T}\left(h_j^N\left(\mathbf{x}^i\right) y_j^i\right) \tag{12}$$

and the loss function is defined as

$$T(r) = \exp(-r) \tag{13}$$

We use gradient-descent through the whole HDBN to refine the weight space. In the supervised learning stage, the stochastic activities are replaced by deterministic, real valued probabilities.

2.5 Classification using HDBN

The training procedure of HDBN is given in Algorithm 1. For the training of HDBN architecture, the parameters are random initialized with normal distribution. All the reviews in the dataset are used to train the HDBN with unsupervised learning. After training, we can determine the label of the new data through:

$$\arg\max_j h^N(\mathbf{x}) \tag{14}$$

3 Experiments

3.1 Experimental setup

We evaluate the performance of the proposed HDBN method using five sentiment classification datasets. The first dataset is MOV (Pang et al., 2002), which is a classical movie review dataset. The other four datasets contain products reviews come from the multi-domain sentiment classification corpus, including books (BOO), DVDs (DVD), electronics (ELE), and kitchen appliances (KIT) (Blitzer et al., 2007). Each dataset contains 1,000 positive and 1,000 negative reviews.

The experimental setup is same as (Zhou et al., 2010). We divide the 2,000 reviews into ten equal-sized folds randomly, maintaining balanced class distributions in each fold. Half of the reviews in each fold are random selected as training data and the remaining reviews are used for test. Only the reviews in the training data set are used for the selection of labeled reviews by active learning. All the algorithms are tested with cross-validation.

We compare the classification performance of HDBN with four representative semi-supervised learning methods, i.e., semi-supervised spectral learning (Spectral) (Kamvar et al., 2003), transductive SVM (TSVM) (Collobert et al., 2006), deep belief networks (DBN) (Hinton et al., 2006), and personal/impersonal views (PIV) (Li et al., 2010). Spectral learning, TSVM methods are two baseline methods for sentiment classification. DBN (Hinton et al., 2006) is the classical deep learning method proposed recently. PIV (Li et al., 2010) is a new sentiment classification method proposed recently.

Table 1: HDBN structure used in experiment.

Dataset	Structure
MOV	100-100-4-2
KIT	50-50-3-2
ELE	50-50-3-2
BOO	50-50-5-2
DVD	50-50-5-2

Table 2: Test accuracy with 100 labeled reviews for semi-supervised learning.

Type	MOV	KIT	ELE	BOO	DVD
Spectral	67.3	63.7	57.7	55.8	56.2
TSVM	68.7	65.5	62.9	58.7	57.3
DBN	71.3	72.6	73.6	64.3	66.7
PIV	-	**78.6**	70.0	60.1	49.5
HDBN	**72.2**	74.8	**73.8**	**66.0**	**70.3**

3.2 Performance of HDBN

The HDBN architecture used in all our experiments have 2 normal hidden layer and 1 convolutional hidden layer, every hidden layer has different number of units for different sentiment datasets. The deep structure used in our experiments for different datasets can be seen in Table 1. For example, the HDBN structure used in MOV dataset experiment is 100-100-4-2, which represents the number of units in 2 normal hidden layers are 100, 100 respectively, and in output layer is 2, the number of groups in 1 convolutional hidden layer is 4. The number of unit in input layer is the same as the dimensions of each datasets. For greedy layer-wise unsupervised learning, we train the weights of each layer independently with the fixed number of epochs equal to 30 and the learning rate is set to 0.1. The initial momentum is 0.5 and after 5 epochs, the momentum is set to 0.9. For supervised learning, we run 30 epochs, three times of linear searches are performed in each epoch.

The test accuracies in cross validation for five datasets and five methods with semi-supervised learning are shown in Table 2. The results of previous two methods are reported by (Dasgupta and Ng, 2009). The results of DBN method are reported by (Zhou et al., 2010). Li et al. (Li et al., 2010) reported the results of PIV method. The result of PIV on MOV dataset is empty, because (Li et al., 2010) did not report it. HDBN is the proposed method.

Through Table 2, we can see that HDBN gets most of the best results except on KIT dataset, which is just slight worse than PIV method. However, the preprocess of PIV method is much more complicated than HDBN, and the PIV results on other datasets are much worse than HDBN method. HDBN method is adjusted by DBN, all the experiment results on five datasets for HDBN are better than DBN. This could be contributed by the convolutional computation in HDBN structure, and proves the effectiveness of our proposed method.

3.3 Performance with variance of unlabeled data

To verify the contribution of unlabeled reviews for our proposed method, we did several experiments with fewer unlabeled reviews and 100 labeled reviews.

The test accuracies of HDBN with different number of unlabeled reviews and 100 labeled reviews on five datasets are shown in Fig. 3. The architectures for HDBN used in this experiment are same as Section 3.2 too, which can be seen in Table 1. We can see that the performance of HDBN is much worse when just using 400 unlabeled reviews. However, when using more than 1200 unlabeled reviews, the performance of HDBN is improved obviously. For most of review datasets, the accuracy of HDBN with 1200 unlabeled reviews is close to the accuracy with 1600 and 2000 unlabeled reviews. This proves that HDBN can get competitive performance with just few labeled reviews and appropriate number of

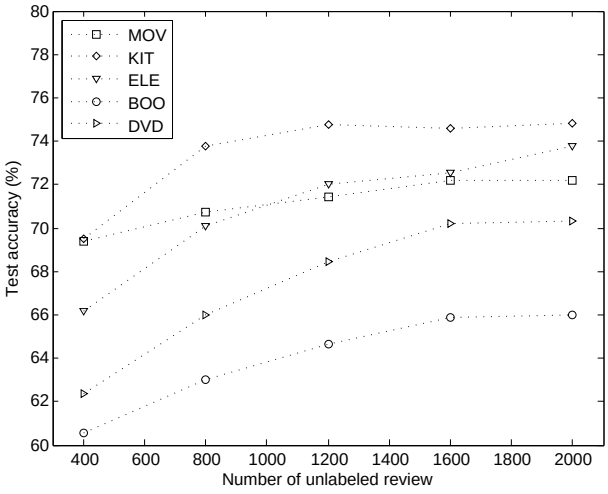

Figure 3: Test accuracy of HDBN with different number of unlabeled reviews on five datasets.

unlabeled reviews. Considering the much time needed for training with more unlabeled reviews and less accuracy improved for HDBN method, we suggest using appropriate number of unlabeled reviews in real application.

4 Conclusions

In this paper, we propose a novel semi-supervised learning method, HDBN, to address the sentiment classification problem with a small number of labeled reviews. HDBN seamlessly incorporate convolutional computation into the DBN architecture, and use CRBM to abstract the review information effectively. To the best of our knowledge, HDBN is the first work that uses convolutional neural network to improve sentiment classification performance. One promising property of HDBN is that it can effectively use the distribution of large amount of unlabeled data, together with few label information in a unified framework. In particular, HDBN can greatly reduce the dimension of reviews through RBM and abstract the information of reviews through the cooperate of RBM and CRBM. Experiments conducted on five sentiment datasets demonstrate that HDBN outperforms state-of-the-art semi-supervised learning algorithms, such as SVM and DBN based methods, using just few labeled reviews, which demonstrate the effective of deep architecture for sentiment classification.

Latent Dynamic Model with Category Transition Constraint for Opinion Classification

Takeshi S. Kobayakawa
NHK / 1-10-11 Kinuta, Setagaya-ku, Tokyo 157-8510, JAPAN
kobayakawa.t-ko@nhk.or.jp

Abstract

Latent models for opinion classification are studied. Training a probabilistic model with a number of latent variables is found unstable in some cases; thus this paper presents how to construct a stable model for opinion classification by constraining classification transitions. The baseline model is a CRF classification model with plural latent variables, dynamically constructed from the dependency parsed tree. The aim of the baseline model is to have each latent variable convey a partial sentiment of the input sentence which is not explicitly given in the training data, and the complete sentiment of the sentence is computed by summing up such partial sentiment where those latent variables hold. Since such a conventional model has many degeneracies in principle, a model with a category transition constraint is proposed, which is expressed by a novel penalty term in the objective function for training the model. The constraint is such that the sentiment of a partial sentence more likely propagates to the same sentiment of the complete sentence, rather than to another sentiment. The effectiveness and the robustness of the proposed model are confirmed by the experiments on binary as well as multi-class opinion classification task.

1 Introduction

Opinion classification is a task to classify sentences into given categories, according to sentiment, evaluation, or some opinion-related points of view. A practical implementation of opinion classification would be very useful for managing customer relationships at contact centers, etc. The classification problem may be binary or sometimes multi-class.

One of the simplest modeling process is to use explicit bag features, such as word surfaces, polarity information from the sentiment dictionary, etc. Thanks to the good behavior of the Maximum Entropy or the Conditional Random Field (CRF) model, the maximum likelihood training is straight-forward, because the local optimum is always the global optimum.

A challenge is to introduce into the model latent variables, which are not explicitly observable. The implicit modeling here is supposed to express ambiguities of natural language; the partial sentiment of the sentence is not determined until the end of the sentence. This paper presents in detail a probabilistic model with latent variables. The baseline model is a CRF model which is constructed dynamically according to the dependency parsed tree and which contains latent variables on the nodes that correspond to the chunked expressions (Nakagawa et al., 2010). The latent variables in the model are expected to convey a partial sentiment of the sentence, such as the sentiment of the dependency-parsed-subtree itself, which is not explicitly observable.

Although this idea is attractive, it actually suffers from numerical instability. Our aim here is to find a way to deal with this problem. We tried using a global optimizer and investigated the behavior of the model, to ensure that this lack of stability comes from the degeneracy of the model.

Our contribution to remedy this problem is as follows: We propose a model with a penalty on category transitions and compare several optimizers to train the model. We also confirm the stability of the model

Proceedings of COLING 2014, the 25th International Conference on Computational Linguistics: Technical Papers, pages 1350–1359, Dublin, Ireland, August 23-29 2014.

by applying it to the multi-class classification problem. We also investigate the origin of the degeneracy and how regularizer works for this type of classification model, to see the robustness of the model.

2 Related Work

Studies on opinion classification have more than a decade of history, including the pioneer work (Turney, 2002; Pang et al., 2002), followed by (Takamura et al., 2005; Brun, 2012). Our baseline model treats the sentiment of a partial sentence (Nakagawa et al., 2010); CRF with latent variables are constructed dynamically by the dependency structure tree of the input sentence.

CRF model was first used in sequence labeling tasks (Lafferty, 2001). The model does not suffer from the label-bias problem as does the Maximum Entropy model, and its parameter estimation is well behaved with the help of a convex loss function. However, the convexity of the loss function of the CRF model does not hold anymore when there are unobserved data or latent variables (Sutton and McCallum, 2007).

Latent variables were first used with CRF for the purpose of noun coreference (McCallum and Wellner, 2005), and object recognition (Quattoni et al., 2005). Latent variables have been used to construct meaning representations in a process called grounded language acquisition (Liang et al., 2009). Another approach with hidden variables has been used an recursive auto-encoder to reduce the reliance on sentiment dictionaries (Socher et al., 2011).

Machine learning, used for training such models, is largely based on the concept of numerical optimization. A general discussion of convex optimization can be found in (Boyd and Vandenberghe, 2004); it can be proven that the `log-sum-exp` type of a convex function is still a convex function. This is the situation with the CRF model without latent variables. Since convexity holds, the best solution to the problem would be a numerical local optimization. A general discussion of local optimization can be found in the textbook (Nocedal and Wright, 2006), who is one of the authors of the Limited memory Broyden-Fletcher-Goldfarb-Shanno (L-BFGS) optimizer program. Many NLP application programs use probabilistic models, including this optimizer or its derived work. As the long name of the BFGS algorithm shows, the state-of-the-art local optimizer has a long history. Another textbook (Press et al., 2007) covers a global optimization algorithm, Simulated Annealing, originating from (Kirkpatrick et al., 1983). The main idea comes from the statistical physics of equilibrium; when a material is warm, its energy is distributed in excited states, whereas when it is cooled, it is very probable that the system will end in the ground state, which corresponds to the global minimum point of the energy.

Previous studies on CRF with latent variables were trained either by setting the initial parameters randomly (Nakagawa et al., 2010), or by online training (McCallum and Wellner, 2005). As far as the author knows, this is the first study to impose a penalty between latent variables in CRF model, and to compare several optimization algorithms.

3 The Model

The model studied is a CRF model, which has set of conditional probabilities whose log is a linear combination of model parameters associated with features given by (Lafferty, 2001):

$$\log p_\Lambda(\mathbf{y}|\mathbf{x}) \propto \sum_{v\in V,k} \mu_k g_k(v, \mathbf{y}|_v, \mathbf{x}) + \sum_{e\in E,k} \lambda_k f_k(e, \mathbf{y}|_e, \mathbf{x}), \tag{1}$$

where $\mathbf{x}$ is an input vector and $\mathbf{y}$ is an output label sequence, and $\mathbf{y}|_v$ and $\mathbf{y}|_e$ are the vertex v and the edge e related to the component of $\mathbf{y}$, respectively. The model parameter vector Λ is estimated from the training data, whose components are the sum of the two sets: a vertex feature set $(\mu_1, \mu_2, \dots)$ and an edge feature set $(\lambda_1, \lambda_2, \dots)$. The complete set of features are supposed to be enumerated and fixed, so that each feature can be indicated by an index k in a rather relaxed way. g_k and f_k are so-called feature functions, to indicate whether the feature in the argument appears in the input, or not.

Nakagawa et al. (2010) proposed a CRF model with latent variables that uses a dependency parsed structure, where the latent variables are expected to convey the sentiment classifying the part underneath the parsed tree. We choose this model as a baseline and continue the same kind of treatment of the latent

variables. Section 3.1 and 3.2 briefly review this baseline model, then the proposed model follows in Section 3.3.

3.1 Sentence Classification Model with Latent Variables

To classify sentence $\mathbf{x}$ into a given set of a class, say C, the classification problem is formulated as:

$$\arg\max_{s_0 \in C} p_\Lambda(s_0|\mathbf{x}), \tag{2}$$

where s_0 is a class label of the complete sentence and $\mathbf{x}$ is a given sentence such that

$$p_\Lambda(s_0|\mathbf{x}) = \sum_{\mathbf{s}} p_\Lambda(s_0, \mathbf{s}|\mathbf{x}), \tag{3}$$

where $\mathbf{s}$ is the latent variables to be summed up, and Λ is the set of all parameters in the model. Each element of $\mathbf{s}$ takes one of these class labels, corresponding to the partial sentiment of the sentence, and is to be summed up to construct the complete sentiment of the sentence. A partial sentiment of a sentence is sometimes ambiguous, so it is treated as such an unobserved variable. The model parameters Λ are estimated from the training data; the sentiment label is only available for a whole sentence, not for a part of the sentence.

3.2 Dependency Structure as a Graphical Model

The given sentence $\mathbf{x}$ is parsed into a dependency structure of phrase chunks:

$$\mathbf{x} \xrightarrow{\text{Dependency Parsing}} G(\mathbf{x}) = \{V(\mathbf{x}), E(\mathbf{x})\}, \tag{4}$$

where $V(\mathbf{x})$ are the set of chunks and $E(\mathbf{x})$ is the set of dependency arcs. The dependency structure is regarded as a graphical model, an example of which is shown in Figure 1. The words are chunked up into phrases, and the dependencies between those chunks are determined by dependency parsing. Each chunk corresponds to a variable that is supposed to convey a sentiment.

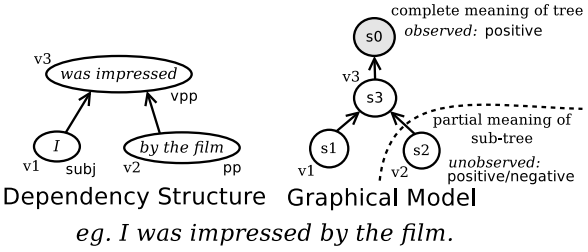

Figure 1: Correspondence between dependency structure and graphical representation of the model

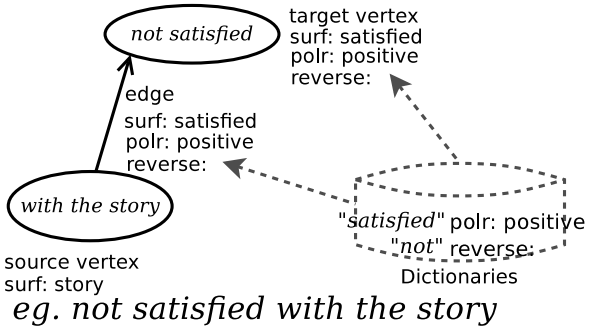

Figure 2: Features attached to vertices and edges

Vertex features	Edge features
word surface unigrams	word surface unigrams of the parent vertex
succeeding word surface bigrams	word surface unigrams of the child vertex
sentiment information from a dictionary	sentiment information from a dictionary
negation expression from a dictionary	negation expression from a dictionary
meaning label of functional expression	meaning label of functional expression of the parent vertex
	meaning label of functional expression of the child vertex

Table 1: Summary of features adopted in the model

Every feature belongs to one of two types: vertex features or edge features. Vertex features are those locally related to a vertex, and edge features are those that affect both sides of vertices of the dependency. The specific features adopted in the model are summarized in Table 1.

A symbol μ as a notation for model parameters related to vertex features. It has two indices since they are related to a vertex feature and a classification category. As for the vertex feature f_v related part, the log probability that the vertex v has the category s is:

$$\log p_{f_v}(s) = \mu_{f_v,s}. \tag{5}$$

A symbol λ as a notation for model parameters related to edge features. It has three indices since they are related to an edge feature and classification categories of both sides of vertices of the edge.

As for the edge feature f_e related part, the log conditional probability that the target vertex takes the category s_2 is:

$$\log p_{f_e}(s_2|s_1) = \lambda_{f_e,s_2,s_1}, \tag{6}$$

given the category of the source vertex is s_1.

Multiple features can be attached either on a vertex or on a edge. So, the whole vertex or edge probability is constructed as follows:

$$\log p_v(s) = \sum_{f_v \in F^{(\text{vertex})}(v)} \log p_{f_v}(s) = \sum_{f_v \in F^{(\text{vertex})}(v)} \mu_{f_v,s}, \tag{7}$$

$$\log p_e(s_2|s_1) = \sum_{f_e \in F^{(\text{edge})}(e)} \log p_{f_e}(s_2|s_1) = \sum_{f_e \in F^{(\text{edge})}(e)} \lambda_{f_e,s_2,s_1}, \tag{8}$$

where $F^{(\text{vertex})}(v)$ is a set of features attached to a vertex v, and where $F^{(\text{edge})}(e)$ is those attached to an edge e.

Finally, the probability of a given sentence $\mathbf{x}$ is constructed as a log-linear model:

$$\log p(s_0, \mathbf{s}|\mathbf{x}) = \sum_{v \in V(\mathbf{x})} \log p_v(s^{(\text{v})}) + \sum_{e \in E(\mathbf{x})} \log p_e(s^{(\text{target}(e))}|s^{(\text{source}(e))}), \tag{9}$$

where the set of vertices and edges are dynamically constructed from the dependency parsed tree of the sentence, *i.e.* eq. (4), and the notation source(e) and target(e) are the source and target vertex of the edge e, respectively (Figure 2.)

Care is necessary when assigning values to the latent variables in eq. (9). Because each latent variable which is assigned on a vertex and the connecting edges, share the same values, the latent variables must be summed up in such way; The summations can be done efficiently by using dynamic programming (*a.k.a.* the factor graph in graphical model terminology.) The tables of probabilities are constructed for each vertex, and the tree is constructed in a bottom up manner.

The sets[1] of all the vertex and edge features appearing in the training data $\mathcal{D}$ are denoted as $\mathcal{V}^{(\mathcal{D})}$ and $\mathcal{E}^{(\mathcal{D})}$ respectively:

$$\mathcal{V}^{(\mathcal{D})} = \sum_{\mathbf{x} \in \mathcal{D}} \sum_{v \in V(\mathbf{x})} F^{(\text{vertex})}(v), \qquad \mathcal{E}^{(\mathcal{D})} = \sum_{\mathbf{x} \in \mathcal{D}} \sum_{e \in E(\mathbf{x})} F^{(\text{edge})}(e), \tag{10}$$

so that the complete set of parameters is:

$$\Lambda = \{\mu_{v,c} | v \in \mathcal{V}^{(\mathcal{D})}, c \in C\} + \{\lambda_{e,c_1,c_2} | e \in \mathcal{E}^{(\mathcal{D})}, \quad c_1, c_2 \in C\},$$

where the number of parameters is $\mathcal{V}^{(\mathcal{D})} \times C + \mathcal{E}^{(\mathcal{D})} \times C \times C$.

[1] Note that the following equations up to eq. (11) are in the terminology of set theory; the addition is done with the elimination of duplicated elements, and a product means a direct product, and a n-th power is an abbreviation of n direct products of the set.

The log likelihood of the training data is given by

$$\mathbb{L}(\Lambda;\mathcal{D}) = \sum_{\mathbf{x}\in\mathcal{D}} \log\left(\sum_{\mathbf{s}\in C^{|V(\mathbf{x})|}} p_\Lambda(s_0,\mathbf{s}|\mathbf{x})\right), \tag{11}$$

where $|V(\mathbf{x})|$ is the number of vertices in a given sentence $\mathbf{x}$, and where s_0 is the correct classification label for $\mathbf{x}$, and where $\mathbf{s}$ is the set of latent variables whose number is as many as $|V(\mathbf{x})|$.

3.3 Category Transition Penalty

We found that the classification accuracy of the trained model remained low, because little number of parameters for edge features moved away from initial non-contributing values during the training. The following form of regularizer[2] is used for the training:

$$\mathbb{R}(\Lambda) = C_{\text{regularizer}} \left|\Lambda - \frac{1}{n}\cdot\mathbb{1}\right|^2. \tag{12}$$

The constant $C_{\text{regularizer}}$ is the strength of the regularizer, and no matter how strong, the classification accuracy did not improve in our preliminary experiments. This phenomenon seems to be because of the degeneracies the model has in principle.

Degeneracy is a notion to explain the same probabilities of different configurations. If the two different configurations are preferably distinguished, an asymmetric treatment of them is required.

In order to avoid such extra degeneracies, we introduce a novel constraint between latent variables expressed by the following penalty term:

$$\mathbb{P}(\Lambda) = C_{\text{penalty}} \sum_{f_e\in\mathcal{E}^{(\mathcal{D})}} \left(\sum_{s_1=s_2} (\log p_{f_e}(s_2|s_1) - \log C_{\text{same}})^2 + \sum_{s_1\neq s_2} (\log p_{f_e}(s_2|s_1) - \log C_{\text{different}})^2\right), \tag{13}$$

to satisfy

$$C_{\text{same}} + (n-1)C_{\text{different}} = 1, \tag{14}$$

where C_{penalty} is the weight of this penalty, and where C_{same} and $C_{\text{different}}$ are constant probabilities for the following two cases; that is the categories connected to the other side of the edge should be the same or different, respectively. This term is incorporated into the objective function for training the model, to form a soft constraint that diminishes the change in the classification category.

3.4 Model Training

The maximum likelihood training of a probabilistic model is a constrained optimization problem. A probabilistic interpretation is possible if and only if 1) all probabilities are non-negative, and 2) the sum of the probabilities are one (or renormalizable to one).

Using log probabilities almost automatically satisfies the first condition: Real number in log space corresponds to positive number in anti-log space, so that the only consideration needed is zero probability (which corresponds to negative infinity in the log space.) In the experiments, overflow is checked that none occurred in the final results. The model parameter to express zero probability could be finite but reasonably small, instead of zero.

As for the second condition, instead of the strict constraint, we adopted a quadratic penalty in log space:

$$\mathbb{C}(\Lambda) = C_{\text{prob}} \left(\sum_{f_v\in\mathcal{V}^{(\mathcal{D})}} \left(\log\sum_{s\in C} p_{f_v}(s)\right)^2 + \sum_{f_e\in\mathcal{E}^{(\mathcal{D})}} \sum_{s_1\in C} \left(\log\sum_{s_2\in C} p_{f_e}(s_2|s_1)\right)^2\right), \tag{15}$$

[2]The offset $\frac{1}{n}\cdot\mathbb{1}$ in the regularizer is so as to avoid singularity around zero probabilities in real space, which causes negative infinity in log space calculation.

where the strictly normalized probabilities lead to zero penalty; otherwise, a quadratic penalty is given according to the amount away from strictly normalized probabilities. The weight of the penalty C_{prob} is chosen to be heavy enough for the sum of the model probability to be adequately normalized.

Finally, we adopted the probability calculation in the log space, with the quadratic penalty for normalization during the training. The objective function for training the model is:

$$\mathbb{O}(\Lambda; \mathcal{D}) = \mathbb{L}(\Lambda; \mathcal{D}) - \mathbb{R}(\Lambda) - \mathbb{P}(\Lambda) - \mathbb{C}(\Lambda). \tag{16}$$

4 Experiments

Experiments are conducted to evaluate the effect of the proposed penalty term expressed by eq. (13).

4.1 Test Sets

Two kinds of test set in Japanese were used: Opinions in the Kyoto University and NTT Blog (KNB) Corpus[3]and Comments on an TV cultural program. Both sets are balanced in the numbers sentence categories. The characteristics of each test set are shown in Table 2.

The first test set, the KNB Corpus, is a collection of opinion sentences about Kyoto sightseeing spots, cellular phones, gourmet food, and sports. The sentences are categorized in terms of many aspects, and we used the sentences labeled with Evaluation+ or Evaluation–. "Evaluation" is a category of subjective but non-emotional opinions.

The second test set is used for non-binary classification. To make this set, viewers were asked to comment (in Japanese natural language) on a certain TV program. The comments are classified into categories, *i.e.* evaluations, impressions, requirements and questions. The following four categories are used: positive and negative evaluations, and impressions of what the viewers learned from the program, and what they thought after watching the program.

Name of Test Set	# of Sentences	Categories
Opinions in KNB Corpus	328	2(Evaluation +/–)
Comments on TV cultural program	432	4(positive/negative evaluations, what viewers learned/think)

Table 2: Characteristics of Test Set

4.2 NLP Resources

The input sentence was processed by a morphological analyzer to split it into words, since Japanese is an agglutinative language. The words were then chunked and the dependencies between those chunks were determined. Functional multi-word expressions were also detected by the analyzer we developed. We used a dictionary of sentiment expressions, and one of negation expressions, both of which were distributed with the KNB Corpus.

We did not prepare any special sentiment dictionary for the second test set because preparing such a dictionary is too costly. Furthermore, robustness can be estimated without a domain-adapted dictionary. The parameter values for training the models were tuned for the first test set, and the tuned values were used without any extra tuning for the second test set. In this situation, the first test set can be regarded as the development test set, and the second as the evaluation test set.

4.3 Latent Dynamic Model with Category Transition Constraint

Experiments on classifying opinions using the KNB Corpus are shown in Table 3. The rightmost column is a trivial baseline, where the classification category is decided by the majority occurrence of sentiment

[3]The corpus is publicly available from `http://nlp.ist.i.kyoto-u.ac.jp/kuntt/\#ga739fe2`, and the details of corpus are explained at `http://alaginrc.nict.go.jp/opinion/index_e.html`. We excluded short sentences, made up of a few words, that were exclamations rather than natural complete sentences. They do not form tree structures, which are not aimed to this study. Accuracy of experiments conducted below are different from that by (Nakagawa et al., 2010) in that only the subset of the test set that satisfy the condition is used.

words in the sentence. This method needs no training, so only one figure is indicated. The other columns are figures for trained CRF; closed tests are the case where all the training data is used for the evaluation as well, shown in the upper row, while 10-folds open test are the case is 1:9 split of data for evaluation and training and the evaluation is done cyclically 10 times, shown in the lower row. The leftmost column is CRF without latent variables. The 2nd left is a model with latent variables but without penalty, which is the model in (Nakagawa et al., 2010). The 3rd left is a model with latent variables that has a category transition penalty, which is the proposed model. The proposed model performs the best accuracy among all the models.

Experiments on classifying opinions using the Comments on the TV cultural Program are shown in Table 4. Majority voting is not possible because a suitable dictionary that has the same class polarity as this classification problem does not exist.

	Trained CRF			(no training)
	without latent variables	with latent variables		Majority
		non-penalized	penalized	Voting
closed test	95.12	95.73	95.73	
10-fold open test	61.59	63.72	**65.55**	64.79

Table 3: Effect of Latent Variables and Penalized Model (Opinions in KNB Corpus)

	Trained CRF			(no training)
	without latent variables	with latent variables		Majority
		non-penalized	penalized	Voting
closed test	99.54	99.77	99.31	
10-fold open test	60.42	60.42	**64.81**	N/A

Table 4: Effect of Penalized Latent Dynamic Model (Comments on TV cultural program)

4.4 Comparison of Optimizers

Three optimization algorithms for model training were compared, two of which are local optimizers (BFGS and Steepest Descent), and one of which is a global optimizer (Simulated Annealing).

BFGS was used as batch training where all of the training data were used during the training iteration. Two types of initial parameter configurations were tried for BFGS; initial parameters have the same fixed values, or were chosen randomly. Steepest Descent (SD) was used as online training where some portion (*i.e.* chunk) of the training data were used during an iteration. Two types of chunk selection scheme were tried for Steepest Descent; chunks were fixed during the training, or chunks were randomly shuffled after every complete loop of the whole training data.

Simulated Annealing was adopted as a global optimizer. We implemented feature level granularity for acceptance or rejection: Every parameter corresponding to a feature was randomly moved, and decided probabilistically whether or not to accept according to the Boltzmann distribution under scheduled cooling down. Although all of these methods utilize random variables, they were used in different ways. The accuracy ranges of ten trials are shown in Table 5 and 6.

The results show that the proposed model trained by a global optimizer outperforms models trained by the other local optimizers (Steepest Descent and BFGS); The penalty in the proposed model works well because the degeneracies in the penalized model seem to decrease, and the computation is noteworthy stable.

5 Discussion

The degeneracy in the model is illustrated in Figure 3 and 4.

Firstly, convergence for penalized model is quicker, as shown in Figure 3; The horizontal axis is the number of iterations, and the left vertical axis is the acceptance ratio, where the lower is well converged.

	Batch Training (BFGS) parameter initialization		Online Training (SD) chunked data selection		Simulated Annealing
	random	*fixed*	*shuffled*	*fixed*	
closed test	89.33-82.32	87.80	76.83-72.56	76.83	95.73-95.73
10-fold open test	62.80-58.54	59.15	66.46-65.55	65.55	65.55-64.63

Table 5: Comparison of Optimizers (Opinions in KNB Corpus)

	Batch Training (BFGS) parameter initialization		Online Training (SD) chunked data selection		Simulated Annealing
	random	*fixed*	*shuffled*	*fixed*	
closed test	85.65-35.65	88.19	47.69-45.37	45.60	99.31-99.31
10-fold open test	58.56-34.72	59.95	38.89-36.81	37.50	**64.81-64.58**

Table 6: Comparison of Optimizers (Comments on TV cultural program)

The acceptance ratio remains high for the non-penalized model, while the penalized model quickly descends. The dash line indicates the log likelihood of the training data, for penalized and non-penalized models, which are almost identical.

Secondly, in order to split degeneracy, only a small penalty is adequate, as illustrated in Figure 4; how less the penalty is, as long as it exists, the improvement remains. The horizontal axis is the strength of the proposed penalty, C_{penalty} in eq.(13). The vertical axis is the classification accuracy. The dash line is a line fit for the accuracy by non-zero penalty. In general, such an extra constraint term for the original model may change the model itself, so, the less it is the better. That is the reason for decreasing accuracy when large penalty is used. The significant jump in the accuracy between zero and non-zero penalty strongly suggests the existence of degeneracies in the original model: Infinitesimally small penalty can lead to break those degeneracies.

Local optima usually do not matter when regularizers are used in training. However, according to our experiments in this type of models, the conventional regularizers are not able to avoid such local optima no matter how strong they are. The reason the introduced penalty works well for this model is considered that the term works for excessive latent variables, which are not controlled by the ordinary regularizers. The ordinary regularizers only works for excessive number of explicitly observed parameters (*i.e.* features). If only a few latent variables are used, such a penalty is not necessary, just as a regularizer is not necessary for a small number of features. When the model is constructed dynamically and the number of latent variables grows, there appear a number of latent variables having excessive freedom, which need to be controlled.

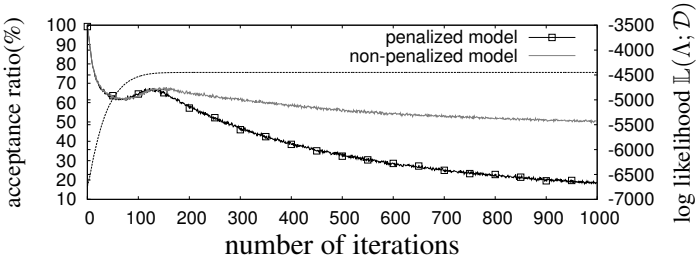

Figure 3: Transition of the Acceptance Ratio

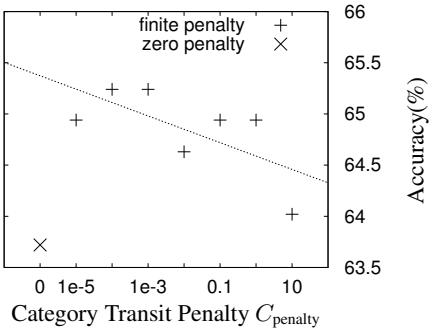

Figure 4: Effect of Weak Penalty

6 Conclusion

A latent dynamic model with a category transition constraint is proposed for opinion classification task. The constraint is such that the sentiment of a partial sentence tends to propagate toward the complete sentiment of the whole sentence, which is realized, in the objective function, by our novel term that penalizes, diminishing the change in the classification category.

According to our experiments, the penalized latent dynamic model outperforms the conventional model, not only in binary but also in multi-class opinion classification.

The comparison of optimizers strongly suggests that the degeneracies in the conventional model deteriorate the performance, and the proposed model solves such a defect. The numerical stability of training the proposed model is also confirmed.

Abstract

Target-polarity word (T-P) collocation extraction, a basic sentiment analysis task, relies primarily on syntactic features to identify the relationships between targets and polarity words. A major problem of current research is that this task focuses on customer reviews, which are natural or spontaneous, thus posing a challenge to syntactic parsers. We address this problem by proposing a framework of adding a sentiment sentence compression (*Sent_Comp*) step before performing T-P collocation extraction. *Sent_Comp* seeks to remove the unnecessary information for sentiment analysis, thereby compressing a complicated sentence into one that is shorter and easier to parse. We apply a discriminative conditional random field model, with some special sentiment-related features, in order to automatically compress sentiment sentences. Experiments show that *Sent_Comp* significantly improves the performance of T-P collocation extraction.

1 Introduction

Sentiment analysis deals with the computational treatment of opinion, sentiment and subjectivity in text (Pang and Lee, 2008), and has received considerable attention in recent years (Liu, 2012). Target-Polarity word (T-P) collocation extraction, which aims to extract the collocation of a target and its corresponding polarity word in a sentiment sentence, is a basic task in sentiment analysis. For example, in a sentiment sentence "这款相机拥有新颖的外形" (*The camera has a novel appearance*), "外形" (*appearance*) is the target, and "新颖" (*novel*) is the polarity word that modifies "外形" (*appearance*). According, ⟨外形, 新颖⟩ (⟨*appearance, novel*⟩) is the T-P collocation. Generally, T-P collocation is a basic and complete sentiment unit, thus is very useful for many sentiment analysis applications.

Features derived from syntactic parse trees are particularly useful for T-P collocation extraction (Abbasi et al., 2008; Duric and Song, 2012). For example, the syntactic relation "Adj $\overset{\text{ATT}}{\curvearrowleft}$ Noun", where the ATT denotes an attributive syntactic relation, can be used as an important evidence to extract the T-P collocation ⟨外形, 新颖⟩ (⟨*appearance, novel*⟩) in the above sentiment sentence (Bloom et al., 2007; Qiu et al., 2011; Xu et al., 2013).

However, one major problem of these approaches is the "naturalness" of sentiment sentences, that is, such sentences are more natural or spontaneous compared with normal sentences, thus posing a challenge to syntactic parsers. Accordingly, many wrong syntactic features have been produced and these can further result in the poor performance of T-P collocation extraction. Taking the sentence in Figure 1(a) as an example, because the word "多亏" (*fortunately*) is so chatty,[1] the parsing result is wrong. Thus, are unable to extract the T-P collocation ⟨键盘, 好⟩ (⟨*keyboard, good*⟩).

To solve the "naturalness" problem, we can train a parser on sentiment sentences. Unfortunately, annotating such data will cost us a lot of time and effort. Instead, in this paper we produce a sentence compression model, *Sent_Comp*, which is designed especially to compress complicated sentiment sentences into formal and easier to parse ones, further improving T-P collocation extraction.

*Correspondence author: tliu@ir.hit.edu.cn

[1]Note that, in Figure 1, the Chinese word "多亏" is chatty, although its translated English word "fortunately" is not. In this paper, we focus on processing the Chinese data.

(a) before compression (b) after compression

Figure 1: Parse trees before and after compression.

This idea is motivated by the observation that, current syntactic parsers usually perform accurately for short, simple and formal sentences, whereas error rates increase for longer, more complex or more natural and spontaneous sentences (Finkel et al., 2008). Hence, the improvement in syntactic parsing performance would have a ripple effect over T-P collocation extraction. For example, we can compress the sentence in Figure 1(a) into a shortened sentence in Figure 1(b) by removing the chatty part "多亏" (*fortunately*). We can see that the shortened sentence is now well-formed (in Chinese) and its parse tree is correct, making it easier to accurately extract T-P collocation.

Traditional sentence compression aims to obtain a shorter grammatical sentence by retaining important information (usually important grammar structure) (Jing, 2000). For example, the sentence "Overall, this is a great camera." can be compressed into "This is a camera." by removing the adverbial "overall" and the modifier "great". However, the modifier "great" is a polarity word and very important for sentiment analysis. Therefore, *Sent_Comp* model for sentiment sentences is different from the traditional compression models, because it needs to retain the important sentiment information, such as the polarity word. Hence, using *Sent_Comp*, the above sentence can be compressed into "This is a great camera."

We regard *Sent_Comp* as a sequence labeling task, which can be solved by a conditional random fields (CRF) model. Instead of seeking the manual rules on parse trees for compression, as in other studies (Vickrey and Koller, 2008), this method is an automatic procedure. In this work, we introduce some sentiment-related features to retain the sentiment information for *Sent_Comp*.

We apply *Sent_Comp* as the first step in the T-P collocation extraction task. First, we compress the sentiment sentences into easier to parse ones using *Sent_Comp*, after which we employ the state-of-the-art T-P collocation extraction approach on the compressed sentences. Experimental results on a Chinese corpus of four product domains show the effectiveness of our approach.

The main contributions of this paper are as follows:

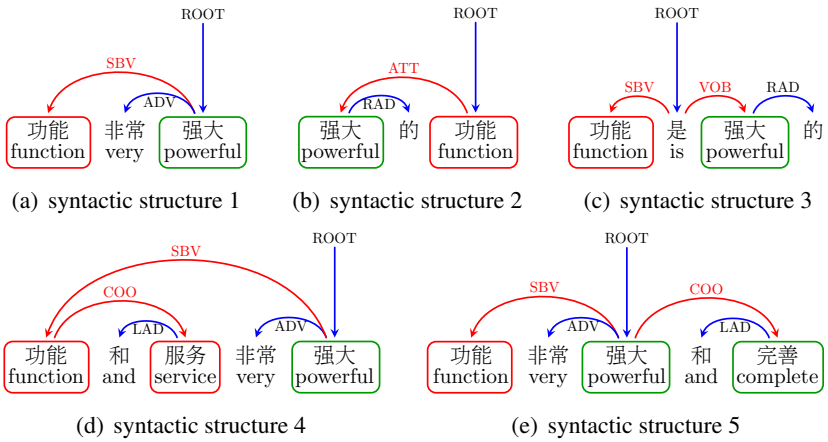
- We present a framework of using sentiment sentence compression preprocessing step to improve T-P collocation extraction. This framework can better solve the "over-natural" problem of sentiment sentences, which poses a challenge to syntactic parsers. More importantly, the idea of this framework can be applied to some other sentiment analysis tasks that rely heavily on syntactic results.

- We develop a simple yet effective compression model *Sent_Comp* for sentiment sentences. To the best of our knowledge, this is the first sentiment sentence compression model.

2 Background

For our baseline system, we used the state-of-the-art method to extract T-P collocations introduced by Qiu et al. (2011), who proposed a double propagation method. This idea is based on the observation that there is a natural syntactic relationship between polarity words and targets owing to the fact that polarity words are used to modify targets. Furthermore, they also found that polarity words and targets themselves have relations in some sentiment sentences (Qiu et al., 2011).

Based on this idea, in the double propagation method, we first used an initial seed polarity word lexicon and the syntactic relations to extract the targets, which can fall into a new target lexicon. Then we used the target lexicon and the same syntactic relations to extract the polarity words and to subsequently expand the polarity word lexicon. This is an iterative procedure, because this method can iteratively produce the new polarity words and targets back and forth using the syntactic relations.



(a) syntactic structure 1 (b) syntactic structure 2 (c) syntactic structure 3

(d) syntactic structure 4 (e) syntactic structure 5

Figure 2: Example of syntactic structure rules for T-P collocation extraction. We showed five examples from a total of nine syntactic structures. For each kind of syntactic structure (a) to (e), the target is shown with a red box and the polarity word is shown with a green box. Syntactic structures (a) to (c) describe the relations between targets and polarity words. Syntactic structure (d), which is extended from (a), describes the relation between two targets. Syntactic structure (e), which is also extended from (a), describes the relation between two polarity words. Similarly, we can summarize the other four rules extended from (b) and (c) to describe the relations between two targets or two polarity words.

We can see that the syntactic relations are important for this method, and Qiu et al. (2011) proposed eight rules to describe these relations. However, their work only focused on English sentences, whereas the relations for Chinese sentences are different. Thus, in accordance with Chinese grammar, we proposed nine syntactic structure rules between target t and polarity word p in a Chinese T-P collocation $\langle t, p \rangle$.[2] The three main rules are shown below and some example rules are illustrated in Figure 2.

Rule 1: $t \overset{\text{SBV}}{\curvearrowleft} p$, the "subject-verb" structure between t and p, such as the example in Figure 2(a).

Rule 2: $p \overset{\text{ATT}}{\curvearrowleft} t$, that p is an attribute for t, such as the example in Figure 2(b).

Rule 3: $t \overset{\text{SBV}}{\curvearrowleft} \circ \overset{\text{VOB}}{\curvearrowright} p$, the "subject-verb-object" structure between t and p, such as the example in Figure 2(c). The $\circ$ denotes any word.

The other six rules can be extended from the three main rules by obtaining the coordination (COO) relation of t or p, such as $t \overset{\text{SBV}}{\curvearrowleft} \circ \overset{\text{COO}}{\curvearrowright} p$ in Figure 2(e). Note that the POS for t should be noun and for p should be adjective.

As described above, the T-P collocation extraction relies heavily on syntactic parsers. Hence, if we can use the *Sent_Comp* model to improve the performance of parsers, the performance of T-P collocation extraction can also be improved accordingly.

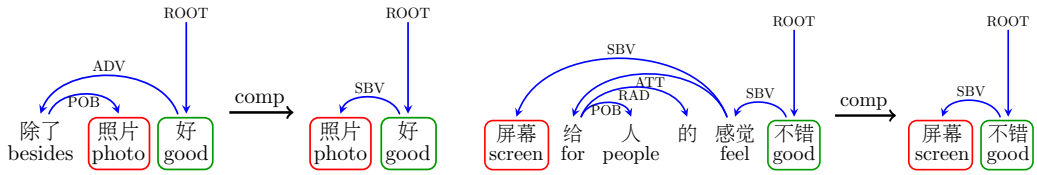
3 Sentiment Sentence Compression

3.1 Problem Analysis

First, we conducted an error analysis for the results of current T-P collocation extraction, from which we observed that the "naturalness" of sentiment sentences is one of the main problems. For examples:

- Chatty form: some sentiment sentences are so chatty, that they bring many difficulties to the parser. For example, in the sentence "多亏键盘好" (*fortunately the keyboard is good*) shown in Figure 1, the usage of the chatty word "多亏" (*fortunately*) affects the accuracy of the syntactic parser.

[2] A Chinese natural language processing toolkit, Language Technology Platform (LTP) (Che et al., 2010), was used as our dependency parser. More information about the syntactic relations can be found in their paper. The state-of-the-art graph-based dependency parsing model, in the toolkit, was trained on Chinese Dependency Treebank 1.0 (LDC2012T05).



(a) parse tree 1 before and after compression

(b) parse tree 2 before and after compression

Figure 3: "Naturalness" problem of sentiment sentences.

- Conjunction word usage: conjunction words are often used in sentiment sentences to show the discourse relations between two sentences. However, there are so many conjunction words in Chinese, some of which can cause errors among parsers. For example, in Figure 3(a), the parse tree of sentence "除了相片较好" (*besides the photo is good*) is wrong because of the usage of the conjunction word "除了" (*besides*).

- Feeling words/phrase usage: in sentiment sentences, people often use some feeling words/phrase, such as "给人的感觉" (*feel like*) in Figure 3(b) or "闻起来" (*smell like*). Given that the current syntactic parser cannot handle the feeling words/phrases very well, the T-P collocation ⟨屏幕, 不错⟩ (⟨$screen, good$⟩) in Figure 3(b) cannot be extracted correctly.

To address the "naturalness" problem, we compressed the sentiment sentences into one that are shorter and easier to parse. Similar to the examples in Figure 1 and 3, the compressed sentences can be easily and correctly parsed. The above analysis can be used as the criteria to guide us in compressing sentiment sentences when annotating, and can also help us exploit more useful features for automatic sentiment sentence compression.

3.2 Task Definition

We focus on studying the methods for extractive sentence compression.[3] Formally, extractive sentence compression aims to shorten a sentence $\mathbf{x} = x_1 \cdots x_n$ into a substring $\mathbf{y} = y_1 \cdots y_m$, where $y_i \in \{x_1, \cdots, x_n\}$, $m \leq n$.

In this paper, similar to Nomoto (2007), we also treated the sentence compression as a sequence labeling task which can be solved by a CRF model. We assigned a compression tag t_i to each word x_i in an original sentence $\mathbf{x}$, where $t_i = \mathsf{N}$ if $x_i \in \mathbf{y}$, else $t_i = \mathsf{Y}$.

A first-order linear-chain CRF is used which defines the following conditional probability:

$$P(\mathbf{t}|\mathbf{x}) = \frac{1}{Z(\mathbf{x})} \prod_i M_i(t_i, t_{i-1}|\mathbf{x}) \quad (1)$$

where $\mathbf{x}$ and $\mathbf{t}$ are the input and output sequences respectively, $Z(\mathbf{x})$ is the partition function, and M_i is the clique potential for edge clique i. Here, we used the CRFsuite toolkit to train the CRF model.[4]

3.3 Features

The features for *Sent_Comp* are listed in Table 1. Aside from the basic word (w), POS tag (t) and their combination context features (01 – 04), we introduced some sentiment-related features (05 – 06) and latent semantic features (07 – 08) to better handle sentiment analysis data and generalize word features. Then we added the syntactic parse features (09), which are commonly used in traditional sentence compression task.

One sentiment-related feature ($\mathsf{feeling}(\cdot)$) indicates whether a word is a feeling word, which is inspired by the naturalness problem in Figure 3(b). As discussed above, the current parser often produces wrong parse trees because of these feeling words. Therefore, the feeling words tend to be removed from a

[3]Generally, there are two kinds of sentence compression methods: extractive method and abstractive method. Because abstractive method needs more resource and is more complicated, in this paper, we only focus on extractive approach.

06: polarity(w_i)
Latent Semantic Features
07: suffix(w_i) if $t(w_i) == n$ else prefix(w_i)
08: cluster(w_i)
Syntactic Features
09: dependency(w_i)

Table 1: Features of sentiment sentence compression

sentiment sentence for *Sent_Comp*. We can obtain a feeling word lexicon from HowNet,[5] a popular Chinese sentiment thesaurus, where a feeling word is defined by DEF={perception|感知} tag. Finally, we collected 38 feeling words, such as 发觉 (*realize*), 发现 (*find*), and 认为 (*think*).

The other sentiment-related feature (polarity$(\cdot)$) indicates whether a word is a polarity word. One of the main differences between a sentiment sentence and a formal sentence is that the former often contains polarity words. In contrast to the features of feeling$(\cdot)$, polarity words (e.g., "great" in the sentence "Overall, this is a great camera") tend to be retained, because they are important and special to sentiment analysis. In this paper, we treat polarity words as important features, considering that they are often tagged as modifiers and are easily removed by common sentence compression methods. We can obtain the polarity feature (polarity$(\cdot)$) from a polarity lexicon, which can also be obtained from HowNet.

To generalize the words in sentiment sentences, we proposed two kinds of semantic features. The first one is a suffix or prefix character feature (prefix$(\cdot)$ or suffix$(\cdot)$). In contrast to English, the suffix (for noun) or prefix (for non noun) characters of a Chinese word often carry that word's core semantic information. For example, 自行**车** (*bicycle*), 汽**车** (*car*), and 火**车** (*train*) are all various kinds of 车 (*vehicle*), which is also the suffix of the three words. Given that all of them may become targets, they tend to be retained in compressed sentences. The verbs, **感**觉 and **感**到, can be denoted by their prefix *feel* (感), and can be removed from original sentences because they are feeling words.

We used word clustering features (cluster$(\cdot)$) as the other latent semantic feature to further improve the generalization over common words. Word clustering features contain some semantic information and have been successfully used in several natural language processing tasks, including NER (Miller et al., 2004; Che et al., 2013) and dependency parsing (Koo et al., 2008). For instance, the words 外观 and 样子 (*appearance*) belong to the same word cluster, although they have a different suffix or prefix. Both words are important for T-P collocation extraction and should be retained. We used the Brown word clustering algorithm (Brown et al., 1992) to obtain the word clusters (Liang, 2005). Raw texts were obtained from the fifth edition of Chinese Gigaword (LDC2011T13).

Finally, similar to McDonald (2006), we also added the dependency relation between a word and its parent as the syntactic features. Intuitively, the dependency relations are helpful in carrying out sentence compression. For example, the ROOT relation typically indicates that the word should not be removed because it is the main verb of a sentence.

4 Experiments

4.1 Experimental Setup

4.1.1 Corpus

We conducted the experiments on a Chinese corpus of four product domains, which came from the Task3 of the Chinese Opinion Analysis Evaluation (COAE) (Zhao et al., 2008).[6] Table 2 describes the corpus,

[5] www.keenage.com

[6] www.ir-china.org.cn/coae2008.html

Domain	# reviews	# sentences	# collocations
Camera	138	1,249	1,335
Car	161	1,172	1,312
Notebook	56	623	674
Phone	123	1,350	1,479
All	478	4,394	4,800

Table 2: Corpus statistics for the Chinese corpus of four product domains.

where 4,394 sentiment sentences containing 4,800 T-P collocations are manually found and annotated from 478 reviews.

We ask annotators to manually compress all the sentiment sentences. Specifically, the annotators removed some words from a sentiment sentence according to two criteria stated as follows: (1) removing the word should not change the essential content of the sentence, and (2) removing the word should not change the sentiment orientation of the sentence. In order to assess the quality of the annotation, we sampled 500 sentences from this corpus and asked two annotators to perform the annotation. The resulting word-based Cohen's kappa (Cohen, 1960) (i.e., a measure of inter-annotator agreement ranging from zero to one) of 0.7 indicated a good strength of agreement.

4.1.2 Evaluation

Generally, compressions are evaluated using three criteria (McDonald, 2006), namely, grammaticality, importance, and compression rate. Obviously, the former two are difficult to evaluate objectively. Previous works used human judgment, which entails a difficult and expensive process. In this paper, similar to a common sequence labeling task, we simply used the F-score metric of removed words to roughly evaluate the performance of sentiment sentence compression. Of course, the final effectiveness of sentence compression model can be reviewed by the derived T-P collocation extraction task.

For T-P collocation extraction, we applied the traditional *P*, *R* and *F-score* for the final evaluations. Specially, a fuzzy matching evaluation is adopted for the T-P collocation extraction. That is to say, given an extracted T-P collocation $\langle t, p \rangle$, whose standard result is $\langle t_s, p_s \rangle$, if t is the substring of t_s, and meanwhile p is the substring of p_s, we consider the extracted $\langle t, p \rangle$ is a correct T-P collocation.

4.2 Sentiment Sentence Compression Results

Features	P(%)	R(%)	F(%)
Basic (01 – 04)	76.4	57.4	65.5
+ feeling (05)	75.9	57.6	65.5
+ polarity (06)	76.6	57.6	65.7
+ suffix or prefix (07)	78.4	56.9	66.0
+ cluster (08)	74.9	58.9	65.9
+ dependency (09)	75.3	57.2	65.0
All (01 – 08)	**77.3**	**59.1**	**67.0**
All - feeling (05)	77.1	58.9	66.8

Table 3: The results of sentiment sentence compression with different features.

Results of *Sent_Comp* with different features are shown in Table 3. All results are reported using five-fold cross validation. We can see that the performance is improved when we added feeling[7] and polarity features (05 – 06) respectively, indicating that the sentiment-related features are useful for sentiment sentence compression. In addition, the latent semantic features (07 – 08) are also helpful, especially the suffix or prefix features, which show better performance than the four other kinds of features.

Nonetheless, the dependency features (09) have a negative on compression performance due to the specificity of compression for sentiment sentences. That is because the lower dependency parsing performance on sentiment sentences introduces many wrong dependency relations, which counteract the

[7]In Table 3, although the performance of adding feeling is comparative to the basic system (Basic (01-04)), the system without feeling (All - feeling (05), the last line) is worse than the system using all the features (All (01-08)). This can illustrate the effectiveness of the feeling feature.

Domain	Method	P(%)	R(%)	F(%)
Camera	no_Comp	74.7	58.4	65.6
	manual_Comp	83.4	62.7	71.6
	auto_Comp	80.4	62.1	70.1
Car	no_Comp	68.2	53.1	59.7
	manual_Comp	76.3	57.7	65.7
	auto_Comp	72.3	56.1	63.2
Notebook	no_Comp	74.1	56.8	64.3
	manual_Comp	82.7	64.5	72.5
	auto_Comp	79.7	62.8	70.2
Phone	no_Comp	77.3	60.9	68.1
	manual_Comp	82.7	65.7	73.2
	auto_Comp	80.3	63.3	70.8
All	no_Comp	73.7	57.5	**64.6**
	manual_Comp	81.2	62.5	**70.6**
	auto_Comp	78.1	60.9	**68.4**

Table 4: Results on T-P collocation extraction for four product domains.

contribution of the dependency relation features. This is also the reason why we need to compress sentiment sentences as the first step for T-P collocation extraction. Finally, when we combine all of useful features (01 – 08), the performance achieves the highest score.

It is worth noting that sentiment sentence compression is a new task proposed in this paper. For simplicity, this paper aims to attempt a simple yet effective sentiment sentence compression model. We will polish the *Sent_Comp* model in the future work.

4.3 *Sent_Comp* for T-P Collocation Extraction

We designed three comparative systems to demonstrate the effectiveness of *Sent_Comp* for T-P collocation extraction. Note that, *Sent_Comp* is the first step to process the corpus before T-P collocation extraction. The method for T-P collocation extraction was based on the state-of-the-art method proposed by Qiu et al. (2011) as described in Section 2.

no_Comp - This refers to the system that only uses the T-P collocation extraction method and does not perform sentence compression as the first step.

manual_Comp - This system **manually** compresses the corpus into a new one as the first step, and then applies the T-P collocation extraction method on the new compressed corpus.

auto_Comp - This system uses *Sent_Comp* as the first step to **automatically** compress the corpus into a new one, and then applies the T-P collocation extraction method on the new corpus.

From the descriptions above, we can draw a conclusion that the performance of **manual_Comp** can be considered as the upper bound for the sentiment sentence compression based T-P collocation extraction task.

Table 4 shows the experimental results of the three systems on T-P collocation extraction for four product domains. Here, **manual_Comp** can significantly ($p < 0.01$) improved the *F-score* by approximately 6%,[8] compared with **no_Comp**. This illustrates that the idea of sentiment sentence compression is useful for T-P collocation extraction. Specifically, the proposed method can transform some over-natural sentences into normal ones, further influencing their final syntactic parsers. Evidently, because the T-P collocation extraction relies heavily on syntactic features, the more correct syntactic parse trees derived from the compressed sentences can help to increase the performance of this task.

Compared with **no_Comp**, the **auto_Comp** system also yielded a significantly better results ($p < 0.01$) that indicated an improvement of 3.8% in the *F-score*, despite the fact that the automatic sentence compression model *Sent_Comp* may wrongly compress some sentences. This demonstrates the usefulness of sentiment sentence compression step in the T-P collocation extraction task and further proves the effectiveness of our proposed model.

[8]We use paired bootstrap resampling significance test (Efron and Tibshirani, 1993).

Moreover, we can observe that the idea of sentence compression and our *Sent_Comp* are useful for all the four product domains on T-P collocation extraction task, indicating that *Sent_Comp* is domain adaptive. However, we can find a small gap between **auto_Comp** and **manual_Comp**, which indicates that the *Sent_Comp* model can still be improved further. In the future, we will explore more effective sentence compression algorithms to bridge the gap between the two systems.

5 Related Works

5.1 Sentiment Analysis

T-P collocation extraction is a basic task in sentiment analysis. In order to solve this task, most methods focused on identifying relationships between targets and polarity words. In early studies, researchers recognized the target first, and then chose its polarity word within a window of size k (Hu and Liu, 2004). However, considering that this kind of method is too heuristic, the performance proved to be very limited. To tackle this problem, many researchers found syntactic patterns that can better describe the relationships between targets and polarity words. For example, Bloom et al. (2007) constructed a linkage specification lexicon containing 31 patterns, while Qiu et al. (2011) proposed a double propagation method that introduced eight heuristic syntactic patterns to extract the collocations. Xu et al. (2013) used the syntactic patterns to extract the collocation candidates in their two-stage framework.

Based on the above, we can conclude that syntactic features are very important for T-P collocation extraction. However, the "naturalness" problem can still seriously affect the performance of syntactic parser. Once our sentiment sentence compression method can improve the quality of parsing, the performance of T-P collocation extraction task can be improved as well. Note that, to date, there is no previous work using a sentence compression model to improve this task.

5.2 Sentence Compression

Sentence compression is a paraphrasing task aimed at generating sentences shorter than the given ones, while preserving the essential content (Jing, 2000). There are many applications that can benefit from a robust compression system, such as summarization systems (Li et al., 2013), semantic role labeling (Vickrey and Koller, 2008), relation extraction (Miwa et al., 2010) and so on.

Commonly used to compress sentences, tree-based approaches (Knight and Marcu, 2002; Turner and Charniak, 2005; Galley and McKeown, 2007; Cohn and Lapata, 2009; Galanis and Androutsopoulos, 2010; Woodsend and Lapata, 2011; Thadani and McKeown, 2013) compress a sentence by editing the syntactic tree of the original sentence. However, the automatic parsing results may not be correct; thus, the compressed tree (after removing constituents from a bad parse) may not produce a good compressed sentence. McDonald (2006), Nomoto (2007), and Clarke and Lapata (2008) tried to solve the problem by using discriminative models.

Aside from above *extractive* sentence compression approaches, there is another research line, namely, *abstractive* approach, which compresses an original sentence by reordering, substituting, and inserting, as well as removing (Cohn and Lapata, 2013). This method needs more resource and is more complicated. Therefore, in this paper, we only focus on *extractive* approach.

At present, the current sentence compression methods all focus on formal sentences, and few methods are being proposed to study sentiment sentences. As discussed in the above sections, the current compression models cannot be directly utilized to T-P collocation extraction owing to the specificity of sentiment sentences. Therefore, a new compression model for sentiment sentences should be established.

6 Conclusion and Future Work

In this work, we presented a framework that adopted a CRF based sentiment sentence compression model *Sent_Comp*, as a preprocessing step, to improve the T-P collocation extraction task. Different from the existing sentence compression models used for formal sentences, *Sent_Comp* incorporated some sentiment-related features to retain the sentiment information. Experimental results showed that the system with the sentence compression step performed better than that without this step, thus demonstrating the effectiveness of the framework and the compression model *Sent_Comp*.

Generally, the idea of this framework maybe useful for many sentiment analysis tasks that rely heavily on syntactic results. Thus in the future, we will try to apply the *Sent_Comp* model for these tasks. Besides, the simplicity and effectiveness of this framework motivates us to pursue the study further. For example, we will polish the *Sent_Comp* model by exploring more sentiment-related features and exploring other types of compression models.

Hybrid Grammars for Discontinuous Parsing

Abstract

We introduce the concept of hybrid grammars, which are extensions of synchronous grammars, obtained by coupling of lexical elements. One part of a hybrid grammar generates linear structures, another generates hierarchical structures, and together they generate discontinuous structures. This formalizes and generalizes some existing mechanisms for dealing with discontinuous phrase structures and non-projective dependency structures. Moreover, it allows us to separate the degree of discontinuity from the time complexity of parsing.

1 Introduction

Discontinuous phrases occur frequently in languages with relatively free word order, and adequate description of their structure requires special care (Kathol and Pollard, 1995; Müller, 2004). Even for languages such as English, with a relatively rigid word order, there is a clear need for discontinuous structures (McCawley, 1982; Stucky, 1987).

Early treebanks for English (Marcus et al., 1993) have often represented discontinuity in a way that makes it tempting to ignore it altogether, certainly for the purposes of parsing, whereas recent approaches tend to represent discontinuity in a more overt form, sometimes after transformation of existing treebanks (Choi and Palmer, 2010; Evang and Kallmeyer, 2011). In many modern treebanks, discontinuous structures have been given a prominent status (Böhmová et al., 2000).

Classes of trees without discontinuity can be specified as the sets of parse trees of context-free grammars (CFGs). Somewhat larger classes can be specified by tree substitution grammars (Sima'an et al., 1994) and regular tree grammars (Brainerd, 1969; Gécseg and Steinby, 1997). Practical parsers for these three formalisms have running time $\mathcal{O}(n^3)$, where n is the length of the input sentence. Discontinuous structures go beyond their strong generative capacity however. Similarly, non-projective dependency structures cannot be obtained by traditional dependency grammars. See (Rambow, 2010) for discussion of the relation between constituent and dependency structures and see (Maier and Lichte, 2009) for a comparison of discontinuity and non-projectivity.

One way to solve the above problems has been referred to as *pseudo-projectivity*, i.e. a parser produces a projective structure, which in a second phase is transformed into a non-projective structure (Kahane et al., 1998; McDonald and Pereira, 2006; Nivre and Nilsson, 2005). In particular, this may involve *lifting*, whereby one end point of a dependency link moves across a path of nodes. A related idea for discontinuous phrase structure is the reversible splitting conversion of (Boyd, 2007). See also (Johnson, 2002; Campbell, 2004; Gabbard et al., 2006).

As shown by (Nivre, 2009), the second phase of pseudo-projective dependency parsing can be interleaved with the first, by replacing the usual one-way input tape by an additional stack, or *buffer*. Where

Proceedings of COLING 2014, the 25th International Conference on Computational Linguistics: Technical Papers, pages 1370–1381, Dublin, Ireland, August 23-29 2014.

non-topmost positions from the parsing stack are moved back to the buffer, input positions are effectively swapped and non-projective dependency structures arise.

Tree adjoining grammars (TAGs) can describe strictly larger classes of word order phenomena than CFGs (Rambow and Joshi, 1997). TAG parsers have a time complexity of $\mathcal{O}(n^6)$ (Vijay-Shankar and Joshi, 1985). However, the *derived* trees they generate are still continuous. Although their *derivation* trees may be argued to be discontinuous, these by themselves are not normally the desired syntactic structures. It was argued by (Becker et al., 1991) that further additions to TAGs are needed to obtain adequate descriptions of scrambling phenomena.

An alternative is proposed by (Kallmeyer and Kuhlmann, 2012): a transformation is added that turns a derivation tree of a (lexicalized) TAG into a non-projective dependency structure. A very similar mechanism is used to obtain non-projective dependency structures using linear context-free rewriting systems (LCFRSs) (Kuhlmann, 2013) that are lexicalized. In a LCFRS the synthesis of strings is normally specified by yield functions associated with rules. By an additional interpretation of the templates of these yield functions in the algebra of dependency trees (with the overt lexical items as roots), the LCFRS generates both strings and (possibly non-projective) dependency structures.

However, the running time of LCFRS parsers is generally very high, still polynomial in the sentence length, but with a degree determined by properties of the grammar; difficulties involved in running LCFRS parsers for natural languages are described by (Kallmeyer and Maier, 2013).

It follows from the above that there is considerable freedom in the design of parsers that produce discontinuous structures for given input sentences. One can distinguish between two main issues. The first is the formalism that guides the parsing of the input. This determines a class of input (string) languages, which can be that of the context-free languages, or tree adjoining languages, etc. We assume parsing with any of these formalisms results in derivations of some sort. The second main issue is the mechanism that translates such derivations into discontinuous structures.

This leads to a number of open questions that are all related. First, what is, or should be, the division of labor between the parser producing the derivations and the mechanism turning those derivations into discontinuous structures? If we want to achieve high degrees of discontinuity in the output structures, should the formalism for the input language be much more powerful than, say, context-free? Or can highly discontinuous structures be obtained equally well through ordinary CFGs in combination with an advanced mechanism producing discontinuous structures out of derivations?

Second, how should one approach the problem of finding the grammar (and grammar class) for the input language and the mapping from derivations to structures if the only thing that is given is a treebank? A third question is which formalisms are suitable to formally describe mappings from derivations to discontinuous structures. Lastly, can we characterize the classes of output (tree-)languages for various combinations of input grammars and derivation-to-structure mappings?

In this paper we provide one possible answer to these questions by a new type of formalism, which we call *hybrid grammars*. Such a grammar consists of a string grammar and a tree grammar. Derivations are coupled so as to achieve synchronous rewriting. The input string language and the output tree language are thereby straightforwardly defined. Different from synchronous grammars (Shieber and Schabes, 1990; Satta and Peserico, 2005) is that occurrences of terminal symbols are also coupled. Thereby the linear order of the symbols in a derived string imposes an order on the coupled symbols in the synchronously derived tree; this allows a straightforward specification of a discontinuous structure.

One can define a hybrid grammar consisting of a simple macro grammar (Fischer, 1968) and a simple context-free tree grammar (Rounds, 1970), but various other combinations of a string grammar and a tree grammar are possible as well. Due to lack of space we will here concentrate on only one kind of hybrid grammar, namely that consisting of a LCFRS as string grammar and a form of definite clause program as tree grammar. We will show that hybrid grammars that induce (finite) sets of hybrid trees can always be constructed, even if the allowable derivations are severely restricted, and we discuss experiments. Lastly, a negative result will be given, which shows that a certain linguistic phenomenon cannot be handled if the string grammar is too restricted.

We cast our definitions in terms of *hybrid trees*, of which discontinuous phrase structures and non-

projective dependency structures are special cases.[1] Thereby the generality of the framework is demonstrated.

2 Preliminaries

Let $\mathbb{N} = \{0, 1, 2, \ldots\}$ and $\mathbb{N}_+ = \mathbb{N} \setminus \{0\}$. For each $n \in \mathbb{N}_+$, we let $[n]$ stand for the set $\{1, \ldots, n\}$, and we let $[0]$ stand for $\emptyset$. We write $[n]_0$ to denote $[n] \cup \{0\}$. We fix an infinite list $x_1, x_2, \ldots$ of pairwise distinct *variables*. We let $X = \{x_1, x_2, x_3, \ldots\}$ and $X_k = \{x_1, \ldots, x_k\}$ for each $k \in \mathbb{N}$.

A *ranked set* Δ is a set of symbols, associated with a rank function assigning a number $\mathrm{rk}_\Delta(\delta) \in \mathbb{N}$ to each symbol $\delta \in \Delta$. A *ranked alphabet* is a ranked set with a finite number of symbols. We let $\Delta^{(k)}$ denote $\{\delta \in \Delta \mid \mathrm{rk}_\Delta(\delta) = k\}$.

The following definitions were inspired by (Seki and Kato, 2008). The sets of *terms* and *sequence-terms* (*s-terms*) over ranked set Δ, with variables in some set $Y \subseteq X$, are denoted by $T_\Delta(Y)$ and $T^*_\Delta(Y)$, respectively, and defined inductively as follows:
(i) $Y \subseteq T_\Delta(Y)$,
(ii) if $k \in \mathbb{N}$, $\delta \in \Delta^{(k)}$ and $s_i \in T^*_\Delta(Y)$ for each $i \in [k]$, then $\delta(s_1, \ldots, s_k) \in T_\Delta(Y)$, and
(iii) if $n \in \mathbb{N}$ and $t_i \in T_\Delta(Y)$ for each $i \in [n]$, then $\langle t_1, \ldots, t_n \rangle \in T^*_\Delta(Y)$.
We let T^*_Δ and T_Δ stand for $T^*_\Delta(\emptyset)$ and $T_\Delta(\emptyset)$ respectively. Throughout this paper, we use variables such as s and s_i for s-terms and variables such as t and t_i for terms. The justification for using s-terms as defined here is that they provide the required flexibility for dealing with both strings ($\Delta = \Delta^{(0)}$) and unranked trees ($\Delta = \Delta^{(1)}$), in combination with derivational nonterminals.

Concatenation of s-terms is given by $\langle t_1, \ldots, t_n \rangle \cdot \langle t_{n+1}, \ldots, t_{n+m} \rangle = \langle t_1, \ldots, t_{n+m} \rangle$. Sequences such as $s_1, \ldots, s_k$ or $x_1, \ldots, x_k$ will typically be abbreviated to $s_{1,k}$ or $x_{1,k}$, respectively. For $\delta \in \Delta^{(0)}$ we sometimes abbreviate $\delta()$ to δ.

In examples we also abbreviate $\langle t_1, \ldots, t_n \rangle$ to $t_1 \cdots t_n$, that is, omitting the angle brackets and commas. Moreover, we sometimes abbreviate $\delta(\langle\rangle)$ to δ. Whether δ then stands for $\delta(\langle\rangle)$ or for $\delta()$ depends on whether $\delta \in \Delta^{(1)}$ or $\delta \in \Delta^{(0)}$, which will be clear from the context.

Subterms in terms or s-terms are identified by *positions*; these can be formalized by a suitable refinement of the familiar notion of Gorn address. The set of all positions in term t or in s-term s is denoted by $\mathrm{pos}(t)$ or $\mathrm{pos}(s)$, respectively. The subset of $\mathrm{pos}(t)$ consisting of all positions where the label is in some set $\Gamma \subseteq \Delta$ is denoted by $\mathrm{pos}_\Gamma(t)$.

3 Hybrid trees

The purpose of this section is to unify existing notions of non-projective dependency structures and discontinuous phrase structures, formalized using s-terms.

We fix an alphabet $\Delta = \Delta^{(1)}$ and a subset $\Gamma \subseteq \Delta$. A *hybrid tree* over (Γ, Δ) is a pair $h = (s, \leq_s)$, where $s \in T^*_\Delta$ and $\leq_s$ is a total order on $\mathrm{pos}_\Gamma(s)$. In words, a hybrid tree combines hierarchical structure, in the form of an s-term over the full alphabet Δ, with a linear structure, which can be seen as a string over $\Gamma \subseteq \Delta$. This string will be denoted by $\mathrm{str}(h)$.

For discontinuous phrase structures, the elements of Γ would typically represent lexical items, and the elements of $\Delta \setminus \Gamma$ would typically represent syntactic categories. For non-projective dependency structures, Δ would be equal to Γ. Simple examples of discontinuous phrase structures are presented in Figures 1 and 2.

4 Basic grammatical formalisms

The concept of hybrid grammars is illustrated in Section 5, by coupling a class of string grammars and a class of tree grammars.

[1] Moreover, we need to avoid any confusion with the term "discontinuous tree" from (Bunt, 1996), which is characterized by the notion of "context daughter", which is absent from our framework. The term "hybrid tree" was used before by (Lu et al., 2008), also for a mixture of a tree structure and a linear structure, generated by a probabilistic model. However, the linear 'surface' structure was obtained by a simple left-to-right tree traversal, whereas a meaning representation was obtained by a slightly more flexible traversal of the same tree. The emphasis in the current paper is rather on separating the linear structure from the tree structure.

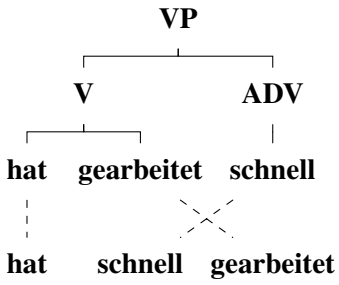

Figure 1: Hybrid tree for German "[...] hat schnell gearbeitet" ("[...] has worked quickly"), after (Seifert and Fischer, 2004). The bottom line indicates the word order in German. (Alternative analyses exist that do not require discontinuity; we make no claim the structure above is the most adequate.)

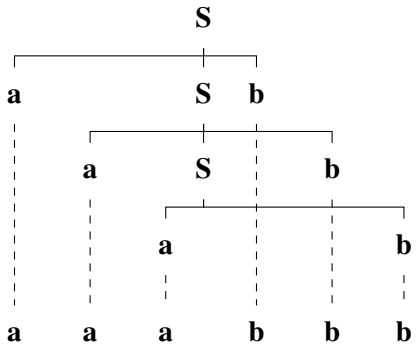

Figure 2: Abstract representation of cross-serial dependencies in Dutch (Bresnan et al., 1982).

4.1 Linear context-free rewriting systems

Much as in (Vijay-Shanker et al., 1987), we define a *linear context-free rewriting system* (LCFRS) as a tuple $G = (N, S, \Sigma, P)$, where N is a ranked alphabet of *nonterminals*, $S \in N^{(1)}$ is the *start symbol*, $\Sigma = \Sigma^{(0)}$ is a ranked alphabet of *terminals* ($\Sigma \cap N = \emptyset$), and P is a finite set of *rules*, each of the form:

$$A_0(s_{1,k_0}) \rightarrow \langle A_1(x_{1,m_1}), A_2(x_{m_1+1,m_2}), \ldots, A_n(x_{m_{n-1}+1,m_n})\rangle \tag{1}$$

where $n \in \mathbb{N}$, $A_i \in N^{(k_i)}$ for each $i \in [n]_0$, and $m_i = \sum_{j:1\leq j\leq i} k_j$ for each $i \in [n]$, and $s_j \in T^*_\Sigma(X_{m_n})$ for each $j \in [k_0]$. In words, the right-hand side is an s-term consisting of nonterminals A_i ($i \in [n]$), with distinct variables as arguments; there are m_n variables altogether, which is the sum of the ranks k_i of all A_i ($i \in [n]$). The left-hand side is an occurrence of A_0 with each argument being a string of variables and terminals. Furthermore, we demand that each x_j ($j \in [m_n]$) occurs exactly once in the left-hand side. The largest rank of any nonterminal is called the *fanout* of the grammar.

A *rule instance* is obtained by choosing a rule of the above form, and consistently substituting variables with s-terms in T^*_Σ (which are strings due to the terminals having rank 0). The language induced is the set of s-terms s such that $\langle S(s)\rangle \Rightarrow^*_G \langle\rangle$, where $\Rightarrow_G$ is the 'derives' relation that uses rule instances. For given s, the set of all LCFRS derivations $\langle S(s)\rangle \Rightarrow^*_G \langle\rangle$ (in compact tabular form) can be obtained in polynomial time in the length of s (Seki et al., 1991).

Example 1

An example of a LCFRS is presented on the right. Terminals are lower case bold letters and nonterminals are upper-case italic letters. All derived strings are of the form $\mathbf{a}^m\mathbf{c}^n\mathbf{b}^m\mathbf{d}^n$ with $m, n \in \mathbb{N}$. The linguistic relevance lies in cross-serial dependencies in Swiss German (Shieber, 1985).

$$\begin{aligned}
S(x_1x_3x_2x_4) &\rightarrow A(x_1, x_2)\ B(x_3, x_4)\\
A(\mathbf{a}x_1, \mathbf{b}x_2) &\rightarrow A(x_1, x_2)\\
A(\langle\rangle, \langle\rangle) &\rightarrow \langle\rangle\\
B(\mathbf{c}x_1, \mathbf{d}x_2) &\rightarrow B(x_1, x_2)\\
B(\langle\rangle, \langle\rangle) &\rightarrow \langle\rangle
\end{aligned}$$

4.2 Definite clause programs

In this section we describe a particular kind of definite clause programs. Our definition is inspired by (Deransart and Małuszynski, 1985), which investigated the relation between logic programs and attribute grammars, together with the "syntactic single use requirement" from (Giegerich, 1988). The values produced are trees (or to be more precise s-terms).

A *simple definite clause program* (sDCP) is a tuple $G = (N, S, \Sigma, P)$, where N is a ranked alphabet of *nonterminals* and $\Sigma = \Sigma^{(1)}$ is a ranked alphabet of *terminals*.[2] Moreover, each nonterminal $A \in N$ has a fixed i-rank (the number of *inherited* arguments) and a fixed s-rank (the number of *synthesized* arguments), denoted by i-rk(A) and s-rk(A), respectively, satisfying i-rk(A) + s-rk(A) = $\mathrm{rk}_N(A)$. In our notation, the inherited arguments precede the synthesized arguments. The *start symbol* S has only one argument, which is synthesized, i.e. $\mathrm{rk}_N(S) =$ s-rk$(S) = 1$ and i-rk$(S) = 0$.

A rule is of the form:

$$A_0(x^{(0)}_{1,k_0}, s^{(0)}_{1,k'_0}) \to \langle A_1(s^{(1)}_{1,k_1}, x^{(1)}_{1,k'_1}), \ldots, A_n(s^{(n)}_{1,k_n}, x^{(n)}_{1,k'_n})\rangle \tag{2}$$

where $n \in \mathbb{N}$, $k_i =$ i-rk(A_i) and $k'_i =$ s-rk(A_i), for $i \in [n]_0$. The set of variables occurring in the lists $x^{(0)}_{1,k_0}$ and $x^{(i)}_{1,k'_i}$ ($i \in [n]$) equals X_m, where $m = k_0 + \sum_{i\in[n]} k'_i$. In other words, every variable from X_m occurs exactly once in all these lists together. This is where values 'enter' the rule. Further, the s-terms in $s^{(0)}_{1,k'_0}$ and $s^{(i)}_{1,k_i}$ ($i \in [n]$) are in $T^*_\Sigma(X_m)$ and together contain each variable in X_m exactly once. This is where values are combined and 'exit' the rule.

The 'derives' relation $\Rightarrow_G$ and other relevant notation are defined as for LCFRSs (where the s-terms in arguments are now trees due to the terminals having rank 1). If the rules in a derivation are given, then the relevant rule instances are uniquely determined, and can be computed in linear time in the size of the derivation, provided the sDCP contains no cycles. The existence of cycles is decidable, as we know from the literature on attribute grammars. There are sufficient conditions for absence of cycles, such as the grammar being L-attributed (Bochmann, 1976). In this article, we will assume that sDCPs contain no cycles.

Example 2

An example of a sDCP is presented on the right, where the first argument of B is inherited and all other arguments are synthesized. A derived s-term is e.g. **c B**(**c B**(**a A**($\langle\rangle$) **b**) **d**) **d**.

$$\begin{aligned}
S(x_2) &\to A(x_1)\ B(x_1, x_2)\\
A(\mathbf{a}\ \mathbf{A}(x_1)\ \mathbf{b}) &\to A(x_1)\\
A(\langle\rangle) &\to \langle\rangle\\
B(x_1, \mathbf{c}\ \mathbf{B}(x_2)\ \mathbf{d}) &\to B(x_1, x_2)\\
B(x_1, x_1) &\to \langle\rangle
\end{aligned}$$

5 Hybrid grammars

We couple derivations in two grammars in a way similar to how this is commonly done for synchronous grammars, namely by *indexed* symbols. However, we apply the mechanism not only to derivational nonterminals but also to terminals.

Let Γ be a ranked alphabet. We define the ranked set $\mathcal{I}(\Gamma) = \{\gamma^{[u]} \mid \gamma \in \Gamma, u \in \mathbb{N}_+\}$, with $\mathrm{rk}_{\mathcal{I}(\Gamma)}(\gamma^{[u]}) = \mathrm{rk}_\Gamma(\gamma)$. Let Δ be another ranked alphabet ($\Delta \cap \Gamma = \emptyset$) and $Y \subseteq X$, with X as in Section 2. We let $\mathcal{I}^*_{\Gamma,\Delta}(Y)$ be the set of all s-terms $s \in T^*_{\mathcal{I}(\Gamma)\cup\Delta}(Y)$ in which each index occurs at most once.

For an s-term s, let $ind(s)$ be the set of all indices occurring in s. The deindexing function $\mathcal{D}$ removes all indices from an s-term $s \in \mathcal{I}^*_{\Gamma,\Delta}(Y)$ to obtain $\mathcal{D}(s) \in T^*_{\Gamma\cup\Delta}(Y)$. The set $\mathcal{I}_{\Gamma,\Delta}(Y) \subseteq T_{\mathcal{I}(\Gamma)\cup\Delta}(Y)$ of terms with indexed symbols is defined much as above. We let $\mathcal{I}^*_{\Gamma,\Delta} = \mathcal{I}^*_{\Gamma,\Delta}(\emptyset)$ and $\mathcal{I}_{\Gamma,\Delta} = \mathcal{I}_{\Gamma,\Delta}(\emptyset)$.

A *LCFRS/sDCP hybrid grammar* (HG) is a tuple $G = ((N_1, S_1, \Gamma), (N_2, S_2, \Sigma), P)$, subject to the following restrictions. The objects Γ and Σ are ranked alphabets with $\Gamma = \Gamma^{(0)}$ and $\Sigma = \Sigma^{(1)}$. As mere sets of symbols, we demand $\Gamma \subseteq \Sigma$ but the rank functions associated with Γ and Σ differ. Let Δ be the ranked alphabet $\Sigma \setminus \Gamma$, with $\mathrm{rk}_\Delta(\delta) = 1$ for $\delta \in \Delta$.

The *hybrid rules* in P are of the form $[\rho_1, \rho_2]$ where ρ_1 has the form in Equation (1) of an LCFRS rule except that $s_i \in \mathcal{I}^*_{\Gamma,\emptyset}(X_{m_n})$ ($i \in [k_0]$) and $A_i \in \mathcal{I}(N_1)$ ($i \in [n]$) and each index in ρ_1 occurs exactly once, and ρ_2 has the form in Equation (2) of a sDCP rule except that the s-terms in $s^{(0)}_{1,k'_0}$ and $s^{(i)}_{1,k_i}$ ($i \in [n]$) are in $\mathcal{I}^*_{\Gamma,\Delta}(X_m)$ and $A_i \in \mathcal{I}(N_2)$ ($i \in [n]$) and each index in ρ_2 occurs exactly once. We require that $ind(\rho_1) = ind(\rho_2)$ and each index either couples a pair of identical terminals or couples a pair of (possibly distinct) nonterminals.

[2]The term 'simple' here has a more restrictive meaning than the term with the same name in (Deransart and Małuszynski, 1985).

Let P_1 and P_2 be the sets of all $\mathcal{D}(\rho_1)$ and $\mathcal{D}(\rho_2)$, respectively, of some hybrid rule $[\rho_1, \rho_2]$. Then we refer to the LCFRS (N_1, S_1, Γ, P_1) and the sDCP (N_2, S_2, Σ, P_2) as the first and second *components*, respectively, of G.

In order to define the 'derives' relation $\Rightarrow_G$, we need rule instantiation as before, in combination with *reindexing*, which is a common notion for synchronous grammars. This allows specification of a set of pairs $[s_1, s_2] \in \mathcal{I}^*_{\Gamma,\emptyset} \times \mathcal{I}^*_{\Gamma,\Delta}$ which are such that $[\langle S_1^{\boxed{1}}(s_1)\rangle, \langle S_2^{\boxed{1}}(s_2)\rangle] \Rightarrow^*_G [\langle\rangle, \langle\rangle]$. For each such pair we can construct a hybrid tree $(s, \leq_s)$ over (Γ, Σ), where $s = \mathcal{D}(s_2)$, and $\leq_s$ is defined as follows. If there is a combination of positions p_1, p'_1, p_2, p'_2 such that at p_1 in s_1 we find the same label as at p_2 in s_2 (this label must then be in $\mathcal{I}(\Gamma)$), and at p'_1 in s_1 we find the same label as at p'_2 in s_2, and p_1 occurs to the left of p'_1, then $p_2 \leq_s p'_2$. The language induced by G is defined as the set of all such hybrid trees.

Given an input string, the desired hybrid trees can be effectively enumerated. To be exact, after construction of the parse table by a LCFRS parser, which takes polynomial time in the length of the string, synchronous derivations can be enumerated. Extracting a single derivation from the table requires linear time in the size of that derivation. Given a derivation, an s-term can be constructed in linear time in the size of that derivation, applying sDCP rules in the second component. This s-term, in combination with the input string and the indices linking the two is then easily extended to a hybrid tree as outlined above.

Example 3

The hybrid tree in Figure 1 is obtained by the HG on the right. (All arguments in the second component are synthesized.) We derive:

$$[\mathit{VP}(x_1x_2x_3) \rightarrow V^{\boxed{1}}(x_1, x_3)\ \mathit{ADV}^{\boxed{2}}(x_2), \mathit{VP}(\mathbf{VP}(x_1x_2)) \rightarrow V^{\boxed{1}}(x_1)\ \mathit{ADV}^{\boxed{2}}(x_2)]$$
$$[V(\mathbf{h}^{\boxed{1}}, \mathbf{g}^{\boxed{2}}) \rightarrow \langle\rangle, V(\mathbf{V}(\mathbf{h}^{\boxed{1}}\mathbf{g}^{\boxed{2}})) \rightarrow \langle\rangle]$$
$$[\mathit{ADV}(\mathbf{s}^{\boxed{1}}) \rightarrow \langle\rangle, \mathit{ADV}(\mathbf{ADV}(\mathbf{s}^{\boxed{1}})) \rightarrow \langle\rangle]$$

$$[\mathit{VP}^{\boxed{1}}(\mathbf{h}^{\boxed{2}}\mathbf{s}^{\boxed{3}}\mathbf{g}^{\boxed{4}}), \mathit{VP}^{\boxed{1}}(\mathbf{VP}(\mathbf{V}(\mathbf{h}^{\boxed{2}}\mathbf{g}^{\boxed{4}})\ \mathbf{ADV}(\mathbf{s}^{\boxed{3}})))] \Rightarrow$$
$$[V^{\boxed{1}}(\mathbf{h}^{\boxed{2}}, \mathbf{g}^{\boxed{4}})\ \mathit{ADV}^{\boxed{5}}(\mathbf{s}^{\boxed{3}}), V^{\boxed{1}}(\mathbf{V}(\mathbf{h}^{\boxed{2}}\mathbf{g}^{\boxed{4}}))\ \mathit{ADV}^{\boxed{5}}(\mathbf{ADV}(\mathbf{s}^{\boxed{3}}))] \Rightarrow$$
$$[\mathit{ADV}^{\boxed{5}}(\mathbf{s}^{\boxed{3}}),\ \mathit{ADV}^{\boxed{5}}(\mathbf{ADV}(\mathbf{s}^{\boxed{3}}))] \Rightarrow [\langle\rangle, \langle\rangle]$$

Note that in the LCFRS that is the first component of the HG above, nonterminal V has rank 2. On the right is an alternative HG deriving the same hybrid tree, but now with all LCFRS nonterminals having rank 1, by which we obtain a syntactic variant of a CFG. Yet another HG for the same hybrid tree will be discussed in the next section, where we will see that the first and second components can be disconnected even further, departing from the traditional way of LCFRS parsing.

$$[\mathit{VP}(x_1) \rightarrow V^{\boxed{1}}(x_1), \mathit{VP}(\mathbf{VP}(x_1)) \rightarrow V^{\boxed{1}}(x_1)]$$
$$[V(\mathbf{h}^{\boxed{1}}x_1\mathbf{g}^{\boxed{2}}) \rightarrow \mathit{ADV}^{\boxed{3}}(x_1), V(\mathbf{V}(\mathbf{h}^{\boxed{1}}\mathbf{g}^{\boxed{2}})\ x_1) \rightarrow \mathit{ADV}^{\boxed{3}}(x_1)]$$
$$[\mathit{ADV}(\mathbf{s}^{\boxed{1}}) \rightarrow \langle\rangle, \mathit{ADV}(\mathbf{ADV}(\mathbf{s}^{\boxed{1}})) \rightarrow \langle\rangle]$$

Example 4

Hybrid trees as in Figure 2 can be obtained by the HG on the right.

$$[A(x_1x_2) \rightarrow S^{\boxed{1}}(x_1, x_2), A(x_1) \rightarrow S^{\boxed{1}}(x_1)]$$
$$[S(\mathbf{a}^{\boxed{1}}x_1, \mathbf{b}^{\boxed{2}}x_2) \rightarrow S^{\boxed{3}}(x_1, x_2), S(\mathbf{S}(\mathbf{a}^{\boxed{1}}x_1\mathbf{b}^{\boxed{2}}) \rightarrow S^{\boxed{3}}(x_1)]$$
$$[S(\langle\rangle, \langle\rangle) \rightarrow \langle\rangle, S(\langle\rangle) \rightarrow \langle\rangle]$$

6 Grammar induction

We define a *recursive partitioning* of a string $s = \alpha_1 \cdots \alpha_n$ as a tree whose nodes are labeled with subsets of $[n]$. The root is labeled with $[n]$. Each leaf is labeled with a single element of $[n]$. Each internal node is labeled with the union of the labels of its children, which furthermore must be disjoint. We say a subset of $[n]$ has *fanout* k if k is the smallest number such that it can be written as the union of k sets of consecutive numbers.

A derivation of an LCFRS relates straightforwardly to a recursive partitioning. Consider for example the derivation of string **h s g** by the LCFRS that is the first component of the first HG in Example 3. The root would be labeled $\{1, 2, 3\}$, with children labeled $\{1, 3\}$ and $\{2\}$. The node labeled $\{1, 3\}$ has children labeled $\{1\}$ and $\{3\}$. The fanout of $\{1, 3\}$ is 2, whereas it is 1 for all other node labels. One may also extract a recursive partitioning directly from a hybrid tree, by associating each node with the set of positions of terminals that it dominates. For example, Figure 1 gives rise to the same recursive partitioning as the one mentioned above.

One central observation of this paper is that for any hybrid tree $h = (s, \leq_s)$ and any recursive partitioning of $\mathrm{str}(h)$, not necessarily extracted from h, we can construct a hybrid grammar G allowing a derivation of h, and moreover, the first (LCFRS) component of that derivation parses $\mathrm{str}(h)$ according to the given recursive partitioning. This observation holds for both dependency structures and constituent structures. The proof for dependency structures is quite technical however, and requires that the second (sDCP) component of a hybrid grammar has rules with inherited arguments. For lack of space, we can only give an outline for constituent structures, or in other words, we consider only input hybrid trees over (Γ, Δ) where labels from Γ occur exclusively at the leaves. In the resulting hybrid grammars, all sDCP rules will have only synthesized arguments.

The intuition is the following. For each node of the given recursive partitioning, the numbers in its label correspond to leaves of s, for the given hybrid tree $h = (s, \leq_s)$. There is a smallest number of maximal disjoint subtrees in s that together contain all those leaves and no others. If we now relate a parent node of the recursive partitioning to its child nodes, then we see that the relevant disjoint subtrees in s for the children can be combined to give the relevant disjoint subtrees for the parent, possibly adding further internal nodes. This process can be expressed in terms of a hybrid rule. Each pair consisting of a hybrid tree and a recursive partitioning gives rise to a number of hybrid rules. For a collection of such pairs, we can combine all the rules into a hybrid grammar.

Example 5 Consider again the hybrid tree in Figure 1, in combination with a recursive partitioning whose root has children labeled $\{1, 2\}$ and $\{3\}$. The relevant disjoint subtrees for $\{1, 2\}$ are **hat** and **ADV**(**schnell**) and for $\{3\}$ there is the subtree **gearbeitet**. (In a real-world grammar we would have parts of speech occurring above all the words.) An appropriate hybrid rule that both respects the recursive partitioning (by the first component LCFRS rule) and puts together relevant parts of the hybrid tree (by the second component sDCP rule) would be of the form:

$$[A(x_1x_2) \rightarrow B^{\boxed{1}}(x_1)\ C^{\boxed{2}}(x_2), A(\mathbf{VP}(\mathbf{V}(x_1x_3)x_2)) \rightarrow B^{\boxed{1}}(x_1, x_2)\ C^{\boxed{2}}(x_3)]$$

Here A, B and C should to be chosen to be consistent with neighboring nodes in the recursive partitioning, to be discussed next. An alternative recursive partitioning whose root has children labeled $\{1, 3\}$ and $\{2\}$ leads to the first hybrid rule in Example 3 (apart from nonterminal names).

We have experimented with two ways of naming nonterminals in the derived hybrid rules. The first encodes the list of labels of the roots of the relevant disjoint subtrees. In the above example, we would have a name such as $\langle \mathbf{hat}, \mathbf{ADV} \rangle$ for A. For fanout greater than 1, the locations of the 'gaps' are explicitly indicated. For example, we might have $\langle \mathbf{hat}, \mathit{gap}, \mathbf{gearbeitet} \rangle$. We will call this *strict* labeling. The second, and less precise, way is to replace lists of labels of siblings by a single name of the form children-of(X), where X is the label of the parent. We will call this *child* labeling.

Because our construction of hybrid grammars works for all recursive partitionings, there is no need to limit ourselves to those extracted directly from the hybrid trees. Moreover, a given recursive partitioning can be transformed into a similar but different one in which fanout is restricted to some given value $k \geq 1$. One possible procedure is to start at the root. If the label J of the present node is a singleton, then we stop. Otherwise, we search breadth-first through the subtree of the present node to identify a descendant such that both its label J' and $J \setminus J'$ have fanout not exceeding k. (It is easy to see such a node always exists: ultimately breadth-first search will reach the leaves, which are labeled with singletons.) The present node is now given two children, the first is the node labeled J' that we identified above, and the second is a copy of the present subtree, but with J' subtracted from the label of every node. (Nodes

labeled with the empty set are removed, and if a node has the same label as its parent then the two are collapsed.) We repeat the procedure for both children recursively. Note that with $k = 1$, we can induce a 'CFG/sDCP' hybrid grammar, that is, with the first component having fanout 1.

Example 6

The recursive partitioning in the left half of Figure 3 has a node labeled $\{1, 3, 6, 7\}$, with fanout 3. With $J = \{1, 2, 3, 5, 6, 7\}$ and $k = 2$, one possible choice for J' is $\{3, 7\}$, as then both J' and $J \setminus J' = \{1, 2, 5, 6\}$ have fanout not exceeding 2. This leads to the partitioning in the right half of the figure. Because now all node labels have fanout not exceeding 2, recursive traversal will make no further changes. Other valid choices for J' would be $\{2\}$ and $\{5\}$. Not a valid choice for J' would be $\{1, 6\}$, as $J \setminus \{1, 6\} = \{2, 3, 5, 7\}$, which has fanout 3.

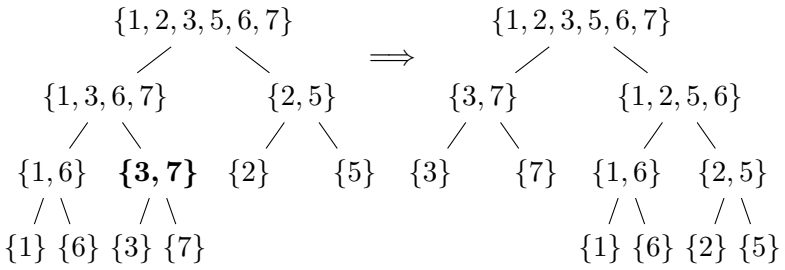

Figure 3: Transformation of recursive partitioning to restrict fanout to 2.

Our procedure ensures that subsequent grammar induction leads to binary grammars. Note that this contrasts with binarization algorithms (Gómez-Rodríguez and Satta, 2009; Gómez-Rodríguez et al., 2009) that are applied *after* a grammar is obtained. Unlike (van Cranenburgh, 2012), our objective is not to obtain a 'coarse' grammar for the purpose of coarse-to-fine parsing.

In experiments we also considered the *right-branching* partitioning, whose internal node labels are $\{m, m + 1, \ldots, n\}$, with children labeled $\{m\}$ and $\{m + 1, \ldots, n\}$. Similarly, there is a left-branching recursive partitioning. In this way, we can induce a 'FA/sDCP' hybrid grammar, with the first component having finite-state power, which means we can parse in linear time.

7 Experiments

The theory developed above shows that hybrid grammars allow considerable flexibility in the first component, leading to a wide range of different time complexities of parsing while, at least potentially, the same kinds of discontinuous structures can be obtained. We have run experiments to measure what impact different choices of the first component have on recall/precision and the degree of discontinuity.

The training data consisted of the first 7000 trees of the TIGER treebank (Brants et al., 2004). From these, recursive partitionings were straightforwardly obtained, and transformed for different values of k. Also the left-branching and right-branching recursive partitionings were considered. Hybrid grammars were then extracted using strict or child labeling. Probabilities of rules were determined by relative frequency estimation, without any smoothing techniques.

Test sentences were taken from the next 500 trees, excluding sentences of length greater than 20 and those where a single tree did not span the entire sentence, leaving 324 sentences. Parsing was on (gold standard) parts of speech rather than words. All punctuation was ignored. Labeled recall, precision and F-measure were computed on objects each consisting of the label of a node and a sequence of pairs of input positions delimiting substrings covered by that node. The algorithms were implemented in Python and the experiments were carried out on a desktop with four 3.1GHz Intel Core i5 CPUs.

Results are reported in Table 1. The choice of $k = 1$ can be seen as a baseline, the first component then being restricted to context-free power. Note that $k = 1, 2, 3$ imply parsing complexities $\mathcal{O}(n^3)$, $\mathcal{O}(n^6)$, $\mathcal{O}(n^9)$, respectively.

In the case of strict labeling, the change from $k = 1$ to $k = 2$ leads to significant changes in running time, but that from $k = 2$ to $k = 3$ less so, which can be explained by the smaller number of constituents that have two gaps, compared to those with zero or one gap. There was no significant change, neither in running time nor in F-measure, for values of k greater than 4, and therefore these values were omitted

here. Note that for $k = \infty$ one would obtain the conventional technique of discontinuous parsing using LCFRSs. For the right-branching recursive partitionings, the running time is significantly higher than that for the left-branching ones, although it is linear-time in both cases. This is due to the directional bias of the implemented parsing strategy. In order to allow a straightforward comparison we have taken the same parsing strategy in all cases. Note the large number of parse failures for the right-branching and left-branching partitionings, which is explained by the large number of very specific nonterminals.

Child labeling leads to much smaller numbers of nonterminals, and thereby also to more ambiguity, and as a result the increase from time complexity $\mathcal{O}(n^3)$ to $\mathcal{O}(n^6)$ is more noticeable in terms of the actual running time. Therefore carrying out the experiment for $k \geq 3$ was outside our reach. Surprisingly, the right-branching partitioning performed very well in this case, with a relatively low number of parse failures, F-measure competing with $k = 1, 2, 3, 4$ and strict labeling, although it is clearly worse than that with $k = 1, 2$ and child labeling, and running time smaller than in the case of any of the hybrid grammars where the first component has power beyond that of finite automata.

	fail	R	P	F1	# gaps	secs
strict labeling						
$k = 1$	16	73.0	70.4	71.2	0.0075	442
$k = 2$	12	73.1	70.7	71.4	0.0111	2,580
$k = 3$	12	73.1	70.7	71.4	0.0121	2,942
$k = 4$	12	73.1	70.7	71.4	0.0127	2,828
r-branch	151	65.6	62.4	63.2	0.0118	775
l-branch	266	82.0	78.9	79.5	0.0124	24
child labeling						
$k = 1$	4	74.3	74.2	73.9	0.0120	939
$k = 2$	4	75.0	75.1	74.7	0.0125	58,164
r-branch	15	73.1	73.0	72.6	0.0117	319
l-branch	56	75.7	76.6	75.7	0.0114	183

Table 1: Number of parse failures, recall, precision, F-measure, average number of gaps per constituent, and running time.

Child labeling generally gave better F-measure than strict labeling (ignoring strict labeling and left-branching partitioning, where the many parse failures distort the recall and precision). This seems to be due to the more accurate parameter estimation that was possible for the smaller numbers of rules obtained with child labeling.

The differences in F-measure are relatively small for varying k. This can be explained by the relatively small portion of discontinuous structures in the test set. We have looked closer at discontinuity in the test set in two ways. First, we measured the average number of gaps per constituent, which in the gold standard was 0.0171. None of the hybrid grammars came close to achieving this, but we do observe that more discontinuity is obtained for higher values of k. Secondly, we reran the experiments for only the 75 sentences out of the aforementioned 324 where the gold structure had at least one discontinuous phrase. For this smaller set, F1 increases from 59.5 ($k = 1$) to 61.9 ($k = 2, 3, 4$) for strict labeling, and it increases from 64.4 ($k = 1$) to 66.5 ($k = 2$) for child labeling. This suggests that with higher k, the additional discontinuous structures found have at least some overlap with those of the gold standard. Note again that there is no a priori bound on the fanout of produced hybrid trees, even when the first component has finite-state power, but the ability to abstract away from discontinuous structures in the training set seems to be enhanced if the first component is more powerful. This is consistent with observations made by (van Cranenburgh, 2012).

8 Limitations

The theory from Section 6 does not necessarily mean that any language of hybrid trees can be induced by a HG whose first-component LCFRS has arbitrarily low fanout. We illustrate this by means of the language of hybrid trees generated by the HG of Example 4, in which the LCFRS has fanout 2. No CFG/sDCP grammar in fact exists for the same language, or in other words, the fanout of the first-component LCFRS cannot be reduced to 1, regardless of how we choose the second-component sDCP.

For a proof, assume that a CFG/sDCP grammar does exist. Let m be the maximum number of members in the right-hand side of any CFG rule. Let k be the maximum rank of any nonterminal in the second-component sDCP. Now consider a CFG/sDCP derivation for a hybrid tree with yield $a^n b^n$, where $n \geq$

$2 \cdot k \cdot m$. In a top-down traversal, identify the first CFG nonterminal occurrence that covers a substring of the input string that has a length smaller than or equal to $n/2$ and greater than k. This substring may contain occurrences of a and of b, but because its length is at most $n/2$, there will not be any pair consisting of an occurrence of a and an occurrence of b that are both part of that substring, and that have a common parent labeled S in the hybrid tree. This means that more than k tree fragments or tree nodes with missing child nodes are involved, which translate to more than k synthesized or inherited arguments, contradicting the assumptions.

9 Conclusions

We have presented hybrid grammars as a novel framework for describing languages of discontinuous syntactic structures. This framework sheds light on the relation between various existing techniques, but it also offers potential for development of novel techniques. Much of what we have shown is merely an illustration of particular instances of this framework. For example, next to the hybrid grammars discussed here, we can consider those with macro grammars as first component, or simple context-free tree grammars as second component. Many variations exist on the illustrated grammar induction technique. For example, next to our strict labeling and child labeling, one can consider approaches using latent variables, combined with expectation-maximization.

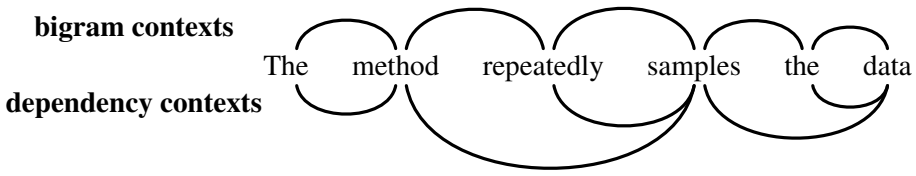
Abstract

We present an effective modification of the popular Brown et al. 1992 word clustering algorithm, using a dependency language model. By leveraging syntax-based context, resulting clusters are better when evaluated against a wordnet for Dutch. The improvements are stable across parameters such as number of clusters, minimum frequency and granularity. Further refinement is possible through dependency relation selection. Our approach achieves a desired clustering quality with less data, resulting in a decrease in cluster creation times.

1 Introduction

Semi-supervised approaches have been successful in various areas of natural language processing. Among a plethora of clustering techniques, Brown clustering (Brown et al., 1992) is popular for its conceptual simplicity, available implementations (Liang, 2005; Stolcke, 2002), and because the resulting word clusters can be helpful for several tasks. Clusters are used as syntactic and semantic *generalizations* of words, requiring fewer model parameters.

Brown clustering (section 2) groups words based on shared context. However, only immediately adjacent words are taken into account as recognized e.g. by Koo et al. (2008), Sagae and Gordon (2009), and Grave et al. (2013). For example, even though verbs constitute an informative context for object nouns, they are rarely considered in Brown clustering, unlike in dependency-based clustering. The difference between the contexts can be illustrated with the following example:



The bigram context thus fails to capture the relation between the object *data* and the predicate *samples*, as well as the one between the subject *method* and the predicate. Furthermore, the dependency representation rightly ignores some of the less informative contexts coming from immediately adjacent words. For example, there is no relation between the predicate *samples* and the article *the* to the right.

It might be preferable therefore to induce word clusters based on the dependency relations in which the words occur. In section 3, we present how this relates to Brown clustering, and we modify the code by Percy Liang, so that dependency clustering can be used. We evaluate clusters in a wordnet-based similarity experiment. Dependency clustering yields superior clusters for Dutch across different settings of parameters such as number of clusters, frequency threshold and level of granularity. Selecting specific dependency relation labels and using data obtained from them as input to clustering further improves the clustering quality. The proposed adaptation of Brown clustering does not change the complexity of the

Proceedings of COLING 2014, the 25th International Conference on Computational Linguistics: Technical Papers, pages 1382–1391, Dublin, Ireland, August 23-29 2014.

algorithm, and—although we assume that syntactically parsed text is available—it requires much less data for a desired level of clustering quality.

2 The Brown clustering algorithm

Brown clustering (Brown et al., 1992) is an agglomerative algorithm that induces a hierarchical clustering of words. It takes a tokenized corpus and groups words into k clusters identified by bit strings, representing paths in the induced binary tree in which the leaves are word clusters. Prefixes of the paths can be used to achieve clusters of coarser granularity (Sun et al., 2011; Turian et al., 2010). The obtained clusters contain words that are semantically related, or are paradigmatic or orthographic variants.[1]

The algorithm starts by putting k most frequent words into distinct clusters. Then, the k+1$^{\text{th}}$ most frequent word is assigned to a new cluster, and two among the resulting k+1 clusters are merged, i.e. the pair that maximizes the average mutual information of the current clustering. This process is repeated until all words have been merged. The resulting k clusters are then merged to build the binary tree. The version of the algorithm optimized for speed runs in $O(k^2|\mathcal{V}|)$, with $|\mathcal{V}|$ the vocabulary size.

Brown clustering has been used extensively in supervised NLP tasks such as parsing (Koo et al., 2008; Candito and Crabbé, 2009; Haffari et al., 2011), named-entity recognition (NER) and chunking (Turian et al., 2010), sentiment analysis (Popat et al., 2013), relation extraction (Plank and Moschitti, 2013), unsupervised semantic role labeling (Titov and Klementiev, 2012), question answering (Momtazi et al., 2010), POS tagging (Owoputi et al., 2013) and speech recognition with recursive neural networks (Shi et al., 2013). Recently, multilingual clustering has also been proposed (Täckström et al., 2012; Faruqui and Dyer, 2013).

Among the most frequently recognized limitations (cf. Koo et al. (2008); Chrupala (2011)) are a) the hard nature of the clustering, b) relatively long running time[2] and c) insensitivity to wider context. Our method attempts to overcome the final disadvantage. As it requires less data, it also reduces the running time.

Leveraging syntactic context for word representations has been explored, among others, in Lin (1998) on distributional thesauri; Haffari et al. (2011) on combining Brown clusters and word groupings from split non-terminals; Sagae and Gordon (2009) on using unlexicalized syntactic context in hierarchical clustering; Van de Cruys (2010) and Padó and Lapata (2007) on comparison of window- and syntactic-based word space models; and Boyd-Graber and Blei (2008) on syntactic topic models.

The work closest to ours is that of Grave et al. (2013). The authors show that clusters obtained from dependency trees outperform standard Brown clustering when used as features in super-sense tagging and NER. Their focus is on a generalization of Brown clustering with Hidden Markov models (extending Markov chains to trees), allowing the creation of soft clusters.[3] Learning and inference are done with online expectation-maximization and belief propagation.

Whereas Grave et al. focus on new learning methods for clustering with HMMs on dependency trees, we take an in-depth look at parameters and choices that are standardly considered using the (Brown et al., 1992) algorithm. We show that the advantage of dependency clustering can be observed throughout different parametrizations of cluster capacity, granularity level, frequency thresholding and other criteria (section 6), and that the advantage is roughly constant for varying amounts of input data. Finally, we provide new insight in the advantage of selective dependency clustering, in which the data obtained only from specific dependency relations lead to better clusters. Our approach constitutes a straightforward extension of Brown clustering, and only required a simple modification of the Brown clustering code.

[1] We are using the term *semantic relatedness* in its broadest possible scope. Words or clusters are semantically related when they have any kind of semantic relation: synonymy, meronymy, antonymy, hypernymy etc. (Turney and Pantel, 2010).

[2] Although coarser clustering (k<1000) can mean more practical running times, as the clustering depends quadratically on k.

[3] This approach allows to capture homonymy/polysemy, with the idea that when a word representation is needed, it can be obtained in a context-sensitive way (Huang et al., 2011; Nepal and Yates, 2014). This is certainly an important advantage over Brown clustering in which the mapping between a word and a cluster is deterministic; however, it comes with its own disadvantages: creating context-sensitive representations requires (potentially) costly inference; furthermore, HMM-based clustering does not build nor lends itself easily to a hierarchy, which is often exploited during feature creation in supervised learning to control cluster granularity (see the end of section 5.2)

3 Extension of the Brown clustering

The bigram language model underlying Brown clustering takes the probability of a sentence as the product of probabilities of words based on immediately preceding words. In contrast, we replace this by a *dependency* language model (DLM), which defines the probability of a sentence over dependency trees (Shen et al., 2008). This probability can be factorized in different ways (Chen et al., 2012; Charniak, 2001; Popel and Mareček, 2010), but the common idea is that a word is conditioned on some history, where the link between the two is a dependency. In practice, the history can include the immediate parent of the word, which can be either a lexical head or the artificial root node, as well as siblings between the child and the parent. Our take on DLM is similar to Charniak (2001) and Popel and Mareček (2010): the probability of a word is conditioned simply on its parent. This is the same view as taken by Grave et al. (2013).

The Brown clustering objective is to find such a deterministic clustering function $\mathcal{C}$ mapping each word from the vocabulary $\mathcal{V}$ to one of K clusters that maximizes the likelihood of the data. The likelihood of a sequence of word tokens, $\mathbf{w} = \langle w_i \rangle_{i=1}^{m}$, with each $w_i \in \mathcal{V}$, factors as

$$L(\mathbf{w}; \mathcal{C}) = \prod_{i=1}^{m} p(\mathcal{C}(w_i)|\mathcal{C}(w_{i-1}))p(w_i|\mathcal{C}(w_i)), \tag{3.1}$$

where $\mathcal{C}(w_0)$ is a special start-of-sequence symbol. As shown by Brown et al. (1992), by taking the negative logarithm and using the ML estimates, the equation 3.1 is decomposed to the negative entropy of the sequence $\mathbf{w}$ and mutual information between adjacent clusters. Since the entropy is independent of the clustering function, the objective amounts to finding such $\mathcal{C}$ that maximizes the mutual information.

For *dependency clustering*, we change the cluster transition probability so that conditioning is on the cluster of the parent of the word at position i, instead of on the cluster of the previous word:

$$L'(\mathbf{w}; \mathcal{C}) = \prod_{i=1}^{m} p(\mathcal{C}(w_i)|\mathcal{C}(w_{\pi(i)}))p(w_i|\mathcal{C}(w_i)), \tag{3.2}$$

where i ranges over all children in a tree and π is a function from the children to their unique parents (which include the special root of the tree). Calculation of the mutual information changes only to the extent that count tables no longer represent adjacency relationship (bigrams) between words but parenthood (child–parent relation).

4 Evaluation task

We evaluate our word clusters by following the method of Van de Cruys (2010) for evaluating vector space models. The method is based on a wordnet for Dutch and assumes that two semantically related words also occur close to each other in the wordnet hierarchy.[4] We use Cornetto (Vossen et al., 2013), which includes more than 92,000 form-POS pairs described in terms of lexical units, synsets and other criteria. For calculating similarity scores, we treat Cornetto as a digraph, with nodes constituting synsets and arcs constituting hypernymic relations, and adopt the Lin similarity measure (Lin, 1998)[5] in combination with the ontological variant of Information Content[6].

Evaluation is guided by a list of 10,000 most frequent words from SoNaR, a 500M-word reference corpus for Dutch.[7] Every word is compared to other words in the same cluster, and the average similarity for all comparisons is taken as the final score. The described method is well suited for measuring intracluster quality, yet useful information about word similarity is available also by looking at neighboring

[4]For English, several semantic similarity datasets are available (such as WordSimilarity-353 (Finkelstein et al., 2001)), some of which can identify the type of relatedness captured. We are not aware of such datasets for Dutch.

[5]Which is a function of the IC of the least common subsumer of two synsets and the IC of individual synsets. The score ranges between 0 and 1.

[6]Which is the negative logarithm of $(|\mathcal{L}| + 1)^{-1}((|\mathcal{L}_s|/|\mathcal{S}_s|) + 1)$, where $\mathcal{L}$ are the leaves of the hierarchy, $\mathcal{L}_s$ are the leaves reachable from a synset s, and $\mathcal{S}_s$ are the subsumers of s (Sánchez et al., 2011).

[7]`http://lands.let.ru.nl/projects/SoNaR`

clusters in the binary tree. This *inter*cluster quality, according to which clusters that are close in the binary tree are more similar than clusters that are far apart, can be captured indirectly by evaluating using different bit substrings. In this way, when a substring is used, two or more semantically related, but isolated clusters are merged, which should result in a drop in clustering quality (semantic relatedness tends to "dissolve" when merging).

For both standard and dependency Brown clustering, the same set of sentences is used. From SoNaR, we sampled sentences amounting to roughly 46M words, which is comparable to the count for English datasets of Koo et al. (2008) and Turian et al. (2010). The sentence length was restricted to five or more words to exclude noisy text. Corpus annotation was removed.

For dependency clustering, the dataset was lemmatized and parsed with the Alpino parser (Van Noord, 2006), an HPSG parser with a maxent disambiguation component, achieving labeled dependency accuracy of around 90.5 for Dutch.[8] The parsing accuracy is likely to be lower on our dataset, but we expect this effect to be small since Alpino has been shown to be relatively insensitive to domain shifts compared to some entirely data-driven parsers (Plank and van Noord, 2010). For default clustering, we only use first-order dependencies produced by the parser. The bilexical counts (head and dependent regardless of the relation label) serve as input for dependency clustering.

5 Experiments and Results

The main parameter for word clustering is the number of clusters k, which we set to either 1000 or 3200,[9] except when measuring clustering capacity, for which smaller values of k are used. Additionally, we limit the minimum frequency of words in clustering to three, unless stated otherwise. The vocabulary size for k=1000 clustering with applied frequency threshold is around 237,000. We use a paired t-test to check for statistical significance of observed differences in means.

5.1 Cluster examples

In Table 1, we show both the versatility of dependency clusters by dividing the examples in five groups (A–E), and the similarity of clusters within group. The longer the common bit substring between clusters, the closer they are in the hierarchy. Group **A** includes words describing professions or people's roles and functions. Group **B** lists personal pronouns, including reflexive pronouns (B2), where substantial differentiation exists with many singleton clusters. Clusters are capable of grouping orthographic variants (D1; *email* and *e-mail*) and diminutives (*sms_DIM*, corresponding to Dutch *smsje*). Because first and last names are extremely common in our corpus, clustering creates fine-grained distinctions between these (**C**). C1 groups names of presidents, whereas C2 and C3 distinguish between feminine and masculine names. Measurable concepts are included in **E**.

5.2 Cluster quality

Table 2 presents the general quality of standard and dependency clustering. The results for 1000 and 3200 clusters (in the latter we use a higher frequency threshold for faster computation) show that we obtain a higher similarity score for 3200 clusters compared to 1000, and a more marked difference between standard and dependency clustering in the case of k=3200 (Δ=0.019). We also looked at how many words from the frequency list were evaluated successfully. The recall depends on the success of mapping between words and synsets as well as the success of finding the word in one of the clusters. The latter factor influences the recall to a much lesser degree, as almost all words are found in the clustering. For 3200 clusters with the minimum frequency set to fifty, approximately 5000 words are successfully evaluated, whereas for 1000 clusters, this number is around 7000.[10] These numbers are not affected by the type of clustering (standard or dependency).

[8] Strictly speaking, the output of lemmatization is root forms. We perform this preprocessing step to increase the number of times that a word is successfully matched in the wordnet hierarchy and evaluated.

[9] Which are standardly encountered throughout the literature. For k above 3200, the algorithm falls short of practicality on current hardware assuming a single-core implementation.

[10] The difference between the figures occurs because of a different frequency threshold.

Group	Cluster id	Most frequent words	Left
A1	001010001011100	aannemer, huis_arts, bakker, notaris, apotheker, makelaar *contractor*, *family doctor*, *baker*, *lawyer*, *pharmacist*, *estate agent*	+57

Table 1: Example dependency clusters obtained from a run with number of clusters set to 3200 and minimum frequency to 50. The underlined part of the bit string indicates the longest common substring within one group. English translation of the Dutch original is given in italics and is left out when clear from the original. Column *Left* indicates the remaining number of (less frequent) words in the cluster.

k	Brown	DepBrown	Δ
1000	0.191	0.196	+.005*
3200	0.279	0.298	+.019**

Table 2: Lin similarity scores for standard *Brown* clustering and dependency Brown clustering (*DepBrown*), with k the number of clusters. Δ=DepBrown – Brown. Frequency threshold of 50 is used for clustering with $k = 3200$. *: statistically significant with $p < 0.05$, **: statistically significant with $p < 0.001$.

Results for four different clustering parametrizations are shown in Table 3. One way of controlling the granularity is to choose the number of output clusters k. As shown in the table under CAP ("capacity"), dependency clustering achieves a better quality regardless of the choice of k, and in general, choosing a smaller k decreases quality, which is compatible with the observations of Turian et al. (2010) in their chunking experiments.

An effect similar to that of controlling capacity can be achieved by making use of the fact that the induced structure is a hierarchy.[11] By choosing a path prefix length that is shorter than the maximum length, we control the cluster granularity (denoted in the table as PREF-*). For different tasks, different path prefixes might be appropriate (Sun et al., 2011; Koo et al., 2008; Miller et al., 2004). For example, one might prefer coarser distinctions (i.e. shorter bit strings) in parsing, while finer granularity might be necessary to obtain effective representations of proper names in NER. We ran the experiment with prefix length ranging from one to eighteen, and show a selection of four settings in the table. Across the board, dependency clustering yields better results than standard clustering. Naturally, with shorter prefixes the quality decreases, which is explained by increasing word population in the clusters, with more and more

[11]The parameter k needs to be chosen before clustering, whereas the hierarchical structure can be exploited during feature preparation based on already existing clusters.

Setting	k	*min*	Brown	DepBrown	Δ
CAP	200	10	0.148	0.157	+.009
	400	10	0.169	0.175	+.006

NOUNS	1000	3	0.272	0.279	+.007

Table 3: Lin similarity scores for standard *Brown* clustering and dependency Brown clustering (*DepBrown*), with *k* the number of clusters, *min* the minimum frequency of words. CAP: varying k, fixed min; FREQ: varying min, fixed k; NOUNS: evaluating only nouns, PREF-n: size of bit-string prefix, Δ=DepBrown – Brown. All the results reported for *DepBrown* are significantly different from *Brown* with $p < 0.001$.

distant (both hierarchically and semantically) clusters being merged.

By inspecting individual clusters, we observe that frequent words in a cluster exhibit clear semantic relatedness, but that rare words are often semantically quite unrelated.[12] This is confirmed by our results in which the quality of the clustering improves approximately logarithmically with frequency threshold increasing (FREQ). The margin between standard and dependency clustering is also increasing as we increase the threshold. In practice, Brown clusters appear to be equally useful with a high frequency threshold (Owoputi et al., 2013) as without thresholding (Koo et al., 2008; Turian et al., 2010).

We also investigate the quality of nouns only, to facilitate the comparison to Van de Cruys (2010). We observe a considerable gain in quality when only nouns are used compared to using all parts of speech — the Lin score is increased by 0.08. In the noun-only evaluation, dependency clustering achieves a higher score (0.279) than standard clustering (0.272). Van de Cruys (2010) shows that syntactic vector space models outperform window-based models, which is confirmed by our finding for word clustering as well. In his work, syntactic vector space models yield a 0.04 advantage in Lin score, whereas our dependency clusters achieve a less marked advantage, reaching up to 0.019 in Lin score. A possible explanation for this difference is that in his evaluation an average over only five most similar nouns is taken, whereas we impose no such restriction. We would like to point out that our work does not aim to compare and discuss the merits of clustering and vector space models as possible techniques for obtaining word representations, but rather to provide a comprehensive comparison of standard Brown clustering and its dependency extension.

5.3 Learning curves

Figure 5.2 shows the amount of data needed to achieve a certain quality of clustering. For clustering on ten thousand sentences the similarity score is around 0.14, with a higher score for standard clustering. For each subsequent addition of data, dependency clustering outperforms standard clustering. In order to achieve the highest score attained by standard clustering (0.19), resulting from clustering on 2.4 million sentences (41 million words), dependency clustering requires only slightly more than 500 thousand sentences (8.5 million words). This observation is advantageous especially because less data means

[12] Although cf. Turian et al. (2010) who show that Brown clustering has a superior representation for rare words than neural word embeddings in their experiment.

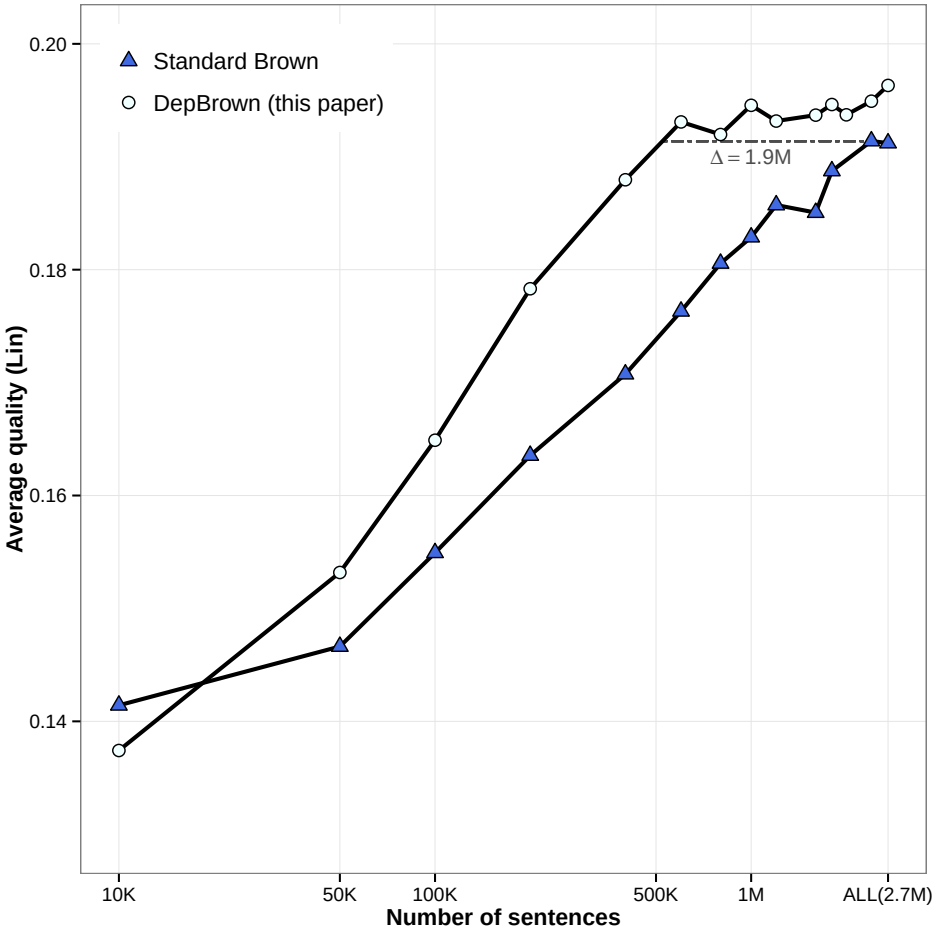

Figure 1: Learning curves for standard and dependency Brown clustering with 1000 clusters and a frequency threshold of 3. Dashed line displays the difference in amount of data needed for *DepBrown* to achieve the best quality of *Brown*. Using all, 2.7 million sentences from the corpus (*ALL*) corresponds to 46 million words.

shorter running time for clustering as the number of word types is reduced.

5.4 Refinement of dependency clusters

Our dependency clustering described in the previous sections operates on words appearing in all dependency relations. We now investigate whether selecting only a particular dependency relation—i.e. using as the input both parent and child words from that dependency relation—leads to clusters with higher semantic relatedness. Each relation can be characterized as either a first- or a second-order relation.[13] A second-order relation is between two words with an intervening preposition, e.g. between a verb and a noun of a directional complement introduced by a preposition, such as in the Dutch "eten achter pc" ("eating at the computer").[14] We ran clustering for each of the forty-five dependency relations separately and measured the quality of each resulting clustering. The cumulative baseline that does not distinguish between dependency relations is given as ALL for first-order relations in Table 4. This is the same result as reported on the first line in Table 2. The addition of second-order dependencies does not change the clustering quality of the baseline (0.196) but increases the number of types.

In the upper part of Table 4, we list six relations leading to clustering quality above the baseline.

[13]The experiments in previous sections included only first-order relations.

[14]The preposition should be seen only as an implicit link between two words and is not included in the input data for clustering. For the example fragment only "eating" and "computer" constitute the data instance actually used by the algorithm.

Type	Ord-1	Ord-2	DepBrown	Population
OBJ2		■	0.238	1,622
LD	■		0.233	2,419
PC		■	0.211	21,157
LD		■	0.208	12,149
OBJ1	■		0.203	108,037
SU	■		0.199	79,844
ALL	■		0.196	495,479
ALL	■	■	0.196	559,908
SU+OBJ1	■		0.202	156,645

Table 4: Lin similarity scores for dependency Brown clustering (*DepBrown*) per type of dependency relation. Ord-1: first-order relation; Ord-2: second-order relation (with intervening preposition); Population: number of word types in the clustering.

Two conclusions can be drawn from the results on these relations. First, some dependency relations contribute better context that leads to increased semantic relatedness compared to clustering without relation selection. Second, both first- and second-order relations appear among the relations outperforming the baseline. The highest score from the top six relations is achieved by taking words exclusively from the second-order secondary object (OBJ2) relation. However, relatively few word types are included in the clusters. The same is true for the first-order directional complements (LD). Of course, clustering with only one of these relations would have quite limited applicability if used in a supervised NLP task due to the low number of word types. However, the main point we want to make here is that these relations yield semantically superior clusters and demonstrate that syntactic functions truly merit further attention in learning semantic clusters using syntax. The remaining four among the top six relations are more frequent relations, and lead to clusterings with higher number of word types. These are the second-order prepositional complement (PC) and directional complement (LD) relations, and the first-order direct object (OBJ1) and subject (SU) relations. Finally, the setting SU+OBJ1 joins words obtained from subject and direct object relations, and achieves a quality that falls between the values obtained for the two relations separately, yet still increases the number of word types.

6 Conclusion and future work

We have presented a detailed study on a simple extension of Brown clustering with a dependency language model. In the first part, we have consolidated the advantage of dependency clustering over standard Brown clustering in a series of experiments, including cluster capacity, granularity level, frequency thresholding, amount of data and other. In the second part, we put forward the idea of selective clustering using data obtained only from specific dependency relations. Several relations lead to a clustering with improved intracluster similarity. We make the code as well as the induced clusters freely available at `https://github.com/rug-compling/dep-brown-cluster`.

Our findings from the selective clustering warrant the development of more complex models capable of including syntactic functions for obtaining semantic clusters. We reserve this work for the future. We find it interesting to apply dependency Brown clustering to languages of different families and compare it in this setting to the standard Brown clustering. The future work further includes a study of the effect of dependency clusters in downstream tasks. Another important point is the effect of parser accuracy on the quality of obtained clusters.

Abstract

In this paper, we investigate the differences between Hungarian sentence parses based on automatically converted and manually annotated dependency trees. We also train constituency parsers on the manually annotated constituency treebank and then convert their output to dependency trees. We argue for the importance of training on gold standard corpora, and we also demonstrate that although the results obtained by training on the constituency treebank and converting the output to dependency format and those obtained by training on the automatically converted dependency treebank are similar in terms of accuracy scores, the typical errors made by different systems differ from each other.

1 Introduction

Nowadays, two popular approaches to data-driven syntactic parsing are based on constituency grammar on the one hand and dependency grammar on the other hand. There exist constituency-based treebanks for many languages and dependency treebanks for most of these languages are converted automatically from constituent trees with the help of conversion rules, which is the case for e.g. the languages used in the SPMRL-2013 Shared Task (Seddah et al., 2013) with the exception of Basque, where constituency trees are converted from manually annotated dependency trees (Aduriz et al., 2003), and Hungarian, where both treebanks are manually annotated (Csendes et al., 2005; Vincze et al., 2010). However, the quality of automatic dependency conversion is hardly investigated.

Hungarian is one of those rare examples where there exist manual annotations for both constituency and dependency syntax on the same bunch of texts, the Szeged (Dependency) Treebank (Csendes et al., 2005; Vincze et al., 2010), which makes it possible to evaluate the quality of a rule-based automatic conversion from constituency to dependency trees, to compare the two sets of manual annotations and also the output of constituency and dependency parsers trained on converted and gold standard dependency trees.

We investigate the effect of automatic conversions related to the two parsing paradigms as well. It is well known that for English, the automatic conversion of a constituency parser's output to dependency format can achieve competitive unlabeled attachment scores (ULA) to a dependency parser's output trained on automatically converted trees[1] (cf. Petrov et al. (2010)). One of the possible explanations for this is that English is a configurational language, hence constituency parsers have advantages over dependency parsers here. We check whether this hypothesis holds for Hungarian too, which is the prototype of free word order languages.

In this paper, we compare three pairs of dependency analyses in order to evaluate the usefulness of converted trees. First, we examine the errors of the conversion itself by comparing the converted dependency trees with the manually annotated gold standard ones. Second, we argue for the importance of training parsers on gold standard trees by looking at the typical differences between the outputs of

[1]However, it has been pointed out that errors in the conversion script may significantly influence the results of parsing, see e.g. Petrov and McDonald (2012) and Pitler (2012)

Proceedings of COLING 2014, the 25th International Conference on Computational Linguistics: Technical Papers, pages 1392–1401, Dublin, Ireland, August 23-29 2014.

dependency parsers trained on converted (silver standard) trees, parsers trained on gold standard trees and the manual annotation itself. Third, we demonstrate that similar to English, training on a constituency treebank and converting the results to dependency format can achieve similar results in terms of ULA to the dependency parser trained on the automatically converted treebank, but the typical errors they make differ in both cases.

2 Parsing Hungarian on the Szeged Treebank

Hungarian is a morphologically rich language, where word order encodes information structure, which makes its syntactic analysis very different from English's as the arguments in a sentence cannot be determined by their position but by their suffixes, cf. É. Kiss (2002). Words' grammatical functions are signified by case suffixes and verbs are marked for the number and person of their subject and the definiteness of their object, thus these arguments may be often omitted from the sentence: *Látlak* (see-1SG2OBJ) "I see you". Due to word order reasons, words that form one syntactic phrase may not be adjacent (long-distance dependencies), which is true for the possessive construction as well: the possessor and the possessed may be situated in two distant positions: *A fiúnak elvette a kalapját* (the boy-DAT take-PAST-3SGOBJ the hat-POSS3SG-ACC) "He took the boy's hat". Verbless clauses are also common in Hungarian, as the copula in third person singular present tense indicative form is phonologically empty, while it is present in all other moods and tenses: *A kalap piros* (the hat red) "The hat is red", but *A kalap piros volt* (the hat red was) "The hat was red".

The Szeged Treebank (Csendes et al., 2005) is a manually annotated constituency treebank for Hungarian consisting of 82,000 sentences. Besides the phrase structure, grammatical roles of the verbs' arguments and morphological information are also annotated. It incorporates texts from six different domains: short business news, newspaper, law, literature, compositions and informatics, however, in this paper, we just focus on the short business news domain.

The Szeged Dependency Treebank (Vincze et al., 2010) contains manual dependency syntax annotations for the same texts. Certain linguistic phenomena – such as discontinuous structures – are annotated in this treebank, but not in the constituency treebank. In the dependency treebank, the possessor is linked to the possession while this connection is not annotated in the constituency treebank. The two types of trees can be seen in Figure 1.

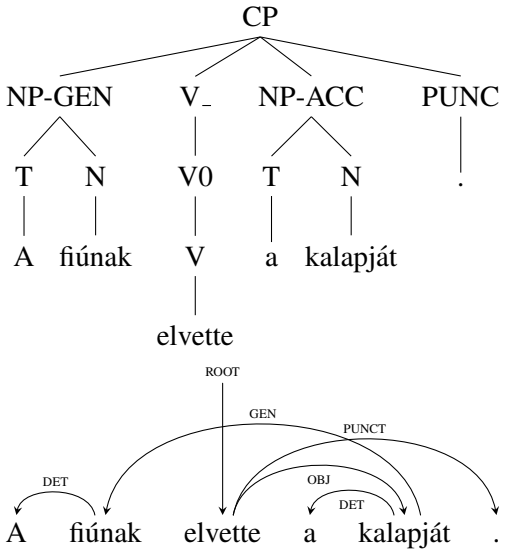

Figure 1: Discontinuous structure *A fiúnak elvette a kalapját* (the boy-DAT take-past3SGOBJ the hat-POSS3SG-ACC) "He took the boy's hat" in constituency and dependency analysis.

Another difference between the two treebanks is the way they represent different types of complex sentences, as can be seen in Figure 2. In the dependency treebank subordinations and coordinations are

handled very similarly. The head of one of the clauses (the subordinated clause or the second clause in the case of coordination) is linked to the head of the other clause (the matrix clause of the subordination or the first clause of the coordination), only the type of relation between the two heads differs in the two structures, in the dependency tree in Figure 2, the heads of the three clauses (*átjött* "came over", *megígérte* "promised" and *eljön* "come") are linked to one another through their conjunctions with either an ATT relation in the case of subordination or COORD for coordination. In the constituency treebank these sentences are represented very differently: in the case of subordination, the subordinated clause is within the matrix clause: CP_3 is within CP_2 in the constituency tree in Figure 2. Coordinated clauses appear at the same level in the structure, in the same figure CP_1 and CP_2 are coordinated clauses.

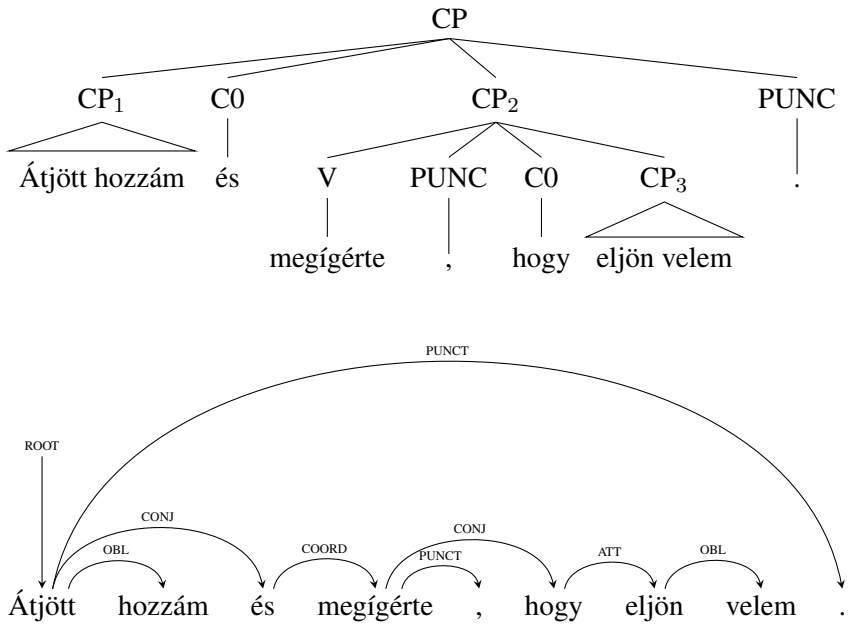

Figure 2: Constituency and dependency analysis of coordination and subordination in the sentence *Átjött hozzám és megígérte, hogy eljön velem* (through.come-PAST-3SG to.me and promise-PAST-3SG-OBJ that away.come-3SG with.me) "He came over and promised that he will come with me".

The parallels of these two manually annotated treebanks make them suitable for testing our hypotheses about automatic dependency conversion. The differences between them originate from the characteristics of constituent and dependency syntax.

3 Converting Constituency Trees to Dependency Trees

In this section, we present our methods to convert constituency trees to dependency trees and we also discuss the most typical sources of errors during conversion.

3.1 Conversion rules

In order to convert constituency trees to dependency trees, we used a rule based system. Sentences with virtual dependency nodes were omitted, as they are not annotated in the constituent treebank and their treatment in dependency trees is also problematic (Farkas et al., 2012; Seeker et al., 2012). As a result, we worked with 7,372 sentences and 162,960 tokens.

First, we determined the head of each clause (CP) and the relations between CPs in complex sentences. In most cases the head of the CP is a finite verb, if the CP contains no finite verb, the head is the either an infinitive verb or a participle, if none of these are present in the CP, the head can be a nominal expression. The relations between the CP heads make up the base of the dependency structure using ROOT relation for the sentence's main verb, COORD for coordination and ATT for subordination, as well as CONJ in the case of conjunctions between the CPs.

The arguments of verbs, infinitives and participles in the CP were linked to their governor and marked for their grammatical role in the Szeged Treebank. We used this information to construct the appropriate dependency relations between governors and their arguments. The main grammatical roles such as subject, object, dative have their own label in dependency syntax, while minor ones are assigned the oblique (OBL) relation. The argument's modifiers were then linked to the head or other modifiers based on the phrase structure with relations according to their morphological code.

Long distance dependencies, like the connection between a genitive case possessor and the possessed are not annotated in the constituency treebank. In these cases we used morphological information to link these elements together in the dependency tree. Figure 3 shows an example of converting a constituency tree to a dependency tree.

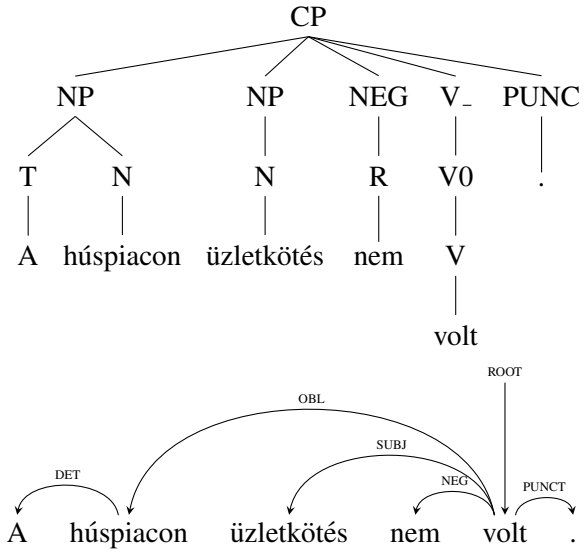

Figure 3: Conversion of the sentence *A húspiacon üzletkötés nem volt* (the meat.market-SUP transaction not was) "There were no transactions at the meat market." from constituency to dependency trees.

3.2 Error Analysis

We automatically converted the constituency treebank into dependency trees following the principles described above and detailed at our website (`http://www.inf.u-szeged.hu/rgai/SzegedTreebank`). For evaluation, we applied the metrics labeled attachment score (LAS) and unlabeled attachment score (ULA), without punctuation marks. The accuracy of the conversion was 96.51 (ULA) and 93.85 (LAS). The errors made during conversion were categorized manually in 200 sentences selected randomly from the short business news subcorpus of the Szeged Dependency Treebank, and the most typical ones are listed in Table 1, Column *convError*.

As it is shown, the most common source of error was when more than one modifier was within a phrase as the example in Figure 4 shows. In each figure, the gold standard parse can be seen on the left hand side while the erroneous one can be seen on the right hand side.

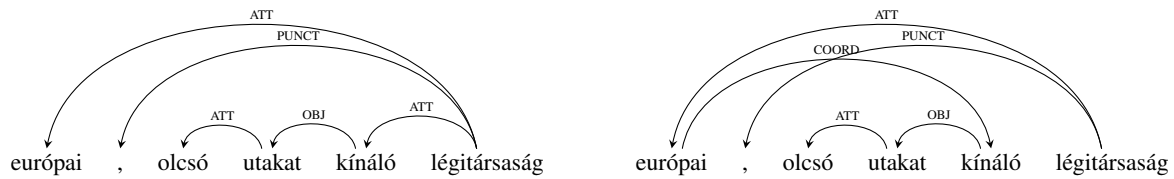

Figure 4: Multiple modifier error in *európai, olcsó utakat kínáló légitársaság* (European cheap trips-ACC offering airline) "European airline offering cheap trips".

Error type	convError		goldTrain		silverTrain		BerkeleyConv		convDep

Table 1: Error Types. convError: errors made during converting constituency trees to dependency trees. goldTrain: errors in the output got by training the Bohnet parser on the gold standard data. silverTrain: errors in the output got by training the Bohnet parser on the silver standard data. BerkeleyConv: errors in the output got by training the Berkeley parser on the gold standard constituency data and converting the output into dependency format. convDep: errors in the output got by training the Bohnet parser without dependency labels on the silver standard data.

Coordination errors occurred when multiple members of a coordination were wrongly connected. On the other hand, the attachment of conjunctions and some adverbs was also problematic, for example in Figure 5 the conjunction *is* "also" is connected to the verb in the gold standard and to the noun in the converted version.

Figure 5: Conjunction attachment error in *a minisztérium is beszáll* (the ministry also steps.in) "the ministry also steps in".

Also, the constituency treebank did not mark all the grammatical relations (e.g. numerals and determiners were simply parts of an NP but had no distinct labeling, like *[NP az öt [ADJP fekete] kutya]* (the five black dog) "the five black dogs"), but it was necessary to assign them a dependency label and a parent node during conversion. However, in some cases it was not straightforward which modifier modifies which parent node: for instance, in *[NP nem [ADJP megfelelő] módszerek]* (not appropriate methods) "inappropriate methods", the negation word *nem* is erroneously attached to the noun instead of the adjective in the converted phrase. Determiner errors were those where the determiner was attached to the wrong noun in a NP with a noun modifier. In CPs with multiple verbal elements (both a finite verb and an infinitive or a participle in the CP) the arguments were sometimes linked to the wrong verb, as in Figure 6.

Figure 6: Verbal argument error in *a saját pecsenyéjükkel voltak elfoglalva* (the own roast-3PLPOSS-INS were busy) “they were busy with their own thing”.

Possessors are sometimes wrongly identified during conversion as long distance dependencies are not marked in the constituency treebank (see Figure 7).

Figure 7: Possessor attachment error in *a gyártó szárítóüzemében hasznosít* (the manufacturer drying.plant-3SGPOSS-INE utilizes) “the manufacturer utilizes it in its drying plant”.

In CPs with more verbal element, sometimes the wrong word is selected as the root, as in Figure 8.

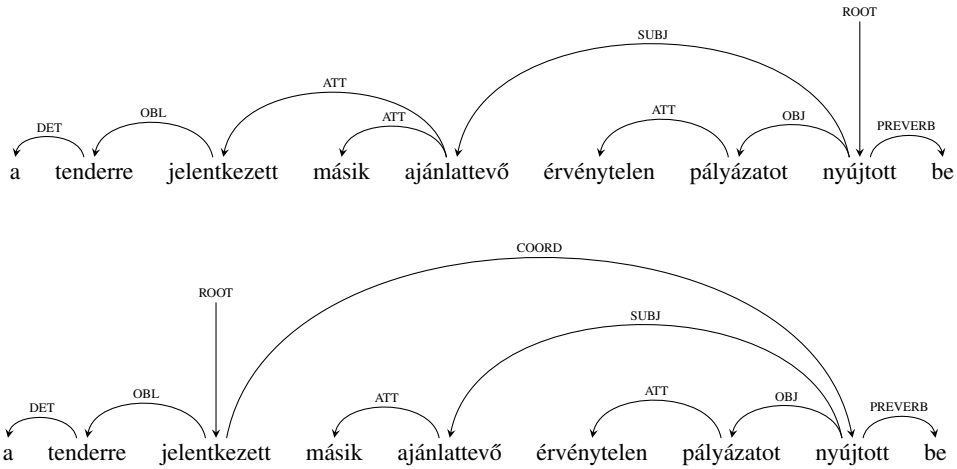

Figure 8: Root error in *a tenderre jelentkezett másik ajánlattevő érvénytelen pályázatot nyújtott be* (the tender-SUB applied other bidder invalid application-ACC submit-PAST-3SG) “the other bidder applying to the tender submitted an invalid application”.

In some cases, consecutive (but separate) noun phrases were taken as one unit as if one noun modified the other, for example in Figure 9.

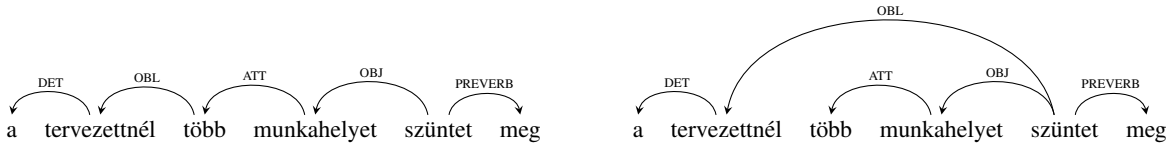

Figure 9: Consecutive noun error in *a tervezettnél több munkahelyet szüntet meg* (the planned-ADE more workplace-ACC terminates) “it terminates more workplaces than planned”.

Multiword NEs also caused some problems in the conversion, as in Figure 10.

Figure 10: Multiword NE error in *Beszállítói Befektető Rt.* (a name of a company) .

In other cases, divergences between the gold standard and the converted trees are due to some erroneous annotations either in the constituency treebank or in the dependency treebank. A typical example of this is the wrong MOD (modifier) label. In the treebank, locative and temporal modifiers were classified according to the tridirectionality typical of Hungarian adverbs and case suffixes: *where*, *from where* and *to where* (or *when*, *from what time and till what time*) the action is taken place. Thus, there are six dependency relations dedicated to these aspects and all the other adverbials are grouped under the relation MOD. However, this distinction is rather semantic in nature and was sometimes erroneously annotated in the constituency treebank, which was later corrected in the dependency one and thus now resulted in conversion errors, as shown in Figure 11.

Figure 11: MOD label error in *nyár vége felé kezdik* (summer end-3SGPOSS around begin) "they begin around the end of the summer".

There were also some atypical errors that occurred too rarely to categorize them in a different class, like cases when an article or determiner got erroneously attached to a verb and so on, so they were lumped into the category of "other errors" in Table 1.

4 Training on Gold Standard and Silver Standard Trees

We also experimented with training the Bohnet dependency parser (Bohnet, 2010) on the manually annotated (gold standard) and the converted (silver standard) treebank. The Bohnet parser (Bohnet, 2010) is a state-of-the-art[2] graph-based parser, which employs online training with a perceptron. The parser contains a feature function for the first order factor, one for the sibling factor, and one for the grandchildren.

From the corpus, 5,892 sentences (130,211 tokens) were used in the training dataset and the remaining 1,480 sentences (32,749 tokens) in the test dataset. For evaluation, we again applied the metrics LAS and ULA. Results are shown in Table 2, Rows *goldTrain* and *silverTrain*.

As the numbers show, better results can be achieved when the gold standard data are used as training database than when the parser is trained on the silver standard data, the differences being 1.6% (ULA) and 3.16% (LAS). Besides evaluation scores, we also compared the outputs of the two scenarios: we used the same set of randomly selected sentences as when investigating conversion errors and carried out a manual error analysis against the gold standard data in each case: see Table 1, Columns *goldTrain* and *silverTrain*.

There are some common error types that seem to cause problems for both ways of parsing. For instance, coordination and multiple modifiers are among the most frequent sources of errors in both cases as for the error rates are concerned. However, with regard to the absolute numbers, we can see that both error types are reduced when the gold standard dataset is used for training. On the other hand, finding the parent node of a conjunction or an adverb seems to improve significantly when the parser is trained on gold standard data. This is probably due to the fact that they are not marked in the constituency treebank and thus training data for these grammatical phenomena are very noisy in the silver standard treebank. All in all, we argue that there are some grammatical phenomena – e.g. the attachment of

[2]For a comparative evaluation with other dependency parsers on the same treebank see Farkas et al. (2012). According to their results, the Bohnet parser achieved the best scores on the treebank hence we also used this parser in our experiments.

Setting	LAS	ULA
Conversion	93.85	96.51
goldTrain	93.48	95.17
silverTrain	90.32	93.57
BerkeleyConv	–	92.78
convDep	–	93.23

Table 2: Results of the experiments. Conversion: converting constituency trees to dependency trees. goldTrain: training the Bohnet parser on the gold standard data. silverTrain: training the Bohnet parser on the silver standard data. BerkeleyConv: training the Berkeley parser on the gold standard constituency data and converting the output into dependency format. convDep: training the Bohnet parser without dependency labels on the silver standard data.

conjunctions or adverbs – that require manual checking even if automatic conversion from constituency to dependency is applied.

5 Pre- or Post Conversion?

It is well known that for English, converting a constituency parser's output to dependency format (post conversion) can achieve competitive ULA scores to a dependency parser's output trained on automatically converted trees (pre conversion) (Petrov et al., 2010; Farkas and Bohnet, 2012). One of the possible reasons for this may be that English is a configurational language, hence constituency parsers are expected to perform better here. In this paper, we investigate whether this is true for Hungarian, which is the prototype of morphologically rich languages with free word order.

We employed the product-of-grammars procedure (Petrov, 2010) of the Berkeleyparser (Petrov et al., 2006), where grammars are trained on the same dataset but with different initialization setups, which leads to different grammars. We trained 8 grammars and used tree-level inference. The output of the parser was then automatically converted to dependency format, based on the rules described in Section 3 (*BerkeleyConv*). Second, we used the silver standard dependency treebank for training the Bohnet parser (*convDep*). Since our constituency parser did not produce grammatical functions for the nodes, we trained the Bohnet parser on unlabeled dependency trees in order to ensure a fair comparison here (that is the difference between the columns *BerkeleyConv* and *convDep* in Table 1).

As the numbers show, competitive results can be obtained with both methods, yielding an ULA score of 92.78 and 93.23, respectively. This means that the same holds for Hungarian as for English and the surprisingly good results of post conversion are not related to the configurational level of the language.

Manually analysing the errors on the same set of sentences as before, there are again some error categories that occur frequently in both cases such as coordination, the attachment of conjunctions, modifiers and determiners. On the other hand, training on constituency trees seems to have some specific sources of errors. First, the possessor in possessive constructions is less frequently attached to its possessed, which may be due to the fact that the genitive possessor is not linked to the possessed in the constituency treebank and thus the parser is not able to learn this relationship. Second, arguments of verbal elements (i.e. verbs, participles and infinitives) are also somewhat more difficult to find when there are at least two verbal elements within the clause, which is especially true for adverbial participles and infinitives. In Figure 6, the differences between the two trees are shown. The noun *pecsenyéjükkel* (roast-3PLPOSS-INS) "with their thing" is linked to the adverbial participle in the correct analysis, but it connects to the main verb in the other. Third, identifying the root node of the sentence may also be problematic for this setting. As Farkas and Bohnet (2012) reported that preconversion can achieve better results for finding the root node in English, this seems to be a language-specific issue and it represents an interesting difference between English and Hungarian. Nevertheless, training on constituency trees has a beneficial effect on finding multiword named entities. Hence, it can be concluded that although the evaluation scores are similar, the errors the two systems make differ from each other.

6 Discussion and Conclusions

Here, we compared dependency analyses of Hungarian obtained in different ways. It was revealed that although the accuracy scores are similar to each other, each system makes different types of errors. On the other hand, there are some specific linguistic phenomena that seem to be difficult for dependency parsing generally as they were among the most frequent sources of errors in each case (e.g. coordination, multiple modifiers and the attachment of conjunctions and adverbs).

Converting constituency trees into dependency trees enabled us to experiment with a silver standard dependency corpus as well. Our results empirically showed that better results can be achieved on the gold standard corpus, hence manual annotation of dependency trees is desirable. However, when there is no access to manually annotated dependency data, converting the output of a constituency parser into dependency format or training the dependency parser on converted data may also be viable: similar to English, both solutions result in competitive scores but the errors the systems make differ from each other.

In the future, we would like to investigate how the advantages of constituency and dependency representations may be further exploited in parsing Hungarian and we also plan to carry out some uptraining experiments with both types of parsers.

Abstract

"Deep-syntactic" dependency structures that capture the argumentative, attributive and coordinative relations between full words of a sentence have a great potential for a number of NLP-applications. The abstraction degree of these structures is in-between the output of a syntactic dependency parser (connected trees defined over all words of a sentence and language-specific grammatical functions) and the output of a semantic parser (forests of trees defined over individual lexemes or phrasal chunks and abstract semantic role labels which capture the argument structure of predicative elements, dropping all attributive and coordinative dependencies). We propose a parser that delivers deep syntactic structures as output.

1 Introduction

Surface-syntactic structures (SSyntSs) as produced by data-driven syntactic dependency parsers are *per force* idiosyncratic in that they contain governed prepositions, determiners, support verb constructions and language-specific *grammatical functions* such as, e.g., SBJ, OBJ, PRD, PMOD, etc. (Johansson and Nugues, 2007). For many NLP-applications, including machine translation, paraphrasing, text simplification, etc., such a high idiosyncrasy is obstructive because of the recurrent divergence between the source and the target structures. Therefore, the use of more abstract "syntactico-semantic" structures seems more appropriate. Following Mel'čuk (1988), we call these structures *deep-syntactic structures* (DSyntSs). DSyntSs are situated between SSyntSs and PropBank- (Palmer et al., 2005) or Semantic Frame-like structures (Fillmore et al., 2002). Compared to SSyntSs, they have the advantage to abstract from language-specific grammatical idiosyncrasies. Compared to PropBank and Semantic Frame stuctures, they have the advantage to be connected and complete, i.e., capture all argumentative, attributive and coordinative dependencies between the meaningful lexical items of a sentence, while PropBank and Semantic Frame structures are not always connected, may contain either individual lexical items or phrasal chunks as nodes, and discard attributive and coordinative relations (be they within the chunks or sentential). In other words, they constitute incomplete structures that drop not only idiosyncratic, functional but also meaningful elements of a given sentence and often contain dependencies between chunks rather than individual tokens. Therefore, we propose to put on the research agenda the task of deep-syntactic parsing and show how a DSyntS is obtained from a SSynt dependency parse using data-driven tree transduction in a pipeline with a syntactic parser.[1] In Section 2, we introduce SSyntSs and DSyntSs and discuss the fundamentals of SSyntS–DSyntS transduction. Section 3 describes the experiments that we carried out on Spanish material, and Section 4 discusses their outcome. Section 5 summarizes the related work, before in Section 6 some conclusions and plans for future work are presented.

2 Fundamentals of SSyntS–DSyntS transduction

Before we set out to discuss the principles of the SSyntS–DSynt transduction, we must specify the DSyntSs and SSyntSs as used in our experiments.

[1]The term 'tree transduction' is used in this paper in the sense of Rounds (1970) and Thatcher (1970) to denote an extension of *finite state transduction* (Aho, 1972) to trees.

Proceedings of COLING 2014, the 25th International Conference on Computational Linguistics: Technical Papers, pages 1402–1413, Dublin, Ireland, August 23-29 2014.

2.1 Defining SSyntS and DSyntS

SSyntSs and DSyntSs are directed, node- and edge-labeled dependency trees with standard feature-value structures (Kasper and Rounds, 1986) as node labels and dependency relations as edge labels.

The features of the node labels in **SSyntSs** are lex_{ssynt}, and "syntactic grammemes" of the value of lex_{ssynt}, i.e., *number*, *gender*, *case*, *definiteness*, *person* for nouns and *tense*, *aspect*, *mood* and *voice* for verbs. The value of lex_{ssynt} can be any (either full or functional) lexical item; in graphical representations of SSyntSs, usually only the value of lex_{ssynt} is shown. The edge labels of a SSyntS are grammatical functions 'subj', 'dobj', 'det', 'modif', etc. In other words, SSyntSs are syntactic structures of the kind as encountered in the standard dependency treebanks; cf., e.g., dependency version of the Penn TreeBank (Johansson and Nugues, 2007) for English, Prague Dependency Treebank for Czech (Hajič et al., 2006), Ancora for Spanish (Taulé et al., 2008), Copenhagen Dependency Treebank for Danish (Buch-Kromann, 2003), etc. In formal terms that we need for the outline of the transduction below, a SSyntS is defined as follows:

Definition 1 (SSyntS) *An SSyntS of a language $\mathcal{L}$ is a quintuple $T_{SS} = \langle N, A, \lambda_{l_s \to n}, \rho_{r_s \to a}, \gamma_{n \to g} \rangle$ defined over all lexical items L of $\mathcal{L}$, the set of syntactic grammemes G_{synt}, and the set of grammatical functions R_{gr}, where*

- *the set N of nodes and the set A of directed arcs form a connected tree,*
- *$\lambda_{l_s \to n}$ assigns to each $n \in N$ an $l_s \in L$,*
- *$\rho_{r_s \to a}$ assigns to each $a \in A$ an $r \in R_{gr}$, and*
- *$\gamma_{n \to g}$ assigns to each $\lambda_{l_s \to n}(n)$ a set of grammemes $G_t \in G_{synt}$.*

The features of the node labels in **DSyntSs** as worked with in this paper are lex_{dsynt} and "semantic grammemes" of the value of lex_{dsynt}, i.e., *number* and *determination* for nouns and *tense*, *aspect*, *mood* and *voice* for verbs.[2] In contrast to lex_{ssynt} in SSyntS, DSyntS's lex_{dsynt} can be any *full*, but not a *functional* lexeme. In accordance with this restriction, in the case of *look after a person*, AFTER will not appear in the corresponding DSyntS; it is a functional (or governed) preposition (so are TO or BY, in Figure 1).[3] In contrast, AFTER in *leave after the meeting* is a full lexeme; it will remain in the DSyntS because there it has its own meaning of "succession in time". The edge labels of a DSyntS are language-independent "deep-syntactic" relations I,...,VI, ATTR, COORD, APPEND. 'I',...,'VI' are argument relations, analogous to $A0$, $A1$, etc. in the PropBank annotation. 'ATTR' subsumes all (circumstantial) ARGM-x PropBank relations as well as the modifier relations not captured by the PropBank and FrameNet annotations. 'COORD' is the coordinative relation as in: *John*-COORD→*and*-II→*Mary*, *publish*-COORD→*or*-II→*perish*, and so on. APPEND subsumes all parentheticals, interjections, direct addresses, etc., as, e.g., in *Listen, John!*: *listen*-APPEND→*John*. DSyntSs thus show a strong similarity with PropBank structures, with four important differences: (i) their lexical labels are not disambiguated; (ii) instead of circumstantial thematic roles of the kind ARGM-LOC, ARGM-DIR, etc. they use a unique ATTR relation; (iii) they capture all existing dependencies between meaningful lexical nodes; and (iv) they are connected.[4] A number of other annotations have resemblance with DSyntSs; cf. (Ivanova et al., 2012) for an overview of deep dependency structures. Formally, a DSyntS is defined as follows:

Definition 2 (DSyntS) *An DSyntS of a language $\mathcal{L}$ is a quintuple $T_{DS} = \langle N, A, \lambda_{l_s \to n}, \rho_{r_s \to a}, \gamma_{n \to g} \rangle$ defined over the full lexical items L_d of $\mathcal{L}$, the set of semantic grammemes G_{sem}, and the set of deep-syntactic relations R_{dsynt}, where*

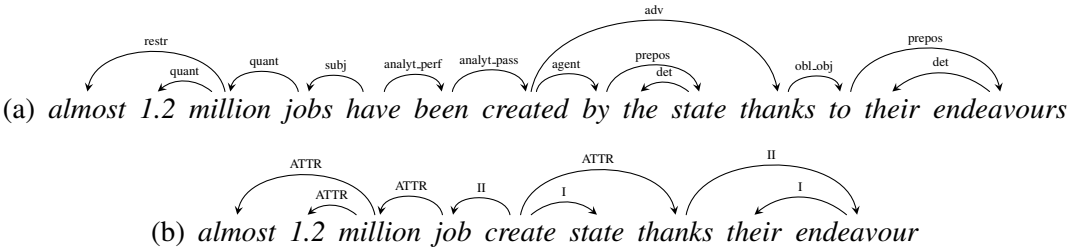
- *the set N of nodes and the set A of directed arcs form a connected tree,*
- *$\lambda_{l_s \to n}$ assigns to each $n \in N$ an $l_s \in L_d$,*
- *$\rho_{r_s \to a}$ assigns to each $a \in A$ an $r \in R_{dsynt}$, and*
- *$\gamma_{n \to g}$ assigns to each $\lambda_{l_s \to n}(n)$ a set of grammemes $G_t \in G_{sem}$.*

Consider in Figure 1 an example for an SSyntS and its corresponding DSyntS.

[2] Most of the grammemes have a semantic and a surface interpretation; see (Mel'čuk, 2013).

[3] Functional lexemes also include auxiliaries (e.g. HAVE, or BE when it is not a copula), and definite and indefinite determiners (THE, A); see Figure 1).

[4] Our DSyntSs are thus DSyntSs as used in the Meaning-Text Theory (Mel'čuk, 1988), only that our DSyntSs do not disambiguate lexical items and do not use *lexical functions* (Mel'čuk, 1996).



(a) *almost 1.2 million jobs have been created by the state thanks to their endeavours*

(b) *almost 1.2 million job create state thanks their endeavour*

2.2 Fleshing out the SSyntS–DSyntS transduction

It is clear that the SSyntS and DSyntS of the same sentence are not isomorphic. The following correspondences between the SSyntS S_{ss} and DSyntS S_{ds} of a sentence need to be taken into account during SSyntS–DSyntS transduction:

(i) a node in S_{ss} is a node in S_{ds};
(ii) a relation in S_{ss} corresponds to a relation in S_{ds};
(iii) a fragment of the S_{ss} tree corresponds to a single node in S_{ds};
(iv) a relation with a dependent node in S_{ss} is a grammeme in S_{ds};
(v) a grammeme in S_{ss} is a grammeme in S_{ds};
(vi) a node in S_{ss} is conflated with another node in S_{ds}; and
(vii) a node in S_{ds} has no correspondence in S_{ss}.

The grammeme correspondences (iv) and (v) and the "pseudo" correspondences in (vi) and (vii)[5] are few or idiosyncratic and are best handled in a rule-based post-processing stage. The main task of the SSyntS–DSyntS transducer is thus to cope with the correspondences (i)–(iii). For this purpose, we can view both SSyntS and DSyntS as vectors indexed in terms of two-dimensional matrices $I = N \times N$ (N being the set of nodes of a given tree $1, \ldots, m$), with $I(i,j) = \rho(n_i, n_j)$, if $n_i, n_j \in N$ and $(n_i, n_j) \in A$ and $I(i,j) = 0$ otherwise (where '$\rho(n_i, n_j)$' is the function that assigns to an edge a relation label and $i, j = 1, \ldots, m; i \neq j$ are nodes of the tree). That is, for a given SSyntS, the matrix $I(i,j)$ contains in the cells (i,j), $i,j = 1, \ldots, m$, the names of the SSynt-relations between the nodes n_i and n_j , and '0' otherwise, while for a given DSyntS, the cells of its matrix I_D contain DSyntS-relations.

Starting from the matrix I_S of a given SSyntS, the task is therefore to obtain the matrix I_D of the corresponding DSyntS, that is, to identify correspondences between i/j, (i,j) and groups of (i,j) of I_S with i'/j' and (i',j') of I_D; see (i)–(iii) above. In other words, the task consists in identifying and removing all functional lexemes, and attach correctly the remaining nodes between them.[6]

As a "token chain→surface-syntactic tree" projection, this task can be viewed as a classification task. However, while the former is isomorphic, we know that the SSyntS–DSyntS projection is not. In order to approach the task to an isomorphic projection (and thus simplify its modelling), it is convenient to interpret SSyntS and the targeted DSyntS as collections of *hypernodes*:

Definition 3 (Hypernode) *Given a SSyntS S_s with its index matrix I_S (a DSyntS S_d with its index matrix I_D), a node partition p (with $|p| \geq 1$) of I_S (I_D) is a hypernode h_{s_i} (h_{d_i}) iff p corresponds to a partition p' (with $|p'| \geq 1$) of S_d (S_s).*

In this way, the SSyntS–DSyntS correspondence boils down to a correspondence between individual hypernodes and between individual arcs, and the transduction embraces the following three (classification) subtasks: 1. Hypernode identification, 2. DSynt tree construction, and 3. DSynt arc labeling, which are completed by a post-processing stage.

[5](vi) covers, e.g., reflexive verb particles such as *se* in Spanish, which are conflated in the DSyntS with the verb: *se*←aux_refl_dir-*conocer* vs. CONOCERSE 'know each other'; (vii) covers, e.g., the zero subject in pro-drop languages (which is absent in the SSyntS and present in the DSyntS).

[6]What is particularly challenging is the identification of functional prepositions: based on the information found in the corpus only, our system must decide if a given preposition is a full or a functional lexeme. That is, we do not resort to any external lexical resources.

1. Hypernode identification. The hypernode identification consists of a binary classification of the nodes of a given SSyntS as nodes that form a hypernode of cardinality 1 (i.e., nodes that have a one-to-one correspondence to a node in the DSyntS) vs. nodes that form part of a hypernode of cardinality > 1. In practice, hypernodes of type one will be formed by: 1) noun nodes that do not govern determiner or functional preposition nodes, 2) full verb nodes that are not governed by any auxiliary verb nodes and that do not govern any functional preposition node, adjective nodes, adverbial nodes, and semantic preposition nodes. Hypernodes of type two will be formed by: 1) noun nodes + determiner / functional preposition nodes they govern, 2) verb nodes + auxiliary nodes they are governed by + functional preposition nodes they govern.

2. DSynt tree reconstruction. The outcome of the hypernode identification stage is thus the set $H_s = H_{s_{|p|=1}} \cup H_{s_{|p|>1}}$ of hypernodes of two types. With this set at hand, we can define an isomorphy function $\tau : H_s \rightarrow H_{d_{|p|=1}}$ (with $h_d \in H_{d_{|p|=1}}$ consisting of $n_d \in N_{ds}$, i.e., the set of nodes of the target DSyntS). τ is the identity function for $h_s \in H_{s_{|p|=1}}$. For $h_s \in H_{s_{|p|>1}}$, τ maps the functional nodes in h_s onto grammemes (attribute-value pairs) of the lexically meaningful node in h_d and identifies the lexically meaningful node as head. Some of the dependencies of the obtained nodes $n_d \in N_{ds}$ can be recovered from the dependencies of their sources. Due to the projection of functional nodes to grammemes (which can be also seen as node removal), some dependencies will be also missing and must be introduced. Algorithm 1 recalculates the dependencies for the target DSyntS S_d, starting from the index matrix I_S of SSyntS S_s to obtain a connected tree.

Algorithm 1: DSyntS tree reconstruction

for $\forall n_i \in N_d$ **do**
  if $\exists n_j : (n_j, n_i) \in S_s \wedge \tau(n_j) \in N_d$ **then**
  $(n_j, n_i) \rightarrow S_d$ // the equivalent of the head node of n_i is included in DSyntS
  else if $\exists n_j, n_a : (n_j, n_i) \in S_s \wedge \tau(n_j) \notin N_d \wedge$
      $\tau(n_a) \in N_d$ **then**
      //n_a is the first ancestor of n_j that has an equivalent in DSyntS
      //the equivalent of the head node of n_i is not included in DSyntS, but the ancestor n_a is
      $(n_a, n_i) \rightarrow S_d$
    else
      //the equivalent of the head node of n_i is not included in DSyntS, but several ancestors of it are
      $n_b := BestHead(n_i, S_s, S_d)$
      $(n_b, n_i) \rightarrow S_d$
endfor

$BestHead$ recursively ascends S_s from a given node n_i until it encounters one or several head nodes $n_d \in N_{ds}$. In case of several encountered head nodes, the one which governs the highest frequency dependency is returned.

3. Label Classification. The tree reconstruction stage produces a "hybrid" connected dependency tree $S_{s \rightarrow d}$ with DSynt nodes N_{ds}, and arcs A_s labelled by SSynt relation labels, i.e., an index matrix we can denote as I^-, whose cells (i, j) contain SSynt labels for all $n_i, n_j \in N_{ds} : (n_i, n_j) \in A_s$ and '0' otherwise. The next and last stage of SSynt-to-DSyntS transduction is thus the projection of SSynt relation labels of $S_{s \rightarrow d}$ to their corresponding DSynt labels, or, in other words, the mapping of I^- to I_D of the target DSyntS.

4. Postprocessing. As mentioned in Section 2, there is a limited number of idiosyncratic correspondences between elements of SSyntS and DSyntS (the correspondences (iv–vii) which can be straightforwardly handled by a rule-based postprocessor because (a) they are non-ambiguous, i.e., $a \leftrightarrow b, c \leftrightarrow d \Rightarrow a = b \wedge c = d$, and (b) they are few. Thus, only determiners and auxiliaries in SSyntS map onto a grammeme in DSyntS, both SSyntS and DSyntS count with less than a dozen grammemes, etc.

3 Experiments

In order to validate the outlined SSyntS–DSyntS transduction and to assess its performance in combination with a surface dependency parser, i.e., starting from plain sentences, we carried out a number of

experiments in which we implemented the transducer and integrated it into a pipeline shown in Figure 2.

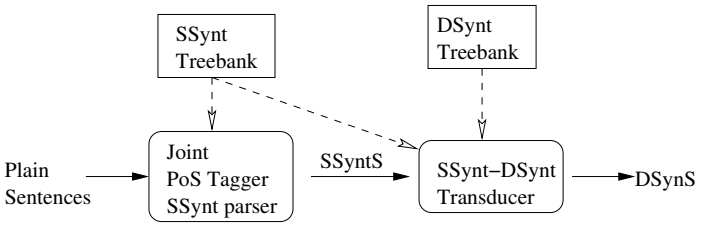

Figure 2: Setup of a deep-syntactic parser

For our experiments, we use the AnCora-UPF SSyntS and DSyntS treebanks of Spanish (Mille et al., 2013) in CoNLL format, adjusted for our needs. In particular, we removed from the 79-tag SSyntS treebank the semantically and information structure influenced relation tags to obtain an annotation granularity closer to the ones used for previous parsing experiments (55 relation tags, see (Mille et al., 2012)).

Our development set consisted of 219 sentences (3271 tokens in the DSyntS treebank and 4953 tokens in the SSyntS treebank), the training set of 3036 sentences (57665 tokens in the DSyntS treebank and 86984 tokens in the SSyntS treebank), and the *test set* held-out for evaluation of 258 sentences (5641 tokens in the DSyntS treebank and 8955 tokens in the SSyntS treebank).

To obtain the SSyntS, we use Bohnet and Nivre (2012)'s transition-based parser, which combines lemmatization, PoS tagging, and syntactic dependency parsing—tuned and trained on the respective sets of the SSyntS treebank. Cf. Table 1 for the performance of the parser on the development set.

POS	LEMMA	LAS	UAS
96.14	91.10	78.64	86.49

Table 1: Results of Bohnet and Nivre's surface-syntactic parser on the development set

In what follows, we first present the realization of the SSyntS–DSyntS transducer and then the realization of the baseline.

3.1 SSyntS–DSyntS transducer

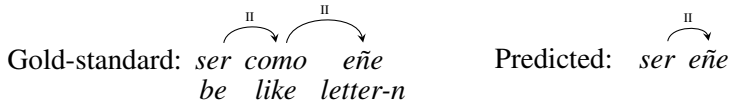
As outlined in Section 2.2, the SSyntS–DSyntS transducer is composed of three submodules and a post-processing stage:

1. Hypernode identification. For the hypernode identification, we trained a binary polynomial (degree 2) SVM from LIBSVM (Chang and Lin, 2001). The SVM allows both features related to the processed node and higher-order features, which can be related to the head node of the processed node or to its sibling nodes. After several feature selection trials, we chose the following features for each node n:

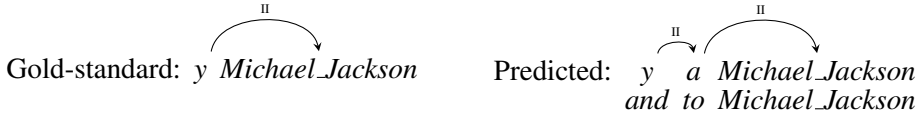
- lemma or stem of the label of n,
- label of the relation between n and its head,
- surface PoS of n's label (the SSynt and DSyntS treebanks distinguish between surface and deep PoS),
- label of the relation between n's head to its own head,
- surface PoS of the label of n's head node.

After an optimization round of the parameters available in the SVM implementation, the hypernode identification achieved over the gold development set 99.78% precision and 99.02% recall (and thus 99.4% F1). That is, only very few hypernodes are not identified correctly. The main error source are *governed prepositions*: the classifier has to learn when to assign a preposition an own hypernode (i.e., when it is lexically meaningful) and when it should be included into the hypernode of the governor (i.e., when it is functional). Our interpretation is that the features we use for this task are appropriate, but that the training data set is too small. As a result, some prepositions are erroneously left out from or introduced into the DSyntS.

2. Tree reconstruction. The implementation of the tree reconstruction module shows an unlabelled dependency attachment precision of 98.18% and an unlabelled dependency attachment recall of 97.43% over the gold development set. Most of the errors produced by this module have their origin in the previous module, i.e., hypernode identification. When a node has been incorrectly removed, the module errs in the attachment because it cannot use the node in question as the destination or the origin of a dependency, as it is the case in the gold-standard annotation:



When a node has erroneously not been removed, no dependencies between its governor and its dependent can be established since DSyntS must remain a tree (which gives the same LAS and UAS errors as when a node has been erroneously removed):



3. Relation label classification. For relation label classification, we use a multiclass linear SVM. The label classification depends on the concrete annotation schemata of the SSyntS and DSyntS treebanks on which the parser is trained. Depending on the schemata, some DSynt relation labels may be easier to derive from the original SSyntS relation labels than others. Table 2 lists all SSynt relation labels that have a straightforward mapping to DSyntS relation labels in the used treebanks, i.e., neither their dependent nor their governor are removed, and the SSyntS label always maps to the same DSynt label.

punc	—
punc_init	—

Table 3: Complex SSynt to DSynt mappings

The final set of features selected for label classification includes: (i) lemma of the dependent node, (ii) dependency relation to the head of the dependent node, (iii) dependency relation label of the head node to its own head, (iv) dependency relation to the head of the sibling nodes of the dependent node, if any.

After an optimization round of the parameter set of the SVM-model, relation labelling achieved 94.00% label precision and 93.28% label recall on the development set. The recall is calculated considering all the nodes that are included in the gold standard. The error sources for relation labelling were mostly the dependencies that involved possessives and the various types of objects (see Table 3) due to their differing valency. For instance, the relation *det* in *su*$\leftarrow det-$*coche* 'his/her car' and *su*$\leftarrow det-$*llamada* 'his/her phone call' have different correspondences in DSyntS: *su*$\leftarrow ATTR-$*coche* vs. *su*$\leftarrow I-$*llamada*. That is, the DSyntS relation depends on the lexical properties of the governor.[7] Once again, more training data is needed in order to classify better those cases.

4. Postprocessing In the postprocessing stage for Spanish, the following rules capture non-ambiguous correspondences between elements of the SSynt-index matrix $I_S = N_s \times N_s$ and DSyntS index matrix $I_D = N_d \times N_d$, with $n_s \in N_s$ and $n_d \in N_d$, and n_s and n_d corresponding to each other (we do not list here identity correspondences such as between the number grammemes of n_s and n_d):

- if n_s is dependent of *analyt_pass* or *analyt_refl_pass* relation, then the voice grammeme in n_d is *PASS*;
- if n_s is dependent of *analyt_progr*, then the voice grammeme in n_d is *PROGR*;
- if n_s is dependent of *analyt_refl_lex*, then add the particle -SE as suffix of node label (word) of d_d;
- if any of the children of n_s is labelled by one of the tokens UN 'a$_{masc}$', UNA 'a$_{fem}$', UNOS 'some$_{masc}$' or UNAS 'some$_{fem}$', then the definiteness grammeme in n_d *INDEF*, otherwise it is *DEF*;
- if the n_s label is a finite verb and n_s does not govern a *subject* relation, then add to I' the relation $n_d - I \rightarrow n'_d$, with n'_d being a newly introduced node.

3.2 Baseline

As point of reference for the evaluation of the performance of our SSyntS–DSyntS transducer, we use a rule-based baseline that carries out the most direct transformations extracted from Tables 2 and 3. The baseline detects hypernodes by directly removing all the nodes that we are sure need to be removed, i.e. punctuation and auxiliaries. The nodes that are only *potentially* to be removed, i.e., all dependents of DepRels that have a possibly governed preposition or conjunction in Table 3, are left in the DSyntS. The new relation labels in the DSyntS are obtained by selecting the label that is most likely to substitute the SSyntS relation label according to classical grammar studies. The rules of the rule-based baseline look as follows:

```
1  if (deprel==abbrev) then deep_deprel=ATTR
2  if (deprel==obl_obj) then deep_deprel=II
...
n  if (deprel==punc) then remove(current_node)
```

4 Results and Discussion

Let us look in this section at the performance figures of the SSyntS parser, the SSyntS–DSyntS transducer, and the sentence–DSyntS pipeline obtained in the experiments.

4.1 SSyntS–DSyntS transducer results

In Table 4, the performance of the subtasks of the SSyntS–DSyntS transducer is contrasted to the performance of the baselines; the evaluation of the postprocessing subtask is not included because the one-to-one projection of SSyntS elements to DSyntS guarantees an accuracy of 100% of the operations performed. The transducer has been applied to the gold standard test set, which is the held-out test set, with gold standard PoS tags, lemmas and dependency trees. It outputs in total 5610 nodes; the rule-based baseline outputs 8653 nodes. As mentioned in Section 3, our gold standard includes 5641 nodes.

[7] Note that lexemes are not generalized: a verb and its corresponding noun (e.g., *construct*/*construction*) are considered distinct lexemes.

Hyper-Node Detection		
Measure	Rule-based Baseline	Tree Transducer
p	64.31 (5565/8653)	99.79 (5598/5610)
r	98.65 (5565/5641)	99.24 (5598/5641)
$F1$	77.86	99.51

Attachment and Labelling		
Measure	Rule-based Baseline	Tree Transducer
LAP	50.02 (4328/8653)	91.07 (5109/5610)
UAP	53.05 (4590/8653)	98.32 (5516/5610)
LA-P	57.66 (4989/8653)	92.37 (5182/5610)
LAR	76.72 (4328/5641)	90.57 (5109/5641)
UAR	81.37 (4590/5641)	97.78 (5516/5641)
LA-R	88.44 (4989/5641)	91.86 (5182/5641)

Table 4: Performance of the SSyntS–DSyntS transducer and of the rule-based baseline over the gold-standard held-out test set (LAP: labelled attachment precision, UAP: unlabelled attachment precision, LA-P: label assignment precision, LAR: labelled attachment recall, UAR: Unlabelled attachment recall and LA-R: Label assignment recall)

Our data-driven SSyntS–DSyntS transducer is much better than the baseline with respect to all evaluation measures.[8] The transducer relies on distributional patterns identified in the training data set, and makes thus use of information that is not available for the rule-based baseline, which studies one node at a time. However, the rule-based baseline results also show that transduction that would remove a few nodes would provide results close to a 100% recall for the hypernode detection because a DSynt tree is a subtree of the SSynt tree (if we ignore the nodes introduced by post-processing). This is also evidenced by the labeled and attachment recall scores. The results of the transducer on the test and development sets are quite comparable. The hypernode detection is even better on the test set. The label accuracy suffers most from using unseen data during the development of the system. The attachment figures are approximately equivalent on both sets.

4.2 Results of deep-syntactic parsing

Let us consider now the performance of the complete DSynt parsing pipeline (PoS-tagger+surface-dependency parser → SSyntS–DSyntS transducer) on the held-out test set. Table 5 displays the figures of the Bohnet and Nivre parser. The figures are in line with the performance of state-of-the-art parsers for Spanish (Mille et al., 2012).

POS	LEMMA	LAS	UAS
96.05	92.10	81.45	88.09

Table 5: Performance of Bohnet and Nivre's joint PoS-tagger+dependency parser trained on Ancora-UPF

Table 6 shows the performance of the pipeline when we feed the output of the syntactic parser to the rule-based baseline SSyntS–DSyntS module and the tree transducer. We observe a clear error propagation from the dependency parser (which provides 81.45% LAS) to the SSyntS–DSyntS transducer, which loses in tree quality more than 18%.

5 Related Work

To the best of our knowledge, data-driven deep-syntactic parsing as proposed in this paper is novel. As *semantic role labeling* and *frame-semantic analysis*, it has the goal to obtain more semantically oriented structures than those delivered by state-of-the-art syntactic parsing. Semantic role labeling received considerable attention in the CoNLL shared tasks for syntactic dependency parsing in 2006 and 2007

[8] We also ran MaltParser by training it on the DSynt-treebank to parse the SSynt-test set; however, the outcome was too weak to be used as baseline.

(Buchholz and Marsi, 2006; Nivre et al., 2007), the CoNLL shared task for joint parsing of syntactic and semantic dependencies in 2008 (Surdeanu et al., 2008) and the shared task in 2009 (Hajič et al., 2009). The top ranked systems were pipelines that started with a syntactic analysis (as we do) and continued with predicate identification, argument identification, argument labeling, and word sense disambiguation; cf. (Johansson and Nugues, 2008; Che et al., 2009). At the end, a re-ranker that considers jointly all arguments to select the best combination was applied. Some of the systems were based on integrated syntactic and semantic dependency analysis; cf., e.g., (Gesmundo et al., 2009); see also (Lluís et al., 2013) for a more recent proposal along similar lines. However, all of them lack the ability to perform structural changes—as, e.g., introduction of nodes or removal of nodes necessary to obtain a DSyntS. Klimeš (2006)'s parser removes nodes (producing tectogrammatical structures as in the Prague Dependency Treebank), but is based on rules instead of classifiers, as in our case. The same applies to earlier works in the TAG-framework, as, e.g., in (Rambow and Joshi, 1997).

However, this is not to say that the idea of the surface→surface syntax→deep syntax pipeline is new. It goes back at least to Curry (1961) and is implemented in a number of more recent works; see, e.g., (de Groote, 2001; Klimeš, 2006; Bojar et al., 2008).

6 Conclusions and Future Work

We have presented a deep-syntactic parsing pipeline which consists of a state-of-the-art dependency parser and a novel SSyntS–DSyntS transducer. The obtained DSyntSs can be used in different applications since they abstract from language-specific grammatical idiosyncrasies of the SSynt structures as produced by state-of-the art dependency parsers, but still avoid the complexities of genuine semantic analysis.[9] DSyntS-treebanks needed for data-driven applications can be bootstrapped by the pipeline. If required, a SSyntS–DSyntS structure pair can be also mapped to a pure predicate-argument graph such as the DELPH-IN structure (Oepen, 2002) or to an approximation thereof (as the Enju conversion (Miyao, 2006), which keeps functional nodes), to an DRS (Kamp and Reyle, 1993), or to a PropBank structure. On the other hand, DSyntS-treebanks can be used for automatic extraction of deep grammars. As shown by Cahill et al. (2008), automatically obtained resources can be of an even better quality than manually-crafted resources. In this context, especially research in the context of CCGs (Hockenmeier, 2003; Clark and Curran, 2007) and TAGs (Xia, 1999) should be also mentioned.

To validate our approach with languages other than Spanish, we carried out an experiment on a Chinese SSyntS-DSyntS Treebank (training the DSynt-transducer on the outcome of the SSynt-parser). The results over predicted input showed an accuracy of about 75%, i.e., an accuracy comparable to the accuracy achieved for Spanish. We are also investigating multilingual approaches, such as the one proposed by McDonald et al. (2013).

In the future, we will carry out further in-depth feature engineering for the task of DSynt-parsing. It proved to be crucial in semantic role labelling and dependency parsing (Che et al., 2009; Ballesteros and Nivre, 2012); we expect it be essential for our task as well. Furthermore, we will join surface syntactic and deep-syntactic parsing we kept so far separate; see, e.g., (Zhang and Clark, 2008; Lluís et al., 2013; Bohnet and Nivre, 2012) for analogous proposals. Further research is required here since although joint models avoid error propagation from the first stage to the second, overall, pipelined models still proved to be competitive; cf. the outcome of CoNLL shared tasks.

The deep-syntactic parser described in this paper is available for downloading at `https://code.google.com/p/deepsyntacticparsing/`.

Abstract

Automatically identifying anomalous newswire events is a hard problem. We discuss the complexity of the problem and introduce a novel technique to model events based on recursive neural networks to represent events as composition of their semantic arguments. Our model learns to differentiate between normal and anomalous events. We model anomaly detection as a binary classification problem and show that the model learns useful features to classify anomaly. We use headlines from the weird news category publicly available on newswire websites to extract anomalous training examples and those from Gigaword as normal examples. We evaluate the classifier on human annotated data and obtain an accuracy of 65.44%. We also show that our model is at least as competent as the least competent human annotator in anomaly detection.

1 Introduction

Understanding events is a fundamental prerequisite for deeper semantic analysis of language. We introduce the problem of automatic anomalous event detection in this paper and propose a novel event model that can learn to differentiate between normal and anomalous events. We generally define anomalous events as those that are unusual compared to the general state of affairs and might invoke surprise when reported. For example, given the event mention in the following sentence

Man recovering after being shot by his dog.

one might think it is strange because *dogs* are not expected to shoot *men*. But the mentions

Man recovering after being shot by cops.

Man recovering after being bitten by a dog.

are not as unusual as the previous one. While all three sentences are equally valid syntactically, and it is not unclear what any of them means, it is our knowledge about the role fillers —both individually and specifically in combination— that enables us to differentiate between normal and anomalous events. Hence we hypothesize that *anomaly is a result of unexpected or unusual combination of semantic role fillers*. Given this idea, an automatic anomaly detection algorithm has to encode the goodness of semantic role filler coherence.

It has to be noted that event level anomaly is not the same as semantic incoherence. An event constructed by randomly choosing words to form each of the semantic arguments is not anomalous since we cannot argue whether the event is normal or anomalous when it is unclear what the event means. Hence, we define anomalous events to be the sub class of those that are semantically coherent, but are unusual only based on real world knowledge.

Automatic anomalous event detection is a hard problem since determining what a good combination of role fillers requires deep semantic and pragmatic knowledge. Moreover, manual judgment of anomaly

Proceedings of COLING 2014, the 25th International Conference on Computational Linguistics: Technical Papers, pages 1414–1422, Dublin, Ireland, August 23-29 2014.

itself may be difficult and people often may not agree with each other in this regard. We describe the difficulty in human judgment in greater detail in Section 4.4. Automatic detection of anomaly requires encoding complex information, which has to be composed from the semantics of the individual words in the sentence. A fundamental problem in doing so is the sparsity in semantic space due to the discrete representations of meaning of words.

In this paper, we describe an attempt to model newswire events as a composition of the predicate with its semantic arguments. Our approach is based on the recent models used for semantic composition using recursive neural networks (RNN). It has been previously shown by Socher et al. (2010) and Socher et al. (2013b) among others that RNN can effectively deal with sparsity in semantic space by representing meaning at a higher level of abstraction than the surface forms of words, and thus being able to learn more general patterns. These models are very relevant to modeling event semantics because the sparsity problem ranges from polysemy and synonymy at the lexical semantic level to entity and event co-reference at the discourse level.

2 Background

2.1 Selectional Preference and Thematic Fit

Selectional preference, a notion introduced by Wilks (1973), refers to the phenomenon of the predicate and the fillers of its arguments affecting the likelihood of fillers of other arguments. Thus the idea is that predicate and the role fillers "prefer" some fillers for other roles. For example, given that the predicate is *writes*, the agent *author* prefers the patient *book*, while the agent *programmer* prefers the patient *code*. This idea is used by Elman (2009), and is very similar to the role-filler composition that we use for anomaly detection.

Erk et al. (2010) also model selectional preferences using vector spaces. They measure the goodness of the fit of a noun with a verb in terms of the similarity between the vector of the noun and some "exemplar" nouns taken by the verb in the same argument role. Baroni and Lenci (2010) also measure selectional preference similarly, but instead of exemplar nouns, they calculate a prototype vector for that role based on the vectors of the most common nouns occurring in that role for the given verb. Lenci (2011) builds on this work and models the phenomenon that the expectations of the verb or its role-fillers change dynamically given other role fillers.

2.2 Recursive Neural Networks

Recursive Neural Networks (RNN), first introduced by Goller and Kuchler (1996), are multilayer neural network models used for efficient processing of structured objects of arbitrary shape. These have been successfully used for modeling semantics of sentences of arbitrary length by Socher et al. (2010), for sentiment analysis by Socher et al. (2013b), for syntactic parsing by Socher et al. (2013a) and for learning morphologically aware word representations by Luong et al. (2013). RNN are attractive because they can encode compositions of meaning guided by syntax or some other linguistic structure known a priori. Moreover, they provide flexibility in terms of learning composition weights based on supervised or unsupervised objectives. Consequently RNN learn feature representations depending on the task. Hence, this is a good choice for modeling event composition.

In its simplest form, an RNN processes information backed by a Directed Acyclic Graph (DAG), where each node represents a neural network with the same parameters. The output produced at each intermediate step of encoding usually has the same dimensionality as each of the inputs, hence RNN projects the representation of a structure of arbitrary length into the same space as the inputs. This property is what makes RNN recursive. An example RNN with a binary DAG (tree) structure is shown in Figure 1. The activation from each neural network node is

$$c = g(y_1 \| y_2) = Sg(W(y_1 \| y_2) + b)$$

where $\|$ represents concatenation of vector representations of the inputs, $y_1, y_2 \in \mathbb{R}^{n \times 1}$ are the inputs, $W \in \mathbb{R}^{n \times 2n}$ is the composition weight matrix and $b \in \mathbb{R}^{n \times 1}$ is the bias. Sg is a element wise sigmoid

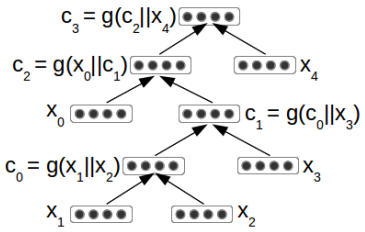

Figure 1: Example of a Recursive Neural Network backed by a binary tree

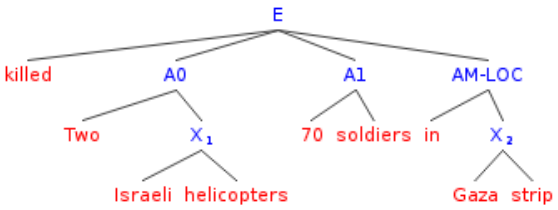

Figure 2: Example of an event tree

function. Apart from encoding the composition, RNN also produce a score of composition

$$s = S^{\mathsf{T}} c$$

where $S \in \mathbb{R}^{n \times 1}$ is a scoring operator and s is a score that shows how good the composition is. (Collobert et al., 2011) take an unsupervised approach to training RNN for semantic composition based on the contrastive estimation technique proposed by (Smith and Eisner, 2005) and assuming that any word and its context is a positive example and a random word in the same context is a negative training example. (Socher et al., 2013b) among others use a supervised objective that is based on the label error at the topmost node in the RNN. The parameters of the simplest model are W, b and S. For representation learning, the inputs x_i are also made parameters. Goller and Kuchler (1996) propose Backpropagation through structure (BPTS), that respects the underlying DAG structure during backpropagation of gradients.

3 Neural Event Model

We define an event as the pair $(V, \mathbf{A})$, where V is the predicate or a semantic verb[1], and $\mathbf{A}$ is the set of its semantic arguments like agent, patient, time, location, so on. Our aim is to obtain a vector representation of the event that is composed from representations of individual words, while explicitly guided by the semantic role structure. This representation can be understood as an embedding of the event in an event space.

Neural Event Model (NEM) is a kind of RNN that is guided by a tree representation of events like the one shown in Figure 2. The edges connected to the root of the tree correspond to the predicate and its semantic roles (arguments). All the other edges form binary sub-trees of arguments. NEM is a supervised model that learns to differentiate between anomalous and normal events by classifying the event embeddings. The inputs to NEM are the semantic arguments, and the representations of words in each argument. We recursively compose the words in each argument to obtain argument level representations, which are then composed to obtain an event embedding.

Intra-argument composition (called argument composition henceforth) is unsupervised, and we use contrastive estimation to learn the parameters. The structure of the binary tree backing argument composition is determined dynamically, composing at each stage the two nodes which give the best composition

[1]By semantic verb, we mean an action word whose syntactic category is not necessarily a verb. For example, in *Terrorist attacks on the World Trade Center..*, *attacks* is not a verb but is still an action word.

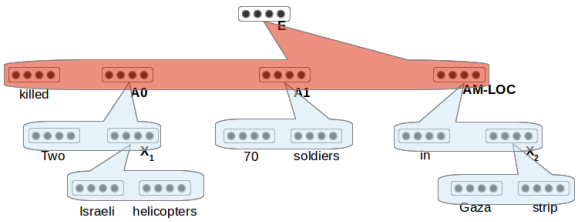

Figure 3: Neural Event Model: Encoding

score. Inter-argument composition (called event composition henceforth) is supervised and we use label error to learn the parameters. Figure 3 shows how NEM encodes the event shown in Figure 2. The blue boxes show argument composition and the red box shows event composition.

3.1 Training

NEM is trained in two phases. The first, argument composition, is unsupervised while the second, event composition, is supervised.

3.1.1 Argument Composition

An argument composition node takes inputs of dimensionality $2n$ and produces an composed output representation of dimensionality n and a composition score. Accordingly, we define the node in terms of the parameters $\theta_{arg} = \{W_{arg} \in \mathbb{R}^{n \times 2n}; b_{arg}, S_{arg} \in \mathbb{R}^{n \times 1}; V\}$ where W_{arg}, b_{arg} and S_{arg} are the composition weight, bias and the scoring operators respectively as described previously, and V is the set of representations of all the words in the vocabulary. All nodes performing argument composition use the same parameters. Training is done in contrastive estimation fashion and the objective is

$$\arg\min_{\theta_{arg}} J_{arg} = \arg\min_{\theta_{arg}} max(0, 1 - s + s_c)$$

where s is the score of the composition of the entire argument produced by the root node of the argument, and s_c is the score produced by randomly replacing one of the words in the argument at a time. The structure of the binary tree backing each argument is determined dynamically. This is done by starting with leaf nodes in the tree for each of the words in the argument, comparing the composition scores of every pair of adjacent leaf nodes, and actually composing the pair that gives the highest score, which gives a new node. The process is repeated until we build a complete binary tree for each argument.

3.1.2 Event Composition

Event composition takes argument representations and produces the event representation and label indicating whether the event is normal or anomalous. We define the event composition node in terms of the parameters $\theta_{event} = \{W_{event} \in \mathbb{R}^{n \times kn}; b_{event}, L_{event} \in \mathbb{R}^{n \times 1}\}$ where k is the number of semantic arguments per event. L_{event} is the label operator. The objective of this phase is

$$\arg\min_{\theta_{event}} J_{event} = \arg\min_{\theta_{event}} \left(-l \log h(e) + (1 - l) \log(1 - h(e))\right)$$

where l is the reference binary label indicating whether the event is normal or anomalous, e is the event representation and $h(e)$ is the output of the logistic function. Concretely,

$$h(e) = \frac{1}{1 + e^{-L_{event}^{\intercal} e}}$$

We implement the functions and perform stochastic gradient descent using Theano (Bergstra et al., 2010).

4 Experiments

4.1 Event Extraction

We extract events by running the Semantic Role Labeling (SRL) tool in SENNA (Collobert et al., 2011). SENNA uses PropBank (Palmer et al., 2005) style semantic tags. We consider only the roles *A0*, *A1*, *AM-TMP* and *AM-LOC* as the arguments of our events[2]. For example, the event in the tree shown in Figure 2 is extracted from the sentence

Two Israeli helicopters killed 70 soldiers in Gaza strip.

and SENNA identifies the following as the semantic roles

verb:*killed* ***A0:****Two Israeli helicopters* ***A1:****70 soldiers* ***AM-LOC:****in Gaza strip*

4.2 Data

Since the second phase of training NEM is supervised, we need newswire events that are normal and those that are anomalous. We crawl 3684 "weird news" headlines available publicly on the website of NBC news[3], such as the following:

- *India weaponizes world's hottest chili.*
- *Man recovering after being shot by his dog.*
- *Thai snake charmer puckers up to 19 cobras.*

We assume that the events extracted from this source, called NBC Weird Events (NWE) henceforth, are anomalous for training. NWE contains 4271 events extracted using SENNA's SRL. We use 3771 of those events as our negative training data, and the remaining for testing. Similarly, we extract events also from headlines in the AFE section of Gigaword, called Gigaword Events (GWE) henceforth. We assume these events are normal. To use as positive examples for training event composition, we sample roughly the same number of events from GWE as our negative examples from NWE. It has to be noted that each headline may contain multiple events and some may not contain events at all.

For argument composition, we use about 100k whole sentences from AFE headlines and the weird news headlines from which NWE are extracted. Since we are training argument composition, we do not use the event structure in the first phase. It has to be noted that all our training data are easily available and do not require any human annotation.

We test the performance of NEM on 1003 events which are not part of the training dataset. These events are sampled with equal probabilities from NWE and GWE and are human annotated for anomaly. Section 4.4 has details of the annotation task.

4.3 Word Vector Initialization

We initialize the vector representations of the words in our vocabulary using the embeddings available in SENNA 3.0 (Collobert et al., 2011) if available, and randomly if not. For event composition, if the event does not have a specific role filler, we input a zero vector for the role.

4.4 Annotation

We post the annotation of the test set containing 1003 events as Human Intelligence Tasks (HIT) on Amazon Mechanical Turk (AMT). We break the task into 20 HITs and ask the workers to select one of the four options - *highly unusual*, *strange*, *normal* and *cannot say* for each event. We ask them to select *highly unusual* when the event seems too strange to be true, *strange* if it seems unusual but still plausible, and *cannot say* only if the information present in the event is not sufficient to make a decision. We present each event along with the original headline and the semantic arguments. Along with marking

[2]These four types cover about 85% of all arguments in our training and test datasets.

Total number of annotators	22
Normal annotations	56.3%
Strange annotations	28.6%
Highly unusual annotations	10.3%
Cannot Say annotations	4.8%
Avg. events annotated per worker	344
4-way Inter annotator agreement (α)	0.34
3-way Inter annotator agreement (α)	0.56

Table 1: Annotation Statistics

one of the four options above, if an event is *strange* or *highly unusual*, we ask the annotators to select the parts of the headline that make it so. Since there can be multiple events in the headline, the annotators decision regarding the parts of the sentence that cause anomaly help us identify which particular event in the headline is anomalous.

Table 1 shows some statistics of the annotation task. We compute the Inter Annotator Agreement (IAA) in terms of Kripendorff's alpha (Krippendorff, 1980). The advantage of using this measure instead of the more popular Kappa is that the former can deal with missing information, which is the case with our task since annotators work on different overlapping subsets of the test set. The 4-way IAA shown in the table corresponds to agreement over the original 4-way decision (including *cannot say*) while the 3-way IAA is measured after merging the *highly unusual* and *strange* decisions.

Additionally we use MACE (Hovy et al., 2013) to assess the quality of annotation. MACE models the annotation task as a generative process of producing the observed labels conditioned on the true labels and the competence of the annotators, and predicts both the latent variables. The average of competence of annotators, a value that ranges from 0 to 1, for our task is 0.49 for the 4-way decision and 0.59 for the 3-way decision.

We generate true label predictions produced by MACE, discard the events for which the prediction remains to be *cannot say*, and use the rest as reference for evaluating NEM, which is described in Section 4.5. This leaves 949 events as our reference dataset, of which only 41% of the labels are *strange* or *highly unusual*. It has to be noted that even though our test set has equal size samples from both NWE and GWE, the true distribution is not uniform.

Language Model Separability Given the annotations, we test to see if the sentences corresponding to anomalous events can be separated from normal events by simpler features. We build a n-gram language model from the training data set used for argument composition and measure the perplexity of the sentences in the test set. Figure 4 shows a comparison of the perplexity scores for different labels. If the n-gram features are enough to separate different classes of sentences, one would expect the sentences corresponding to *strange* and *highly unusual* labels to have higher perplexity ranges than *normal* sentences, because the language model is built from a dataset that is expected to have a distribution of sentences where majority of them contain normal events. As it can be seen in Figure 4, except for a few outliers, most data points in all the categories are in similar perplexity ranges. Hence, sentences with different labels cannot be separated based on an n-gram language model features.

4.5 Evaluation

We evaluate the performance of event composition by comparing the predicted labels from the classifier against the ones given by MACE. We merge the two anomaly classes and calculate accuracy of the binary classifier, and the precision and recall of anomaly detection.

Baseline We compare the performance of our model against a baseline that is based on how well the semantic arguments in the event match the selectional preferences of the predicate. We measure selectional preference using Point-wise Mutual Information (PMI) (Church and Hanks, 1990) of the head words of each semantic argument with the predicate. The baseline model is built as follows. We perform

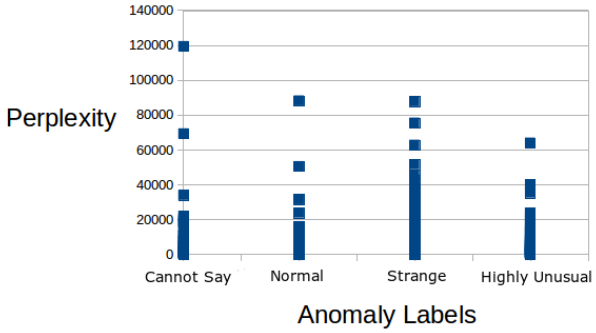

Figure 4: Comparison of perplexity scores for different labels

		NEM	Baseline
Accuracy		65.44%	45.22%
Anomalous	Precision	56.55%	36.30%
	Recall	48.22%	59.50%
Normal	Precision	64.62%	42.08%
	Recall	77.66%	33.60 %

Table 2: Classification Performance and Comparison with Baseline

dependency parsing using MaltParser (Nivre et al., 2007) on the sentences in the training data used in the first phase of training to obtain the head words of the semantic arguments. We then calculate the PMI values of all the pairs $< h_A, p >$ where h is the head word of argument A and p is the predicate of the event. For training our baseline classifier, we use the labeled training data from the event composition phase. The features to this classifier are the PMI measures of the $< h_A, p >$ pairs estimated from the larger dataset. The classifier thus trained to distinguish between anomalous and normal events is applied to the test set.

Table 2 shows the results and a comparison with the PMI based baseline. The accuracy of the baseline classifier is lower than 50%, which is the expected accuracy of a classifier that assigns labels randomly. The precision of that random classifier in predicting anomalous events is expected to be 41%, since that is the percentage of anomaly labels in our reference set as described in Section 4.4. The accuracy of NEM is higher than the baseline model. One possible reason for the PMI based baseline having higher recall in predicting anomaly and lower precision is that the statistics estimated from larger training data cannot be generalized to the test set due to sparsity issues. This indicates the advantage of using continuous representations at a higher level of abstraction as features for classification.

To further compare NEM with human annotators, we give to MACE, the binary labels produced by NEM along with the annotations and measure the competence. For the sake of comparison, we also give to MACE, a list of random binary labels as one of the annotations to measure the competence of a hypothetical worker that made random choices. These results are reported in Table 3. It can be seen that the performance of NEM is comparable at least to the least competent human.

5 Discussion and Future Work

The two evaluation experiments show that the neural network does learn to distinguish between normal and anomalous events. Future improvements to this model will include better event extraction techniques.

Since the current approach is supervised, the training data size for learning event composition is limited. We plan to develop unsupervised approaches that can learn good models of normal events, and detect anomalies based on how well new events fit in the model. One possible approach is to do learning

Human average	0.59
Human highest	0.70
Human lowest	0.26
Random	0.02
NEM	0.26

Table 3: Anomaly Detection Competence

based on contrastive estimation in the second phase as well. The assumption behind taking this approach for learning is that a randomly generated data point is likely to be a negative example, which is not necessarily true for learning event composition. Generating malformed events that are syntactically valid but anomalous without much human effort can greatly help in developing such an unsupervised algorithm.

One important aspect of anomaly that is currently not handled by NEM is the level of generality of the concepts the events contain. Usually more general concepts cause events to be more normal since they convey lesser information. For example, an American soldier shooting another American soldier may be considered unusual, while a soldier shooting another soldier may not be as unusual, and at the highest level of generalization, a person shooting another person is normal. This information of generality has to be incorporated into the event model. This can be achieved by integrating real world knowledge from knowledge bases like Wordnet (Miller, 1995) or from corpus statistics like the work by Lin (1998) into the event model. Bordes et al. (2011) learn continuous representations of entities and relations in knowledge bases. More recently, an alternative approach for doing the same was proposed by Chen et al. (2013). These representations can greatly help modeling events.

Finally, the idea of modeling event composition can help processing event data in general and can be applied to other tasks like finding co-referent events.

6 Conclusion

We introduced the problem of anomalous newswire event detection and illustrated its difficulty. Our approach is similar to the ones successfully used for modeling semantic composition. We showed that while our event composition model does learn to distinguish between normal and anomalous events, there is scope for improved models that can effectively incorporate real world information and can be trained in an unsupervised fashion. We note that in general event composition is more difficult than traditional semantic composition since the former also deals with pragmatics. Consequently the set of nonsensical events is different from the set of anomalous sentences, and while meaningless events and well composed normal events are two ends of the semantic spectrum, semantically valid anomalous events lie somewhere between them.

Abstract

We manually created a semantic taxonomy called *Phased Predicate Template Taxonomy* (*PPTT*) that covers 12,023 predicate templates (i.e., predicates with one argument slot like "*rescue X*") and derived from it various semantic relations between these templates on a million-instance scale (70%-80% precision level). The derived relations include entailment (e.g., *rescue X*$\supset$*X is alive*), happens-before (e.g., *buy X*$\Rightarrow$*drink X*), and a novel relation type *anomalous obstruction* (e.g., *X is sold out*$\rightsquigarrow$*cannot buy X*). Such derivation became possible thanks to PPTT's design and the use of statistical methods.

1 Introduction

Databases of various semantic relations between natural language expressions are indispensable knowledge for many NLP applications. For instance, entailment relations are crucial in information extraction and QA (Dagan et al., 2009; Weisman et al., 2012; Berant et al., 2012; Turney and Mohammad, 2014). Temporal relations such as happens-before (Chklovski and Pantel, 2004b; Regneri et al., 2010) are important for enhancing deep semantic processing. A problem, however, is that it is difficult to acquire those relations with a broad coverage. Although many sophisticated machine learning techniques have been applied to various kinds of corpora for this task (Szpektor et al., 2007; Chambers and Jurafsky, 2008; Hashimoto et al., 2009; Chambers and Jurafsky, 2009; Hashimoto et al., 2012; Talukdar et al., 2012; Kloetzer et al., 2013), no satisfactory coverage has been achieved, probably due to data sparseness in the input data. In this work we take a completely different approach: we manually construct a semantic lexicon called *Phased Predicate Template Taxonomy* (*PPTT*), and derive various types of semantic relations on a large-scale by using it. Our target language is Japanese, but examples are given in English for simplicity throughout this paper.

PPTT is a taxonomy of predicate templates (predicates with one argument slot like *rescue X*, "Template" hereafter) that classifies templates according to *phases of story* concerning an entity denoted by *X*. In the story, or the "life" of the entity *X*, *X* can be *anticipated*, *created*, then *execute* its function and finally it may *collapse* and become *deficient*. Anticipation, creation, execution, collapse, deficiency of *X* can be seen as such *phases of story* concerning *X*, and PPTT classifies templates into 41 semantic classes each of which corresponds to a phase. In other words, PPTT provides a way to describe the stories of various entities that constitute this world, and we believe that PPTT (partly) reflects how we understand the world and its entities. Accordingly, PPTT can also provide a way to derive various semantic knowledge about this world such as the happens-before relation between events involving an entity, e.g., since the creation phase usually occurs before the execution phase, *invent X* (creation phase) is likely to happen-before *use X* (execution phase). In addition, entailment relations can be derived: since the creation phase of an object *X must* have occurred if *X* is in its execution phase, it implies that *use X* is likely to entail *invent X*.

In addition, there are ups and downs in stories; some entities suffer setbacks in their stories. PPTT describes such "ups and downs" by means of a recently proposed semantic polarity, *excitation* (Hashimoto

Proceedings of COLING 2014, the 25th International Conference on Computational Linguistics: Technical Papers, pages 1423–1434, Dublin, Ireland, August 23-29 2014.

et al., 2012). Excitation classifies templates into *excitatory*, *inhibitory*, and *neutral*; an excitatory template like *install X* and *buy X* indicates that the main function, effect, purpose or role of the entity referred to by the *X* of the template is *activated*, *enhanced*, or *prepared*,[1] while an inhibitory template like *uninstall X* and *X is canceled* roughly indicates that it is *deactivated* or *suppressed*. Neutral templates are neither excitatory nor inhibitory (e.g., *consider X*). Roughly speaking, an excitatory template expresses the events that contribute to *turn on* the function of X, while an inhibitory template expresses the events that contribute to *turn off* or *not to turn on* the function of X. Then, in PPTT, excitatory and inhibitory respectively correspond to "ups" and "downs" in the story of *X*. The phases in PPTT are marked according to these ups and downs. Accordingly, PPTT can derive many antonymous contradiction pairs like *install X*⇔*uninstall X*, as Hashimoto et al. did, though we omit the detail for space limitation. Moreover, PPTT can derive a huge volume of *anomalous obstruction*, a contradiction-like novel semantic relation that we propose in this paper, like *X is canceled*⇝*(cannot) buy X* and *X is sold out*⇝*(cannot) buy X*, which indicate that if *X* is canceled or sold out, you cannot buy X. Anomalous obstruction should be used for Why-type QA (Oh et al., 2013), as well as a novel system that warns a user who wants to buy a commercial product that the product is started to be *sold out* or *canceled* in various e-commerce sites without any application-specific coding.

As suggested, a story has a temporal order between its phases, which we call the *canonical temporal order*. In addition, some phases in a story would *enable* or *necessitate* another phase in the same story to occur. In PPTT, these relations are embodied in various temporal-semantic links between phases. Note that each link between two phases does not *guarantee* that every possible pair of templates taken from the two phases has such semantic relations; it just indicates that there exists such *tendencies*. Despite the absence of the guarantee, PPTT's links enable a million-scale derivation of semantic relations with the help of distributional similarity. In existing resources such as WordNet (Fellbaum, 1998), the links are assumed to be 100% correct, but it would be hard to have such absolutely correct links in a million-scale. Hence, we believe that our *approximate* links are more useful for a large-scale relation derivation.

Note that the goal of our PPTT project is to derive a wide range of semantic relations on a large scale, rather than to complete a comprehensive template taxonomy. As such, PPTT lacks some templates as described in later sections. Nevertheless, we believe that our design brings much more good than harm, since we could generate various semantic relations on a million scale thanks to PPTT. Our experimental results show that we can derive 4.4 million happens-before relation instances with 79.5% precision, 0.5 million entailment relation instances with 70.0% precision, and one million anomalous obstruction relation instances with 73.5% precision. Constructing the PPTT taxonomy requires a manual labor cost, which amounted to three man-months in our case; however, we believe that this cost is *lower* than the cost for developing highly-precise automatic acquisition methods for all of happens-before, entailment, contradiction, and anomalous obstruction relations.

We plan to release PPTT and the derived relation instances after the manual annotation of the derived instances to the NLP community.

2 Related Works

PPTT might resemble other semantic lexicons created in the long history of NLP (Levin, 1993; Kipper et al., 2006; Fellbaum, 1998; Bond et al., 2009; Fillmore, 1976; Baker et al., 1998; Halliday, 1985; Pustejovsky et al., 2003; Puscasu and Mititelu, 2008; Bejar et al., 1991; Jurgens et al., 2012). PPTT is different in that it primarily aims at deriving various types of semantic relations on a large scale exploiting the notion of the *phase of story*, rather than being a comprehensive taxonomy like those existing semantic lexicons. As a result, PPTT can derive more varieties of semantic relations between templates than any one of those existing lexicons. From **WordNet** (Fellbaum, 1998; Bond et al., 2009), we can derive entailment and contradiction relations using synsets and synset-links that represent relations such as 'troponym', 'antonym' and 'entailment'. However, happens-before and anomalous obstruction relations

[1]The above definition is slightly different from the original one in Hashimoto et al. (2012). We inserted the verb "prepared" into the original definition. This clarifies that various preparation processes for X, such as *buy X*, can be regarded as excitatory templates. We also assume that such templates as *X exists* and *have X*, which mean little more than just existence, are regarded as excitatory templates in PPTT based on the assumption that *existence* can be regarded as *preparation* for the function of X.

cannot be derived from it, since there is no information on temporal ordering except that on causality. From **VerbNet** (Levin, 1993; Kipper et al., 2006), the hyponymy/synonymy type of entailment relations may be derived using templates in the same verb classes constructed based on shared syntactic behavior, possibly with the help of statistical methods. However, the other types of relations that can be derived from PPTT cannot be derived from VerbNet, since there is no link representing relationships between the verb classes. **FrameNet** (Fillmore, 1976; Baker et al., 1998) was used to derive hyponymy/synonymy types of entailment (Coyne and Rambow, 2009; Aharon et al., 2010) using information such as a Frame-to-frame relation 'Inheritance' (*is-a* relation). In addition, happens-before relations can be derived using 'Precedes' (*Later-Earlier* relations). However, since it does not contain semantic constraints like *enablement* and *necessity* that PPTT contains, it is not trivial to derive presupposition type of entailment or anomalous obstruction instances from it. **TimeML** (Pustejovsky et al., 2003; Puscasu and Mititelu, 2008) contains various temporal information and can be used to derive *context-dependent* happens-before relations such as the relation between "leaves" and "will not hear" in the sentence "If Graham leaves today, he will not hear Sabine" through TLINK (Pustejovsky et al., 2003) annotated manually; thus, it is difficult to derive *context-independent* relations from it, while they can be derived from PPTT. Besides, since it covers only temporal information, it is difficult to derive other types of relations from it. From **Bejar et al.'s semantic relation taxonomy of lexical pairs** (Bejar et al., 1991; Jurgens et al., 2012), using semantic relation categories such as "act: act attribute" (e.g., creep:slow), lexical entailment relations were extracted (Turney and Mohammad, 2014). However, it is not trivial to derive happens-before or anomalous obstruction relations from it since it does not contain information on temporal sequences between verbs.

Furthermore, our work differs from automatic methods for extracting temporal or causal relations (Szpektor et al., 2007; Chambers and Jurafsky, 2008; Chambers and Jurafsky, 2009; Talukdar et al., 2012; Hashimoto et al., 2012; Hashimoto et al., 2014) in that our method does not require that target pairs co-occur in a document, unlike the previous methods. Hence, our method is likely to be immune to data sparseness. We could actually derive a wide range of relation instances that were rarely written in documents because they were too commonsensical (e.g., *X is constructed* happens-before *sew (something) at X*). Needless to say, such commonsensical knowledge is often needed to develop intelligent systems.

3 PPTT Design

In PPTT, templates are organized hierarchically into three levels. In each level, there are classes that correspond to phases of stories, which we call Level-0 (L0), Level-1 (L1), and Level-2 (L2) classes. Each template belongs to only one class at each level. In the following, we describe each level.

3.1 L0-Classes and L0-Links

First we divided the *entire story* concerning an entity *X* into five phases: *non-existence*, *existence*, *functioning*, *non-existence to existence transition* and *existence to non-existence transition*. Then we created the five L0-classes listed below, each of which corresponds to one of these five phases.

Non-existence Class The class of templates that do not entail the existence of X, e.g., *plan X*.[2]

Existence Class The class of templates that entail X's existence but does not imply the execution of its main function or the achievement of its objectives, e.g., *buy X*, *X exists*.

Functioning Class The class of templates that imply the execution of X's main function or the achievement of its objectives, e.g., *use X*, *eat X*.

Non-existence to Existence Transition Class (NET Class) The class of templates that express the transition from a situation in which X does not exist to a situation in which it exists, e.g., *manufacture X*.

[2]One might think the definition of the Non-existence Class should be "the templates that DO entail X's NON-EXISTENCE". We did not use such a definition because it would overlook many templates that are consistent with X's NON-EXISTENCE but DO NOT entail X's NON-EXISTENCE, like *order X*.

Existence to Non-existence Transition Class (ENT Class) The class of templates that express the transition from a situation in which X exists to a situation in which it does not exist, e.g., *dismantle X*.

As mentioned in the introduction, we assume a canonical temporal order among L0-classes. For instance, templates in the **NET class** (e.g., *manufacture X*) should refer to events that usually happen before those events referred to by templates in the **Existence class** (e.g., *buy X*), **Functioning class** (e.g., *use X*) and **ENT class** (e.g., *dismantle X*). We enumerated such temporal restrictions, each of which is represented by a link in Figure 1, which we call *L0-links* and used them for deriving relations. Note that we did not set any L0-link between the **Existence class** and the **Functioning class** because the events described by them may happen in various orders or have temporal overlap. For example, *X exists* should have temporal overlap with *use X*.

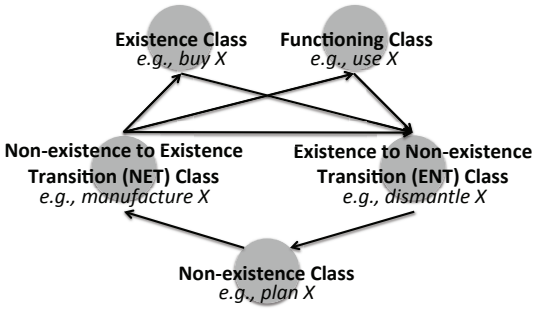

Figure 1: L0-links among L0-classes.

Of course, such *metaphysical* notions as the canonical temporal order and the phases must have many complications and exceptions. First, many templates that have the neutral excitation polarity (Hashimoto et al., 2012) did not seem to follow the canonical temporal order among L0-classes. For instance, since the neutral template *think about X* does not entail the existence of *X*, it belongs to the **Non-existence** class but one can consider *X* while *X* exists or while it is functioning or even after it is collapsed and violate canonical temporal ordering. For this reason, we excluded neutral templates from PPTT and will deal with them in a different framework as a future work. In addition, although we did not assume a temporal order between the **Existence class** and the **Functioning class**, some templates in these classes have a happens-before relation as special cases (e.g., *buy X* in the **Existence class** happens before *eat X* in the **Functioning class**). The proposed L0-links also cause problems. For instance, *order X* (**Non-Existence class**) may not always happen before *create X* (**NET class**) even though the L0-links indicate a happens-before relation between their classes. We dealt as far as possible with such cases in level 2 with L2-classes, which are finer than L0-classes. Nonetheless, we stress that the overall plausibility of the canonical temporal order among L0-classes was experimentally confirmed through the derivation of happens-before relations only using L0-links. Note that the design of the L0-classes was inspired by the Generative Lexicon (Pustejovsky, 1998) and Aristotle's *Entelecheia* (Aristotle, 1987).

3.2 L1-Classes

Next, we divided some L0-classes into L1-classes using the excitation polarity (Hashimoto et al., 2012) to introduce "ups and downs" to PPTT, which enables to capture semantic inconsistencies between templates (e.g., *install X⇔uninstall X*) and negative interaction between the events referred to by the templates in PPTT (e.g., *X is canceled⇝(cannot) hold X*). Excitation was originally proposed for recognizing contradictions and causal relations between templates and then was successfully applied to other deep semantic processing (Oh et al., 2013; Varga et al., 2013; Kloetzer et al., 2013; Hashimoto et al., 2014).

L0-class	Excitation	
	Excitatory	**Inhibitory**
Non-existence class	POTENTIAL class e.g., *plan X*	FORECLOSING class e.g., *prevent X*
Existence class	ENABLING class e.g., *buy X*	INCOMMODE class e.g., *weaken X*
Functioning class	ACTUALIZING class e.g., *X functions*	DISORDERING class e.g., *X loses*
NET class	GENERATING class e.g., *X is born*	N/A
ENT class	N/A	CORRUPTING class e.g., *destroy X*

Table 1: L1-classes.

As shown in Table 1, we divided each of three L0-classes (**Non-existence class**, **Existence class** and **Functioning class**) into two L1-classes, each of which corresponds to excitatory and inhibitory. Since the transition to an existence situation can be interpreted as an enhancement of an entity's function, we assumed that all the templates in the NET classes are excitatory because they express a transition of entity *X* from a non-existence situation to an existence situation. Similarly, we assume all the templates from the ENT class are inhibitory. Also, L1-classes do not have specific links between them beside the L0-links from their parent classes.

3.3 L2-Classes and L2-Links

Finally, we divided L1-classes into 41 L2-classes. Specifically, we first roughly grouped together semantically similar templates from the same L1-class and identified the common semantic properties among them. Note that in the rough grouping, we classified templates so that the resulting groups fit into fine-grained phases in the story concerning *X*.

After this initial grouping, we classified all the templates into the L2-classes that are listed in Table 3 alongside the classification criteria and the number of templates in each class. As the classification criteria, we used the identified common semantic properties among members of each class. Note that some L2-classes can be regarded as a subset of another L2-class. For instance, the PROHIBIT L2-class can be seen as a subset of the PREVENTION L2-class. When a template meets the classification criteria of both a subset class and its superset class, we classified it into the subset class.

We also made links called L2-links between the L2-classes. The motivation behind this is to capture finer temporal-semantic constraints that could not be specified at Level-0 and Level-1 as well as to capture the temporal-semantic constraints inside a single L0 or L1-class. For example, the temporal order between *buy X* and *eat X* is encoded in a L2-link between the ACQUISITION and EXECUTION L2-classes, while there is no L0-link between the Existence L0-class (class of *buy X*) and the Functioning L0-class (class of *eat X*). This exemplifies that the L2- and L0-links complement each other.

Each L2-link has one of the six types of temporal-semantic links that are summarized in Table 2 with the number of links of each type. The link types were designed to capture how the events referred to by the templates in a class *affect* the *occurrence or non-occurrence* of the events referred to by the templates in a class in the *past*, *present*, or *future*. C_1 and C_2 being two L2-classes, C_1's effect on the occurrence or non-occurrence of C_2 is represented by Positive ($^+$) and Negative ($^-$) links, respectively, while C_1's effect on the past, present, or future phase of *X* expressed by C_2 is represented by Past, Present, and Future links, respectively. For instance, the Past$^+$ link from the ABANDONMENT class to the ACQUISITION class indicates that a template from the ACQUISITION class (e.g., *obtain X*) *must occur* before a template from the ABANDONMENT class (e.g., *get rid of X*), and the Future$^-$ link from the PROHIBIT class to the EXECUTION class indicates that templates from the PROHIBIT class (e.g., *ban X*) *disable* templates from the EXECUTION class (e.g., *utilize X*). Notice that L2-links represent such semantic constraints as *enablement* and *necessity* in addition to temporal order, and they are useful for deriving various kinds of semantic relations including entailment and anomalous obstruction, as shown in a later section. The first author of this paper hand-labeled the links between every combination of L2-class pairs by considering the name of the classes and a few example templates in each.

	Positive	**Negative**
Past	If C_1 occurred, C_2 must have occurred. e.g.,FORGETTING $\overset{Past^+}{\rightarrow}$ RECOGNITION; *X is forgotten* $\overset{Past^+}{\rightarrow}$ *X is recognized* (55 links)	If C_1 occurred, C_2 COULD NOT have occurred. e.g.,CREATION $\overset{Past^-}{\rightarrow}$ PREVENTION; *X is generated* $\overset{Past^-}{\rightarrow}$ *X is prevented* (438 links)
Present	While C_1 is taking place, C_2 must be taking place. e.g.,INITIATION $\overset{Present^+}{\rightarrow}$ BEING; *X is started* $\overset{Present^+}{\rightarrow}$ *X exists* (73 links)	While C_1 is taking place, C_2 CANNOT take place. e.g.,ENHANCEMENT $\overset{Present^-}{\rightarrow}$ DEGRADATION; *X is enhanced* $\overset{Present^-}{\rightarrow}$ *X is deteriorated* (496 links)
Future	C_1 enables C_2 to occur. e.g.,PREPARATION $\overset{Future^+}{\rightarrow}$ EXECUTION; *X is customized* $\overset{Future^+}{\rightarrow}$ *X is executed* (90 links)	C_1 DISABLEs C_2 to occur. e.g., DEFICIENCY $\overset{Future^-}{\rightarrow}$ PROVISION; *X does not exist* $\overset{Future^-}{\rightarrow}$ *X is provided* (210 links)

Table 2: Types and numbers of L2-links in PPTT. Link direction is $C_1 \rightarrow C_2$.

Non-existence L0-class: **Potential L1-class (578) / Foreclosing L1-class (178)**	
DESIRE	entails that *X* is desired but unlike PLANNING or DEMAND, it does not entail that *X* is planned or requested, e.g., *desire X, want X* (48).
PLANNING	entails that *X* is planned but does not entail that *X* is requested. Unlike DEMAND, it does not assume that a person other than the Planner will carry out X, e.g., *plan X, conspire X* (72).
DEMAND	entails that *X* is requested. Unlike PLANNING, it assumes that a person other than the Demander will carry out X, e.g., *order X* (252).
APPROVAL	entails that *X* is approved or permitted and that there was a plan or a demand before approving, e.g., *permit X, accept X* (80).
FEAR	entails that *X* is expected and that *X* is a source of anxiety or fear, e.g., *fear X, worry about X* (13).
ANTICIPATION	entails that *X* is expected but unlike FEAR, does not entail that *X* is a source of anxiety or fear, e.g., *forecast X, predict X* (24).
SEARCH	entails that *X* is searched for but unlike DESIRE or DEMAND, does not entail that X is desired or requested, e.g., *search for X* (89).
PREVENTION	entails that *X* is prevented. Unlike CANCELATION, it does not entail that there was a plan or a demand before preventing, e.g., *preclude X* (54).
CANCELATION	entails that *X* is canceled and that there was a plan or demand before canceling, e.g., *cancel X, give up X* (34).
PROHIBIT	entails that *X* is prohibited. X's right or ability to be generated or used is taken away. e.g., *ban X, forbid X* (39).
POSTPONE	entails that *X* is postponed, e.g., *postpone X, defer X* (15).
DEFICIENCY	entails that *X* does not exist but does not entail that it is prevented, canceled, prohibited, or postponed, as in other L2-classes of Foreclosing L1-class. e.g., *lack X, X is absent* (36).
NET L0-class: **Generating L1-class (596)**	
SYMBOLIZATION	entails that *X* transits from non-existence to existence as a kind of (semiotic) representation, e.g., *write X, compose (music) X* (13).
CREATION	entails that *X* transits from non-existence to existence. Unlike SYMBOLIZATION, *X* is not limited to a semiotic representation, and unlike TRANSFORMATION, it focuses less on transformation from another entity. *generate X, cause X* (509).
TRANSFORMATION	entails that *X* transits from non-existence to existence as a result of transformation. Unlike CREATION, it focuses on the transformation from another entity, e.g., *turn into X* (74).
ENT L0-class: **Corrupting L1-class (622)**	
COLLAPSE	entails that *X* transits from existence to non-existence by dying, being eliminated, or being destroyed. Unlike CONVERSION , it focuses less on transformation, e.g., *destroy X, kill X* (588).
CONVERSION	entails that *X* transits from existence to non-existence by transforming *X* into an another entity, e.g., *turned from X, changed from X* (34).
Existence L0-class: **Enabling L1-class (3,536) / Incommode L1-class (1,355)**	
RECOGNITION	entails that *X* is recognized or sensed, e.g., *find X, feel X* (308).
SELECTION	entails that *X* is selected, e.g., *appoint X, choose X* (139).
ENCOUNTER	entails that *X* emerges as a result of transportation, e.g., *send X, X arrives* (407).
ACQUISITION	entails that *X* is obtained and possessed, e.g., *buy X, catch X* (482).
PROVISION	entails that *X* is handed to be possessed, e.g., *sell X, render X* (422).
ENHANCEMENT	entails that *X* is extended, improved, or supported, e.g., *increase X, help X* (880).
PREPARATION	entails that *X* is arranged, connected, or qualified in preparation to execute its function, e.g., *cook X, install X* (822).
BEING	entails that *X* is existing or living but does not entail that *X* is recognized, selected, encountered, acquired, enhanced, or prepared, as in other L2-classes of the Enabling L1-class, e.g., *X exists, X lives* (76).
UNRECOGNIZING	entails that *X* is not recognized or sensed but unlike FORGETTING, does not entail that *X* was previously recognized, e.g., *overlook X* (8).
FORGETTING	entails that *X* is forgotten and that *X* was once recognized, e.g., *forget X, lose memory of X* (8).
UNSELECTING	entails that *X* is not selected, e.g., *alternate X, reject X* (46).
SEPARATION	entails that *X* is left or separated as a result of transportation, e.g., *X leaves, send X away* (114).
ABANDONMENT	entails that *X* is not possessed as a result of being thrown away, e.g., *throw X away, renounce X* (58).
DEPRIVATION	entails that *X* was taken away without the permission of a possessor, e.g., *steal X, take X away* (102).
DEGRADATION	entails that *X* is reduced, deteriorated, or interrupted, e.g., *X is weakened, attack X* (908).
UNPREPARED	entails that *X* is unprepared, disconnected, or unqualified, e.g., *X is uninstalled, X is disconnected* (111).
Functioning L0-class: **Actualizing L1-class (4,460) / Disordering L1-class (698)**	
EXECUTION	entails that the function of *X* is executed but unlike WORKING, does not entail that *X* successfully satisfies its function, e.g., *ignite X* (966).
WORKING	entails that the function of *X* is carried out and that *X* successfully satisfies its function, e.g., *X functions, cleaned by X* (3,106).
INITIATION	entails that *X* is started or continued, e.g., *start X, open X* (185).
SUCCESS	entails that *X* accomplished its goal and the result of the execution of its function is evaluated positively, e.g., *accomplish X, X wins* (203).
SUSPENSION	entails that the function of *X* is suspended but unlike FINISHING, does not entail that its function is terminated, e.g., *suspend X* (133).
DYSFUNCTION	entails that the function of *X* is executed but *X* is performing poorly, e.g., *X is sluggish, bored by X* (196).
FINISHING	entails that *X* is terminated, e.g., *end X, finish X*. (110).
FAILURE	entails that *X* fails to accomplish its goal and the result of the execution of its function is evaluated negatively, e.g., *X is defeated* (259).

Table 3: PPTT classes. The number in parentheses indicates the number of templates in PPTT.

Note that the existence of an L2-link does not guarantee that the semantic properties specified by it hold for all the possible template pairs taken from the class pair it connects. The cost of hand-labelling the links with such guarantees is prohibitively high because we would have to check all of the template combinations. We empirically evaluated the validity of the links in our experiments below although this is not a *direct* evaluation since the relations we derived are different from the ones given to the links.

4 Construction of PPTT and Relation Derivation

Using the automatic acquisition method proposed by Hashimoto et al. (2012), we collected 10,825 candidates of excitatory/inhibitory templates from a 600-million-page web corpus (hereafter, $WCorpus$). Hashimoto et al.'s method constructs a network of templates based on their co-occurrence in sentences with a small number of seed templates of which excitation polarity are assigned manually, and infers the polarity of all the templates in the network by a constraint solver based on the spin model (Takamura et al., 2005). Then, we added the 20,000 most frequent templates in the corpus that could not be extracted automatically for a total of 30,825 templates.

Three human annotators (not the authors) judged the polarity of the templates, and we included the excitatory and the inhibitory templates but excluded the neutral templates in PPTT due to the reason discussed in Section 3.1. We also excluded templates whose variable *X* is the subject of a transitive verb. This is because the subject position is often occupied by living things, and since the *functions/objectives* of such subjects seem difficult to identify, it is often difficult to judge whether such templates should be classified into the **Functioning** class or another. After applying these two restrictions, the first author classified the remaining 12,023 templates in PPTT.

In this work, we derived happens-before, entailment and anomalous obstruction relations among templates from PPTT. The target data is the set of all the template pairs such that a noun exists with which both templates of the pair co-occur at least 100 times in $WCorpus$. We denote this set of the template pairs by $TP100$, and all the relation derivations pick up template pairs as relation instances from it. This is because in our preliminary experiments, we found that the relation instance candidates taken from outside of $TP100$ had much lower precision. The relation derivation itself is quite simple and consists of the following two steps.

Step 1 Select L0-links or types of L2-links that are expected to represent a target semantic relation (e.g., *Present*$^+$ links are expected to represent entailment, since they represent the relations between classes where "While C_1 is taking place, C_2 must be taking place".) and extract all the class pairs connected by the selected links (e.g., INITIATION L2-class $\overset{Present^+}{\rightarrow}$ BEING L2-class). Enumerate all the template pairs from the intersection between $TP100$ and the extracted class pairs (e.g., *X is started* $\overset{Present^+}{\rightarrow}$ *X exists*).

Step 2 If necessary, rank the relation instance candidates that are extracted in Step1 by distributional similarity scores between the templates that compose the candidates, computed with $WCorpus$.

5 Experiments

This section reports our experiments on semantic relation derivation. Derived relation instances were marked by three human annotators (not the authors) who voted to break ties. Unless stated otherwise, we asked them to mark a template pair as negative if they found any noun that can be placed in both templates' argument slots and makes the template pair a negative sample for the target relation, and positive otherwise.

5.1 Happens-Before Relation

Following Regneri et al. (2010), we assumed template$_1$ (T_1) has a *happens-before relation* with template$_2$ (T_2) iff one event expressed by T_1 normally happens before another expressed by T_2, provided that both events occur. Below are our four methods to derive happens-before relation instances, each of which uses different links. Note that we did not use distributional similarity in this experiment.

H1 uses the 55 pairs of L2-classes connected by L2-link Past$^+$, meaning that a template in a class *must occur before* another.

H2 uses the 90 pairs of L2-classes connected by L2-link Future$^+$, i.e., a template in a class often *enables* another to occur.

H3 uses the 474 pairs of L2-classes connected by one of the seven L0-links in Figure 1, i.e., the canonical temporal order links.

All is the union of **H1**-**H3** results.

We prepared two baselines; **HB-Ptn** is a pattern-based method based on Chklovski and Pantel (2004a). It extracts template pairs in $TP100$ that were connected in $WCorpus$ by one of manually collected 73 conjunctives expressing temporal order, such as *after* and *before*, and which either shared the same argument or the second template was filled by the pronouns *it, this, or that*. **Random** is a random sampling from $TP100$.

Three annotators annotated 200 random samples from each method's output. Fleiss' kappa was .56 (moderate agreement). The results of their majority vote are summarized in Table 4. The recall was estimated against the number of positive samples in $TP100$ based on the precision of **Random**. The precision of all of our four methods is reasonably high for such a difficult task, and the number of relations derived by **All** reached about 4.4 million. The recall of **All** exceeds 65%, which we believe is quite high. **HB-Ptn** suffered from low recall, probably due to the data sparseness in $WCorpus$. Table 5 shows examples of the derived happens-before relations alongside L2-classes of the templates, the L2-links between the classes and the original Japanese templates. The acquired relations included many unexpected but correct happens-before relations, like *compose (a piece of music) X⊃relax by X*.

Actually, it is difficult to fairly compare our work and previous works on temporal relation acquisition, due to differences in language, the data used, and the methodologies. Nonetheless, our result with 79.5% precision is at least five times larger than the English data released by Chambers et al. (`cs.stanford.edu/people/nc/schemas`), which contains around 870,000 "before" relation candidates and happens-before database in the VerbOcean (Chklovski and Pantel, 2004a) that covers 4,205 relations. Considering our method is completely different from theirs, we believe that our contribution is valuable.

Setting/Method	Precision (%)	# of Pairs	Recall (%)
H1	**83.5**	1,113,280	18.0
H2	70.5	1,524,557	20.8
H3	67.0	3,837,116	49.7
All	79.5	4,387,781	**67.5**
HB-Ptn	53.0	32,288	0.3
Random	18.0	28,717,454	100.0

X `wo niru` ⇒ X `wo taberu`

compose (a piece of music) X⇒relax by X

SYMBOLIZATION Class $\overset{Past^+}{\leftarrow}$ WORKING Class

X `wo sakkyoku-suru` ⇒ X `de rirakkusu-suru`

Table 5: Examples of happens-before relation.

5.2 Entailment Relation

Below are our proposed methods to derive entailment relations.

Present+.DIFF extracts the 32 class pairs that are composed of *DIFFERENT* L2-classes and are connected by the *Present*$^+$ links, meaning that a template in a class *must occur simultaneously with* another template in another class, and ranks all the possible template pairs taken from each class pair using Hashimoto et al.'s (2009) conditional probability based similarity measure for entailment recognition.

Present+.SAME extracts the 41 class pairs that are composed of the *SAME* L2-classes and are connected with the *Present*$^+$ links, and ranks all the template pairs from each class pair using Hashimoto et al.'s similarity.

Past+ extracts the 55 pairs of L2-classes that are connected with the *Past*$^+$ links, meaning that a template in a class *must occur before* another, and ranks all the template pairs from each class pair using Hashimoto et al.'s similarity.

Baseline-HAS is our baseline which is our implementation of Hashimoto et al. (2009) for entailment recognition; it ranks all the template pairs in $TP100$ by Hashimoto et al.'s score. Our methods can be seen as the restrictions of the output of the baseline method using the extracted PPTT's class pairs.

Three annotators hand-labeled 500 random samples from the top 100,000 template pairs for each method. The kappa was .59 (moderate agreement), and the results of their majority vote are presented in Figure 2. Table 6 shows examples of Proposed methods' outputs. The restriction of the class pairs in our method contributed to much higher precision than using the state-of-the-art method alone.

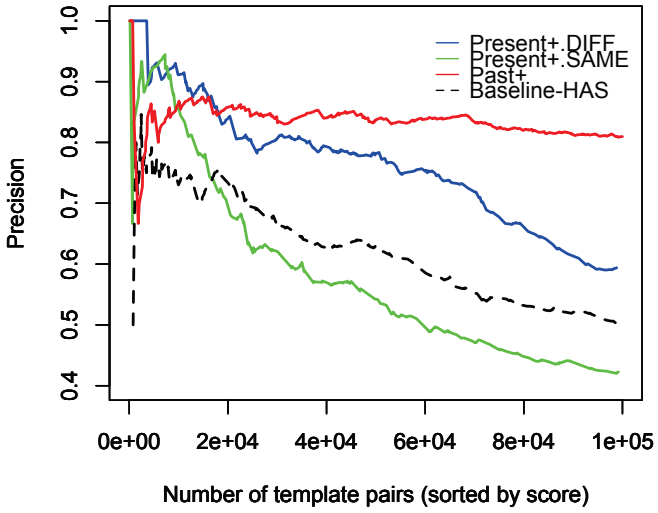

Figure 2: Entailment derivation performance.

Since the precision of **Past+** is quite high for the top 100,000 pairs, we annotated an additional 500 random samples from the top 500,000 pairs. According to this annotation, the top 408,610 pairs had 70% precision, implying that after merging all the top pairs extracted by **Present+.DIFF**, **Present+.SAME** and **Past+** whose precisions exceeded 70%, we had 0.49 million entailment pairs with 70% precision. With **Baseline-HAS**, we derived only 24,000 with the same precision. Also, the Japanese WordNet (v.1.1) covers only 2.4% of the pairs in the manually annotated positive samples from our proposed methods through the 'synsets' or any 'synlinks'. We analyzed 200 samples from the positive samples not covered by WordNet and found that 49.5% are the hyponymy type (e.g., *boil X⊃heat X*), 39.0% are the backward presupposition type (e.g., *complete X⊃start X*), and 11.5% are the synonymy type (e.g., *X passes away⊃X dies*). This seems to imply that our methods are better at deriving all types of entailment, while WordNet might be effective for only the synonymy type. In addition, by analyzing all the positive samples, we confirmed that the different types of entailment pairs were derived with different L2-links; 88.1% of the positive samples from *Present+.DIFF* and *Present+.SAME* require that two events referred to by the two templates occur with temporal overlap (e.g., *equip X⊃X exists*, i.e. *X* is equipped while *X* exists), while 96.7% of those from *Past+* were the backward presupposition type, in which an event entails another event that happened before it. This shows that the L2-links were useful for deriving various fine-grained types of entailment.

get X⊃X exists (X `wo nyuushu-suru` ⊃ X `ga sonzai-suru`) ACQUISITION Class $\overset{Present^+}{\rightarrow}$ BEING Class
evolve into X⊃change into X (X `ni shinka-suru` ⊃ X `ni kawaru`) TRANSFORMATION Class $\overset{Present^+}{\rightarrow}$ TRANSFORMATION Class
close (a shop) X⊃make X (X `wo heiten-suru` ⊃ X `wo tsukuru`) FINISHING Class $\overset{Past^+}{\rightarrow}$ CREATION Class

Table 6: Examples of entailment.

5.3 Anomalous Obstruction Relation

We assumed that template$_1$ (T_1) like *X is sold out* has an *anomalous obstruction relation* with template$_2$ (T_2) like *buy X* (denoted as *X is sold out*$\rightsquigarrow$*(cannot) buy X*) iff: (A) the event expressed by T_1 prevents the event expressed by T_2 from occurring; (B) T_1 expresses an event that should not happen if everything about the variable *X* goes as expected; and (C) T_2 expresses another event in which the function of *X* is executed, enhanced, or prepared. We derived anomalous obstructions, by generating all of the possible template pairs from the 88 L2-class pairs connected by Future$^-$ L2-links. These indicate that the events expressed by the templates in the first class of a pair *disable* the events expressed by the templates in the second class. Also, to confirm that the templates of the first class in a pair express an unexpected event,

we required the *disabler* class to have the inhibitory polarity and the *disabled* class to be excitatory. Otherwise, we would obtain such pairs as INITIATION⇝PLANNING (e.g., *start X⇝schedule X*), which indeed express the *prevention* relation (Barker and Szpakowicz, 1995), i.e., "*scheduling X* would not occur after *starting X*," which is different from anomalous obstruction.

Three annotators annotated 200 random samples for each method, and the results of their majority vote are summarized in Table 7, where **Random** refers to a random baseline using $TP100$. The recall was estimated using the number of positive samples provided by **Random**. The kappa was .60 (moderate agreement). 73.5% precision, 26.4% recall against the positive samples in $TP100$, and more than one million outputs of our proposed method are reasonably high/large results for this difficult task. Table 8 shows examples of **Proposed**'s outputs. "(cannot)" was attached to *disabled* templates for readability.

Setting/Method	Precision	# of Pairs	Recall
Proposed	**73.5**	1,081,405	26.4
Random	10.5	28,717,454	100.0

Table 7: Performance of anomalous obstruction derivation.

prohibit X⇝(cannot) exhibit X PROHIBIT Class $\overset{Future^-}{\rightarrow}$ EXECUTION Class
X `wo kinshi-suru⇝X wo kookai-suru`
break X⇝(cannot) utilize X COLLAPSE CLASS $\overset{Future^-}{\rightarrow}$ EXECUTION CLASS
X `wo kowasu⇝X wo riyo-suru`

Table 8: Examples of anomalous obstruction.

6 Conclusion

In this work, we manually constructed a Phased Predicate Template Taxonomy (PPTT), which is a network of semantically coherent classes of templates and derived semantic relations including entailment from it in a million-instance scale. Future work will extend PPTT to cover non-excitatory/non-inhibitory templates and generate richer structural knowledge similar to *full-fledged* scripts (Schank and Abelson, 1977) and narrative schemas (Chambers and Jurafsky, 2011).

Acknowledgements

We would like to thank three anonymous reviewers for many useful comments and advices on the manuscript of this paper.

Combining Supervised and Unsupervised Parsing for Distributional Similarity

Abstract

In this paper, we address the role of syntactic parsing for distributional similarity. On the one hand, we are exploring distributional similarities as an extrinsic test bed for unsupervised parsers. On the other hand, we explore whether single unsupervised parsers, or their combination, can contribute to better distributional similarities, or even replace supervised parsing as a preprocessing step for word similarity. We evaluate distributional thesauri against manually created taxonomies both for English and German for five unsupervised parsers. While for English, a supervised parser is the best single parser in this evaluation, we find an unsupervised parser to work best for German. For both languages, we show significant improvements in word similarity when combining features from supervised and unsupervised parsers. To our knowledge, this is the first work where unsupervised parsers are systematically evaluated extrinsically in a semantic task, and the first work to show that unsupervised parsing can complement and even replace supervised parsing, when used as a pre-processing feature.

1 Introduction

While the field has seen increased interest in automatically inducing syntactic structures from raw or part-of-speech (POS) tagged text, the evaluation of unsupervised data-driven parsers has almost exclusively been conducted either by introspection or by automatic comparison to treebanks. It might be due to comparatively low scores on reproducing a treebank's syntactic annotation that hardly anyone has yet attempted to use the output of unsupervised parsers for an NLP task other than parsing itself.

A further complication with unsupervised parsers – be it dependency parsers, constituency parsers or combinatory categorial grammar parsers – is that the categories induced by such parsers cannot be straightforwardly mapped to linguistically-inspired categories as defined in a treebank. But also when considering only unlabeled syntactic annotations, an unsupervised parser is hardly to blame if it does not adhere to sometimes arbitrary conventions: e.g. for dependencies, it is not a priori clear how to connect auxiliary and main verbs, where to attach the complementizer of subordinate clauses, how to represent a conjunction and its conjuncts, how to relate the preposition and the nominal in prepositional phrases, and how to handle punctuation, cf. Nivre and Kübler (2006), Schwartz et al. (2011).

When it comes to *utilizing* syntactic structures, however, it is more important that they are consistent across different sentences than that they adhere to specific syntactic theories and conventions. Here, we choose a task that makes only intermediary use of syntactic structures: we employ unsupervised parsing for preprocessing corpora for the purpose of computing distributional similarities. Since it is generally accepted (e.g. (Lin, 1997; Curran and Moens, 2002)), that syntactic preprocessing plays an important role for the quality of distributional thesauri, and comparing words along their syntactic contexts does rely on the existence of such a structure rather than its actual representation, we believe that distributional similarities are an excellent test bed for addressing the following two research questions: (1) How do unsupervised parsers compare to supervised parsers when used as feature providers for building Dis-

Proceedings of COLING 2014, the 25th International Conference on Computational Linguistics: Technical Papers, pages 1435–1446, Dublin, Ireland, August 23-29 2014.

tributional Thesauri (DTs) in comparison to supervised parsers? (2) Can the combination of syntactic parsers increase DT quality?

2 Related Work

2.1 Unsupervised Parser Evaluation

As with other unsupervised approaches, the premise of unsupervised induction of syntactic structure is to alleviate the bottleneck of expensive manual annotations for improving NLP applications. For grammar induction, the potential is extremely high due to the complexity of the subject matter: treebanks belong to the most work-intensive NLP datasets. On the other hand, this complexity is hard to grasp for unsupervised systems, which is probably the reason why unsupervised parsing technology is still in its infancy, despite more than a decade of work on this topic.

One of the early works inducing structure from raw sentences and yielding better performance than a random baseline was achieved by van Zaanen and of Leeds. School of Computer Studies (2001), who used an Alignment Based Learning (ABL) approach. This algorithm compares all sentences of a given set and considers matching sequences as constituents. Klein and Manning (2002) presented another approach focusing on constituent sequences called the Constituent-Context Model (CCM). It is an EM-based iterative approach that makes use of the linguistic phenomenon that long constituents often have shorter representations of the same grammatical function that occur in similar contexts. A hybrid approach combining CCM with a dependency model, called Dependency Model with Valence (DMV), shows even better performance and is the first unsupervised system to outperform the right-branching baseline (Klein and Manning, 2004). A great number of recent works are based on DMV, such as the system by Headden III et al. (2009), who improved DMV by adding lexical information, and Gillenwater et al. (2010) who added posterior regularization during the training process. Bod (2007) takes a slightly different direction by following an "all subtrees approach", where all possible binary trees are generated for each sentence. It generates all possible binary trees for each sentence. The parse of a new sentence is determined by selecting the most probable tree based on the previously accumulated subtree frequencies. Most of the evaluation of these parsers was performed against a treebank, offering manually annotated and linguistically motivated parse trees. Schwartz et al. (2011) underline the fact that treebanks contain linguistically problematic annotations, cases without linguistic consensus, such as the decision on the head of a verb phrase or a sequence of nouns. They show that the neglectance of these cases has a significant but unjustified negative influence on the evaluation outcomes and propose a new measure, Neutral Edge Direction (NED), which alleviates this problem. Bod (2007) argues that parser evaluation against a treebank favors supervised approaches and therefore measures the parser quality on the outcome of a syntax based Machine Translation (MT) task where the dependency parsers are evaluated as language models. In Motazedi et al. (2012), a single unsupervised parser is evaluated in an extrinsic evaluation for realisation ranking, and does not compare favorably against a supervised parser. Other extrinsic evaluations with supervised dependency parsers have been performed in information extraction systems (Miyao et al., 2008; Buyko and Hahn, 2010) or semantic role labeling (Johansson and Nugues, 2008).

2.2 Evaluating Distributional Similarity

Distributional thesauri have been evaluated both extrinsically and intrinsically. Extrinsic evaluations have been performed e.g. for automatic set expansion (Pantel et al., 2009) or phrase polarity identification (Goyal and Daumé, 2011). In this work, we will conduct an intrinsic evaluation, which is more common for the evaluation of DTs and lexical semantic similarity. Lin (1997; 1998) introduced two measures using WordNet (Miller, 1995) and Roget's Thesaurus. Using WordNet, he defines context (synsets a word occurs in Wordnet or subsets when using Roget's Thesaurus) and then builds a gold standard thesaurus using a similarity measure on these contexts. Then he evaluates his automatically computed Distributional Thesaurus (DT) with respect to the gold standard thesauri. Weeds et al. (2004) evaluate various similarity measures based on 1000 frequent and 1000 infrequent target terms. Curran (2004) created a gold standard thesaurus by manually extracting entries from several English thesauri for 70 words. His automatically generated DTs are evaluated against this gold standard thesaurus. All these

systems employ context representations based on syntactic parsing for computing word similarity.

We are going to use a comparatively simple WordNet-based measure, which calculates the similarity between two terms using the WordNet::Similarity path measure (Pedersen et al., 2004), and averages path scores between a target term and its n most similar terms. The score between two terms is inversely proportional to the shortest path between all the synsets of both terms. If two terms share a synset, the highest possible score of one is assigned. The score is 0.5 for terms that stand in a direct hypernym relation, and so on. While the absolute scores are hard to interpret due to inhomogeneity in the granularity of WordNet, they are well-suited for relative comparison when operating on the same set of target terms. The evaluation in this work is performed by comparing the average score of the top ten entries in the DT for each of the target terms and report separately on frequent and rare words. Riedl and Biemann (2013) also show that the results, using the WordNet based approach, are highly correlated to the results observed with Curran's approach using a manually created thesaurus. This justifies the usage of manually created taxonomies for this evaluation.

3 Methodology

3.1 Parsers

In our evaluation, we use five unsupervised parsers, which we will describe briefly. They have been selected to span several paradigms of unsupervised syntax induction, and due to software availability.

Gillenwater et al. (2010)[1] use a model based on the DMV (Klein and Manning, 2004) and improve performance by adding sparsity biases on dependency types. They assume a corpus annotated with POS tags. The aim of this bias is to limit unique head-dependent tag pairs, which is achieved by a constraint on model posteriors during the learning process.

The work of Marecek and Straka (2013)[2] is another enhancement of the DMV and is subsequently referred to as Unsupervised Dependency Parser (UDP). It additionally uses prior knowledge in the form of stop estimates that are computed on a large raw corpus using the reducibility principle: a sequence of words is considered as reducible if a word can be removed from the phrase and the remaining part appears another time in the corpus. The assumed property, that the first word of a reducible sequence does not have any left children and the last word of this sequence does not have any right children, is used for the calculation of such stop estimates. The authors show that estimates computed on a large corpus such as Wikipedia can be used for the parsing of new text.

Bisk and Hockenmaier (2013) use an EM approach to induce a Combinatory Categorial Grammar (CCG), based on very general linguistic assumptions. It creates a model that can be used to parse unseen data. The algorithm requires a corpus, previously assigned with POS tags, in order to be able to distinguish between word classes (mainly to find the verb), and employs general knowledge such as that sentences are headed by verbs. Further language-specific properties are induced from the training data.

Seginer (2007)[3] takes an incremental parsing and learning approach. It operates directly on the plain text without the need for POS tags, by using Common Cover Links (CCL), which can be directly converted to dependency arcs. This parser learns during parsing and can be used without a prior learning step. This should result in increased parsing quality towards later stages, which suggests several passes over the training data. The obtained model can then be reused to parse unseen data.

The approach of Søgaard (2012) is different from all other approaches discussed here: This algorithm does not require any training data and can operate with or without POS tags. For this reason, it can be applied to arbitrary amounts of data, since it operates sentence-wise without memorizing previous inputs, and produces non-projective dependency parses. The words of a phrase are ordered by centrality and a parse is determined by the ranking of a parsing algorithm, which uses general linguistic knowledge for grammar induction. This knowledge is inspired by the rules of Naseem et al. (2010), and the approach has been tuned (once and for all, for all languages) on development data from the Penn Treebank.

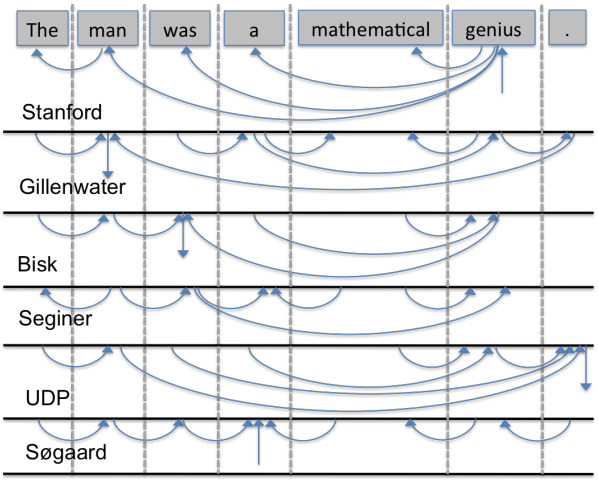

Figure 1: Parses for an example sentence for several parsers. Here, Bisk's parser looks most similar to the parses extracted from the Stanford parser. Gillenwater and UDP seem to have some problems with the full stop. Søgaards parser mostly connects neighbors.

	Baseline	Søgaard	Gillenwater	UDP	Bisk	Seginer	Seginer
English	53.2	59.9	64.4	55.4	70.3	55.6 (WSJ 40)	74.2 (WSJ 10)
German	33.7	57.6	35.7	52.4	68.4	38.2 (Negra 40)	48.0 (Negra 10)

Table 1: Unlabeled accuracy values of different unsupervised parsers based on the CoNLL-X shared task (Buchholz and Marsi, 2006). Seginers results show F-measure values for the Negra and the WSJ corpus, used with maximum sentence of lengths of 10 and 40.

An example sentence and the according parses coming from the 10M model, except for UDP, where the 1M model is used (cf. Table 2 in Section 4.3.1), are shown in Figure 1.

Table 1 reports the accuracy of four parsers for the English and the German treebanks from the CoNLL-X shared task (Buchholz and Marsi, 2006) predicting unlabeled dependency parses for sentences with length equal and smaller than 10 tokens. Seginer reports only F-scores for WSJ and Negra considering sentences with a maximum length of 10 and 40. The best baselines reported in Canisius et al. (2006) are a left branching method for English and a nearest neighbor branching method for German, which is a combination of left and right branching.

3.2 Computing Distributional Thesauri

The extraction of context features, used to calculate similarities between terms, is performed in accordance with the generic scheme proposed in (Biemann and Riedl, 2013): A (typed or untyped) parser arc is split into term and context feature, which consists of the edge direction and label (if any), and the connected term. Similarity between terms is subsequently computed on the overlap of their most salient context features. We represent the term t and the context feature c as a pair $< t, c >$ and extract a dependency triple (or dependency pair, as most unsupervised dependency parsers do not label the edges). For the dependency between *I* and *gave* `(nsub;gave;I)` in *I gave her the book*, terms and context features would look like `<gave,(nsub,I,@)>` and `<I,(nsub,@,gave)>`. In this example, the term *gave* is characterized by the context information that *I* is its nominal subject, and term *I* is characterized by being the subject of *gave*. We build distributional thesauri using the JoBimText[4] open-source framework. This framework scales to large data and has proven to outperform other methods, when using large data (Riedl and Biemann, 2013). The computation of the distributional thesaurus within this framework is following the MapReduce paradigm and scales to very large corpora. This is achieved by applying a significance measure between term and context feature, retaining only the most salient 1000 context features per term, and computing the cardinality of the set overlap between the respective context features

[4] `www.jobimtext.org`, (Biemann and Riedl, 2013)

per term, which defines the similarity between terms. Per term, the most similar terms are subsequently ranked, resulting in a distributional thesaurus as introduced by Lin (1997).

4 Evaluation

We report experimental results on German and English corpora. Both corpora are compiled from 10 million sentences (about 2 Gigawords) each from the Leipzig Corpora Collection[5], randomly sampled from online newspapers. The semantic similarity in English DTs is assessed using WordNet 3.1 as a lexical resource, as proposed by Riedl and Biemann (2013). For evaluating the German DTs, we replace WordNet by its German counterpart, GermaNet 8 (Hamp and Feldweg, 1997). We report results separately for frequent and infrequent targets and average the path scores for the most similar 10 words per entry. The evaluation of the English DTs is performed using 1000 frequent and 1000 infrequent nouns, as previously employed by Weeds et al. (2004). These nouns are randomly sampled from the British National Corpus (BNC) and all occur in WordNet. For the evaluation of German DTs, we randomly selected 1000 frequent and 1000 infrequent nouns from our German corpus that all occur in GermaNet.

4.1 Experimental Settings

The DTs are calculated using the dependencies from the unsupervised parsers, one at a time. To show the impact of corpus size, we down-sampled our corpora, and used 1 million (1M), 100,000 (100K) and 10,000 (10K) sentences (raw or automatically POS-tagged with the TreeTagger[6]) for training/inducing the parsers. Not all parsers were able to deal with the large training sets in feasible runtime, which might either be due to their computational complexity or their implementation. While it would be preferable to keep the corpus size for DT computations constant, this was not possible since some of our unsupervised parsers cannot be applied to unseen text. Hence, we decided to report DT quality results for two setups: Setup A uses the same data for training the parsers and the DT computation. Setup B uses the full corpus of 10M sentences for DT computation, parsed with unsupervised parsers induced on differently sized corpus samples. We feel that Setup B is better reflecting the possible utilization of unsupervised parsers for semantic similarity, since DT quality is known to increase with corpus size. However, we still wanted to assess the quality of parsers that cannot be operated on unseen text in their current state of development.

4.2 Four Baselines

We compare the results of unsupervised parsers against four baselines. As a lower-bound baseline, we use a random dependency parser that connects each word in a sentence with a randomly chosen other word. As a supervised upper-bound baseline, we use Stanford collapsed dependencies (Marneffe et al., 2006) for the English data and dependencies coming from the Mate tools (Bohnet, 2010) for the German corpus. Finally, to gauge whether the potential of unsupervised parsing to model long-range dependencies – as opposed to local n-gram contexts – lead to better distributional similarities, we use word bigrams and trigrams as n-gram-based systems. The bigram system simulates left- and right-branching. We characterize the word in the first and in the second position of two neighboring words, which results to the following term feature pairs according to the example in Section 3.2: `<I,(@,gave)>` and `<gave,(I,@)>`. Using the trigram, we characterize the word in the second position with the context feature formed by the pair of words in first and third position. The term-feature pair for *gave* would be `<gave, (I,@,her)>`.

While we expect the scores of any reasonable unsupervised parser to fall somewhere between the lower bound and the upper bound when compared in the same setting, the n-gram baselines serve as a measure for whether it is worth the trouble to induce and run the unsupervised parser for our evaluation application, as opposed to relying on an arguably simpler system for this purpose.

4.3 Results

4.3.1 Single Parser Results for English

We summarize the results for the English evaluation for Setup A and Setup B in Table 2. All unsupervised parsers beat the random baseline in all setups, with higher improvements observed using more training data, which somewhat validates their approaches. Also, more data for DT computation results in higher similarity scores, and rare words generally receive lower scores on average, which is expected and validates the DT computation framework.

		10k		100k		1M		10M	
	Parser	freq	rare	freq	rare	freq	rare	freq	rare
Setup A	Random	0.115	0.029	0.128	0.082	0.145	0.103	0.159	0.113
	Trigram	0.133	0.020	0.179	0.082	0.200	0.120	0.236	0.151
	Bigram	0.140	0.029	0.173	0.088	0.208	0.129	0.246	0.159
	Stanford	0.151	0.028	0.209	0.128	0.261	0.176	0.280	0.209
	Seginer	0.136	0.027	0.176	0.085	**0.211**	0.127	0.240	0.155
	Gillenwater	0.135	0.026	0.159	0.077	0.195	0.117	0.223	0.141
	Søgaard	0.120	0.027	0.147	0.083	0.185	0.117	0.227	0.144
	UDP	0.127	0.017	0.169	0.063	0.204	0.119	*	*
	Bisk	0.118	0.017	*	*	*	*	*	*
Setup B	Seginer	0.200	0.063	0.236	0.139	0.241	0.156	0.240	0.155
	Gillenwater	0.220	0.140	0.221	0.142	0.221	0.141	0.223	0.141
	Søgaard	0.227	0.144	0.227	0.144	0.227	0.144	0.227	0.144
	Bisk	0.220	0.139	*	*	*	*	*	*

Table 2: Setup A English: Parser induction and DT computation on the same corpus. Wordnet path scores averaged on top 10 similar words, for 1000 frequent and 1000 rare nouns. A * denotes that the evaluation failed because of computational constraints. Setup B English: Parser induction on different corpus sizes, and DT computation on 10M sentences.

In comparison to the n-gram baselines, only the parser by Seginer yields a higher score for frequent words and 1M sentences training in Setup A. However, the difference is very small and is confirmed on the 10M sentences only in comparison to the Trigram baseline. It seems that Seginer's training procedure saturates somewhere between 100K and 1M sentences, and shows even slightly worse performance on 10M sentences of training in Setup B. All parsers do not seem to be particularly useful as preprocessing steps for DT computation, since better similarity can consistently be reached by context features based on bigram statistics.

Comparing the unsupervised parsers, we note that Seginer's approach consistently scores highest in Setup A, while UDP comes in second for frequent words but not for rare words. While Gillenwater's approach reaches comparably high scores for small corpora in Setup A, it is beaten by Søgaard's no-training approach for larger corpora: It seems that Gillenwater's training procedure can hardly make use of additional training, which is shown in Setup B, where practically no differences are observed between 10K and 10M sentences of parser training. Differences in Setup A are thus solely due to increased corpus size for DT computation for the Gillenwater experiments.

UDP did not finish parsing 10M sentences after running for 157 days, and it is not trivial to disable its update procedure, which is why we could not include UDP in Setup B. Bisk's parser is a special case in this evaluation, since it only selects sentences shorter than 15 tokens for training, and hence was effectively trained on a 5400 sentence subset of the 10K corpus. While we did not manage to train it on larger corpora, we could apply this model on 10M sentences in Setup B, where it lands slightly below the no-training Søgaard parser, but clearly above Seginer's approach for 10K training.

4.3.2 Single Parser Results for German

A different picture is drawn for the German evaluation (see Setup A in Table 3). Comparing the results of the unsupervised parsers, Seginer's parser does not only outperform the trigram and bigram baseline for frequent nouns but also the supervised Mate parser for all corpus sizes. Yet, the improvements over

the Mate parser are not significant for all results using a paired t-test[7]. Also, Søgaards parser exceeds the trigram and bigram baseline for 10 million sentences. The remaining unsupervised parsers can beat the random baseline for frequent nouns but none of the n-gram baselines. Again we are not able to parse the 10 million sentences using UDP and also Gillenwater's parser failed, parsing this corpus. Comparing the baselines in Setup A (see Table 3), we observe a difference between the sophisticated baselines and the random baseline only for frequent words.

		10k		100k		1M		10M	
	Parser	freq	rare	freq	rare	freq	rare	freq	rare
Setup A	Random	0.097	0.002	0.108	0.010	0.123	0.051	0.143	0.077
	Trigram	0.102	0.002	0.130	0.014	0.159	0.067	0.179	0.086
	Bigram	0.112	0.003	0.130	0.009	0.163	0.053	0.192	0.082
	Mate	0.111	0.004	0.126	0.014	0.170	0.027	0.204	0.090
	Seginer	**0.113**†	0.002	**0.137**†	0.012	**0.171**	0.068	**0.208**	0.091
	Gillenwater	0.104	0.002	0.118	0.009	0.132	0.040	*	*
	Søgaard	0.104	0.002	0.123	0.010	0.161	0.054	0.193	0.077
	UDP	0.107	0.001	0.129	0.004	0.151	0.021	*	*
	Bisk	0.101	0.002	*	*	*	*	*	*
Setup B	Seginer	0.153	0.004	0.186	0.021	0.200	0.092	0.208	0.091
	Gillenwater	0.189	0.080	0.190	0.082	0.189	0.080	*	*
	Søgaard	0.193	0.077	0.193	0.077	0.193	0.077	0.193	0.077
	Bisk	0.185	0.069	*	*	*	*	*	*

Table 3: Setup A and B for German corpora.

Furthermore, we see that the supervised Mate parser results in worse scores for the frequent nouns using the 10k and 100k dataset in comparison to the bigram baseline. This could be attributed to the heavier tail in German's word frequency distribution, which results in sparser context features for small data[8]. For the 1M and 10M datasets, the supervised parser yields the best similarities for frequent nouns.

The results for Setup B for the German corpora are shown at the bottom in Table 3. We observe similar trends to the ones for the English data: using more data for the training does not seem to help the performance of Gillenwater's algorithm. Noticeable is the increase of Seginer's results for rare words as training data size increases. Seginer's algorithm even beats both n-gram baselines for the 10M corpus when trained only on 1 million sentences.

4.3.3 Combining Parsers for DT Quality Improvement

To clarify the best practice for building a DT of high quality, we combine different parsers: the two best-performing unsupervised parsers (Søgaard's and Seginer's), the baselines and the supervised parser. Additionally, these two parsers where the only ones which could be applied to the largest dataset for both languages.

For English (see Table 4), we observe a boost in performance when combining unsupervised parsers. Combining the supervised Stanford parser with the bigram and the trigram baselines also leads to a significant improvement ($p < 0.01$)[9] over the Stanford parser alone, which is about the same as combining the supervised parser with the two unsupervised parsers, and combining all five types of features for DT construction. Overall, a relative improvement of 3.5% on the average WordNet::Path measure for frequent words and a relative 4% improvement for rare words is obtained over the Stanford parser alone.

The results for German (see Table 5) show a similar trend. It is remarkable that merging the two unsupervised parsers already outperforms the supervised Mate parser significantly[9] with $p < 0.01$ (6.7% for frequent and 8% relative improvement for rare words). The combination of the supervised and unsupervised parsers again leads to further improvement, which is also significant over the supervised parser alone, and again, adding the bigram and trigram baselines to the three parsers does not help.

[7]Significant improvements ($p < 0.01$) against the Mate parser are marked with the symbol † in Table 3 for frequent nouns.

[8]Within the 10M sentences, there are 22 million word types in the German corpus and 10 million word types in the English corpus.

[9]We use a paired t-test to compare the DTs built using the supervised parser and the combinations.

Parser	frequent	rare
Stanford (supervised)	0.280	0.209
Seginer	0.240	0.155
Søgaard	0.227	0.144
Seginer & Søgaard	0.248	0.162
Stanford & Bigram & Trigram	**0.290**†	**0.217**†
Stanford & Seginer & Søgaard	**0.291**†	**0.217**†
Stanford & Seginer & Søgaard & Bigram & Trigram	**0.290**†	**0.218**†

Table 4: Combinations of different parsers for computing English thesauri. The cross (†) indicates significant improvements over the supervised parser.

Parser	frequent	rare
Mate (supervised)	0.204	0.090
Seginer	0.208	0.091
Søgaard	0.193	0.077
Seginer & Søgaard	0.218†	0.097†
Mate & Bigram & Trigram	0.204	0.091
Mate & Seginer & Søgaard	**0.222**†	**0.100**†
Mate & Seginer & Søgaard & Bigram & Trigram	**0.222**†	**0.100**†

Table 5: Combinations of different parsers for computing German thesauri

4.3.4 Discussion

Overall, it is surprising how well Søgaard's parser performs in comparison to others on this task, since it neither uses training nor relies on POS tags. This hints at either unsupervised parsing being simpler than commonly assumed or rather the immaturity of all unsupervised parsers tested. Further, we would have expected that trained unsupervised parsers, as most unsupervised methods, would exhibit a better performance when trained on larger corpora. This could not be confirmed for both systems that we trained on various corpus sizes, i.e. Seginer's and Gillenwater's approach. The findings are only moderately correlated with evaluations on treebanks, cf Table 1: Whereas Seginer's and Søgaard's parsers perform favorably in our evaluation, they are outperformed by Bisk's parser on treebanks, which currently does not scale to large data. Gillenwater's parser seems to be overly tuned to English treebanks, but cannot capitalize on this in our evaluation for English.

POS information does not seem beneficial for unsupervised parser induction in noun similarity evaluation, since the highest-scoring approach by Seginer does not use POS tags and a version of Søgaard's parser with POS tags scored slightly but consistently lower than the version without POS, as we found in further experiments. This is in line with the findings of Cramer (2007), who reports no benefit from manually corrected or unsupervised POS tags for a range of unsupervised parsers.

Comparing the results of previous intrinsic evaluations (see Table 1) and the results of our extrinsic evaluation (see Table 2 and 3), we observe that the ranking of parsers is only mildly correlated. Thus, our proposed evaluation covers different aspects than the adherence to (partially arbitrary) conventions of manually labeled dependency data. Also, our current evaluation disregards all arcs that do not involve nouns.

When combining parsers, we observe that we can improve the quality of DTs significantly. This leads us to conclude that unsupervised parsers should at least be used for generating features when computing distributional thesauri of high quality. In case no high-quality supervised parser is available for the language or domain of interest, it might suffice to use combinations of unsupervised parsers.

We also report the computation times of the different parsers, for the English dataset for Setup A (see Table 6). The results were computed on a server with 80 GB and 16 cores. Whereas all parsers require different amounts of memory, all parsers are single-threaded[10]. While Søgaard's parser is the fastest for small datasets, Seginer's runs faster on 10 million sentences. Whereas Gillenwater's and Seginer's

	10k	100k	1M	10M
Seginer	210	224	261	**508**
Gillenwater	3248	3248	3280	5546
Søgaard	**3**	**21**	**182**	975
UDP	183	1220	11316	-

Table 6: Computation time in minutes for parsing the data according to the English corpora used in Setup A, cf. Table 2

[10] As Søgaards algorithm parses sentence-wise without storing any information, it could be easily run multi-threaded.

algorithm require almost the same time for parsing 10k, 100k or 1M sentences, the runtime of the UDP and Søgaard's parser is linear in time with the number of sentences to be parsed. We cannot report the parsing times for the Bisk algorithm, as the parsing was not performed by us. Again it is noticeable that the best two parsers are also the two unsupervised parsers that run quickest.

5 Conclusion

The contribution of this paper is two-fold: First, we have proposed and conducted a comparative extrinsic evaluation procedure for unsupervised parsers based on noun similarity in DTs. Second, we have explored how to improve DT quality by combining features from several parsers. The transparency of this method with respect to the kind of induced structures (dependencies, constituent trees, combinatory categorial grammar) and with respect to labels of nodes and edges in the parse graph makes it possible to compare different unsupervised parsers without having to rely on treebanks. Since semantic similarity, especially for nouns, is a building block for many NLP applications, we feel that removing the dependency on high-quality supervised parsers can give rise to semantic technologies in many languages. We have conducted this evaluation with five different unsupervised parsers, and examined the influence of corpus size for parser training and for the similarity computation in a series of experiments. Using established methods for evaluating distributional similarity against lexical semantic resources, we were able to measure differences between parsers in this task that are not reflected by intrinsic evaluations that compare their induced structures to treebanks. These include the influence of corpus size on the training procedure and the consistency of parse fragments on "frequent versus rare words" as well as different languages. Further, we were able to pinpoint a crucial point in unsupervised parsers that has not received much attention: approaches that do not induce an actual parser that can be run on unseen sentences but merely produce syntactic annotations for a given fixed training corpus are hardly useful in applications.

Our evaluation results can be summarized as follows: For English, with its relatively fixed order, Seginer's parser achieves very scarce to no improvements compared to a simple n-gram baseline when used to compute distributional similarities. But for German, Seginer's parser outperforms all baselines including a state-of-the-art supervised parser, and Søgaard's simplistic approach compares favorably to the n-gram baselines. Furthermore, we demonstrate that the quality of noun similarity can be improved significantly when combining the features from supervised and unsupervised parsers.

While today's unsupervised parsers might not be ready for their utilization for semantic similarity for the English language, they can be applied to a large number of other languages where highly optimized supervised parsers are not available. Additionally, we feel that our proposed evaluation method exhibits enough sensitivity to be a meaningful test bed for future unsupervised parsers.

6 Outlook

Where do we go from here? We strongly argue that in times of availability of very large monolingual corpora from the web, we should strive at unsupervised parser induction systems that can make use of large training data, as opposed to focussing our efforts on complex models that scale poorly, and thus cannot elevate to the performance levels needed in order to make unsupervised parsing a building block in natural language processing applications.

For further work, we want to proceed in several ways: we would like to extend our evaluation framework from nouns to other parts of speech. Furthermore, we will explore whether unsupervised parsers can be tuned towards the task of computing a distributional thesaurus, e.g. by using only assignments with a certain confidence, type, or from sentences with limited length. Additionally, we would like to explore the interaction of unsupervised POS induction and grammar induction (Headden, III et al., 2008), in order to entirely remove language-dependent preprocessing for the purpose of semantic similarity computations, while at the same time being able to leverage the advantages of structured representations, cf. Erk and Padó (2008). Finally, we would like to test whether we can also detect a different ranking for different supervised parsers when comparing their scores in the normal treebank setting versus using them for building distributional thesauri.

Abstract

In this article, we describe a new approach to distributional semantics. This approach relies on a generative model of sentences with latent variables, which takes the syntax into account by using syntactic dependency trees. Words are then represented as posterior distributions over those latent classes, and the model allows to naturally obtain in-context and out-of-context word representations, which are comparable. We train our model on a large corpus and demonstrate the compositionality capabilities of our approach on different datasets.

1 Introduction

It is often considered that words appearing in similar contexts tend to have similar meaning (Harris, 1954). This idea, known as the *distributional hypothesis* was famously summarized by Firth (1957) as follow: "you shall know a word by the company it keeps." The distributional hypothesis has been applied in computational linguistics in order to automatically build word representations that capture their meaning. For example, simple distributional information about words, such as co-occurence counts, can be extracted from a large text corpus, and used to build a vectorial representation of words (Lund and Burgess, 1996; Landauer and Dumais, 1997). According to the distributional hypothesis, two words having similar vectorial representations must have similar meanings. It is thus possible and easy to compare words using their vectorial representations.

In natural languages, sentences are formed by the *composition* of simpler elements: words. It is thus reasonable to assume that the meaning of a sentence is determined by combining the meanings of its parts and the syntactic relations between them. This principle, often attributed to the German logician Frege, is known as *semantic compositionality*. Recently, researchers in computational linguistics started to investigate how the principle of compositionality could be applied to distributional models of semantics (Clark and Pulman, 2007; Mitchell and Lapata, 2008). Given the representations of individual words, such as *federal* and *agency*, is it possible to combine them in order to obtain a representation capturing the meaning of the noun phrase *federal agency*?

Most approaches to distributional semantics represent words as vectors in a high-dimensional space and use linear algebra operations to combine individual word representations in order to obtain representations for complex units. In this article, we propose a probabilistic approach to distributional semantics. This approach is based on the generative model of sentences with latent variables, which was introduced by Grave et al. (2013). We make the following contributions:

- Given the model introduced by Grave et al. (2013), we describe how in-context and ouf-of-context words can be represented by posterior distributions over latent variables (section 4).
- We evaluate out-of-context representations on human similarity judgements prediction tasks and determine what kind of semantic relations are favored by our approach (section 5).
- Finally, we evaluate in-context representations on two similarity tasks for short phrases (section 6).

Proceedings of COLING 2014, the 25th International Conference on Computational Linguistics: Technical Papers, pages 1447–1456, Dublin, Ireland, August 23-29 2014.

2 Related work

Most approaches to distributional semantics are based on vector space models (VSM), in which words are represented as vectors in a high-dimensional space. These vectors are obtained from a large text corpus, by extracting distributional information about words such as the contexts in which they appear. A corpus is then represented as a word-by-context co-occurence matrix. Contexts can be defined as documents in which the target word appear (Deerwester et al., 1990; Landauer and Dumais, 1997) or as words that appear in the neighbourhood of the target word, for example in the same sentence or in a fixed-size window around the target word (Schutze, 1992; Lund and Burgess, 1996).

Next to vector space models, other approaches to distributional semantics are based on probabilistic models of documents, such as probabilistic latent semantic analysis (pLSA) introduced by Hofmann (1999) and which is inspired by latent semantic analysis, or latent Dirichlet allocation (LDA), introduced by Blei et al. (2003). In those models, each document is viewed as a mixture of k topics, where each topic is a distribution over the words of the vocabulary.

The previous models do not take into account the linguistic structure of the sentences used to build word representations. Several models have been proposed to address this limitation. In those models, the contexts are defined by using the syntactic relations between words (Lin, 1998; Curran and Moens, 2002; Turney, 2006; Padó and Lapata, 2007; Baroni and Lenci, 2010). For example, two words are considered in the same context if there exists a syntactic relation between them, or if there is a path between them in the dependency graph.

One of the first approaches to semantic compositionality using vector space models was proposed by Mitchell and Lapata (2008). In this study, individual word representations are combined using linear algebra operations such as addition, componentwise multiplication, tensor product or dilation. Those different composition operations are then used to disambiguate intransitive verbs given a subject (Mitchell and Lapata, 2008) or to compute similarity scores between pairs of small phrases (Mitchell and Lapata, 2010).

Another approach to semantic compositionality is to learn the function used to compose individual word representations. First, a semantic space containing representations for both individual words and phrases is built. For example, the words *federal*, *agency* and the phrase *federal agency* all have a vectorial representation. Then, a function mapping individual word representations to phrase representations can be learnt in a supervised way. Guevara (2010) proposed to use partial least square regression to learn this function. Similarly, Baroni and Zamparelli (2010) proposed to learn a matrix $\mathbf{A}$ for each adjective, such that the vectorial representation $\mathbf{p}$ of the adjective-noun phrase can be obtained from the vectorial representation $\mathbf{b}$ of the noun by the matrix-vector multiplication:

$$\mathbf{p} = \mathbf{A}\mathbf{b}.$$

Socher et al. (2012) later generalized this model by proposing to represent each node in a parse tree by a vector capturing the meaning and a matrix capturing the compositional effects. A composition function, inspired by artificial neural networks, is recursively applied in the tree to compute those representations.

Following the theoretical framework introduced by Coecke et al. (2010), Grefenstette and Sadrzadeh (2011) proposed to represent relational words (such as verbs) by tensors and theirs arguments (such as nouns) by vectors. Composing a relational word with its arguments is then performed by taking the pointwise product between the tensor and the Kronecker product of the vectors representing the arguments. Jenatton et al. (2012) and Van de Cruys et al. (2013) proposed two approaches to model subject-verb-object triples based on tensor factorization.

Finally, research in computation of word meaning in context is closely related to distributional semantic compositionality. Erk and Padó (2008) proposed a structured vector space model in which a word is represented by multiple vectors, capturing its meaning but also the selectional restrictions it has for the different arguments. Those different vectors can then be combined to compute a word representation in context. This model was later generalized by Thater et al. (2010). Dinu and Lapata (2010) introduced a probabilistic model for computing word representations in context. In their approach, words are represented as probability distributions over latent senses.

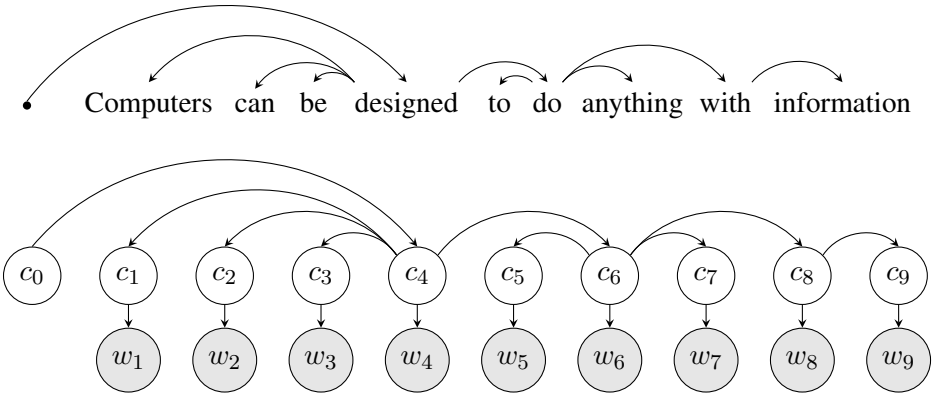

Figure 1: Example of a dependency tree and its corresponding graphical model.

3 Model of semantics

In this section we briefly review the generative model of sentences introduced by Grave et al. (2013), and which serves as the basis of our approach to distributional semantics.

3.1 Generative model of sentences

We denote the tokens of a sentence of length K by the K-uple $\mathbf{w} = (w_1, ..., w_K) \in \{1, ..., V\}^K$, where V is the size of the vocabulary and each integer represents a word. We suppose that each token w_k is associated to a corresponding semantic class $c_k \in \{1, ..., C\}$, where C is the number of semantic classes. Finally, the syntactic dependency tree corresponding to the sentence is represented by the function $\pi : \{1, ..., K\} \mapsto \{0, ..., K\}$, where $\pi(k)$ represents the parent of word k and 0 is the root of the tree (which is not associated to a word).

Given a tree π, the semantic classes and the words of a sentence are generated as follows. The semantic class of the root of the tree is set to a special start symbol, represented by the integer 0.[1] Then, the semantic classes corresponding to words are recursively generated down the tree: each semantic class c_k is drawn from a multinomial distribution $p_T(c_k \mid c_{\pi(k)})$, conditioned on the semantic class $c_{\pi(k)}$ of its parent in the tree. Finally, each word w_k is also drawn from a multinomial distribution $p_O(w_k \mid c_k)$, conditioned on its corresponding semantic class c_k. Thus, the joint probability distribution on words and semantic classes can be factorized as

$$p(\mathbf{w}, \mathbf{c}) = \prod_{k=1}^{K} p_T(c_k \mid c_{\pi(k)}) p_O(w_k \mid c_k),$$

where the variable $c_0 = 0$ represents the root of the tree. The initial class probability distribution $p_T(c_k \mid c_0 = 0)$ is parameterized by the probability vector $\mathbf{q}$, while the transition probability distribution between classes $p_T(c_k \mid c_{\pi(k)})$ and the emission probability distribution $p_O(w_k \mid c_k)$ are parameterized by the stochastic matrices $\mathbf{T}$ and $\mathbf{O}$ (*i.e.*, matrices with non-negative elements and unit-sum columns). This model is a hidden Markov model on a tree (instead of a chain). See Fig. 1 for an example of a sentence and its corresponding graphical model.

3.2 Corpus and learning

We train the generative model of sentences on the ukWac corpus (Baroni et al., 2009). This corpus, which contains approximately 1.9 billions tokens, was POS-tagged and lemmatized using TreeTagger (Schmid, 1994) and parsed using MaltParser (Nivre et al., 2007). Each word of our vocabulary is a pair of lemma and its part-of-speech. We perform smoothing by only keeping the V most frequent pairs, the infrequent ones being replaced by a common token. The parameters $\theta = (\mathbf{q}, \mathbf{T}, \mathbf{O})$ of the model are learned using the algorithm described by Grave et al. (2013). The number of latent states C and the number of lemma/POS pairs V were set using the development set of Bruni et al. (2012).

[1] We recall that the semantic classes corresponding to words are represented by integers between 1 and C.

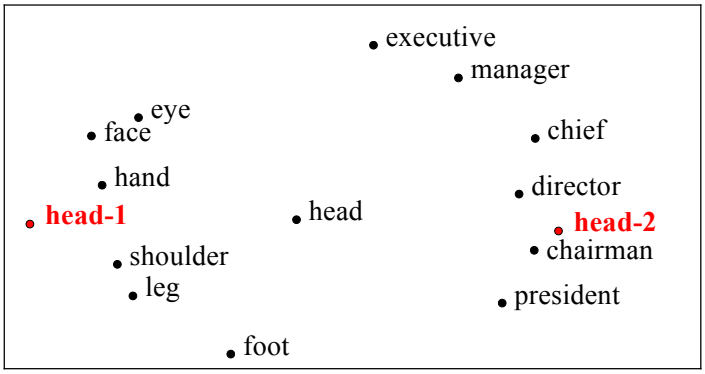

Figure 2: Comparison of out-of-context (black) and in-context (red) word representations. The two-dimensional visualization is obtained by using multidimensional scaling (Borg, 2005). See text for details.

4 Word representations

Given a trained hidden Markov model, we now describe how to obtain word representations, for both in-context and out-of-context words. In both cases, words will be represented as a probability distribution over the latent semantic classes.

In-context word representation. Obtaining a representation of a word in the context of a sentence is very natural using the model introduced in the previous section: we start by parsing the sentence in order to obtain the syntactic dependency tree. We then compute the posterior distribution of semantic classes c for that word, and use this probability distribution to represent the word. More formally, given a sentence $\mathbf{w} = (w_1, ..., w_K)$, the kth word of the sentence is represented by the vector $\mathbf{u}^k \in \mathbb{R}^C$ defined by

$$u_i^k = \mathbb{P}(C_k = i \mid W = \mathbf{w}).$$

The vector $\mathbf{u}^k$ is the posterior distribution of latent classes corresponding to the kth word of the sentence, and thus, sums to one. It is efficiently computed using the message passing algorithm (a.k.a. forward-backward algorithm for HMM).

Out-of-context representation. In order to obtain word representations that are independent of the context, we compute the previously introduced in-context representations on a very large corpus, and for each word type, we average all the in-context representations for all the occurrences of that word type in the corpus. More formally, given a large set of pairs of tokens and their in-context representations $(w_k, \mathbf{u}^k) \in \mathbb{N} \times \mathbb{R}^C$, the representation of the word type a is the vector $\mathbf{v}^a \in \mathbb{R}^C$, defined by

$$\mathbf{v}^a = \frac{1}{Z_a} \sum_{k \,:\, w_k = a} \mathbf{u}^k,$$

where Z_a is the number of occurrences of the word type a. The vector $\mathbf{v}^a$ is thus the posterior distribution of semantic classes averaged over all the occurrences of word type a.

Comparing in-context and out-of-context representations. Since in-context and out-of-context word representations are defined on the same space (the simplex of dimension C) it is possible to compare in-context and out-of-context representations easily. As an example, we have plotted in Figure 2 the out-of-context representation for the words *head, president, chief, chairman, director, executive, eye, face, shoulder, hand, leg, etc.* and the in-context representations for the word *head* in the context of the two following sentences:

1. *The nurse stuck her* head *in the room to announce that Dr. Reitz was on the phone.*
2. *A well-known Wall Street figure may join the Cabinet as* head *of the Treasury Department.*

Distance	RG65	WS353
Cosine	0.68	0.50
Kullback-Leibler	0.69	0.47
Jensen-Shannon	0.72	0.50
Hellinger	0.73	0.51
Agirre et al. (BoW)	0.81	0.65

Distance	SIM.	REL.
Cosine	0.68	0.34
Kullback-Leibler	0.64	0.31
Jensen-Shannon	0.69	0.33
Hellinger	0.70	0.34
Agirre et al. (BoW)	0.70	0.62

Table 1: Left: Spearman's rank correlation coefficient ρ between human and distributional similarity, on the RG65 and WORDSIM353 datasets. Right: Spearman's rank correlation coefficient ρ between human and distributional similarity on two subsets (similarity *v.s.* relatedness) of the WORDSIM353 dataset.

The two-dimensional visualization is obtained by using multidimensional scaling (Borg, 2005). First of all, we observe that the words are clustered in two groups, one containing words belonging to the *body part* class, the other containing words belonging to the *leader* class, and the word *head*, appears between those two groups. Second, we observe that the in-context representations are shifted toward the cluster corresponding to the disambiguated sense of the ambiguous word *head*.

5 Out-of-context evaluation

In this section, we evaluate out-of-context word representations on a similarity prediction task and determine what kind of semantic relations are favored by our approach.

5.1 Similarity judgements prediction

In word similarity prediction tasks, pairs of words are presented to human subjects who are asked to rate the relatedness between those two words. These human similarity scores are then compared to distributional similarity scores induced by our models, by computing the correlation between them.

Methodology. We use the RG65 dataset, introduced by Rubenstein and Goodenough (1965) and the WORDSIM353 dataset, collected by Finkelstein et al. (2001). These datasets comprise 65 and 353 word pairs respectively. Human subjects rated the relatedness of those word pairs. We use the Spearman's rank correlation coefficient ρ to compare human and distributional score distributions.

Comparison of similarity measures. Since words are represented by posterior distributions over latent semantic classes, we have considered distances (or divergences) that are adapted to probability distributions to compute the similarity between word representations: the symmetrised Kullback-Leibler divergence, the Jensen-Shannon divergence, and the Hellinger distance. We use the opposite of these dissimilarity measures in order to obtain similarity scores. We also included the cosine similarity measure as a baseline, as it is widely used in the field of distributional semantics.

We report results on both datasets in Table 1. Unsurprisingly, we observe that the dissimilarity measures giving the best results are the one tailored for probability distribution, namely the Jensen-Shannon divergence and the Hellinger distance. The Kullback-Leibler divergence is too sensitive to fluctuations of small probabilities and thus does not perform as well as other similarity measures between probability distributions. In the following, we will use the Hellinger distance. It should be noted that the results reported by Agirre et al. (2009) were obtained using a corpus containing 1.6 terawords, making it 1,000 times larger than ours. They also report results for various corpus sizes, and when using a corpus whose size is comparable to ours, their result on WORDSIM353 drops to 0.55.

Relatedness *v.s.* similarity. As noted by Agirre et al. (2009), words might be rated as related for different reasons since different kinds of semantic relations exist between word senses. Some words, such as *telephone* and *communication* might even be rated as related because they belong to the same semantic field. Thus, they proposed to split the WORDSIM353 dataset into two subsets: the first one comprising words that are *similar*, *i.e.*, synonyms, antonyms and hyperonym-hyponym and the second

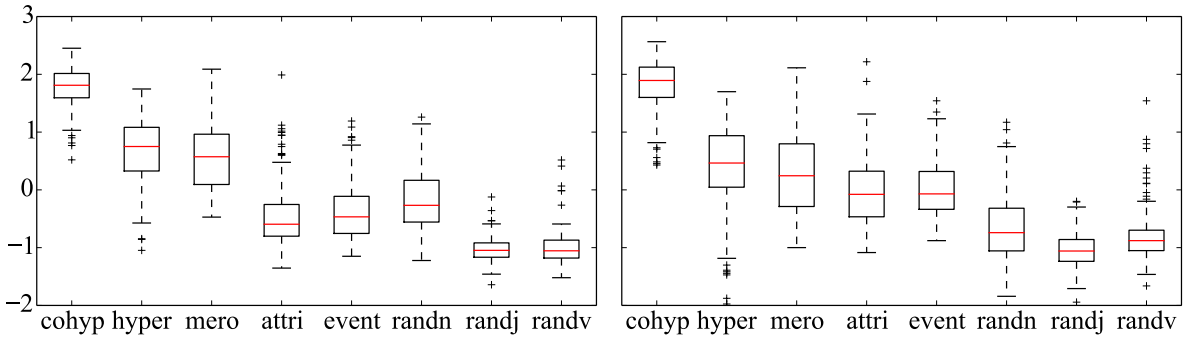

Figure 3: Similarity score distributions for various semantic relations on the BLESS dataset, without using the transition matrix (left) and with using the transition matrix (right) for comparing adjectives and verbs with nouns.

one comprising words that are *related*, *i.e.*, meronym-holonym and topically related words. We report results on these two subsets in Table 1. We observe that our model capture *similarity* ($\rho = 0.70$) much better than *relatedness* ($\rho = 0.34$). This is not very surprising since our model takes the syntax into account.

5.2 Semantic relations captured by our word representations

As we saw in the previous section, different semantic relations between words are not equally captured by our word representations. In this section, we thus investigate which kind of semantic relations are favored by our approach.

The BLESS dataset. The BLESS dataset (Baroni and Lenci, 2011) comprises 200 concrete concepts and eight relations. For each pair of concept-relation, a list of related words, referred to as relatum, is given. Five semantic relations are considered: *co-hyponymy*, *hypernymy*, *meronymy*, *attribute* and *event*. The *attribute* relation means that the relatum is an adjective expressing an attribute of the concept, while the *event* relation means that the relatum is a verb designing an activity or an event in which the concept is involved. The dataset also contains three *random* relations (*randn*, *randj* ans *randv*), obtained by the association of a random relatum, for different POS: noun, adjective and verb.

Methodology. We follow the evaluation proposed by the authors: for each pair of concept-relation, we keep the score of the most similar relatum associated to that pair of concept-relation. Thus, for each concept, we have eight scores, one for each relation. We normalize these eight scores (mean: 0, std: 1), in order to reduce concept-specific effects. We then report the score distributions for each relation as box plots in Figure 3 (left).

Results. We observe that the co-hyponymy relation is the best captured relation by a large margin. It is followed by the hypernymy and meronymy relations. The random noun relation is prefered over the attribute and the event relations. This happens because words with different part-of-speeches tend to appear in different semantic classes. It is thus impossible to compare words with different parts-of-speeches and thus to capture relation such as the event or the attribute relation as defined in the BLESS dataset. It is however possible to make a more principled use of the model to overcome this issue.

Comparing adjectives with nouns and nouns with verbs. In syntactic relations between nouns and adjectives, the noun is the head word and the adjective is the dependent. Similarly, in syntactic relations between nouns and verbs, most often the verb is the head and the noun is the dependent. Given a vector $\mathbf{v}_a$ representing an adjective and a vector $\mathbf{v}_n$ representing a noun, it is thus natural to left multiply them by the transition matrix of the model to obtain a vector $\mathbf{u}_a$ comparable to nouns and a vector $\mathbf{u}_n$ comparable to verbs:

$$\mathbf{u}_a = \mathbf{T}^\top \mathbf{v}_a \quad \text{and} \quad \mathbf{u}_n = \mathbf{T}^\top \mathbf{v}_n.$$

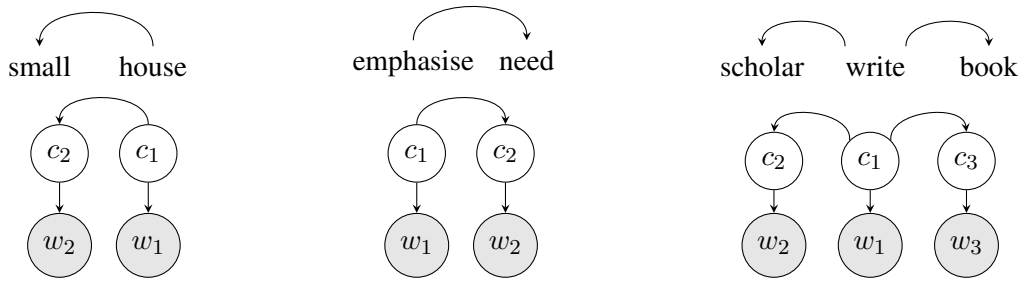

Figure 4: Graphical models used to compute in-context word representations for the compositional tasks.

We report in Figure 3 (right) the new score distributions obtained when adjective and noun representations are transformed before being compared to nouns and verbs. We observe that, when using these transformations, the attribute and event relations are better captured than the random relations. This demonstrates that the transition matrix $\mathbf{T}$ captures selectional preferences.

6 Compositional semantics

So far, we have only evaluated how well our representations are able to capture the meaning of words taken as individual and independent units. However, natural languages are highly compositional, and it is reasonable to assume that the meaning of a sentence or a phrase can be deduced from the meanings of its parts and the syntactic relations between them. This assumption is known as the principle of semantic compositionality.

In this section, we thus evaluate our representations on semantic composition tasks. More precisely, we determine if using in-context word representations helps to compute the similarity between short phrases such as adjective-noun, verb-object, compound-noun or subject-verb-object phrases. We use two datasets of human similarity scores, introduced respectively by Mitchell and Lapata (2010) and Grefenstette and Sadrzadeh (2011).

6.1 Methodology

We compare different ways to obtain a representation of a short phrase given our model. First, as a baseline, we represent a phrase by the out-of-context representation of its head word. In that case, there is no composition at all. Second, following Mitchell and Lapata (2008), we represent a phrase by the sum of the out-of-context representations of the words forming that phrase. Third, we represent a phrase by the in-context representation of its head word. Finally, we represent a phrase by the sum of the two in-context representations of the words forming that phrase. The graphical models used to compute in-context word representations are represented in Fig 4. The probability distribution $p(c_1)$ of the head's semantic class is set to the uniform distribution (and not to the initial class distribution $p_T(c_k \mid c_0 = 0)$).

6.2 Datasets

The first dataset we consider was introduced by Mitchell and Lapata (2010), and is composed of pairs of adjective-noun, compound-noun and verb-object phrases, whose similarities were evaluated by human subjects on a $1-7$ scale. We compare our results with the one reported by (Mitchell and Lapata, 2010). The second dataset we consider was introduced by Grefenstette and Sadrzadeh (2011). Each example of this dataset consists in a triple of subject-verb-object, forming a small transitive sentence, and a landmark verb. Human subjects were asked to evaluate the similarity between the verb and its landmark in the context of the small sentence. Following Van de Cruys et al. (2013), we compare the contextualized verb with the non-contextualized landmark, meaning that the landmark is always represented by its out-of-context representation. We do so because it is believed to better capture the compositional ability of our model and it works better in practice. We compare our results with the one reported by Van de Cruys et al. (2013).

	AN	NN	VN
head (out-of-context)	0.44	0.26	0.41
add (out-of-context)	0.50	0.45	0.42
head (in-context)	0.49	0.42	**0.43**
add (in-context)	**0.51**	0.46	0.41
M&L (vector space model)	0.46	**0.49**	0.38
Humans	0.52	0.49	0.55

	SVO
head (out-of-context)	0.25
add (out-of-context)	0.25
head (in-context)	**0.41**
add (in-context)	0.40
Van de Cruys et al.	0.37
Humans	0.62

Table 2: Spearman's rank correlation coefficients between human similarity judgements and similarity computed by our models on the Mitchell and Lapata (2010) dataset (left) and on the Grefenstette and Sadrzadeh (2011) dataset (right). AN stands for adjective-noun, NN stands for compoundnoun and VN stands for verb-object.

6.3 Discussion

Before discussing the results, it is interesting to note that our approach provides a way to evaluate the importance of disambiguation for compositional semantics. Indeed, the in-context representations proposed in this paper are a way to disambiguate their out-of-context equivalents. It was previously noted by Reddy et al. (2011) that disambiguating the vectorial representations of words improve the performance on compositional tasks.

Mitchell and Lapata (2010) dataset. We report results on the Mitchell and Lapata (2010) dataset in Table 2 (left). Overall, in-context representations achieves better performance than out-of-context ones. For the adjective-noun pairs and the verb-noun pairs, using only the in-context representation of the head word works almost as well (AN) or even better (VN) than adding the representations of the two words forming a pair. This means that for those particular tasks, disambiguation plays an important role. On the other hand, this is not the case for the noun-noun pairs. On that task, most improvement over the baseline comes from the *add* operation.

Grefenstette and Sadrzadeh (2011) dataset. We report results in Table 2 (right). First, we observe that in-context representations clearly outperform out-of-context ones. Second, we note that adding the subject, object and verb representations does not improve the result over only using the representation of the verb. These two conclusions are not really surprising since this task is mainly a disambiguation task, and disambiguation is achieved by using the in-context representations. We also note that our approach yields better results than those obtained by Van de Cruys et al. (2013), while their method was specifically designed to model subject-verb-object triples.

7 Conclusion and future work

In this article, we introduced a new approach to distributional semantics, based on a generative model of sentences. This model is somehow to latent Dirichlet allocation as structured vector space models are to latent semantic analysis. Indeed, our approach is based on a probabilistic model of sentences, which takes the syntax into account by using dependency trees. Similarly to LDA, our model can be viewed as a topic model, the main difference being that the topics are generated using a Markov process on a syntactic dependency tree instead of using a Dirichlet process.

The approach we propose seems quite competitive with other distributional models of semantics. In particular, we match or outperform state-of-the-art methods on semantic compositionality tasks. Thanks to its probabilistic nature, it is very easy to derive word representations for various tasks: the same model can be used to compute in-context word representations for adjective-noun phrases, subject-verb-object triples or even full sentences, which is not the case of the tensor based approach proposed by Van de Cruys et al. (2013).

Currently, the model of sentences does not use the dependency labels, which is the most significant limitation that we would like to address in future work. We also plan to explore spectral methods (Anandkumar et al., 2012) to provide better initialization for learning the parameters of the model. Indeed, we believe this could speed up learning and yields better results, since the expectation-maximization algorithm is quite sensitive to bad initialization. Finally, the code corresponding to this article will be available on the first author webpage.

A Beam-Search Decoder for Disfluency Detection

Abstract

In this paper[1], we present a novel beam-search decoder for disfluency detection. We first propose node-weighted max-margin Markov networks (M3N) to boost the performance on words belonging to specific part-of-speech (POS) classes. Next, we show the importance of measuring the quality of cleaned-up sentences and performing multiple passes of disfluency detection. Finally, we propose using the beam-search decoder to combine multiple discriminative models such as M3N and multiple generative models such as language models (LM) and perform multiple passes of disfluency detection. The decoder iteratively generates new hypotheses from current hypotheses by making incremental corrections to the current sentence based on certain patterns as well as information provided by existing models. It then rescores each hypothesis based on features of lexical correctness and fluency. Our decoder achieves an edit-word F1 score higher than all previous published scores on the same data set, both with and without using external sources of information.

1 Introduction

Disfluency detection is a useful and important task in Natural Language Processing (NLP) because spontaneous speech contains a significant proportion of disfluency. The disfluencies in speech introduce noise in downstream tasks like machine translation and information extraction. Thus, the task of disfluency detection not only can help improve the readability of automatically transcribed speech, but also the performance of downstream NLP tasks.

There are mainly two types of disfluencies: filler words and edit words. Filler words include filled pauses (e.g., 'uh', 'um') and discourse markers (e.g., "I mean", "you know"). They are insertions in spontaneous speech that indicate pauses or mark boundaries in discourse. Thus, they do not convey useful content information. Edit words are words that are spoken wrongly and then corrected by the speaker. For example, consider the utterance:

Edit Filler Repair

I want a flight ~~*to Boston*~~ *uh I mean* to Denver

The phrase "to Boston" forms the edit region to be replaced by "to Denver". The words "uh I mean" are filler words that serve to cue the listener about the error and subsequent correction. So, the cleaned-up sentence would be "I want a flight to Denver", which is what the speaker originally intended to say. In general, edit words are more difficult to detect than filler words, and so edit word prediction accuracy is much lower. Thus, in this work, we mainly focus on edit word detection.

In Section 2, we briefly introduce previous work. In Section 3, we describe our improved baseline system that will be integrated into our beam-search decoder. Section 4 presents our beam-search decoder in detail. In Section 5, we describe our experiments and results. Section 6 gives the conclusion.

[1]The research reported in this paper was carried out as part of the PhD thesis research of Xuancong Wang at the NUS Graduate School for Integrated Sciences and Engineering.

Proceedings of COLING 2014, the 25th International Conference on Computational Linguistics: Technical Papers, pages 1457–1467, Dublin, Ireland, August 23-29 2014.

2 Previous Work

Researchers have tried many models for disfluency detection. Johnson and Charniak (2004) proposed a TAG-based (Tree-Adjoining Grammar) noisy channel model, which showed great improvement over a boosting-based classifier (Charniak and Johnson, 2001). Maskey et al. (2006) proposed a phrase-level machine translation approach for this task. Liu et al. (2006) used conditional random fields (CRFs) (Lafferty et al., 2001) for sentence boundary and edit word detection. They showed that CRFs significantly outperformed maximum entropy models and hidden Markov models (HMM). Zwarts and Johnson (2011) extended this model using minimal expected F-loss oriented n-best reranking. Georgila (2009) presented a post-processing method during testing based on integer linear programming (ILP) to incorporate local and global constraints. In addition to textual information, prosodic features extracted from speech have been incorporated to detect edit words in some previous work (Kahn et al., 2005; Liu et al., 2006; Zhang et al., 2006). Zwarts and Johnson (2011) also trained extra language models on additional corpora, and compared the effects of adding scores from different language models as features during reranking. They reported that the language models gained approximately 3% in F1-score for edit word detection on the Switchboard development dataset. Qian and Liu (2013) proposed multi-step disfluency detection using weighted max-margin Markov networks (M3N) and achieved the highest F-score of 84.1% without using any external source of information. In this paper, we incorporate the M3N model into our beam-search decoder framework with some additional features to further improve the result.

3 The Improved Baseline System

Weighted max-margin Markov networks (M3N) (Taskar et al., 2003) have been shown to outperform CRF in (Qian and Liu, 2013), since it can balance precision and recall easily by assigning different loss penalty to different label misclassification pairs. In this work, we made use of M3N in expanding the search space and rescoring the hypotheses. To facilitate the integration of the M3N system into our decoder framework, we made several modifications that slightly improve the M3N baseline system. Our improved baseline system has two stages: the first stage is filler word prediction using M3N to detect words which can potentially be fillers, and the second stage is joint edit and filler word prediction using M3N. The output of the first stage is passed as features into the second stage. Both stages perform filler word prediction, since we found that joint edit and filler word detection performs better than edit word detection alone as edit words tend to co-occur with filler words, and the first-stage output can be fed into the second stage to extract additional features. We also augmented the M3N toolkit to support additional feature functions, allow weighting of individual nodes, and control the total number of model parameters.[2]

3.1 Node-Weighted and Label-Weighted Max-Margin Markov Networks (M3N)

A max-margin Markov network (M3N) (Taskar et al., 2003) is a sequence labeling model. It has the same structure as conditional random fields (CRF) (Lafferty et al., 2001) but with a different objective function. A CRF is trained to maximize the conditional probability of the true label sequence given the observed input sequence, while an M3N is trained to maximize the difference between the conditional probability of the true label sequence and the incorrectly predicted label sequence (i.e., maximizing the margin). Thus, we can regard M3N as a support vector machine (SVM) analogue of CRF (Suykens and Vandewalle, 1999).

The dual form of the training objective function of M3N is formulated as follows:

$$\begin{aligned} &\min_{\alpha} \frac{1}{2} C \| \sum_{\mathbf{x},\mathbf{y}} \alpha_{\mathbf{x},\mathbf{y}} \Delta \mathbf{f}(\mathbf{x},\mathbf{y}) \|_2^2 + \sum_{\mathbf{x},\mathbf{y}} \alpha_{\mathbf{x},\mathbf{y}} L(\mathbf{x},\mathbf{y}) \\ s.t. \quad &\sum_{\mathbf{y}} \alpha_{\mathbf{x},\mathbf{y}} = 1, \forall \mathbf{x} \qquad \text{and} \qquad \alpha_{\mathbf{x},\mathbf{y}} \geq 0, \forall \mathbf{x},\mathbf{y} \end{aligned} \tag{1}$$

[2]The source code of our augmented M3N toolkit can be downloaded at http://code.google.com/p/m3n-ext/

where $\mathbf{x}$ is the observed input sequence, $\mathbf{y} \in \mathcal{Y}$ is the output label sequence, $\alpha_{\mathbf{x},\mathbf{y}}$ are the dual variables to be optimized, and $C \geq 0$ is the regularization parameter to be tuned. $\Delta\mathbf{f}(\mathbf{x}, \mathbf{y}) = \mathbf{f}(\mathbf{x}, \widetilde{\mathbf{y}}) - \mathbf{f}(\mathbf{x}, \bar{\mathbf{y}})$ is the residual feature vector, where $\widetilde{\mathbf{y}}$ is the true label sequence, $\bar{\mathbf{y}}$ is the predicted label sequence given the model, and $\mathbf{f}(\mathbf{x}, \mathbf{y})$ is the feature vector. It is implemented as a sum over all nodes:

$$\mathbf{f}(\mathbf{x}, \mathbf{y}) = \sum_t \mathbf{f}(\mathbf{x}, \mathbf{y}, t) \tag{2}$$

where t is the position index of the node in the sequence. Each component of $\mathbf{f}(\mathbf{x}, \mathbf{y}, t)$ is a feature function, $f(\mathbf{x}, \mathbf{y}, t)$. For example, $f(w_0$='so', y_0='F', y_{-1}='O', $t)$ has a value of 1 only when the word at node t is 'so', the label at node t is 'F' (filler word), and the label at node $(t-1)$ is 'O' (outside edit/filler region, i.e., fluent). The maximum length of the y history (for this feature function, it is 2 since only y_0 and y_{-1} are covered) is called the *clique order* of the feature. $L(\mathbf{x}, \mathbf{y})$ is the loss function. A standard M3N uses an unweighted hamming loss, which is the number of incorrect nodes:

$$L(\mathbf{x}, \mathbf{y}) = \sum_t \delta(\widetilde{y}_t, \bar{y}_t) \qquad \text{where } \delta(a, b) = \begin{cases} 1, & \text{if } a = b \\ 0, & \text{otherwise} \end{cases} \tag{3}$$

Qian and Liu (2013) proposed using label-weighted M3N to balance precision and recall by adjusting the penalty on false positives and false negatives, i.e., $v(\widetilde{y}_t, \bar{y}_t)$ in Eqn. 4. In this work, we further extend this technique to individual nodes to train expert models, each specialized in a specific part-of-speech (POS) class. Our loss function is:

$$L(\mathbf{x}, \mathbf{y}) = \sum_t u_c(t) v(\widetilde{y}_t, \bar{y}_t) \delta(\widetilde{y}_t, \bar{y}_t) \qquad \text{where } u_c(t) = \begin{cases} B_c, & \text{if POS}(t) \in S_c \\ 1, & \text{otherwise} \end{cases} \tag{4}$$

where B_c is a factor which controls the extent to which the model is biased to minimize errors on specific nodes, POS(t) is the POS tag of the word at node t, and S_c is the set of POS tags corresponding to that expert class c. We show that by integrating these expert models into our decoder framework, we can achieve further improvement.

3.2 Features

The feature templates for filler word and edit word prediction are listed in Table 1 and Table 2 respectively. w_i refers to the word at the i^{th} position relative to the current node; *window size* is the maximum number of words before and after the current word that the template covers, e.g., $w_{-1}w_0$ with a window size of 4 means $w_{-4}w_{-3}$, $w_{-3}w_{-2}$, ..., w_3w_4; p_i refers to the POS tag at the i^{th} position relative to the current node; $w_{i\sim j}$ refers to any word from the i^{th} position to the j^{th} position relative to the current node; $w_{i,\neq F}$ refers to the i^{th} word (w.r.t. the current node) not being a filler word; the multi-pair comparison function $I(a, b, c, ...)$ indicates whether each pair (a and b, b and c, and so on) are identical, for example, if $a = b \neq c = d$, it will output "101" ('1' for being equal, '0' for being unequal); and *ngram-score* features are the natural logarithm of the following probabilities: $P(w_{-3}, w_{-2}, w_{-1}, w_0)$, $P(w_0|w_{-3}, w_{-2}, w_{-1})$, $P(w_{-3}, w_{-2}, w_{-1})$, $P(\langle/s\rangle|w_{-3}, w_{-2}, w_{-1})$, $P(w_{-3})$, $P(w_{-2})$, $P(w_{-1})$, $P(w_0)$ ("$\langle/s\rangle$" denotes sentence-end). We use language models (LM) in two ways: individual n-gram scores as M3N features, and an overall sentence-level score for rescoring in our beam-search decoder. Our experiments show that this way of using LM gives the best performance.

We set the frequency pruning threshold to 5, so that the resulting model has about the same total number of parameters (7.6M) as (Qian and Liu, 2013). The clique order for each template is determined by considering the total number of features given that template. For example, for pause duration, there are 10 features (after cumulative binning), so we can set its clique order to 3 since there will be $10 \times 3^3 = 270$ weights; but for word 3-grams, there are 5M features, so setting its clique order to 3 or 2 will give rise to too many weights ($5\text{M} \times 3^3 = 135\text{M}$ for order 3; $5\text{M} \times 3^2 = 45\text{M}$ for order 2), thus we will reduce its clique order to 1. The same principle applies to other feature templates.

Feature Template	Window Size	Clique Order
w_0	4	1
$w_{-1}w_0$	4	2
$I(w_i, w_j)$	10	2
$I(w_i, w_j, w_{i+1}, w_{j+1})$	10	2
p_0	4	1
$p_{-1}p_0$	4	2
$p_{-2}p_{-1}p_0$	4	2
$I(p_i, p_j)$	10	2
$I(p_i, p_j, p_{i+1}, p_{j+1})$	10	2
transitions	0	3

4 The Beam-Search Decoder Framework

4.1 Motivation

There are several limitations in the current M3N or CRF approach. Firstly, current models do not measure the quality of the cleaned-up sentences, i.e., the resulting sentence after removing all predicted filler and edit words. Secondly, one pass of disfluency detection may not be sufficient to detect all disfluencies. Qian and Liu (2013) showed that we can improve the performance significantly by running a second pass of edit detection. Our preliminary experiments also show that additional passes of edit detection further improve the performance. Lastly, we find that edit word detection accuracy differs significantly on words of different POS tags (Table 3). This is because words of different POS tags have different feature distributions. Thus, depending on the POS tag of the current word, the same feature may have different implications for disfluency. For example, consider the feature $I(p_0, p_2)$. When the current word is a determiner, the feature does not strongly suggest an edit word. In "You give me a book, a pen, a pencil, ...", the determiner 'a' gets repeated. However, when the current word is a verb, the feature strongly suggests it is an edit word. In "The hardest thing for us ~~*has been*~~ is to ...", both 'has' and 'is' are third-person singular verbs. Hence, it might be helpful if we train expert models each specialized in detecting edit words belonging to a specific POS and combine them dynamically according to the POS. Motivated by the beam-search decoder for grammatical error correction (Dahlmeier and Ng, 2012) and social media text normalization (Wang and Ng, 2013), we propose a novel beam-search decoder for

disfluency detection to overcome these limitations.

POS	Freq. (%)	Edit F1 (%)
PRP	25.5	92.33

4.2 General Framework

The goal of the decoder is to find the best hypothesis for a given input sentence $\mathbf{w}$. A hypothesis $\mathbf{h}$ is a label sequence, one label for every word in the sentence. To find the best hypothesis, the decoder iteratively generates new hypotheses from current ones using a set of *hypothesis producers* and rescores each hypothesis using a set of *hypothesis evaluators*. For each hypothesis produced, the decoder cleans up the sentence by removing all the predicted filler words and edit words so that subsequent operations can act on the cleaned-up sentence $\bar{\mathbf{w}}$ if needed. Each hypothesis evaluator produces a score f which measures the quality of the current hypothesis based on certain aspects of fluency specific to that hypothesis evaluator. The overall score of a hypothesis is the weighted sum of the scores from all the hypothesis evaluators:

$$score(\mathbf{h}, \mathbf{w}) = \sum_i \lambda_i f_i(\mathbf{h}, \mathbf{w}) \tag{5}$$

The weights λ_is are tuned on the development set using minimum error rate training (MERT) (Och, 2003). The decoding algorithm is shown in Algorithm 1.

In our description, h_i denotes the hypothesized label at the i^{th} position; w_i denotes the word at the i^{th} position; $|\mathbf{h}|$ denotes the length of the label sequence; $f_{M3N}(h_i, \mathbf{w})$ denotes the M3N log-posterior probability of the label (at the i^{th} position of hypothesis $\mathbf{h}$) being the hypothesized label; $f_{M3N}(\mathbf{h}, \mathbf{w})$ denotes the normalized joint log probability of hypothesis $\mathbf{h}$ given the M3N model ('normalized' means divided by the length of the label sequence); $\bar{\mathbf{w}}$ denotes the cleaned-up sentence; $f_{LM}(\bar{\mathbf{w}}) = f_{LM}(\mathbf{h}, \mathbf{w})$ denotes the language model score of the sentence $\bar{\mathbf{w}}$ (cleaned up according to hypothesis $\mathbf{h}$) divided by sentence length; and $\bar{\mathbf{h}}$ denotes the sub-hypothesis obtained by running M3N on the cleaned-up sentence with updated features. Note that a sub-hypothesis will have a shorter label sequence if some words are labeled as filler word or edit word in the parent hypothesis. We can obtain $\mathbf{h}$ from $\bar{\mathbf{h}}$ by inserting all predicted filler and edit words from the parent hypothesis into the sub-hypothesis so that its label sequence has the same length as the original sentence.

4.3 Hypothesis Producers

The goal of hypothesis producers is to create a search space for rescoring using various hypothesis evaluators. Based on the information provided by the existing models and certain patterns where disfluencies may occur, we propose the following hypothesis producers for our beam-search decoder:

Confusable-phrase-dictionary: The motivation of using this hypothesis producer is to hypothesize labels for phrases which are commonly misclassified in the development data. We build a dictionary of

Algorithm 1
The beam-search decoding algorithm for a sentence. S: hypothesis stack; $\mathbf{h}$: hypothesis; $\mathbf{f}$: hypothesis evaluator score vector; $\mathbf{\Lambda}$: hypothesis evaluator weight vector

INPUT: a sentence $\mathbf{w}$ with N words
OUTPUT: a sequence of N labels, from {E, F, O}
initialize hypothesis $\mathbf{h}_0$, h_i='O'$\forall i \in [1, N]$
$S_A \leftarrow \{\mathbf{h}_0\}, S_B \leftarrow \emptyset$
for $iter$ = [1, $maxIter$] **do**
  for each $\mathbf{h}$ in S_A **do**
    for each *producer* in hypothesisProducers **do**
      for each $\mathbf{h}'$ in *producer*($\mathbf{h}$) **do**
        compute $\mathbf{f}(\mathbf{h}', \mathbf{w})$ from hypothesisEvaluators
        compute $score(\mathbf{h}', \mathbf{w}) = \mathbf{\Lambda}^\top \cdot \mathbf{f}(\mathbf{h}', \mathbf{w})$
        $S_B \leftarrow S_B + \{\mathbf{h}'\}$
  prune S_B according to $score$
  $S_A \leftarrow S_B, S_B = \emptyset$
return $argmax_{\mathbf{h}}\{score(\mathbf{h}, \mathbf{w})\}, \mathbf{h} \in S_A$

phrases (up to 5 words) and their corresponding true labels by considering the most frequent incorrectly predicted phrases in the development set. During decoding, whenever such a phrase occurs in a sentence and its label is not the same as that in the dictionary, it is changed to that in the dictionary and a new hypothesis is produced. For example, if the phrase "you know" has occurred 1144 times and has been misclassified 31 times, out of which 9 times it should be 'O', then an entry "you know O || 1144 31 9" will be added to the dictionary. If the original sentence contains "you know" and it is not labeled as O, a new hypothesis will be generated by labeling it as 'O'.

Repetition: Whenever the i^{th} word and the j^{th} word ($j > i$) are the same, all words from the i^{th} position (inclusive) to the j^{th} position (exclusive) are labeled as edit words. For example, in "I want to be able to um I just want it more for multi-tasking", three hypotheses are produced. The first hypothesis is produced by labeling every word in "I want to be able to um" as edit words since 'I' is repeated. The second hypothesis is produced by labeling every word in "want to be able to um I just" as edit words since 'want' is repeated. The third hypothesis is produced by labeling "to be able" as edit words since 'to' is repeated. The window size within which we search for repetitions is set to 12 (i.e., $j - i \leq 12$), since the longest edit region (due to repetition) in the development set is of that size. We introduce this hypothesis producer because the baseline system tends to miss long edit regions, especially when very few words in the region are repeated. However, sometimes a speaker does change what he intends to say by aborting a sentence so that only the beginning few words are repeated, as in the above sentence.

Filler-word-marker: We trained an M3N model for filler word detection. Multiple passes of filler word detection on cleaned-up sentences can sometimes detect filler words that are missed in earlier passes. This hypothesis producer runs before every iteration starts. It performs filler word prediction and modifies the feature table by setting the filler-indicator feature to true so that subsequent operations see the updated feature. However, it does not remove filler words during the clean up process because some words are defined as both filler word and edit word simultaneously.

Edit-word-marker: We run our baseline M3N (the second stage) on the cleaned-up sentence and obtain the N-best hypotheses, i.e., the top N hypotheses $\mathbf{h}$ with $max\{f_{M3N}(\bar{\mathbf{h}}, \bar{\mathbf{w}})\}$. This producer essentially performs multiple passes of disfluency detection.

4.4 Hypothesis Evaluators

Our decoder uses the following hypothesis evaluators to select the best hypothesis:

Fluent language model score: This is the normalized language model score of the cleaned-up sentence, i.e., $f_{fluentLM}(\bar{\mathbf{w}})$. A 4-gram language model is trained on the cleaned-up version of the training

texts (both filler words and edit words are removed). This score measures the fluency of the resulting cleaned-up sentence w.r.t. a fluent language model.

Disfluent language model score: This is the normalized language model score of the cleaned-up sentence, i.e., $f_{disfluentLM}(\bar{\mathbf{w}})$. A 4-gram language model is trained on the original training texts which contain disfluencies. This score measures the fluency of the resulting cleaned-up sentence w.r.t. a disfluent language model. These two LM scores provide contrastive measures because if a cleaned up sentence still contains disfluencies, the disfluent LM will be preferred over the fluent LM.

M3N disfluent score: This is the normalized joint log probability score of the current hypothesis $\mathbf{h}$, i.e., $f_{M3N}(\mathbf{h}, \mathbf{w})$. This score measures how much the baseline M3N model favors the disfluency label assignment of the current hypothesis.

M3N fluent score: This is the normalized joint log probability score of labeling the entire cleaned-up sentence as fluent, i.e.,

$$f_{M3N}(\bar{\mathbf{h}}\text{=}\mathbf{O}, \bar{\mathbf{w}}) = \frac{1}{|\bar{\mathbf{h}}|} \sum_{i=1}^{|\bar{\mathbf{h}}|} f_{M3N}(\bar{h}_i\text{='O'}, \bar{\mathbf{w}}) \tag{6}$$

This score measures how much the baseline M3N model favors the cleaned-up sentence of the current hypothesis. It acts as a discriminative LM in measuring the fluency of the cleaned-up sentence. If the cleaned-up sentence contains disfluencies, this evaluator function will tend to give a lower score.

Expert-POS-class c disfluent score: This is the normalized joint log probability score of the current hypothesis $\mathbf{h}$ under the expert M3N model for POS class c dynamically combined with the baseline M3N model, i.e.,

$$f_c(\mathbf{h}, \mathbf{w}) = \frac{1}{|\mathbf{h}|} \sum_{i=1}^{|\mathbf{h}|} g_c(h_i, \mathbf{w}), \qquad g_c(h_i, \mathbf{w}) = \begin{cases} f_{\text{M3N-}c}(h_i, \mathbf{w}) \text{ if POS}(w_i) \in S_c \\ f_{\text{M3N}}(h_i, \mathbf{w}) \text{ if POS}(w_i) \notin S_c \end{cases} \tag{7}$$

Training of the expert M3N models is described in Section 4.6.

4.5 Integrating M3N into the Decoder Framework

In most previous work such as (Liu et al., 2006) and (Qian and Liu, 2013) that performed filler and edit word detection using sequence models, the begin-inside-end-single (BIES) labeling scheme was adopted, i.e., for edit words (E), 4 labels are defined: E_B (beginning of an edit region), E_I (inside an edit region), E_E (end of an edit region), and E_S (single-word edit region). However, since our beam-search decoder needs to change the labels dynamically among filler words, edit words, and fluent words, it will be problematic if the label sequence has to conform to the BIES constraint especially when the posteriors are concerned. Thus, we use the minimal set of labels: E (Edit word), F (Filler word), O (Outside edit and filler region).

For the first-stage filler word detection, only 'F' and 'O' are used. To compensate for degradation in performance, we increase the clique order of features to 3. We found that increasing the clique order has a similar effect as using the BIES labeling scheme. For example, $f(w_i$='so', y_0='E_B', $t)$ means the previous word is not an edit, both the current word and the next word are edit words, i.e., the previous word, the current word, and the next word can be either O-E-E or F-E-E. So in our minimal labeling scheme, this feature will be decomposed into $f(w_i$='so', y_{-1}='O', y_0='E', y_{+1}='E', $t)$ and $f(w_i$='so', y_{-1}='F', y_0='E', y_{+1}='E', $t)$, both having a higher clique order.

Our preliminary experiments show that by increasing the clique order of features while reducing the number of labels (keeping about the same total number of parameters), we can maintain the same performance. However, training takes a longer time.

4.6 POS-Class Specific Expert Models

We trained 6 expert M3N models, each focusing on disfluency prediction of words belonging to the corresponding set of POS tags. The expert M3N models are trained in the same way as the baseline M3N model, except that we increase the loss weights (Eqn. 4) if the word of that node belongs to

the corresponding POS class. That is, M3N-Expert-POS-class-1 is trained to optimize performance on words belonging to POS-class-1. Nonetheless, it can still predict disfluency for words in other POS classes, except that the error rate may be higher because of the way training is biased.

Class	POS tags	Freq. (%)	F1 range
1	RBS POS PDT NNPS HVS PRP$ BES PRP	33.5	92.3 – 100
2	MD EX CC DT VBP WP WRB	32.2	86.0 – 90.8
3	RB IN	16.7	82.8 – 83.8
4	TO VBD WDT RP JJS	5.1	80.0 – 82.1
5	VBZ VB VBN JJ	6.1	69.3 – 78.1
6	VBG NN CD JJR UH NNS NNP XX RBR	3.2	42.1 – 64.2

Table 4: POS classes for expert M3N models and their baseline F1 scores

We split all POS tags into 6 classes, by first sorting all POS tags in descending order of their F1 scores. Next, for POS tags with higher F1 scores, we form larger classes (higher total proportion), and for POS tags with lower F1 scores, we form smaller classes. The POS classes are shown in Table 4. The algorithm dynamically selects posteriors from different M3N models, depending on the POS tag of the current word.

5 Experiments

5.1 Experimental Setup

We tested all the systems on the Switchboard Treebank corpus (LDC99T42), using the same train/develop/test split as previous work (Johnson and Charniak, 2004; Qian and Liu, 2013). We removed all partial words and punctuation symbols to simulate the condition when automatic speech recognition (ASR) output is used. Our training set contains 1.3M words in 174K sentences; our development set contains 86K words in 10K sentences; and our test set contains 66K words in 8K sentences. The original system has high precision but low recall, i.e., the system tends to miss out edit words. The imbalance can be solved by setting a larger penalty for mis-labeling edits as fluent, i.e., 2 instead of 1 for the weighted hamming loss. We used the loss matrix, $v(\widetilde{y}_t, \bar{y}_t)$, in Table 5 to balance precision and recall. We set the biasing factor B_c to 2, for every class c. We also added two pause duration features (pause duration before and after the current word) from the corresponding Switchboard speech corpus (LDC97S62). We trained our acoustic model on the Fisher corpus and used it to perform forced alignment on the Switchboard corpus to obtain the word boundary time information for calculating pause durations. For the *ngram-score* features, we used the small 4-gram language model trained on the training set with filler words and edit words removed. All continuous features are quantized into 10 discrete bins using cumulative binning (Liu et al., 2006). We set $maxIter$ to 4 in Algorithm 1. The regularization parameter C is set to 0.006, obtained by tuning on the development set.

Label	E	F	O
E	0	1	2
F	1	0	2
O	1	1	0

5.2 Results

We use the standard F1 score as our evaluation metric, the same as (Qian and Liu, 2013). Performance comparison of the baseline model and expert models on subsets belonging to specific POS classes is shown in Table 6. It shows that by assigning larger loss weights to nodes belonging to a specific POS class, we can to various extent boost the performance on words in that POS class. However, doing so

will sacrifice the overall performance on the entire data set especially on POS classes with lower baseline scores (see Table 7). But since we have several expert models, if we combine them, they can complement each other's weakness and give an overall slightly better performance. The result also shows that the gain by training expert models decreases as the baseline performance on that POS class increases. For example, POS class 6 has the poorest baseline performance and the gain is 2.1%. This gain decreases gradually as we move up the table rows because the baseline performance gets better.

POS class	Expert-M3N F1	Baseline-M3N F1
1	92.5	92.2
2	87.1	86.9
3	84.9	84.7
4	85.3	84.1
5	71.8	70.4
6	57.3	55.2

Table 6: Edit detection F1 scores (%) of expert models on all words belonging to that POS class in the test set (expert-M3N column), and baseline model on all words belonging to that POS class in the test set (baseline-M3N column)

System	F1 (%)
Baseline-M3N	84.7
Expert-M3N(1)	84.6
Expert-M3N(2)	84.4
Expert-M3N(3)	84.3
Expert-M3N(4)	84.6
Expert-M3N(5)	84.0
Expert-M3N(6)	83.8

Table 7: Degradation of the overall performance by expert models compared to the baseline model

Table 8 shows the performance comparison of our baseline models and our beam-search decoder. Statistical significance tests show that our best decoder model incorporating all hypothesis evaluators gives a higher F1 score than the 3-label baseline M3N model (statistically significant at $p < 0.001$), and the 3-label baseline M3N model gives a higher F1 score than the M3N system of (Qian and Liu, 2013) (statistically significant at $p = 0.02$). Our three baseline models have about the same total number of parameters (7.6M). The BIES baseline M3N system uses the same feature templates as shown in Table 2 with reduced clique order. The 2-label baseline M3N system uses the same feature templates with the same clique order. Our results also show that joint filler and edit word prediction performs 0.4% better than edit word prediction alone. Direct combination of expert models is done by first running the general model and the expert models on each sentence to obtain all the label sequences (one for each model). Then for every word in the sentence, if its POS belongs to any one of those POS classes, we choose its label from the output of the corresponding expert model; otherwise, we choose its label from the output of the baseline model.

For the decoder, *M3N-disfluent-score* needs to be present in all cases (except when POS experts are present); otherwise, the F1 score is much worse because the entire sequence is not covered (i.e., just looking at the scores from the cleaned-up sentences is not sufficient in deciding how well filler and edit words have been removed). Adding *M3N-fluent-score*, *Fluent-LM*, or *Disfluent-LM* alone with *M3N-disfluent-score* gives about the same improvement; but when combined, higher improvement is achieved.

Similar to (Qian and Liu, 2013), our system does not make use of any external sources of information except for the last two rows in Table 8 where we added pause duration features. We found that adding pause duration features gave a small but consistent improvement in all experiments, about 0.3% absolute gain in F1 score. Our beam-search decoder (multi-threaded implementation) is about 4.5 times slower

System	F1 (%)
M3N system of (Qian and Liu, 2013)	84.1
Our baseline M3N (using BIES for E and F)	84.4
Our baseline M3N (using 2 labels: E,O)	84.3
Our baseline M3N (using 3 labels: E,F,O)	84.7
Direct combination of the 6 POS-expert-models according to each word's POS	85.2
Decoder: M3N-disfluent-score + M3N-fluent-score	85.1

Decoder: M3N-disfluent-score + POS-experts	85.2
Decoder: M3N-disfluent-score + M3N-fluent-score + Fluent-LM + Disfluent-LM	85.6
Decoder: M3N-disfluent-score + M3N-fluent-score + Fluent-LM + Disfluent-LM + POS-experts	85.7
Decoder: M3N-disfluent-score + M3N-fluent-score + Fluent-LM + Disfluent-LM + PauseDur	85.9
Decoder: M3N-disfluent-score + M3N-fluent-score + Fluent-LM + Disfluent-LM + POS-experts + PauseDur	86.1

Table 8: Performance of the beam-search decoder with different combinations of components

than our baseline M3N model (single-threaded). Overall, it took about 0.4 seconds to detect disfluencies in one sentence with our proposed beam-search decoder approach.

To the best of our knowledge, the best published F1 score on the Switchboard Treebank corpus is 84.1% (Qian and Liu, 2013) without the use of external sources of information, and 85.7% (Zwarts and Johnson, 2011) with the use of external sources of information (large language models from additional corpora were used in (Zwarts and Johnson, 2011)). Without the use of external sources of information, our decoder approach achieves an F1 score of 85.7%, significantly higher than the best published F1 score of 84.1% of (Qian and Liu, 2013). Our decoder approach also achieves an F1 score of 86.1% after adding external sources of information (pause duration features), higher than the F1 score of 85.7% of (Zwarts and Johnson, 2011).

5.3 Discussion

We have manually analyzed the improvement of our decoder over the M3N baseline. For example, consider the sentence in Table 9. Both the baseline M3N system and the first pass output of the decoder will give the cleaned-up sentence "*are these do these programs ...*", which is still disfluent and has a relatively lower fluent LM score but a relatively higher disfluent LM score because of the erroneous n-gram "*are these do these*". The decoder makes use of the fluent LM and disfluent LM hypothesis evaluators during the beam search and performs additional passes of cleaning and eventually gives the correct output.

Sentence	*Um*	*and*	*uh*	*are*	*these*	*like*	*uh*	*do*	*these*	*programs*	...

Table 9: An example showing the effect of measuring the quality of the cleaned-up sentence.

Overall, our proposed decoder framework outperforms existing approaches. It also overcomes the limitations mentioned in Section 4.1. For example, hypothesis evaluators like *fluent language model score* and *M3N fluent score* achieve the purpose of measuring the quality of cleaned-up sentences. Repeatedly applying the *edit-word-marker* hypothesis producer on a sentence achieves the purpose of cleaning up

the sentence in multiple passes. Hypothesis evaluators corresponding to expert models achieve the purpose of combining POS class-specific expert models. All of these components extend the flexibility of the decoder framework in performing disfluency detection.

6 Conclusion

In conclusion, we have proposed a beam-search decoder approach for disfluency detection. Our beam-search decoder performs multiple passes of disfluency detection on cleaned-up sentences. It evaluates the quality of cleaned-up sentences and use it as a feature to rescore hypotheses. It also combines multiple expert models to deal with edit words belonging to a specific POS class. In addition, we also proposed a way (using node-weighted M3N in addition to label-weighted M3N) to train expert models each focusing on minimizing errors on words belonging to a specific POS class. Our experiments show that combining the outputs of the expert models directly according to POS tags can give rise to some improvement. Combining the expert model scores with language model scores in a weighted manner using our beam-search decoder achieves further improvement. To the best of our knowledge, our decoder has achieved the best published edit-word F1 score on the Switchboard Treebank corpus, both with and without using external sources of information.

Single Document Keyphrase Extraction Using Label Information

Abstract

Keyphrases have found wide ranging application in NLP and IR tasks such as document summarization, indexing, labeling, clustering and classification. In this paper we pose the problem of extracting *label specific* keyphrases from a document which has document level metadata associated with it namely *labels* or *tags* (i.e. multi-labeled document). Unlike other, supervised or unsupervised, methods for keyphrase extraction our proposed methods utilizes both the document's text and label information for the task of extracting *label specific* keyphrases. We propose two models for this purpose both of which model the problem of extracting label specific keyphrases as a random walk on the document's text graph. We evaluate and report the quality of the extracted keyphrases on a popular multi-label text corpus.

1 Introduction

The use of graphs to model and solve various problems arising in Natural Language Processing have lately become very popular. Graph theoretical methods or graph based approaches have been successfully applied for a varied set of NLP tasks such as Word Sense Disambiguation, Text Summarization, Topic detection etc. One of the earliest and most prominent work in this area has been the TextRank (Mihalcea and Tarau, 2004) method - an unsupervised graph-based ranking model for extracting keyphrases and "*key*" sentences from natural language text. This unsupervised method extracts prominent terms, phrases and sentences from text. The TextRank models the text as a graph where, depending on the end application, text units of various sizes and characteristics can be added as vertices e.g. open class words, collocations, sentences etc. Similarly, based on the application, connections can be drawn between these vertices e.g. lexical or semantic relation, contextual overlap etc. To identify "central" or "key" text units in this text graph, TextRank runs the *PageRank* algorithm on this constructed graph. The ranking over vertices (text units), which indicates their centrality and importance, is obtained by finding the stationary distribution of the random walk on the text graph.

In this paper, we consider the problem of extracting *label specific* keyphrases from a document which has document level metadata associated with it namely *labels* (i.e. multi-labeled document). To elaborate, consider a document as shown in Figure 1. This document has been assigned to two categories as indicated by the labels "*Air Pollution*" and "*Plant Physiology*". Running TextRank on this article yields top ranked key-phrases such as "*calibrated instrument*", "*polluting gases*", "*industrial development*" etc. These keyphrases, though central to the article, are not specific to any of the *labels* that have been assigned to the article. For instance, one would associate keyphrases such as "*carbon monoxide* ", "*air pollutants*" to be more relevant to the "*Air Pollution*" label and keyphrases such as "*stomatal movement*", "*cell defense*" to be more closely associated with the "*Plant Physiology*" label. The objective of this paper is to explore extensions to TextRank for extracting label-specific keyphrases from a multi-labeled document. Such label-specific keyphrases can be useful for a number of practical applications namely: highlighting such terms within the body of a document could provide a label-specific (topic-focussed) view of the document thus facilitating fast browsing and reading of the document, such key terms could also be useful for generating topic-driven or label-specific summaries and in multifaceted search.

Proceedings of COLING 2014, the 25th International Conference on Computational Linguistics: Technical Papers, pages 1468–1476, Dublin, Ireland, August 23-29 2014.

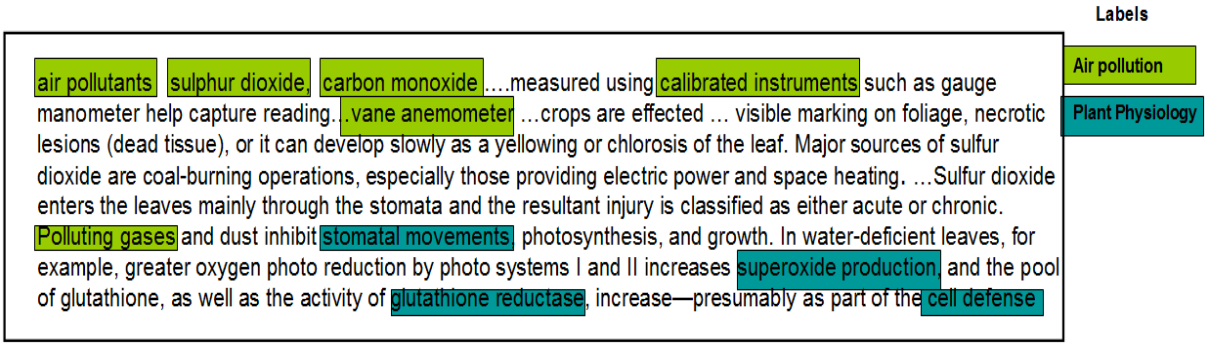

Figure 1: Label specific keyphrases (best viewed in color). Note that there could be keyphrases that are common to both labels. Due to space restrictions only a snippet of the document is shown.

The rest of the paper is organized as following. We discuss related work and provide an overview of our approach in Section 2. Details of the proposed method is discussed in Section 3 followed by evaluation in Section 4. Future work and conclusion is presented in Section 5.

2 Related Work

The methods for keyphrase (or keyword) extraction can be roughly categorized into either *unsupervised* or *supervised*. *Unsupervised methods* usually involve assigning a saliency score to each candidate phrase by considering various features. Popular work in this area include the use of point-wise KL-divergence between multiple language models for scoring both *phrase-ness* and *informativeness* of candidate phrases (Tomokiyo and Hurst, 2003), use of TF-IDF weighting (A. Hulth, 2003) etc. *Supervised machine learning algorithms* have been proposed to classify a candidate phrase into either keyphrase or not using features such as the frequency of occurrence, POS information, and location of the phrase in the document. All the above methods only make use the document text for generating keyphrases and cannot be used (as-is) for generating label-specific keyphrases.

One possible method for extracting label-specific keyphrases from a document could be based on post-processing the output of the TextRank algorithm in the following way (1) Identify a set of *label specific features* f_l^{cand} (unigram terms) that are strongly correlated with the *label*. This could be done by applying feature selection methods (Forman, 2003), (Forman, 2003) on a multi-label text corpus (we discuss this step in more detail in a later section). For instance, $f_{air\_pollution}^{cand}$={"*pollutant*","*gases*",...} (2) Run the TextRank algorithm on the document d to generate a list of keyphrases $keyphrase_d$ (3) *Filter* the resultant list $keyphrase_d$ based on lexical or semantic match with the label specific features f_l^{cand} to generate $keyphrase_d^l$ or label-l specific keyphrase for document d.

This approach suffers from the following limitations (a) The keyphrase list generated in Step (2) i.e. $keyphrase_d$ might be dominated by keyphrases which have little to do with label l. Post processing this list (Step 3) using f_l^{cand} might result in only very few keyphrases in $keyphrase_d^l$. (b) The label specific features f_l^{cand}, which are derived from corpus level statistics[1], might not be the best indicator of the *keyphrase-ness* of a term in the document. (c) Moreover, consider a scenario where a document is associated with more than one label. Consider the previous example where the document is associated with two labels "*Air Pollution*" and "*Plant Physiology*". When extracting keyphrases specific to the label/category "*Air Pollution*" from document d one would expect that the extracted keyphrases are *closer* to the *Air Pollution* label/category and *distant* from other labels associated with document d i.e. "*Plant Physiology*". It is not evident how this can be modeled in this approach. In this paper we propose an approach that models the problem of finding label-specific keyphrases in a document as a random walk on the document's text-graph. Two approaches are proposed namely *PTR: Personalized TextRank* and *TRDMS: TextRank using Ranking on Data Manifolds with Sinks*.

[1]Using feature selection methods

PTR: Personalized TextRank : In this setting the PageRank algorithm, which is the underpinning of the *TextRank* keyphrase extraction algorithm, is replaced with the personalized page rank (Haveliwala, 2002) algorithm. By using the label specific features f_l^{cand} as the *personalization vector* we are able to bias the walk on the underlying text graph towards terms relevant to the label. We discuss this approach in more detail in Section 3.3. Even though using a label specific *transport* or *personalization vector* helps bias the walk towards terms specific to that label, terms relevant to labels other than l continue to influence the walk. The *Personalized TextRank* method offers no elegant solution which would penalize terms unrelated to l while simultaneously preferring terms relevant to label l.

To achieve both these goals in one model we propose the *TRDMS: TextRank using Ranking on Data Manifolds with Sinks* approach. We model the problem of identifying label specific keyphrases in a given document as a random walk over the document's *weighted* text graph with *sink* and *query* nodes[2]. Ranking on data manifolds was first proposed by (Zhou et al., 2004) and has been used for multi-document summarization (Wan et al., 2007), image retrieval (He et al., 2004) etc. An intuitive description of the ranking algorithm is described as follows. A weighted network is constructed first, where nodes represent all the data and query points, and an edge is put between two nodes if they are "*close*". *Query* nodes are then initialized with a positive ranking score, while the nodes to be ranked are assigned a zero initial score. All the nodes, except the *sink* nodes, then propagate their ranking scores to their neighbor via the weighted network. The propagation process is repeated until a global state is achieved, and all the nodes except the query nodes are ranked according to their final scores. Manifold ranking gives high rank to nodes that are close to the query nodes on the manifold (*relevance*) and that have strong centrality (*importance*). Sink nodes, whose ranking is fixed to the minimum (zero) during the ranking process, do not spread any ranking score to their neighbors thus penalizing the nodes that are connected to them. To use this method for extracting label-(l) specific keyphrases , f_l^{cand} are modeled as *query* nodes while features associated with labels other than l are modeled as *sink* nodes. This approach is inspired by the work done by (Cheng et al., 2011) for query recommendation and update summarization. Section 3.4 discusses this method in more detail. To summarize, to the best of our knowledge we are the first to propose the problem of extracting *label* specific keyphrases from a multi-labeled document. Our modifications to TextRank for achieving this task are novel. Moreover, our idea of of using *Ranking on Data Manifolds* on the document-level text graphs for extracting label specific keyphrases is a new contribution.

3 Generating Label Specific Keyphrases

3.1 Notation

In this section we introduce notations which we use throughout the paper. Let D represent a multi-label document corpus and $\Im$ be the set of all possible labels which could be associated with documents in D. A document from this corpus is denoted by d and the set of labels associated with document d is denoted by ℓ, where $d \in D$ and $\ell \subseteq \Im$. The text graph for document d is denoted by G_d and M denotes the number of vertices in G_d . We describe how this text graph is constructed in Section 3.2. Features specific to label l, which are extracted from the corpus D, are represented as f_l^{cand}, where $l \in \Im$. Section 3.5 describes how these *label specific features* are extracted from a multi-label document corpus.

3.2 Building the Text Graph

For a given document d the text graph G_d is built in the following way. All open-class, unigram tokens occurring in d are treated as vertices. Two vertices are connected if their corresponding lexical units co-occur within a window of maximum N words, where N is set to 10 for all our experiments. As indicated by (Mihalcea and Tarau, 2004) co-occurrence links express relations between syntactic elements and represent cohesion indicators for a given text. Note that the methods described in Section 3.3 and Section 3.4 provide a score/rank for each vertex (unigram term) in the graph. To generate keyphrases (n-grams) from these candidate terms the following post-processing is performed on the top ranked terms. Vertices are sorted in reverse order of their score and the top K vertices in the ranking are retained

[2]Nodes correspond to terms in a text graph

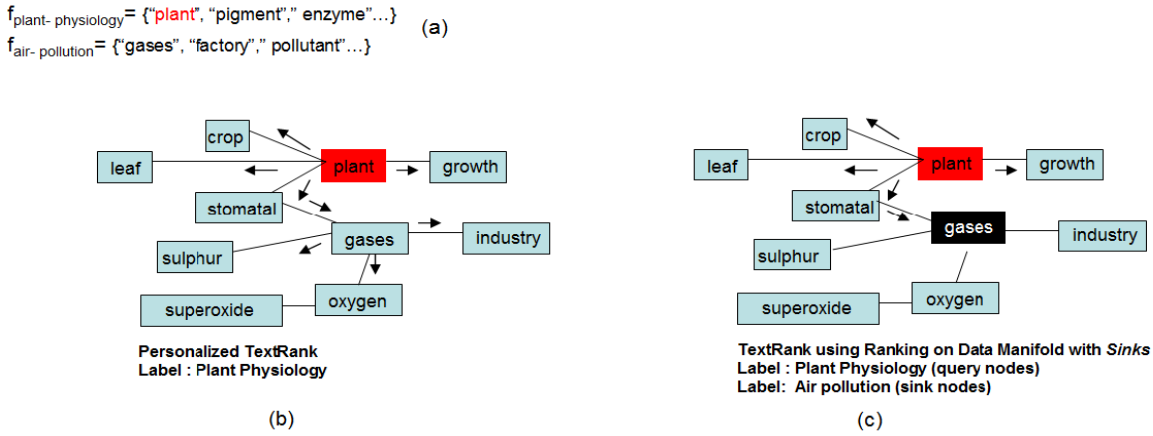

Figure 2: (a) Label specific features f_l^{cand} (b) *Personalized TextRank* - walk biased towards terms related to $f_{plant\_physiology}^{cand}$ (shown in red color). (c) *TextRank using Ranking on Data Manifold with Sinks*: walk biased towards terms related to $f_{plant\_physiology}^{cand}$, while simultaneously penalizing terms that are related to $f_{air\_pollution}^{cand}$. The sink points, which are shown in black color, are vertices whose ranking scores are fixed at the minimum score (zero in our case) during the ranking process. Hence, the sink points will never spread any ranking score to their neighbors. Arrows indicate diffusion of ranking scores (Figure best viewed in color)

for post-processing. Let this ranked list be represented as <T_K>. During post-processing, all terms selected as potential keywords are marked in the text, and sequence of adjacent keywords are collapsed into a multi-word keyphrase. For example, in the text *calibrated instruments are used to measure*, if the unigram terms *calibrated* and *instruments* are selected as potential/candidate terms by the PTR or TRDMS method, since they are adjacent they are collapsed into one single keyphrase "*calibrated instruments*". This heuristic is implemented as a function which is referred as $kphrase_{gen}$(<T_K>,d). This function takes as input the ranked term list <T_K> and the document text d and returns the collapsed set of keyphrases. A similar approach was adopted in the *TextRank* (Mihalcea and Tarau, 2004) work.

3.3 *PTR*: Personalized TextRank

For extracting label-l specific keyphrases from document d we modify the TextRank (Mihalcea and Tarau, 2004) algorithm. We replace the *PageRank* algorithm used in the *TextRank* method with the *Personalized Page Rank* (Haveliwala, 2002) algorithm. PageRank gives a stationary distribution of a random walk which, at each step, with a certain probability ϵ jumps to a random node, and with probability 1-ϵ follows a randomly chosen outgoing edge from the current node. More formally, let G_d denotes the text graph of document d with M vertices where d_i denotes the out degree of node w_i, then $p = \epsilon Lp + (1\text{-}\epsilon)v$. Where p is the page rank vector, L is a $M \times M$ transition probability matrix with L_{ji}=$\frac{1}{d_i}$. In the page rank equation v is a stochastic normalized vector whose element values are all $\frac{1}{M}$. This assigns equal probabilities to all nodes in the graph in case of random jumps. In the *personalized* page rank formulation the vector v can be non-uniform and can assign stronger probabilities to certain kind of nodes effectively biasing the PageRank vector. In the *PTR* approach v is modeled to capture the evidence that is available for label l in document d. Doing so biases the walk towards terms that are more specific to label l in the document. This is achieved by considering vertices (terms) that are common between the label l feature vector i.e. f_l^{cand} and the text graph for document d i.e. G_d. More precisely, for a label l associated with a document d, let V_d^l denote the intersection of the set V_d with f_l^{cand}, i.e. $V_d^l = V_d \cap f_l^{cand}$, where V_d denote the vertex set for the text graph G_d[3] and $l \in \ell$. In this way V_d^l indicates the *evidence* we have for label l in the text graph G_d. To illustrate this point consider Figure 2. The label specific features for label $Plant\ Physiology$ is shown in Figure 2 (a) denoted as $f_{plant-physiology}^{cand}$. The term colored in red

[3] G_d is the text graph built for document d using the method outlined in Section 3.2.

indicates the term that is common between $f^{cand}_{plant-physiology}$ and G_d i.e. $V^{plant-physiology}_d$

Having identified the nodes (V^l_d) which should be allocated stronger probabilities in v the next step is to devise a mechanism to determine these probabilities. We experiment with four approaches. In the first approach, referred to as $seed\_nodes\_only$, we allocate all the probability mass in v uniformly to the nodes in V^l_d, all other nodes i.e. nodes $\notin V^l_d$ are assigned zero probability. In the second approach, referred to as the $seed\_and\_eta$ approach, we keep aside a small fraction η of the probability mass, which is distributed uniformly to all the nodes $\notin V^l_d$, the rest of the probability mass i.e. 1-η[4] is uniformly distributed to all nodes $\in V^l_d$. The third approach, referred to as $non\_uniform\_seed\_only$, is similar to the $seed\_nodes\_only$ approach except that in this case the probability mass in v is not allocated uniformly to the nodes in V^l_d. Probability mass is allocated to the nodes in proportion to their importance, as indicated by the weights allocated to the feature in f^{cand}_l by the feature selection method used. As we discuss in Section 3.5 the feature selection methods, which are used for generating label specific feature f^{cand}_l, compute weights for individual features in f^{cand}_l. These weights (e.g mutual information score, t-score) indicate the strength of association between the feature and the label. In the $non\_uniform\_seed\_only$ approach we allocate probability mass to nodes in V^l_d in proportion to their *feature weights*. Finally, in the $non\_uniform\_eta$ approach we distribute the probability mass i.e. 1-η amongst the V^l_d in proportion to their *feature weights*. The left probability mass of η is distributed uniformly amongst other nodes $\notin V^l_d$. Performance of these different configurations are evaluated in Section 4.1.

One shortcoming of the *PTR* approach is that it does not provides a clean mechanism to integrate features from labels other than l which are associated with the document d. The motivation of doing so is to on one hand bias the walk on the text graph towards terms in f^{cand}_l while simultaneously penalizing terms which are in F_{cand} = $\cup_{k \neq l \text{ and } k \in \ell} f^{cand}_k$[5]. As shown in Figure 2 (b) not incorporating this information results in a leakage of scores (indicated using arrows) to nodes not relevant to label l (e.g. *gases*, *sulphur* etc) . In the next section we describe the ***TRDMS*** or ***TextRank using Ranking on Data Manifold with Sinks*** approach which allows us to simultaneously consider both f^{cand}_l and F_{cand} in the same model.

3.4 *TRDMS*: TextRank using Ranking on Data Manifold with Sinks

Algorithm 1: Algorithm for generating label-l specific keyphrases for document d

Data: Document d, label-l specific unigram features f^{cand}_l, unigram features for label categories other than l represented as F_{cand} = $\cup_{k \neq l and\ k \in \ell} f^{cand}_k$
Result: label-l specific keyphrases from document d
1. Build a Text Graph G_d for document d as discussed in Section 3.2. Let w_i indicate the vertices in G_d ;
2. Construct an *affinity matrix* A, where A_{ij} = *sim*(w_i,w_j) if there is an edge linking w_i, w_j in G_d. *sim*(w_i,w_j) indicates similarity between vertices w_i, w_j ;
3. Symmetrically, normalize A as S = $D^{-1/2}AD^{-1/2}$. D is a diagonal matrix matrix with its (*i*,*i*)-element equal to the sum of the *i*-th row A;
4. **while** *(!*converge*(p))* **do**
   Iterate $p(t+1)$ = $\alpha SIp(t)$ + (1-α)y ;
   /* where 0 <α <1 and I is an indicator diagonal matrix with it's (i,i)-element equal to 0 if $w_i \in V^{\neg l}_d$ and 1 otherwise.*/
end
5. Sort the vertices $w_q \in V_q$ in descending order of their scores $p[q]$. Let this ranked list be represented as <T_K>;
6. $kphrase^l_d$ = $kphrase_{gen}$(<T_K>,d) , where $kphrase^l_d$ is the label-l specific keyphrase list for document d;
7. return $kphrase^l_d$;

In this section we describe the *TextRank using Ranking on Data Manifold with Sinks* approach that allows us to simultaneously consider both f^{cand}_l and F_{cand} when extracting label l specific keyphrases from document's d text graph. For ease of exposition we repeat a few notations and introduce some new ones. Let V_d denote the vertex set for the text graph G_d. Vertices for the text graph G_d are represented by w_i where $i \in$ [1..M], M is the number of vertices i.e. M=$|V_d|$. As introduce earlier, V^l_d denotes the

[4]Please note v is a stochastic normalized vector whose elements sum to 1. In our experiments we set η=0.2
[5]Where ℓ indicates the label set associated with document d

intersection of the set V_d with f_l^{cand}, i.e. $V_d^l = V_d \cap f_l^{cand}$. V_d^l indicates the *evidence* we have for label l in the text graph G_d, where $l \in \ell$. These vertices are also referred to as *query nodes* in the ranking on data manifold literature. Let $V_d^{\neg l}$ denote the intersection of the set V_d with F_{cand}, where $F_{cand} = \cup_{k \neq l \text{ and } k \in \ell} f_k^{cand}$ i.e. all the unigram features associated with label categories other than l[6]. These vertices are also referred to as *sink nodes* in the ranking on data manifold literature. All other vertices are indicated by V_d^q, where $V_d^q = V_d \setminus (V_d^{\neg l} \cup V_d^l)$ denote the set of points to be ranked. Let $p{:}V \rightarrow \Re$ denote the ranking function which assigns a ranking score p_i to each vertex w_i in G_d. One can view p as a vector i.e. $p = [p_1,....,p_M]$. A binary vector $y = [y_1,....,y_M]$ is defined in which $y_i = 1$ if $w_i \in V_d^l$ otherwise $y_i = 0$.

Algorithm 1 gives a detailed outline of the *TRDMS* method. This algorithm is based on the algorithm proposed by (Cheng et al., 2011) for ranking on data manifold with sink points. To generate label-l specific keyphrase for document d the algorithm considers document d, label-l specific unigram features f_l^{cand}, and unigram features for labels other than l represented as F_{cand}. It begins by first building a text graph G_d. After this an affinity matrix A is constructed. This is shown in Step 2. The affinity matrix A, which captures the similarity between vertices (terms in the text graph) w_i and w_j, is built using WordNet. We use the popular WordNet::Similarity (Pedersen et al., 2004) package which measures the semantic similarity and relatedness between a pairs of concepts. After symmetrically normalizing A (Step 3) and initializing the *query* and *sink* nodes the scores are propagated till convergence (Step 4). The routine *converge(p)* checks for convergence by comparing the value of p between two consecutive iterations. If there is little or no change in p the routine return *true*. To generate n-gram keyphrases we follow the approach described in Section 3.2. In Step 6 of Algorithm 1 the $kphrase_{gen}$[7] routine is invoked. In order to choose top-k, label-l specific keyphrases for document d one can select the first k elements of the $kphrase_d^l$ list.

3.5 Generating label specific features from a multi-label corpus

As discussed in previous sections the label specific features f_l^{cand} play an important role in the overall ranking process. When searching for label-l specific keyphrases, the unigram features f_l^{cand} helps bias the walk on the document's text graph towards terms that are relevant and central to label l. We also saw that by considering F_{cand} i.e. unigram features belonging to label categories other than l[8] as *sink* nodes prevents *leakage* of the ranking score to terms not relevant or central to l. We show through experiments in Section 4 that this improves the quality of label-l specific keyphrases extracted from document d. In order to generate *label specific features* from a multi-label corpus D we adopt the *problem transformation* approach commonly used in multi-label learning. In this approach the multi-label corpus D is transformed into $\mid \Im \mid$ single-label data sets, where $\Im$ is the set of labels associated with corpus D. Post this transformation any single-*label* feature selection method can be used to extract label l specific features from these single-label data sets. For our setup we experiment with unigram features selected using mutual information and chi-squared based feature selection methods.

4 Experiment

In order to assess the quality of the label-specific keyphrases generated by our system we conduct a manual evaluation of the generated output. Details of this evaluation are provided in Section 4.1. For our experiments we use a subset of the multi-label corpus EUR-Lex[9]. The EUR-Lex text collection is a collection of documents about European Union law. It contains many different types of documents, including treaties, legislation, case-law and legislative proposals, which are labeled with EUROVOC descriptors. A document in this data-set could be associated with multiple EUROVOC descriptors[10]. The data set that was downloaded contained 16k documents documents and 3,993 EUROVOC descriptors.

[6] We do not assume that $f_l^{cand} \cap F_{cand} = \emptyset$

[7] Details of this routine are provided in Section 3.2

[8] In cases where the document is associated with more than one label or category

[9] http://www.ke.tu-darmstadt.de/resources/eurlex

[10] We treat these as labels

Method	*Precision*$^{\text{avg}}$	*Recall*$^{\text{avg}}$	*F-measure*$^{\text{avg}}$

$PTR_{\text{non\_uniform\_eta}}$	0.237	0.257	0.247
TRDMS	0.397	0.387	0.392

Table 1: Keyphrase Extraction Results

We removed labels that were under represented[11] in this data set. We refer to this data set as the $EUR-Lex_{filtered}$ data set. We randomly selected 100 documents from the $EUR-Lex_{filtered}$ data set. Two criteria were considered when selecting these documents (a) Each document should be associated with at least 2 but not more than 3 labels (b) The size of the *evidence* set i.e. $|V_d^l|$ where $V_d^l = V_d \cap f_{cand}^l$ is at least 10% of $|V_d|$, where V_d represents the vertex set of the text graph associated with d. The resulting data set is referred to as the $EUR-Lex_{filtered}^{keyphrase}$ data set. The reason for enforcing these two criteria is the following. Ensuring that a document in $EUR-Lex_{filtered}^{keyphrase}$ has at least 2 labels allows us to experiment with *sink nodes* i.e. F_{cand}. As we discuss in Section 4.1 for each *label* associated with a document, a human evaluator was asked to generates a label specific list of keyphrases. For example, if a document is associated with 3 labels, three label specific keyphrase list had to be generated by the human evaluator. Allowing documents with more than 3 labels makes this process tedious. The reason for putting restriction (b) when building the $EUR-Lex_{filtered}^{keyphrase}$ is explained in Section 4.1.1. For generating label-l specific features we use the approach described in Section 3.5. For our experiments mutual information based feature selection method was used with a feature size of 250 i.e. $|f_l^{cand}| = 250$.

4.1 Label-specific Keyphrase Evaluation

Two graduate students were asked to manually extract label-specific keyphrases for each document in the $EUR-Lex_{filtered}^{keyphrase}$ data set. At most 10 keyphrases could be assigned to each document-label pair. This results in a total of 1721 keyphrases. The Kappa statistics for measuring inter-agreement among the annotation was 0.81. Any annotation conflicts between the two subjects was resolved by a third graduate student. For evaluation, the automatically extracted label-specific keyphrases for a given document were compared with the manually extracted/annotated keyphrases. Before comparing the keyphrase, the words in the keyphrase were converted to their corresponding base form using word stemming. We calculate three evaluation metrics namely Precision, Recall and F-measure for each document-label pair. Precision (P) = $\frac{count_{correct}}{count_{system}}$, Recall (R) = $\frac{count_{correct}}{count_{human}}$ and F-measure (F) = $\frac{2PR}{P+R}$, where $count_{correct}$ is the total number of correct keyphrases extracted by our method, $count_{system}$ is the total number of automatically extracted keyphrases and $count_{human}$ is the total number of keyphrases labeled by the human annotators. These metrics are calculated for each document-label pair in the $EUR-Lex_{filtered}^{keyphrase}$ data set and then averaged to obtain $Precision^{avg}$, $Recall^{avg}$ and $F-measure^{avg}$. These results are shown in Table 1

We compare the performance of our system against the *TextRank with Post-Processing:* $TPP_{baseline}$ baseline which was explained in Section 2. Briefly, in this setup to identify label-l specific keyphrases in document d, we run *TextRank* on document d and filter the generated keyphrase list based on f_l^{cand} i.e. label l specific features. In all setups the document text graph is built in the same fashion i.e. N = 10 and co-occurrence relationship is used to draw edges between nodes in the text graph. For generating the affinity matrix A, which is used in the *TRDMS* method, the *res* semantic similarity method is used[12]. To reiterate, when generating label-l specific keyphrases for document d the *PTR* method only uses f_l^{cand}, whereas the *TRDMS* method uses both f_l^{cand} (as *query* nodes) and $F_{cand} = \cup_{k \neq l \text{ and } k \in \ell} f_k^{cand}$ (where

[11] Any label which occurred less than 10% times in the data set was removed. The documents associated with these labels were also removed from the data set

[12] We experimented with other semantic similarity measures such as *lin* and *jcn*. The *res* measure gave us the best results

ℓ is the set of labels associated with document d) i.e. all the unigram features associated with label categories other than l (as *sink* nodes). One can observe from Table 1 that for *PTR* the *non_uniform_eta* configuration gives the best result. Overall the *TRDMS* approach significantly outperforms all *PTR* configurations and our baseline. This validates our belief that one can significantly improve the quality of extracted keyphrase by not only considering label-l specific features i.e. f_l^{cand} but also features associated with label categories other than l. When we analyzed the performance of *TRDMS* at the document level we observed that the keyphrase extraction metrics for documents which had *strongly correlated labels* e.g. "*tariff_quota*" and "*import_license*" was 9-11% lower than the reported average scores. On the contrary, keyphrase extraction metrics for documents which had labels that had no or weak correlation e.g. "*aid_contract*" and "*import_license*" was 3-5% higher than the reported average scores. One reason for this could be the substantial overlap between f_l^{cand} and F_{cand} for highly correlated labels. This large overlap results in the *query* nodes being considered as *sink* nodes which negatively impacts the score propagation in the underlying text graph.

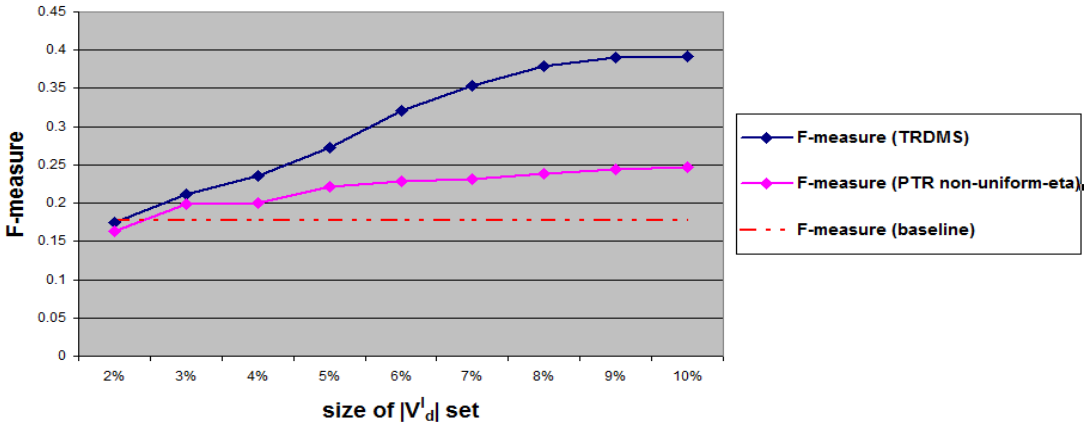

Figure 3: Impact of evidence set size on F-measure (best viewed in color)

4.1.1 Impact of evidence set size ($|V_d^l|$) on keyphrase generation results

To recap, elements in set V_d^l indicate the *evidence* we have for label l in the text graph of document d i.e. G_d. In order to investigate how the size of the evidence set i.e. $|V_d^l|$ impacts the performance of our system the following simulation was carried out. In different setups we randomly drop out elements from V_d^l so that the size of the resulting evidence set ranges from 2% to 10% of $|V_d|$, where $|V_d|$ represents the vertex set size of text graph G_d. We plot the impact this has on the F-measure in Figure 3. One observes that when the *evidence* set size is in the range 2-4% the gains over the $TPP_{baseline}$ baseline (0.177) are low to modest. As the evidence set size increases the gains over the baseline increases substantially.

5 Conclusion and Future Work

In this paper we presented the problem of extracting label specific keyphrases from a document. We pose the problem of extracting such keyphrases from a document as a random walk on a document's text graph. The methods proposed in this paper utilizes the *label specific features*, which are strongly associated with the label, to bias the walk towards terms that are more relevant to the label. We show through experiments that when generating label-l specific keyphrases it helps to consider both label-l specific features and features associated with labels other than l. As future work we would like to further assess the quality of the generated keyphrases by using these keyphrases for generating topic (or label) focused document summaries.

Abstract

While reading a document, a user may encounter concepts, entities, and topics that she is interested in exploring more. We propose models of "interestingness", which aim to predict the level of interest a user has in the various text spans in a document. We obtain naturally occurring interest signals by observing user browsing behavior in clicks from one page to another. We cast the problem of predicting interestingness as a discriminative learning problem over this data. We leverage features from two principal sources: textual context features and topic features that assess the semantics of the document transition. We learn our topic features without supervision via probabilistic inference over a graphical model that captures the latent joint topic space of the documents in the transition. We train and test our models on millions of real-world transitions between Wikipedia documents as observed from web browser session logs. On the task of predicting which spans are of most interest to users, we show significant improvement over various baselines and highlight the value of our latent semantic model.

1 Introduction

Reading inevitably leads people to discover interesting concepts, entities, and topics. Predicting what interests a user while reading a document has important applications ranging from augmenting the document with supplementary information, to ad placement, to content recommendation. We define the task of predicting **interesting things (ITs)** as ranking text spans in an unstructured document according to whether a user would want to know more about them. This desire to learn more serves as our proxy for interestingness.

There are many types of observable behavior that indicate user interest in a text span. The closest one to our problem definition is found in web browsing, where users click from one document to another via named anchors. The click process is generally governed by the user's interest (modulo erroneous clicks). As such, the anchor name can be viewed as a text span of interest for that user. Furthermore, the frequency with which users, in aggregate, click on an anchor serves as a good proxy for the level of interest[1].

What is perceived as *interesting* is influenced by many factors. The semantics of the document and candidate IT are important. For example, we find that when users read an article about a movie, they are more likely to browse to an article about an actor or character than to another movie or the director. Also, user profile and geo-temporal information are relevant. For example, interests can differ depending on the cultural and socio-economic background of a user as well as the time of the session (e.g., weekday versus weekend, daytime versus late night, etc.).

[1] Other naturally occurring expressions of user interest, albeit less fitting to our problem, are found in web search queries, social media engagement, and others.

Proceedings of COLING 2014, the 25th International Conference on Computational Linguistics: Technical Papers, pages 1477–1488, Dublin, Ireland, August 23-29 2014.

Strictly speaking, human interestingness is a psychological and cognitive process (Varela et al., 1991). Clicks and long dwell times are salient observed behavioral signals of interestingness that have been well accepted in the information retrieval literature (Claypool et al., 2001; Mueller and Lockerd, 2001). In this paper, we utilize the observed user's browsing behavior as a supervision signal for modeling interestingness. Specifically, we cast the prediction of ITs as a discriminative learning task. We use a regression model to predict the likelihood of an anchor in a Wikipedia article to be clicked, which as we have seen above can serve as a proxy for interestingness. Based on an empirical study of a sample of our data, we use features in our model from the document context (such as the position of the anchor text, frequency of the anchor text in the current paragraph, etc.) as well as semantic features that aim to capture the latent topic space of the documents in the browsing transition. These semantic features are obtained in an unsupervised manner via a joint topic model of source and target documents in browsing transitions. We show empirical evidence that our discriminative model is effective in predicting ITs and we demonstrate that the automatically learned latent semantic features contribute significantly to the model performance. The main contributions of this paper are:

- We introduce the task of predicting interesting things as identifying what a user likely wants to learn more about while reading a document.
- We use browsing transitions as a proxy for interestingness and model our task using a discriminative training approach.
- We propose a semantic probabilistic model of interestingness, which captures the latent aspects that drive a user to be interested in browsing from one document to another. Features derived from this semantic model are used in our discriminative learner.
- We show empirical evidence of the effectiveness of our model on an application scenario.

2 Related Work

Salience: A notion that might at first glance be confused with interestingness is that of salience (Paranjpe 2009; Gamon et al. 2013). Salience can be described as the centrality of a term to the content of a document. Put another way, it represents what the document is about. Though salience and interestingness can interact, There are clear differences. For example, in a news article about President Obama's visit to Seattle, Obama is salient, yet the average user would probably not be interested in learning more about Obama while reading that article.

Click Prediction: Click prediction models are used pervasively by search engines. Query based click prediction aims at computing the probability that a given document in a search-result page is clicked on after a user enters some query (Joachims, 2002; Joachims et al., 2005; Agichtein et al., 2006; Guo et al., 2009a). Click prediction for online advertising is a core signal for estimating the relevance of an ad to a search result page or a document (Chatterjee et al., 2003; Broder et al., 2007; Craswell et al., 2008; Graepel et al., 2010). Also related are personalized click models, e.g., (Shen et al., 2012), which use user-specific click through rate (CTR). Although these applications and our task share the use of CTR as a supervision signal, there is a key difference: Whereas in web search CTR is used as a predictor/feature at runtime, our task specifically aims at predicting interestingness in the absence of web usage features: Our input is completely unstructured and there is no assumption of prior user interaction data.

Use of probabilistic models: Our semantic model is built over LDA (Blei et al., 2003) and has resemblances to Link-LDA models (Erosheva et al., 2004) and Comment-LDA models (Yano et al., 2009). However, these are tailored for blogs and associated comment discussions which is very different from our source to destination browsing transition logs. Guo et al., (2009b) used probabilistic models for discovering entity classes from query logs and in (Lin et al., 2012), latent intents in entity centric search were explored. Gao et al. (2011) employ statistical machine translation to connect two types of content, learning semantic translation of queries to document titles. None of the above models, however, are directly applicable to the joint topic mappings that are involved in source to destination browsing transitions which are the focus of our work.

Predicting Popular Content: Modeling interestingness is also related to predicting popular content in the Web and content recommenders (Lerman and Hogg, 2010; Szabo and Huberman, 2010; Bandari et al., 2012). In contrast to these tasks, we strive to predict what term a user is likely to be interested in when reading content. We do not rely on prior browsing history, since we aim to predict interestingness

in unstructured text with no interaction history. We show in our experiments that a popularity signal alone is not a sufficient predictor for interestingness.

3 The Interestingness Task

The process of identifying interesting things (ITs) on a page consists of two parts: (1) generating candidate things (e.g., entities, concepts, topics); and (2) scoring and ranking these according to interestingness. In this paper, we fix step 1 and focus our effort on step 2, i.e., the assignment of an interestingness score to a candidate. We believe that this scope is appropriate in order to understand the factors that enter into what is perceived as interesting by a user. Once we have gained an understanding of the interestingness scoring problem, however, there are opportunities in identifying candidates automatically, which we leave for future work.

In this section we begin by formally defining our task. We then introduce our data set of naturally occurring interest signals, followed by an investigation of the factors that influence them.

3.1 Formal Task Definition

We define our task as follows. Let U be the set of all documents and A be the set of all candidate text spans in all documents in U, generated by some candidate generator. Let $A_u \subset A$ be the set of candidates in $u \in U$. We formally define the interestingness task as learning the function below, where $\sigma(u, a)$ is the interestingness of candidate a in [2]:

$$\sigma: U \times A \to \mathbb{R} \quad (1)$$

3.2 Data Set

User browsing events on the web (i.e., a user clicking from one document to another) form a naturally occurring collection of interestingness signals. That is when a user clicks on an anchor in a document, we can postulate that the user is interested in learning more about it, modulo erroneous clicks.

We collect a large set of many millions of such user browsing events from session logs of a commercial web browser. Specifically, we collect from these logs each occurrence of a user click from one Wikipedia page to another during a one month period, from all users in all parts of the world. We refer to each such event as a *transition*. For each transition, our browser log provides metadata, including user profile information, geo-location information and session information (e.g., time of click, source/target dwell time, etc.) Our data set includes millions of transitions between Wikipedia pages.

For our task we require: (1) a mechanism for generating candidate things; (2) ample clicks to serve as a reliable signal of interestingness for training our models; and (3) accessible content. Our focus on Wikipedia satisfies all. First, Wikipedia pages tend to contain many anchors, which can serve as the set of candidate things to be ranked. Second, Wikipedia attracts enough traffic to obtain robust browsing transition data. Finally, Wikipedia provides full content[3] dumps. It is important here to note that our choice of Wikipedia as a test bed for our experiments does not restrict the general applicability of our approach: We propose a semantic model (Section 4.2) for mining latent features relevant to the phenomenon of interestingness which is general and can be applied to generic Web document collections.

Using uniform sampling, we split our data into three sets: a development set (20%), a training set (60%) and a test set (20%). We further subdivide the test set by assigning each transition as belonging to the HEAD, TORSO, or TAIL, which we compute using inverse CDF sampling on the test set. We do so by assigning the most frequently occurring transitions, accounting for 20% of the (source) traffic, to the HEAD. Similarly, the least frequently occurring transitions, accounting for 20% of the (source) traffic, are assigned to the TAIL. The remaining transitions are assigned to the TORSO. This three-way split reflects a common practice in the IR community and is based on the observation that web traffic frequencies show a very skewed distribution, with a small set of web pages attracting a large amount of traffic, and a very long tail of infrequently visited sites. Different regions in that distribution often show marked differences in behaviour, and models that are useful in one region are not necessarily as useful in another.

---

[2] We fix $\sigma(u, a) = 0$ for all $a \notin A_u$.

[3] We utilize the May 3, 2013 English Wikipedia dump from http://dumps.wikimedia.org, consisting of roughly 4.1 million articles.

3.3 What Factors Influence Interestingness?

We manually inspected 200 random transitions from our development set. Below, we summarize our observations.

Only few things on a page are interesting: The average number of anchors on a Wikipedia page is 79. Of these, only very few are actually clicked by users. For example, the Wikipedia article on the TV series "The Big Bang Theory" leads to clicks on anchors linking to the pages of the series' actors for 90% of transitions (while these anchors account for only a small fraction of all unique anchors on that page).

The semantics of source and destination pages is important: We manually determined the entity type of the Wikipedia articles in our sample, according to schema.org classes. 49% of all source urls in our data sample are of the `Creative Work` category, reflecting the strong popular interest in movies (37%), actors (22%), artists (18%), and television series (8%). The next three most prominent categories are `Organization` (12%), `Person` (11%) and `Place` (6%). We observed that transitions are influenced by these categories. For example, when the source article category is `Movie`, the most frequently clicked pages are of category `Actor` (63%) and `Character` (13%). For source articles of the `TVSeries` category, `Actor` destination articles account for 86% of clicks. `Actor` articles lead to clicks on `Movie` articles (45%) and other `Actor` articles (26%), whereas `Artist` articles lead to clicks on other `Artist` articles (29%), `Movie` articles (17%) and `MusicRecording` articles (18%).

The structure of the source page plays a role: It is well known that the position of a link on a page influences user click behavior: links that are higher on a page or in a more prominent position tend to attract more clicks. We noticed similar trends in our data.

The user plays a role: We hypothesized that users from different geographic and cultural backgrounds might exhibit different interests, or that interests are time-bound (e.g., interests on weekends differ from those on week days, daytime from nighttime, etc.) Initial experiments showed small effects of these factors, however, a more thorough analysis on a larger sample is necessary, which we leave for future work.

4 Modeling Interestingness

We cast the problem of learning the interestingness function σ (see Eq. 1) as a discriminative regression learning problem. Below, we first describe this model, and then we introduce our semantic topic model which serves to provide semantic features for the discriminative learner.

4.1 Discriminative Model

Although our task is to predict ITs from unstructured documents, we can leverage the user interactions in our data, described in Section 3.2 as our training signal.

Given a source document $s \in U$, and an anchor in s leading to destination document d, we use the aggregate click frequency of this anchor as a proxy for its interestingness, i.e.:

$$\sigma(s, d) = p(d|s) \qquad (2)$$

where $p(d|s)$ is the probability of a user clicking on the anchor to d when viewing s[4]. We use $p(d|s)$ as our regression target computed from our training data.

For our learning algorithm, we use boosted decision trees (Friedman, 1999). We tune our hyperparameters (i.e., number of iterations, learning rate, minimum instances in leaf nodes, and the maximum number of leaves) using cross-validation on the development set. Each transition in our training data is represented as a vector of features, where the features fall into three basic families:

1 Anchor features (**Anc**): position of the anchor in the document, frequency of the anchor, anchor density in the paragraph, and whether the anchor text matches the title of the destination page.
2 User session features (**Ses**): city, country, postal code, region, state and timezone of the user, as well as day of week, hour, and weekend vs. workday of the occurrence of the transition.

[4] For notational convenience, we use $\sigma(s, d)$ even though Eq. 1 defines its second argument as being a candidate text span. Here, it is implicit that *d* consists of both the target document and the anchor text (which serves as the candidate text span).

3 Semantic features: sourced in various experimental configurations from (1) Wikipedia page categories as assigned by Wikipedia editors (**Wiki**) or from (2) an unsupervised joint topic transition model (**JTT**) of source and destination pages (described in detail in the next section).

In some experimental configurations we use Wikipedia page categories as semantic features. We show in our experiments (see Section 5) that these are highly discriminative. It is important to note that editor-labeled category information is available in the Wikipedia domain but not in others. In other words, we can use this information to verify that semantics indeed is influential for interestingness, but we should design our models to not rely on this. We thus build an unsupervised semantic model of source and destination pages, which serves the purpose of providing semantic information without any domain-specific annotation.

4.2 The Semantics of Interestingness

As indicated in Section 3, the semantics of source and destination pages, s and d, influence the likelihood that a user is interested in d after viewing s. In this section we propose an unsupervised method for modeling the transition semantics between s and d. As outlined in the previous section, this model then serves to generate semantic features for our discriminative model of interestingness.

Referring to the notations in Table 1, we start by positing a distribution over the joint latent transition topics (in the higher level of semantic space), θ_t for each transition t. The corresponding source $t(s)$ and destination $t(d)$ articles of a given transition t are assumed to be admixtures of latent topics that are conditioned on the joint topic transition distribution, θ_t. For ease of reference, we will refer to this model as the Joint Transition Topic Model (**JTT**). The variable names and their descriptions are provided in Table 1. Figure 1 shows the plate notation of our model and the generative process:

1. For each topic k, draw $\varphi_k \sim Dir(\beta)$
2. For each transition t:
   a. Draw the joint topic transition distribution, $\theta_t \sim Dir(\alpha)$
   b. For each word token $j \in \{1 \dots N_S\}$:
      i. Draw $z^S_{t,j} \sim Mult(\theta_t)$
      ii. Emit $w^S_{t,j} \sim Mult(\varphi_k)$
   c. For each word token $j \in \{1 \dots N_D\}$:
      i. Draw $z^D_{t,j} \sim Mult(\theta_t)$
      ii. Emit $w^D_{t,j} \sim Mult(\varphi_k)$

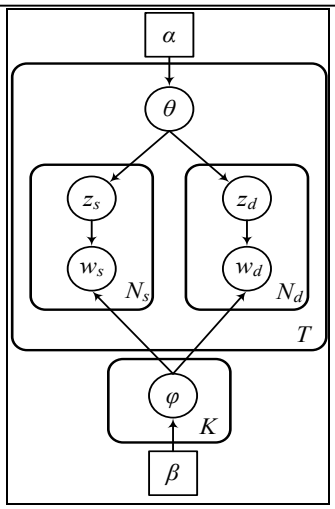

Figure 1. Generative Process and Plate Notation of JTT.

Variable	Description	Variable	Description
t	A transition t	Z^S, Z^D	Set of all topics in src, dest pages
$t(s)$, $t(d)$	The src and dest pages of t	W^S, W^D	Set of all word tokens in src, dest pages
$\theta_t \sim Dir(\alpha)$	Joint src/dest topic distribution	$\Theta = \{\theta_t\}$	Set of all latent joint transition topic distributions
z_s, z_d	Latent topics of $t(s)$, $t(d)$	$\Phi = \{\varphi_k\}$	Set of all latent topics
w_s, w_d	Observed word tokens of $t(s)$, $t(d)$	$\theta_{t,k}$	Contribution of topic k in transition t
$\varphi_k \sim Dir(\beta)$	Latent topic-word distributions for topic k	$w^S_{t,j}, w^D_{t,j}$	jth word of transition t in $t(s)$, $t(d)$
α, β	Dirichlet parameters for θ, φ	$z^S_{t,j}, z^D_{t,j}$	Latent topic of jth word of t in $t(s)$, $t(d)$
N_s, N_d	No. of terms in src and dest pgs of t	$n^S_{t(s),k}$	No. of words in $t(s)$ assigned to topic k
$T = \{t\}$	Set of all transitions, t	$n^D_{t(d),k}$	No. of words in $t(d)$ assigned to k
K	No. of topics	$n^S_{k,v}$	No. of times word v assigned to k in W^S
V	No. of unique terms in the vocab.	$n^D_{k,v}$	No. of times word v assigned to k in W^D

Table 1. List of notations.

Exact inference for JTT is intractable. Hence, we use Markov Chain Monte Carlo (MCMC) Gibbs sampling. Rao-Blackwellization (Bishop, 2006) is used to reduce sampling variance by collapsing latent variables θ and φ. Owing to space constraints, we omit the full derivation details. The full joint can be written succinctly as follows:

$$P(W^S, W^D, Z^S, Z^D) = \left(\prod_{t=1}^{T} \frac{B\left(n^S_{t(s),[\,]} + n^D_{t(d),[\,]} + \alpha\right)}{B(\alpha)}\right) = \left(\prod_{t=1}^{K} \frac{B(n^S_{k,[\,]} + n^D_{k,[\,]} + \beta)}{B(\beta)}\right) \quad (3)$$

Omission of a latter index in the count variables, denoted by [ ], corresponds to the row vector spanning over the latter index. The corresponding Gibbs conditional distributions for z^S and z^D are detailed below, where the subscript $(\neg(t,j))$ denotes the value of the expression excluding the counts of the term (t,j):

$$p(z^S_{t,j} = k| \ldots) \propto \frac{\left(n^S_{t(s),k}\right)_{\neg(t,j)} + n^D_{t(d),k} + \alpha}{\sum_{k=1}^{K}\left(\left(n^S_{t(s),k}\right)_{\neg(t,j)} + n^D_{t(d),k} + \alpha\right)} \times \frac{(n^S_{k,v})_{\neg(t,j)} + n^D_{k,v} + \beta}{\sum_{v=1}^{V}\left((n^S_{k,v})_{\neg(t,j)} + n^D_{k,v} + \beta\right)} \quad (4)$$

$$p(z^D_{t,j} = k| \ldots) \propto \frac{n^S_{t(s),k} + \left(n^D_{t(d),k}\right)_{\neg(t,j)} + \alpha}{\sum_{k=1}^{K}\left(n^S_{t(s),k} + \left(n^D_{t(d),k}\right)_{\neg(t,j)} + \alpha\right)} \times \frac{n^S_{k,v} + (n^D_{k,v})_{\neg(t,j)} + \beta}{\sum_{v=1}^{V}\left(n^S_{k,v} + (n^D_{k,v})_{\neg(t,j)} + \beta\right)} \quad (5)$$

We learn our joint topic model from a random traffic-weighted sample of 10,000 transitions, which are randomly sampled from the development set outlined in Section 3.2[5]. The decision to use this sample of 10,000 transitions is based on the observation that there were no statistically significant performance gains for models trained on more than 10k transitions. The Dirichlet hyperparameters are set to $\alpha = 50/K$ and $\beta = 0.1$ according to the values suggested in (Griffiths and Steyvers, 2004). The number of topics, K, is empirically set to 50. We also conducted pilot experiments with other hyperparameter settings, larger transition sets and more topics but we found no substantial difference in the end-to-end performance. Although increasing the number of topics and modeling more volume usually results in lowering perplexities and better fitting in topic models (Blei et al., 2003), it can also result in redundancy in topics which may not be very useful for downstream applications (Chen et al., 2013). For all reported experiments we use the posterior estimates of our joint model learned according to the above settings. In our discriminative interestingness model, we use three classes of features from JTT to capture the latent topic distributions of the source page, the destination page, and the joint topics for that transition. These correspond to source topic features (Z^S, labeled as JTTsrc in charts), destination topic features (Z^D, labeled as JTTdst), and transition topic features (Θ, labeled as JTTtrans). Each of these three sets comprises 50 features, for a total of 150.Θ is the distribution over joint src and dst topics that

[5] Note that we use the development set to train our semantic model since it is ultimately used to generate features for our discriminative learner of Section 4. Since the learner is trained using the training set, this strategy avoids overfitting our semantic model to the training set.

appear in a particular transition. Z^S and Z^D are the actual topic assignments for individual words in src and dst. Upon learning the JTT model, for each K topics, we get a probability of that topic appearing in the transition, in the src, and in the dst document (by taking the posterior point estimates for latent variables Θ, Z^S, Z^D respectively). The GBDT implementation we use for our discriminative model performs binning of these real-valued features over an ensemble of DTs.

5 Experiments

We evaluate our interestingness model on the task of proposing k anchors on a page that the user will find interesting (*highlighting* task). Recall the interestingness function σ from Eq. 1. In the highlighting task, a user is reading a document $s \in U$ and is interested in learning more about a set of anchors. Our goal in this task is to select k anchors that maximize the cumulative degree of interest of the user, i.e.:

$$\underset{A_s^k=(a_1,\ldots,a_k|a_i\in A_s)}{\operatorname{argmax}} \sum_{a_i\in A_s^k} \sigma(s,a_i) \qquad (6)$$

In other words, we consider the ideal selection to consist of the *k* most interesting anchors according to $\sigma(s,a)$.We compare the interestingness ranking of our models against a gold standard function, σ', computed from our test set. Recall that we use the aggregate click frequency of an anchor as a proxy for its interestingness. As such, the gold standard function for the test set is computed as:

$$\sigma'(s,a) = p(a|s) \qquad (7)$$

where $p(a|s)$ is the probability of a user clicking on the anchor a when viewing s.

Given a source document s, we measure the quality of a model's interestingness ranking against the ideal ranking defined above using the standard nDCG metric (Manning et al., 2008). We use the interestingness score of the gold standard as the relevance score.

Table 2 shows the nDCG results for two baselines and a range of different feature sets. The first high-level observation is that the task is difficult, given the low baseline results. Since there are many anchors on an average page, picking a random set of anchors yields very low nDCG scores. The nDCG numbers of our baselines increase as we move from HEAD to TORSO to TAIL, due to the fact that the average number of links per page (not unique) decreases in these sets from 170 to 94 to 41[6]. The second baseline illustrates that it is not sufficient to simply pick the top *n* anchors on a page.

Next, we see that using our set of anchor features (see Section 4.1) in the regression model greatly improves performance over the baselines, with the strongest numbers on the HEAD set and decreasing effectiveness in TORSO and TAIL. This shows that the distribution of interesting anchors on a page differs according to the popularity of the source content, possibly also with the length of the page. Our best performing model is the one using anchor features and all three sets of latent semantic features (Table 2, row 6; source, destination, and transition topics).

The biggest improvement is obtained on the HEAD data. This is not surprising given that the topic model is trained on a traffic weighted sample of Wikipedia articles and that HEAD pages tend to have more content, making the identification of topics more reliable. Regarding the individual contributions of the latent semantic features (Table 2, rows 4, 5), destination features alone hurt performance on the HEAD set. Latent semantic source features lead to a boost across the board, and the addition of latent semantic transition topic features produces the best model, with gains especially pronounced on the HEAD data. Figure 2 further shows the performance of our best configuration across ALL, HEAD, TORSO, and TAIL. Interestingly, the TAIL exhibits better performance of the model than the TORSO (with the exception of nDCG at rank 3 or higher). We hypothesize that this is because the average number of anchors in a TAIL page is less than half of that in a TORSO page.

[6] Wikipedia editors tend to spend more time on more frequently viewed documents, hence they tend contain more content and more anchors.

nDCG %	HEAD				TORSO				TAIL			
n	@1	@2	@5	@10	@1	@2	@5	@10	@1	@2	@5	@10

Table 2. Highlighting performance (% nDCG @ n) for different feature sets across HEAD, TORSO, and TAIL. Bold indicates statistically significant best systems (with 95% confidence).

Not shown in these results are the effects of using user session features. We consistently found that these features did not improve upon the configurations where anchor and JTT features are used. We do not, however, rule out the potential of such features on this task, especially in light of our data analysis observations from Section 3.3, which suggest an effect from these factors. We leave a more in-depth study of the potential contribution of these types of features for future research.

We now address the question how our unsupervised latent semantic features perform compared to the editor-assigned categories for Wikipedia pages, for two reasons. First, it is reasonable to consider the manually assigned Wikipedia categories as a (fine-grained) oracle for topic assignments. Second, outside of Wikipedia, we do not have the luxury of manually assigned categories/topics. As illustrated in Figure 3, we found that Wikipedia categories outperform the JTT topic features, but the latter can recover about two thirds of the nDCG gain compared to Wikipedia categories.

Finally, in the HEAD part of the data, we have enough historical clickthrough data that we could directly leverage for prediction. We conducted experiments where we used the prior probability $p(d|s)$ obtained from the development data (both smoothed and unsmoothed). Following this strategy we can achieve up to 65% nDCG@10 as shown in Figure 4 where the use of prior history (labeled "History: Target | Source Prior") is compared to our best model and to baselines. As stressed before, in most real-life applications, this is not a viable option since anchors or user-interaction logs are unavailable. Even in web browsing scenarios, the TORSO and TAIL have no or only very sparse histories. Furthermore, the information is not available in a "cold start" scenario involving new and unseen pages. We also examined whether the general popularity of a target page is sufficient to predict an anchor's interestingness, and we found that this signal performs better than the baselines, but significantly worse than our models. This series is labeled "History: Target Prior" in Figure 4.

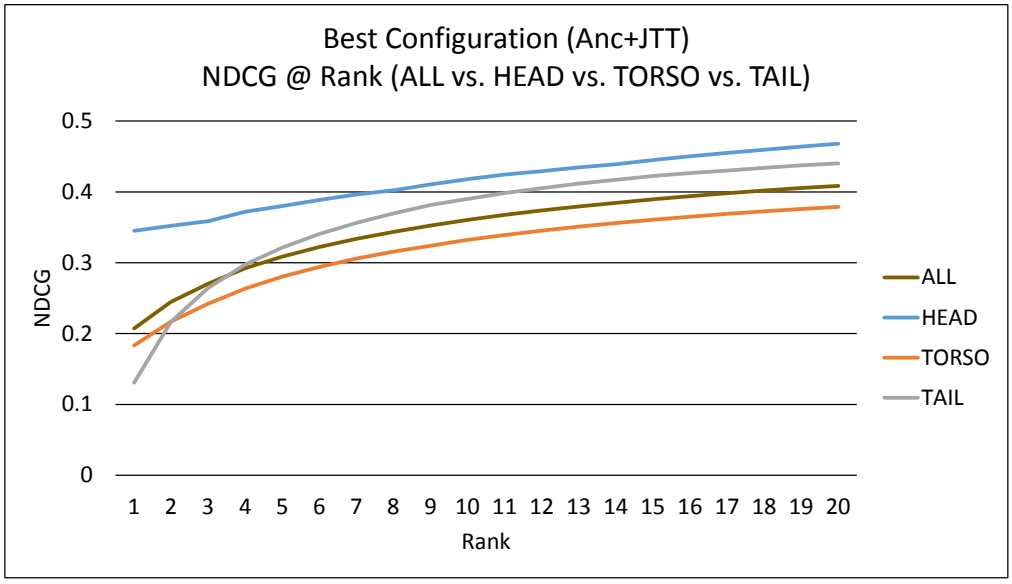

Figure 2. NDCG comparison across overall performance (ALL) versus HEAD, TORSO, and TAIL subsets, on the Highlighting task.

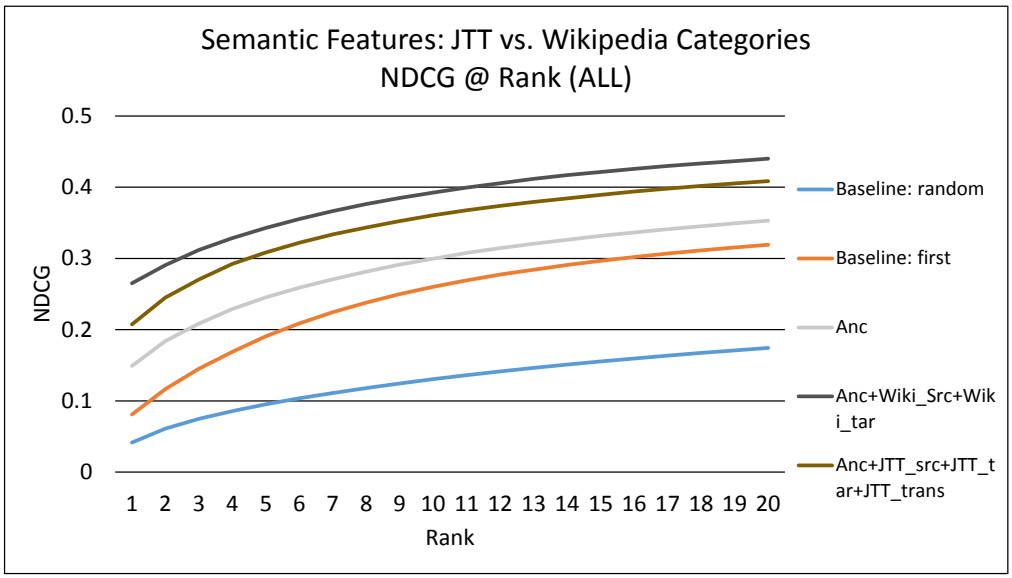

Figure 3. JTT features versus Wikipedia category features on Highlighting task.

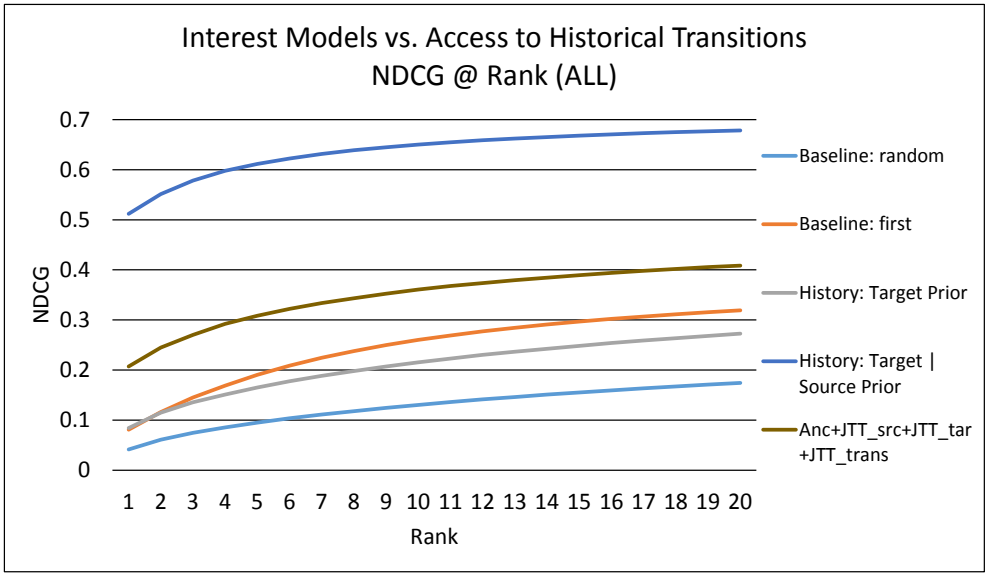

Figure 4. Highlighting task comparison between baselines, best configuration using JTT, and models with historical transitions.

Our highlights task reflects the main goal of our paper, i.e., to predict interestingness in the context of any document, whether it be a web page, an email, or a book. A natural extension of our work, especially in our experimental setting with Wikipedia transitions, is to predict the next click of a user, i.e., *click prediction*.

There is a subtle but important difference between the two tasks. Highlights aims to identify a set of interesting nuggets for a source document. A user may ultimately click on only a subset of the nuggets, and perhaps not in the order of most interest. Our experimental metric, nDCG, reflects this ranking task well. Click prediction is an inherently more difficult task, where we focus on predicting exactly the next click of a specific user. Unlike in the highlights task, there is no partial credit for retrieving other interesting anchors. Only the exact clicked anchor is considered a correct result. As such, we utilize a different metric than nDCG on this task. We measure our model's performance on the task of click prediction using cumulative precision. Given a unique transition event $\tau(s,a,d)$ by a particular user at a particular time, we present the transition, minus the gold anchor a and destination d, to our models, which in turn predict an ordered list of most likely anchors on which the user will click. The cumulative precision at k of a model, is 1 if any of the predicted anchors matched a, and 0 otherwise.

Table 3 outlines the results on this task and Figure 5 shows the corresponding chart for our best configuration. Note that in the click prediction task, the model performs best on the TAIL, followed by TORSO and HEAD. This seems to be a reflection of the fact that in this harder task, the total number of anchors per page is the most influential factor in model performance.

Cumulative Precision %	**HEAD**				**TORSO**				**TAIL**			
n	@1	@2	@5	@10	@1	@2	@5	@10	@1	@2	@5	@10

6 Conclusion and Future Directions

We presented a notion of an IT on a page that is grounded in observable browsing behavior during content consumption. We implemented a model for prediction of interestingness that we trained and tested within the domain of Wikipedia. The model design is generic and not tied to our experimental choice of the Wikipedia domain and can be applied to other domains. Our model takes advantage of semantic features that we derive from a novel joint topic transition model. This semantic model takes into account the topic distributions for the source, destination, and transitions from source to destination. We demonstrated that the latent semantic features from our topic model contribute significantly to the performance of interestingness prediction, to the point where they perform nearly as well as using editor-assigned Wikipedia categories as features. We also showed that the transition topics improve results over just using source and destination semantic features alone.

A number of future directions immediately suggest themselves. First, for an application that marks interesting ITs on an arbitrary page, we would need a detector for IT candidates. A simple first approach would be to use a state-of-the-art Named Entity Recognition (NER) system to cover at least a subset of potential candidates. This does not solve the problem entirely, since we know that named entities are not the only interesting nuggets – general terms and concepts can also be of interest to a reader. On the other hand we do have reason to believe that entities play a very prominent role in web content consumption, based on the frequency with which entities are searched for (see, for example Lin et al. 2012 and the references cited therein). Using an NER system as a candidate generator would also allow us to

add another potentially useful feature to our interestingness prediction model: the type of the entity. One could also envision jointly modeling interestingness and candidate detection.

A second point concerns the observation from the previous section on the different regularities that seem to be at play according to the popularity and possibly the length of an article. More detailed experiments are needed to tease out this influence and possibly improve the predictive power of the model. User session features did not contribute to model performance when used in conjunction with other feature families, but closer investigation of these features is warranted for more personalized models of interestingness. Finally, a number of options regarding JTT could be explored further. Being trained on a traffic-weighted sample of articles, the topic model predominantly picks up on popular topics. This could be remedied by training on a non-weighted sample, or, more promisingly, on a larger non-weighted sample with a larger K, i.e. more permissible total topics.

Abstract

While discussing a concrete controversial topic, most humans will find it challenging to swiftly raise a diverse set of convincing and relevant claims that should set the basis of their arguments. Here, we formally define the challenging task of automatic claim detection in a given context and discuss its associated unique difficulties. Further, we outline a preliminary solution to this task, and assess its performance over annotated real world data, collected specifically for that purpose over hundreds of Wikipedia articles. We report promising results of a supervised learning approach, which is based on a cascade of classifiers designed to properly handle the skewed data which is inherent to the defined task. These results demonstrate the viability of the introduced task.

1 Introduction

The ability to argue in a persuasive manner is an important aspect of human interaction that naturally arises in various domains such as politics, marketing, law, and health-care. Furthermore, good decision making relies on the quality of the arguments being presented and the process by which they are resolved. Thus, it is not surprising that argumentation has long been a topic of interest in academic research, and different models have been proposed to capture the notion of an argument (Toulmin, 1958; Freeley and Steinberg, 2008). A fundamental component which is common to all these models is the concept of a *claim* (or *conclusion*). Specifically, at the heart of every argument lies a single claim, which is the assertion the argument aims to prove. Given a concrete topic, or context, most humans will find it challenging to swiftly raise a diverse set of convincing and relevant claims that should set the basis of their arguments. The purpose of this work is to formally define the challenging task of automatic claim detection *in a given context*, to outline a preliminary solution to this task, and to assess its performance over annotated real world data, collected specifically for this purpose.

In his classical argument model, Toulmin defined a claim as a conclusion whose merit must be established (Toulmin, 1958). Since we are interested not in detecting claims in general (Mochales Palau and Moens, 2009; Teufel, 1999), but rather in detecting claims that are specifically relevant to a pre-defined concrete context, we suggest a definition with a more functional flavor. In practice, we found this definition easy to convey to human labelers, and consequently feasible to capture by automatic detection methods. In particular, we define the following two concepts:

- **Topic** – a short phrase that frames the discussion.
- **Context Dependent Claim (CDC)** – a general, concise statement that directly supports or contests the given Topic.

Given these definitions, as well as a few more detailed criteria to reduce the variability in the manually labeled data, human labelers were asked to detect CDCs for a diverse set of Topics, in relevant Wikipedia articles. The collected data, that were used to train and assess the performance of the statistical models, are now freely available upon request for academic research.

Proceedings of COLING 2014, the 25th International Conference on Computational Linguistics: Technical Papers, pages 1489–1500, Dublin, Ireland, August 23-29 2014.

The distinction between a CDC and other related texts can be quite subtle, as illustrated in Table 1. For example, automatically distinguishing a CDC like S1 from a statement that simply defines a relevant concept like S2, from a claim which is not relevant enough to the given Topic like S3, or from a statement like S4 that merely repeats the given Topic in different words, is clearly challenging. Further, CDCs can be of different flavors, ranging from factual assertions like S1 to statements that are more of a matter of opinion (Pang and Lee, 2008) like S5, adding to the complexity of the task. Finally, our data suggest that even if one focuses on Wikipedia articles that are highly relevant to the given Topic, only $\approx 2\%$ of their sentences include CDCs. Moreover, as illustrated in Table 2, detecting the exact CDC boundaries is far from trivial, as in a typical single Wikipedia sentence there are many optional boundaries to consider. Thus, we are faced with a large number of candidate CDCs, of which only a tiny fraction represents positive examples, that might be quite reminiscent of some of the negative examples. Nonetheless, as we demonstrate, a supervised learning approach – which is based on a cascade of classifiers, carefully designed to properly handle the exceptionally skewed data – can address these difficulties to attain promising results.

Topic: The sale of violent video games to minors should be banned		
S1	Violent video games can increase children's aggression	V
S2	Video game addiction is excessive or compulsive use of computer and video games that interferes with daily life	X
S3	Many TV programmers argue that their shows just mirror the violence that goes on in the real world	X
S4	Violent video games should not be sold to children	X
S5	Video game publishers unethically train children in the use of weapons	V

Table 1: Examples for CDCs and for statements that should not be considered as CDCs. The V and X indicate if the candidate is a CDC for the given Topic, or not, respectively.

Topic: The sale of violent video games to minors should be banned	
S1	Because violence in video games is interactive and not passive, critics such as Dave Grossman and Jack Thompson argue *that* **violence in games hardens children to unethical acts**, calling first-person shooter games "murder simulators", although no conclusive evidence has supported this belief.

Table 2: A CDC is often only a small part of a single Wikipedia sentence – e.g., the part marked in bold in this example. Detecting the exact CDC boundaries represents an additional challenge.

In summary, the key contribution of this work is three fold: we define the new task of Context Dependent Claim Detection; introduce a novel manually labeled benchmark dataset, collected specifically for this task; and outline an automatic solution for which we report first results over these data. These results are encouraging, demonstrating the viability of the introduced task.

2 Task Definition and Related Work

We assume that we are given a Topic and a relatively small set of relevant free-text articles, provided either manually or by automatic retrieval methods (Macdonald et al., 2010; Zhang et al., 2007). Our goal is to automatically pinpoint CDCs within these documents. We further require that the detected CDCs are reasonably well phrased, so that they can be instantly and naturally used in a discussion about the given Topic.This task, which we term *Context Dependent Claim Detection (CDCD)*, can be of great practical importance in decision support and persuasion enhancement, in various domains where relevant massive corpora are available for mining.

CDCD can be seen as a sub-task in the emerging wider field of argumentation mining that involves identifying argumentative structures within a document, as well as their potential relations

(Mochales Palau and Moens, 2009; Cabrio and Villata, 2012; Wyner et al., 2012). However, CDCD has several distinctive key features. Most importantly, as implied by its name, a CDC is defined with respect to a given context – the input Topic. Thus, identifying general characteristics of a claim-like statement as done in (Mochales Palau and Moens, 2009) is not sufficient, since one should further identify the relevance of the candidate claim to the Topic. In addition, we do not restrict ourselves to a particular domain nor to structured data (Mochales Palau and Moens, 2009), but rather consider free-text Wikipedia articles in a diverse range of subject matters. Moreover, in CDCD we require pinpointing the exact claim boundaries, which do not necessarily match a whole sentence or even a clause in the original text, thus adding a significant burden to the task, compared to classical tasks that are focused on sentence classifications (Guo et al., 2011).

CDCD also shares some relations with Argumentative Zoning (Teufel, 1999; Guo et al., 2011). There, the aim is to divide the text of a scientific article into "zones", each characterized by the rhetorical nature of its content. However, our work is not limited to scientific literature that often has a more objective and less persuasive style. Further, as mentioned, we go beyond sentence classification, aiming to detect the exact claim boundaries, and require detecting only claims relevant to a given Topic, rather than just any claim mentioned in a given article.

Finally, another important line of research is the Textual Entailment (TE) framework (Dagan et al., 2009). In this framework, a text fragment, T, is said to entail a textual hypothesis H if the truth of H can be most likely inferred from T. While TE can be an important underlying utility in CDCD, and perhaps vice versa, the tasks are quite different. For example, common instances of TE are rephrases or summarizations of a sentence; however these cannot serve to support or contest a given Topic, as they merely repeat it (Table 1, S4). Furthermore, TE focuses on factual assertions, which can be true or false, whilst CDC may represent a relevant opinion that perhaps does not have a strict truth value associated to it (Table 1, S5). More generally, TE is typically focused on declarative statements. However, persuasion and argumentation often have an emotional aspect and thus may involve additional sentence types. Correspondingly, in our framework it is quite natural that the Topic, or the associated CDCs, will correspond to imperative sentences, or even to exclamatory sentences.

3 Data

Our supervised learning approach relies on labeled data that were collected as described below. A detailed description of the labeling process is given in (Aharoni et al., 2014). Due to the high complexity of the labeling task, we worked with in-house labelers which were provided with detailed guidelines, and went through rigorous training.

At the core of the labeling guidelines, we outlined the definition of a CDC as *a general, concise statement that directly supports or contests the given Topic*. In practice, the labelers were asked to label a text fragment as a CDC if and only if it complies with *all* the following five criteria:

- **Strength** – Strong content that directly supports/contests the Topic.
- **Generality** – General content that deals with a relatively broad idea.
- **Phrasing** – The labeled fragment should make a grammatically correct and semantically coherent statement.
- **Keeping text spirit** – Keeps the spirit of the original text.
- **Topic unity** – Deals with one topic, or at most two related topics.

The guidelines further included concrete examples, taken from Wikipedia articles, to clarify these criteria. When in doubt, the labelers were naturally asked to make a judgment call. The labelers work was carefully monitored, and they were provided with detailed feedback as needed.

We selected at random 32 debate motions from *http://idebate.org/debatabase*, covering a wide variety of topics, from atheism to the US responsibility in the Mexican drug wars. Each motion served as a single Topic and went through a rigorous labeling process, consisted of three stages. First, given a Topic, 5 labelers searched Wikipedia independently for articles that they believe contain CDCs. Next, each of the articles identified in this search stage was read by 5 labelers, that worked independently to detect

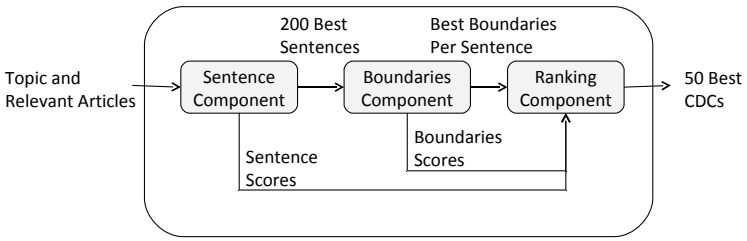
candidate CDCs. Finally, each of the candidate CDC proposed in the previous stage, was examined by 5 labelers that independently decided whether to confirm or reject the candidate. For the purposes of this work, we only considered candidate CDCs that were confirmed by a majority, i.e., by at least three labelers participating in the confirmation stage. The resulting labeled CDCs correspond to claims that can be naturally used in a discussion about the given Topic.

Through this process, for the 32 examined Topics, a total of 326 Wikipedia articles were labeled, yielding a total of 976 CDCs. Thus, even when considering articles that are presumably relevant to the given Topic, on average only 2 out of 100 sentences include a CDC. On the other hand, it should be noted that it was not clear to begin with that Wikipedia articles will contain CDCs that satisfy our relatively strict labeling guidelines. Nonetheless, on average, the labeling process yielded around 30 CDCs per Topic. Finally, the average Kappa agreement between pairs of labelers in the confirmation stage was 0.39, which is a relatively high agreement considering the complexity of the labeling task and the inherent elusiveness of the involved concepts.

4 Technical Approach

Our CDCD approach is designed as a cascade, or funnel, of three components (depicted in Figure 1), which receives as input a Topic along with relevant articles and should output the CDCs contained therein. The purpose of the funnel is to gradually focus on smaller and smaller CDC-containing text segments, while filtering out irrelevant text. Thus, the cascade divides the high level CDCD problem into smaller and more tangible problems – given an article, detect sentences that include CDCs; given a sentence, detect the exact CDC boundaries; given a set of CDC candidates, rank them so that true candidates are on top.

Figure 1: High level design of our CDCD approach. The indicated numbers are the ones used in our experiments, and in general should be determined based on the data and use case.



To appreciate the need for this cascade, let us first consider the scale of this detection problem. In our labeled data, per Topic we have an average of 10 relevant Wikipedia articles that contain at least 1 CDC. Each article contains an average of 155 sentences, each sentence spans on average 23 words, i.e., ≈ 200 sub-sentences, each of which may represent a candidate CDC. Thus, in principle, for each Topic we consider around 300,000 candidate CDCs, of which typically only 30 represent positive examples. By breaking the problem into independent sub-problems, at each stage the skew between positive examples and negative examples is less daunting, thus easier to handle by classical machine learning techniques. In addition, since much surplus text is filtered along the cascade, "downstream" components typically examine much smaller amounts of text, and thus can plausibly make use of more demanding algorithms. Finally, this conceptual separation naturally allows to develop features tailored individually to each task; for example, the grammatical correctness of a text fragment is clearly relevant for boundaries detection, while being irrelevant when classifying whole sentences.

In general, each component was developed independently within the classical supervised learning paradigm. Namely, numeric features are extracted from binary-labeled text segments, and are used to train a classifier. Next, this classifier is used to assign a score to each incoming test candidate and high-scoring candidates are passed on to the next component. In addition, rule-based filters might be used to discard some of the candidates. Note, while developing a "downstream" component we implicitly assumed that the previous "upstream" components have worked perfectly. Hence, for example, the *train-*

ing data for the boundary-detection component comprised only of sentences that truly contain CDCs. In what follows, we discuss each component in greater detail.

4.1 Sentence Component

The **Sentence Component** is responsible for detecting CDC-sentences, that is, to determine whether a candidate sentence contains a CDC or not. Some sentences contain more than one CDC but this is not very common. Hence, we consider this as a binary classification problem. The component receives an average of 1500 sentences per Topic and passes the top scoring 200 sentences to the next component. Specifically, we used Logistic Regression (LR) classifier due to its efficiency and its model interpretability, and focused our efforts on developing highly discriminative features for this classifier.

Since our focus is on detecting claims that are relevant to a given Topic, we naturally developed two main types of features – **Context features**, which examine the relation between the candidate sentence and the Topic; and **Context-free features**, which rely solely on the content of the candidate sentence, aiming to capture the probability it includes a "claim like" statement. For computing the context-features, we use the topic as it appears in debatabase (see Section 3). Specifically, the most dominant features we identified included:

MatchAtSubject: Cosine similarity between the Topic and the subjects of the candidate sentence – namely, all tokens that are marked as the subject of some sub-tree in the sentence ESG parse tree (McCord et al., 2012).

ExpandedCosineSimilarity: Cosine similarity between the Topic and semantic expansions of the candidate sentence. We use WordNet (Miller, 1995) to expand nouns into synonyms, hypernyms and hyponyms.

ESGFeatures: Binary features obtained from the ESG parser (McCord et al., 2012). The most prominent among them is an indicator of whether the sentence contains the token "that" that is assigned the "conjugate" feature by the ESG – see, for example, the emphasized "that" in the example in Table 2. Other features include: verb in present tense, infinitive verb, year, and named location.

SubjectivityScore: A classifier-based score that captures the degree of subjectivity in the sentence (Raykar et al., 2014).

Sentiment: Ratio of sentiment words in the sentence, based on a list of sentiment words from (Hu and Liu, 2004).

In addition to these Context features and Context-free features, we also developed a feature that represents a mix of these two types, that was proven essential to our performance, and relied on an extension of the Sequential Pattern Matching (SPM) algorithm (Srikant and Agrawal, 1996). Specifically, for this **SequentialPatternMatch** feature, each sentence token was encoded as a tuple describing several attributes for that token – e.g., the token's text, the token's POS tag, and various binary indicators, indicating if the token is a sentiment word, if it is mentioned in the given Topic, if it is included in an automatically learned lexicon of "claim words", and if it is identified by a NER utility (Finkel et al., 2005). A variant of the SPM algorithm (Srikant and Agrawal, 1996) was then used to detect patterns that characterize CDC-sentences, and these patterns were added to the features examined by the LR classifier. Specifically, each of these feature values was set to 1 if a candidate sentence had a match with the relevant pattern, and to 0 otherwise. For example, in Table 2, the word "that" is encoded as [that,IN,CDC] implying it is included in the "claim words" lexicon with POS tag IN; the word "games" is encoded as [games,NNS,Topic] implying it is mentioned in the Topic with POS tag NNS; and the word "unethical" is encoded as [unethical,JJ,Sentiment] implying it is a sentiment word with POS tag JJ. Correspondingly, in this sentence there is a match to the sequential pattern: [that,IN], [Topic], [Sentiment], which is one of the patterns detected automatically by our algorithm, as characterizing CDC-sentences. A more detailed description of this extended SPM approach will be given elsewhere.

It is worthwhile mentioning that one can envision this component as being broken up into two: One component that detects general claim-sentences, regardless of whether or not they relate to the Topic, based on the context-free features; Another component will detect relation to the Topic, regardless of whether or not the sentence is a claim. (Or some variation of this setting.)

The problem with this approach, as we see it, is that it greatly complicates the annotation guidelines and the associated annotation work. That is, without a topic, it is less clear how to define what a claim is, and deciding when a sentence is related to the topic is bound to be highly subjective. Furthermore, taking this approach would require adding additional detection and confirmation stages, lowering the amount of collected annotated data. For these reasons we have adopted the combined approach, even though it makes error analysis more difficult - without manual analysis it is not clear whether the errors are sentences which do not contain claims or which are unrelated to the topic, or both.

4.2 Boundaries Component

The **Boundaries Component** is responsible for detecting the exact CDC boundaries within CDC-sentences. Notice, that our definition of a CDC and the associated labeling guidelines – that gave rise to our ground-truth data – imply that in free text articles a CDC often do not correspond to an easily identified sub-tree in the sentence parse tree. For example, since we are interested in detecting focused claims the labelers are often led to mark a concise claim rather than a compound claim as in the following sentence – *"The argument of deprivation states that* **abortion is morally wrong** *because it deprives the fetus of a valuable future"*. Note that choosing the boundaries from *"abortion"* to *"future"* would have included two distinct claims. Similarly, since the labelers are guided to prefer more general versions of the CDC, as long as the original text spirit is kept, determining where the CDC should start could be quite a subtle decision. Thus, the exact CDC boundaries often rely on the semantics of the text, and not just on its grammatical structure. Correspondingly, identifying the exact CDC boundaries is far from trivial.

Based on similar considerations to those mentioned above, we divide this component into two sub-components.

Boundaries Coarse Filter: This sub-component is based on a Maximum Likelihood probabilistic model that given a sentence, selects the 10 sub-sentences whose boundaries most probably correspond to a CDC. Specifically, given a sentence, for each of its sub-sentences[1] we consider the token preceding it; the token with which it starts; the token with which it ends; and the token following it, where a token here can be a word or a punctuation mark. Given these four tokens, the algorithm estimates the probability that this sub-sentence represents a CDC. For practical purposes, the probability is estimated naively, by assuming that each token is independent of the others. In addition, the Boundaries Coarse Filter employs simple rules to filter out trivial cases such as sub-sentences that do not contain a verb and a noun, or sub-sentences for which the parse root is tagged as a sentence-fragment.

Boundaries Fine-Grained Filter: This sub-component is based on a LR classifier that selects one sub-sentence out of the 10 provided by the Boundaries Coarse Filter. Here as well we considered Context-free features and Context features, where the former type were typically weighted as more dominant by the LR classifier. Importantly, though, the Context-free features examined by this sub-component relied on the division of the entire sentence, as implied by the examined boundaries. Specifically, the candidate boundaries induce a division of the containing sentence into three parts: prefix, candidate body, and suffix, where the prefix and/or suffix might be empty. The features are then calculated for each of these three parts independently. Thus, for example, the presence of the word "that" in the prefix as opposed to its presence in the candidate body, will increase or decrease the confidence of the examined boundaries, respectively. In addition, the LR classifier considered features derived from the probabilistic model defined by the Boundaries Coarse Filter, that also aim to assess the probability that the examined boundaries yield a CDC.

Next, we elaborate on some of the dominant features examined by the Boundaries Fine-Grained Filter.

CDC-Probability features: These features indicate the conditional probability that the examined boundaries define a CDC, given the tokens around and within these boundaries. For example, the **Word-Before-Word-After** numeric feature, denoted $P(ta, tb)$, is defined as follows. Let $\{t_1, \ldots, t_n\}$ represent the list of tokens in a sentence, where a token is a word or a punctuation mark, then $P(ta, tb)$ is the probability that the sub-sentence $\{t_i, \ldots, t_j\}$ represents a CDC, given that $t_{i-1} = t_a,\ t_{j+1} = t_b$, as

[1] Here, a "sub-sentence" is any consecutive sequence of three tokens or more, that is included in the examined sentence.

estimated from our training data. Similarly, the **Word-Before-First-PoS** feature is based on the estimated conditional probability that the candidate defined by the examined boundaries is a CDC, given the token before the boundaries, t_{i-1}, and the POS-tag of the first token within the boundaries, t_i. Other features of this type include the conditional probability based on the presence of single tokens within the boundaries, and the initial score assigned to the examined boundaries by the Boundaries Coarse Filter.

Sentence-Probability features: These features aim to indicate the probability that the examined boundaries induce a grammatically correct sentence. For this purpose we examine a set of 100,000 presumably grammatically correct sentences, taken from a separate set of Wikipedia articles, and estimate the probability of each word to appear in a given position in a valid sentence. Next, given the examined boundaries, we ask for each of its first three tokens and each of its last three tokens, what is the probability of having a grammatically correct sentence, given that the observed token is in its observed position.

ModifierSeparation: The ESG parser (McCord et al., 2012) describes the modifiers of its parsed tokens, such as the object of a verb. Typically, a token and its modifier should either be jointly included in the CDC, or not included in it. This notion gave rise to several corresponding features.

Parse Sentence Match: These are binary features that indicate whether the examined boundaries correspond to a sub-tree whose root is labeled "S" (sentence) by the Stanford parser (Socher et al., 2013) or by the ESG parser (McCord et al., 2012), while parsing the entire surrounding sentence.

"that-conj" matches CDC: A binary feature indicating whether in the ESG parsing we have a subordinator "that" token, whose corresponding covered text matches the examined boundaries.

DigitCount: Counts the number of digits appearing in the sentence – before, within, and after the examined boundaries.

UnbalancedQuotesOrParenthesis: Binary features, indicating whether there is an odd number of quote marks, or unbalanced parenthesis, within the examined boundaries.

4.3 Ranking Component

The **Ranking Component** is responsible for the final scoring of the CDC candidates. It is also based on a LR classifier, that considers the scores of all previous components, as well as additional features described below. A simpler alternative could have been to rely solely on the initial sentence component ranking. However, since CDCs often correspond to much smaller parts of their surrounding sentence, considering the scores of all previous components is more effective. In contrast to the components described above, for which the training set is fully defined by the labeled data, the Ranking Component needs be trained also on the output of its "upstream" components, since it relies on the scores produced by these components.

In addition, the Ranking Component is using the following features:

CandidateComplexity, a score based on counting punctuation marks, conjunction adverbs (e.g., "likewise", "therefore"), sentiment shifters (e.g., "can not", "undermine") and references, included in the candidate CDC.

Sentiment, **ExpandedCosineSimilarity** and **MatchAtSubject**, as in the Sentence Component above, estimated specifically for the CDC candidate.

5 Experiments

We describe the results of running the cascade of aforementioned components, in the designed order, in a Leave-One-Out (LOO) fashion, over 32 Topics. In each LOO fold, the training data consisted of the labeled data for 31 Topics, while the test data consisted of articles that included at least one CDC for the designated test Topic.

The **Sentence Component** was run with the goal of selecting 200 sentences for the test Topic, and sorting them so that CDC-containing sentences are ranked as high as possible. As shown in Table 3, the mean precision and recall of this component, averaged across all 32 folds, were 0.09 and 0.73, respectively. When looking at the top scoring 50 sentences per Topic, the mean precision and recall are 0.18 and 0.4, respectively. As evident by the last row in Table 3, these results are way beyond a trivial

random selection of sentences, indicating that the Sentence Component is capturing a strong statistical signal associated with CDCs.

	Precision	Recall	Precision @ 50	Recall @ 50
mean	0.09	0.73	0.18	0.4
std	0.05	0.19	0.10	0.21
min	0.01	0.27	0.02	0.10
max	0.18	1.00	0.40	1.00
rand	0.02	0.13	0.02	0.03

Table 3: Sentence component. Last line indicates the expected values had selection been made at random.

Next, we employed the two sub-components of the **Boundaries Component**. First, the Boundaries Coarse Filter selected 10 sub-sentences for each candidate sentence. Recall that for sentences which actually contain CDCs, the aim is to have this CDC kept among the selected 10 sub-sentences. As shown in Table 4, this happens for 98% of the CDC-containing sentences (see Table 4). In other words, if the examined sentence included a CDC, the Boundaries Coarse Filter almost always included this CDC as one of the top 10 sub-sentences it suggested for that sentence. In the second step, for each candidate sentence, the Boundaries Fine-Grained Filter sorted the 10 sub-sentences proposed by the Boundaries Coarse Filter, aiming to have the CDC – if one exists – at the top. As indicated in Table 4, if indeed a CDC was present amongst the 10 sub-sentences sorted by this component, then it was ranked first in 50% of the cases. These results as well are clearly way beyond what is expected by random sorting, indicating a strong statistical signal that was properly captured by this component.

	Boundaries Coarse Filter Recall	Boundaries Fine-Grained Filter Recall
mean	0.98	0.50
std	0.39	0.16
min	0.67	0.25
max	1.00	1.00
rand	0.04	0.004

Table 4: Boundaries component - The left column relates to the fraction of sentences where the labeled CDC is among the top 10 candidates ranked by the Coarse Filter. The right column relates to to the fraction of sentences where the labeled CDC is identified correctly by the Fine-Grained Filter. The last row indicates the expected values had selection been made at random.

Finally, the **Ranking Component** combines the scores generated in the previous steps, as well as additional features, to set the final order of CDC candidates. The goal of this component – similar to that of the entire CDCD task – is to select 50 CDC candidates with high precision. Note, that on average, there are around 30 labeled CDCs per Topic. Thus, on average, the maximal precision at 50 should be around 0.6. As indicated in Table 5, our final precision at 50, averaged across all 32 folds, was 0.12, which is again way beyond random performance. Focusing at our top predicions naturally results with even higher precision – for example, the precision of our top 5 predictions was on average 0.23.

It should be noted that the analysis presented here is fairly strict. A predicted CDC is considered as True Positive if and only if it precisely matches a labeled CDC, that was confirmed as such by at least three labelers. Thus, for example, if a predicted CDC was confirmed by only two out of five annotators, it will be considered as an error in the analysis above. Furthermore, if the predicted CDC has a significant overlap with a labeled CDC, it will still be considered as an error, even if it represents a grammatically correct variant of the labeled CDC, that was simply less preferred by the labelers due to relatively minor considerations. Thus, although we still need to quantify the frequency of these "weak" errors, it is clear that for most practical scenarios, the performance of our system are above the strict numbers described here.

	Precision @ 5	Precision @ 10	Precision @ 20	Precision @ 50
mean	0.23	0.20	0.16	0.12
std	0.21	0.20	0.11	0.07
min	0.00	0.00	0.00	0.00
max	0.80	0.60	0.50	0.32
rand	0.00008	0.00008	0.00008	0.00008

Table 5: Ranking component

Category	Number of candidates
Accept	27
Accept with corrections	3
Generality failed	9
Strength failed	145
Text Spirit failed	1
Multiple candidates	5
Repeats topic	5
Incoherent	37
Not a sentence	17

Table 6: Number of ”false” claims in each rejection category

6 Error Analysis

We present an analysis of the errors (using a slightly earlier version of the system). The analysis covered the same 32 Topics described above, where for each Topic we analyzed the errors among the top 10 predictions. In total there were 249 sentences which did not exactly match the annotated data. Each of these seemingly-erroneous CDC candidates was then given to 5 annotators, who had to confirm or reject it and select a rejection reason. The goal of the analysis is to understand the types of errors the system makes as well as to obtain feedback on text spans that were not originally detected by the labelers (possible misses). Specifically, the labelers were instructed to choose one of the options in the following list:

Accept - The candidate should be accepted as is.

Accept with correction - The candidate should be accepted with minor corrections.

Generality failed - The candidate is too specific.

Multiple Candidates - The candidate contains more than one claim.

Repeats Topic - The candidate simply reiterates the topic (or its negation) rather than claim something about it.

Strength failed - The candidate does not directly and explicitly supports or contests the topic.

Text Spirit failed - The candidate does not keep the spirit of text in which it appeared.

Incoherent - The candidate is not a coherent claim.

Not a sentence - The candidate is not grammatical.

A majority vote was used to obtain the final answer. Table 6 gives the number of candidates in each category. As can be seen, about 10% of the candidates were actually accepted in this round. Most of the errors were attributed to ”Strength Failed”, which is a fairly wide category. In future analysis we plan to break it down into more specific sub-categories. Table 7 gives some examples of candidates generated by the system (which do not exactly match the annotated data) and their corresponding categories.

7 Discussion and Future Work

We introduced the CDCD task which is scientifically challenging, and moreover, potentially invaluable for various novel applications. We outlined a machine learning approach to address this task, which is designed based on a cascade of classifiers for handling the special difficulties of this task, and in

Category	Topic	Candidate claim
Accept	The sale of violent video games to minors should be banned	Some researchers believe that while **playing violent video games leads to violent actions**, there are also biological influences that impact a person's choices.
Accept with corrections	Democratic governments should require voters to present photo identification at the polling station	Proponents of a similar law proposed for Texas In March 2009 also argued that **photo identification was necessary to prevent widespread voter fraud**.
Generality failed	Parents should be allowed to genetically screen foetuses for heritable diseases	While psychological stress experienced during a cycle might not influence an IVF outcome, it is possible that **the experience of IVF can result in stress that leads to depression**.
Strength failed	Physical eduaction should be compulsory	**Physical education trends have developed recently to incorporate a greater variety of activities**.
Strength failed	Parents should be allowed to genetically screen a for heritable diseases	However, **the trade-off between risk of birth defect and risk of complications from invasive testing is relative and subjective**; some parents may decide that even a 1:1000 risk of birth defects warrants an invasive test while others wouldn't opt for an invasive test even if they had a 1:10 risk score.
Strength failed	Parents should be allowed to genetically screen foetuses for heritable diseases	This has made international news, and had led to accusations that **many doctors are willing to seriously endanger the health and even life of women in order to gain money**.
Multiple candidates	Wind power should be a primary focus of future energy supply	**The use of wind power reduces the necessity for importing electricity from abroad and strengthens the regional economy**.
Repeats topic	Affirmative action should be used	More recently, a Quinnipiac poll from June 2009 finds that 55% of Americans feel that **affirmative action should be abolished**, yet 55% support affirmative action for disabled people.
Incoherent	Bribery is sometimes acceptable	**The difference with bribery is that this is a tri-lateral relation**.
Incoherent	Parents should be allowed to genetically screen foetuses for heritable diseases	Having this information in advance of the birth means that **healthcare staff as well as parents can better prepare themselves for the delivery of a child with a health problem**.
Not a sentence	A mandatory retirement age should be instituted	**Mandatory retirement is the age** at which persons who hold certain jobs or offices are required by industry custom or by law to leave their employment, or retire.

Table 7: Example sentences for each rejection category

particular the inherently skewed ratio between positive examples and negative examples. We assessed the performance of the proposed approach over a novel benchmark dataset, carefully developed for this task. Our results verify the soundness of our definitions, and the validity of the introduced CDCD task.

In future work we intend to expand the collected labeled data and to generate new versions of this benchmark, that will be further released for academic research. In parallel, we intend to explore various ways to improve the accuracy of our predictions. One intriguing direction, highlighted by examining our data, is the possibility of defining different CDC types. For example, it might be that developing separate classifiers for factual CDCs – like S1 in Table 1, and other classifiers designed to detect more subjective CDCs – like S5 in Table 1, will yield better performance, assuming that each of these two types has a distinguished statistical signature. Similarly, it might be that developing domain-orineted statistical models will further enhance the quality of the CDC predictions.

In this work we analyzed labeled data in which for a given Topic, the relevant articles were manually identified. Combining a CDCD solution with automatic opinion retrieval techniques (Macdonald et al., 2010; Zhang et al., 2007) would be a natural next step towards developing an even more powerful CDCD system. Moreover, while compelling arguments start with high quality and relevant claims, they must include reliable evidence to support the validity of the introduced claims. Thus, combining a CDCD system with a system that automatically detects such supportive evidence , may give rise to a new generation of automatic argumentation methods. In principles, such methods may detect relevant CDCs in some articles, and support these CDCs with evidence detected within other articles, or even within entirely different corpora, ending up with automatically generated arguments, that were never explicitly proposed before in this form by humans. Developing successful solutions for the CDCD task is a fundamental step in pursuing this vision.

Abstract

In this paper, we present a novel approach to model arguments, their components and relations in persuasive essays in English. We propose an annotation scheme that includes the annotation of claims and premises as well as support and attack relations for capturing the structure of argumentative discourse. We further conduct a manual annotation study with three annotators on 90 persuasive essays. The obtained inter-rater agreement of $\alpha_U = 0.72$ for argument components and $\alpha = 0.81$ for argumentative relations indicates that the proposed annotation scheme successfully guides annotators to substantial agreement. The final corpus and the annotation guidelines are freely available to encourage future research in argument recognition.

1 Introduction

The ability of formulating persuasive arguments is a crucial aspect in writing skills acquisition. On the one hand, well-defined arguments are the foundation for convincing an audience of novel ideas. On the other hand, good argumentation skills are essential for analyzing different stances in general decision making. By automatically recognizing arguments in text documents, students will be able to inspect their texts for plausibility as well as revise the discourse structure for improving argumentation quality. This assumption is supported by recent findings in psychology, which confirm that even general tutorials effectively improve the quality of written arguments (Butler and Britt, 2011). In addition, *argumentative writing support systems* will enable tailored feedback by incorporating argument recognition. Therefore, it could be expected that they provide appropriate guidance for improving argumentation quality as well as the student's writing skills.

An argument consists of several components (i.e. claims and premises) and exhibits a certain structure constituted by argumentative relations between components (Peldszus and Stede, 2013). Hence, recognizing arguments in textual documents includes several subtasks: (1) separating argumentative from non-argumentative text units, (2) identifying claims and premises, and (3) identifying relations between argument components.

There exist a great demand for reliably annotated corpora including argument components as well as argumentative relations (Reed et al., 2008; Feng and Hirst, 2011) since they are required for supervised machine learning approaches for extracting arguments. Previous argument annotated corpora are limited to specific domains including legal documents (Mochales-Palau and Moens, 2008), newspapers and court cases (Reed et al., 2008), product reviews (Villalba and Saint-Dizier, 2012) and online debates (Cabrio and Villata, 2012). To the best of our knowledge, no work has been carried out to annotate argument components and argumentative relations in persuasive essays (section 2). In addition, the reliability of the corpora is unknown, since only few of these works provide holistic inter-rater agreement scores and none a detailed analysis and discussion of inter-rater agreement.

In this work, we introduce a new argument annotation scheme and a corpus of persuasive essays annotated with argument components and argumentative relations. Our primary motivation is to create

Proceedings of COLING 2014, the 25th International Conference on Computational Linguistics: Technical Papers, pages 1501–1510, Dublin, Ireland, August 23-29 2014.

a corpus for argumentative writing support and to achieve a better understanding of how arguments are represented in texts. In particular, the contributions of this paper are the following: First, we introduce a novel annotation scheme for modeling arguments in texts. Second, we present the findings of a pre-study and show how the findings influenced the definition of the annotation guidelines. Third, we show that the proposed annotation scheme and guidelines lead to substantial agreement in an annotation study with three annotators. Fourth, we provide the annotated corpus as freely available resource to encourage future research.[1]

2 Related Work

2.1 Previous Argument Annotated Corpora

Currently, there exist only a few corpora that include argument annotations. The work most similar to ours with respect to the annotation scheme is Araucaria (Reed et al., 2008) since it also includes structural information of arguments. It is based on the *Argumentation Markup Language* (AML) that models argument components in a XML-based tree structure. Thus, it is possible to derive argumentative relations between components though they are not explicitly included. In contrast to our work, the corpus consists of several text genres including newspaper editorials, parliamentary records, judicial summaries and discussion boards. In addition, the reliability of the annotations is unknown. Nevertheless, researchers use the corpus for different computational tasks, e.g. separating argumentative from non-argumentative sentences (Mochales-Palau and Moens, 2011), identifying argument components (Rooney et al., 2012) and classifying argumentation schemes (Feng and Hirst, 2011).

Mochales-Palau and Moens (2008) conduct an argument annotation study in legal cases of the *European Court of Human Rights* (ECHR). They experiment with a small corpus of 10 documents and obtain an inter-rater agreemnt of $\kappa = 0.58$. In a subsequent study, they elaborated their guidelines and obtain an inter-rater agreement of $\kappa = 0.75$ on a corpus of 47 documents (Mochales-Palau and Moens, 2011). Unfortunately, the annotation scheme is not described in detail, but it can be seen from the examples that it includes annotations for claims and supporting or refuting premises. Unlike our work, the annotation scheme does not include argumentative relations.

Cabrio and Villata (2012) annotate argumentative relations in debates gathered from *Debatepedia*. Instead of identifying argument components, they are interested in relations between arguments to identify which are the ones accepted by the community. They apply textual entailment for identifying support and attack relations between arguments and utilize the resulting structure for identifying accepted arguments. Therefore, they annotate a pair of arguments as either entailment or not. In contrast to our work, the approach models relationships between pairs of arguments and does not consider components of individual arguments. In addition, the work does not include an evaluation of the annotation's reliability.

Villalba and Saint-Dizier (2012) study argumentation annotation in a corpus of French and English product reviews. Their goal is to identify arguments related to opinion expressions for recognizing reasons of customer opinions. Their annotation scheme is limited to eight types of support (e.g. justification, elaboration, contrast). Compared to our annotation scheme, the work distinguishes between different premise types. However, the approach is tailored to product reviews, and the work does not provide an inter-rater agreement study.

In contrast to previous work, our annotation scheme includes argument components and argumentative relations. Both are crucial for argument recognition (Sergeant, 2013) and argumentative writing support. First, argumentative relations are essential for evaluating the quality of claims, since it is not possible to examine how well a claim is justified without knowing which premises belong to a claim (Sampson and Clark, 2006). Second, methods that recognize if a statement supports or attacks a claim enable the collection of additional evidence from other resources to recommend argument improvement. In addition, we provide a detailed analysis of the inter-rater agreement and an analysis of disagreements.

[1] http://www.ukp.tu-darmstadt.de/data/argumentation-mining

2.2 Persuasive Essays

Persuasive essays are extensively studied in the context of *automated essay grading* (Shermis and Burstein, 2013), which aims at automatically assigning a grade to a student's essay by means of several features. Since the argument structure is crucial for evaluating essay quality, Burstein et al. (1998) propose an approach for identifying the argumentative discourse structure by means of discourse marking. They utilize a surface cue word and phrase lexicon to identify the boundaries of arguments at the sentence level in order to evaluate the content of individual arguments and to enrich their feature set for determining precise grades. Although the identification of argument boundaries is important for argument recognition, our work allows a more fine-grained analysis of arguments since it also includes argument components and argumentative relations.

Madnani et al. (2012) studied persuasive essays for separating organizational elements from content. They argue that the detection of organizational elements is a step towards argument recognition and inferring the structure of persuasive discourse. Further, they refer to organizational elements as claim and premise indicating word sequences which they call *shell expressions*. They annotate 200 essays and estimate an inter-rater agreement of $\kappa = 0.699$ and $F_1 = 0.726$ on a subset of 50 essays annotated by two annotators. However, their annotation scheme is limited to shell expressions and compared to our work it does not include argument components or argumentative relations.

Additional annotation studies on persuasive essays focus on identifying style criteria (Burstein and Wolska, 2003), factual information (Beigman Klebanov and Higgins, 2012), holistic scores for argumentation quality (Attali et al., 2013) or metaphors (Beigman Klebanov and Flor, 2013). We are not aware of an annotation study including argument components and argumentative relations in persuasive essays.

3 Annotation Scheme

The goal of our proposed annotation scheme is to model argument components as well as argumentative relations that constitute the argumentative discourse structure in persuasive essays. We propose an annotation scheme including three argument components and two argumentative relations (figure 1).

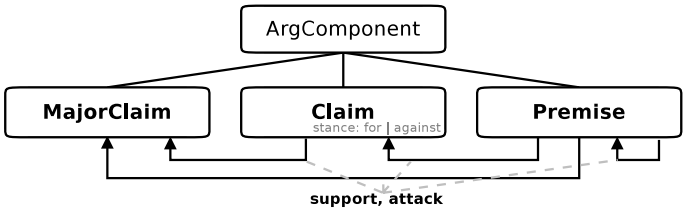

Figure 1: Argument annotation scheme including argument components and argumentative relations indicated by arrows below the components.

3.1 Argument Components

Persuasive essays exhibit a common structure. Usually, the introduction includes a *major claim* that expresses the author's stance with respect to the topic. The major claim is supported or attacked by arguments covering certain aspects in subsequent paragraphs. Sentences (1–3) illustrate three examples of major claims (the major claim is in bold face).[2]

(1) "*I believe that* ***we should attach more importance to cooperation during education***."
(2) "*From my viewpoint,* ***people should perceive the value of museums in enhancing their own knowledge***."
(3) "*Whatever the definition is,* ***camping is an experience that should be tried by everyone***."

In the first example, the author explicitly states her stance towards cooperation during education. The major claims in the second and third example are taken from essays about museums and camping

[2]We use examples from our corpus (5.1) without correcting grammatical or spelling errors.

respectively. In (1) and (2) a *stance indicating expression* (*"I believe"* and *"From my viewpoint"*) denotes the presence of the major claim. Although, these indicators are frequent in persuasive essays, not every essay contains an expression that denotes the major claim. In those cases, the annotators are asked to select the expression that is most representative with respect to the topic and author's stance (cf. (3)).

The paragraphs between introduction and conclusion of persuasive essays contain the actual arguments which either support or attack the major claim.[3] Since argumentation has been a subject in philosophy and logic for a long time, there is a vast amount of argumentation theories which provide detailed definitions of argument components (Toulmin, 1958; Walton et al., 2008; Freemen, 2011).[4] All these theories generally agree that an *argument* consists of several components and that it includes a *claim* that is supported or attacked by at least one *premise*. Examples (4) and (5) illustrate two arguments containing a claim (in bold face) and a premise (underlined).

(4) "***It is more convenient to learn about historical or art items online***. *With Internet, people do not need to travel long distance to have a real look at a painting or a sculpture, which probably takes a lot of time and travel fee.*"
(5) "***Locker checks should be made mandatory and done frequently*** *because they assure security in schools, makes students healthy, and will make students obey school policies.*"

The claim is the central component of an argument. It is a controversial statement that is either true or false and should not be accepted by readers without additional support. The premise underpins the validity of the claim. It is a reason given by an author for persuading readers of the claim. For instance, in (4) the author underpins his claim that Internet usage is convenient for exploring cultural items because of time and travel fee savings. In this example, both components cover a complete sentence. However, a sentence can also contain several argument components like in example (5). Therefore, we do not predefine the boundaries of the expression to be annotated (markable) in advance and annotate each argument as a *statement*, which is a sequence of words that constitutes a grammatically correct sentence.

To indicate if an argument supports or attacks a major claim, we add a *stance attribute* to the claim that denotes the polarity of an argument with respect to the author's stance. This attribute can take the values *for* or *against*. For example, the argument given in (4) refutes the major claim in example (2). Thus, the stance attribute of the claim in (4) is set to *against* in this example.

3.2 Argumentative Relations

Argumentative relations model the discourse structure of arguments in persuasive essays. They indicate which premises belong to a claim and constitute the structure of arguments. We follow the approach proposed by Peldszus and Stede (2013) and define two directed relations between argument components: *support* and *attack*.[5] Both relations can hold between a premise and another premise, a premise and a (major-) claim, or a claim and a major claim (figure 1). For instance, in example (4) the premise in the second sentence is a reason or justification for the claim in the first sentence and the claim in (4) attacks the major claim of example (2). Thus, an argumentative relation between two components indicates that the source component is a reason or a refutation for the target component. The following example illustrates a more complex argument including one claim and three premises.

(6) "***Living and studying overseas is an irreplaceable experience when it comes to learn standing on your own feet***. *One who is living overseas will of course struggle with loneliness, living away from family and friends*$_1$ *but those difficulties will turn into valuable experiences in the following steps of life*$_2$. *Moreover, the one will learn living without depending on anyone else*$_3$."

Figure 2 illustrates the structure of this argument. The claim is attacked by premise$_1$, whereas premise$_2$ is a refutation of premise$_1$. The third premise is another reason that underpins the claim in this paragraph.

[3] In some cases, the introduction or conclusion contains arguments as well, those are also annotated in the annotation study.
[4] A review of argumentation theory is beyond the scope of this paper but a survey can be found in (Bentahar et al., 2010)
[5] Peldszus and Stede also define a *counter-attacking relation* that is omitted in our scheme, since it can also be represented as a chain of attacking premises.

This shows that it is not necessary to explicitly distinguish between supporting and attacking premises, since the relational structure and the type of argumentative relations implicitly denote the role of argument components. Additionally, argumentative relations enable the modeling of relationships between pairs of arguments on the macro level, e.g., by linking claims to the major claim.

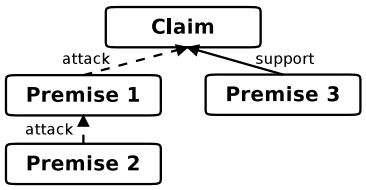

Figure 2: Argumentation structure of example (6)

4 Pre-Study

We conduct a preliminary study to define the annotation guidelines on a corpus of 14 short text snippets (1–2 sentences) that are either gathered from example essays or written by one of the authors. We ask five non-trained annotators to classify each text as argumentative or non-argumentative. If a text is classified as argumentative, the annotators are asked to identify the claim and the premise. In the first task, we obtain an inter-rater agreement of 58.6% and multi-$\pi = 0.171$ (Fleiss, 1971)[6]. We identified the markables for measuring the inter-rater agreement of the second task by manually determining the statements in each of the 14 text snippets. In total, we determined 32 statements and obtained an inter-rater agreement of 55.9% and multi-$\pi = 0.291$. These results indicate a low reliability of the annotations. In addition, they emphasize the demand for a precisely defined argument annotation strategy. In subsequent discussions, we discovered that the primary source of uncertainty is due to the missing context. Since the text snippets are provided without any information about the topic, the annotators found it difficult to decide if a snippet includes an argument or not. In addition, the annotators report that the author's stance might facilitate the separation of argumentative from non-argumentative text and to determine the components of arguments.

According to these findings, we define a new *top-down annotation process* starting with the major claim and drill-down to the claims and premises. Therefore, the annotators are aware of the author's stance after identifying the major claim. In addition, we ask the annotators to read the entire essay in order to identify the topic before starting with the actual annotation task. Although, this approach is more time-consuming than a direct identification of argument components, we show in our annotation study (section 5) that it yields reliably annotated data. In particular, the annotation guidelines consist of the following steps:

1. *Topic and stance identification*: Before starting with the annotation process, annotators identify the topic and the author's stance by reading the entire essay.

2. *Annotation of argument components*: In this step, the major claim is identified either in the introduction or in the conclusion of an essay. Subsequently, annotators identify the claims and premises in each paragraph. We instruct the annotators to annotate each argument component as a statement covering an entire sentence or less. We consolidate the annotations of all annotators before continuing with the next step (section 5.4).

3. *Annotation of argumentative relations*: Finally, the claims and premises are linked within each paragraph, and the claims are linked to the major claim either with a support or attack relation.

[6]Although the coefficient was introduced by Fleiss as a generalization of Cohen's κ (Cohen, 1960), it is actually a generalization of Scott's π (Scott, 1955), since it assumes a cumulative distribution of annotations by all annotators (Artstein and Poesio, 2008). We follow the naming proposed by Artstein and Poesio and refer to the measure as multi-π.

5 Annotation Study

Three annotators participate in the study and annotate the essays independently using our described annotation scheme. We conduct several training sessions after each annotator has read the annotation guidelines. In these sessions, annotators collaboratively annotate 8 example essays for resolving disagreements and obtaining a common understanding of the annotation guidelines. For the actual annotation task, we used the *brat annotation tool* that is freely available.[7] It allows the annotation of text units with arbitrary boundaries as well as the linking of annotations for modeling argumentative discourse structures.

5.1 Data

Our corpus consists of 90 persuasive essays in English, which we selected from *essayforum*[8]. This forum is an active community that provides writing feedback for different kinds of texts. For instance, students post their essays for retrieving feedback about their writing skills while preparing themselves for standardized tests. We randomly selected the essays from the *writing feedback* section of the forum and manually reviewed each essay. Due to the non-argumentative writing style and significant language flaws, we replaced 4 of them during a manual revision of the corpus. The final corpus includes 1,673 sentences with 34,917 tokens. On average, each essay has 19 sentences and 388 tokens.

5.2 Inter-rater Agreement

We evaluate the reliability of the argument component annotations using two strategies. Since there are no predefined markables in our study, annotators have to identify the boundaries of argument components. We evaluate the annotations using Krippendorff's α_U (Krippendorff, 2004). It considers the differences in the markable boundaries of several annotators and thus allows for assessing the reliability of our annotated corpus. In addition, we evaluate if a sentence contains an argument component of a particular category using percentage agreement and two chance-corrected measures: multi-π (Fleiss, 1971) and Krippendorff's α (Krippendorff, 1980). Since only 5.6% of the sentences contain several annotations of different argument components, evaluating the reliability at the sentence-level provides a good approximation of the inter-rater agreement. In addition, it enables comparability with future argument annotation studies that are conducted at the sentence-level. The annotations yield the following class distribution at the token-level: 3.5% major claim, 18.2% claim, 48.1% premise and 30.2% are not annotated. At the sentence-level 5.4% contain a major claim, 26.4% a claim, 61.1% a premise and 19.3% none annotation. Thus, 12.2% of the sentences contain several annotations.

	%	π	α	α_U
MajorClaim	.9827	.8334	.8365	.7726
Claim	.8690	.6590	.6655	.6033
Premise	.8618	.7075	.7131	.7594

Table 1: Inter-rater agreement of argument component annotations

We obtain the highest inter-rater agreement for the annotations of the major claim (table 1). The inter-rater agreement of 98% and multi-$\pi = 0.833$ indicates that the major claim can be reliably annotated in persuasive essays. In addition, there are few differences regarding the boundaries of major claims ($\alpha_U = 0.773$). Thus, annotators identify the sentence containing the major claim as well as the boundaries reliably. We obtain an inter-rater agreement of multi-$\pi = 0.708$ for premise annotations and multi-$\pi = 0.66$ for claims. This is only slightly below the "*tentative conclusion boundary*" proposed by Carletta (1996) and Krippendorff (1980). The unitized α of the major claim and the claim are lower than the sentence-level agreements (table 1). Only the unitized α of the premise annotations is higher compared to the sentence-level agreement. Thus, the boundaries of premises are more precisely identified. The joint unitized measure for all categories is $\alpha_U = 0.724$. Hence, we tentatively conclude that the annotation of argument components in persuasive essays is reliably possible.

[7] http://brat.nlplab.org

[8] http://www.essayforum.com

The agreement of the stance attribute is computed for each sentence. We follow the same methodology as for the computation of the argument component agreement, but treat each sentence containing a claim as either for or against according to the stance attribute (sentences not containing a claim are treated as not annotated, but are included in the markables). Thus, the upper boundary for the stance agreement constitutes the agreement of the claim annotations. The agreement of the stance attribute is only slightly below the agreement of the claim (86%; multi-$\pi = 0.643$; $\alpha = 0.65$). Hence, the identification of either attacking or rebutting claims is feasible with high agreement.

We determine the markables for evaluating the reliability of argumentative relations as the set of all pairs between argument components according to our annotation scheme. So, the markables correspond to all relations that were possible during the annotation task. In total, the markables include $5{,}137$ pairs of which 25.5% are annotated as support relation and 3.1% as attack relations. We obtain an inter-rater agreement above 0.8 for both support and attack relations (table 2) that is considered by Krippendorff (1980) as good reliability. Therefore, we conclude that argumentative relations can be reliably annotated in persuasive essays.

	$\%$	π	α
support	.9267	.8105	.8120
attack	.9883	.8052	.8066

Table 2: Inter-rater agreement of argumentative relation annotations

5.3 Error Analysis

To study the disagreements encountered during the annotation study, we created *confusion probability matrices* (CPM) (Cinková et al., 2012) for argument components and argumentative relations. A CPM contains the conditional probabilities that an annotator assigns a certain category (column) given that another annotator has chosen the category in the row for a specific item. In contrast to traditional confusion matrices, a CPM also enables the evaluation of confusions if more than two annotators are involved in an annotation study.

	Major Claim	Claim	Premise	None
Major Claim	.675	.132	.148	.045
Claim	.025	.552	.338	.086
Premise	.014	.163	.754	.069
None	.012	.123	.204	.660

Table 3: Confusion probability matrix for argument component annotations (Category 'None' indicates argument components that are not identified by an annotator.)

The major disagreement is between claims and premises (table 3). This could be expected since a claim can also serve as premise for another claim, and it is difficult to distinguish these two concepts in the presence of reasoning chains. For instance, examples (7–9) constitute a reasoning chain in which (7) is supported by (8) and (8) is supported by (9):

(7) "*Random locker checks should be made obligatory*."
(8) "*Locker checks help students stay both physically and mentally healthy*."
(9) "*It discourages students from bringing firearms and especially drugs*."

Considering this structure, (7) can be classified as claim. However, if (7) is omitted, (8) becomes a claim that is supported by (9). Thus, the distinction between claims and premises depends not only on the context and the intention of the author but also on the structure of a specific argument. Interestingly, the distinction between major claims and claims is less critical. Apparently, the identification of the major claim is easier since it is directly related to the author's stance in contrast to more general claims that cover a certain aspect with respect to the overall topic of the essay.

The CPM for relations (table 4) reveals that the highest confusion is between support/attack relations and none classified relations. This could be due to the fact that it is difficult to identify the correct target of a relation, especially in the presence of multiple claims or reasoning chains in a paragraph. For instance,

	support	attack	none
support	.750	.013	.238
attack	.104	.691	.205
none	.092	.001	.898

Table 4: Confusion probability matrix for argumentative relation annotations

in the previous example an annotator could also link (9) directly to (7) or even to (7) and (8). In both cases, the argument would be still meaningful. The distinction between support and attack relations does not reveal high disagreements. To sum up, the error analysis reveals that the annotation of argumentative relations yields more reliable results than that of argument components. This could be due to the fact that in our studies, argument components are known before annotating the relations and thus the task is easier. Nevertheless, it could be interesting to annotate relations before classifying the types of argument components and to investigate if it positively influences the reliability of annotations.

5.4 Creation of the Final Corpus

The creation of the final corpus consists of two independent tasks. First, we consolidate the argument components before the annotation of argumentative relations. So each annotator works on the same argumentative components when annotating the relations. Second, we consolidate the argumentative relations to obtain the final corpus. We follow a majority voting in both steps. Thus, an annotation is adopted in the final corpus if at least two annotators agree on the category as well as on the boundaries. In applying this strategy, we observed seven cases for argument components and ten cases for argumentative relations that could not be solved by majority voting. Those cases were discussed in the group of all annotators to reach an agreement. Table 5 shows an overview of the final corpus. It includes 90 major

	ALL	avg. per essay	standard deviation
Sentence	1,673	19	7
Tokens	34,917	388	124
MajorClaim	90	1	0
Claim	429	5	2
Claim (for)	365	4	2
Claim (against)	64	1	1
Premises	1,033	11	6
support	1,312	15	7
attack	161	2	2

Table 5: Statistics of the final corpus

claims (each essay contains exactly one), 429 claims and 1,033 premises. This proportion between claims and premises is common in argumentation and confirms the findings of Mochales-Palau and Moens (2011, p. 10) that claims are usually supported by several premises for "*ensuring a complete and stable standpoint*".

6 Conclusion & Future Work

We presented an annotation study of argument components and argumentative relations in persuasive essays. Previous argument annotation studies suffer from several limitations: Either they do not follow a systematic methodology and do not provide detailed inter-rater agreement studies or they do not include annotations of argumentative relations. Our annotation study is the first step towards computational argument analysis in educational applications that provides both annotations of argumentative relations and a comprehensive evaluation of the inter-rater agreement. The results of our study indicate that the annotation guidelines yield substantial agreement. The resulting corpus and the annotation guidelines are freely available to encourage future research in argument recognition.

In future work, we plan to utilize the created corpus as training data for supervised machine learning methods in order to automatically identify argument components as well as argumentative relations. In addition, there is a demand to scale the proposed annotation scheme to other genres e.g. scientific articles or newspapers and to create larger corpora.

Abstract

We construct a hierarchically aligned Chinese-English parallel treebank by manually doing word alignments and phrase alignments simultaneously on parallel phrase-based parse trees. The main innovation of our approach is that we leave words without a translation counterpart (which are mostly language-particular function words) unaligned on the word level, and locate and align the appropriate phrases which encapsulate them. In doing so, we harmonize word-level and phrase-level alignments. We show that this type of annotation can be performed with high inter-annotator consistency and have both linguistic and engineering potentials.

1 Introduction

The value of human annotated syntactic structures for Statistical Machine Translation has been clearly demonstrated in string-to-tree (Galley et al., 2004; Galley et al., 2006; Huang et al., 2006), tree-to-string (Liu et al., 2006; Liu and Gildea, 2008), and tree-to-tree (Eisner, 2003; Liu et al., 2009; Chiang, 2010) models. One recurring issue which hampers the utility of syntactic structures is the incompatibility between word alignments and syntactic structures (Denero and Klein, 2007; Fossum et al., 2008; Pauls et al., 2010). The incompatibility arises because word alignments and syntactic structures are established independently of each other. In the case of tree-to-tree models, there is also the issue of incompatible parallel tree structures resulting from divergent syntactic annotation standards that have been independently conceived based on monolingual corpora (Chiang, 2010). In this paper, we report an effort in building a Hierarchically Aligned Chinese-English Parallel Treebank (HACEPT) where we manually do word-level and phrase-level alignments simultaneously on parallel phrase-based parse trees. In this process, we attempt to establish an annotation standard that harmonizes word-level and phrase-level alignments. We also analyze a common incompatibility issue between Chinese-English parallel parse trees exposed in the annotation process, with the goal of solving the issue by semi-automatically revising the trees.

In the rest of this paper, we describe how we construct the HACEPT and discuss issues arising in the construction process. In Section 2, we discuss the problems of word alignment done without considering its interaction with syntactic structures. In Section 3, we describe our annotation procedure where we perform word-level and phrase-level alignments simultaneously in a coordinated manner, and show how our approach is free of the problems discussed in Section 2. In Section 4, we report a common incompatibility issue between parse trees and propose a solution. We also compare the issue with translation divergence (Dorr, 1994) and show that they are different in nature and occurrence frequency. In Section 5, we present the results of two experiments we have done on our annotation to show the intuitiveness of our approach and the linguistic and engineering potentials of our corpus. We then describe related work in Section 6 and conclude our paper in Section 7.

Proceedings of COLING 2014, the 25th International Conference on Computational Linguistics: Technical Papers, pages 1511–1520, Dublin, Ireland, August 23-29 2014.

2 Incompatibilities between word alignments and syntactic structures

All the existing word alignment practice we know of treats word alignment as a stand-alone task without systematically considering its interaction with the syntactic structure of a sentence. The inevitable consequence of the practice is that both redundancies and incompatibilities between word alignments and syntactic structures will arise in many places. In this section, we illustrate the issues through language-particular function words, where the problems are most frequently found. Due to language-particular idiosyncrasy and lack of lexical content, these function words usually do not have a translation counterpart, which presents a great challenge to alignment annotation. There are two logical possibilities of dealing with these words, both of which are represented in existing annotation practice. The first is to leave them unaligned or link them to a fictitious NULL word (Ahrenberg, 2007; Brown et al., 1990), and the second, which also seems to be the more common pratice, is to attach these function words to a word that has a translation counterpart, and then align the function word and its host with the counterpart of the host (Melamed, 1998; Li et al., 2009). For ease of discussion, below we will refer to the latter pratice as the "glue-to-a-host" strategy (GTAHS). Both approaches are less than desirable: the former leaves the function words unaccounted for, and the latter leads to incompatibility issues we discuss in detail below.

First note that, by attaching language-particular function words to a host, the GTAHS creates redundancies between word alignments and syntactic structures since many of these function words have already been associated with a host within a constituent in the parse tree (e.g., the English determiner *the* is placed inside the projection of its host, namely an NP). A more serious issue is that the GTAHS creates spurious ambiguities. Lexical ambiguity is inevitable in translation. For instance, the English noun *bank* has more than one lexical meaning and each of the meanings corresponds to a different Chinese word. That fact aside, the GTAHS creates spurious ambiguities, which, in our view, would be harmful to Machine Translation (MT) if extracted as translation rules. Consider the following example, where the Chinese noun 苹果 is aligned to six English strings (aligned elements are underlined):

(1) a. eat apples <> 吃 苹果
b. eat an apple <> 吃 苹果
c. eat the apple <> 吃 苹果
d. fond of apples <> 喜欢 苹果
e. talk about apples <> 谈论 苹果
f. provide them with apples <> 给 他们 苹果

The English *apple* and the Chinese 苹果 match in meaning and are both unambiguous. In cases where the English noun is used with a determiner as in (1b) and (1c), since Chinese has no determiners and the bare noun 苹果 can be the appropriate translation for either *an apple* or *the apple* given a context, the GTAHS attaches the determiner to *apple* and the whole string is aligned with 苹果. In other similar cases where an English element such as a preposition is absent in Chinese as in (1d), (1e) and (1f), the GTAHS glues the preposition to *apple* and the whole PP is aligned with 苹果. With the GTAHS, the unambiguous Chinese 苹果 ends up being aligned with more than one English string. This kind of spurious ambiguity is very common given the GTAHS.

The second issue is that, by attaching function words to a host, the GTAHS effectively creates rudimentary syntactic structures, which are often incompatible with the syntactic structures annotated based on existing treebanking annotation standards. For example, all the aligned multi-word strings underlined in (2) do not correspond to a constituent in a Penn TreeBank (Marcus et al., 1993) or Chinese TreeBank (Xue et al., 2005) parse tree:

(2) a. If I were him <> 如果 我 是 他 的话
b. He is visiting Beijing <> 他 正 访问 北京

c. the beginning of the new year <> 新 年 伊始

d. to quickly and efficiently solve the problem <> 迅速 有效地 解决 问题

Given the incompatibilities between existing word alignments and syntactic structures, in the next section we describe an approach where we perform word-level and phrase-level alignments simultaneously on parallel phrase-based parse trees, attempting to construct a hierarchically aligned corpus where word alignments are harmonized with syntactic structures.

3 Annotation specification and procedure

The data we annotate is the Chinese-English portion of the Parallel Aligned Treebank (PAT) described in (Li et al., 2012). Our data consists of two batches, one of which is weblogs and the other of which is postings from online discussion forums. The English sentences in the data set are annotated based on the original Penn TreeBank (PTB) annotation stylebook (Bies et al., 1995) as well as its extensions (Warner et al., 2004), while the Chinese sentences in the data set are annotated based on the Chinese TreeBank (CTB) annotation guidelines (Xue and Xia, 2000) and its extensions (Zhang and Xue, 2012). The PAT only has word alignments, which are done under the GTAHS, and no phrase alignments.

The main departure of our approach is that we loosen the requirement that every word in a sentence pair needs to be word-aligned. On the word level, we only align words that have an equivalent in terms of lexical meaning and grammatical function. For words that do not have a translation counterpart, we leave them unaligned and locate the appropriate phrases in which they appear to be aligned. This way, we eliminate both the redundancies and spurious ambiguities discussed in Section 2. Since phrase alignment is done between syntactic nodes on parallel parse trees, we also eliminate the incompatibilities between word alignments and syntactic structures. See the discussion of the concrete example in Figure 1 below to see the points made here.

Next we discuss our annotation procedure in detail. Our annotators are presented with sentence pairs that come with parallel parse trees. The task of the annotator is to decide, first on the word level and then on the phrase level, if a word or phrase needs to be aligned at all, and if so, to which word or phrase it should be aligned. The decisions about word alignment and phrase alignment are not independent, and must obey well-formedness constraints as outlined in (Tinsley et al., 2007):

a. A non-terminal node can only be aligned once.
b. if Node n_c is aligned to Node n_e, then the descendants of n_c can only be aligned to descendants of n_e.
c. if Node n_c is aligned to Node n_e, then the ancestors of n_c can only be aligned to ancestors of n_e.

This means that once a word alignment is in place, it puts constraints on phrase alignments. A pair of non-terminal nodes (n_c, n_e) cannot be aligned if a word that is a descendant of n_c is aligned to a word that is not a descendant of n_e on the word level.

Let us use the concrete example in Figure 1 to illustrate the annotation process, which is guided by a set of detailed annotation guidelines. On the word level, only those words that are connected with a dashed line are aligned since they have equivalents. Note that the Chinese words 把 (a function word used to prepose the object to the left of the verb), 这样 (an adverb meaning "this way"), 可 (a modal meaning "can") and the English discourse connective *so that*, the auxiliary verb *is* and the preposition *from* are all left unaligned on the word level. Aligning these function words will generate artificial ambiguous cases and create incompatibilities between word alignments and parse trees that have already been illustrated and discussed in Section 2. For instance, if 把 is to be word-aligned, it would be glued to the noun 重力 and the whole string 把 重力 will be aligned to the English *gravity*. Note that both 重力 and *gravity* are unambiguous and form a one-to-one correspondence. With the word alignment between 把 重力 and *gravity*, we make the unambiguous *gravity* correspond to both 重力 and 把 重力 (and possibly

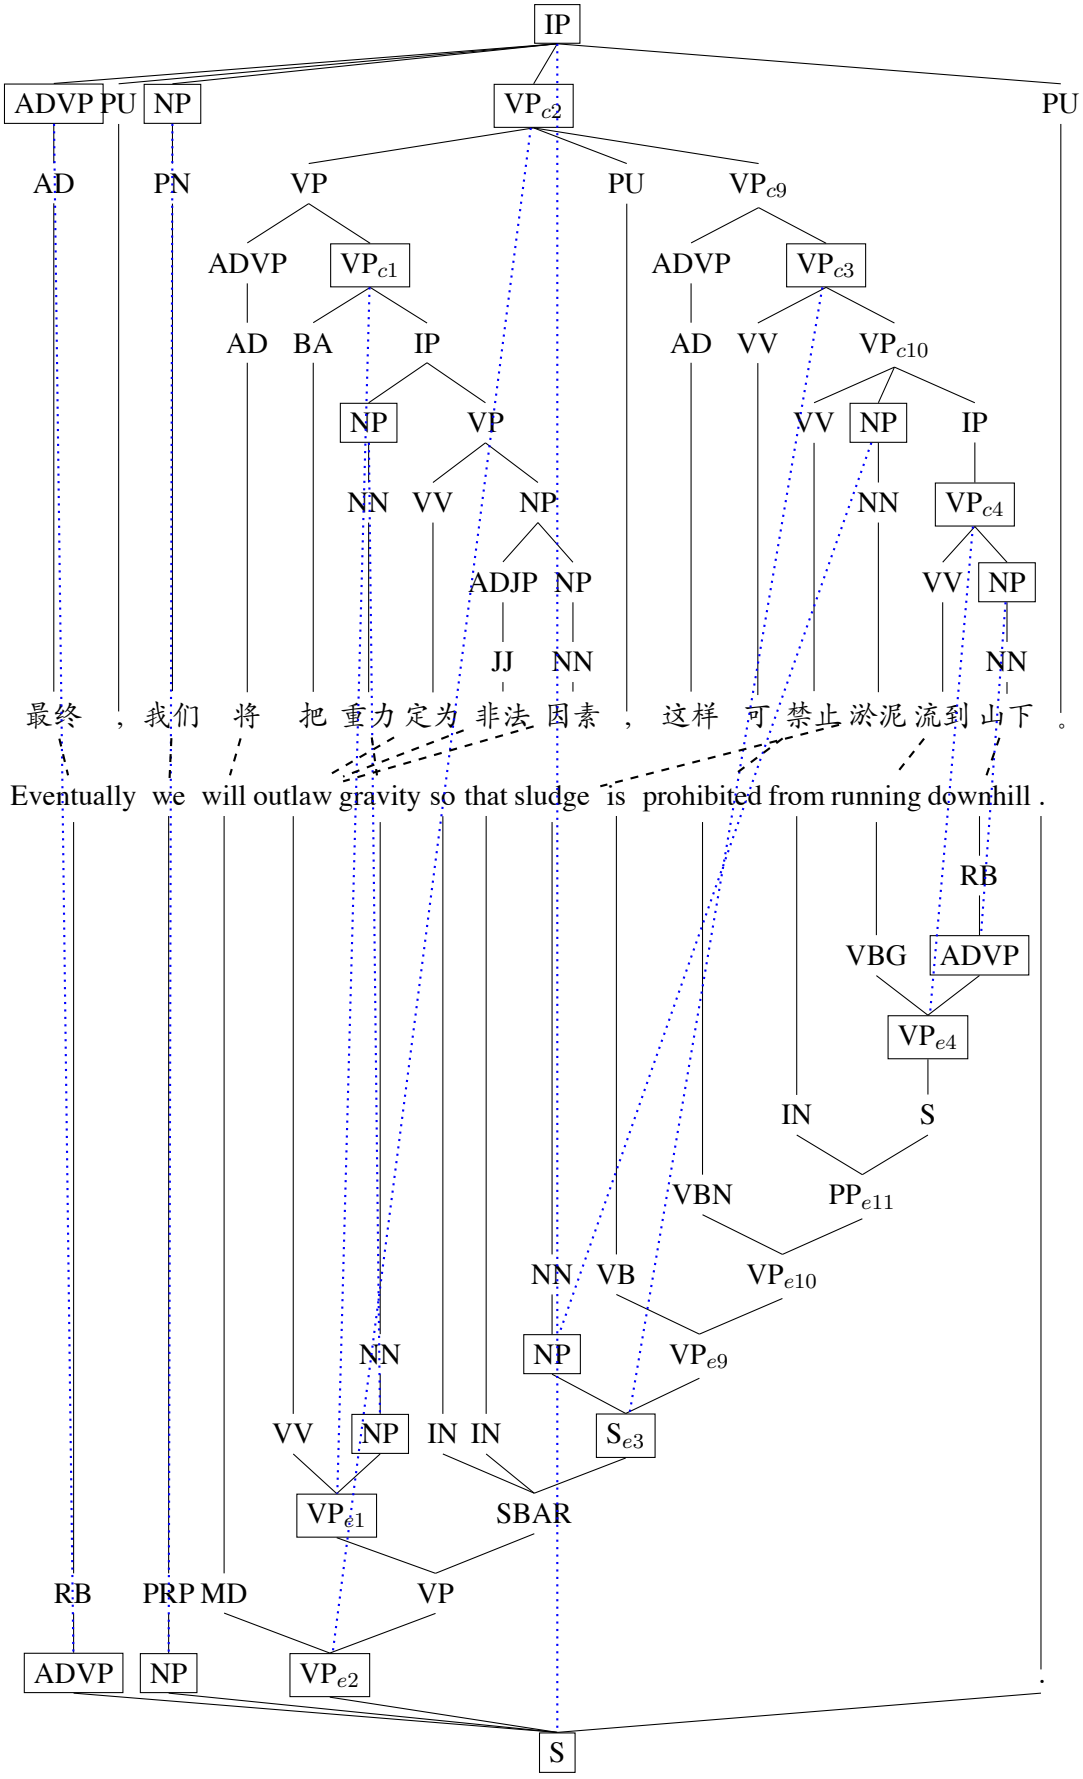

Figure 1: A hierarchically aligned sentence pair

more strings), thus creating a spurious ambiguity. Also note that the string 把 重力 does not form a constituent in the Chinese parse tree, so the word alignment is incompatible with the syntactic structure of the sentence. By leaving 把 unaligned, we avoid both the spurious ambiguity and the incompatibility.

With word alignments in place, next the annotator needs to perform phrase alignments. Note that word alignments place restrictions on phrase alignments. For instance, e_9 and e_{10} will be ruled out as possible alignments for c_{10}, because 淤泥, a descendant of c_{10}, is aligned to *sludge*, which is not a descendant of either e_9 or e_{10}. By contrast, e_3 is a possible alignment for c_{10} because the alignment does not violate the well-formedness constraints. The annotator then needs to decide whether this possible phrase alignment can be actually made. This is a challenging task since, for a given phrase, there usually are more than one candidate from which a single alignment needs to be picked. For instance, for e_3, there are in total three possible phrase alignments, namely c_{10}, c_3 and c_9, all of which obey the well-formedness constraints. Since a non-terminal node is not allowed to be aligned to multiple non-terminal nodes on the other side, the annotator needs to choose one among all the candidates. This highlights the point that the alignment of non-terminal nodes cannot be deterministically inferred from the alignment of terminal nodes. This is especially true given our approach where some terminal nodes are left unaligned on the word level. For instance, the reason why c_9 is a possible alignment for e_3 is because the word 这样 is left unaligned. If 这样 were aligned with *so that*, c_9 could not be aligned with e_3 since *so that* is not a descendant of e_3 and aligning the two nodes will violate Constraint *b*.

While Constraints *b* and *c* can be enforced automatically given the word alignments, the decisions regarding the alignment of non-terminal nodes which satisfy Constraint *a* are based on linguistic considerations. One key consideration is to determine which non-terminal nodes encapsulate the grammatical relations signaled by the unaligned words so that the alignment of the non-terminal nodes will effectively capture the unaligned words in their syntactic context. When identifying non-terminal nodes to align, we follow two seemingly conflicting general principles:

- Phrase alignment should not sever key dependencies involving the grammatical relation signaled by an unaligned word.
- Phrase alignment should be minimal, in the sense that the phrase alignment should contain only the elements involved in the grammatical relation, and nothing more.

The first principle ensures that the grammatical relation is properly encapsulated in the aligned non-terminal nodes. For example in Figure 1, if we attach the English preposition *from* to *running* and aligning them to 流到, we would fail to capture the fact that *from* signals a relation between *prohibit* and *running downhill*. Aligning VP_{c3} with S_{e3} captures this relation.

The first principle in and of itself is insufficient to produce desired alignment. Taken to the extreme, it can be trivially satisfied by aligning the two root nodes of the sentence pair. We also need the alignment to be minimal, in the sense that aligned non-terminal nodes should contain only the elements involved in the grammatical relation, and nothing more. These two requirements used in conjunction ensure that a unique phrase alignment can be found for each unaligned word. The phrase alignments (VP_{c1}, VP_{e1}), (VP_{c2}, VP_{e2}), (VP_{c3}, S_{e3}), as illustrated in Figure 1, all satisfy these two principles.

In addition to making phrase alignments, the annotator needs to assign labels to phrase alignments. We have four labels that are designed along two dimensions: the presence/absence of word order difference and the presence/absence of unaligned function words. The name and definition of each of the four labels are listed below, and an example for each label is given in Figure 2:

a REO, reordering that does not involve unaligned function words (Figure 2a)
b UFW, unaligned function words (Figure 2b)
c REU, reordering that also involves unaligned function words (Figure 2c)
d STD, structural divergence due to cross-linguistic differences (Figure 2d)

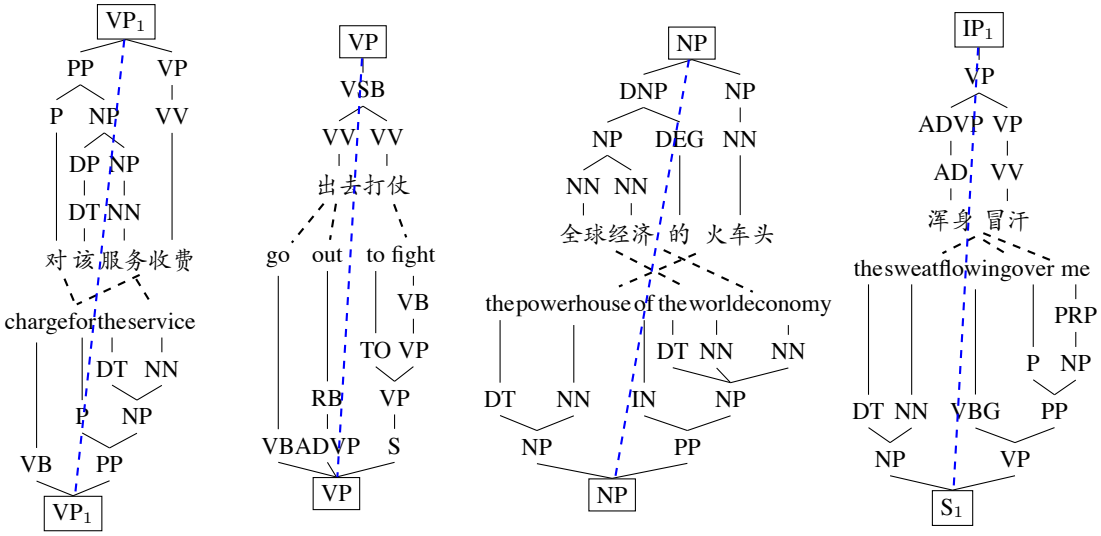

Figure 2: Phrase alignment types

Figure 2a is an example where there is a reordering of the immediate children of the aligned VP nodes. This is a very typical word order difference between Chinese and English. In Chinese, the PP modifier is before the verb while in English the PP modifier is after the verb. The phrase alignment illustrated by Figure 2b has an unaligned function word, namely the English infinitive marker *to*, which has no counterpart in Chinese. There are both reordering (difference in the relative order of *powerhouse* and *economy*) and unaligned function words (Chinese 的 and English *of*) in the phrase alignment in Figure 2c. Figure 2d provides an example where the aligned phrases have structural divergence caused by cross-linguistic differences between Chinese and English, which we will discuss in some detail in Section 4.

4 A common incompatibility issue between parse trees

During the annotation process, we encountered some incompatibility issues between parse trees. For a comprehensive and detailed discussion of the issues, see (Deng and Xue, 2014). Here we report the most common issue, which is caused by differences between treebank annotation guidelines. As already mentioned, the English parse trees we use are annotated based on the original PTB annotation stylebook (Bies et al., 1995) as well as its extensions (Warner et al., 2004), while the Chinese parse trees are annotated based on the CTB annotation guidelines (Xue and Xia, 2000) and its extensions (Zhang and Xue, 2012). Since PTB and CTB are independently annotated, there are some differences in how certain structures are annotated. The main issue is that certain structures are so flat as to make some nodes that should be aligned impossible to be aligned. In general, our alignment task favors deeper structures over shallower ones so that the annotator can have more choices. This is an issue for both Chinese and English parse trees. To get a concrete idea of the issue, take a look at Figure 3.

As shown by Figure 3, VP_{c1} and the English string *probably decrease rapidly with distance*, and VP_{e1} and the Chinese string 随 距离 而 快速 减少, cannot be aligned although they match in meaning and should be aligned. They cannot be aligned because there is no node for either of the two strings in the respective parse tree. Note that the incompatibility between the two trees here is due to a difference in annotation style but not a deep cross-linguistic difference. Both PTB and CTB simplified the annotation task by making the tree structures flatter to increase annotation speed, but the simplification does not always come from the same places. The consequence of these annotation decisions is that relevant structures are sometimes incompatible, which has negatively affected their utility for MT purposes (Chiang,

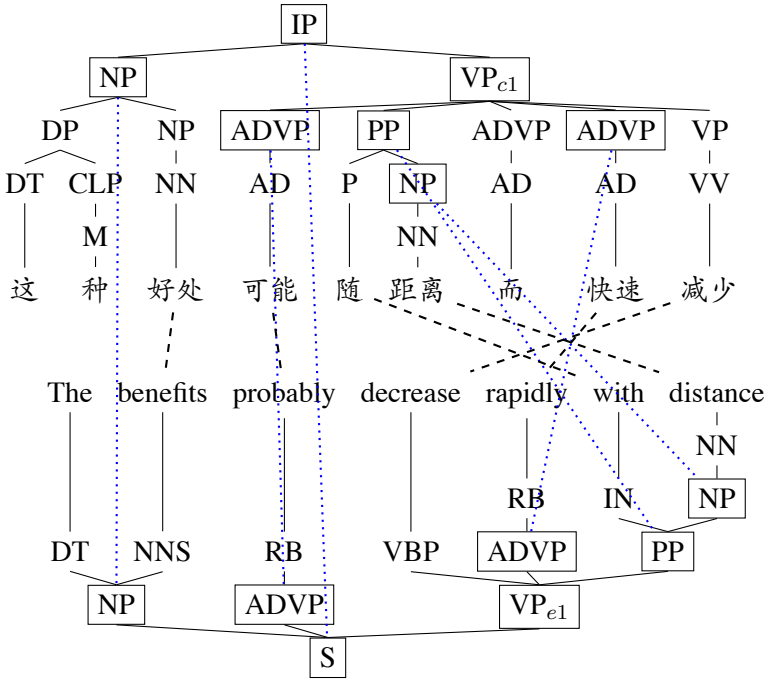

Figure 3: Unalignable nodes due to differences in tree representation

2010).

To solve this incompatibility issue, we need to create more structures through binarization, which can be done automatically. Still take Figure 3 for instance, on the English side, if we create a new VP by combining VP$_{e1}$ and its sister ADVP, the resulting VP can be aligned with VP$_{c1}$. On the Chinese side, if we do binarization to create a VP that dominates the string 随 距离 而 快速 减少, VP$_{e1}$ would have an alignment. Since changing tree structures has the potential risk of causing inconsistency with parse trees in the original treebanks and had better be done systematically after all the annotation is finished, we have not done binarization as of the writing of this paper. For the time being, we assign the label UA (short for Unalignable Node) to nodes which should be aligned but cannot be aligned so that we can gather some statistics on the extent of the problem. We will come back to revisit the nodes carrying UA such as VP$_{c1}$ and VP$_{e1}$ by proposing systematic changes to the original treebanks.

The UA case discussed above should not be confused with another case of incompatibility, namely structural divergence between parallel sentences in translation (Dorr, 1994). As shown above, UA is basically an artificial issue that is caused by difference in parsing guideline design and fixable through automatic binarization. Structural divergence arises mainly due to genuine cross-linguistic differences. We provide an example of structural divergence (STD) in Figure 2d. As shown in the figure, the two aligned phrases (VP and S) are structurally quite different: the English string is a clause with the NP *the sweat* as the subject and the VP *flowing over me* as the predicate (the example is taken out of the sentence *I felt the sweat flowing over me* to save space). The Chinese string is a simple verb phrase where the adverb 浑身 (literally whole-body) modifies the verb 冒汗 (literally emerge-sweat). In terms of meaning correspondence, 浑身 expresses the meaning of the English PP *over me* and the verb matches in meaning with *the sweat flowing*. We have run an experiment on STD and found that the STD cases are pretty rare (on average 5 instances in a file with 500 sentence pairs), indicating that the structural difference between Chinese and English is not so fundamental as to make a big impact on alignment annotation.

5 Annotation experiments

We did two experiments on our annotation. The first is about inter-annotator agreement (IAA), which is a way of both evaluating the annotation quality and judging the intuitiveness of the annotation task. An unintuitive annotation task would force the annotator to make subjective choices, which would result in low IAA. Since the annotation task involves parse trees, ideally we need annotators who are trained in syntax, but that would put a constraint on the pool of qualified annotators and make it difficult for the annotation to scale up. In our annotation experiments, we use four annotators who are fluent in both English and Chinese but have no prior linguistic training, led by a syntactician who performs the final adjudication.

As of this writing, we have completed the single annotation of 8,932 sentence pairs, 2,500 of which are double annotated. The IAA statistics presented in Table 1 are based on the double-annotated 2,500 sentence pairs, which are divided into 5 chunks of 500 sentence pairs each. The statistics are for phrase alignment only, and the micro-average for the 5 chunks is 0.87 (F1), indicating we are able to get good quality annotation for this task. In addition, the agreement statistics for the 5 chunks are very stable, even though they are performed by different pairs of annotators, indicating we are getting consistent annotation from different annotators.

Table 2 shows the result of the second experiment, namely the distribution of the different types of phrase alignment. It shows that alignments that contain unaligned function words outnumber those that do not, and that alignments that do not involve reordering outnumber those that do. It also shows that an overwhelming number of alignments that involve reordering also have unaligned function words. This means that the function words are potentially useful "triggers" for reordering, which is an important issue that MT systems are trying to address.

Chunk No.	precision	recall	F1-measure
1	0.91	0.86	0.89
2	0.92	0.80	0.86
3	0.89	0.89	0.89
4	0.88	0.88	0.88
5	0.89	0.89	.086
micro-average	0.90	0.85	0.87

Table 1: Statistics of IAA

6 Related work

Parallel treebanks are not something new. However, most of the existing parallel treebanks (Li et al., 2012; Megyesi et al., 2010) do not have phrase alignments. Some (Sulger et al., 2013; Kapanadze, 2012) do have phrase alignments, but neither discussion about the interaction between word-level and phrase-level alignments nor report of IAA is provided. There have been a few recent attempts at automatically aligning subtrees (comparable to our phrases) in the context of MT research, and the automatic alignments are evaluated against a small manually aligned data set. For example, (Tinsley et al., 2007) evaluated an unsupervised algorithm on 810 parsed English-French pairs annotated with subtree alignment. (Xiao and Zhu, 2013) also developed unsupervised subtree alignment methods (EM and Variational Bayes) and evaluated their automatic alignment model on 637 sentences from the Chinese TreeBank (and use the other 99 for tuning). (Sun et al., 2010b; Sun et al., 2010a) also report work on aligning subtrees and evaluate their impact on MT. However, we are not aware of any attempt to systematically harmonize word alignment with the alignment of phrases, or subtrees, or to systematically study the incompatibilities between parallel parse trees.

7 Conclusion

In this paper we report our effort on the construction of a Chinese-English parallel treebank with both word-level and phrase-level alignments. When constructing the treebank, we systematically consider the interaction between word alignments and phrase alignments, and try to harmonize the two kinds of alignments by removing redundancies and incompatibilities between them. We show that this type of annotation can be performed with high inter-annotator consistency. Given our intention for the treebank to be a resource for MT, the next step is to synchronize the parallel parse trees, and of course, to perform automatic hierarchical alignment experiments and MT experiments.

Abstract

We present *3arif*[1], a large-scale corpus of Modern Standard and Egyptian Arabic tweets annotated for epistemic modality[2]. To create *3arif*, we design an interactive crowdsourcing annotation procedure that splits up the annotation process into a series of simplified questions, dispenses with the requirement for expert linguistic knowledge and captures nested modality triggers and their attributes semi-automatically.

1 Introduction

Epistemic modality, according to Palmer (2001), defines the speaker's subjective knowledge, beliefs and judgments about the world's states of affairs. Epistemic modality is used as a linguistic feature for multiple NLP tasks and applications, including sentiment analysis (Abdul-Mageed and Diab 2011), opinion mining (Benamara et al. 2012) and scientific discourse evaluation (Waard and Maat 2012), among others.

To-date, there are no large-scale modality-annotated Arabic corpora compared to English (Baker et al. 2010, 2012; Rubinstein et al. 2013), Chinese (Cui and Chi 2013), Portuguese (Hendrickx et al. 2012) and Japanese (Matsuyoshi et al. 2010). The creation of modality-annotated corpora is non-trivial because there is no consensus definition of modality and its attributes in theoretical linguistics to be rendered into annotation tasks and guidelines. Furthermore, most current modality annotation schemes rely on sophisticated theoretically-grounded guidelines that require annotators from linguistics background; hence, annotation is usually restricted to small-scale in-lab settings.

In this paper, we present *3arif*, a large-scale Arabic corpus annotated for epistemic modality. *3arif* comprises 9822 unique tweets in Modern Standard Arabic (MSA) and Egyptian Arabic (EA), annotated for 9966 tokens that map to 214 unique types of epistemic modality. Each epistemic modality is annotated for sense, polarity, intensification, tense, holder(s) and scope(s). The reason that *3arif* features the tweets' genre with an emphasis on MSA and EA tweets is that it comes as part of a larger project to incorporate linguistic features, such as modality, with network-based features to automatically identify the key players of Twitter's political discourse in counties of political unrest such as Egypt. We harvested *3arif* from a variety of Twitter users including newspapers, TV stations, political campaigns, among others, as well as individuals. As a result *3arif* is diglossic for MSA, the formal Arabic variety, and EA, the native Arabic dialect of Egypt.

For the annotation of *3arif*, we design a simplified procedure that depicts the following ideas: first, it defines each annotation task as a series of open and closed questions that do not require sophisticated linguistics background and, meanwhile, provide annotators with self-explanatory annotation guidelines; second, it is interactive so that questions are displayed/hidden based on annotators' prior answers; and finally, it semi-automatically identifies and merges nested epistemic modality based on annotators' answers to a number of easy-to-administer questions.

[1] Pronounced as *ʕa:rif* in Arabic IPA and as *EArif* in Buckwalter's transliteration scheme. It means *I/he know(s)*.
[2] *3arif* is available at http://www.rania-alsabbagh.com/3arif.html

Proceedings of COLING 2014, the 25th International Conference on Computational Linguistics: Technical Papers, pages 1521–1532, Dublin, Ireland, August 23-29 2014.

We evaluate our annotation results using Krippendorff's reliability (Krippendorff 2011) and agreement. Results show high inter-annotator reliability and agreement rates and indicate that our annotation scheme and procedure are efficient. The contribution of this research, therefore, is twofold: first, we create a novel resource for Arabic NLP which is expected to enhance research on modality automatic identification and extraction; second, we present an efficient and easy-to-administer annotation procedure with interactive crowdsourcing potentials for the complex task of modality annotation.

The rest of this paper is organized as follows: Section 2 outlines our annotation scheme including annotation tasks, guidelines and the interactive structure; Section 3 gives examples for the representation of the final annotation outputs; Section 4 describes corpus harvesting and sampling; Section 5 discusses the results and presents a disagreement analysis; Section 6 compares and contrasts our work to related work; and Section 7 highlights the points not covered in this current version of *3arif*.

2 Annotation Scheme

Our annotation scheme consists of six tasks to label sense, polarity, intensification, tense, holders and scopes for each epistemic modality. Prior to the beginning of the interactive annotation procedure, we highlighted all candidate epistemic modalities in each tweet using a string-match algorithm and the lexicons from Al-Sabbagh et al. (2013, 2014). The algorithm finds all potential epistemic modality triggers (i.e. words and phrases that may convey epistemic modality) within each tweet in our corpus and marks them as annotation units. A total of 9966 candidate epistemic modality triggers are highlighted in 9822 tweets.

2.1 Task 1: Sense

Sense annotation is to decide for each highlighted candidate trigger in context whether it actually conveys epistemic modality. The same lexical verb اشعر *A$Er* is used as an epistemic modality trigger anticipating a future possibility in example 1; but as a non-modal lexical verb in example 2.

1. [3] **اشعر** ان[نا سنكسر رقم ال30 مليون متظاهر]
A$Er *An[nA snksr rqm Al30 mlywn mtZAhr]*
I **feel** that [we will get 30+ million protesters].

2. #هيكل: **اشعر** بالفخر والقلق أيضا في ذكرى حرب أكتوبر
#hykl: ***A$Er*** *bAlfxr wAlqlq >yDA fy *krY Hrb >ktwbr*
#Heikl: I **feel** proud but also worried when I remember October's war.

We define sense annotation as a synonymy judgment task, following Al-Sabbagh et al. (2013). Epistemic modality is represented by an exemplar set manually selected so that: (1) each exemplar is an unambiguous epistemic trigger, (2) exemplars are in both MSA and EA, (3) exemplars comprise both simple words and multiword expressions, (4) exemplars are both affirmative and negative, and (5) exemplars are of different lexical intensities. Furthermore, we create multiple versions of the same set so that we cover the inflections for gender, number, person, tense, mood, and aspect in Arabic. We then use the set that morphologically matches the candidate trigger to be annotated. Presented with a pre-highlighted candidate trigger in context and the exemplar set, annotators are to decide whether the given candidate trigger is synonymous to the exemplar set, and is hence an epistemic modality trigger, or not.

If an annotator decides that a given candidate trigger does not convey epistemic modality, no further questions about polarity, intensification, tense, holders or scopes are displayed. To guarantee that annotators do not select the non-synonymous option as an easy escape, they are not allowed to move forward without submitting at least one synonym of their own to the candidate trigger.

Designing the interactive procedure as such results in disagreement propagation. If one annotator decides that a given candidate trigger is not epistemic, but another annotator decides that it is, the former will not have to answer any further questions about polarity, intensification, tense, holders or scopes; whereas the latter will have to provide answers for each of those annotation tasks.

[3] Throughout the examples, epistemic modality triggers are represented in boldface and scopes are in-between square brackets.

2.2 Task 2: Polarity

Task 2 uses as input the candidates labeled as valid epistemic modality triggers in Task 1 and labels each as either affirmative or negative. An affirmative trigger indicates that the speaker holds the given state of affairs (i.e. propositions) as TRUE; whereas a negative trigger indicates that the given propositions are held as FALSE by the speaker.

To decide on whether the polarity is affirmative or negative, annotators are instructed to look for the absence/presence of such negation markers as:

- **Negation particles** such as مش *m$* (not), لا *lA* (not) and غير *gyr* (not), among others.
- **Negation affixes** like the circumfix *m...$* in مظنش *mZn$* (I do not think).
- **Negative polarity items** like عمري *Emry* (never) and لم يعد *lm yEd* (no longer).
- **Negative auxiliaries** where negation is placed on the past tense auxiliary as in مكنتش واثق *mknt$ wAvq* (I was not sure).
- **Inherently-negative triggers** that encode negation in their lexical meanings such as مستحيل *mstHyl* (impossible).

Annotators are instructed that using multiple negation markers results in an affirmative sense. Thus, ليس من المستحيل *lys mn AlmstHyl* (it is not impossible) means that the proposition is actually possible according to the speaker. Put differently, it means that the speaker holds the proposition as TRUE. Annotators are required to give the reason for negation if they decide that a given trigger is negative.

2.3 Task 3: Intensification

Epistemic modality triggers can have different lexical intensities (i.e. intensities encoded in the lexical meaning of the word/phrase regardless of the context). For instance, even without a context, Arabic speakers know that متأكد *mt>kd* (I am/he is sure) expresses higher possibility than متهيألي *mthy>ly* (I imagine). When used in context, the trigger's lexical intensity can be maintained as is. Yet, it can also be amplified or mitigated by various linguistic means such as:

- **Modification:** adverbs like تماما *tmAmA* (absolutely) and بالفعل *bAlfEl* (indeed), among others, amplify lexical intensity; whereas mitigation can be caused by such adverbs as تقريبا *tqrybA* (almost) and غالبا *gAlbA* (most probably), among others.
- **Categorical negation** typically amplifies lexical intensity as in مش ممكن أبدا *m$ mmkn >bdA* (it is not possible at all).
- **Emphatic expressions** such as قد *qd* (indeed) and والله *wAllh* (I swear), among others, lead to lexical intensity amplification.
- **Coordination** of two or more triggers usually results in intensity amplification as in عارف ومتأكد *EArf wmt>kd* (I know and I am sure).

The annotators' task for intensification is to decide for each candidate labeled as a valid epistemic modality trigger in Task 1 whether its lexical intensity is amplified (AMP), mitigated (MTG), or maintained (AS IS). During interactive annotation, annotators are asked to provide the reason for their selection; that is, whether the lexical intensity is affected by an adverb, categorical negation, an emphatic expression, coordination, or any other reason.

2.4 Task 4: Tense

In this version of *3arif*, we work on the present and past tenses only. Thus, Task 4 is to decide for each valid epistemic trigger from Task 1 whether it is present (PRS) or past (PST). Tense can be marked either morphologically by inflections and affixes or contextually by auxiliary verbs such as كان *kAn* (was), among others. Annotators are also required to give their reasons for selecting either PRS or PST.

2.5 Task 5: Holder

Holder annotation is to identify the holder of the epistemic modality which is the ±RATIONAL entity that expresses its knowledge, beliefs or judgments about the world's states of affairs.

Holders can be −RATIONAL entities as in example 3. The entity that is making the assumption that the former Palestinian president - Yasser Arafat - may have died of natural causes is the report issued by the French government.

3. [تقرير فرنسي: [وفاة #عرفات **ربما** تعود لاسباب طبيعية]
*tqryr frnsy: [wfAp #ErfAt **rbmA** tEwd lAsbAb TbyEyp]*
A French report: [natural causes **might** be behind the death of #Arafat].

The holder is not necessarily the same as the trigger's grammatical subject. In example 4, the grammatical subject of يبدو *ybdw* (seems) is الاعلان الدستوري *AlAElAn Aldstwry* (the constitutional declaration). However, the entity that is making the judgment about this declaration is the French government, which is then the real holder of *ybdw*.

4. [فرنسا: [الاعلان الدستوري الجديد لمرسي لا **يبدو** انه يسلك الاتجاه الصحيح]
*frnsA: [AlAElAn Aldstwry Aljdyd lmrsy lA **ybdw** Anh yslk AlAtjAh AlSHyH]*
France: [Morsi's new constitutional declaration does not **seem** to be a correct move].

Twitter users do not only post their own knowledge, beliefs and judgments about the world's states of affairs, but also they (1) directly and indirectly quote others and (2) make assumptions about others' knowledge, beliefs and judgments. This means that we can have nested holders, according to Wiebe et al. (2005) and Saurí and Pustejovsky (2009), where we know about others' knowledge, beliefs and judgments only though the writer or the Twitter user in our case.

In example 5, the Twitter user quotes Elbaradei stating that he may run for presidency if the people want him to. That is, the holder of the epistemic modality is actually Elbaradei not the Twitter user.

5. البرادعي: **قد** [أترشح في انتخابات الرئاسة] إذا طلب الشعب
*AlbrAdEy: **qd** [>tr$H fy AntxAbAt Alr}Asp] <*A Tlb Al$Eb*
Elbaradei: I **may** [run for presidency] if the people want me to.

The holder of the epistemic modality in example 6 is not the Twitter user, either. However, the Twitter user is not quoting anyone here, but is rather making an assumption about what the Egyptian National Party holds as TRUE.

6. [الحزب الوطني **مقتنع** ان[ه ممكن يرجع] #Jan25
*AlHzb AlwTny **mqtnE** An[h mmkn yrjE] #Jan25*
The National Party is **convinced** that [it may get back to authority]. #Jan25

We can have two or more nested holders. In example 5, we have two: the first is ElBaradei and the second is the Twitter user who is quoting ElBaradei. Similarly, in example 6, we have two nested holders: the first is the Egyptian National Party and the second is the Twitter user who makes the assumptions about the party's beliefs.

In example 7, however, we have three nested holders. The first is الاخوان *AlAxwAn* (the Muslim Brotherhood) that holds as TRUE the proposition that the Military Council is conspiring against them. That belief of the Muslim Brotherhood is communicated to us through the politician ابو الفتوح *Abw AlftwH* (Abulfotoh) who is then the second holder. Yet, Abulfotoh has not posted his assumption about the Muslim Brotherhood's belief on his personal account. Instead, he has been quoted by another Twitter user, who is the third holder.

7. [ابو الفتوح: الاخوان **تصوروا** ان [هناك مؤامرة من العسكري]
*Abw AlftwH: AlAxwAn **tSwrwA** An [hnAk m&Amrp mn AlEskry]*
Abulfotoh: The Muslim Brotherhood members **thought** that [there was a conspiracy by the Military Council].

During the interactive procedure, annotators are first asked whether the holder is the same as the Twitter user. If not, more questions are displayed to determine: (1) who the real holder is; (2) whether the tweet is a(n) (in)direct quote (e.g. there are direct quotation markers or such words as قال *qAl* (he said) and صرح *SrH* (he declared), among others), or the tweet conveys the Twitter user's assumptions about others.

When the holder is not the same as the Twitter user, annotators are asked to mark the boundaries of the linguistic unit that corresponds to the holder in the tweet's text, following the maximal length principle from Szarvas et al. (2008), so that they mark the largest possible, meaningful linguistic unit. Hence, in example 8 the holder is *the Islamist opponents in #KSA* not only *the Islamist opponents*.

8. [الإسلاميون المعارضون في #السعودية **موقنون** أن[ها تسعى لقتل الثورة في #مصر]
*Al<slAmywn AlmEArDwn fy #AlsEwdyp **mwqnwn** >n[hA tsEY lqtl Alvwrp fy #mSr]*
Islamist opponents in #KSA **know for sure** that [it tries to put an end to #Egypt's revolution].

2.6 Task 6: Scope

Scopes are the states of affairs modified by the epistemic modality triggers. Modality scopes in Arabic are most likely realized as clauses, deverbal nouns or to-infinitives, according to Al-Sabbagh et al. (2013). We use the same maximal length guideline from Task 5 so that the scope segment marked by the annotators is the largest possible segment typically delimited by: (1) punctuation markers and (2) subordinate conjunctions such as لان *lAn* (because) and لو *lw* (if), among others.

In the case of nested triggers as in example 9, where a trigger and its scope are both embedded in another trigger's scope, the interactive procedure prompts the annotators to label each trigger and its scope separately at first. Afterwards, we automatically merge them as we further explain in Section 3.

9. [[الحزب الوطني **مقتنع** أن[ه **ممكن** [يرجع]] #Jan25
*AlHzb AlwTny **mqtnE** >n[h **mmkn** [yrjE]] #Jan25*
The National Party is **convinced** that [it **may** [get back to power]] #Jan25

Annotators are instructed that a single trigger may have one or more scopes. In example 10, the trigger بيتهيألهم *bythy>lhm* (they imagine) scopes over two complement clauses, which annotators are required to identify. Furthermore, annotators are given the guideline that two or more triggers - typically conjoined by a coordinating conjunction - can share the same scope as in example 11. In the cases like example 11, each trigger and its attributes are first annotated separately and then once our system finds out that they share the same polarity, intensification, tense, holder, and scope, they are merged together as we show in Section 3.

10. [أولادنا **بيتهيألهم** ان [دم اخواتهم راح هدر] وان[هم عندهم ثأر مع السلطة بكل أشكالها]
*>wlAdnA **bythy>lhm** An [dm AxwAthm rAH hdr] wAn[hm Endhm v>r mE AlslTp bkl >$kAlhA]*
Our children **imagine** that [their friends were killed for no reason] and that [they now have to take revenge from the authorities].

11. البرادعي **عارف ومتاكد** ان [نسبة 12 % بس هتنتخبه] وعلشان كدة مش هيرشح نفسه
*AlbrAdEy **EArf wmtAkd** An [nsbp 12% bs htntxbh] wEl$An kdp m$ hyr$H nfsh*
Elbaradei **knows and is sure** that [only 12% will vote for him]. So, he will not run for presidency.

Annotators are instructed that scopes are not necessarily adjacent to their triggers. In example 12, the scope starts three words to the right of its trigger باقتنع *bAqtnE* (get convinced) given that the adverbial phrase اكتر واكتر *Aktr wAktr* (more and more) falls in between it and its scope.

12. [كل يوم بيعدي **باقتنع** اكتر واكتر ان[نا كنا محتاجيين دكتاتور وطني عادل]
*kl ywm byEdy **bAqtnE** Aktr wAktr An[nA knA mHtAjyn dktAtwr wTny EAdl]*
Every day, I **get more and more convinced** that [we needed a patriotic and fair dictator].

Annotators are also instructed that scopes can (1) precede, (2) follow or (3) surround their triggers. Many of the aforementioned examples have the scopes following their triggers. Yet, in example 13 the scope surrounds its trigger and in example 14 it precedes its trigger.

13. [وعود مرسي ليست **فيما يبدو** دين عليه]
*[wEwd mrsy lyst **fymA ybdw** dyn Elyh]*
[Morsi's promises are not **seemingly** doable].

14. **فيما يبدو** [حملة تشويه ثورة يناير وإعادة عقارب الساعة تماما إلى الوراء بدأت]
*[Hmlp t$wyh vwrp ynAyr w<EAdp EqArb AlsAEp tmAmA <lY AlwrA' bd>t] **fymA ybdw***

[A campaign to distort the image of January's revolution and to restore everything back to its original state has started], **seemingly**.

3 Final Output Representation

All elicited answers during annotation are automatically organized into the representations illustrated in the examples below. The representation of example 15 reads as follows: the USER (i.e. the Twitter user) used to moderately hold as TRUE the proposition that the revolutionist candidates were unable to compete for presidency. We know that this is a past belief that the USER used to have because annotators have labeled the trigger تصورت *tSwrt* (I thought) as past (PST). There are no nested holders given that the USER is the same as the holder. The intensity value of MODerate comes from the fact that تصورت *tSwrt* (I thought) is of a moderate lexical intensity being weaker than such epistemic triggers as متاكد *mtAkd* (I am sure) and عارف *EArf* (I know) but stronger than such epistemic triggers as اظن *AZn* (I guess) and متهيالي *mthyAly* (I imagine). Meanwhile, the lexical intensity of *tSwrt* is neither amplified nor mitigated; hence annotators have given it an AS IS intensification label in Task 3. Consequently, in the final annotation output the original lexical intensity value has been used to represent how far the holder used to consider his/her belief as TRUE.

15. [في البداية **تصورت** ان [مرشحي الثورة اضعف من المنافسة للرئاسة]
*fy AlbdAyp **tSwrt** An [mr$Hy Alvwrp ADEf mn AlmnAfsp llr}Asp]*
At first, I **thought** that [the revolutionist candidates are too weak to compete for presidency].

rep. USER, MOD PST TRUE, (*mr$Hy Alvwrp ADEf mn AlmnAfsp llr}Asp*)

Example 16 shows how two epistemic modality triggers in the same tweet are given two separate representations because they share the same holder but neither the same intensity nor the same scopes. The first representation illustrates the epistemic trigger ارى *ArY* (I think) and reads as follows: the USER currently holds as TRUE the proposition that the media is misleading the people; s/he is MODerately confident about that. The second representation is for the epistemic trigger واضح *wADH* (obviously). It indicates that the same USER strongly holds as TRUE the proposition that the media is trying to stop the change that the people are longing for. Both triggers are labeled as present (PRS) tense. Furthermore, both triggers are labeled as maintaining their lexical intensity AS IS. The trigger ارى *ArY* (I think) is then labeled in the final representation as being of MODerate intensity because it is weaker than متاكد *mtAkd* (I am sure), for instance, but stronger than متهيالي *mthyAly* (I imagine); whereas the trigger واضح *wADH* (obviously) is labeled as indicating a strong (STRG) belief being synonymous to متاكد *mtAkd* (I am sure) and اعرف *AErf* (I know) among other triggers that express speakers' high confidence about their knowledge, beliefs and judgments.

16. [ارى ان [الاعلام يقدم شباب يخدرون الشعب] **واضح** ان[هم يقاومون التغيير الذى نطمح له]
***ArY** An [AlAElAm yqdm $bAb yxdrwn Al$Eb] **wADH** An[hm yqAwmwn Altgyyr Al*y nTmH lh]*
I **think** [the media presents young speakers who mislead the people]. **Obviously**, [they are resisting the change we are longing for].

rep1. USER, MOD PRS TRUE, (*AlAElAm yqdm $bAb yxdrwn Al$Eb*)
rep2. USER, STRG PRS TRUE, (*hm yqAwmwn Altgyyr Al*y nTmH lh*)

Example 17 illustrates how two coordinating epistemic triggers sharing the same polarity, tense, intensification, holder and scope are represented. They are simply merged in one representation. The same example shows how assumptions made by Twitter users about others' knowledge, beliefs and judgments are represented. The representation reads as follows: the USER MODerately holds as TRUE the proposition that Elbaradei strongly (STRG) holds as TRUE that only 12% of the Egyptians will vote for him for presidency. The values of TRUE, MODerate and present (PRS) assigned to the USER's assumption about Elbaradei are default values used to mark Twitter users' assumptions about others' knowledge, beliefs and judgments.

17. البرادعى **عارف ومتاكد** ان [نسبة 12 % بس هتنتخبه] وعلشان كدة مش هيرشح نفسه
*AlbrAdEy **EArf wmtAkd** An [nsbp 12% bs htntxbh] wEl$An kdp m$ hyr$H nfsh*
Elbaradei **knows and is sure** that [only 12% will vote for him]. So, he will not run for presidency.

rep. USER, MOD PRS TRUE, (*AlbrAdEy*, STRG PRS TRUE, (*nsbp 12% bs htntxbh*))

Example 18 represents an epistemic trigger with multiple scopes. The example also represents Twitter users making assumptions about others' knowledge, beliefs and judgments. As we mentioned in example 17, the values of TRUE, MODerate and present (PRS) assigned to the USER's assumption are assigned by default. The trigger بيتهيألهم *bythy>lhm* (they imagine) is labeled as a present (PRS) tense affirmative trigger. Its original lexical intensity - which is weak (WK) - is labeled as being maintained AS IS. The trigger بيتهيألهم *bythy>lhm* (they imagine) is of a weak lexical intensity because it is weaker than متاكد *mtAkd* (I am sure) and even اظن *AZn* (I think).

18. [أولادنا بيتهيألهم ان [دم اخواتهم راح هدر] وان[هم عندهم ثأر مع السلطة بكل أشكالها]
*>wlAdnA **bythy>lhm** An [dm AxwAthm rAH hdr] wAn[hm Endhm v>r mE AlslTp bkl >$kAlhA]*
Our children **imagine** that [their friends were killed for no reason] and that [they now have to take revenge from the authorities].

rep. USER, MOD PRS TRUE, (*>wlAdnA,* WK PRS TRUE ,(*dm AxwAthm rAH hdr; hm Endhm v>r mE AlslTp bkl >$kAlhA*))

Example 19 illustrates embedded triggers. Its representation reads as: the USER MODerately holds as TRUE that the Egyptian National Party strongly (STRG) holds as TRUE that it (i.e. the Egyptian National Party) may get back to ruling. It is important to notice that both the matrix trigger مقتنع *mqtnE* (is convinced) and the embedded trigger (i.e. ممكن *mmkn* (may)) share the same holder which is the Egyptian National Party.

19. [[الحزب الوطني **مقتنع** ان[ه **ممكن** [يرجع]] #Jan25
*AlHzb AlwTny **mqtnE** An[h mmkn [yrjE]] #Jan25*
The National Party is **convinced** that [it **may** [get back to power]].

rep. USER, MOD PRS TRUE, (*AlHzb AlwTny*, STRG PRS TRUE,(MOD PRS TRUE, (*yrjE*)))

Example 20 shows how reported knowledge, beliefs and judgments are represented. The USER in this example has no other role but to report Darrag's strong belief that the army will interfere to stop the chaos.

20. دراج: [#الجيش **حتما** سيتدخل في حالة الفوضى] #مصر #مرسي #الاخوان
*drAj: [#Aljy$ **HtmA** sytdxl fy HAlp AlfwDY] #mSr #mrsy #AlAxwAn*
Darrag: [the #army will **definitely** interfere in the case of chaos] #Egypt #Morsi #Ikhwan

rep. USER, report, (*drAj*, STRG PRS TRUE (*#Aljy$ sytdxl fy HAlp AlfwDY*))

4 Corpus Harvesting

In order to restrict our corpus to political discourse and ensure that we compile a representative corpus of epistemic modality, we harvested our corpus so that each tweet (1) has at least one trendy political English or Arabic hashtag such as #Egypt and #مرسي *mrsy* (Morsi)[4], and (2) has at least one epistemic modality trigger from the Arabic Modality Lexicons of Al-Sabbagh et al. (2013, 2014). Table 1 gives statistics for the sampled corpus that comprises 9822 unique tweets, with 9966 candidate epistemic modality triggers that map to 214 unique types.

	Tokens	**Types**
Epistemic candidates	9966	214
All words	175964	47696

Table 1: Statistics for the sampled corpus

5 Annotation Results

5.1 Evaluation Methodology and Metrics

Our annotation tasks are of two types: (1) Tasks 1-4 are label-based where there is a pre-defined set of labels from which annotators choose; and (2) Tasks 5-6 are segmentation-based where the output of the annotation is a text segment. For the segmentation-based tasks, we use an all-or-nothing method to

[4] A total of 304 unique English and Arabic hashtags are found in the sampled corpus.

measure reliability and agreement: for segments to be considered as agreement, they must share both the beginning and end boundaries. We use Krippendorff's alpha α (Krippendorff 2011) as our inter-annotator reliability measure, following the most recent work on modality annotation for other languages including English (Rubinstein et al. 2013) and Chinese (Cui and Chi 2013). For more details on Krippendorff's alpha and a comparison of inter-annotator agreement measures, we refer the reader to Artstein and Poesio (2008).

5.2 Results

We use the surveygizmo services to implement our interactive annotation procedure given that their survey structure is one that allows for using conditional branching and skip logic[5]. We distributed the survey on Twitter and we had three annotators participating. According to the short qualifying quiz given at the beginning of the survey, all three participants are native Egyptian Arabic (EA) speakers who have at least two-year experience with using Twitter. They are also university graduates who, therefore, master Modern Standard Arabic. None of the participants has a linguistics background.

Table 2 shows alpha and agreement rates for each annotation task. We measure the rates in four different scenarios so that we can (1) estimate the effect of the inclusion of the NON-EPISTEMIC category agreement, (2) estimate the effect of disagreement propagation from Task 1, and (3) evaluate the guidelines and procedures for each annotation task separately. The four scenarios are:

- **w/NONE w/DP:** candidates agreed upon as non-epistemic and disagreement propagating from Task 1 are both included.
- **w/NONE w/o DP:** candidates agreed upon as non-epistemic are included, but disagreement propagating from Task 1 is excluded.
- **w/o NONE w/DP:** candidates agreed upon as non-epistemic are excluded, but disagreement propagating from Task 1 is included.
- **w/o NONE w/o DP:** candidates agreed upon as non-epistemic and disagreement propagating from Task 1 are both excluded. This scenario focuses on each annotation task separately without any distractions.

		Alpha				**Agreement**			
		w/NONE		**w/o NONE**		**w/NONE**		**w/o NONE**	
Annotation Task		**w/ DP**	**w/o DP**	**w/ DP**	**w/o DP**	**w/ DP**	**w/o DP**	**w/ DP**	**w/o DP**
1	Sense	--	0.899	--	--	--	0.949	--	--
2	Polarity	0.904	0.974	0.798	0.949	0.939	0.983	0.895	0.976
3	Intensification	0.880	0.942	0.658	0.768	0.926	0.966	0.844	0.939
4	Tense	0.911	0.995	0.772	0.983	0.947	0.997	0.909	0.994
5	Holder	0.878	0.930	0.672	0.727	0.933	0.956	0.884	0.969

Table 2: Inter-annotator alpha reliability and agreement rates

In the case of Task 1 (i.e. sense annotation), only the second scenario is applicable: we cannot exclude the candidates agreed upon as non-epistemic because the target is to know how reliable the annotation is with regards to distinguishing between epistemic and non-epistemic candidates. It is the first annotation task, thus there is no prior disagreement propagation. From Table 2, we derive the following observations:

- Disagreement in Task 1 propagates ~ 0.05 to 0.1 disagreement for the other annotation tasks.
- Adding the agreed upon non-epistemic candidates yields up to ~ 0.2 gain for both alpha reliability and agreement rates.
- For an end-to-end automatic system that first identifies triggers and then their attributes, the benchmark rates are those from the w/NONE w/DP scenario.

[5] http://www.surveygizmo.com/

5.3 Discussion and Disagreement Analysis

Among the factors that lead to high inter-annotator alpha reliability and agreement rates are that: (1) the vast majority of negation is explicitly marked by negation particles that are easy to detect by human annotators; (2) the vast majority of triggers are used without any amplification or mitigation markers; and (3) punctuation markers are surprisingly informative for marking scope boundaries and direct quotations and, hence, holders.

Sense-related disagreement is attributed to: (1) nominal triggers with main grammatical functions, (2) stative triggers, (3) opinionated-evidential triggers and (4) highly-polysemous triggers.

The majority of epistemic triggers are adjunct constituents that add an extra-layer of meaning and can be removed without disturbing the syntactic structure of their propositions. Yet, in example 21, احتمال *AHtmAl* (a possibility) is the grammatical subject of the proposition it modifies. Most of the exemplars from Section 2.1 are adjuncts and, thus, none can be both a lexical and a grammatical substitute for احتمال *AHtmAl* (a possibility) in such a context.

21. **احتمال** ان [رئيس منتخب يحل المجلس اثناء صياغة دستور جديد] **احتمال** وهمي
AHtmAl *An [r}ys mntxb yHl Almjls AvnA' SyAgp dstwr jdyd]* ***AHtmAl*** *whmy*
The **possibility** that [an elected president dissolves the parliament during the constitution's write-up] is an unrealistic **possibility**.

Stative triggers such as يعرف *yErf* (he knows) and يدرك *ydrk* (he realizes) invoke disagreement as to whether they indicate the acquisition of new information; that is, they literally mean *perceive*, or they mark confirmed beliefs as in *be sure that*. For example 22, the annotators have two interpretations: (1) a non-modal interpretation that *whoever says so does not perceive that the Supreme Guide cannot make resolutions without the Brotherhood*, and (2) a modal interpretation that *whoever says so does not believe that the Supreme Guide cannot make resolutions without the Brotherhood.*

22. [الذي يقول هذا الكلام لا **يعرف** ان [المرشد لا يستطيع اخذ قرار دون الرجوع الى الجماعة]
*Al*y yqwl h*A AlklAm lA* ***yErf*** *An [Almr$d lA ystTyE Ax* qrAr dwn AlrjwE AlY AljmAEp].*
Whoever says so does not **perceive/believe** that [the Supreme Guide cannot make resolutions without the Brotherhood].

Opinionated-evidential triggers like يزعم *yzEm* (he claims) do not only mark reported speech, but also they communicate the reporter's own opinion about the truth value of the reported proposition. They entail that from the reporter's perspective the proposition is FALSE. Hence, annotators disagree as to whether *yzEm* and similar triggers should be labeled as epistemic or not. We have eventually excluded such triggers as epistemic and have included them as evidential triggers for another corpus that is left for a future publication.

Highly-polysemous triggers like يمكن *ymkn* (can/possible) lead to disagreement because in many cases even the context is ambiguous. In example 23, both interpretations of *it is not possible that* (epistemic) and *it is not doable that* (abilitive) seem to be acceptable.

23. [لا **يمكن** [فهم كتاب مرسي "ثائر من الشرق" الا بتامل الكتابين المجاورين: "سرقات صغيرة" و"جنون الحكم"]
lA ***ymkn*** *[fhm ktAb mHmd mrsy "vA}r mn Al$rq" AlA btAml AlktAbyn AlmjAwryn: "srqAt Sgyrp" w "jnwn AlHkm"*]
It is **not possible/doable** [to understand Morsi's book - *A Revolutionist from the East* - without reading the other two books of *Small Robberies* and *Ruling Mania*].

Intensity-related disagreement is attributed to (1) intensity on the holder that propagates to the trigger and (2) negation with moderate-intensity triggers. In example 24, the USER uses categorical negation on the holder لا يوجد اي انسان عاقل *lA ywjd Ay AnsAn EAql* (there is no one sane person). For some annotators, the power of categorical negation spreads to the trigger, moving its intensity up the scale. As for negation with moderate-intensity triggers, some annotators think that لا يمكن *lA ymkn* (not possible) is synonymous to *impossible*. Hence, they consider the negation as an amplification marker.

24. لا يوجد أي انسان عاقل **يعتقد** بأن [الارهاب يعالج بالسياسة]
lA ywjd >y AnsAn EAql ***yEtqd*** *b>n [AlArhAb yEAlj bAlsyAsp]*
There is no one sane person who **thinks** that [terrorism can be defeated through politics].

Polarity-related disagreement is mainly caused by negation due to (1) negated holders and (2) contextual negation. Negated holders as in example 24 perplex the annotators as to whether the negation scopes over the holder only or both the holder and the trigger. Thus, for some annotators, يعتقد *yEtqd* (he thinks) is affirmative; and for others it is negative. By contextual negation we mean using words such as المشكلة *Alm$klp* (the problem) to describe triggers as in example 25. The USER says that *the problem is to think that it is a small-scale conflict.* To describe this as a *problem* means that the USER thinks of the proposition as FALSE; that is, according to the USER it is actually a large-scale conflict.

25. المشكلة إننا **نتصور** إن [الصراع محصور فى الدائرة الضيقة اللى بنتحرك فيها]
*Alm$klp <nnA **ntSwr** <n [AlSrAE mHSwr fY AldA}rp AlDyqp AllY bntHrk fyhA]*
The problem is to **think** that [the conflict is only happening at this small-scale we are working on].

Holder-related disagreement is attributed mainly to generic nouns and impersonal pronouns such as الشعب *Al$Eb* (the people) and الواحد *AlwAHd* (one). Some annotators interpret them as implicitly referring to the USER. Therefore, they select the USER as the only holder with zero nesting in example 26. Other annotators interpret them as referring to people in general but not necessarily with the USER included; and thus, they select two-level nested holders.

26. الشعب **يعرف** ان [الممارسة الديمقراطية هى التي ستأتي باعضاء مجلس الشعب والرئيس القادم]
*Al$Eb **yErf** An [AlmmArsp AldymwqrATyp hy Alty st>ty bAEDA' mjls Al$Eb wAlr}ys AlqAdm]*
People **know** that [democracy will result in real parliamentary and presidential elections].

Scope-related disagreement is attributed to (1) ambiguous subordinate conjunctions, (2) triggers modifiers, (3) absent punctuation markers, and (4) embedding within the scope boundaries. For instance, in example 27, the adverbial clause starting with بعد *bEd* (after) confuses the annotators as to whether it is part of the scope or it describes the verb epistemic trigger اتوقع *AtwqE* (I expect).

27. **اتوقع** جدا ان [اعتصام التحرير يتفض بنفس طريقة فض الاعتصام الاخير بعد ظهور اشكال غريبة فلجان الامن]
***AtwqE** jdA An [AEtSAm AltHryr ytfD bnfs Tryqp fD AlAEtSAm AlAxyr bEd Zhwr A$kAl grybp fljAn AlAmn]*
I very much **expect** that [the sit-in in Tahrir will be broken up in the same way as the last sit-in after seeing some strange faces at the security checkpoints].

Tense yields almost perfect inter-annotator alpha reliability and agreement rates. The one main disagreement factor, however, is such contexts as ابتديت اصدق *Abtdyt ASdq* (I started to believe). While the majority of annotators agree that such contexts mark present tense knowledge, beliefs and judgments, some annotators consider them as past tense.

5.4 Majority Statistics for *3arif*

Based on majority annotations, Table 3 gives statistics for *3arif* in terms of sense, polarity, intensification and tense. Furthermore, approximately 62% of the triggers have zero-nested holders (i.e. the Twitter user is the same as the holder). As for scope syntactic structures, they are distributed as 86% clauses, 9% deverbal nouns and the rest are to-infinitives.

	Sense		**Polarity**		**Intensification**			**Tense**	
	Epistemic	Non-epistemic	True	False	Amplified	Mitigated	As is	Present	Past
Tokens	5591	4375	3425	2166	1083	330	4178	4399	1192
Types	209	175	176	134	133	50	150	175	104

Table 3: Majority statistics for *3arif*

6 Related Work

Epistemic modality has been the focus of many annotation projects for multiple languages. Diab et al. (2009) annotate three belief categories for English: (1) committed belief is when writers indicate that they hold propositions as TRUE, (2) non-committed belief is when writers hold propositions as FALSE, and (3) not applicable is when propositions are not denoting beliefs at all. Interest is given to writers' beliefs only. Thus, a default value for the modality holder is the writer, and nested holders are not an-

notated. Their corpus contains 10k words of running text from different domains and genres, including newswire, blog data, email and letter correspondence and transcribed dialogue data. Inter-annotator agreement rate is 0.95 including the NONE category where no belief markers exist.

Baker et al. (2010, 2012) simultaneously annotate modality and modality-based negation to build modality taggers to enhance Urdu-English machine translation systems. Their annotation scheme distinguishes eight modality types: requirements, permissions, success, effort, intention, ability, desires and beliefs. Originally, their annotation scheme labels three attributes for each modality type: triggers, holders and targets (i.e. scopes). Yet, holders have not been eventually labeled. A unique feature of their annotation scheme is using a simplified operational procedure to label modality semantic meanings. The procedure relies on a list of thirteen choices of the form of H (modal) [P true/false] where H is a holder and P is a proposition or an event. The annotators' task is then to select the best form to represent the modality meaning of a given trigger. Reported kappa κ inter-annotator agreement rates are 0.82 for triggers and 0.76 for targets.

Rubinstein et al. (2013) propose a linguistically-motivated scheme for modality annotation in the MPQA English corpus. They attain macro alpha inter-annotator reliability rates of 0.89 and 0.65 for sense and scope, respectively. Cui and Chi (2013) apply the same scheme from Rubinstein et al. (2013) to the Chinese Penn Treebank and get alpha inter-annotator reliability rates of 0.81and 0.39 for sense and scope annotation, respectively.

Al-Sabbagh et al. (2013) annotate epistemic modality in MSA and EA tweets. We attain kappa inter-annotator agreement rates of 0.90 and 0.93 for sense and scope annotation, respectively, for only 548 epistemic tokens.

Our annotation results, therefore, are comparable to the results in the literature. Furthermore, our annotation scheme is orthogonal to most of the aforementioned schemes. However, the key differences between our work and related work are:

- We annotate nested modality, unlike Diab et al. (2009) and Baker et al. (2010, 2012).
- We use a wider range of negation and intensification markers compared to prior work, especially Al-Sabbagh et al. (2013)
- We use interactive crowdsourcing with simplified guidelines, unlike in-lab annotations including Rubinstein et al. (2013) and Cui and Chi (2013), among others.

7 Uncovered Points in *3arif*

The current version of *3arif* does not cover modality entailment that example 28 illustrates. The USER criticizes whoever holds as TRUE the proposition that Egypt can blackmail UAE using the Iranian threat. This criticism entails that the USER holds the same proposition as FALSE.

28. [يخطئ من **يظن** ان [#مصر يمكن ان تساوم الامارات بورقة #ايران]
*yxTY' mn **yZn** An [#mSr ymkn An tsAwm #Al<mArAt bwrqp #<yrAn]*
Whoever **thinks** that [Egypt can blackmail #UAE using #Iran] is wrong.

We do not also cover the future tense, the interrogative, the imperative or the hypothetical moods. This is because they have different interpretations when it comes to intensification and polarity that we do not cover in this version of *3arif* but we will in future work.

8 Conclusion

We presented *3arif*, a large-scale corpus annotated for epistemic modality in MSA and EA tweets. We used a simplified approach that defines each annotation task as a series of questions, implemented interactively. Our scheme covers a wide range of the most common annotation units mentioned in the literature, including modality sense, polarity, intensification, tense, holders and scopes. We deal with nested holders that are crucial in a highly interactive genre such as tweets where users frequently quote others and make assumptions about them. We also automatically merge triggers with shared holders and scopes based on elicited annotators' answers. The annotation procedure yields reliable results and creates a novel resource for Arabic NLP. For future versions of the corpus, we plan to cover the points

from Section 7. *3arif* will also be used to train and test an automatic machine learning system to identify epistemic modality and its attributes in MSA and EA tweets.

Abstract

We investigate methods for aggregating the judgements of multiple individuals in a linguistic annotation task into a collective judgement. We define several aggregators that take the reliability of annotators into account and thus go beyond the commonly used majority vote, and we empirically analyse their performance on new datasets of crowdsourced data.

1 Introduction

Human annotation of linguistic resources has become indispensable in computational linguistics, especially with regards to semantic and pragmatic information, which is yet beyond the reach of robust automatic labelling. Most annotation campaigns involve a small group of trained annotators who may not always agree on their judgements. The reliability of the annotation is typically assessed by quantifying the level of inter-annotator agreement, while the final annotation to be released is consensuated amongst experts. In recent years, however, crowdsourcing methods such Amazon's Mechanical Turk (AMT) have shaken up this scenario by making it possible to rapidly recruit large numbers of untrainned annotators at a low cost. This offers great opportunities—in particular, if we consider that the community of speakers is the highest authority regarding linguistic knowledge—but also creates several challenges: amongst others, how to obtain good quality annotations from untrainned and unmonitored individuals, and how to combine large numbers of possibly conflicting judgements into a single joint annotation. In this paper we focus on the latter challenge. Our aim is to investigate and empirically test methods for aggregating the judgements of large numbers of individuals in a linguistic annotation task conducted via crowdsourcing into a *collective judgement*.

Most researchers who turn to crowdsourcing to collect data use majority voting to combine the participants' responses (Sayeed et al., 2011; Zarcone and Rüd, 2012; Venhuizen et al., 2013). Although in the limit it makes sense to take the judgement of the majority as reflecting the view of the community, in practice we cannot reach out to the full population of speakers, which means that the possible biases amongst the participants we manage to recruit may distort the outcome. Also, given the nature of crowsourcing (rewarding speed rather than quality), some participants may not respond truthfully according to their intuitions as speakers. To address these issues, we propose aggregation methods that go beyond majority voting by taking into account the reliability of individual annotators at the time of aggregation.[1] Our approach is related to existing work on analysing the quality of annotated data by examining, for instance, (dis)agreement patterns amongst annotators (Bhardwaj et al., 2010; Peldszus and Stede, 2013; Ramanath et al., 2013). However, while the main aim of this kind of studies is to gain insight into the difficulty of an annotation task or into the feasibility of using untrainned annotators for particular tasks, our focus is on exploiting patterns of judgements for the purpose of aggregation into a single collective annotation—an aspect that has received far less attention in the literature.

We make the following contributions: (i) we make available two new datasets of judgements gathered with AMT for two multi-category annotation tasks; (ii) we define several aggregation methods based, on

[1] Other aspects can contribute to reduce the shortcomings of crowdsourcing at earlier stages, such as task design and annotator recruiting constraints. However, here we specifically deal with improving quality at the time of aggregation.

Proceedings of COLING 2014, the 25th International Conference on Computational Linguistics: Technical Papers, pages 1533–1542, Dublin, Ireland, August 23-29 2014.

the one hand, on an approach by inspired by social choice theory (Endriss and Fernández, 2013; Kruger et al., 2014), and on the other hand, on probabilistic generative models pioneered by Dawid and Skene (1979); and (iii) we systematically evaluate the performance of the proposed methods on three different annotation tasks.[2]

The paper is structured as follows: In the next section, we introduce our aggregation methods. In Section 3, we evaluate their performance on different datasets and analyse the results. We then examine two further aspects: the impact of the number of annotators in Section 4 and the presence of highly unreliable annotators in Section 5. We conclude in Section 6 with plans for future work.

2 Aggregation Methods

In this section, we define several methods for deriving a collective judgement in a linguistic annotation task from a set of individual annotations. We focus on simple classification tasks where collecting these individual annotations via a crowdsourcing platform is feasible.

2.1 Notation and Terminology

In our model, an *annotation task* consists of three finite sets: the *items* J, the *categories* K, and the *annotators* N. Each annotator is asked to label some of the items with a category. A *group annotation* A is an $|N| \times |J|$ matrix, with a_{ij} representing the category $k \in K$ that annotator $i \in N$ assigned to item $j \in J$. Let N_j denote the set of annotators who annotated item j (i.e., a_{ij} is undefined if $i \notin N_j$).

We want to aggregate the information contained in a group annotation into a single *collective annotation* that assigns a category to each item. An *aggregator* is a function F that maps a group annotation A into a collective annotation $F(A)$, a vector of categories with dimensionality $|J|$ labelling every item with a category. The most widely used aggregator is the *simple plurality rule* (SPR)—known as *simple majority* in the two-category case—which returns a collective annotation where each item j is labelled with the category chosen most often for j by the group, i.e., $\text{SPR}(A)_j \in \text{argmax}_{k \in K} |\{i \in N_j \mid a_{ij} = k\}|$. Since the SPR may lead to a tie, if we require a single category for each item, a tie-breaking method (such as random tie-breaking) must be adopted. For the purposes of this paper, we assign the special category *'undecided'* whenever an aggregator produces a tie (this is reasonable also in practice: we would not want to commit to a randomly chosen category for an annotated linguistic resource).

2.2 Frequency-based Aggregation

In previous work, we introduced (Endriss and Fernández, 2013) and further refined (Kruger et al., 2014) a framework for deriving a collective annotation inspired by social choice theory. They propose so-called *bias-correcting rules* (BCR's), which try to take the reliability of annotators into account by considering the *frequencies* with which annotators choose certain categories. For example, if annotator i uses category k very often, then this might be a sign that i is overusing k and we should give her votes for k less weight. However, if k is also a frequent choice of the population of annotators at large, then this might again temper that effect.

For a given group annotation A, define the *individual frequency* of annotator i choosing category k—$\text{Freq}_i(k)$—as the number of times i chooses k, divided by the total number of items she annotates. Define the *global frequency* of k—$\text{Freq}(k)$—as the number of times k is chosen by someone, divided by the total number of individual annotations. Thus, if $\text{Freq}_i(k)$ is high, particularly if $\text{Freq}_i(k) > \text{Freq}(k)$, we may want to give a relatively low weight to any instance of annotator i choosing catgeory k.

Every BCR defines a family of weights w_{ik}, specifying for each annotator $i \in N$ and each category $k \in K$ how much weight to give to i's choice of k:

$$F_w(A)_j \quad \in \quad \operatorname*{argmax}_{k \in K} \sum_{i \in N_j | a_{ij} = k} w_{ik}$$

[2]The new datasets and an implementation of our aggregation methods are available at `http://www.illc.uva.nl/Resources/CollectiveAnnotation/`.

Diff	*difference-based BCR*	$w_{ik} = 1 + \text{Freq}(k) - \text{Freq}_i(k)$	**Rat**	*ratio-based BCR*	$w_{ik} = \text{Freq}(k)/\text{Freq}_i(k)$
Com	*complement-based BCR*	$w_{ik} = 1 + 1/\lvert K\rvert - \text{Freq}_i(k)$	**Inv**	*inverse-based BCR*	$w_{ik} = 1/\text{Freq}_i(k)$

Table 1: Weights used for canonical Bias Correcting Rules.

In case of a tie, we assign category *'undecided'*. Table 1 defines the weights for four specific BCR's. Thus, for example, if an annotator uses k in 50% of the cases, while the general population only uses k in 20% of all cases, then under Diff she has weight 0.7 whenever she chooses k. Note that Com and Inv do not take global frequencies into account, while Diff and Rat do.

2.3 Agreement-based Aggregation

Suppose each item has a *true* (but unknown) category (its *gold standard*). We may view an annotator's judgement as a noisy signal of the gold standard. We now want to design an aggregator as a maximum likelihood estimator for this ground truth. This approach has been pioneered by Dawid and Skene (1979). Variants have been used for diverse purposes by, amongst others, Snow et al. (2008), Carpenter (2008), Raykar et al. (2010), Ipeirotis et al. (2010), Li et al. (2013), and Passonneau and Carpenter (2013).

Let $p(a_{ij} = k \mid g_j = k^\star)$, with k not necessarily distinct from $k^\star$, be the probability of agent $i \in N_j$ annotating item j with category $k \in K$, given that the gold standard category of j is $k^\star \in K$. If we can obtain estimates of these probabilities, then we can use them to calibrate the weights of the annotators. The challenge, particularly for multi-category annotation tasks, is that the number of probabilities to estimate is fairly large (in particular, it is quadratic in $|K|$). To be able to provide reasonable estimates, we need a large amount of data *from every individual annotator*. But this precisely we do not have in crowdsourcing: we have a lot of data, but it comes from many different annotators. We thus make two simplifying assumptions, aimed at aggressively reducing the number of parameters to estimate:[3]

(1) We assume that $p(a_{ij} = k^\star \mid g_j = k^\star)$, i.e., annotator i's probability of choosing the *correct* category, does not depend on either j or $k^\star$. It only depends on i's accuracy. Thus, we can abbreviate $\text{acc}_i := p(a_{ij} = k^\star \mid g_j = k^\star)$.

(2) We assume that when annotator i does not choose the correct category $k^\star$, then she is equally likely to pick any of the *wrong* categories $k \neq k^\star$: $p(a_{ij} = k \mid g_j = k^\star) = \frac{1-\text{acc}_i}{|K|-1}$.

Assumption (1) is not uncommon (Li et al., 2013), but it clearly is a limiting assumption: accuracy not depending on j means that we cannot model the fact that some items are more difficult to label correctly; accuracy not depending on k means that we cannot model the fact that some categories are harder to comprehend than others. Assumption (2) and its alternatives only come into play when there are more than two categories; as large parts of the literature focus on the two-category case, this issue has received less attention. One of the limitations of assumption (2) is that we cannot model that some categories may "look similar" and are likely to get confused with each other.

On the positive side, in our simplified model we only have a single parameter to estimate for each annotator, namely its accuracy acc_i. Now suppose, hypothetically, we knew the acc_i's (which we do not in practice). Which category should we pick for item j? To answer this question we need to consider probabilities such as $p(g_j = k \mid A_j)$, the probability that k is the true category for item j given our observation of column A_j. If we do not want to make any assumptions regarding possible priors for either gold standards or annotation biases (i.e., if we opt for the default assumption of uniform priors), then we can instead work with $p(A_j \mid g_j = k)$. Specifically, we should choose k over k' if $p(A_j \mid g_j = k) > p(A_j \mid g_j = k')$, i.e., if:

$$\prod_{i|a_{ij}=k} \text{acc}_i \prod_{i|a_{ij}=k'} \frac{1-\text{acc}_i}{|K|-1} \prod_{i|a_{ij}\notin\{k,k'\}} \frac{1-\text{acc}_i}{|K|-1} > \prod_{i|a_{ij}=k'} \text{acc}_i \prod_{i|a_{ij}=k} \frac{1-\text{acc}_i}{|K|-1} \prod_{i|a_{ij}\notin\{k,k'\}} \frac{1-\text{acc}_i}{|K|-1}$$

$$\prod_{i|a_{ij}=k} \frac{(|K|-1)\cdot\text{acc}_i}{1-\text{acc}_i} > \prod_{i|a_{ij}=k'} \frac{(|K|-1)\cdot\text{acc}_i}{1-\text{acc}_i}$$

[3] That is, we are trading generality of the model against estimation quality of its parameters (see also Section 3.4).

Taking logarithms on both sides, we see that giving each annotator a weight of $\log \frac{(|K|-1)\cdot \text{acc}_i}{1-\text{acc}_i}$ results in an optimal aggregator. Let us call the corresponding aggregator the *oracle rule* **Ora**. Importantly, this is not a practically useful rule, as in reality we do *not* know the acc_i's. As we shall see, however, it is a useful benchmark, as it allows us to distinguish between loss in quality due to the simplicity of our model and loss in quality accrued during estimation (given that Ora is perfect w.r.t. the latter dimension).[4]

In practice, we need to estimate the acc_i's. We use a particularly simple method and estimate acc_i as i's *agreement* agr_i with the SPR, defined as follows:[5]

$$\text{agr}_i \quad := \quad \frac{|\{j \in J \mid a_{ij} = \text{SPR}(A)_j\}| + 0.5}{|\{j \in J \mid i \text{ annotates } j\}| + 1}$$

We call the rule we obtain using this method, i.e., the rule giving weight $\log \frac{(|K|-1)\cdot \text{agr}_i}{1-\text{agr}_i}$ to annotator i, the *agreement-based rule* **Agr**. There are two natural refinements of Agr one might consider. First, we could attempt to take priors regarding gold standards into account. If $p(k)$ is the prior probability of encountering (true) category k, then we get $p(g_j = k \mid A_j) \propto p(A_j \mid g_j = k) \cdot p(k)$. This corresponds to adding $\log p(k)$ as an extra weight in favour of category k. We can estimate $p(k)$ using either $\text{Freq}(k)$ or the SPR. The second possible refinement is to iterate the process used to estimate acc_i, i.e., to use Agr in place of SPR to compute better estimates agr'_i of acc_i, and so forth. That is, we could use the EM algorithm (Dawid and Skene, 1979) to estimate acc_i. As we shall see, Agr outperforms both of these refinements for the datasets considered in this paper.

3 Performance on Different Datasets

In this section, we evaluate the performance of our aggregation methods on three datasets from three different categorical annotation tasks for which gold standard annotations are readily available. One of these tasks—Recognising Textual Entailment—is a binary classification task and includes non-expert annotations collected by Snow et al. (2008). The other two tasks—Preposition Sense Disambiguation and Question Dialogue Acts—are multi-category tasks for which we have collected new crowdsourced annotations for the purposes of the present study.[6]

3.1 Recognising Textual Entailment (RTE)

This dataset is based on the task proposed by Dagan et al. (2006) in the PASCAL Recognizing Textual Entailment (RTE) Challenge. The RTE task involves deciding whether the meaning of a sentence (the *hypothesis*) can be inferred from a *text*. The original RTE1 Challenge testset consists of 800 text-hypothesis pairs (e.g., T:*"In central Antioquia two ranges of the Colombian Andeas meet"*, H:*"Antioquia is in Colombia."*) with a gold standard annotation that classifies each of them as either *true* (1) or *false* (0), depending on whether H can be inferred from T or not. The released expert annotation is perfectly balanced, with 400 items annotated as 0 and 400 as 1.

Snow et al. (2008) used Amazon's *Mechanical Turk* (AMT) to collect 10 non-expert annotations for each of the 800 items. The annotation task included a total of 164 AMT workers who annotated between 20 items (124 annotators) and 800 items each (only one annotator). Amongst the non-expert annotations, category 1 is slightly more frequent ($\approx 57\%$) than category 0.

Table 2a shows the results of applying the aggregation rules (and the oracle rule) to this data. Here (as later in Tables 2b and 2c), the first columns shows observed agreement (A) between the collective annotation output by each rule and the gold standard.[7] The following columnss show precision and recall for each category. We can see that all rules outperform the SPR.[8] Agr yields better results (93.3%)

[4]Snow et al. (2008) used Dawid and Skene's model to calibrate annotator judgements in terms of the gold standard. In contrast, we only use Ora as a benchmark to get a better understanding of the limitations of our probabilistic model.

[5]The smoothing terms (0.5 and 1) ensure that agr_i will never be 0 or 1, i.e., $\log \frac{(|K|-1)\cdot \text{agr}_i}{1-\text{agr}_i}$ is always well-defined.

[6]For practical reasons, we have opted for evaluating our methods against a gold standard. However, we note that in linguistic tasks, especially those concerning semantics and pragmatics, there may simply not be a 'true' category—a collective annotation may be the closest we can get to representing the view of the community.

[7]All aggregators assign category *'undecided'* in case of a tie. Therefore, any ties are counted as instances of disagreement.

[8]The SPR leads to 65 ties; the other rules lead to none.

Table 2: Observed agreement with the gold standard and precision/recall per category for each task.

than any of the BCR's in this case. For the SPR, category 1 has higher recall than precision, while the opposite is the case for category 0. This is in line with the slightly higher frequency of category 1 in the AMT annotations. The BCR's should be able to correct for this bias and to some extent they do (note the increase in category 0's recall: 88% or higher for any of the BCR's vs. 79% for the SPR). In this dataset, the best-performing BCR is Com (91.6% agreement), keeping a good balance between precision and recall for both categories. If we use the refinement of Agr with priors, then the observed agreement drops slightly (to 92.9% if we estimate gold standard distributions using Freq(k), and to 93.1% if we use the SPR). If we use the EM algorithm to estimate acc_i, the system stabilises after six iterations and the resulting rule also does slightly worse than Agr (93.0%).

3.2 Preposition Sense Disambiguation (PSD)

This annotation task is based on the dataset used in the SemEval 2007 task on word-sense disambiguation of prepositions (Litkowski and Hargraves, 2007). The SemEval dataset consists of roughly 25,000 sentences each containing one of the 34 most common English prepositions. The gold standard annotation was constructed by a single lexicographer who tagged each preposition instance with a sense from the sense inventories given by the Oxford Dictionary of English (ODE).

For our non-expert data collection, we used the 150 sentences with the preposition *among*, which according to ODE has four senses. We simplified the task by collapsing senses 3 and 4, as there is only one item classified with sense 4 by the gold standard and that sense is closest to sense 3.[9] The annotation task was conducted using AMT. We showed the workers the following sense definitions of *among* and asked them to select the appropriate sense for each sentence:

(1) situated more or less centrally in relation to other things, e.g., *"There are flowers hidden among the roots of the trees."*

(2) being a member of a larger set, e.g., *"Snakes are among the animals most feared by man."*

(3) shared by some members of a group or community, e.g., *"Members of the government bickered among themselves."*

The distribution of categories according to the gold standard is 37.3%, 23.3%, and 39.3% for sense 1, 2, and 3, respectively. The non-expert annotation task included 45 AMT workers who annotated between 15 items (26 annotators) and 150 items each (only one annotator; another annotated 135 items). Amongst the AMT annotations, the relative frequency of the categories is 40.6%, 18.8%, and 40.6%, respectively.

The results are shown in Table 2b.[10] The rules with the highest agreement with the gold standard are Diff (83.3%) and Rat (84%), i.e., the rules that take into account the global frequency of the categories. Rat outperforms not only the other three BCR's and the SPR (81.3%) but also Agr (82.7%) and Ora (83.3%). Recall for sense 2 (the rarest category) is low across rules, although less so for the BCR's, which manage to correct slightly for the annotators' bias against this category.[11]

[9] The original ODE sense definitions for *among* can be found at `http://tinyurl.com/ode-among`.

[10] The SPR leads to 6 ties; the other rules lead to none. The two refinements of Agr (priors and EM) do not affect the outcome.

[11] After inspecting the data, we suspect that the gold standard overuses sense 2. For instance, in the folowing sentence *among* is tagged with sense 2 although sense 1 seems more appropriate: "[...] *like icebergs 90 per cent is under the water and that is making them incredibly difficult to see* **among** *the waves."*

3.3 Question Dialogue Acts (QDA)

The second dataset we collected is based on the Switchboard corpus (Godfrey et al., 1992). The corpus includes a gold standard annotation prepared by trained annotators, labelling each utterance with a dialogue act tag from the SWBD-DAMSL annotation scheme (Jurafsky et al., 1997).

For our crowdsourcing experiment, we restricted ourselves to four types of question dialogue acts: Yes-No questions, Wh-questions, Declarative questions (including both declarative wh- and yes-no questions), and Rhetorical questions. We extracted 300 questions from the corpus, 35% of which were annotated as Yes-No in the gold standard, 30% as Wh, 20% as Declarative, and 15% as Rhetorical. The AMT workers were shown the following category definitions (here slightly simplified for space reasons):

(1) Yes-No: Questions with a standard form that could be answered with "yes" or "no" (*"Is that the only pet that you have?"*)

(2) Wh: Questions with a standard form that ask for specific information using wh-words (*"What kind of pet do you have?"*)

(3) Declarative: Questions with a statement-like form that nevertheless ask for an answer (*"You have how many pets."*)

(4) Rhetorical: Questions that do not need to be answered. They can have the form of any of the question types above, but they are asked only to make a point (*"If I ever wanted to have a pet, how could I work?"*)

Each item consists of a short dialogue fragment showing three utterances before and after the question to be annotated. The AMT workers were asked to classify the highlighted question with one of the four question types above. Here is a sample item (with reduced context for space reasons):

A: I understand.
A: **Where is home for you?**
B: Originally, was born in Missouri.

A total of 63 AMT workers participated in the annotation task, annotating between 10 items (24 annotators) and 200 items each (only one annotator). Amongst these non-expert annotations, the relative frequencies for category 1 to 4 are 36.6%, 34.1%, 18.4%, and 10.9%, respectively.

Table 2c shows the results of applying the aggregation rules to this data, plus the outcome of the oracle. [12] Inv yields the best result (87.7%), even outperforming Ora (87%). The annotators tend to overuse the common categories (1 and 2), resulting in high recall but low precision. In contrast, the less frequent categories (3 and 4) tend to be underused, resulting in high precision but low recall. Note how applying Inv leads to particularly high recall for rhetorical questions (category 4). The price to pay is the drop in precision for this category compared to the other rules. The dual effect is that precision for Yes-No (1) and Wh (2) is higher with Inv than with the other rules, while recall is lower.

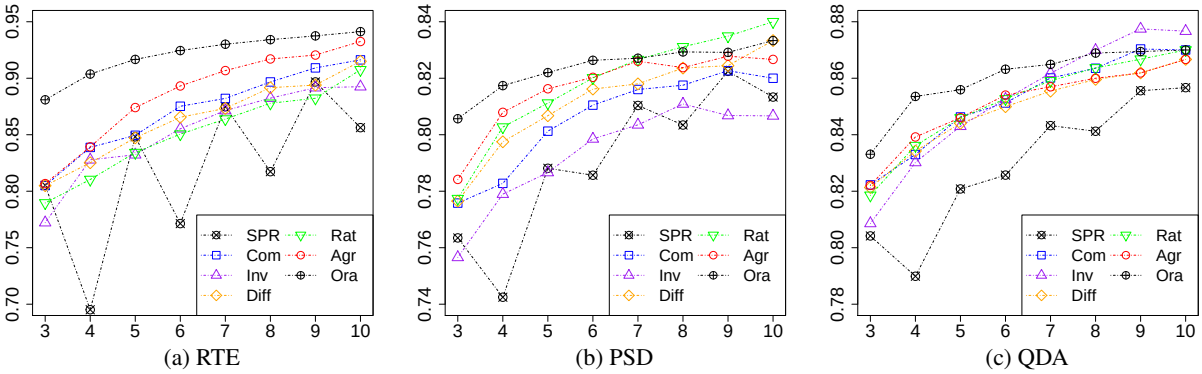
3.4 Comparative Analysis

First, let us compare Agr and Ora. The good performance of Agr suggests that our simple probabilistic model is not *too* simplistic; the trade-off between loss in generality and gain in ability to estimate parameters mentioned in Section 2 appears to be appropriate. The fact that Ora outperforms Agr only slightly suggests that the number of parameters in our model is sufficiently small to be estimated well using the amount of data typically available in linguistic annotation taks conducted via crowdsourcing.

Second, the fact that Agr (modestly) outperforms its refinement using an estimated prior can be explained by the fact that, in our datasets, annotators tend to overuse frequent categories and underuse rare categories. The reason why iterating the rule used to estimate accuracies did not improve performance of Agr for our datasets is less clear, but may be related to the well-known fact that EM can get stuck in a local optimum. The positive take-away message is that the simplest form of our agreement rule resulted in the best performance (at least for our three datasets).

Third, the differences in performance between different BCR's point at an interesting difference in types of bias. Recall that Com and Inv judge the reliability of an annotator only in terms of her own annotations and penalise frequent use of a category. Diff and Rat correct for this effect in case the global frequency is high as well. This means that if a population of annotators has a *shared bias* against or in favour of a category, then Diff and Rat cannot track this well. This explains the fact that Com outperforms Diff and Inv outperforms Rat in the QDA data (see Table 2c): in this task many annotators appeared to

[12] The SPR leads to 7 ties; the other rules to none. Once again, the observed agreement for Agr drops slightly for the two refinements discussed (priors and EM).



(a) RTE (b) PSD (c) QDA

Figure 1: Observed agreement with the gold standard (y-axis) for varying NAI (x-axis).

have difficulties recognising rhetorical questions, i.e., they had a shared bias against labelling an item as Rhetorical. For a dataset with clear *individual biases*, on the other hand, we would expect Diff/Rat to outperform Com/Inv. We do not have a clear case of such a phenomenon in the data analysed here. For the PSD task, Diff/Rat do outperform Com/Inv (see Table 2b), but we believe that the explanation for this finding is a different one: Arguably, the gold standard annotation overuses category 2 (see Footnote 11). This means that high-quality annotators are seen as underusing it and get penalised by Com/Inv. For Diff/Rat this effect is tempered by the fact that the population as a whole is underusing category 2 (relative to the questionable gold standard).

Finally, much can be learned from contraposing the frequency- and agreement-based approach. Suppose the gold standard is uniformly distributed (as for RTE). Then the expected value of $\text{Freq}_i(k)$ is $\frac{1}{|K|}$, i.e., it does not depend on acc_i at all. Thus, the two approaches track entirely different parameters, yet both achieve respectable results. This suggests that combining them might prove fruitful (see Section 5). Certainly, an approach based on a richer probabilistic model would be able to track both kinds of parameters, but as we had argued, this might be infeasible with the relatively small amount of data per annotator we can collect through crowdsourcing. In some sense, what we have done with our rules is trying to make up for the scarcity of data by exploiting our domain knowledge (e.g., regarding the relationships between observed frequency and annotator reliability) to reduce the parameter space.

4 Impact of Number of Annotators

The cost and quality of an annotated linguistic resource created via crowdsourcing crucially depends on the number of annotators that label each item. Having low numbers of coders will make the task more affordable (in terms of time and money), but it will also make the aggregation process more vulnerable to low-quality annotators. Snow et al. (2008) showed how the number of annotators per item (henceforth NAI) influences the performance of the SPR. Here we further explore the impact of NAI on the quality of the collective annotation obtained by different aggregation methods.

For each of the three datasets and each NAI n ($3 \leqslant n \leqslant 9$), we randomly resampled n annotations for each set of items presented to a worker in one go (i.e., for each HIT in AMT terminology). This allowed us to generate a subset of the original dataset with n annotators per item. We generated 1000 such random subsets for each n, applied our aggregators to each subset (and also computed the oracle outcome). We then calculated the average observed agreement with the gold standard. To test whether the differences observed are statistically significant, we calculated the difference in performance between pairs of rules on each subset and computed the 95% (one-sided) confidence intervals by using its distribution over the 1000 subsets. If the proportion of subsets on which this difference is strictly greater than 0 is higher than 95%, we consider the difference to be significant.

The results are shown in Figure 1. We can see that, as the NAI increases, the performance of the rules generally improves (except for the oscillation of the SPR due to tie-breaking). This improvement is greater when the NAI is small (from 3 to 5), which suggest that a minimum of 5 annotators per item is

(c) QDA

Table 3: Effect on observed agreement when removing 6 spammers in RTE, 9 in PSD, and 6 in QDA.

recommended. We can also observe that Agr has a robust performance on all datasets when the NAI is between 5 and 7: its improvement over the SPR is statistically significant in all cases for the three tasks, except on PSD when NAI is 7, in which case it is neither significantly better nor significantly worse than the SPR. Note that in all datasets Agr only needs 6 or 7 annotators per item to achieve an accuracy comparable to the SPR using 10 annotators per item.

The robustness of Agr with low NAI is not surprising, given that it already assigns low weights to workers who consistently disagree with the majority. Discounting such problematic workers is particularly important when there are relatively few workers per item. But as the NAI increases, it becomes more likely that random annotators will cancel each other out. It is then that we observe the greatest advantage of using BCR's. This can be seen in the plots for PSD and QDA with high NAI. In those cases the improvement of the best performing BCR's (Rat on PSD and Inv on QDA) over the other rules approaches significance although does not reach the 95% threshold (e.g., on QDA when the NAI is 9, Inv is strictly better than Agr for 93.4% of the subsets).

5 Removal of Low-Quality Annotators

Next we discuss how removing easily recognisable low-quality annotators ("spammers") before aggregation affects the quality of results. The BCR's make the implicit assumption that annotators are sincere. This can be problematic, given the nature of crowdsourcing, where it is not uncommon to encounter workers giving random rather than truthful responses (Sheng et al., 2008; Raykar and Yu, 2012). BCR's are vulnerable to this phenomenon. Here we propose to combine the frequency- and agreement-based approach by using the agreement rate of an annotator with the SPR outcome to identfy and remove spammers prior to applying the frequency-based BCR's.

We take *spammers* to be those annotators that annotate a large number of items (i.e., we have sufficient evidence to judge) and that systematically deviate from the plurality outcome. In the specific context of our datasets, we have implemented this idea by labelling as spammers those annotators who annotated at least 20% of the total number of items and whose agreement rate with the SPR is below the median agreement rate. This corresponds to 6 annotators in the RTE dataset, 9 in the PSD dataset, and 6 in the QDA dataset. The effect of removing these low-quality annotators from the population can be seen in Table 3 showing observed agreement of the different aggregation rules (and the oracle rule) with the gold standard before and after spammer removal.

The results show that, with one exception, after removing spammers the performance of the BCR's improves significantly. The exception concerns Diff and Rat for the PSD dataset. Recall that the gold standard for this dataset, arguably, overuses category 2 (see Footnote 11 and Section 3.4). That is, high-quality annotators are (wrongly) judged to be underusing category 2. Before spammer removal, this effect is tempered by the presence of a few annotators delivering 'random' annotations (thereby artificially increasing the frequency of category 2). After spammer removal, this positive effect is diminished and rules such as Diff and Rat suffer in performance. Con and Inv, on the other hand, can compensate for this effect simply by giving very high weights to those (high-quality) annotators who still use the relatively rare category 2. Also for RTE and QDA, amongst the BCR's the rules not based on global frequencies, i.e., Com and Inv, benefit most. Indeed, after spammer removal Com/Inv perform better than Diff/Rat for all three datasets. Overall, Inv with spammer removal is our best-performing rule.

Not surprisingly, Agr and Ora gain relatively little from spammer removal since, given our definition of a spammer, the removed annotators already had very low weights to begin with. In fact, the performance of these aggregation rules may even drop slightly after removing spammers (see Tables 3a and 3b).

6 Conclusions

We have argued that simply using the majority/plurality rule to aggregate individual linguistic judgments in a crowdsourcing annotation task is far from optimal. Instead, we have proposed several methods that weight the annotators' judgements by exploiting either the frequency with which they choose particular categories or the degree to which they agree with the full population of annotators. We have tested our methods on existing datasets and we have also created two new datasets. Our results show how annotation tasks with different characteristics can benefit from different types of aggregation methods. Our aggregation methods result in small but robust gains across datasets, both in terms of accuracy achieved and in terms of the number of annotators required to obtain acceptable results.

Besides BCR's, in our previous work we also proposed a *greedy consensus rule*, albeit only for the two-category case (Endriss and Fernández, 2013) . This rule sequentially locks in simple majorities in the order of relative majority strength, but along the way disregards annotators who disagree with too many of those strong majorities. It performs well on the RTE dataset (almost as well as Agr). Intuitively speaking, it can track *item difficulty*, by first settling the easy items (with clear majorities) and thereby learning which annotators are most reliable to then have them decide on the harder items. Here we have not included this rule as there is no single most natural way of generalising it to the multi-category case. Arriving at such a generalisation in a principled manner is an important direction for future work.

It would also be interesting to get a clearer understanding of the links between methods for assessing inter-annotator agreement (Artstein and Poesio, 2008) and methods of aggregation (i.e., methods that may be applied to data of possibly rather poor inter-annotator agreement, as is the case for parts of our datasets). A relevant observation in this context is that the notions of individual and global frequency at the core of our BCR's also play a role in agreement coefficients, namely to compute chance agreement: π (Scott, 1955) uses global frequencies and κ (Cohen, 1960) uses individual frequencies.

While the definition of Agr was motivated by a simple probabilistic model, the BCR's were motivated by rules of thumb regarding links between observed frequencies and reliability. We have noted before that the BCR's do not track the same phenomena as Agr; rather, they seem to complement each other, an observation we have exploited explicitly when removing spammers before applying a BCR. Identifying a suitable probabilistic model for our frequency-based BCR's promises to be a fruitful future line of research, as it would allow for a better comparison (and eventually integration) of the two approaches.

Invited Speaker Abstract

Adaptation technologies are always useful in NLP when there is discrepancy between the training scenario and use scenario. They are also effective in alleviating the data scarcity problem. Domain adaptation is the most popular kind of adaptation technologies and is intensively researched. In this talk we will introduce two other kinds of adaptation technologies: annotation adaptation and language adaptation. Annotation adaptation is used to improve the performance of an automatic annotation task by leveraging corpora with different annotation schemas, while language adaptation is used to solve an NLP problem in one language by utilizing the linguistic knowledge which is learnt from solving the same problem in another language. We investigate these technologies mainly for the tasks of word segmentation and parsing, however similar technologies may be developed for other NLP tasks also.

Abstract

Disambiguating named entities (NE) in running text to their correct interpretations in a specific knowledge base (KB) is an important problem in NLP. This paper presents two collective disambiguation approaches using a graph representation where possible KB candidates for NE textual mentions are represented as nodes and the coherence relations between different NE candidates are represented by edges. Each node has a local confidence score and each edge has a weight. The first approach uses Page-Rank (PR) to rank all nodes and selects a candidate based on PR score combined with local confidence score. The second approach uses an adapted Clique Partitioning technique to find the most weighted clique and expands this clique until all NE textual mentions are disambiguated. Experiments on 27,819 NE textual mentions show the effectiveness of both approaches, outperforming both baseline and state-of-the-art approaches.

1 Introduction

Named entities (NEs) have received a lot of attention from the NLP community over the last two decades (see, e.g. Nadeau and Sekine (2007)). Most of this work has focussed on the task of recognizing the boundaries of NE mentions in text and classifying them into one of several classes, such as Person, Organization or Location. However, references to entities in the real world are often ambiguous: there is a many-to-many relation between NE mentions in text and the entities denoted by these mentions in the world. For example, the same NE mention "Norfolk" may refer to a person, "Peter Norfolk, a wheelchair tennis player", a place in the United Kingdom, "Norfolk County", or a place in the United States like "Norfolk, Massachusetts"; conversely, one entity many be known by many names, such as "Cat Stevens", "Yusuf Islam" and "Steven Georgiou". The task of named entity disambiguation (NED) is to establish a correct mapping between each NE mention in a document and the entity it denotes in the real world. Following most researchers in this area, we treat entries in a large knowledge base (KB) as surrogates for real world entities when carrying out NED and, in particular, use Wikipedia as the reference KB against which to disambiguate NE mentions. NED is important for tasks like KB population, where we want to extract new information from text about an entity and add it to a pre-existing entry for that entity in a KB, or for information retrieval where we may want to cluster or filter results for different entities with the same textual mentions.

The main hypothesis underlying this work is that different NEs in a document help to disambiguate each other. However, other textual mentions in the document are also ambiguous. So, what is needed is a *collective disambiguation* approach that jointly disambiguates all NE textual mentions.

In our approaches we model each possible candidate for every NE mention in a document as a distinct node in a graph and model candidate coherence by links between the nodes. Figure 1 shows an example of the disambiguation graph for three mentions "A", "B", and "C" found in a document, where the candidate entities for each mention are referred to using the lower case form of the mention's letter together with a distinguishing subscript. The goal of disambiguation is to find a set of nodes where only one candidate is selected from the set of entities associated with each mention, e.g. a_3, b_2, c_2.

Proceedings of COLING 2014, the 25th International Conference on Computational Linguistics: Technical Papers, pages 1544–1555, Dublin, Ireland, August 23-29 2014.

We propose two different approaches to find the best disambiguation candidates in the graph. The first approach starts by finding the most confident and coherent set of disambiguation entities and iteratively expands this set until all NE textual mentions are disambiguated. The second approach ranks all nodes in the solution graph using the Page-Rank algorithm, then re-ranks all nodes by combining the initial confidence and graph ranking scores. We consider several different measures for computing the initial confidence assigned to each node and several measures for determining and weighting the graph edges. Node linking relies on the fact that the textual portion of KB entries typically contains mentions of other NEs. When these mentions are hyper-linked to KB entries, we can infer that there is some relation between the real world entities corresponding to the KB entries, i.e. that they should be linked in our solution graph. These links also allow us to build up statistical co-occurrence counts between entities that occur in the same context, which may be used to weight edges in our graph.

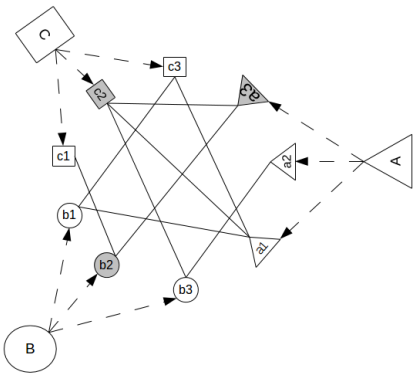

Figure 1: Example of solution graph

We evaluate our approaches on the AIDA dataset (Hoffart et al., 2011). Comparison with the baseline and some state-of-the-art approaches shows our proposed approaches offers substantial improvements in disambiguation accuracy.

The rest of the paper is organized as follows: Section 2 discusses related work. Section 3 discusses selection of NE candidate entities from the Wikipedia knowledge base and the assignment of confidence scores to each candidate. Formulation of the NE disambiguation problem in terms of a graph model is presented in section 4. Sections 5 and 6 describe the clique partitioning and ranking disambiguation approaches for collective NED. The experimental dataset and experimental results are presented in Section 7. Section 8 concludes the paper and presents some suggestions for future work to improve the results.

2 Related Work

Named Entity Disambiguation has received a lot attention in the past few years. Perhaps the best known related work is the Entity Linking (EL) shared task challenge first proposed by the National Institute of Standards and Technology (NIST) as part of the Knowledge Base Population (KBP) track within the Text Analysis Conference (TAC) in 2009 (McNamee and Dang, 2009). EL is a similar but broader task than NED: NED is concerned with disambiguating a textual NE mention where the correct entity is known to be one of the KB entries, while EL also requires systems to deal with the case where there is no entry for the NE in the reference KB. Ji et al. (2011) group and summarise the different approaches to EL taken by participating systems.

In general, there are two main lines of approach to the NED problem. The first, *single entity disambiguation approaches (SNED)*, disambiguates one entity at a time without considering the effect of other NEs. These approaches use local context textual features of the mention and compare them to the textual features of NE candidate documents in the KB, and link to the most similar. The first approach in this line was Bunescu and Pasca (2006), who measure similarity between the textual context of the NE mention and the Wikipedia categories of the candidate. More similarity features were added by Cucerzan (2007) who realized that topical coherence between a candidate entity and other entities in the context will improve NED accuracy by calculating the nodes' coherence based on the their incoming links in Wikipedia and the overlaps in Wikipedia categories. Milne and Witten (2008) improve Cucerzan's work by calculating the topical coherence using Normalized Google Distance and restrict the context entities to the unambiguous entities. Different query expansion approaches are incorporated into this framework, such as using context term expansion (Gottipati and Jiang, 2011) and acronym expansion (Zhang et al., 2011). Sen (2012) proposed a latent topic model to learn the context entity association. Machine learning is widely used in SNED as some approaches deal with the problem as a search result ranking problem. Supervised learn-to-rank models are used to re-rank the ambiguous candidate set (Zheng et al., 2010; Dredze et al., 2010; Alhelbawy and Gaizauskas, 2012; Nebhi, 2013).

The second line of approach is *collective named entity disambiguation (CNED)*, where all mentions of entities in the document are disambiguated jointly. These approaches try to model the interdependence between the different candidate entities for different NE mentions in the query document, and reformulate the problem of NED as a global optimization problem whose aim is to find the best set of entities. As this new formulation is NP-hard, many approximations have been proposed. Kulkarni et. al. (2009) presents a collective approach for entity linking that models the coherence between all pairs of entity candidates for different mentions as a probabilistic factor graph. They present two approximations to solve this optimization problem where the interdependence between decisions is modelled as the sum of the pairs' dependencies. Alhelbawy and Gaizauskas (2013) proposed a sequence dependency model using HMMs to model NE interdependency. Another approximation uses a mixture of local and global features to train the coefficients of a linear ranking SVM to rank different NE candidates (Ratinov et al., 2011). Shirakawa et al. (2011) cluster related textual mentions and assign a concept to each cluster using a probabilistic taxonomy. The concept associated with a mention is used in selecting the correct entity from the Freebase KB.

Graph models are widely used in collective disambiguation approaches. All these approaches model NE interdependencies, while different methods may be used for disambiguation. Han (2011) uses local dependency between NE mention and the candidate entity, and semantic relatedness between candidate entities to construct a referent graph, proposing a collective inference algorithm to infer the correct reference node in the graph. Hoffert (2011) poses the problem as one of finding a dense sub-graph, which is infeasible in a huge graph. So, an algorithm originally used to find strongly interconnected, size-limited groups in social media is adapted to prune the graph, and then a greedy algorithm is used to find the densest graph.

The word sense disambiguation (WSD) task has many similarities to NED, since in both cases the goal is to determine which of a set of predefined senses or reference entities is the correct interpretation of a surface string in context. Many researchers have used graph-based approaches successfully for the WSD task. Sinha and Michalecea (2007) proposed using four different graph centrality algorithms – Indegree, PageRank, Closeness and Betweenness for WSD. We propose to use a clique partitioning algorithm, originally proposed by Born et al. (1973), for NED. Clique algorithms have been successfully used for WSD problems. Gutiérrez et al. (2011; 2012), for example, use an N-cliques graph partitioning technique to identify sets of highly related senses. However, this approach has not been used for NED.

Our second proposed model uses the Page-Rank algorithm (PR), which to our knowledge has also not previously been applied to NED. PR was proposed by Page et al. (1999) to produce a global rank for web pages based on the hyperlink structure of the web. Xing and Ghorbani (2004) adapted PR to take into account the weights of links and the nodes' importance. PR and Personalized PR algorithms have been used successfully in WSD (e.g. Sinha and Mihalcea (2007), Agirre and Soroa (2008; 2009)).

3 Named Entity Candidates Selection

Given an input document D containing a set of pre-tagged NE textual mentions $M = \{m_1, m_2, m_3 \dots m_k\}$, we need to select all possible candidate interpretations for each m_i from the knowledge base. I.e. for each NE textual mention $m_i \in M$ we select a set of candidates $E_i = \{e_{i,1}, e_{i,2}, e_{i,3} \dots e_{i,j}\}$ from the KB. The NE textual mention m_i is used to search the KB entry titles using Lucene[1] to find entries with titles that fully or partially contain the NE textual mention. The following example shows the possible candidates for the textual mention "Sheffield": "Sheffield, New Zealand,", "University of Sheffield", "Sheffield United F.C.", "Sheffield, Massachusetts", "Fred Sheffield", "Sheffield, Alabama", etc. The result of this search is quite large and this increases the likelihood of the correct entry occurring somewhere in the list, i.e. it improves recall. However, the challenge now moves to the disambiguation step. In this step, we need to assign a confidence score to each candidate, as shown in the following section.

[1] https://lucene.apache.org/

3.1 Candidate Confidence Score

For each candidate $e_{i,j}$, a set of initial confidence scores $IConf(e_{i,j})$ is assigned. These scores are calculated for each NE candidate independent of other candidates or the candidates for other NE textual mentions in the document. Three scores are calculated locally using the NE textual mention context. There is also one global confidence score, entity popularity (EP), which is calculated globally independent of the document or the textual mention context by using the Freebase KB (Bollacker et al., 2008). The four confidence scores to be calculated for each NE candidate as follows:

- Cos: The cosine similarity between the NE textual mention and the KB entry title.

- JwSim: While the cosine similarity between a textual mention in the document and the candidate NE title in the KB is widely used in NED, this similarity is a misleading feature. For example, the textual mention "Essex" may refer to either of the following candidates "Essex County Cricket Club" or "Danbury, Essex", both of which are returned by the candidate generation process. The cosine similarity between "Essex" and "Danbury, Essex" is higher than that between "Essex" and "Essex County Cricket Club", which is not helpful in the NED setting. We adopted a new mention-candidate similarity function, $jwSim$, which uses Jaro-Winkler similarity as a first estimate of the initial confidence value for each candidate. This function considers all terms found in the candidate entity KB entry title, but not in the textual mention as disambiguation terms. The percentage of disambiguation terms found in the query document is used to boost in the initial $jwSim$ value, in addition to an acronym check (whether the NE textual mention could be an acronym for a specific candidate entity title). Experiments show that $jwSim$ performs much better than the standard cosine similarity.

- Ctxt: The cosine similarity between the sentence containing the NE mention in the query document and the textual description of the candidate NE in the KB (we use the first section of the Wikipedia article as the candidate entity description).

- EP: Entity popularity refers to connectivity to this entity. It has been used successfully as a discriminative feature for NED (Nebhi, 2013). Freebase provides an API interface to get an entity's popularity score, which is computed during Freebase data indexing. This score is a function of the entity's inbound and outbound link counts in Freebase and Wikipedia[2].

Initial confidence scores are calculated independently for each candidate entity for an NE mention. However, after the initial calculation, initial confidence scores for all candidates for a single NE mention are normalized to sum to 1.

4 Disambiguation Graph Model

In this section we discuss the graph model we use for NED. All candidate entities for the different NE textual mentions in the document are represented as an undirected graph $G = (V, D)$ where V is the node set of all possible candidate entities for different NE textual mentions in the input document and D is the set of edges between nodes. Because the same entity may be found multiple times as a candidate for different textual mentions and each occurrence must be evaluated independently, each node is formed as an ordered pair of textual mention m_i and candidate entity $e_{i,j}$. So, the graph nodes are formulated as a set $V = \{(m_i, e_{i,j}) \mid \forall e_{i,j} \in E_i, \forall m_i \in M\}$.

A set of entities is coherent if real world relations hold between them. We use such relations to link candidate entities for different NE textual mentions in our graph model. Edges are not drawn between different nodes for the same mention. However, they are drawn between two entities when there is a relation between them. Different approaches to determine and weight entity coherence relations are presented in the following section.

[2]https://developers.google.com/freebase/v1/search

4.1 Entity Coherence

Entity coherence refers to the real world relatedness of different entities which are candidate interpretations of different textual mentions in the document. Such relatedness is not based on documentcontext, so the relatedness of two candidate entities is always the same regardless of the query document. Coherence is represented as an edge between nodes in the graph. We used two measures for coherence:

- Entity Reference Relation (Ref): This is a boolean relation between two entities e_1 and e_2. The Ref relation holds if the Wikipedia document for either entity has a link to the other. Since the Wikipedia hyperlinks are directed, this relation is implicitly directed. However, we assume an inverse relation also exists and represented the relation as undirected.

$$\text{Ref}(e_i, e_j) = \begin{cases} 1, & \text{if } e_i \text{ or } e_j \text{ refers to the other} \\ 0, & \text{otherwise} \end{cases} \quad (1)$$

- Entity Co-occurrence ($Jprob$): An estimate of the probability of both entities appearing in the same sentence. Wikipedia documents are used to estimate this probability, as shown in (2), where $S(e)$ is the set of all sentences that contain a hyperlink reference to the entity e and S is the set of sentences containing any such entity references.

$$\text{Jprob}(e_i, e_j) = \frac{|S(e_i) \bigcap S(e_j)|}{|S|} \quad (2)$$

5 Cliques Partitioning Disambiguation

The clique model originated in social network studies when Luce and Perry (1949) defined a clique as a set of two or more people who are mutual friends. In graph theory, this pattern is known as a complete sub-graph. Assuming that NEs that appear in the same document can be split into groups of highly cohesive entities, we adopt the clique partitioning technique to find the biggest clique in terms of size and weight. Given an undirected graph $G(V, D)$ where V is the set of all nodes and D is the set of all edges, $G_s = (V_s, D_s)$ is a sub-graph of G where $V_s \subseteq V$ and $D_s \subseteq D$. G_s is called complete sub-graph or clique if and only if each node in V_s has a link in D_s to all other nodes in V_s. The clique partitioning algorithm aims to find all possible complete sub-graphs G_s in an undirected graph G. Our approach iteratively finds the 'best' clique, deletes all 'wrong' candidate entities for textual mentions that are disambiguated by the selected clique and converts the selected clique to a node in the graph to be used in the next iteration. The details are shown in algorithm 1. Figure 2 shows an exampler of the clique partitioning disambiguation algorithm given a graph of candidate entities for six NE textual mentions, 'A','B','C','D','E','F'. Candidate entities are coded with the lower case letter of the NE textual mention plus an index subscript, e.g., 'a1', 'a2', 'a3', etc. Cliques are shown with bold links in different colours.

As described in section 4, one of the properties of the disambiguation graph is that there are no links between candidates of the same NE textual mention. Because of this property, we can guarantee that there is no more than one candidate for each textual mention in any clique.

Data: Undirected graph $G(V, E)$ and for each node $v \in V$ an associated $IConf$ score
Result: Solution sub-graph
while *not all textual mentions are disambiguated* **do**
  1- clique-List = find cliques(G);
  2- weight each clique by summing the $IConf$ scores of all nodes in the clique;
  3- select the highest scoring clique and use its nodes as disambiguation candidates;
  4- remove all wrong candidates for any mention disambiguated in step 3;
  5- merge all nodes in the selected clique into one node with $IConf$ score of the new node = sum of the $IConf$ scores of the merged nodes;
end

Algorithm 1: Clique Disambiguation Algorithm

This approach does not use an entity coherence weighting (e.g. $Jprob$). Rather it just uses the entity

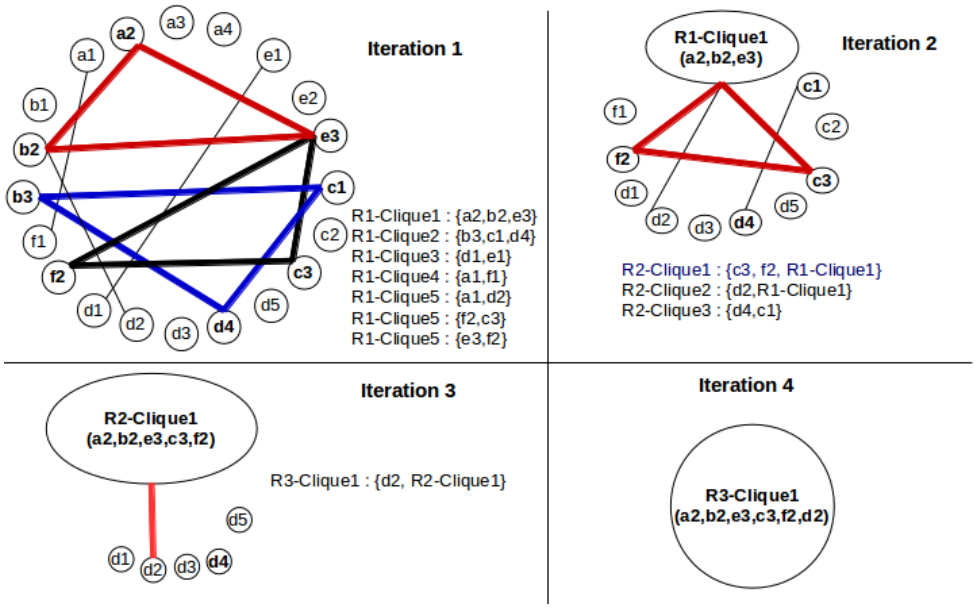

Figure 2: Example of Clique Partitioning Disambiguation

links to find the cliques regardless the relation strength. Because of the huge number of nodes, the clique finder algorithm is not fast. To speed-up the disambiguation, we filtered the nodes with low confidence in the graph, keeping only the top confidence scored 50 NE candidates for each NE textual mention.

6 Graph Ranking Disambiguation

The clique approach disambiguates different NE textual mentions iteratively, where in each iteration one or more NE mentions are disambiguated taking into account the disambiguated mentions from the previous iteration. The graph Ranking approach iteratively ranks all graph nodes depending on the links. So, all NE candidates of all NE textual mentions in the text are ranked together without ignoring any of them. Hence, a selection algorithm is used to combine the initial confidence and the graph rank score, and select the most appropriate NE candidate.

Graph Ranking: The links between different candidates in the graph represent real world relations. These relations are used to reliably boost relevant candidates. In some setups, the weight of these links are set to 1 and in some others they are set to the entities' coherence score. All nodes in the graph are ranked according to these relations using Page-Rank. We adapted a version of the PR algorithm with normalization term to rank the different NE candidates according to entity coherence as shown in equation 3, where N is the number of nodes in the graph, $coh(e_i)$ is the set of nodes that cohere with node e_i and $W(e_i, e_j)$ is the weight of the edge between e_i and e_j nodes. The original PR uses a directed graph while our graph is an undirected graph; so all links are treated as bidirectional.

$$PR(e_i) = \frac{(1-d)}{N} + \frac{d}{F(e_i)} \sum_{e_j \in coh(e_i)} PR(e_j) \times W(e_i, e_j) \tag{3}$$

$$F(e_i) = \sum_{e_j \in coh(e_i)} W(e_i, e_j) \tag{4}$$

The standard PR algorithm assumes the initial rank of all nodes is uniformly equal, while in our approach we used the initial confidence as an initial weight for the candidate nodes. A problem with Page-Rank for our purposes is the dissipation of initial node weight (confidence) over all linked nodes. The final rank of a node is based solely on the importance of linked nodes and the initial confidence plays no further role. In our case this is not appropriate, so the final rank for each mention is calculated after

graph ranking, by combining the graph rank with the initial confidence score. Let us refer to the graph rank of a candidate as $PR(e_i)$. We used two different combination schemes R_s and R_m as described in equations 6 and 5.

$$R_m(e_{i,j}) = ICONF(e_{i,j}) \times PR(e_{i,j}) \quad (5) \qquad R_s(e_{i,j}) = ICONF(e_{i,j}) + PR(e_{i,j}) \quad (6)$$

Decision Making: Selecting the proper candidate is the final phase in the disambiguation process. The simplest approach is to select the highest ranked entity in the list for each mention m_i according to equation 7 or 8, which correpond to the rank combining schemes expressed in equations 5 and 6. Experiments show that overall using the R_m combining scheme is better than the R_s scheme. However, the highest rank, after combining graph rank score and initial confidence score, is not always correct. So we developed a dynamic selection algorithm which uses both combination schemes to pick the best disambiguation candidate. We found that a dynamic choice between the re-ranking schemes, based on the difference between the top two candidates, as described in Algorithm 2, works best. The selected candidate entity is referred to as $\hat{e}$ with the superscript showing the selection scheme.

Data: E_i is a candidate list of one NE textual mention m_i
Result: The best disambiguation NE candidate $\hat{e}_i^g$
$R1 = \{(R_m(e_{i,j}), e_{i,j}) \mid \forall e_{i,j} \in E_i\}$;
$R2 = \{(R_s(e_{i,j}), e_{i,j}) \mid \forall e_{i,j} \in E_i\}$;
Sort $R1$ in descending order ;
Sort $R2$ in descending order ;
$R1diff$ = $R1$[0]-$R1$[1];
$R2diff$ = $R2$[0]-$R2$[1];
if *R1diff* > *R2diff* **then**
  return highest rank scored entity of $R1$, ($R1$[0])
else
  return highest rank scored entity of $R2$, ($R2$[0])
end
Algorithm 2: Selection Algorithm

$$\hat{e}_i^m = \underset{e_{i,j}}{\operatorname{argmax}}\, R_m(e_{i,j}) \quad (7) \qquad \hat{e}_i^s = \underset{e_{i,j}}{\operatorname{argmax}}\, R_s(e_{i,j}) \quad (8)$$

7 Experiments and Results

7.1 Dataset

NIST has released a dataset for use in the TAC KBP entity linking task (EL). But, the task of named entity disambiguation is different from entity linking task, as noted above in Section 2. Also, the NIST dataset is not suitable for evaluating the collective NE disambiguation task because only one NE mention is annotated and disambiguated per query document while we need all mentions of NEs in the document to be annotated and disambiguated to evaluate the performance of the collective named entity disambiguation technique. Another dataset manually annotated for NED is reported in (Kulkarni et al., 2009), but it uses an old version of Wikipedia and it is quite small. We have used another dataset, the AIDA dataset, which is based on the CoNLL 2003 data for NER tagging and in which most tagged NE mentions have been manually disambiguated against Wikipedia (Hoffart et al., 2011). This dataset contains 1393 documents, and 34,965 annotated mentions, where 7136 mention are not linked to Wikipedia[3].

We compare our results to Hoffart's work – Accurate Online Disambiguation of Named Entities (AIDA). For fair comparison, we only considered NE mentions with an entry in the Wikipedia KB, ignoring the 20% of query mentions without a link to the KB, as Hoffart did.

7.2 Evaluation Metric

We use accuracy as the evaluation metric. Micro-averaged accuracy is used as the official metric for the disambiguation task and has been used in much previous and related work. Micro-averaged accuracy

[3]AIDA dataset is available on the web to download http://www.mpi-inf.mpg.de/yago-naga/aida/

corresponds to the percentage of the correctly disambiguated textual mentions and it is calculated as shown in equation 9.

$$A_{micro} = \frac{\text{\#correctly disambiguated mentions}}{\text{Number of NE Mentions}} \tag{9}$$

Macro-averaged accuracy is used to calculate the average percentage of correctly identified named entities. Macro-averaged accuracy is calculated as shown in equation 10.

$$A_{macro} = \frac{\sum_{i}^{num} \frac{\text{Num Correct}(E_i)}{\text{Num Queries}(E_i)}}{\text{\# of unique entities}} \tag{10}$$

7.3 Results

In addition to the state-of-the-art, we used two strong baselines to evaluate the performance of the proposed approaches. The first baseline is a setup where the $IConf$ scores only are used to disambiguate the NE textual mention. In this setup a ranking based on Entity Popularity (EP) does best, with micro- and macro-averaged accuracy scores of 80.55% and 78.09% respectively. This high baseline is close to the state-of-the-art. A summary of the first baseline is shown in Table 1. The second baseline is the basic PR algorithm, where both $IConf$ scores and link weights are ignored. Links between nodes are created wherever any non-zero entity coherence relation, REF or JProb, is found. Micro- and macro-averaged accuracy scores of 70.60% and 60.91% respectively were obtained with this baseline.

	Baseline1		Cliques		PR_I		$\hat{e}^g$	
$IConf$	A_{micro}	A_{macro}	A_{micro}	A_{macro}	A_{micro}	A_{macro}	A_{micro}	A_{macro}
cos	38.44	45.68	71.59	64.83	70.6	60.83	78.41	72.35
jwSim	61.01	58.81	72.26	69.53	70.61	60.94	83.16	78.28
ctxt	24.58	21.44	58.06	57.37	70.61	60.83	75.45	65.22
EP	80.55	78.09	86.10	81.79	71.78	81.07	87.59	84.19

Table 1: Results using different $IConf$ scores with different approaches

The clique partitioning disambiguation algorithm experiments are setup so a link between nodes is created whenever a non-zero coherence relation is found between nodes regardless its weight. We used different settings for the candidates filter. In the case where no candidates filter is applied, all nodes are considered to find the best initial clique. So, bigger cliques with nodes that have lower confidence may be selected in the first iteration. This approach is very sensitive to the results of the first iteration. Consequently, the accuracy goes down. Also, because of the huge graph size, the clique partitioning algorithm takes a long time. At the other extreme, if we use only a small number of candidates with the highest confidence scores, then the accuracy also goes down because in most cases the correct disambiguation entity is filtered out of the graph. We used the highest 50 candidates in the graph and all other nodes are deleted. Table 1 shows the results of using different initial confidence scores in clique partitioning disambiguation.

Graph ranking disambiguation experiments were setup in three different settings in order to evaluate the contribution of different features like initial confidence and link weights. For all setups, we used different decision making approaches $\hat{e}^m$, $\hat{e}^s$ and $\hat{e}^g$. The results when using $\hat{e}^g$ are better than $\hat{e}^m$ and $\hat{e}^s$ for all setups. So, we report the results of $\hat{e}^g$ only. Different setups are as follows:

- PR_I: In this setup, the $IConf$ scores are used to be the initial rank for Page-Rank while the links between nodes are uniformly weighted to one. As in the PR baseline, links are created wherever Ref or $Jprob$ are not zero. Table 1 shows the results both without $IConf$ combination, i.e. using only the PR score for ranking, and after combining the initial confidence score using dynamic decision making (indicated by $\hat{e}^g$) When comparing these results to the PR baseline, we notice a slight positive effect of using the initial confidence as an initial rank instead of uniform ranking. The major improvement comes by combining the initial confidence with the PR score. All combining

methods improve the results over the baseline results when using the the same confidence score while the dynamic selection algorithm overcomes other basic methods, i.e. $\hat{e}^m$ and $\hat{e}^s$.

- PR_C: In the second setup, entity coherence features are tested by setting the edge weights to the coherence score and the initial node rank is set to be uniform when running the PR algorithm. So, initial confidence scores are not considered in graph ranking but just considered in disambiguation decision making. This setting is intended to evaluate the contribution of different coherence relations. We compared $Jprob$ and Ref edge weighting approaches, where for each approach edges were created only where the coherence score according to the approach was non-zero. We also investigated a variant, called $Jprob + Ref$, in which the Ref edge weights are normalized to sum to 1 over the whole graph and then added to the JProb edge weights (here edges result wherever $Jprob$ and Ref scores are non-zero). Results in Table 2 show the $JProb$ feature seems to be more discriminative than the Ref feature but the combined $Jprob + Ref$ feature performs better than each separately, just outperforming the baseline. We used the best $IConf$ score, i.e. EP, for re-ranking. Again, combining the $IConf$ with the PR score improves the results.

- PR_{IC}: This setup uses different combinations of $IConf$ and entity coherence scores in PR. Table 3 shows the accuracy when using different combinations of all entity coherence scores and some selected (i.e. the best) $IConf$ scores. Here the $Jprob + Ref$ combination does not add any value over $Jprob$ alone. Interestingly using $IConf$ score with differentially weighted edges does not show any benefit over using $IConf$ score and uniformly weighted edges (Table 1).

	PR		$\hat{e}^g$	
Edge Weight	A_{micro}	A_{macro}	A_{micro}	A_{macro}
$Jprob$	66.52	55.83	83.31	80.38
Ref	67.48	59.76	81.80	78.53
$Jprob + ref$	72.69	65.71	83.46	80.69

Table 2: Results using weighted edges (PR_C)

		$\hat{e}^g$	
$IConf$	Edge Weight	A_{micro}	A_{macro}
jwSim	$Jprob$	82.56	76.16

EP	Ref	83.16	80.01
EP	$Jprob + Ref$	86.10	82.80

Table 3: Results using initial confidence and weighted edges (PR_{IC})

To compare our results with the state-of-the-art, we report Hoffart et al.'s (2011) results as they re-implemented two other systems and ran them over the AIDA dataset which we used to evaluate our approach. We also compare with Alhelbawy and Gaizauskas (2013) and Shirakawa et al. (2011) who carried out their experiments using the same dataset. Table 4 shows a comparison between the results of our proposed approaches and the state-of-the-art. Both proposed approaches exceed the results of the state-of-the-art. However our approaches are very simple and direct to apply, unlike Hoffart et al.'s and Shirakawa et al.'s which are considerably more complex. Also, our approaches do not need any kind of training, unlike the Alhelbawy approach.

7.4 Discussion

The Page-Rank algorithm was originally designed for directed graphs while our coherence features are undirected. So, the node rank depends on both incoming and outgoing links (when converting the undirected graph to a directed graph). That explains the little improvement over basic PR when using the

	B1	B2	Cliques	PR_C	PR_I	PR_{CI}	Cucerzan	Kulkarni	Hoffart	Shirakawa	Alhelbawy
A_{macro}	78.09	60.91	81.79	80.98	84.19	82.80	43.74	76.74	81.91	83.02	74.18
A_{micro}	80.55	70.60	86.11	83.59	87.59	86.10	51.03	72.87	81.82	82.29	78.49

Table 4: Summary of Presented Approaches and State-of-the-art Results. B1 and B2 are baselines.

initial confidence as an initial rank before using PR (see Table 1). However, when comparing PR results in Tables 2 and 1, we can see that the PR algorithm is more sensitive to the links than to initial ranks. The combined coherence approach ($Jprob + Ref$) actually has a value other than the different weighting it supplies; the approach results in more edges than either of the combined approaches do alone. In all PR results wherever edge weights are applied, the result of using the combined coherence measures outperforms either of them singly.

Informal failure analysis was carried out to determine reasons for disambiguation failure. Reasons identified include:

1. The correct NE candidate does not exist in the graph. In such cases the disambiguation approach selected is irrelevant and what is needed is improved candidate selection.
2. Lack of edges. When there are no edges between any of the query NE mention candidate entities and other mentions' candidates. In this case the decision depends only on the $IConf$ score.
3. Where the Freebase popularity score (EP) is used, whenever this score for the correct NE candidate is 0, which means the selection process is based on the PR score.

Table 5 shows an example of the highest three NE candidates for three NE mentions taken from a document (overall the document contains textual mentions for ten different NEs). The first one is "Ford" and is disambiguated correctly to "Ford Motor Company", where the PR and popularity scores are higher than any of the other candidates. The second one is ,"Magna", disambiguated correctly, where the first two NE candidates have the same PR score but the popularity score discriminates between them. The third, "Markham", is disambiguated to "Clements Markham" while it should be disambiguated to "Markham, Ontario". The problem in this case is that all NE candidates for the mention "Markham" are not linked to any entity candidates for any other NE mentions in the document (problem 2 above). Therefore, the popularity score dominates the final rank score.

NE Candidate	PR score $\times 10^{-3}$	FB Rank $\times 10^{-3}$	our Rank $\times 10^{-3}$
Ford			
Ford Motor Company	21.37	62.12	1.32
Ford Galaxie	4.59	10.94	0.05
Ford GT	2.83	11.43	0.03
Magna			
Magna International	2.65	4.78	0.013
Magna Powertrain	2.65	2.18	0.005
Germania	0.83	3.46	0.003
Markham			
Clements Markham	0.83	4.42	0.004
Markham Waxers	0.83	3.67	0.003
Edwin Markham	0.83	2.89	0.002

Table 5: Example show the first three NE candidates for three NE mentions with scores

8 Conclusion

Our results show that graph ranking and cliques partitioning approaches in conjunction with the candidate confidence scores and entity coherence across a disambiguation graph can be used as an effective approach to collectively disambiguate named entity textual mentions in a document. Our proposed features are very simple and easy to extract, and work well when employed in PR or clique partitioning algorithms. Also, entity coherence is a discriminative feature when using graph models for NED. In future work we plan to explore enriching the edges between nodes, by incorporating semantic relations extracted from an ontology, and extending the scope of entity co-occurrence to be the document instead of the sentence. Also, it is worth investigating whether using the entity coherence score can help when evaluating clique weight in the clique partitioning algorithm.

Abstract

To obtain a complete temporal picture of a relation it is necessary to aggregate fragments of temporal information across relation instances in text. This process is non-trivial even for humans because temporal information can be imprecise and inconsistent, and systems face the additional challenge that each of their classifications is potentially false. Even a small amount of incorrect proposed temporal information about a relation can severely affect the resulting aggregate temporal knowledge. We motivate and evaluate three methods to modify temporal relation information prior to aggregation to address this challenge.

1 Introduction

Temporal information about relations is conveyed in text at varying levels of completeness and specificity. A sentence may indicate that a relation starts, ends, or that it is ongoing at a particular time. Furthermore, a time expression may be expressed at a variety of granularity levels (e.g., hour, day, or year). For instance, *"Collins, ..., is a 61-year-old veteran who went 444-434 in six seasons as a manager, 1994-1996 with Houston"* provides bounds on both the start and end date of the a relation but at a coarse granularity. Conversely, *"Ivory Coast President Laurent Gbagbo on state television Friday dissolved parliament"* conveys temporal information about an arbitrary part of Gbagbo's presidency at a finer granularity: the relation simply holds true at the document creation time (DCT). Single instances in which a relation of interest is related to a time expression often fail to convey complete, fine-grained temporal information. Thus, it is necessary to *aggregate* information from multiple relation-time *temporal relationship* mentions to gain a complete temporal picture of a relation.

We focus on the aggregation of temporal information about relations within the context of the Temporal Slot-Filling (TSF) Task (Ji et al., 2011; Surdeanu, 2013). TSF focusses on a class of relations called *fluents* (Russell and Norvig, 2010), which are properties of named entities whose values may vary over time. Systems must succinctly describe all temporal information about each query relation R – e.g., `title`(Gbagbo, President) – available in a source document collection by assigning it a single, final temporal *four-tuple* (Amigo et al., 2011). Given a relation mention r of R and a time expression γ, a four-tuple $T_\gamma^r = \langle t^{(1)}, t^{(2)}, t^{(3)}, t^{(4)} \rangle$ characterizes their temporal relationship; namely, $t^{(1)}$ and $t^{(2)}$ represent the earliest and latest possible start date for R, while $t^{(3)}$ and $t^{(4)}$ represent the earliest and latest possible end dates, as inferred from the relation mention's context (sec. 3). For instance, a sentence indicating that Gbagbo was President on 2010-02-12 yields $\langle -\infty, \text{2010-02-12}, \text{2010-02-12}, +\infty \rangle$, while the sentence *"Gbagbo has been in power since 2000"* yields $\langle \text{2000-01-01}, \text{2000-12-31}, \text{2000-01-31}, +\infty \rangle$. The intuitively best aggregation of these four-tuples expresses what we learn from both texts, that the relation started in 2000 and remained ongoing at 2010-02-12, i.e. $\langle \text{2000-01-01}, \text{2010-02-12}, \text{2010-02-12}, +\infty \rangle$, with no clear indication as to its end. Straightforward cases like these were used to justify the simple aggregation methods used by all TSF systems to date (Surdeanu, 2013; Ji et al., 2011). However, in reality even humans often must deal with vague and/or conflicting temporal information across documents,

Proceedings of COLING 2014, the 25th International Conference on Computational Linguistics: Technical Papers, pages 1556–1566, Dublin, Ireland, August 23-29 2014.

and systems must furthermore deal with the fact that each of their temporal relationship classifications is potentially false.

To address the various properties of text and temporal representation that influence aggregation and affect final four-tuple quality, we first improve an existing gold standard dataset (sec. 4.1). We then describe two key factors affecting systems' aggregation performance: (1) erroneous classifications attributed high confidence by systems, and (2) a lack of relation-bounding classifications (sec. 4.2). We propose three methods to better prepare a relation's multiple mention context derived four-tuples for aggregation into a final four-tuple. The first applies simple rules to predicative nominal titles with explicit time information (e.g., *"former President"*), the second filters and re-labels four-tuples based on entity lifespan (sec. 5.3), and the third adds four-tuples based on mentions of relations other than, but temporally linked to, the query relation (sec. 5.4). We then discuss results and identify remaining challenges for aggregating temporal information across relation mentions (sec. 6 and 7). A Glossary of selected terms can be found in the appendix.

2 Related Work

The most similar work on temporal relation information aggregation are Wang et al. (2012), who use an Integer Linear Programming framework to enforce the validity of induced temporal relation information as well as enforce inter-relation constraints, and Dylla et al. (2013), who collect temporal information about relations, mostly about start and end times, using a temporal probabilistic data base framework to aggregate and enforce constraints based on relation argument existence. All TSF systems we are aware of have used either max-constrain or Validity-Ensured Incremental max-constrain aggregation algorithms (Surdeanu, 2013; Ji et al., 2011), which we cover in section 4. None we are aware of have applied background knowledge to constrain intermediate four-tuples (sec. 3) before or after aggregation. In this work we modified our previous work CUNYTSF (Artiles et al., 2011), which is the only publicly available TSF system we are aware of. CUNYTSF employs two supervised models, one based on a string kernel defined in terms of dependency paths between named entities involved in a relation and context time expressions, and the other based on bags-of-words derived from small windows surrounding these tokens and shallow dependency relations. CUNYTSF achieved the highest and second-highest scores of five systems in two TSF shared tasks (Surdeanu, 2013; Ji et al., 2011).

3 Temporal Slot Filling (TSF)

The 2013 Temporal Slot-Filling (TSF) (Surdeanu, 2013) task was part of the Knowledge Base Population (KBP) track of the Text Analysis Conference (TAC). Systems were given a list of 273 fluent relation instances as queries, each with a supporting document. Query relations were evenly distributed across relation types, which consisted of people's *titles, marriages, employments or memberships, and residences (city, state, and country)*, and companies' *top members or employees*. The task was to obtain a final four-tuple T_R for each query relation $R = \langle q,\ s \rangle$ using the source corpus for provenance. For each element in T_R a system must provide a document in which R is entailed, and offsets for the relation arguments (the query-entity q and slot-filler s) and the normalized time expression from which the four-tuple element is derived.

The KBP source collection consists of about 1 million newswire, 1 million web text, and 100,000 discussion forum documents. Gold standard annotation was obtained by annotators who, using a tool, searched the source corpus for documents that provide temporal information about each query relation. Given a mention r of R in a document d for which temporal information about R could be inferred, annotators assigned an intermediate temporal relationship label (Table 1) (Ji et al., 2011) to $\langle r, \gamma \rangle$, where γ is viewed as an interval of dates $[\gamma_s, \gamma_e]$ derived either based on (1) a normalized time expression in d, or (2) the document creation time of d. We denote the temporal extension of R at the day granularity $R_{ex} = [R_s, R_e]$, where R_s and R_e are the start and end dates of R. The intermediate label l mediates the relationship between γ and R_{ex}, characterizing a possible relationship between R and γ. [1] After systems submitted results for the shared task, any corresponding document not included in the original annotation

[1] We add AFTER_END* and BEFORE_START* but omit motivation due to space constraints.

that were determined to express R was exhaustively annotated for temporal information about R. A gold standard final four-tuple G_R is obtained for each R by applying an aggregation procedure (sec. 4.1) to the intermediate temporal relationship labels assigned to mention-time classification instances (Surdeanu, 2013).

In this work we adopt the evaluation metric used for the TSF shared task (Ji et al., 2011; Surdeanu, 2013).

Intermediate Relation	**four-tuple**
BEGINNING	$\langle \gamma_s, \gamma_e, \gamma_s, \infty \rangle$
ENDING	$\langle -\infty, \gamma_e, \gamma_s, \gamma_e \rangle$
BEG_AND_END	$\langle \gamma_s, \gamma_e, \gamma_s, \gamma_e \rangle$
WITHIN	$\langle -\infty, \gamma_e, \gamma_s, \infty \rangle$
THROUGHOUT	$\langle -\infty, \gamma_s, \gamma_e, \infty \rangle$
BEFORE_START	$\langle \gamma_e, \infty, \gamma_e, \infty \rangle$
AFTER_END	$\langle -\infty, \gamma_s, -\infty, \gamma_s \rangle$
BEFORE_START*	$\langle \gamma_s, \infty, \gamma_s, \infty \rangle$
AFTER_END*	$\langle -\infty, \gamma_e, -\infty, \gamma_e \rangle$
NONE	$\langle -\infty, \infty, -\infty, \infty \rangle$

Table 2: Reasons for Invalidity in Gold Standard Final Four-Tuples

4 Aggregating Intermediate Relations

Temporal information about instances of R must be aggregated to yield a complete temporal picture of the relation with respect to the background corpus. We denote with $I(R)$ the set of intermediate four-tuples associated with R. The purpose of the four-tuple representation is to be as accurate as possible in representing the extent to which a given corpus provides information about the start and end time of R, R_s and R_e, while preserving the vagueness inherent in the text. Each four-tuple element of $I(R)$ represents temporal information about R_s and/or R_e, most often with respect to the context associated with a particular mention r of R. Temporal information at a corpus level is derived via a process of aggregation over the elements of $I(R)$. In this section we describe how both human annotators and systems have approached aggregation.

4.1 Aggregating Manually Annotated Intermediate Relations

Gold standard four-tuples were obtained by applying the Max-Constrain (MC) algorithm (Equation 1) to each $I(R)$ obtained via manual annotation using the labels in Table 1 (Surdeanu, 2013; Ji et al., 2011).[2]

$$T_R = \langle max(t^{(1)}), min(t^{(2)}), max(t^{(3)}), min(t^{(4)}) \rangle \quad (1)$$

Here, $max(t^{(k)})$ is the greatest $t^{(k)}$ from any intermediate four-tuple $T_r \in I(R)$, while $min(t^{(k)})$ is the least.

Let a four-tuple T be *valid* iff. $t^{(1)} \leq t^{(2)} \wedge t^{(3)} \leq t^{(4)} \wedge t^{(1)} \leq t^{(4)}$, and *correct* if $t^{(1)} \leq R_s \leq t^{(2)} \wedge t^{(3)} \leq R_e \leq t^{(4)}$. If R has only one start and one end date, and $R_s \leq R_e$, and each intermediate four-tuple $T_r^{\gamma} \in I(R)$ is valid and correct, then the final four-tuple obtained via MC is guaranteed to be valid and correct. Fifty-six gold standard final four-tuples were invalid and therefore discarded prior to evaluation (Surdeanu, 2013). We analyzed them by hand to determine the source of their invalidity (see Table 2). [3] We corrected instances until IMC (Algorithm 1) yielded a valid four-tuple.

[2] See http://surdeanu.info/kbp2013 for more details.

[3] Note that there may be more instances of each type described in table 2

[4] Here, $\max(t^{(i)} \leq x^{(i)}) := \max(\left\{ t^{(i)} \in \mathbf{t}^{(i)} \middle| t^{(i)} \leq x^{(i)} \right\})$, where $\mathbf{t}^{(i)} := \left\{ t^{(i)} \in T \middle| T \in I(R) \right\}$

Algorithm 1 Inclusive Max-Constrain (IMC)[4]

Require: $I(R) = \{T_0, T_1, \ldots, T_{N-1}\}$
Ensure: T_R
  $X \leftarrow$ max-constrain$(I(R)) = \langle x^{(1)}, x^{(2)}, x^{(3)}, x^{(4)} \rangle$
  $Y \leftarrow \langle \max(t^{(1)} \leq x^{(2)}), \min(t^{(2)} \geq x^{(1)}), \max(t^{(3)} \leq x^{(4)}), \min(t^{(4)} \geq x^{(3)}) \rangle$
  $T_R \leftarrow \langle \max(t^{(1)} \leq y^{(2)}), \min(t^{(2)} \geq y^{(1)}), \max(t^{(3)} \leq y^{(4)}) \rangle, \min(t^{(4)} \geq y^{(3)})$
  return T_R

4.2 System Derived Intermediate Relations

As suggested in section 4.1, MC is sensitive to inconsistent four-tuples. In response to this all prior work that has not used MC to combine system-produced $I(R)$ has used an algorithm similar to Validity-Ensured Incremental (VEI) Max-Constrain (Algorithm 2) (Artiles et al., 2011). Here, $I(R)$ is ordered by classifier confidence and T_R is initialized as the trivial four-tuple and updated incrementally. Starting with the highest-confidence four-tuple $T_{R,0} \in I(R)$, MC is applied to $\{T_R, T_{R,i}\}$ to yield T^*. In a given iteration, T^* is only accepted as the updated T_R if it is valid. Intuitively, higher confidence intermediate four-tuples are more likely to be correct, thus the incremental algorithm tries to ensure that erroneous low-confidence four-tuples are less likely to be aggregated. In practice, however, a single high-confidence incorrect label can derail the entire process (sec. 5).

Algorithm 2 Validity-Ensured Incremental (VEI) Max-Constrain Aggregation to yield final four-tuple

Require: $I(R) = \{T_0, T_1, \ldots, T_{N-1}\}$
Ensure: $T_R = \langle t^{(1)}, t^{(2)}, t^{(3)}, t^{(4)} \rangle$
  $T_R \leftarrow \langle -\infty, \infty, -\infty, \infty \rangle$
  $i \leftarrow 0$
  while $i < N$ **do**
    $T^* \leftarrow \langle max(t^{(1)}, t_i^{(1)}), min(t^{(2)}, t_i^{(2)}), max(t^{(3)}, t_i^{(3)}), max(t^{(4)}, t_i^{(4)}) \rangle$ {Pairwise MC}
    if $t^{*(1)} \leq t^{*(2)} \wedge t^{*(3)} \leq t^{*(4)} \wedge t^{*(1)} \leq t^{*(4)}$ **then**
      $T_R \leftarrow T^*$ {Validity Check}
    end if
  end while
  return T_R

5 Challenges and Solutions

This section outlines our modifications to CUNYTSF, inspired by a preliminary error analysis. We implement three methods geared toward better preparing $I(R)$ for aggregation into a final four-tuple..

5.1 Preliminary Error Analysis

We ran the publicly available system CUNYTSF described in (Artiles et al., 2011) on the queries used in TSF2013, using the KBP2013 source collection, and evaluated against the corrected gold standard described in section 4.1. [5]

Error analysis revealed the main source of errors to be WITHIN labels with high confidence. To be exact, the final four-tuple for 116 queries (of 271) was influenced by a WITHIN label that yielded a $t^{(3)}$ later than the $g^{(4)}$ date, while 20 were influenced by WITHIN dates that were too early. Under VEI, once a labeled instance $\langle r, \gamma, \text{WITHIN} \rangle$ is aggregated into T_R, if $\gamma > R_e$ then any correctly labeled instance $\langle r, \gamma, \text{ENDING} \rangle$ will yield an invalid four-tuple and thus be rejected. (Similarly, correct BEGINNING labels will be blocked by incorrect WITHIN labels that are too early). Even correct WITHIN labels cannot set the corrupted aggregation back on track, since pairwise MC will always take the later $t^{(3)}$

[5] System downloaded from http://nlp.cs.rpi.edu/software.html

(algorithm 2). That said, WITHIN labels are often required to retrieve a complete temporal picture of a relation conveyed in a corpus. WITHIN is the most common intermediate label in the source collection, constituting 44% of correct labels, and furthermore, over half of the query relations require at least one WITHIN label to achieve the gold standard final four-tuple, with 10% relying solely on instances labeled WITHIN. To make matters worse, almost all TSF systems to date (except Garrido et al. (2013)) use neither the BEFORE_START* nor AFTER_END* labels in their intermediate temporal relationships classification models, even though high-confidence instances with those labels could prevent the sort of erroneous WITHIN labels alluded to above.

This analysis motivated three methods to curtail the extent to which aggregation-derailing four-tuples were included in $I(R)$ described in sections 5.2, 5.3, and 5.4. We favor VEI over IMC for system-derived $I(R)$ because IMC strongly relies on the assumption that there is a high probability of correctness for each intermediate relationship annotation.

5.2 Title Time of Predication

Nominal predicates are commonly used in English to refer to fluents. For example, attribution of a title to a person can be performed using a transitive verb or copula as in *"Serra was elected Governor"*, or *"Serra is the Governor"*, or as a Noun Phrase (NP) within a clause, as in *"Governor Jose Serra"* or *"Jose Serra, Governor, ..."* (among other ways). We refer to cases in which the subject and object of the relation are contained within a phrase headed by a Noun as Relational NP's (RNP).[6] For RNP that are mentions of fluent relations, there is a time of predication (TOP), i.e. a time at which the relation conveyed is asserted to hold, though this time is not overtly marked by tense or aspect (in English) as in the case of VP's. Tonhauser (2002)'s analysis assumes that the verbal time of predication (VTOP) is the "most salient" time in an utterance, thus relational NP's take their containing clause's verbal time of predication by default though contextual justification may override this tendency. We propose that in news the DCT is just as salient a time since the focus is centered on current affairs, an important entities are often "already introduced" into the discourse by virtue of being public figures. Ad-hoc analysis of the instances considered by CUNYTSF indicate that a compelling reason is required to override RNP's from taking both DCT and VTOP. For instance, in, *"O'Donnell ... suggested Wednesday that the Obama administration - particularly **Vice President Joe Biden**, who **represented** Delaware in the Senate for decades - was behind them"*, *"Vice President"* holds true at DCT, and rejects the VTOP of *"represented"*, presumably only based on logical inference: *no person is both Vice President and represents (a state) in the Senate at the same time*. Similarly, we know that the DCT (2010-08-04) is an invalid TOP in *"In November 2000, Chinese **President Jiang Zemin** paid a state visit to Laos, the first visit to Laos by a Chinese president"*, only because of world knowledge, or, *"The following is a chronology of major events in China- Laotian relations since 1990:"*, earlier in the document.

Though NP's lack tense and aspect, overt temporal modifiers such as *former, then-,* and *ex-* make explicit a *post-relational state* directly following an RNP's relation (Tonhauser, 2002).[7] The tendency for RNP's to take both the verbal predication time as well as the DCT extends to post-relational states. There are many examples in the corpus similar to the following: *"Former US President Bill Clinton and US journalists Euna Lee and Laura Ling returned Wednesday from North Korea, one day after North Korea's leader Kim Jong-Il pardoned the two women"*. Each RNP holds at the DCT, and *"Wednesday"*, as well as the day before that (the VTOP of *"pardoned"*). However, as for VTOP's further into the past, whether the post-relational state holds is less clear. For example, in, *"Secretary of State Hillary Rodham Clinton says former Philippines President Corazon Aquino "helped bring democracy back" to her country after years of authoritarian rule"*, we cannot rule out the possibility that Aquino helped bring democracy back *as President*; whether she did so *as former President* is left open, to be resolved by historical knowledge. This is likely because, unless the relation is of the "Grover Cleveland" type, once the relation becomes a "former" relation it will remain so thereafter.

[6] We adopt a Noun Phrase rather than a Determiner Phrase framework for simplicity.

[7] In this work we omit similar constructions that indicate a pre-relational state at the time of verbal predication, such as "future-", "soon-to-be", and "-elect". These words to not occur often in our data. That said, the extent to which their meanings are analogous to the overt temporal modifiers that introduce post-relational states is not clear, and requires further investigation.

The nature of the contexts that override default TOP for RNP's is complicated, and not well understood. In addition, determining VTOP automatically remains a difficult problem in and of itself (Uz-Zaman et al., 2012). We have shown that newswire data contains relational NP's whose default times of predication - both DCT and verbal - are overridden by context. In addition, even post-relation states of modified RNP's may reject VTOP's. Post-relational states introduced by RNP's modified with *"former"*, *"then"*, and *"ex-"*, however, do appear to unambiguously take the DCT as a time of predication. Furthermore, we observe that CUNYTSF often incorrectly classifies modified RNP's introducing a post-relational state as expressing $\langle r, DCT, \text{WITHIN} \rangle$. To correct these errors we apply hand-written **Title Time of Predication Fix** rules to change the label for all such classification instances to AFTER_END* when the associated time expression is (or is closely related to) the DCT, and attribute 100% confidence to this new label. This correction both removes erroneous WITHIN labels and introduces labeled instances that bound query relations.

5.3 Entity Existence

VEI suffers when confidence values are inaccurate. For the relation `spouse`(Marylin Monroe, Arthur Miller), given the sentence, *"Editor Courtney Hodell said the book would include poems , photographs , reflections on third husband Arthur Miller and other men in Monroe 's life "*, a system is likely to mislabel $\langle r, \gamma \rangle$ as WITHIN, where γ is the document creation time 2010-04-27. The pattern *"husband s"* is a strong indicator of the WITHIN relationship for the `spouse` relation, so confidence for the resulting four-tuple $\langle -\infty, \text{2010-04-27}, \text{2010-04-27}, \infty \rangle$ is likely to be high. Once aggregated, it would be impossible to later aggregate $\langle -\infty, \text{1961-12-31}, \text{1961-01-01}, \text{1961-12-31} \rangle$ upon learning of the couple's divorce in 1961, since the proposed $T^* = \langle -\infty, \text{1961-12-31}, \text{2010-04-27}, \text{1961-12-31} \rangle$ is invalid. A basic clue that a WITHIN label should be changed to AFTER_END* is that q or s no longer exists (either the person has died or the business has dissolved).

To address this challenge we propose **Existence-based Correction and Filtering**. For each relation R we obtain the *existence four-tuple* E_R, by applying MC aggregation to the set of birth and death times in a knowledge base (KB) for the query-entity and slot-filler.[8] The KB is obtained via the Freebase API and scraping Wikipedia Infoboxes. We use a four-tuple instead of an interval of dates because birth and/or death information may not be available at the date granularity. Given the relation `spouse`(Jennifer Jones, Norton Simon) and the KB excerpt in Table 3, we obtain an existence constraint four-tuple $\langle \text{1919-03-02}, \text{1919-03-02}, \text{1993-06-02}, \text{1993-06-02} \rangle$.

Entity	Birth	Death
Jennifer Jones	1919-03-02	2009-12-17
Norton Simon	1907-02-05	1993-06-02

Table 3: Existence Information

We apply algorithm 3, where C contains classifier confidence for each labeled instance in $I(R)$. Above, $I(R)$ was introduced as a list of intermediate four-tuples for a relation R. In our approach, each of these four-tuples is derived deterministically (see Table 1). From here on (as in Algorithm 3) we allow a slightly abuse of notation in which $I(R)$ is viewed as a set of labeled classification instances, each of which yields a four-tuple for R. We omit pseudo-code to handle the analogous cases where instances are re-labeled BEFORE_START* based on the relative position of γ and ϵ_1.

5.4 Relation Precedence

The context of a relation mention often contains temporal information not explicitly tied to a time expression. For example, in, *"Myasnikovich will replace Sergei Sidorsky, who was prime minister since 2003"*, there is no date explicitly tied to the transition of power. Many titles are held by one person after another, in succession, without overlap. Intuitively, if we know the order in which several individuals held the same title then temporal information about one such relation can be used to constrain the other.

[8] For organization query-entities their foundation and defunct dates are considered their "birth" and "death" dates.

Algorithm 3 Existence Based Correction & Filtering Algorithm

Require: $I(R) = \{\langle\gamma_0, l_0\rangle, \ldots, \langle\gamma_k, l_k\rangle\}$; $C = \{c_0, \ldots, c_k\}$; $E_R = \langle\epsilon^{(1)}, \epsilon^{(2)}, \epsilon^{(3)}, \epsilon^{(4)}\rangle$
  while $i < N$ **do**
    if $\gamma_i.s \geq \epsilon_4 \wedge \neg(l_i = \text{NONE})$ **then**
      if $l_i = \text{ENDING} \wedge \gamma.s - \epsilon_4 \leq 31$ **then**
        $c_i \leftarrow 1.0$ {Most likely R holds at the time of death}
      else
        $l_i \leftarrow$ AFTER_END*; $c_i \leftarrow 1.0$
      end if
    else if $\gamma_i.s \leq \epsilon_4 \leq \gamma_i.e \wedge \neg(l_i = \text{NONE})$ **then**
      if $l_i = \text{ENDING}$ **then**
        $c_i \leftarrow 1.0$ {Most likely R holds at the time of death}
      else
        $l_i \leftarrow$ AFTER_END*; $c_i \leftarrow 1.0$
      end if
    end if
  end while
  return $I(R)$

To address this challenge we propose **Precedence-based Query Expansion and Re-labeling**. The title relation is well-represented in Wikipedia, and the infobox for many political title holders contains fields for *preceded by* and *succeeded by*, which specify the person that held the same title before and after the title holder in question. Given a title query R, we extracted the person who preceded and succeeded the query entity from the query entity's infobox (when available). Additional title relation *supporter* queries – R_{pre} and R_{suc}, respectively – were generated using these names, and the same title name as in the official query.[9]

After all classification instances are labeled and existence based correction is applied, we transform all labeled instances for supporter queries into labeled instances for official queries. Given a labeled instance $\langle r_x, \gamma, l\rangle$, where $x =$ pre or suc, we apply the mapping in Table 4 to yield the transformed labeled classification instance $\langle r, \gamma, l'\rangle$. Labeled supporter instances transformed into labeled official query instances are added to $I(R)$, the set of labeled instances for R. The set $I(R)$ is then passed to Aggregation (see Algorithm 2).

Supporter Label l	**Official label** l' ($x =$ pre)	**Official label** l' (when $x =$ suc)
NONE	NONE	NONE
BEFORE_START*	BEFORE_START*	NONE
AFTER_END*	NONE	AFTER_END*
All Others	BEFORE_START*	AFTER_END*

Table 4: Mapping to convert $\langle r_x, \gamma, l\rangle$ to $\langle r, \gamma, l'\rangle$, where x indicates whether the supporter query precedes or succeeds the official query

Just about any instance $\langle r_{\text{pre}}, \gamma, l\rangle$ yields $\langle r, \gamma, \text{BEFORE\_START*}\rangle$ because R_{pre} is known to both start and end before R starts. (And conversely $\langle r_{\text{suc}}, \gamma\rangle$ tends to yield AFTER_END* for $\langle r, \gamma\rangle$.) This is because the last (first) day of R_{pre} and all days before (after) it are guaranteed to be before (after) the start (end) of R. However, note that a AFTER_END* label for $\langle r_{\text{pre}}, \gamma\rangle$ yields NONE for R since dates after the end of R_{pre} may be before, during, or after R. For example, the headline, *"Former President*

[9]In general, knowing that two relations stand in a particular interval relation to one another allows us to posit constraints on one relation upon discovering temporal information about the other. We apply this intuition to the title relation in this work since the information is readily available in a structured form (i.e., the *preceded by* and *succeeded by* fields in Wikipedia info boxes).

Lee Teng-hui on visit in Japan Tokyo", while clearly indicating AFTER_END* for R_{pre} tells us very little about the relationship between the document creation time and R.

6 Results and Analysis

We scored the output for five conditions using the modified gold standard (section 4.1). TF means that title time of predication fix was applied (section 5.2), EC means existence corrections were applied, and Pr means that precedence-based query expansion was applied (section 5.4).

System	P	R	F
CUNYTSF	.337	.294	.314
CUNYTSF + TF	.341	.298	.318
CUNYTSF + EC	.349	.305	.326
CUNYTSF + TF + EC	.353	.309	.329
CUNYTSF + TF + EC + Pr	**.360**	**.315**	**.336**

Table 5: Results calculated using official TSF2013 scorer against corrected gold standard (sec. 4.1), with `anydoc` and `ignore-offsets` parameters set to true, augmented to calculate recall and precision

6.1 Title Time of Predication Fix

The gold standard for `title` had 142 non-infinity tuple element outputs of the form $\langle R, i, t^{(i)} \rangle$. The baseline output had 80 values while baseline + TF had 91. Applying TF, 10 baseline outputs were replaced while 11 were added. In most cases erroneous WITHIN labels are corrected by inserting high-confidence AFTER_END* into $I(R)$. In some cases this allows a correct $t^{(3)}$ to replace a later, incorrect $t^{(3)}$ that came from an erroneous WITHIN label. It is important to note that while some changes barely affect F-measure, they are important because they allow for correct information that would have otherwise been blocked to be aggregated. For example, a bad baseline WITHIN for *"General Prosecutor 's Office of Kyrgyzstan on Tuesday charged the country's former Prime Minister Igor Chudinov with abuse of power"* had blocked a correct WITHIN for *"Kyrgyz Prime Minister Igor Chudinov left Beijing Thursday evening"* - removing this block allowed $t^{(3)}$ to change from 2010-05-04 to 2009-10-14, which is the gold standard value.

6.2 Existence-based Correction and Filtering

Most changes made from existence constraints are beneficial both in terms of an increase in F-measure and in blocking the aggregation of incorrect information. For instance, it is difficult to prevent labeling the following sentence with WITHIN for DCT: *"The **London** home of composer George Frideric Handel is holding an exhibition about its other famous resident – **Jimi Hendrix**"*, but the document context permits AFTER_END*, given *"**Hendrix** died in **London** on Sept. 18 , 1970"*. Given the existence constraint we label the instance AFTER_END*.

On the other hand, in some cases we erroneously change WITHIN to BEFORE_START* using existence constraints, but this type of change does little damage. For example, the fact that CNN was founded on 1980-06-01 changes the label on 1980 from WITHIN to BEFORE_START* for EMPLOYEE(Novak, CNN), given *"Novak , editor of the Evans-Novak Political Report , is perhaps best known as a co-host of several of CNN 's political talk shows , where he often jousted with liberal guests from 1980 to 2005"*. We set $t^{(1)} =$ 1980-01-01 which does not block later inclusion of a correct $\langle R, 1980, \text{BEGINNING} \rangle$, which would set $t^{(1)} =$ 1980-01-01 if it were not already set, and does set $t^{(2)} =$ 1980-12-31. Changing this relation's label from WITHIN to START is not a catastrophic error because it allows for a finer grained, correct start date to be aggregated using VEI (see Algorithm 2) to yield a superior final four-tuple (though CUNYTSF finds no suitable candidates to facilitate this).

6.3 Precedence-based Query Expansion & Re-labeling

Output for affected official queries were improved simply because supporter queries were accurately labeled. For example, *"Kim Choongsoo, Korea's Central Bank Governor, said here on Thursday his nation's economic situation was getting better"* provides a $t^{(4)}$ value for `title`(Lee Seong-tae, Governor) due given the successor relation.

Some gains from label transformation are only possible given the title time of predication fix. For example, multiple instances of *"former president Chen Shui-bian"* and *"Former President Lee Teng-hui"* were converted from WITHIN to AFTER_END* for their respective relations. Because Chen succeeded Lee, the latter instances were transformed to NONE instances for `title`(Chen, President) using Table 4. [10] Changing these labels to NONE made room for a valid $t^{(3)} =$ 2000-01-01 based converting the WITHIN for `title`(Lee, President) to BEFORE_START* for `title`(Chen, President) given, *"... since former President Lee Teng-hui promulgated it 19 years ago, Wang said, and the [DPP] did not try to make any changes to the framework during its eight-year rule between 2000 and 2008 either"*.

Label transformation is robust to misclassification. For example, any of BEFORE_START*, BEGINNING, WITHIN, or ENDING for a predecessor relation R_{pre} will map to before_start* for R. But other types of errors propagate and can lead to disastrous results. For example, due to a normalization quirk *"Utatu President George Strauss"* is recognized as *"Johannes Rau"*, thus the relation `title`(Rau, President) was assigned WITHIN at DCT, which is converted to a BEFORE_START* for Horst Kohler, Rau's successor.

A deeper problem that can lead to error propagation is that fact one person can have the same title in different contexts. When a title is attributed to a person there is often a geo-political or organization entity involved. Mentions that fail to include this third entity are ambiguous; often, this information needs to be inferred from other context sentences. Such errors may be propagated from supporter to official queries. For example, *"Francophonie president Abdou Diouf of Senegal ... "* appears to support the `title`(Abdou Diouf, President). Diouf preceded Abdoulaye Wade as President of Senegal, but the context in question (inaccurately) refers to Diouf's leadership position of Secretary-General (not President) of Organisation internationale de la Francophonie, thus an erroneous BEFORE_START* is aggregated, blocking a correctly labeled (less confident) $\langle r, 2000, \text{START} \rangle$.

7 Conclusion

We have analyzed within the particular context of TSF the process of aggregating partially-specified temporal information about relations across documents. Our analysis and and results indicate that text mentions of relations often ground only a portion of the referent relation in time and that correct interpretation relies on background knowledge about relation participants. In future work we plan a more rigorous data-driven study of nominal time of predication and to attack more ambiguous context-sensitive cases. In addition we aim to induce relation order from text automatically to multiple relation types as well as events.

Appendix A. Glossary of Selected Terms

Fluent Relation: A property of a person or organization whose value may change over time. For example, a person's employer.
Temporal Extension: For a relation R, the temporal extension is the interval $[R_s, R_e]$, which represents the period of time between and including the start date R_s and end date R_e of the relation.
Relation Mention: An excerpt of text that expresses a relation.
Time Expression: An excerpt of text that refers to a portion of time, such as "Tuesday" or "next year".
Normalized Time Expression: The portion of time indicated by a time expression expressed in a standard form.
Granularity: The level at which a portion of time is expressed, in terms of calendar and clock units. For example, years are of a coarser granularity than days.
Temporal Four-tuple: For a relation R, a temporal four-tuple $T_R = \left\langle t^{(1)}, t^{(2)}, t^{(3)}, t^{(4)} \right\rangle$ represents an assertion that, based on some evidence, the start date for R is between $t^{(1)}$ and $t^{(2)}$, and its end date is between $t^{(3)}$ and $t^{(4)}$.
Final Temporal Four-tuple: The four-tuple assigned to R (by an annotator or system) after aggregating all temporal information about R.
Valid Temporal Four-tuple: A four-tuple $T = \left\langle t^{(1)}, t^{(2)}, t^{(3)}, t^{(4)} \right\rangle$ is valid if and only if iff. $t^{(1)} \leq t^{(2)} \wedge t^{(3)} \leq t^{(4)} \wedge t^{(1)} \leq t^{(4)}$.
Correct Temporal Four-tuple: A temporal four-tuple $T_R = \left\langle t^{(1)}, t^{(2)}, t^{(3)}, t^{(4)} \right\rangle$ if and only if $t^{(1)} \leq R_s \leq t^{(2)} \wedge t^{(3)} \leq R_e \leq t^{(4)}$
Intermediate Temporal Relationship: Given a relation mention r of relation R and a normalized time expression γ (viewed as a temporal interval), the intermediate temporal relationship between the two characterizes the relationships between the end points of γ and the endpoints of the temporal extension of R, namely γ_s, γ_e, R_s, and R_e. In this work, each intermediate temporal relationship used serves as a mapping from temporal interval to four-tuple (see Table 1 for the relationships used in this work and their mappings).

Intermediate Temporal Four-tuple Set: For a relation R, a system or annotator may derive an intermediate temporal four-tuple for each relation mention r and a corresponding time expression γ by based on an intermediate temporal relationship expressed between the two. The elements of each intermediate four-tuple are derived using the mapping in Table 1. We denote the set of intermediate temporal four-tuples for R as $I(R)$.
Query Relation: A relation that serves as input to a TSF system tasked with returning a final temporal four-tuple for that relation.
Relational Noun Phrase: A noun phrase that expresses a relation. For example, "President Obama" expresses a relation that "Obama"'s title is "President".
Time of Predication: For a given predicate, the time of predication is a time interval for which the predicate is asserted to apply to a specified set of arguments.
Post-relational State: A state immediately following the end of a relation characterized by the relation now longer holding. For example, prepending a title with "former", as in "former President X", introduces a state characterized by X no longer holding the title President.
Temporally Linked Relations: Two relations are temporally linked if their temporal extensions are not independent. For example, if it is known that one's end precedes the other's start.
Provenance: The relevant text that supports the output.

The Wisdom of Minority: Unsupervised Slot Filling Validation based on Multi-dimensional Truth-Finding

Abstract

Information Extraction using multiple information sources and systems is *beneficial* due to multi-source/system consolidation and *challenging* due to the resulting inconsistency and redundancy. We integrate IE and truth-finding research and present a novel unsupervised *multi-dimensional truth finding* framework which incorporates signals from multiple sources, multiple systems and multiple pieces of evidence by knowledge graph construction through multi-layer deep linguistic analysis. Experiments on the case study of Slot Filling Validation demonstrate that our approach can find truths accurately (9.4% higher F-score than supervised methods) and efficiently (finding 90% truths with only one half the cost of a baseline without credibility estimation).

1 Introduction

Traditional Information Extraction (IE) techniques assess the ability to *extract information from individual documents in isolation*. However, similar, complementary or conflicting information may exist in multiple heterogeneous sources. We take the Slot Filling Validation (SFV) task of the NIST Text Analysis Conference Knowledge Base Population (TAC-KBP) track (Ji et al., 2011) as a case study. The Slot Filling (SF) task aims at collecting from a large-scale multi-source corpus the values ("slot fillers") for certain attributes ("slot types") of a query entity, which is a person or some type of organization. KBP 2013 has defined 25 slot types for persons (per) (*e.g.*, age, spouse, employing organization) and 16 slot types for organizations (org) (*e.g.*, founder, headquarters-location, and subsidiaries). Some slot types take only a single slot filler (*e.g.*, per:birthplace), whereas others take multiple slot fillers (*e.g.*, org:top employees).

We call a combination of query entity, slot type, and slot filler a ***claim***. Along with each claim, each system must provide the ID of a source document and one or more detailed context sentences as ***evidence*** which supports the claim. A ***response*** (*i.e.*, a claim, evidence pair) is *correct* if and only if the claim is true *and* the evidence supports it.

Given the responses produced by multiple systems from multiple sources in the SF task, the goal of the SFV task is to determine whether each response is true or false. Though it's a promising line of research, it raises two complications: (1) different information ***sources*** may generate claims that vary

Proceedings of COLING 2014, the 25th International Conference on Computational Linguistics: Technical Papers, pages 1567–1578, Dublin, Ireland, August 23-29 2014.

in trustability; and (2) a large-scale number of SF ***systems*** using different resources and algorithms may generate erroneous, conflicting, redundant, complementary, ambiguously worded, or inter-dependent claims from the same set of documents. Table 1 presents responses from four SF systems for the query entity ***Ronnie James Dio*** and the slot type ***per:city_of_death***. Systems A, B and D return *Los Angeles* with different pieces of evidence [1] extracted from different information sources, though the evidence of System D does not decisively support the claim. System C returns *Atlantic City*, which is neither true nor supported by the corresponding evidence.

Such complications call for "*truth finding*": determining the *veracity* of multiple conflicting claims from various sources and systems. We propose a novel unsupervised multi-dimensional truth finding framework to study credibility perceptions in rich and wide contexts. It incorporates signals from multiple sources and systems, using linguistic indicators derived from knowledge graphs constructed from multiple evidences using multi-layer deep linguistic analysis. Experiments demonstrate that our approach can find truths accurately (9.4% higher F-score than supervised methods) and efficiently (find 90% truths with only one half cost of a baseline without credibility estimation).

System	Source	Slot Filler	Evidence
A	Agence France-Presse, News	Los Angeles	The statement was confirmed by publicist Maureen O'Connor, who said ***Dio*** died in ***Los Angeles***.
B	New York Times, News	Los Angeles	***Ronnie James Dio***, a singer with the heavy-metal bands Rainbow, Black Sabbath and Dio, whose semioperatic vocal style and attachment to demonic imagery made him a mainstay of the genre, died on Sunday in ***Los Angeles***.
C	Discussion Forum	Atlantic City	***Dio*** revealed last summer that he was suffering from stomach cancer shortly after wrapping up a tour in ***Atlantic City***.
D	Associated Press Worldstream, News	Los Angeles	***LOS ANGELES*** 2010-05-16 20:31:18 UTC ***Ronnie James Dio***, the metal god who replaced Ozzy Osbourne in Black Sabbath and later piloted the bands Heaven, Hell and Dio, has died, according to his wife and manager.

Table 1: Conflicting responses across different SF systems and different sources (query entity = ***Ronnie James Dio***, slot type = ***per:city_of_death***).

2 Related Work & Our Novel Contributions

Most previous SFV work (*e.g.*, (Tamang and Ji, 2011; Li and Grishman, 2013)) focused on filtering incorrect claims from multiple systems by simple heuristic rules, weighted voting, or costly supervised learning to rank algorithms. We are the first to introduce the truth finding concept to this task.

The "truth finding" problem has been studied in the data mining and database communities (*e.g.*, (Yin et al., 2008; Dong et al., 2009a; Dong et al., 2009b; Galland et al., 2010; Blanco et al., 2010; Pasternack and Roth, 2010; Yin and Tan, 2011; Pasternack and Roth, 2011; Vydiswaran et al., 2011; Ge et al., 2012; Zhao et al., 2012; Wang et al., 2012; Pasternack and Roth, 2013)). Compared with the previous work, our truth finding problem is defined under a unique setting: each *response* consists of a claim and supporting evidence, automatically generated from unstructured natural language texts by a SF *system*. The judgement of a *response* concerns both the truth of the claim and whether the *evidence* supports the claim. This has never been modeled before. We mine and exploit rich linguistic knowledge from multiple lexical, syntactic and semantic levels from evidence sentences for truth finding. In addition, previous truth finding work assumed most claims are likely to be true. However, most SF systems have hit a performance ceiling of 35% F-measure, and false responses constitute the majority class (72.02%) due to the imperfect algorithms as well as the inconsistencies of information sources. Furthermore, certain truths might only be discovered by a minority of good systems or from a few good sources. For example, 62% of the true responses are produced only by 1 or 2 of the 18 SF systems.

[1] Hereafter, we refer to "pieces of evidence" with the shorthand "evidences". Note that SF systems may include multiple sentences as "evidence" within their responses.

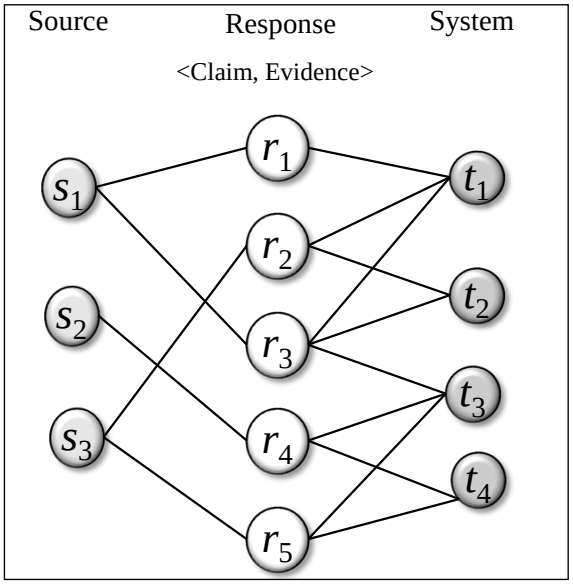

Figure 1: Heterogeneous networks for MTM.

3 MTM: A Multi-dimensional Truth-Finding Model

MTM Construction

A response is trustworthy if its claim is true and its evidence supports the claim. A trusted source always supports true claims by giving convincing evidence, and a good system tends to extract trustworthy responses from trusted sources. We propose a *multi-dimensional truth-finding model (MTM)* to incorporate and compute multi-dimensional credibility scores.

Consider a set of responses $R = \{r_1, \ldots, r_m\}$ extracted from a set of sources $S = \{s_1, \ldots, s_n\}$ and provided by a set of systems $T = \{t_1, \ldots, t_l\}$. A heterogeneous network is constructed as shown in Fig. 1. Let weight matrices be $W^{rs}_{m\times n} = \{w^{rs}_{ij}\}$ and $W^{rt}_{m\times l} = \{w^{rt}_{ik}\}$. A link $w^{rs}_{ij} = 1$ is generated between r_i and s_j when response r_i is extracted from source s_j, and a link $w^{rt}_{ik} = 1$ is generated between r_i and t_k when response r_i is provided by system t_k.

Credibility Initialization

Each source is represented as a combination of publication venue and genre. The credibility scores of sources S are initialized uniformly as $\frac{1}{n}$, where n is the number of sources. Given the set of systems $T = \{t_1, \ldots, t_l\}$, we initialize their credibility scores $c^0(t)$ based on their interactions on the predicted responses. Suppose each system t_i generates a set of responses R_{t_i}. The similarity between two systems t_i and t_j is defined as $similarity(t_i, t_j) = \frac{|R_{t_i} \cap R_{t_j}|}{\log(|R_{t_i}|)+\log(|R_{t_j}|)}$ (Mihalcea, 2004). Then we construct a weighted undirected graph $G = \langle T, E\rangle$, where $T(G) = \{t_1, \ldots, t_l\}$ and $E(G) = \{\langle t_i, t_j\rangle\}$, $\langle t_i, t_j\rangle = similarity(t_i, t_j)$, and apply the TextRank algorithm (Mihalcea, 2004) on G to obtain $c^0(t)$.

We got negative results by initializing system credibility scores uniformly. We also got negative results by initializing system credibility scores using system metadata, such as the algorithms and resources the system used at each step, its previous performance in benchmark tests, and the confidence values it produced for its responses. We found the quality of an SF system depends on many different resources instead of any dominant one. For example, an SF system using a better dependency parser does not necessarily produce more truths. In addition, many systems are actively being improved, rendering previous benchmark results unreliable. Furthermore, most SF systems still lack reliable confidence estimation.

The initialization of the credibility scores for responses relies on deep linguistic analysis of the evidence sentences and the exploitation of semantic clues, which will be described in Section 4.

Credibility Propagation

We explore the following heuristics in MTM.

HEURISTIC 1: *A response is more likely to be true if derived from many trustworthy sources. A source is more likely to be trustworthy if many responses derived from it are true.*

HEURISTIC 2: *A response is more likely to be true if it is extracted by many trustworthy systems. A system is more likely to be trustworthy if many responses generated by it are true.*

Based on these two heuristics we design the following credibility propagation approach to mutually reinforce the trustworthiness of linked objects in MTM.

By extension of Co-HITS (Deng et al., 2009), designed for bipartite graphs, we develop a propagation method to handle heterogeneous networks with three types of objects: *source, response* and *system*. Let the weight matrices be W^{rs} (between responses and sources) and W^{rt} (between responses and systems), and their transposes be W^{sr} and W^{tr}. We can obtain the transition probability that vertex s_i in S reaches vertex r_j in R at the next iteration, which can be formally defined as a normalized weight $p_{ij}^{sr} = \frac{w_{ij}^{sr}}{\sum_k w_{ik}^{sr}}$ such that $\sum_{r_j \in R} p_{ij}^{sr} = 1$. We compute the transition probabilities p_{ji}^{rs}, p_{jk}^{rt} and p_{kj}^{tr} in an analogous fashion.

Given the initial credibility scores $c^0(r)$, $c^0(s)$ and $c^0(t)$, we aim to obtain the refined credibility scores $c(r)$, $c(s)$ and $c(t)$ for responses, sources, and systems, respectively. Starting with sources, the update process considers both the initial score $c^0(s)$ and the propagation from connected responses, which we formulated as:

$$c(s_i) = (1 - \lambda_{rs})c^0(s_i) + \lambda_{rs} \sum_{r_j \in R} p_{ji}^{rs} c(r_j) \tag{1}$$

Similarly, the propagation from responses to systems is formulated as:

$$c(t_k) = (1 - \lambda_{rt})c^0(t_k) + \lambda_{rt} \sum_{r_j \in R} p_{jk}^{rt} c(r_j) \tag{2}$$

Each response's score $c(r_j)$ is influenced by both linked sources and systems:

$$c(r_j) = (1 - \lambda_{sr} - \lambda_{tr})c^0(r_j) + \lambda_{sr} \sum_{s_i \in S} p_{ij}^{sr} c(s_i) + \lambda_{tr} \sum_{t_k \in T} p_{kj}^{tr} c(t_k) \tag{3}$$

where $\lambda_{rs}, \lambda_{rt}, \lambda_{sr}$ and $\lambda_{tr} \in [0, 1]$. These parameters control the preference for the propagated over initial score for every type of random walk link. The larger they are, the more we rely on link structure[2]. The propagation algorithm converges (10 iterations in our experimental settings) and a similar theoretical proof to HITS (Peserico and Pretto, 2009) can be constructed. Algorithm 1 summarizes MTM.

4 Response Credibility Initialization

Each evidence along with a claim is expressed as a few natural language sentences that include the query entity and the slot filler, along with semantic content to support the claim. We analyze the evidence of each response in order to initialize that response's credibility score. This is done using heuristic rules defined in terms of the binary outputs of various *linguistic indicators* (Section 4.1).

4.1 Linguistic Indicators

We encode linguistic indicators based on deep linguistic knowledge acquisition and use them to determine whether responses provide supporting clues or carry negative indications (Section 4.3). These indicators make use of linguistic features on varying levels - surface form, sentential syntax, semantics, and pragmatics - and are defined in terms of knowledge graphs (Section 4.2). We define a heuristic rule for each slot type in terms of the binary-valued linguistic indicator outputs to yield a single binary value (1 or 0) for each response. If a response's linguistic indicator value is 1, the credibility score of a response is initialized at 1.0, and 0.5 otherwise.

[2]We set $\lambda_{rs} = 0.9$, $\lambda_{sr} = 0.1$, $\lambda_{rt} = 0.3$ and $\lambda_{tr} = 0.2$, optimized from a development set. See Section 5.1.

Input: A set of responses (R), sources (S) and systems (T).
Output: Credibility scores ($c(r)$) for R.

Initialize the credibility scores $c^0(s)$ for S as $c^0(s_i) = \frac{1}{|S|}$;
Use TextRank to compute initial credibility scores $c^0(t)$ for T;
Initialize the credibility scores $c^0(r)$ using linguistic indicators (Section 4);
Construct heterogeneous networks across R, S and T;
$k \leftarrow 0$, diff $\leftarrow 10e6$;
while $k <$ MaxIteration and diff $>$ MinThreshold **do**
    Use Eq. (1) to compute $c^{k+1}(s)$;
    Use Eq. (2) to compute $c^{k+1}(t)$;
    Use Eq. (3) to compute $c^{k+1}(r)$;
    Normalize $c^{k+1}(s)$, $c^{k+1}(t)$, and $c^{k+1}(r)$;
    diff $\leftarrow \sum(|c^{k+1}(r) - c^k(r)|)$;
    $k \leftarrow k + 1$
end while

Algorithm 1: Multi-dimensional Truth-Finding.

4.2 Knowledge Graph Construction

A semantically rich knowledge graph is constructed that links a query entity, all of its relevant slot filler nodes, and nodes for other intermediate elements excerpted from evidence sentences. There is one knowledge graph per sentence.

Fig. 2 shows a subregion of the knowledge graph built from the sentence: "***Mays***, ***50***, *died in his sleep at his* ***Tampa*** *home the morning of* ***June 28***.". It supports 3 claims: [*Mays, per: city_of_death, Tampa*], [*Mays, per: date_of_death, 06/28/2009*] and [*Mays, per: age, 50*].

Formally, a knowledge graph is an annotated graph of entity mentions, phrases and their links. It must contain one query entity node and one or more slot filler nodes. The annotation of a node includes its entity type, subtype, mention type, referent entities, and semantic category (though not every node has each type of annotation). The annotation of a link includes a dependency label and/or a semantic relation between the two linked nodes.

The knowledge graph is constructed using the following procedure. First, we annotate the evidence text using dependency parsing (Marneffe et al., 2006) and Information Extraction (entity, relation and event) (Li et al., 2013; Li and Ji, 2014). Two nodes are linked if they are deemed related by one of the annotation methods (*e.g.*, [*Mays, 50*] is labeled with the dependency type *amod*, and [*home, Tampa*] is labeled with the semantic relation *located_in*). The annotation output is often in terms of syntactic heads. Thus, we extend the boundaries of entity, time, and value mentions (*e.g.*, people's titles) to include an entire phrase where possible. We then enrich each node with annotation for entity type, subtype and mention type. Entity type and subtype refer to the role played by the entity in the world, the latter being more fine-grained, whereas mention type is syntactic in nature (it may be pronoun, nominal, or proper name). For example, "*Tampa*" in Fig. 2 is annotated as a *Geopolitical (entity type) Population-Center (subtype) Name (mention type)* mention. Every time expression node is annotated with its normalized reference date (*e.g.*, "*June, 28*" in Fig. 2 is normalized as "*06/28/2009*").

Second, we perform co-reference resolution, which introduces implicit links between nodes that refer to the same entity. Thus, an entity mention that is a nominal or pronoun will often be co-referentially linked to a mention of a proper name. This is important because many queries and slot fillers are expressed only as nominal mentions or pronouns in evidence sentences, their canonical form appearing elsewhere in the document.

Finally, we address the fact that a given relation type may be expressed in a variety of ways. For example, "*the face of*" indicates the membership relation in the following sentence: "*Jennifer Dunn was the face of the Washington state Republican Party for more than two decades*." We mined a large

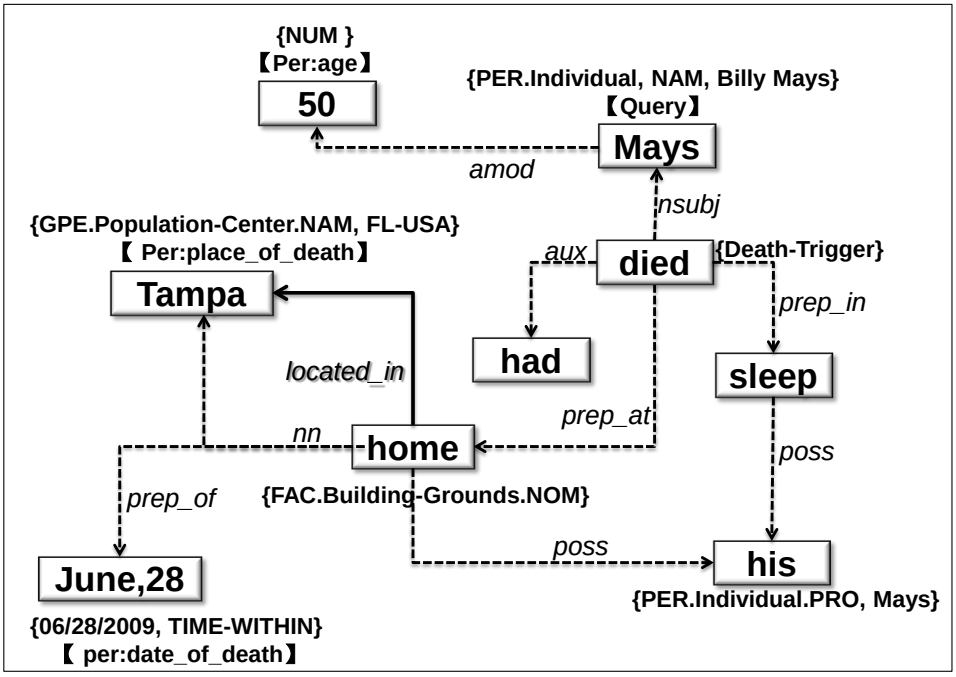

Figure 2: Knowledge Graph Example.

number of trigger phrases for each slot type by mapping various knowledge bases, including Wikipedia Infoboxes, Freebase (Bollacker et al., 2008), DBPedia (Auer et al., 2007) and YAGO (Suchanek et al., 2007), into the Gigaword corpus[3] and Wikipedia articles via distant supervision (Mintz et al., 2009)[4]. Each intermediate node in the knowledge graph that matches a trigger phrase is then assigned a corresponding semantic category. For example, "*died*" in Fig. 2 is labeled a *Death-Trigger*.

4.3 Knowledge Graph-Based Verification

We design linguistic indicators in terms of the properties of nodes and paths that are likely to be bear on the response's veracity. Formally, a *path* consists of the list of nodes and links that must be traversed along a route from a query node to a slot filler node.

Node indicators contribute information about a query entity or slot filler node in isolation, that may bear on the trustworthiness of the containing evidence sentence. For instance, a slot filler for the ***per:date_of_birth*** slot type must be a time expression.

Node Indicators

1. *Surface*: Whether the slot filler includes stop words; whether it is lower cased but appears in news. These serve as negative indicators.

2. *Entity type, subtype and mention type*: For example, the slot fillers for "*org:top_employees*" must be person names; and fillers for "*org:website*" must match the url format. Besides the entity extraction system, we also exploited the entity attributes mined by the NELL system (Carlson et al., 2010) from the KBP source corpus.

Each path contains syntactic and/or semantic relational information that may shed light on the manner in which the query entity and slot filler are related, based on dependency parser output, IE output, and trigger phrase labeling. Path indicators are used to define properties of the context in which which query-entity and slot-filler are related in an evidence sentence. For example, whether the path

[3]http://catalog.ldc.upenn.edu/LDC2011T07

[4]Under the distant supervision assumption, sentences that appear to mention both entities in a binary relation contained in the knowledge base were assumed to express that relation.

associated with a claim about an organization's top employee includes a title commonly associated with decision-making power can be roughly represented using the *trigger phrases* indicator.

Path Indicators

1. *Trigger phrases*: Whether the path includes any trigger phrases as described in Section 4.2.

2. *Relations and events*: Whether the path includes semantic relations or events indicative of the slot type. For example, a "*Start-Position*" event indicates a person becomes a "*member*" or "*employee*" of an organization.

3. *Path length*: Usually the length of the dependency path connecting a query node and a slot filler node is within a certain range for a given slot type. For example, the path for "*per:title*" is usually no longer than 1. A long dependency path between the query entity and slot filler indicates a lack of a relationship. In the following evidence sentence, which does not entail the "*per:religion*" relation between "*His*" and the religion "*Muslim*", there is a long path ("*his-poss-moment-nsubj-came-advcl-seized-militant-acmod-Muslim*"): "*His most noticeable moment in the public eye came in 1979, when Muslim militants in Iran seized the U.S. Embassy and took the Americans stationed there hostage.*".

Detecting and making use of interdependencies among various claims is another unique challenge in SFV. After initial response credibility scores are calculated by combining linguistic indicator values, we identify responses that have potentially conflicting or potentially supporting slot-filler candidates. For such responses, their credibility scores are changed in accordance with the binary values returned by the following indicators.

Interdependent Claims Indicators

1. *Conflicting slot fillers*: When fillers for two claims with the same query entity and slot type appear in the same evidence sentence, we apply an additional heuristic rule designed for the slot type in question. For example, the following evidence sentence indicates that compared to "*Cathleen P. Black*", "*Susan K. Reed*" is more likely to be in a "*org:top_employees/members*" relation with "*The Oprah Magazine*" due to the latter pair's shorter dependency path: "*Hearst Magazine's President Cathleen P. Black has appointed Susan K. Reed as editor-in-chief of the U.S. edition of The Oprah Magazine.*". The credibility scores are accordingly changed (or kept at) 0.5 for responses associated with the former claim, and 1.0 for those associated with the latter.

2. *Inter-dependent slot types*: Many slot types are inter-dependent, such as "*per:title*" and "*per:employee_of*", and various family slots. After determining initial credibility scores for each response, we check whether evidence exists for any implied claims. For example, given initial credibility scores of 1.0 for two responses supporting the claims that (1)"*David*" is "*per:children*" of "*Carolyn Goodman*" and (2)"*Andrew*" is "*per:sibling*" of "*David*", we check for any responses supporting the claim that (3)"*Andrew*" is "*per:children*" of "*Carolyn Goodman*", and set their credibility scores to 1.0. For example, a response supporting this claim included the evidence sentence, "*Dr. Carolyn Goodman, her husband, Robert, and their son, David, said goodbye to David's brother, Andrew.*".

5 Experimental Results

This section presents the experiment results and analysis of our approach.

5.1 Data

The data set we use is from the TAC-KBP2013 Slot Filling Validation (SFV) task, which consists of the merged responses returned by 52 runs (regarded as systems in MTM) from 18 teams submitted to the Slot

Methods	Precision	Recall	F-measure	Accuracy	Mean Average Precision
1.Random	28.64%	50.48%	36.54%	50.54%	34%
2.Voting	42.16%	70.18%	52.68%	62.54%	62%
3.Linguistic Indicators	50.24%	70.69%	58.73%	72.29%	60%
4.SVM (3 + System + Source)	56.59%	48.72%	52.36%	75.86%	56%
5.MTM (3 + System + Source)	53.94%	**72.11**%	**61.72**%	**81.57**%	**70**%

Table 2: Overall Performance Comparison.

Filling (SF) task. The source collection has 1,000,257 newswire documents, 999,999 web documents and 99,063 discussion forum posts, which results in 10 different sources (combinations of publication venues and genres) in our experiment. There are 100 queries: 50 person and 50 organization entities. After removing redundant responses within each single system run, we use 45,950 unique responses as the input to truth-finding. Linguistic Data Consortium (LDC) human annotators manually assessed all of these responses and produced 12,844 unique responses as ground truth. In order to compare with state-of-the-art supervised learning methods for SFV (Tamang and Ji, 2011; Li and Grishman, 2013), we trained a SVMs classifier [5] as a counterpart, incorporating the same set of linguistic indicators, sources and systems as features. We picked 10% (every 10th line) to compose the development set for MTM and the training set for the SVMs. The rest is used for blind test.

5.2 Overall Performance

Table 2 shows the overall performance of various truth finding methods on judging each response as true or false. MTM achieves promising results and even outperforms supervised learning approach. Table 3 presents some examples ranked at the top and the bottom based on the credibility scores produced by MTM.

We can see that majority voting across systems performs much better than random assessment, but its accuracy is still low. For example, the true claim *T5* was extracted by only one system because most systems mistakenly identified "*Briton Stuart Rose*" as a person name. In comparison, MTM obtained much better accuracy by also incorporating multiple dimensions of source and evidence information.

Method 3 using linguistic indicators alone, already achieved promising results. For example, many claims are judged as truths through trigger phrases (*T1* and *T5*), event extraction (*T2*), coreference (*T4*), and node type indicators (*T3*). On the other hand, many claims are correctly judged as false because their evidence sentences did not include the slot filler (*F1*, *F4*, *F5*) or valid knowledge paths to connect the query entity and the slot filler (*F2*, *F3*). The performance gain (2.99% F-score) from Method 3 to Method 5 shows the need for incorporating system and source dimensions. For example, most truths are from news while many false claims are from newsgroups and discussion forum posts (*F1*, *F2*, *F5*).

The SVMs model got very low recall because of the following two reasons: (1) It ignored the inter-dependency between multiple dimensions; (2) the negative instances are dominant in the training data, so the model is biased towards labeling responses as false.

5.3 Truth Finding Efficiency

Table 3 shows that some truths (*T1*) are produced from low-ranked systems whereas some false responses from high-ranked systems (*F1*, *F2*). Note that systems are ranked by their performance in KBP SF task. In order to find all the truths, human assessors need to go through all the responses returned by multiple systems. This process was proven very tedious and costly (Ji et al., 2010; Tamang and Ji, 2011).

Our MTM approach can expedite this process by ranking responses based on their credibility scores and asking human to assess the responses with high credibility first. Traditionally, when human assess responses, they follow an alphabetical order or system IDs in a "passive learning" style. This is set as our baseline. For comparison, we also present the results using only linguistic indicators, using voting in which the responses which get more votes across systems are assessed first, and the oracle method assessing all correct responses first. Table 2 shows our model can successfully rank trustworthy responses at high positions compared with other approaches.

[5] We used the LIBSVM toolkit (Chang and Lin, 2011) with Gaussian radial basis function kernel.

	Response Ranked by MTM							System Rank

Table 3: Top and Bottom Response Examples Ranked by MTM.

Fig. 3 summarizes the results from the above 6 approaches. The common end point of all curves represents the cost and benefit of assessing all system responses. We can see that the baseline is very inefficient at finding the truths. If we employ linguistic indicators, the process can be dramatically expedited. MTM provides further significant gains, with performance close to the Oracle. With only half the cost of the baseline, MTM can already find 90% truths.

5.4 Enhance Individual SF Systems

Finally, as a by-product, our MTM approach can also be exploited to validate the responses from each individual SF system based on their credibility scores. For fair comparison with the official KBP evaluation, we use the same ground-truth in KBP2013 and standard precision, recall and F-measure metrics as defined in (Ji et al., 2011). To increase the chance of including truths which may be particularly difficult for a system to find, LDC prepared a manual key which was assessed and included in the final ground truth. According to the SF evaluation setting, F-measure is computed based on the number of unique true claims. After removing redundancy across multiple systems, there are 1,468 unique true claims. The cutoff criteria for determining whether a response is true or not was optimized from the development set.

Fig. 4 presents the F-measure scores of the best run from each individual SF system. We can see that our MTM approach consistently improves the performance of almost all SF systems, in an absolute gain range of [-1.22%, 5.70%]. It promotes state-of-the-art SF performance from 33.51% to 35.70%. Our MTM approach provides more gains to SF systems which mainly rely on lexical or syntactic patterns than other systems using distant supervision or logic rules.

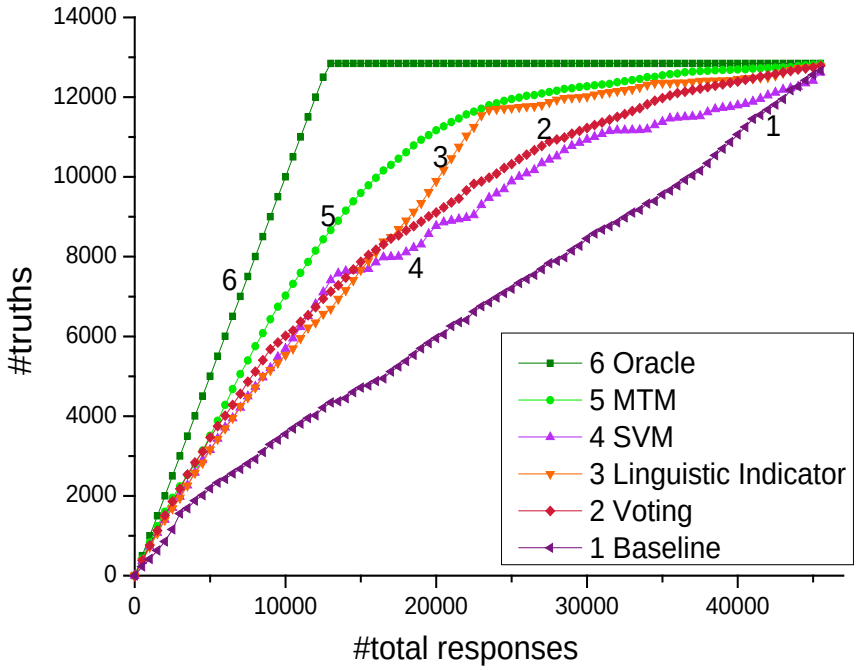

Figure 3: Truth Finding Efficiency.

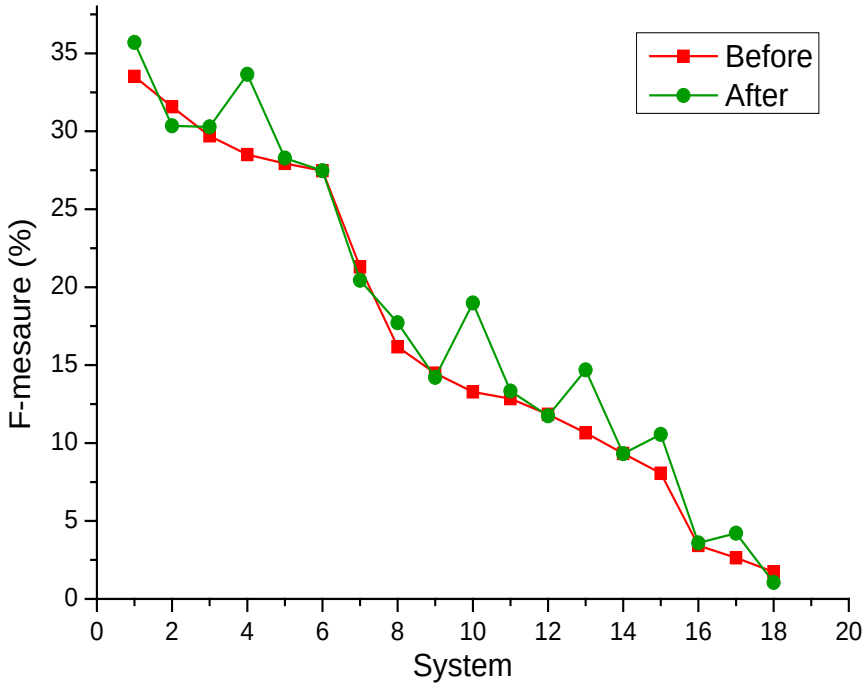

Figure 4: Impact on Individual SF Systems.

6 Conclusions and Future Work

Truth finding has received attention from both Natural Language Processing (NLP) and Data Mining communities. NLP work has mostly explored linguistic analysis of the content, while Data Mining work proposed advanced models in resolving conflict information from multiple sources. They have relative strengths and weaknesses. In this paper we leverage the strengths of these two distinct, but complementary research paradigms and propose a novel unsupervised multi-dimensional truth-finding framework incorporating signals both from multiple sources, multiple systems and multiple evidences based on knowledge graph construction with multi-layer linguistic analysis. Experiments on a challenging SFV task demonstrated that this framework can find high-quality truths efficiently. In the future we will focus on exploring more inter-dependencies among responses such as temporal and causal relations.

Abstract

Explicit continuous vector representation such as vector representation of words, phrases, etc. has been proven effective for various NLP tasks. This paper proposes a novel method of constructing such vector representation for both entity-pairs and relation expressions which link them in text. Based on the insight of the duality of relations, the representation is constructed by embedding of two separately constructed semantic spaces, one for entity-pairs and the other for relation expressions, into a common semantic space. By representing the two different types of objects (i.e. entity-pairs and relation expressions) in the same semantic space, we can treat the two tasks, relation mining and relation expression mining (a.k.a. pattern mining), systematically and in a unified manner. The approach is the first attempt to construct a continuous vector representation for expressions whose validity can be explicitly checked by their proximities to known sets of entity-pairs. We also experimentally validate the effectiveness of the common space for relation mining and relation expression mining.

1 Introduction

Learning continuous vector representation for expressions which consist of more than one word has gained attention in recent years. Various representations have been constructed and used to measure semantic similarities between expressions in various tasks, such as analogical reasoning (Turney et al., 2003; Mikolov et al., 2013) and sentiment analysis (Turney and Littman, 2003; Socher et al., 2012). Many algorithms have been proposed to construct such continuous representations, depending on specific tasks in mind. In this paper, we propose a method for constructing a vector representation for binary relations, i.e., relations with two arguments. We demonstrate the effectiveness of the representation for relation mining and relation expression mining.

The method exploits the duality of a relation (Bollegala et al., 2010). While Bollegala et al. (2010) uses the duality in their co-clustering algorithm, we construct an explicit semantic space which reflects the two aspects of a given relation. We first construct two separate semantic spaces, one for pairs of named entities and another for relation expressions in text which link an entity-pair. A relation is supposed to correspond to a subset in each of these two spaces. The subset of entity-pairs is a set of pairs between which the relation holds. The subset is called the extension set of the relation. The subset of relation expressions consists a set of expressions which are used to link entity-pairs in the extension set.

The two semantic spaces are then embedded into a single common space. Figure 1 illustrates a brief summary of constructing a common semantic space. While the subsets which correspond to a specific relation are supposed to constitute natural clusters in the two original spaces, objects in the two spaces exchange useful information to each other and form a tighter cluster in the common space. Exchange of information takes place through common space embedding.

Since both entity-pairs and relation expressions have their vector representations in the common semantic space, one can easily enumerate relation expressions specific to a certain set of entity-pairs (re-

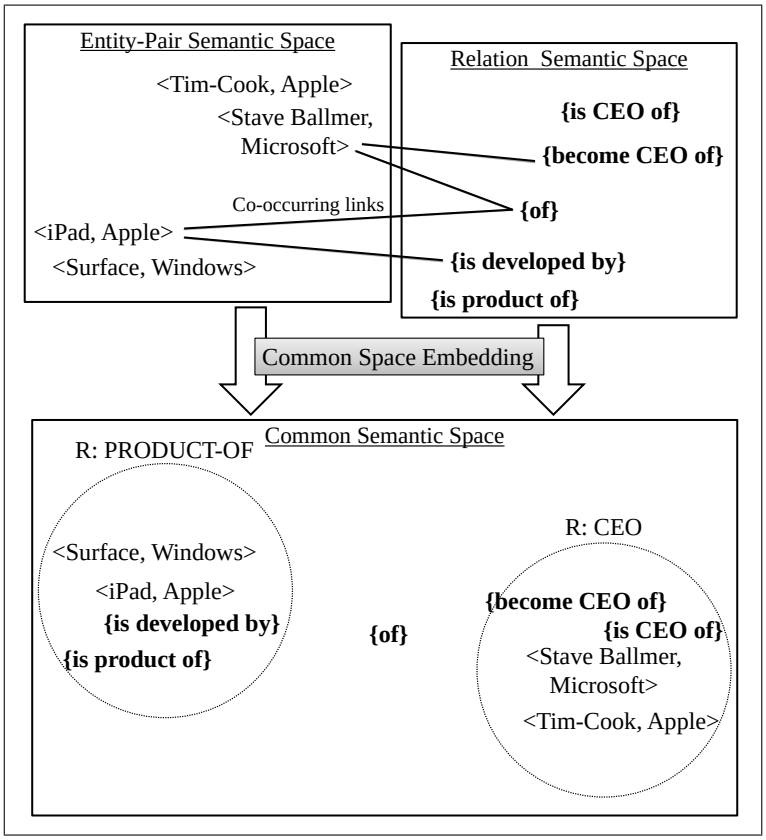

Figure 1: Overview of our framework to construct common semantic space.

lation expression mining). Furthermore, unlike the conventional pattern-based relation mining, one can perform relation mining in the common space without explicit reference to relation expressions.

2 Basic Framework

2.1 Duality of Relation and a Common Space

A binary relation is defined either extensionally by a set of pairs in the relation or intensionally by a set of conditions which a pair in the relation should satisfy. However, in actual applications of text mining, either of these definitions is given in a complete form. We are only given a subset of the whole set of pairs and have to complete the set (i.e. relation mining). Instead of an explicit intensional definition, we only have a set of observations in text where pairs in a relation are linked by certain linguistic expressions. Based on such observations, we have to judge whether a given pair holds the relation or not. Though some observed expressions are non-ambiguous and explicit for a relation (for example, "the birth place of A is B"), most of expressions are not (such as"A comes from B").

We call a set of pairs which define a relation as Extension set of a relation, while we call their observed expressions in text as Manifestation set. While these two sets are only partially given, they define relations which we are interested in. Such duality of a relation has been recognized by many previous work and has been exploited in relation mining and relation expression mining. (Bollegala et al., 2010), for example, used the duality in their work on co-clustering of entity-pairs and relation expressions. (Baroni and Lenci, 2010) presented a more general approach which defines a tensor associating a triplet $< e_1, l, e_2 >$ with a weight. e_1 and e_2 are entity pairs, while l is a linking expression in text. By projecting the tensor to matrices, they showed that diverse concepts used in distributional semantics could be captured in a unified manner. In particular, their tensors capture directly the duality of entity pairs and their linking expressions (i.e. relation expressions).

These previous works implicitly assume that the semantic space of entity pairs and that of relation ex-

pressions are tightly coupled. That is, the space of entity pairs is defined in terms of their co-occurrences with linking expressions (or the weights in a tensor between them) and vice versa. However, such tight coupling between the semantic spaces of entity pairs and relation expressions is not a logical necessity, and harmful in the sense that it restricts available information only to their co-occurrences.

An entity pair and a linking expression are complex objects by themselves, and their semantic spaces can be defined independently of each other. Two entities in a sentence, for example, are linked not only by single verbs or predicates but by a long sequence of words. This means that we can define a semantic space of linking expressions independently of entity pairs which they link. For example, one can use sequence similarities of words among relation expressions. Since knowledge resources of large scale have become available of late, we can define a semantic space of entity pairs by using paths in these knowledge graphs, regardless of their textual occurrences with relation expressions.

In this paper, we first define two separate semantic spaces (i.e. dual primal spaces) for entity pairs and relation expressions, and then use their textual co-occurrences to construct a common space consistent with the two primal spaces. In this approach, the co-occurrences of entity pairs with relation expressions play only an auxiliary role to project the two spaces into a common space.

The approach allows us to integrate information richer than mere co-occurrences of two objects (i.e. entity pairs and relation expressions). Furthermore, the common space provides us with direct means by which one can grasp finer grained relationships between two objects. Given a set of seed pairs of entities, one can gather a set of relation expressions in their nearest neighbor in the common space. Another set of seed pairs, even though conceptually they belong to the same relation, one may get a different set of relation expressions. The previous approaches, in which the semantics of the two objects are captured in two separate spaces, can capture only indirectly the hierarchical nature of natural relations, and how such a hierarchy is mapped on association of extension sets with manifestation sets.

2.2 Extension set and Manifestation Set

Let E be a set of named entities. Let $\langle e_i, e_j \rangle$ denote a pair of entities ($e_i, e_j \in E$) and E^2 a set of all entity-pairs. Then, a relation, R, is extensionally defined as a set of entity-pairs $E_R \subset E^2$, such as CEO = { $\langle$Tim-Cook, Apple$\rangle$, $\langle$Ballmer, Microsoft$\rangle$, ...}, COMPETE = {$\langle$Apple, Samsung$\rangle$, $\langle$Google, Microsoft$\rangle$, ...} between which the relation holds. We call such a set of entity-pairs the extension set of a relation R.

On the other hand, a relation R is manifested in text in various forms of expressions. For example, "is the CEO of" in "Tim-Cook is the CEO of Apple" is a direct manifestation of the relation CEO. While "overtook" in "Samsung overtook Apple in the smartphone market in China" can be a manifestation of the relation COMPETE, this manifestation is rather indirect, based on inference. We denote a relation expression by r_i and the whole set of relation expressions by D. We call a subset of relation expressions which manifest, directly or indirectly, a relation R, as the manifestation set of R.

2.3 Primal-dual semantic spaces

A relation, R, is characterized by the two sets, the extension set and the manifestation set. In other words, the two sets are implicitly associated with each other via the relation R. This association between the two sets constitutes the foundation of the common semantic space to be constructed in this paper.

We first construct primal-dual semantic spaces, one for entity-pairs and another for relation expressions. A sentence where two entities appear can be seen from two different perspectives. One view is to see the sentence as characterization of the entity-pair, while the other takes the sentence as characterization of the relation expression which links the two entities. Based on these two views, we construct two semantic spaces from a given set of sentences (corpus). One space is for a set of entity-pairs (E^2) and the other for a set of relation expressions (D). $e^2 \in E^2$ and $r \in D$ are represented by vectors $\mathbf{e}^2 \in \mathbf{E}^2$ and $\mathbf{r} \in \mathbf{D}$ in the corresponding spaces. We assume that the two spaces are vector spaces, i.e., $\mathbf{E}^2$ and $\mathbf{D}$ are an n-dimensional vector space and an m-dimensional one, respectively.

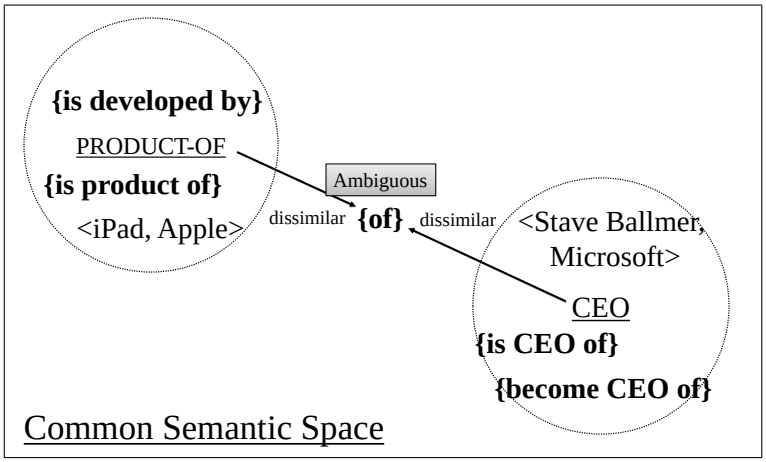

Figure 2: Illustration of common semantic space defined by our approach.

2.4 Triplets

The two objects, entity-pairs and relation expressions, whose spaces are separate, are linked through their co-occurrences in text. Co-occurrence of a relation expression (r) and an entity-pair ($e^2 = \langle e_1^2, e_2^2 \rangle$) means that r links in a sentence the entities of e_1^2 and e_2^2. A triplet represents such a co-occurrence with its frequency ($f \in \mathcal{R}$) in text. An instance of triplets is denoted as $\langle \mathbf{e}^2, \mathbf{r}, f \rangle \in T$. T indicates a set of triplets. These co-occurrence frequencies between entity-pairs and relation expressions play a critical role in common space embedding as linkage clues.

2.5 Common space embedding from $\mathbf{E}^2$ and $\mathbf{D}$

We use Multi-View Partial Least Squares (MVPLS) (Wu et al., 2013) as the basic framework to construct a common space from $\mathbf{E}^2 \subset \mathcal{R}^m$ and $\mathbf{D} \subset \mathcal{R}^n$. MVPLS was originally developed for web search and has been proven to be effective for embedding the semantic space of queries and that of documents into a common space. This framework is an extension of the conventional well-used approach, Partial Least Square. The framework is general enough to be used for our purpose.

Let k be the dimension of common latent space such that $k \leq m$ and $k \leq n$. $\mathbf{e}_i^2 \in \mathbf{E}^2$ is a i-th entity-pair feature vector in the entity-pair space and $\mathbf{r}_i \in \mathbf{D}$ is a i-th phrase feature vector. $\mathbf{L}_e$, $\mathbf{L}_r$ are linear projection matrices for embedding the original feature vector space into the common latent space. $\mathbf{L}_e$ is $m \times k$ and $\mathbf{L}_r$ is $n \times k$ size matrices.

MVPLS learns these two projection matrices for generating a well-constructed common space from the two separated spaces. Construction of latent common space can be formulated as an optimization problem which maximizes the sum of the similarities between entity-pairs and relation expressions in the common space when they co-occur. This optimization problem is as follows:

$$\underset{\mathbf{L}_e, \mathbf{L}_r}{\operatorname{argmax}} \sum_{(\mathbf{e}_i^2, \mathbf{r}_i, f_i) \in T} \log(f_i) \mathbf{r}_i^T \mathbf{L}_r \mathbf{L}_e^T \mathbf{e}_i^2 \quad s.t. \quad \mathbf{L}_e^T \mathbf{L}_e = \mathbf{I}, \quad \mathbf{L}_r^T \mathbf{L}_r = \mathbf{I} \,. \tag{1}$$

Note that the similarity score is weighted by the logarithmic scale of the co-occurrence counts. The outputs of this optimization problem are $\mathbf{L}_e$ and $\mathbf{L}_r$ which maximize the objective value where the orthogonal constraints on these matrices are satisfied. We do not necessarily solve (1) again when the system receives a new instance because the derived matrices can be applied not only for the existing entity-pairs and relation expressions but new ones. The problem is not convex, but Wu et al. (2013) proved that the global optimal solution can be obtained by SVD of $\sum_T \log(f_i) \mathbf{e}_i^2 \mathbf{r}_i^T$. $\mathbf{L}_e$ corresponds to left singular vectors and $\mathbf{L}_r$ consists of right singular vectors.

2.6 Ambiguity of Relation Expressions in the Common Space

Due to the ambiguity of relation expressions, the assumption that the manifestation set of the same R cluster around in proximity does not hold in reality. "of" in "Steve Ballmer of Microsoft" belongs to

the manifestation set of CEO, while "of" in "iPad of Apple" belongs to the set of a different relation, PRODUCT-OF. Indirect manifestation such as "overtake" is another cause of ambiguity. Inference involved here is abductive in nature and not always valid. We may be able to infer COMPETE relation from "X overtake Y", but "X overtake Y" can be a consequence of another relation such as COOPERATE.

Such an ambiguous expression belongs to the manifestation sets of more than one relation and thus would be located in a rather neutral position in the space. Since the common space reflects how frequently certain expressions are used to link entity-pairs, their positions in the space reflect the relative specificity to each relation cluster. Figure 2 illustrates how the ambiguity of a relation expression captured in the common space.

3 Relation Mining and Relation Expression Mining

In an actual situation, both the extension set and the manifestation set of a relation R are only partially known. To produce more comprehensive sets of these objects from large corpora is generally called mining. Two mining tasks have been studied so far, which are different, though mutually related.

We define relation mining as a task which, given a relation R, enumerates entity-pairs in the extension set. Another mining task (i.e. relation expression mining which is often performed as an auxiliary task of relation mining) is to gather a set of relation expressions which are manifestations of a given R.

3.1 Relation Mining

Relation mining is the task to enumerate entity-pairs of a relation R from a small given set of objects of a relation R. For example, if a set of relation expressions as the manifestation set of a relation R are given, one can produce a set of entity-pairs simply by identifying occurrences of relation expressions in text and producing the entity-pairs which are linked by them. Alternatively, if a small set of entity-pairs as a subset of the extension set of a relation R are given, one can produce a set of entity-pairs simply by gathering similar entity-pairs measured by relation expression co-occurrence vectors. These ideas have been shared by many mining systems called pattern-based relation mining systems.

The recall and precision of such a system are determined by the quality and quantity of the given set. If the given set is small, a system suffers low recall. On the other hand, if the set is large but contains many 'ambiguous' or 'weak' objects, a system suffers low precision.

Therefore, one of the keys for success of relation mining is how to gather a large initial set, which are effective, i.e. objects less ambiguous with high frequency. The common semantic space can be used not only to generate a comprehensive set but to measure the specificity of objects in terms of a given R, it also provides refined semantic measures between entity-pairs.

3.2 Relation Expression Mining

We have discussed semantic spaces of relation expressions and the common semantic space as if to define what constitutes a relation expression is straightforward. However, it is not trivial to define what constitutes a relation expression.

In the previous section, we treat "overtake" in "Apple overtook Samsung in the smart phone market" as a relation expression which manifests the relation "COMPETE". However, one may argue that a pattern such as "X overtake Y in ... market" should be treated as a basic unit of manifestation of the relation COMPETE. This longer expression is less ambiguous and thus more effective than the shorter pattern of "overtake". On the other hand, the frequency of this pattern would be much less and thus less effective, compared with the shorter version. Mining of effective relation expressions (sometimes called "pattern mining") has to address the problem of balancing the specificity and generality of relation expressions. Furthermore, one would like to identify the same relation expression in "Apple announced yesterday that it had overtaken Samsung which ..." as in "Apple overtook Samsung in the smart phone market".

In the experiments, we do not treat the process of pattern mining seriously. Instead, we used two conventional methods. The first method is to enumerate subsequences of words in the intervening part in a sentence between two entities, and use them as relation expressions. We expect less effective expressions as manifestation to be recognized in the common space. Another method is to use the shortest paths in

dependency structures of sentences as relation expressions. Shortest paths can generalize surface variants of essentially the same relation expressions and reduce unnecessary proliferation of relation expressions.

4 Experiments

This section empirically evaluates our approach of embedding the two original spaces into a common space. We show that the common space provides a continuous vector space for relation expressions, in which not only similarities among expressions but also their ambiguities are properly captured.

4.1 Experiment Settings

4.1.1 Dataset

We use the ENT benchmark dataset (Bollegala et al., 2009) for our experiments. The dataset consists of 661,502 snippets, which are brief summaries provided by Web search engines. Most web search engines provide links to webpages and snippets as search results and snippets contains a subset of texts including the query words derived from the webpages. Table 1 shows how many distinct entity pairs, relation expressions and triplets were extracted as results of NER and expression extraction (See Section 4.1.2 and 4.1.3). The dataset is accompanied with 100 entity-pairs that are classified into five semantic categories: ACQUISITION, HEADQUARTERS, FIELD, CEO, and BIRTHPLACE. We use the ENT dataset not only for evaluation of relation mining but also for examining the characteristics of the common space for relation expression mining. Note that, due to the nature of snippets, the dataset is very noisy. It contains many non-sentences and even non-English texts, which may adversely affect the performance of mining systems.

	Entity-pair	Relation	Triplet
Enumeration	12,174	12,185	521,454
Shortest Path	10,251	92,797	130,897

Table 1: The specifications of the ENT dataset: Sizes of distinct entity-pairs, relation expressions, and triplets. "Enumeration" indicates the results of pattern mining based on word subsequences. "Shortest Path" shows that of shortest path extraction.

4.1.2 Entity and Entity-Pair Extraction

We first extracted entities from the ENT dataset. After splitting snippets into sentences, we applied named entity recognizer (NER) (Finkel et al., 2005) to recognize entities in sentences. We used Stanford Core NLP tools 2[1] for sentence splitting and NER. As relevant semantic classes for the ENT dataset, entities which are recognized as ORGANIZATION, LOCATION, or PERSON are treated as entities in the further process. We only used sentences in which at least two entities of these three classes appear.

4.1.3 Extraction of Relation Expressions

The definition of relation expressions which link two entities in text is not trivial. We adopt two methods of extracting candidates of relation expressions, and compare them in experiments.

The first method is to use, as relation expressions, subsequences of words which appear between two entities. We assume that two entities which appear apart in a sentence by more than 10 words are not explicitly linked in the sentence. From the word sequence whose length is less than 10, we enumerate all possible subsequences whose length is less than 6 words. Since a set of such subsequences include many noises as relation expressions, we use only subsequences the frequency of which is higher than 100.

This shallow approach can be run very fast, thanks to the advances of sequential pattern mining (Pei et al., 2004). Although the method is similar to that used in Bollegala et al. (2010) , we do not use any further constraints based on part-of-speech tags, lexical-syntactic information, etc. Our contention is that such ad-hoc constraints unnecessarily restrict a set of relation expressions. Our method treats ambiguous expressions (e.g. "of", "in", "with", etc.) as relation expressions. Instead, the effectiveness or the degree of ambiguities of a relation expression is captured in the common space after embedding.

[1] http://nlp.stanford.edu/software/corenlp.shtml

The second method is based on dependency parsing. We obtain the dependency tree of a sentence by a publicly available deep parser, Enju3[2] (Miyao and Tsujii, 2005; Miyao and Tsujii, 2008), and then extract shortest paths between two entities. Unlike the first method, this method uses linguistic information to extract the skeleton of a relation expression.

Each node in shortest paths consists of a base form (e.g., "like", "player"), syntactic category (e.g., "verb", "noun"), and predicate-argument links. The length of shortest paths was restricted to the range from 1 to 6. Compared with the first method, a set of shortest paths contains much less noises, so that we do not filter out those with low frequency. In the same way as the first method, a set of shortest paths contains highly ambiguous paths (e.g. the path of "of").

4.1.4 Generation of the Space for Entity-Pairs

The primal semantic space for entity pairs can be constructed in several ways. The co-training method constructed a space of entity pairs based on their co-occurrences with relation expressions. Their method requires the two spaces of entity pairs and relation expressions have to be tightly coupled.

On the other hand, our approach allows us to design the two spaces independently. In addition to the tightly coupled spaces, we design a new space for entity pairs based on the distributional hypothesis (Harris, 1954). We used the point-wise mutual information (PMI) score of each word with an entity-pair. PMI score is defined as $\mathrm{PMI} = \log_e p(w_a|\langle e_i, e_j\rangle)/p(w_a)$ where $p(w_a)$ is an occurrence probability of a word w_a and $p(w_a|\langle e_i, e_j\rangle)$ is a conditional probability with respect to an entity-pair $\langle e_i, e_j\rangle$. We filtered words whose PMI scores were below 1.0 and all the rest were used as the features.

To maximize the effectiveness of the space, we performed preliminary experiments by changing parameters in the definition of context in the distributional hypothesis, such as how the context around entities is distinguished, whether the whole of a sentence or limited windows around entities are used as context, etc. As a result, we chose the settings in which right, left, and intervening contexts are distinguished. We used three different window sizes as the context (e.g. 4, 5 and 6 words). That is, when we set the window size to 4, we used the four words in the left side of the first entity as the left context, those in the right side of the second entity as the right context, and the words in the intervening part as the intervening context. If the intervening part consists of more than 8 words, the four words in the neighborhood of the two entities are used as the intervening context.

4.1.5 Generation of the Space for Relation Expressions

Following the work (Lin and Pantel, 2001), we constructed a simple space, in which a relation expression is characterized by the entities which it links. We counted the entities in the left-hand side and the right hand side of a relation expression. The same as the vector of an entity-pair, we used the PMI score as the feature value. As for feature selection, we chose the entities whose PMI scores are no less than 1.0[3].

4.1.6 Dimension Reduction

After generating vectors for entity-pairs and relation expressions, we applied a dimension reduction. Since both of the primary semantic spaces use surface words or entities, their vectors tend to have a very large dimension (i.e. about $100,000$ for entity pairs and about $2,500$ for relation expressions). Since the cardinalities of the two sets of distinct entity pairs and relations expressions are also very high (See Table 1 of the specification of the ENT dataset), the high dimensions of the two spaces would make the computation cost of MVPLS embedding in terms of time and space prohibitively high.

To take advantage of the sparseness of both spaces, we used Randomized SVD (Halko et al., 2011) which can produce low-dimensional feature vectors from a large-scale sparse feature matrix efficiently. We produced spaces with $3,000$-dimensions for entity-pairs and $1,000$ for relation expressions.

4.1.7 Common Space Embedding

Lastly, we applied MVPLS (1) to construct common space projection matrices. We set the dimension of common space as $1,000$. We verified that the dimension does not affect much the evaluation results,

[2] `http://www.nactem.ac.uk/enju/`

[3] Other than context-based characterization methods, we have applied path kernel method (Reichartz et al., 2009; Reichartz et al., 2010) to shortest path relations as preliminary works, however, their performances were definitely worse.

Window Size	4	5	6

Embedded $(1,000)$	**0.90**	**0.89**	**0.90**

Table 2: Entity-Pair space evaluation results (Enumeration) : Each figure shows the average precision. The best figures in each window size are written in **bold**. Figures in parentheses denote the number of dimensions.

Window Size	4	5	6
VSM (Turney, 2005)		0.68	
LRA (Turney, 2005)		0.68	
(Bollegala et al., 2010)		0.76	
Relation $(1,000)$		0.62	
Original $(1,000)$	**0.91**	0.90	**0.91**
Embedded $(1,000)$	**0.91**	**0.91**	**0.91**

Table 3: Entity-Pair space evaluation results (Shortest Path). Each figure shows the average precision. The best figures in each window size are written in **bold**. Figures in parentheses denote the number of dimensions.

when we set it to larger than 300. So we used a common space with $1,000$ dimensions for the sake of comparison with the original spaces.

4.2 Relation Mining Evaluation

We evaluated the embedding approach by a quantitative analysis on the relation mining task used in (Bollegala et al., 2010). The experimental setting is the same as the previous work. The objective is to assess whether the derived common semantic space provides a good space for measuring semantic distances among entity-pairs. We expected that in a good semantic space, entity-pairs which belong to the same semantic category would be clustered in proximity.

We used the ENT dataset (Bollegala et al., 2009). We used the same evaluation measures used in (Bollegala et al., 2010). The measure assumes that a semantic space would be judged as appropriate if it assigned higher similarity scores to entity-pairs the relationships of which belong to the same category. Therefore, the measure evaluated the top 10 similar pairs to each entity-pair and calculated average precision defined as $\sum_{t=1}^{10} \mathrm{Rel}(t) \cdot \mathrm{Pre}(t)/10$. Here, $\mathrm{Rel}(t)$ is a binary valued function that returns 1 if the entity-pair at rank t and $\langle e_i, e_j \rangle$ have the same semantic category. $\mathrm{Pre}(t)$ is the precision at rank t, which is defined by the percentage of correct objects in top t pairs.

For the sake of comparison, we prepared several models, which used different semantic spaces for entity pairs. One space (called Relation) is to characterize an entity pair by the relation expressions which it co-occur. Another space (called Original) is to characterize an entity pair by the context vector discussed in Section 4.1.4. There are three Original spaces which use different window sizes (4, 5 and 6 words). Then, the final space is the common space obtained by embedding (called Embedded).

Table 2 and 3 correspond to the experiment results using the two definitions of relation expressions, one by enumerated word sequences and the other by shortest paths. We note that the previous works only use co-occurrences information and cannot use any context information. The previous work and Relation have no ways of changing the size of windows. Therefore, these results are independent of the window size. These tables show the limitation of co-training which can only use tightly coupled vector spaces for entity pairs and relation expressions. Both the original and the common embedded space outperform significantly the performance obtained by previous works, regardless of the definitions of relation expressions (i.e. enumerated subsequence and shortest paths). Since the space for relation expressions is simple and poor, we expected that it would hardly add extra information to the space of entity pairs. However, the common space embedded from the two spaces improve the performance.

4.3 Relation Expression Mining

While the primary space for relation expressions is rather poor, vector representations of relation expressions are much richer in the common space. This is because they receive extra information from the rich space of entity-pairs through their co-occurrences. For evaluation, we first chose representative relation expressions, and then gathered relations that are close to them in the primary space of relation

{announce acquisition}		{president ,}	
Embedded	Original	Embedded	Original
{announce that have acquire}	{announce that have acquire}	{chairman ,}	{'s president be}
{complete acquisition}	{acquire}	{, ceo &}	{would say}
{say have it buy}	{pay}	{'s president ,}	{would that say}
{acquire}	{buy}	{ceo &}	{'s blue and}
{pay}	{compra}	{chief ,}	{'s chairman ,}
{'s acquisition}	{buy company}	{, ceo)}	{chairman ,}
{'s out_of}	{say that it buy}	{chief ,}	{palmisano}
{'s purchase}	{nor}	{would that say}	{,}
{acquisition}	{do}	{executive ,}	{, reader ,}
{'s takeover}	{announce be buy}	{ceo become}	{palmisano include door '}

Table 4: Evaluation of similarity measure between relation expressions. This table shows the top-10 ranked relation expressions that are closest to two representative relation expressions.

expressions and in the common space. If our expectation was correct, the list of expressions close to the chosen expression in the common space should be more appropriate than that in the primary space.

We show the result of the experiment in which we use shortest paths as relation expressions. We used the same dataset as the previous experiment. We removed shortest paths with frequency less than 10. As for the primary space for entity pairs, we use the one with the window size of 5. We used {announce acquisition} and {president ,} as two representatives.

Table 4 shows the lists of relation expressions closest to the chosen representatives in the common space and the primary space. For the ease of interpretation, we do not show syntactic categories and predicates attached to the shortest paths. One can easily see that the common space successfully moved down many ambiguous expressions such as {compra} and {nor} in {announce acquisition}, and {would say} and{,} in {president ,}. On the other hand, some relation expressions which are specific and semantically similar to the chosen ones moved up in the rank, for example {'s purchase} and {chief ,}.

We have also conducted the same experiment for relation expressions produced by the enumeration method. While the enumeration method improves the relation mining which gathering similar entity-pairs, it gave much poorer results to expressing mining than the shortest paths. This is because the enumeration method generated a large amount of non-meaningful relation expressions. For example, to generate a complex relation expression such as {say have it buy} appeared in Table 4, the enumeration method has to generate a large variety of noisy ones that co-occur with a complex relation expression.

4.4 Similarity measure between entity-pair and relation expressions
