COLING 2014

The 25th International Conference on Computational Linguistics

Proceedings of COLING 2014: Technical Papers

August 23-29, 2014
Dublin, Ireland

ISBN 978-1-941643-26-6

Preface

This volume contains papers from the 25th International Conference on Computational Linguistics (Coling 2014) held in Dublin, Ireland. The conference is organized by the Centre for Global Intelligent Content (CNGL) and held at the Helix Conference Centre at Dublin City University (DCU) from 25–29 August 2014, under the auspices of the International Committee on Computational Linguistics (ICCL).

COLING is almost 50 years old, its first gathering having taken place in New York in 1965. It has been organized once every two years, initially in odd years and then in even years, after COLING 1976 in Ottawa. Throughout its long history, COLING's aspiration to provide an amicable forum for participants with broad backgrounds to present and share their ideas remains the same. We believe that the inherent complexity of language is worthy of study from diverse perspectives and that COLING provides a venue for fruitful interdisciplinary interaction.

We accepted 217 papers (138 oral presentations and 79 poster presentations) from 685 effective submissions, having received 705 submissions in total. Regardless of the format of presentation, all of the accepted papers were allocated 12 pages in the proceedings.

The review process of a large conference such as COLING is always complex and occasionally encounters difficulties. The program committee has to cope with the challenges of selecting which papers to accept among a large quantity of high quality submissions. The task of choosing 217 papers from 685 strong submissions covering the ever broadening fields of computational linguistics was not an easy one.

To cope with the anticipated difficulties, we asked six senior colleagues to join the Scientific Advisory Board (SAB) and help us through all stages of reviewing papers. They are: Ralph Grishman (New York University, USA), Yuji Matsumoto (NAIST, Japan), Joakim Nivre (Uppsala Univ., Sweden), Michael Picheny (IBM TJ Watson Research Center, USA), Donia Scott (Univ. of Sussex, UK), and Chengqing Zong (CAS, China).

We had 20 thematic areas and each area was chaired by two or more area chairs. Thanks to over 800 responsive reviewers, the review process proceeded in a very smooth manner, and each paper was read at least by three reviewers. In some cases, papers and their reviews were carefully assessed by Area Co-Chairs, one of the SAB members and by us, in our roles as Program Committee Co-Chairs. We are extremely happy with the very strong set of papers that has been accepted for presentation at the conference. It is, however, with regret that we had no choice but to reject a large number of high quality papers, due to the sheer volume of submissions received.

We would like to thank the SAB members and the Program Committee Area Chairs for their dedicated and efficient review work, and our reviewers for their professionalism in delivering high quality reviews. We also thank the authors of all the papers for submitting their fruits of labour to COLING. Although we were only able to accept a small subset of the submitted papers, we do hope that all authors and reviewers have benefited from this process of indirect dialogue.

Last but not least, we would like to thank the people who made COLING 2014 and this volume possible. We thank General Chairs, Josef van Genabith (Universität des Saarlandes/DFKI) and Andy Way (CNGL, DCU), and the chairs of the Local Organizing Committee, Cara Green (CNGL, DCU) and John Judge (CNGL/NCLT, DCU), for their tireless work. We are especially grateful to the Publications Chairs, Joachim Wagner (CNGL, DCU), Liadh Kelly (CNGL, DCU) and Lorraine Goeuriot (CNGL, DCU), for their hard work in preparing the proceedings.

Prof. Jan Hajic (Charles University, Czech Republic)
Prof. Junichi Tsujii (Microsoft Research, China)
COLING 2014 Program Committee Co-Chairs
July 8, 2014

Welcome from the General Chairs

We are very pleased indeed to welcome you all to COLING 2014, the 25th International Conference on Computational Linguistics. We are particularly proud that the ICCL selected Dublin City University (DCU) as the location of COLING 2014.

DCU and its National Centre for Language Technology (NCLT) have a long track record in NLP. Unlike India, the previous COLING host country, Ireland is a very small country. A unique feature of the Irish University landscape is that universities team up with industry partners and each other to pool expertise to form large research centres. DCU is a founding member of CNGL, the Centre for Gobal Intelligent Content. COLING 2014 is organised by DCU in partnership with the CNGL, and as General Chairs we are proud to represent both DCU and CNGL.

The conference is taking place at the Helix Conference Centre, a stunning building added to the DCU campus in 2002. DCU is a young, dynamic and ambitious university; since admitting its first students in 1980, DCU has grown in both student numbers and size and now occupies a 72-acre site in Glasnevin, just to the north of Dublin city centre. To date almost 50,000 students have graduated from DCU and are now playing significant roles in enterprise and business globally. Today in 2014, DCU delivers more than 200 programmes to over 12,000 students across its four faculties — Humanities and Social Sciences, Science and Health, Engineering and Computing and DCU Business School. DCU's excellence is recognised internationally and it is ranked among the top-50 young Universities worldwide (QS 'Top 50 under 50' 2013). In the last eight years, DCU has twice been named Sunday Times 'University of the Year'.

At the time of writing, the total number of people registered to attend COLING has exceeded 675. With delegates from 58 countries, COLING 2014 will witness a colourful diversity of language and culture, which is appropriate given that Dublin is known as the localisation capital of the world. Some evidence for this comes from our sponsors, to whom we are extremely grateful: Baidu, eBay, Microsoft, Symantec and Google.

We are very pleased with the programme that has been assembled for you, comprising of four days for the main conference with a total of 138 oral presentations, 79 posters and a special track with 28 demo presentations, two days of workshops and tutorials before the main conference, and other satellite workshops immediately after. 18 topical workshops with a sharp focus on issues of key interest today will be attended by about 191 delegates, and the 6 high-quality tutorials are sure to attract large crowds. Social events include a welcome reception on the evening of 24th August, the conference banquet in the Guinness Storehouse on 26th, and excursions to some beautiful places of interest on 27th.

When DCU was awarded COLING two years ago, our own personal situations were quite different. One of us was away working in the translation industry in the UK, while the other was leading the Science Foundation Ireland and Industry-funded CNGL research center. Over the past few months, we have changed countries, and jobs: Andy is back as Deputy Director of the CNGL's Centre for Intelligent Content, while Josef has moved to Saarbrücken to take up a Chair and a Scientific Directorship at DFKI.

While these changes were taking place, we both had the backing of a remarkable team. The organization of an event on the scale of COLING takes enormous energy, planning and commitment from a large number of individuals. We have assembled a large, competent team of volunteers who are available to assist you while you are here in Dublin. We are sure that all of you participating at COLING — at tutorials, workshops, or the main conference — will enjoy the time you spend here in Ireland, and will look back on the event as one of the most memorable that you attend. Finally, thanks to all of you for coming. We hope you all enjoy the conference, that you benefit from the excellent programme that has been assembled, and that you go away from here having made new friends.

Prof. Josef Van Genabith (Universität des Saarlandes/DFKI, Germany)
Prof. Andy Way (CNGL, DCU, Ireland)

Organisers

General Chairs

Prof. Andy Way, CNGL, Dublin City University, Ireland

Prof. Josef van Genabith, Universität des Saarlandes/DFKI, Germany

Programme Chairs

Prof. Junichi Tsujii, Microsoft Research, China

Prof. Jan Hajic, Charles University, Czech Republic

Workshops Chairs

Dr. Jennifer Foster, CNGL, Dublin City University, Ireland

Prof. Dan Gildea, University of Rochester, USA

Prof. Tim Baldwin, University of Melbourne, Australia

Publication Chairs

Dr. Joachim Wagner, CNGL, Dublin City University, Ireland

Dr. Liadh Kelly, CNGL, Dublin City University, Ireland

Dr. Lorraine Goeuriot, CNGL, Dublin City University, Ireland

Publicity Chairs

Dr. Dorothy Kenny, SALIS, Dublin City University, Ireland

Prof. Seong-Bae Park, Kyungpook National University, Korea

Local Chairs

Dr. Cara Greene, CNGL, Dublin City University, Ireland

Dr. John Judge, CNGL / NCLT, Dublin City University, Ireland

Scientific Advisory Board

Prof. Joakim Nivre, Uppsala Univ., Sweden

Prof. Yuji Matsumoto, NAIST, Japan

Dr. Michael Picheny, IBM TJ Watson Research Center, USA

Prof. Donia Scott, Univ. of Sussex, UK

Prof. Chengqing Zong, CAS, China

Prof. Ralph Grishman, New York University, USA

Tutorial Chairs

Prof. Qun Liu, CNGL, Dublin City University, Ireland

Prof. Fei Xia, University of Washington, USA

Demo Chairs

Dr. Lamia Tounsi, CNGL, Dublin City University, Ireland

Dr. Rafal Rak, NaCTeM, University of Manchester, UK

Sponsorship Chairs

Dr. Páraic Sheridan, CNGL, Dublin City University, Ireland

Prof. Hans Uszkoreit, DFKI, Germany

Dr. Huaping Zhang, Beijing Institute of Technology, China

Dr. Hiromi Nakaiwa, NTT, Japan

Programme Committee

Programme Chairs

Junichi Tsujii, Microsoft Research, China
Jan Hajic, Charles University, Czech Republic

Linguistic Issues in CL and NLP

Emily M. Bender, University of Washington, USA
Eva Hajicova, Charles University, Czech Republic
Igor Boguslavsky, Universidad Politecnica de Madrid, Spain

Machine Learning for CL and NLP

Jason Eisner, Johns Hopkins University, USA
Yoshimasa Tsuruoka, University of Tokyo, Japan

Cognitive Issues in CL and NLP

Philippe Blache, CNRS & Université d'Aix-Marseille, France
Ted Gibson, MIT, USA

Morphology, Word Segmentation, Tagging and Chunking

Reut Tsarfaty, Weizmann Institute of Science, Israel
Yue Zhang, Singapore University of Technology and Design, Singapore

Syntax, Grammar Induction, Syntactic and Semantic Parsing

Laura Kallmeyer, Heinrich-Heine-Universität, Germany
Ryan McDonald, Google, USA

Lexical Semantics and Ontologies

Chu-Ren Huang, Hong Kong Polytechnic University, Hong Kong
Alessandro Oltramari, Carnegie Mellon University, USA

Semantic Processing, Distributional Semantics and Compositional Semantics

Stephen Clark, University of Cambridge, UK
Alessandro Lenci, University of Pisa, Italy

Modeling of Discourse and Dialogue

Nicolas Asher, CNRS & Université Paul Sabatier, France
Marilyn Walker, University of California Santa Cruz, USA

Natural Language Generation and Summarisation

Albert Gatt, University of Malta, Malta
Advaith Siddharthan, University of Aberdeen, UK

Paraphrasing and Textual Entailment

Ido Dagan, Bar Ilan University, Israel
Kentaro Inui, Tohoku University, Japan

Sentiment Analysis, Opinion Mining and Social Media

Rada Mihalcea, University of Michigan, USA
Bing Liu, University of Illinois at Chicago, USA

Information Retrieval and Question Answering

Gareth Jones, CNGL, Dublin City University, Ireland
Siddharth Patwardhan, IBM Research, USA

Information Extraction and Database Linking

Danushka Bollegala, University of Liverpool, UK

Seung-won Hwang, Postec, Korea

Applications

Srinivas Bangalore, AT&T Labs-Research, USA

Heyan Huang, Beijing Institute of Technology, China

Guillaume Jacquet, Joint Research Centre, Italy

Multimodal and Natural Language Interfaces and Dialog Systems

Kristiina Jokinen, University of Helsinki, Finland

David Traum, University of Southern California, USA

Speech Recognition, Text-To-Speech, Spoken Language Understanding

Nick Campbell, Trinity College Dublin, Ireland

Alex Potamianos, National Technical University Crete, Greece

Machine Translation

Phillip Koehn, University of Edinburgh, UK / Johns Hopkins University, USA

Chris Quirk, Microsoft Research, USA

Tiejun Zhao, Harbin Institute of Technology, China

Resources

Pushpak Bhattacharyya, IIT Bombay, India

Nicoletta Calzolari, ILC-CNR, Italy

Martha Palmer, University of Colorado, USA

Languages with less resources

Steven Bird, University of Melbourne, Australia

Mark Liberman, University of Pennsylvania, USA

Rajeev Sangal, IIT Banaras Hindu University, India

Koenraad De Smedt, University of Bergen, Norway

Software and Tools

Jesús Cardeñosa, Universidad Politecnica de Madrid, Spain

Jing-Shin Chang, National Chi Nan University, Taiwan

Invited Speakers

Mary Harper — *Learning from 26 languages: Program Management and Science in the Babel Program*

Mary will give her invited talk on Monday August 25th.

Ted Gibson — *Language for Communication: Language as Rational Inference*

Ted will give his invited talk on Tuesday August 26th.

Qun Liu — *Annotation Adaptation and Language Adaptation in NLP*

Qun will give his invited talk on Thursday August 28th.

Martin Kay — *Does a Computational Linguist have to be a Linguist?*

Martin will give his invited talk on Friday August 29th.

After Dinner Speaker

Tony Veale — *Creative Twitterbots: Putting Words (and Wit) Into the Mouths of Bots*

Tony will give his talk after the conference dinner on Wednesday August 27th.

Table of Contents

Conference Program

Monday, August 25, 2014

08:45-09:00 Welcome and Opening by General, Progam and Local Chairs

Session Mo11: (09:00-10:15) Invited Talk 1

09:00–10:15 *Learning from 26 Languages: Program Management and Science in the Babel Program*
Mary Harper

10:15-10:45 Coffee Break

Session Mo21: (10:45-12:25) Modeling of Discourse and Dialogue I

10:45–11:10 *Unsupervised learning of rhetorical structure with un-topic models*
Diarmuid Ó Séaghdha and Simone Teufel

11:10–11:35 *Cross-lingual Coreference Resolution of Pronouns*
Michal Novak and Zdenek Zabokrtsky

11:35–12:00 *A Context-Aware NLP Approach For Noteworthiness Detection in Cellphone Conversations*
Francesca Bonin, Jose San Pedro and Nuria Oliver

12:00–12:25 *Hierarchical Topical Segmentation with Affinity Propagation*
Anna Kazantseva and Stan Szpakowicz

Session Mo22: (10:45-12:25) Sentiment Analysis, Opinion Mining and Social Media I

10:45–11:10 *Capturing Cultural Differences in Expressions of Intentions*
Marc Tomlinson, David Bracewell and Wayne Krug

11:10–11:35 *Identification of Implicit Topics in Twitter Data Not Containing Explicit Search Queries*
Suzi Park and Hyopil Shin

11:35–12:00 *Deep Convolutional Neural Networks for Sentiment Analysis of Short Texts*
Cicero dos Santos and Maira Gatti

Monday, August 25, 2014 (continued)

12:00–12:25 *Joint Inference and Disambiguation of Implicit Sentiments via Implicature Constraints*
Lingjia Deng, Janyce Wiebe and Yoonjung Choi

Session Mo23: (10:45-12:25) Information Retrieval and Question Answering

10:45–11:10 *Group Non-negative Matrix Factorization with Natural Categories for Question Retrieval in Community Question Answer Archives*
Guangyou Zhou, Yubo Chen, Daojian Zeng and Jun Zhao

11:10–11:35 *Multi-Objective Search Results Clustering*
Sudipta Acharya, Sriparna Saha, Jose G. Moreno and Gaël Dias

11:35–12:00 *Query-by-Example Image Retrieval using Visual Dependency Representations*
Desmond Elliott, Victor Lavrenko and Frank Keller

12:00–12:25 *Augmenting Business Entities with Salient Terms from Twitter*
Riham Mansour, Nesma Refaei and Vanessa Murdock

Session Mo24: (10:45-12:25) Machine Learning for CL and NLP

10:45–11:10 *A PAC-Bayesian Approach to Minimum Perplexity Language Modeling*
Sujeeth Bharadwaj and Mark Hasegawa-Johnson

11:10–11:35 *Co-learning of Word Representations and Morpheme Representations*
Siyu Qiu, Qing Cui, Jiang Bian, Bin Gao and Tie-Yan Liu

11:35–12:00 *A Probabilistic Model for Learning Multi-Prototype Word Embeddings*
Fei Tian, Hanjun Dai, Jiang Bian, Bin Gao, Rui Zhang, Enhong Chen and Tie-Yan Liu

12:00–12:25 *Learning Task-specific Bilexical Embeddings*
Pranava Swaroop Madhyastha, Xavier Carreras and Ariadna Quattoni

12:25-14:00 Lunch Break

Monday, August 25, 2014 (continued)

Session Mo3P: (14:00-15:15) Posters I

Building Large-Scale Twitter-Specific Sentiment Lexicon : A Representation Learning Approach
Duyu Tang, Furu Wei, Bing Qin, Ming Zhou and Ting Liu

Political Tendency Identification in Twitter using Sentiment Analysis Techniques
Ferran Pla and Lluís-F. Hurtado

A Study of using Syntactic and Semantic Structures for Concept Segmentation and Labeling
Iman Saleh, Scott Cyphers, Jim Glass, Shafiq Joty, Lluís Màrquez, Alessandro Moschitti and Preslav Nakov

Time-aware Personalized Hashtag Recommendation on Social Media
Qi Zhang, Yeyun Gong, Xuyang Sun and Xuanjing Huang

Sarcasm Detection on Czech and English Twitter
Tomáš Ptáček, Ivan Habernal and Jun Hong

A Three-Step Transition-Based System for Non-Projective Dependency Parsing
Ophélie Lacroix and Denis Béchet

Collaborative Topic Regression with Multiple Graphs Factorization for Recommendation in Social Media
Qing Zhang and Houfeng Wang

High Performance Word Sense Alignment by Joint Modeling of Sense Distance and Gloss Similarity
Michael Matuschek and Iryna Gurevych

Multi-view Chinese Treebanking
Likun Qiu, Yue Zhang, Peng Jin and Houfeng Wang

Rapid Development of a Corpus with Discourse Annotations using Two-stage Crowdsourcing
Daisuke Kawahara, Yuichiro Machida, Tomohide Shibata, Sadao Kurohashi, Hayato Kobayashi and Manabu Sassano

Chinese Word Ordering Errors Detection and Correction for Non-Native Chinese Language Learners
Shuk-Man Cheng, Chi-Hsin Yu and Hsin-Hsi Chen

Unsupervised Training Set Generation for Automatic Acquisition of Technical Terminology in Patents
Alex Judea, Hinrich Schütze and Soeren Bruegmann

A Data Driven Approach for Person Name Disambiguation in Web Search Results
Agustín D. Delgado, Raquel Martínez, Víctor Fresno and Soto Montalvo

Picking the Amateur's Mind - Predicting Chess Player Strength from Game Annotations
Christian Scheible and Hinrich Schütze

Zipf's Law and Statistical Data on Modern Tibetan
Huidan Liu, Minghua Nuo and Jian Wu

Simple or Complex? Assessing the readability of Basque Texts
Itziar Gonzalez-Dios, María Jesús Aranzabe, Arantza Díaz de Ilarraza and Haritz Salaberri

Influence of Target Reader Background and Text Features on Text Readability in Bangla: A Computational Approach
Manjira Sinha, Tirthankar Dasgupta and Anupam Basu

Inducing Word Sense with Automatically Learned Hidden Concepts
Baobao Chang, Wenzhe Pei and Miaohong Chen

Inferring Knowledge with Word Refinements in a Crowdsourced Lexical-Semantic Network
Manel Zarrouk and Mathieu Lafourcade

A Supervised Learning Approach Towards Profiling the Preservation of Authorial Style in Literary Translations
Gerard Lynch

Author Verification Using Common N-Gram Profiles of Text Documents
Magdalena Jankowska, Evangelos Milios and Vlado Keselj

Dynamically Integrating Cross-Domain Translation Memory into Phrase-Based Machine Translation during Decoding
Kun Wang, Chengqing Zong and Keh-Yih Su

Machine Translation Quality Estimation Across Domains
José G. C. de Souza, Marco Turchi and Matteo Negri

Investigating the Usefulness of Generalized Word Representations in SMT
Nadir Durrani, Philipp Koehn, Helmut Schmid and Alexander Fraser

Confusion Network for Arabic Name Disambiguation and Transliteration in Statistical Machine Translation
Young-Suk Lee

Fourteen Light Tasks for comparing Analogical and Phrase-based Machine Translation
Rafik Rhouma and Phillippe Langlais

Finding Zelig in Text: A Measure for Normalising Linguistic Accommodation
Simon Jones, Rachel Cotterill, Nigel Dewdney, Kate Muir and Adam Joinson

The annotation of the Central Unit in Rhetorical Structure Trees: A Key Step in Annotating Rhetorical Relations
Mikel Iruskieta, Arantza Díaz de Ilarraza and Mikel Lersundi

Measuring Lexical Cohesion: Beyond Word Repetition
Anna Kazantseva and Stan Szpakowicz

Fast Tweet Retrieval with Compact Binary Codes
Weiwei Guo, Wei Liu and Mona Diab

Learning Sense-specific Word Embeddings By Exploiting Bilingual Resources
Jiang Guo, Wanxiang Che, Haifeng Wang and Ting Liu

Using unmarked contexts in nominal lexical semantic classification
Lauren Romeo, Sara Mendes and Núria Bel

Skill Inference with Personal and Skill Connections
Zhongqing Wang, Shoushan Li, Hanxiao Shi and Guodong Zhou

Jointly or Separately: Which is Better for Parsing Heterogeneous Dependencies?
Meishan Zhang, Wanxiang Che, Yanqiu Shao and Ting Liu

An LR-inspired generalized lexicalized phrase structure parser
Benoit Crabbé

Modeling Review Argumentation for Robust Sentiment Analysis
Henning Wachsmuth, Martin Trenkmann, Benno Stein and Gregor Engels

Biber Redux: Reconsidering Dimensions of Variation in American English
Rebecca J. Passonneau, Nancy Ide, Songqiao Su and Jesse Stuart

Cross-lingual Discourse Relation Analysis: A corpus study and a semi-supervised classification system
Junyi Jessy Li, Marine Carpuat and Ani Nenkova

Enforcing Topic Diversity in a Document Recommender for Conversations
Maryam Habibi and Andrei Popescu-Belis

Identifying Important Features for Graph Retrieval
Zhuo Li, Sandra Carberry, Hui Fang and Kathleen McCoy

15:15-15:45 Coffee Break

Session Mo41: (15:45-17:25) Modeling of Discourse and Dialogue II

15:45–16:10 *Inducing Discourse Connectives from Parallel Texts*
Majid Laali and Leila Kosseim

16:10–16:35 *Lyrics-based Analysis and Classification of Music*
Michael Fell and Caroline Sporleder

16:35–17:00 *Interpretation of Chinese Discourse Connectives for Explicit Discourse Relation Recognition*
Hen-Hsen Huang, Tai-Wei Chang, Huan-Yuan Chen and Hsin-Hsi Chen

17:00–17:25 *Unsupervised Coreference Resolution by Utilizing the Most Informative Relations*
Nafise Sadat Moosavi and Michael Strube

Session Mo42: (15:45-17:25) Sentiment Analysis, Opinion Mining and Social Media II

15:45–16:10 *Knowledge Sharing via Social Login: Exploiting Microblogging Service for Warming up Social Question Answering Websites*
Yang Xiao, Wayne Xin Zhao, Kun Wang and Zhen Xiao

16:10–16:35 *Review Topic Discovery with Phrases using the Pólya Urn Model*
Geli Fei, Zhiyuan Chen and Bing Liu

16:35–17:00 *Joint Opinion Relation Detection Using One-Class Deep Neural Network*
Liheng Xu, Kang Liu and Jun Zhao

17:00–17:25 *A Generative Model for Identifying Target Companies of Microblogs*
Yeyun Gong, Yaqian Zhou, Ya Guo, Qi Zhang and Xuanjing Huang

Session Mo43: (15:45-17:25) Semantic Processing, Distributional Semantics and Compositional Semantics I

15:45–16:10 *Inducing Latent Semantic Relations for Structured Distributional Semantics*
Sujay Kumar Jauhar and Eduard Hovy

16:10–16:35 *Improving distributional thesauri by exploring the graph of neighbors*
Vincent Claveau, Ewa Kijak and Olivier Ferret

16:35–17:00 *Towards Syntax-aware Compositional Distributional Semantic Models*
Lorenzo Ferrone and Fabio Massimo Zanzotto

17:00–17:25 *Low-Dimensional Manifold Distributional Semantic Models*
Georgia Athanasopoulou, Elias Iosif and Alexandros Potamianos

Monday, August 25, 2014 (continued)

Session Mo44: (15:45-17:25) Software, Tools

15:45–16:10 *An Entity-Centric Coreference Resolution System for Person Entities with Rich Linguistic Information*
Marcos Garcia and Pablo Gamallo

16:10–16:35 *Unsupervised Multiword Segmentation of Large Corpora using Prediction-Driven Decomposition of n-grams*
Julian Brooke, Vivian Tsang, Graeme Hirst and Fraser Shein

16:35–17:00 *docrep: A lightweight and efficient document representation framework*
Tim Dawborn and James R. Curran

17:00–17:25 *Why Implementation Matters: Evaluation of an Open-source Constraint Grammar Parser*
Dávid Márk Nemeskey, Francis Tyers and Mans Hulden

Tuesday, August 26, 2014

Session Tu11: (09:00-10:15) Invited Talk 2

09:00–10:15 *Language for Communication: Language as Rational Inference*
Edward Gibson

10:15-10:45 Coffee Break

Session Tu21: (10:45-12:25) Syntax, Grammar Induction, Syntactic and Semantic Parsing I

10:45–11:10 *Soft Cross-lingual Syntax Projection for Dependency Parsing*
Zhenghua Li, Min Zhang and Wenliang Chen

11:10–11:35 *Automatic Feature Selection for Agenda-Based Dependency Parsing*
Miguel Ballesteros and Bernd Bohnet

11:35–12:00 *Predicate-Argument Structure Analysis with Zero-Anaphora Resolution for Dialogue Systems*
Kenji Imamura, Ryuichiro Higashinaka and Tomoko Izumi

12:00–12:25 *Feature Embedding for Dependency Parsing*
Wenliang Chen, Yue Zhang and Min Zhang

Tuesday, August 26, 2014 (continued)

Session Tu22: (10:45-12:25) Sentiment Analysis, Opinion Mining and Social Media III

10:45–11:10 *Identifying Emotional and Informational Support in Online Health Communities*
Prakhar Biyani, Cornelia Caragea, Prasenjit Mitra and John Yen

11:10–11:35 *Identifying Emotion Labels from Psychiatric Social Texts Using Independent Component Analysis*
Liang-Chih Yu and Chun-Yuan Ho

11:35–12:00 *Modeling Mutual Influence Between Social Actions and Social Ties*
Xiaofeng Yu and Junqing Xie

12:00–12:25 *Discovering Topical Aspects in Microblogs*
Abhimanyu Das and Anitha Kannan

Session Tu23: (10:45-12:25) Applications I

10:45–11:10 *Utilizing Microblogs for Automatic News Highlights Extraction*
Zhongyu Wei and Wei Gao

11:10–11:35 *A Step Towards Usable Privacy Policy: Automatic Alignment of Privacy Statements*
Fei Liu, Rohan Ramanath, Norman Sadeh and Noah A. Smith

11:35–12:00 *An Off-the-shelf Approach to Authorship Attribution*
Jamal A. Nasir, Nico Görnitz and Ulf Brefeld

12:00–12:25 *Automatic Prediction of Aesthetics and Interestingness of Text Passages*
Debasis Ganguly, Johannes Leveling and Gareth Jones

Tuesday, August 26, 2014 (continued)

Session Tu24: (10:45-12:25) Modeling of Discourse and Dialogue III

10:45–11:10 *Triple based Background Knowledge Ranking for Document Enrichment*
Muyu Zhang, Bing Qin, Ting Liu and Mao Zheng

11:10–11:35 *Towards an open-domain conversational system fully based on natural language processing*
Ryuichiro Higashinaka, Kenji Imamura, Toyomi Meguro, Chiaki Miyazaki, Nozomi Kobayashi, Hiroaki Sugiyama, Toru Hirano, Toshiro Makino and Yoshihiro Matsuo

11:35–12:00 *The Impact of Deep Hierarchical Discourse Structures in the Evaluation of Text Coherence*
Vanessa Wei Feng, Ziheng Lin and Graeme Hirst

12:00–12:25 *Lexical Chaining for Measuring Discourse Coherence Quality in Test-taker Essays*
Swapna Somasundaran, Jill Burstein and Martin Chodorow

12:25-14:00 Lunch Break

Session Tu3P: (14:00-15:15) Posters II

Improving Cloze Test Performance of Language Learners Using Web N-Grams
Martin Potthast, Matthias Hagen, Anna Beyer and Benno Stein

A Framework for Translating SMS Messages
Vivek Kumar Rangarajan Sridhar, John Chen, Srinivas Bangalore and Ron Shacham

A Hybrid Approach to Features Representation for Fine-grained Arabic Named Entity Recognition
Fahd Alotaibi and Mark Lee

Prior-informed Distant Supervision for Temporal Evidence Classification
Ridho Reinanda and Maarten de Rijke

Identification of Basic Phrases for Kazakh Language using Maximum Entropy Model
Gulila Altenbek, Xiaolong Wang and Gulizhada Haisha

Collecting Bilingual Audio in Remote Indigenous Communities
Steven Bird, Lauren Gawne, Katie Gelbart and Isaac McAlister

Inclusive yet Selective: Supervised Distributional Hypernymy Detection
Stephen Roller, Katrin Erk and Gemma Boleda

Automatic Discovery of Adposition Typology
Rishiraj Saha Roy, Rahul Katare, Niloy Ganguly and Monojit Choudhury

What good are 'Nominalkomposita' for 'noun compounds': Multilingual Extraction and Structure Analysis of Nominal Compositions using Linguistic Restrictors
Patrick Ziering and Lonneke van der Plas

Automatic Classification of Communicative Functions of Definiteness
Archna Bhatia, Chu-Cheng Lin, Nathan Schneider, Yulia Tsvetkov, Fatima Talib Al-Raisi, Laleh Roostapour, Jordan Bender, Abhimanu Kumar, Lori Levin, Mandy Simons and Chris Dyer

Argument structure of adverbial derivatives in Russian
Igor Boguslavsky

Active Learning in Noisy Conditions for Spoken Language Understanding
Hossein Hadian and Hossein Sameti

A Self-adaptive Classifier for Efficient Text-stream Processing
Naoki Yoshinaga and Masaru Kitsuregawa

A Dependency Edge-based Transfer Model for Statistical Machine Translation
Hongshen Chen, Jun Xie, Fandong Meng, Wenbin Jiang and Qun Liu

Fast Domain Adaptation of SMT models without in-Domain Parallel Data
Prashant Mathur, Sriram Venkatapathy and Nicola Cancedda

Discriminative Language Models as a Tool for Machine Translation Error Analysis
Koichi Akabe, Graham Neubig, Sakriani Sakti, Tomoki Toda and Satoshi Nakamura

A Structured Language Model for Incremental Tree-to-String Translation
Heng Yu, Haitao Mi, Liang Huang and Qun Liu

A Lexicalized Reordering Model for Hierarchical Phrase-based Translation
Hailong Cao, Dongdong Zhang, Mu Li, Ming Zhou and Tiejun Zhao

Automatic Corpus Expansion for Chinese Word Segmentation by Exploiting the Redundancy of Web Information
Xipeng Qiu, ChaoChao Huang and Xuanjing Huang

Fast High-Accuracy Part-of-Speech Tagging by Independent Classifiers
Robert Moore

Morfessor FlatCat: An HMM-Based Method for Unsupervised and Semi-Supervised Learning of Morphology
Stig-Arne Grönroos, Sami Virpioja, Peter Smit and Mikko Kurimo

Japanese Word Reordering Integrated with Dependency Parsing
Kazushi Yoshida, Tomohiro Ohno, Yoshihide Kato and Shigeki Matsubara

Query-focused Multi-Document Summarization: Combining a Topic Model with Graph-based Semi-supervised Learning
Yanran Li and Sujian Li

Ranking Multidocument Event Descriptions for Building Thematic Timelines
Kiem-Hieu Nguyen, Xavier Tannier and Véronique Moriceau

Integrating Language and Vision to Generate Natural Language Descriptions of Videos in the Wild
Jesse Thomason, Subhashini Venugopalan, Sergio Guadarrama, Kate Saenko and Raymond Mooney

Cross-Topic Authorship Attribution: Will Out-Of-Topic Data Help?
Upendra Sapkota, Thamar Solorio, Manuel Montes, Steven Bethard and Paolo Rosso

Online Gaming for Crowd-sourcing Phrase-equivalents
A Kumaran, Melissa Densmore and Shaishav Kumar

Unsupervised Verb Inference from Nouns Crossing Root Boundary
Soon Gill Hong, Sin-hee Cho and Mun Yong Yi

Enriching Wikipedia's Intra-language Links by their Cross-language Transfer
Takashi Tsunakawa, Makoto Araya and Hiroyuki Kaji

Chinese Irony Corpus Construction and Ironic Structure Analysis
Yi-jie Tang and Hsin-Hsi Chen

Global Methods for Cross-lingual Semantic Role and Predicate Labelling
Lonneke van der Plas, Marianna Apidianaki and Chenhua Chen

Multilingual Semantic Parsing : Parsing Multiple Languages into Semantic Representations
Zhanming Jie and Wei Lu

Unsupervised Word Sense Induction using Distributional Statistics
Kartik Goyal and Eduard Hovy

Group based Self Training for E-Commerce Product Record Linkage
Xin Zhao, Yuexin Wu, Hongfei Yan and Xiaoming Li

Reducing Over-Weighting in Supervised Term Weighting for Sentiment Analysis
Haibing Wu and Xiaodong Gu

Sentiment Classification with Graph Co-Regularization
Guangyou Zhou, Jun Zhao and Daojian Zeng

Hybrid Deep Belief Networks for Semi-supervised Sentiment Classification
Shusen Zhou, Qingcai Chen, Xiaolong Wang and Xiaoling Li

Latent Dynamic Model with Category Transition Constraint for Opinion Classification
Takeshi Kobayakawa

Sentence Compression for Target-Polarity Word Collocation Extraction
Yanyan Zhao, Wanxiang Che, Honglei Guo, Bing Qin, Zhong Su and Ting Liu

15:15-15:45 Coffee Break

Tuesday, August 26, 2014 (continued)

Session Tu41: (15:45-17:25) Syntax, Grammar Induction, Syntactic and Semantic Parsing II

15:45–16:10 *Hybrid Grammars for Discontinuous Parsing*
Mark-Jan Nederhof and Heiko Vogler

16:10–16:35 *From neighborhood to parenthood: the advantages of dependency representation over bigrams in Brown clustering*
Simon Suster and Gertjan van Noord

16:35–17:00 *An Empirical Evaluation of Automatic Conversion from Constituency to Dependency in Hungarian*
Katalin Ilona Simkó, Veronika Vincze, Zsolt Szántó and Richárd Farkas

17:00–17:25 *Deep-Syntactic Parsing*
Miguel Ballesteros, Bernd Bohnet, Simon Mille and Leo Wanner

Session Tu42: (15:45-17:25) Semantic Processing, Distributional Semantics and Compositional Semantics II

15:45–16:10 *Modeling Newswire Events using Neural Networks for Anomaly Detection*
Pradeep Dasigi and Eduard Hovy

16:10–16:35 *Million-scale Derivation of Semantic Relations from a Manually Constructed Predicate Taxonomy*
Motoki Sano, Kentaro Torisawa, Julien Kloetzer, Chikara Hashimoto, István Varga and Jong-Hoon Oh

16:35–17:00 *Combining Supervised and Unsupervised Parsing for Distributional Similarity*
Martin Riedl, Irina Alles and Chris Biemann

17:00–17:25 *A Markovian approach to distributional semantics with application to semantic compositionality*
Edouard Grave, Guillaume Obozinski and Francis Bach

Tuesday, August 26, 2014 (continued)

Session Tu43: (15:45-17:25) Applications II

15:45–16:10 *A Beam-Search Decoder for Disfluency Detection*
Xuancong Wang, Hwee Tou Ng and Khe Chai Sim

16:10–16:35 *Single Document Keyphrase Extraction Using Label Information*
Sumit Negi

16:35–17:00 *Predicting Interesting Things in Text*
Michael Gamon, Arjun Mukherjee and Patrick Pantel

17:00–17:25 *Context Dependent Claim Detection*
Ran Levy, Yonatan Bilu, Daniel Hershcovich, Ehud Aharoni and Noam Slonim

Session Tu44: (15:45-17:25) Language Resources

15:45–16:10 *Annotating Argument Components and Relations in Persuasive Essays*
Christian Stab and Iryna Gurevych

16:10–16:35 *Building a Hierarchically Aligned Chinese-English Parallel Treebank*
Dun Deng and Nianwen Xue

16:35–17:00 *3arif: A Corpus of Modern Standard and Egyptian Arabic Tweets Annotated for Epistemic Modality Using Interactive Crowdsourcing*
Rania Al-Sabbagh, Roxana Girju and Jana Diesner

17:00–17:25 *Empirical Analysis of Aggregation Methods for Collective Annotation*
Ciyang Qing, Ulle Endriss, Raquel Fernandez and Justin Kruger

Wednesday, August 27, 2014

Full Day Excursions

Thursday, August 28, 2014

Session Th11: (09:00-10:15) Invited Talk 3

09:00–10:15 *Annotation Adaptation and Language Adaptation in NLP*
Qun Liu

10:15-10:45 Coffee Break

Session Th21: (10:45-12:25) IE/Database Linking I

10:45–11:10 *Collective Named Entity Disambiguation using Graph Ranking and Clique Partitioning Approaches*
Ayman Alhelbawy and Robert Gaizauskas

11:10–11:35 *Analysis and Refinement of Temporal Relation Aggregation*
Taylor Cassidy and Heng Ji

11:35–12:00 *The Wisdom of Minority: Unsupervised Slot Filling Validation based on Multi-dimensional Truth-Finding*
Dian Yu, Hongzhao Huang, Taylor Cassidy, Heng Ji, Chi Wang, Shi Zhi, Jiawei Han, Clare Voss and Malik Magdon-Ismail

12:00–12:25 *Common Space Embedding of Primal-Dual Relation Semantic Spaces*
Hidekazu Oiwa and Jun'ichi Tsujii

Thursday, August 28, 2014 (continued)

Session Th22: (10:45-12:25) Lexical Semantics and Ontologies I

10:45–11:10 *An Enhanced Lesk Word Sense Disambiguation Algorithm through a Distributional Semantic Model*
Pierpaolo Basile, Annalina Caputo and Giovanni Semeraro

11:10–11:35 *Word Sense Induction Using Lexical Chain based Hypergraph Model*
Tao Qian, Donghong JI, Mingyao Zhang, Chong Teng and Congling Xia

11:35–12:00 *Minimally Supervised Classification to Semantic Categories using Automatically Acquired Symmetric Patterns*
Roy Schwartz, Roi Reichart and Ari Rappoport

12:00–12:25 *Novel Word-sense Identification*
Paul Cook, Jey Han Lau, Diana McCarthy and Timothy Baldwin

Session Th23: (10:45-12:25) Natural Language Generation and Summarization I

10:45–11:10 *Learning to Summarise Related Sentences*
Emmanouil Tzouridis, Jamal Nasir and Ulf Brefeld

11:10–11:35 *Learning to Generate Coherent Summary with Discriminative Hidden Semi-Markov Model*
Hitoshi Nishikawa, Kazuho Arita, Katsumi Tanaka, Tsutomu Hirao, Toshiro Makino and Yoshihiro Matsuo

11:35–12:00 *Query-Focused Opinion Summarization for User-Generated Content*
Lu Wang, Hema Raghavan, Claire Cardie and Vittorio Castelli

12:00–12:25 *Generating Supplementary Travel Guides from Social Media*
Liu Yang, Jing Jiang, Lifu Huang, Minghui Qiu and Lizi Liao

Thursday, August 28, 2014 (continued)

Session Th24: (10:45-12:25) Modeling of Discourse and Dialogue IV and Multimodal Processing

10:45–11:10 *Ensemble-Based Medical Relation Classification*
Jennifer D'Souza and Vincent Ng

11:10–11:35 *Combining Natural and Artificial Examples to Improve Implicit Discourse Relation Identification*
Chloé Braud and Pascal Denis

11:35–12:00 *Reinforcement Learning of Cooperative Persuasive Dialogue Policies using Framing*
Takuya Hiraoka, Graham Neubig, Sakriani Sakti, Tomoki Toda and Satoshi Nakamura

12:00–12:25 *Towards multimodal modeling of physicians' diagnostic confidence and self-awareness using medical narratives*
Joseph Bullard, Cecilia Ovesdotter Alm, Qi Yu, Pengcheng Shi and Anne Haake

12:25-14:00 Lunch Break

Session Th31: (14:00-15:15) Semantic Processing, Distributional Semantics and Compositional Semantics III

14:00–14:25 *Towards Semantic Validation of a Derivational Lexicon*
Britta Zeller, Sebastian Padó and Jan Šnajder

14:25–14:50 *Detecting Learner Errors in the Choice of Content Words Using Compositional Distributional Semantics*
Ekaterina Kochmar and Ted Briscoe

14:50–15:15 *A Novel Distributional Approach to Multilingual Conceptual Metaphor Recognition*
Michael Mohler, Bryan Rink, David Bracewell and Marc Tomlinson

Thursday, August 28, 2014 (continued)

Session Th32: (14:00-15:15) Morphology, Word Segmentation, Tagging and Chunking I

14:00–14:25 *Part of Speech Tagging for French Social Media Data*
Farhad Nooralahzadeh, Caroline Brun and Claude Roux

14:25–14:50 *Morphological Analysis for Japanese Noisy Text based on Character-level and Word-level Normalization*
Itsumi Saito, Kugatsu Sadamitsu, Hisako Asano and Yoshihiro Matsuo

14:50–15:15 *Adapting taggers to Twitter with not-so-distant supervision*
Barbara Plank, Dirk Hovy, Ryan McDonald and Anders Søgaard

Session Th33: (14:00-15:15) Speech Recognition, Text-To-Speech, Spoken Language Understanding

14:00–14:25 *Interpolated Dirichlet Class Language Model for Speech Recognition Incorporating Long-distance N-grams*
Md. Akmal Haidar and Douglas O'Shaughnessy

14:25–14:50 *Situated Incremental Natural Language Understanding using a Multimodal, Linguistically-driven Update Model*
Casey Kennington, Spyros Kousidis and David Schlangen

14:50–15:15 *Quality Estimation for Automatic Speech Recognition*
Matteo Negri, Marco Turchi, José G. C. de Souza and Falavigna Daniele

Session Th34: (14:00-15:15) Lesser Resourced Languages

14:00–14:25 *A Generic Anaphora Resolution Engine for Indian Languages*
Sobha Lalitha Devi, Vijay Sundar Ram and Pattabhi RK Rao

14:25–14:50 *Converting Phrase Structures to Dependency Structures in Sanskrit*
Pawan Goyal and Amba Kulkarni

14:50–15:15 *Uncertainty Detection in Hungarian Texts*
Veronika Vincze

15:15-15:45 Coffee Break

Thursday, August 28, 2014 (continued)

Session Th41: (15:45-17:25) Syntax, Grammar Induction, Syntactic and Semantic Parsing III

15:45–16:10 *Rediscovering Annotation Projection for Cross-Lingual Parser Induction*
Jörg Tiedemann

16:10–16:35 *Synchronous Constituent Context Model for Inducing Bilingual Synchronous Structures*
Xiangyu Duan, Min Zhang and Qiaoming Zhu

16:35–17:00 *Syntactic Parsing and Compound Recognition via Dual Decomposition: Application to French*
Joseph Le Roux, Antoine Rozenknop and Matthieu Constant

17:00–17:25 *Learning the Taxonomy of Function Words for Parsing*
Dongchen Li, Xiantao Zhang, Dingsheng Luo and Xihong Wu

Session Th42: (15:45-17:25) Machine Translation I

15:45–16:10 *A Neural Reordering Model for Phrase-based Translation*
Peng Li, Yang Liu, Maosong Sun, Tatsuya Izuha and Dakun Zhang

16:10–16:35 *Recurrent Neural Network-based Tuple Sequence Model for Machine Translation*
Youzheng Wu, Taro Watanabe and Chiori Hori

16:35–17:00 *Class-Based Language Modeling for Translating into Morphologically Rich Languages*
Arianna Bisazza and Christof Monz

17:00–17:25 *Latent Domain Translation Models in Mix-of-Domains Haystack*
Cuong Hoang and Khalil Sima'an

Thursday, August 28, 2014 (continued)

Session Th43: (15:45-17:25) Linguistic and Cognitive Issues in CL and NLP I

15:45–16:10 *Language Family Relationship Preserved in Non-native English*
Ryo Nagata

16:10–16:35 *Why Gender and Age Prediction from Tweets is Hard: Lessons from a Crowdsourcing Experiment*
Dong Nguyen, Dolf Trieschnigg, A. Seza Doğruöz, Rilana Gravel, Mariet Theune, Theo Meder and Franciska De Jong

16:35–17:00 *Exploring Syntactic Features for Native Language Identification: A Variationist Perspective on Feature Encoding and Ensemble Optimization*
Serhiy Bykh and Detmar Meurers

17:00–17:25 *Applying automatically parsed corpora to the study of language variation*
Jelke Bloem, Arjen Versloot and Fred Weerman

Session Th44: (15:45-17:25) Natural Language Generation and Summarization II and Paraphrasing

15:45–16:10 *Empirical analysis of exploiting review helpfulness for extractive summarization of online reviews*
Wenting Xiong and Diane Litman

16:10–16:35 *Lexico-syntactic text simplification and compression with typed dependencies*
Mandya Angrosh, Tadashi Nomoto and Advaith Siddharthan

16:35–17:00 *Learning when to point: A data-driven approach*
Albert Gatt and Patrizia Paggio

17:00–17:25 *Generating Acrostics via Paraphrasing and Heuristic Search*
Benno Stein, Matthias Hagen and Christof Bräutigam

Friday, August 29, 2014

Session Fr11: (09:00-10:15) Invited Talk 4

09:00–10:15 *Does a Computational Linguist have to be a Linguist?*
Martin Kay

10:15-10:45 Coffee Break

Session Fr21: (10:45-12:25) Machine Translation II

10:45–11:10 *Query Lattice for Translation Retrieval*
Meiping Dong, Yong Cheng, Yang Liu, Jia Xu, Maosong Sun, Tatsuya Izuha and Jie Hao

11:10–11:35 *RED: A Reference Dependency Based MT Evaluation Metric*
Hui Yu, Xiaofeng Wu, Jun Xie, Wenbin Jiang, Qun Liu and Shouxun Lin

11:35–12:00 *Quality Estimation of English-French Machine Translation: A Detailed Study of the Role of Syntax*
Rasoul Kaljahi, Jennifer Foster, Johann Roturier and Raphael Rubino

12:00–12:25 *Effective Incorporation of Source Syntax into Hierarchical Phrase-based Translation*
Tong Xiao, Adrià de Gispert, Jingbo Zhu and Bill Byrne

Session Fr22: (10:45-12:25) IE/Database Linking II

10:45–11:10 *BEL: Bagging for Entity Linking*
Zhe Zuo, Gjergji Kasneci, Toni Gruetze and Felix Naumann

11:10–11:35 *Exploratory Relation Extraction in Large Text Corpora*
Alan Akbik, Thilo Michael and Christoph Boden

11:35–12:00 *An Analysis of Causality between Events and its Relation to Temporal Information*
Paramita Mirza and Sara Tonelli

12:00–12:25 *Exploring Fine-grained Entity Type Constraints for Distantly Supervised Relation Extraction*
Yang Liu, Kang Liu, Liheng Xu and Jun Zhao

Friday, August 29, 2014 (continued)

Session Fr23: (10:45-12:25) Linguistic and Cognitive Issues in CL and NLP II

10:45–11:10 *Using Collections of Human Language Intuitions to Measure Corpus Representativeness*
Reinhard Rapp

11:10–11:35 *Limited memory incremental coreference resolution*
Kellie Webster and James R. Curran

11:35–12:00 *Left-corner Transitions on Dependency Parsing*
Hiroshi Noji and Yusuke Miyao

12:00–12:25 *Data-driven Measurement of Child Language Development with Simple Syntactic Templates*
Shannon Lubetich and Kenji Sagae

Session Fr24: (10:45-12:25) Lexical Semantics and Ontologies II

10:45–11:10 *Employing Event Inference to Improve Semi-Supervised Chinese Event Extraction*
Peifeng Li, Qiaoming Zhu and Guodong Zhou

11:10–11:35 *Supervised Ranking of Co-occurrence Profiles for Acquisition of Continuous Lexical Attributes*
Julian Brooke and Graeme Hirst

11:35–12:00 *Unsupervised extraction of semantic relations using discourse cues*
Juliette Conrath, Stergos Afantenos, Nicholas Asher and Philippe Muller

12:00–12:25 *HARPY: Hypernyms and Alignment of Relational Paraphrases*
Adam Grycner and Gerhard Weikum

12:25-14:00 Lunch Break

Friday, August 29, 2014 (continued)

Session Fr31: (14:00-15:15) Machine Translation III

Invited Speaker Abstract

This presentation will illustrate how program management and science can cooperate to increase our understanding of human languages and algorithms for processing them. In this presentation, I will use the IARPA Babel program as an example. The goal of the Babel Program is to rapidly develop speech recognition capability for keyword search in new languages, working with speech recorded in a variety of conditions and with limited amounts of transcription. The speech data is recorded in native countries and contains variability in speaker demographics and recording conditions. The Program will ultimately address a broad set of languages with a variety of phonotactic, phonological, tonal, morphological, and syntactic characteristics. I will discuss the data resources collected to support the research, the challenges that performers have faced when working with a variety of languages collected in realistic environments, the lessons learned, and future directions.

Abstract

In this paper we investigate whether unsupervised models can be used to induce conventional aspects of rhetorical language in scientific writing. We rely on the intuition that the rhetorical language used in a document is general in nature and independent of the document's topic. We describe a Bayesian latent-variable model that implements this intuition. In two empirical evaluations based on the task of argumentative zoning (AZ), we demonstrate that our generality hypothesis is crucial for distinguishing between rhetorical and topical language and that features provided by our unsupervised model trained on a large corpus can improve the performance of a supervised AZ classifier.

1 Introduction

Scientific writing has many conventions. Some exist at the level of sentence construction, such as a preference for the passive voice or for deverbal nominalisations. Others relate to the high-level organisation of a paper: a typical paper at an NLP conference may be divided into sections covering the introduction, related work, methods, experimental results and conclusion. There are also intermediate levels of convention that use lexical and phrasal items to signal the role played by each part of the text in the argument the authors wish to construct. The theory of *argumentative zoning* (AZ) describes how a scientific article can be analysed in terms of text blocks (or *zones*) that share a rhetorical function (Teufel, 2010). For example: part of the article may consist of background information, another part may describe the aim of the research, other parts may report the authors' own work or compare that work to alternative approaches in the literature. Supervised computational systems can be trained to mark up the AZ structure of a text automatically (see Section 2); the output of such systems has been shown to aid summarisation and human browsing of the scientific literature (Teufel and Moens, 2002; Guo et al., 2011a; Contractor et al., 2012). However, supervised systems require manually annotated training data that must be created anew for each discipline (and language) before they can be deployed, while large quantities of unannotated text are often available. For this reason, there is considerable value in developing unsupervised systems that induce aspects of rhetorical structure from unannotated text.

In this paper we advance a hypothesis about the *generality* of rhetorical language. We propose that the words and linguistic constructs used to express rhetorical function in a scientific paper are independent of the paper's topic. Naturally there will be some variation across research areas and there may be large differences across disciplines, but within a discipline we do not expect that the specific subject of a paper plays a significant role in how the authors construct their argument. For example, the following template could be used to generate an abstract for very many papers in NLP and other fields:

> The problem of _____ has received a lot of attention because of its relevance to _____. CITATION proposed an approach based on the method of _____. In this paper we present a method for _____ that has the following advantages over prior work: _____. We demonstrate the empirical effectiveness of our method by reporting experiments on _____ data, where it outperforms the approach of CITATION by __%.

Proceedings of COLING 2014, the 25th International Conference on Computational Linguistics: Technical Papers, pages 2–13, Dublin, Ireland, August 23-29 2014.

This leads us to the idea of two-stage "recipes" for scientific papers, whereby the authors start with a framework of boilerplate text that matches the rhetorical argument they wish to make. The authors can then fill in the gaps with the substance of their research contribution.

The two-stage model is of course an idealisation of how scientists construct their papers, but it is useful as an inspiration for a computational model that implements the generality hypothesis. We propose BOILERPLATE-LDA, a generative model that assigns responsibility for generating each word in an abstract to a document-specific topic model or to a rhetorical language model that is not specific to the document. Essentially, we induce argumentative structure from the parts of the text that are not well-explained by the topic model. Hence we describe BOILERPLATE-LDA as an "un-topic model". We evaluate our model in two settings: a clustering evaluation that treats BOILERPLATE-LDA as performing unsupervised argumentative zoning, and a downstream evaluation where the induced structure is not taken as explicitly modelling argumentative zones but is used to provide informative features for a supervised AZ classifier. In both cases, we show that BOILERPLATE-LDA performs well on a very challenging task.

2 Related work

There has been great interest in unsupervised learning among NLP researchers due to the availability of large amounts of unprocessed text through the Web, newswire providers, scientific repositories and other sources in contrast to the onerous requirements of creating task-specific manually annotated data for training supervised analysers. Particularly relevant to our work is the field of topic modelling, where Bayesian latent-variable models are used to induce meaningful generalisations from observations of co-occurrences. Blei et al. (2003) introduced Latent Dirichlet Allocation (LDA) as a model of thematic structure in documents, but subsequent work has adapted the general framework to many different purposes in modelling text as well as other kinds of data. This includes research on modelling aspects of document structure such as topic segmentation, implementing the intuitions that neighbouring blocks of text are coherent in the sense of lexical similarity (Purver et al., 2006; Gruber et al., 2007; Eisenstein and Barzilay, 2008; Du et al., 2013). The model most similar to ours (that we are aware of) is the model of Ritter et al. (2010), which captures dialogue acts and transitions between them in Twitter conversations.

Despite the general popularity of unsupervised approaches, rhetorical analysis has generally been treated as a problem for supervised machine learning. Classification-based approaches to argumentative zoning typically use a sequence classifier such as a maximum-entropy Markov model or conditional random field (Teufel and Moens, 2002; Siddharthan and Teufel, 2007; Hirohata et al., 2008; Guo et al., 2010). Guo et al. (2011b) take a semi-supervised approach based on active learning and self-training.

Two unsupervised approaches in the literature are Varga et al. (2012) and Reichart and Korhonen (2012). Varga et al. use a topic model variant called ZONE-LDA that assigns each sentence a latent variable index or "topic" and assumes that the words in the sentence are generated from a distribution particular to the topic; in this situation each topic is assumed to correspond to a distinct argumentative zone. Such a model will have the effect of clustering sentences that share lexical items. Varga et al. also propose a model they call ZONE-LDA-B, in which some common words are assigned to a "background" distribution that is independent of the sentence category; this model performs worse than ZONE-LDA in their evaluation. Reichart and Korhonen take an approach based on Markov random fields. They construct a graphical model in which sentence vertices are connected by potentials weighted according to adjacency and sentence similarity, as well as hand-defined rules about passivisation and sentence location.

The papers cited in the two preceding paragraphs have focused on rhetorical analysis in scientific writing, yet there are many other textual genres where argumentation is conventionalised. For example, Burstein et al. (2003) identify building blocks analogous to AZ zones in the writing of English language learners and demonstrate that a supervised classification approach can be used to mark up their essays. Also in the educational domain, Madnani et al. (2012) train a supervised classifier to detect the "shell" language that learners use to organise the high-level structure of their compositions; this is quite close to our idea of "templates" or "recipes" for scientific papers. Sauper and Barzilay (2009) and Chen et al. (2009) both present models that learn structural conventions in Wikipedia articles without relying on human annotation. Sauper and Barzilay's model induces the typical section structure of Wikipedia articles

about a specific entity type (e.g., *Actors* or *Diseases*) and retrieves web snippets relevant to each section for a target entity, before performing multidocument summarisation to produce a new entry for posting to Wikipedia. Chen et al. take a Bayesian segmentation approach to implicitly learn the topical section structure of articles and use a generalised Mallows model, a distribution over permutations, to identify a canonical ordering for sections.[1] Other forms of general rhetorical analysis include Rhetorical Structure Theory (Mann and Thompson, 1988; Marcu, 2000), which captures local discourse relations between segments of text; RST provides a layer of analysis that is separate and complementary to more global schemes such as argumentative zoning.

3 Intuitions

The performance of unsupervised learning depends on how intuitions about the task are incorporated in the statistical model. Our approach relies on three main intuitions:

Sentence similarity: All else being equal, we expect that lexically similar sentences will have similar purposes. At the same time, lexical similarity alone is not sufficient to capture shared argumentative function: all sentences in a paper about parsing will be similar to each other, while the introductory sentences of a parsing paper and a machine translation paper may share few similar lexical items.

Adjacency: The theory of argumentative zones suggests that sentences with the same rhetorical function will often be grouped together into blocks. Additionally, we expect that authors will follow general conventions about the order of zones, e.g., starting with background and goal statements and progressing to results and conclusions.

Generality: We expect that the language used to convey rhetorical function is independent of the topical content of the paper.

Sentence similarity can be captured using standard lexical similarity measures or through the clustering effects of a topic model. The adjacency assumption can be implemented using a linear-chain sequence model such as a Hidden Markov Model. The ZONE-LDA approach of Varga et al. (2012) relies on sentence similarity alone. Reichart and Korhonen's (2012) model combines sentence similarity and adjacency. To the best of our knowledge, the generality hypothesis has not previously been investigated. The model we describe in Section 4 incorporates all three intuitions in its structure.

4 Models

The model we propose assumes that each word in a sentence is generated either from an LDA-style topic model or from a distribution associated with the rhetorical category assigned to the sentence. The former captures the subject matter of the document; the latter captures conventional language that is independent of the document's subject matter. The sentence categories are generated from a first-order Markov model. The assignment of responsibility for a word is implemented through a so-called "switching variable", a binary-valued latent variable. This is a commonly used mechanism for interpolating language models (Griffiths et al., 2004; Reisinger and Mooney, 2010; Ahmed and Xing, 2010); in many cases, the goal is to assign common words to a "background" distribution that is not considered an object of interest from a topic modelling perspective. In our case it is this non-topical part of the text that is the object of interest.

The dependencies between variables in our full BOILERPLATE-LDA model are shown by the plate diagram in Figure 1. The corresponding "generative story" is as follows:

[1] It would be interesting to swap in Chen et al.'s generalised Mallows model for the HMM-style ordering model in BOILERPLATE-LDA. The former has the advantage of capturing non-local ordering effects, while the latter has the advantage of not assuming a single canonical ordering.

for topic $t \in \{1 \dots |T|\}$ **do**
  (Draw a distribution over words)
  $\boldsymbol{\Phi}_t \sim Dirichlet(\boldsymbol{\beta})$
end for
for zone $z \in \{1 \dots |Z|\}$ **do**
  (Draw a distribution over words)
  $\boldsymbol{\Psi}_z \sim Dirichlet(\boldsymbol{\gamma})$
  (Draw a transition distribution)
  $\boldsymbol{\Lambda}_z \sim Dirichlet(\boldsymbol{\lambda})$
end for
(Draw the switch distribution)
$\Sigma \sim Beta(\sigma_0, \sigma_1)$
for doc $d \in \{1 \dots |D|\}$ **do**
  (Draw a distribution over topics)
  $\boldsymbol{\theta}_d \sim Dirichlet(\boldsymbol{\alpha})$
  for sentence $s \in Sentences(d)$ **do**
    $z_s \sim Multinomial(\boldsymbol{\Lambda}_{z_{s-1}})$
    for word $i \in Words(s)$ **do**
      (Draw a switch indicator)
      $b_i = Beta(\Sigma)$
      if $b_i = 0$ **then**
        (Draw a word from the zone-word distribution)
        $w_i \sim Multinomial(\boldsymbol{\Psi}_{z_s})$
      else
        (Draw a topic)
        $t_i \sim Multinomial(\boldsymbol{\theta}_d)$
        (Draw a word from the topic-word distribution)
        $w_i \sim Multinomial(\boldsymbol{\Phi}_{t_i})$
      end if
    end for
  end for
end for

We train the model using Gibbs sampling. Due to Dirichlet-multinomial and beta-Bernoulli conjugacy it is relatively straightforward to integrate out the multinomial and Bernoulli distribution parameters $\boldsymbol{\theta}$, $\boldsymbol{\Phi}$, $\boldsymbol{\Psi}$ and Σ and derive update rules for a collapsed Gibbs sampler. Each iteration of the sampler visits each sentence in the corpus in turn, first sampling the sentence label assignment z_s and then sampling for each word in the sentence the switch indicator b_i and (if $b_i = 1$) the topic assignment t_i. The sentence label update is performed using what Gao and Johnson (2008) call a pointwise collapsed Gibbs sampler. Omitting hyperparameters for clarity, the sampling probabilities can be written as

$$P(z_i = z|\boldsymbol{z}^{-i}, \boldsymbol{w}, \boldsymbol{b}) \propto \frac{f_{z_{i-1}\to z} + \kappa_z}{f_{z_{i-1}} + \sum_{z'} \kappa_{z'}} \frac{f_{z\to z_{i+1}} + I(z = z_{i+1}) + \kappa_{z_{i+1}}}{f_z^{-i} + I(z = z_{i+1}) + \sum_{z'} \kappa_{z'}} \prod_{v \in V} \frac{\Gamma(f^{-i}_{zv,b=0} + f_{s_i v,b=0} + \gamma)}{\Gamma(f_z^{-i} + f_{s_i} + \gamma|V|)} \tag{1}$$

where $f_{z->z'}$ is the transition frequency from zone z to zone z', f_z is the number of sentences assigned zone z; $I(z = z_{i+1})$ has value 1 if the two zone assignments are equal and 0 otherwise; V is the vocabulary of word types; $f_{zv,b=0}$ is the number of words of type z that appear in sentences assigned zone z and whose corresponding switch variable has value 0; $f_{s_i v,b=0}$ is the number of words of type v that appear in sentence s_i and whose corresponding switch variable has value 0; the superscript $^{-i}$ indicates that the frequency is calculated over all sentences except s_i. We introduce observed start and end state variables z_s and z_e to handle the boundaries at the beginning and end of each document.

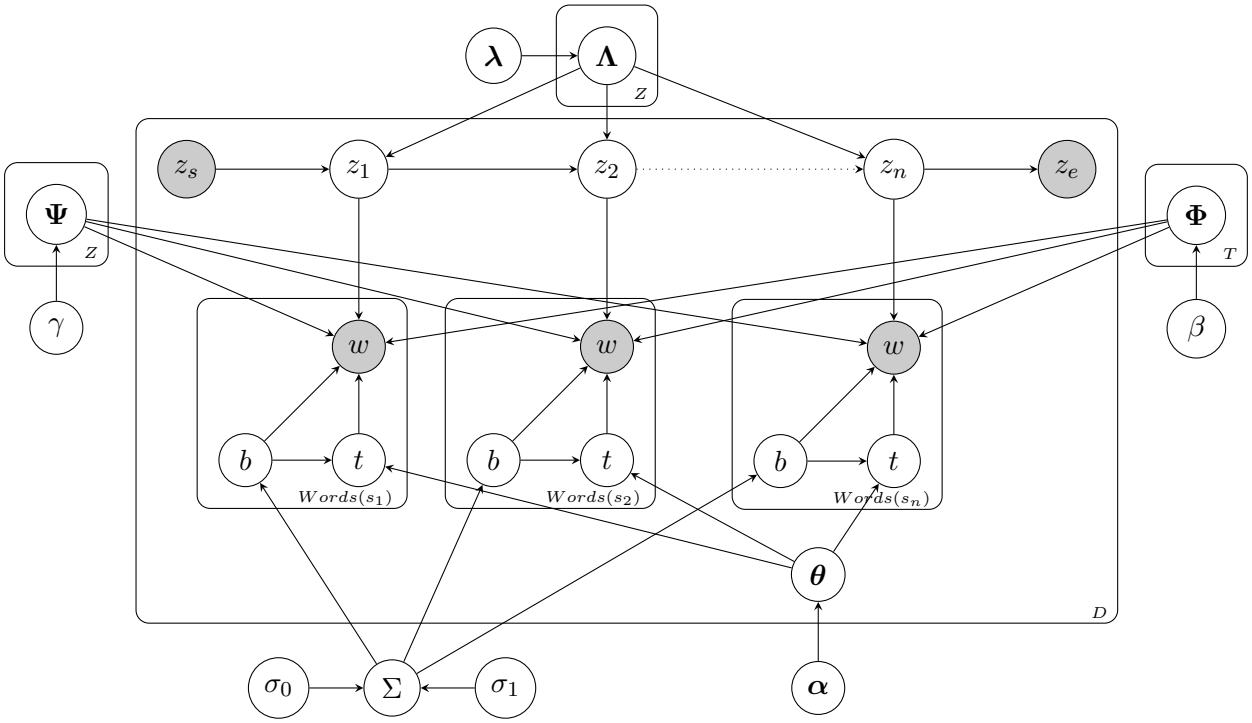

Figure 1: Plate diagram for BOILERPLATE-LDA

The topic and switch variables for each word are sampled in a blocked fashion; the sampling probabilities are similar to the standard LDA updates:

$$
\begin{aligned}
P(b_j = 0, t_j = \emptyset | \mathbf{z}^{-j}, \mathbf{b}^{-j}, \mathbf{t}, \mathbf{w}) &\propto (f^{-j}_{b=0} + \Sigma_0) \frac{f^{-j}_{z_i w_j, b=0} + \gamma}{f_{z_i, b=0} + |V|\gamma} \\
P(b_j = 1, t_j = t | \mathbf{z}^{-j}, \mathbf{b}^{-j}, \mathbf{t}, \mathbf{w}) &\propto (f^{-j}_{b=1} + \Sigma_1) \frac{f^{-j}_{tw_j} + \alpha_z}{f^{-j}_{w_j, b=1} + \sum_{z'} \alpha_{z'}} \frac{f^{-j}_{zw_j} + \beta}{f^{-j}_{z} + |V|\beta} \\
P(b_i = 0, t_i \neq \emptyset | \mathbf{z}^{-j}, \mathbf{b}^{-j}, \mathbf{t}, \mathbf{w}) &= 0 \\
P(b_i = 1, t_i = \emptyset | \mathbf{z}^{-j}, \mathbf{b}^{-j}, \mathbf{t}, \mathbf{w}) &= 0
\end{aligned} \tag{2}
$$

where we use j to index words and i to index sentences; f_{tw_j} is the number of words of type w_j that are assigned topic t; the superscript $^{-j}$ indicates that the frequency is calculated over all words except j.

5 Experiments

5.1 Data

For evaluation, we use a collection of abstracts compiled by Guo et al. (2010). These abstracts had originally been collected in the context of semi-automated cancer risk assessment by searching PubMed for abstracts mentioning one or more of a list of chemicals known to have carcinogenic properties (Korhonen et al., 2009). Guo et al. annotated abstracts for five of these chemicals using an AZ scheme with seven categories: *Background*, *Objective*, *Method*, *Result*, *Conclusion*, *Related work* and *Future work*.[2] In order to test whether our models can also perform over a large, heterogeneous dataset, we also used a collection of 129,595 abstracts taken from a collection of open-access journal articles. Preprocessing involved sentence splitting, tokenisation and part-of-speech tagging using the Stanford CoreNLP toolkit[3] and the removal of all tokens containing non-alphanumeric characters, all tokens of character length one

[2]The annotated dataset has been made available at `http://www.cl.cam.ac.uk/~yg244/abstract_az.html`.
[3]`http://nlp.stanford.edu/software/corenlp.shtml`

and a small set of stop words.[4] This left a training corpus of 16,841,280 tokens.

5.2 Clustering Evaluation

5.2.1 Evaluation

Our first quantitative evaluation investigates whether the zones induced by BOILERPLATE-LDA correspond to the argumentative zones identified by human theorists. We treat this as a clustering task with the gold standard provided by Guo et al.'s (2010) dataset. The clustering evaluation measures we use are the Adjusted Rand Index (Hubert and Arabie, 1985) and Adjusted Mutual Information (Vinh et al., 2010); both measures are normalised to have a maximum value of 1 and are adjusted for chance so that the expected score given to a random clustering is 0. This second property makes them conservative in comparison to other evaluation measures. We report results with the number of zones $|Z| \in \{10, 20, 50\}$ and number of topics $|T| \in \{10, 20, 50, 100\}$; for each combination of settings we report the average evaluation score attained by three independent runs of the learning algorithm.

5.2.2 Models

For our evaluation, we test the following models:

BOILERPLATE-LDA: Our full model, as described in Section 4.

BOILERPLATE-LDA-MULT: A simplified model where the Markov dependencies between zone assignments are replaced by a flat multinomial; the probability of a zone is independent of the adjacent sentences.

BOILERPLATE-LDA-NOTOPICS: A simplified model where all words in a sentence are generated from the zone distribution $\boldsymbol{\Psi}_{z_s}$; this is almost identical to Varga et al.'s (2012) ZONE-LDA model.

K-MEANS: A standard k-means clustering model run until convergence. The features for each sentence consist of tf-idf-transformed lexical frequencies, part-of-speech tags and a location feature computed by dividing the abstract into 5 bins.

The BOILERPLATE-LDA models are all trained for 1000 iterations of Gibbs sampling. The Dirichlet hyperparameters are re-estimated every 10 iterations; the topic hyperparameters $\boldsymbol{\alpha}$ are optimised using a fixed-point iteration to maximise the log-evidence (Minka, 2003; Wallach, 2008), while the other hyperparameters are sampled using Hamiltonian Monte Carlo (Neal, 2010). K-MEANS was run until convergence.

5.2.3 Results

Figure 2 gives an illustration of the zone representation induced at the end of one run of BOILERPLATE-LDA with the settings $|Z| = 10$, $|T| = 100$. Firstly, we list the most probable words for each zone (2a). While the model may not find a perfect match for the gold-standard inventory of argumentative zones, we can see that some induced zones describe standard methodology (8,9), others describe results and implications (1,3,7) and others describe motivations (2,5,6). Inspection of the transition matrix (2b) confirms our expectation that self-transitions have the highest probability; we also observed that the zones most frequently transitioned to from the start state are the motivational zones and the zones most frequently transitioned from to the end state are the results/implications zones. The example abstracts in Figure 3 illustrate how BOILERPLATE-LDA can be used to mark up the text of an abstract as "boilerplate" or "non-boilerplate" based on the values of the switch variables b_i.

[4] The part-of-speech tags are not used by BOILERPLATE-LDA but they are used as features for other models.

VASP: A Volumetric Analysis of Surface Properties Yields Insights into Protein-Ligand Binding Specificity

Many algorithms that compare protein structures can reveal similarities that suggest related biological functions, even at great evolutionary distances. Proteins with related function often exhibit differences in binding specificity, but few algorithms identify structural variations that effect specificity. To address this problem, we describe the Volumetric Analysis of Surface Properties (VASP), a novel volumetric analysis tool for the comparison of binding sites in aligned protein structures. VASP uses solid volumes to represent protein shape and the shape of surface cavities, clefts and tunnels that are defined with other methods. Our approach, inspired by techniques from constructive solid geometry, enables the isolation of volumetrically conserved and variable regions within three dimensionally superposed volumes. We applied VASP to compute a comparative volumetric analysis of the ligand binding sites formed by members of the steroidogenic acute regulatory protein (StAR)-related lipid transfer (START) domains and the serine proteases. Within both families, VASP isolated individual amino acids that create structural differences between ligand binding cavities that are known to influence differences in binding specificity. Also, VASP isolated cavity subregions that differ between ligand binding cavities which are essential for differences in binding specificity. As such, VASP should prove a valuable tool in the studyof protein-ligand binding specificity.

A new usage of functionalized oligodeoxynucleotide probe for site-specific modification of a guanine base within RNA

Site-specific modification of RNA is of great significance to investigate RNA structure, function and dynamics. Recently, we reported a new method for sequence- and cytosine-selective chemical modification of RNA based on the functional group transfer reaction of the 1-phenyl-2-methylydene-1,3-diketone unit of the 6-thioguanosine base incorporated in the oligodeoxynucleotide probe. In this study, we describe that the functionality transfer rate is greatly enhanced and the selectivity is shifted to the guanine base when the reaction is performed under alkaline conditions. Detailed investigation indicated that the 2-amino group of the enolate form of rG is the reactant of the functionality transfer reaction. As a potential application of this efficient functionality transfer reaction, a pyrene group as a relatively large fluorescent group was successfully transferred to the target guanine base of RNA with a high guanine and site selectivity. This functionality transfer reaction with high efficiency and high site-selectivity would provide a new opportunity as a unique tool for the study of RNA.

	20	0.10	0.13	0.04	0.09	0.03	0.07
	50	0.21	0.16	0.13	0.14	0.06	0.10
	100	0.18	0.16	0.14	0.14	0.07	0.11
BOILERPLATE-LDA-NOTOPICS	0	0.00	0.02	0.04	0.05	0.06	0.05
K-MEANS	0	0.05	0.05	0.03	0.06	0.03	0.04

Table 1: Results of the clustering evaluation. $|Z|$ is the number of zones; $|T|$ is the number of topics.

The results of the clustering evaluation are presented in Table 1. Clearly, this is a challenging task; the BOILERPLATE-LDA-NOTOPICS and K-MEANS models, which do not filter out topic-specific vocabulary, perform little better than chance in terms of identifying argumentative zones (recall that for the ARI and AMI measures, zero means "not greater than expected by chance" rather than "no correlation at all"). BOILERPLATE-LDA-MULT performs better than those models though not as well as the full BOILERPLATE-LDA model, indicating that sequential structure is important for inducing rhetorical regularities. In general, the best results are attained with low settings of $|Z|$ and high settings of $|T|$; this seems to create the "bottleneck" effect needed to focus the model on purely rhetorical information. The highest scores (ARI = 0.32, AMI = 0.28) are attained by BOILERPLATE-LDA with the settings $|Z| = 10$, $|T| = 100$.

5.3 Supervised Evaluation

5.3.1 Evaluation

A second evaluation of BOILERPLATE-LDA's usefulness is to test whether it can yield features that improve the performance of a supervised argumentative zoning system. It is possible for an unsupervised model to induce structure that does not map exactly onto a pre-existing set of labels but still captures valuable information about the underlying phenomenon that can be of use to a supervised classifier when combined with other information sources. To this end, we train and evaluate supervised models on the same dataset of Guo et al. (2010) that we used for the clustering evaluation. We perform 10-fold cross-validation and report Accuracy (proportion of sentences labelled correctly) as well as macro-averaged Precision, Recall and F-Score. To measure statistical significance we use two-tailed paired t-tests, following Dietterich (1998).[5]

5.3.2 Models

We use two supervised sequence classification algorithms for training models:

LR: A logistic regression classifier with a "history" feature encoding the previous sentence's label, trained with L_1 regularisation, using the implementation in LibLinear.[6]

CRF: A first-order conditional random field classifier, trained with L_1 regularisation, using the implementation in Mallet.[7]

In both cases, the predicted labelling for a test document is given by the most probable (Viterbi) sequence according to the trained model. We use the following feature sets:

[5] In order to address concerns about the suitability of the t-tests under non-normality, we replicated the tests using Wilcoxon's signed-ranks test as recommended by Demšar (2006); the results were identical.

	LR				CRF			
Model	Acc	P	R	F	Acc	P	R	F
BASELINE	0.83	0.71	0.70	0.70	0.85	**0.75**	0.64	0.67
+BOILERPLATE-LDA	**0.84**	**0.72**	**0.71**	**0.71**	**0.86**	0.74	**0.65**	**0.68**
+LDA-BAG (50)	0.83	0.69	0.68	0.68	0.84	0.73	0.62	0.64
+LDA-BAG (100)	0.83	0.69	0.69	0.69	0.84	0.72	0.64	0.66
+LDA-MAX (50)	0.83	0.71	0.69	0.69	0.85	0.72	0.64	0.66
+LDA-MAX (100)	**0.84**	0.71	0.69	0.70	0.85	0.74	0.63	0.66

Table 2: Results of the supervised evaluation

BASELINE: Our baseline set of features is a standard set for supervised argumentative zoning: all unigrams and bigrams in the sentence, all part-of-speech tags in the sentence and a location feature computed by dividing the abstract into 5 bins.

+BOILERPLATE-LDA: The baseline model with additional features corresponding to the zone index assigned by BOILERPLATE-LDA to the sentence. We set $|Z| = 10$, $|T| = 100$ since that setting performed best in the clustering evaluation. As before, we use the output of three independently learned sampling chains, giving each sentence three zone features; the classifier should learn which chains are better than others during training.

+LDA-BAG: The baseline model with additional features derived from standard Latent Dirichlet Allocation models trained on the same corpus as BOILERPLATE-LDA. As LDA assigns a topic to each word in a sentence, we add all topics assigned to all words in the sentence as additional features. As above, we use the output of three sampling chains. We report results for models with 50 topics and 100 topics.

+LDA-MAX: The baseline model with additional features derived from LDA models. Here each model assigns each sentence the single topic assigned to the greatest number of words in the sentence (ties are broken randomly).

5.3.3 Results

Results for the supervised evaluation are presented in Table 2. +BOILERPLATE-LDA is the only augmented feature set that consistently gives an improvement over the baseline features. The improvements in accuracy are statistically significant ($p < 0.01$). In every case but one (which is not statistically significant), the LDA models fail to improve on the baseline in either accuracy or F-Score, showing that the latent structure induced by BOILERPLATE-LDA captures aspects of rhetorical language that are not captured by topical word clustering.

6 Conclusion

We consider the work presented in this paper to be a first step towards the ambitious goal of inducing latent descriptions of the templates used by scientists and writers in other fields. We have shown how our hypothesis about the generality of rhetorical language allows the construction of models that can separate out topical and rhetorical language use. One focus for future work will be to enrich the model structure; an approach based on adaptor grammars (Johnson et al., 2006) could be used to break the reductive unigram assumption in BOILERPLATE-LDA and identify multiword collocations that carry rhetorical information. Another focus will be to broaden our understanding of how unsupervised rhetorical models trained on large corpora can improve the robustness of supervised systems. For example, we have observed that lexicalised AZ classifiers trained on texts from one scientific domain will often perform poorly on texts from another domain; unsupervised models have the potential to induce relevant lexical commonalities across domains.

Cross-lingual Coreference Resolution of Pronouns

Michal Novák and Zdeněk Žabokrtský

Abstract

This work is, to our knowledge, a first attempt at a machine learning approach to cross-lingual coreference resolution, i.e. coreference resolution (CR) performed on a bitext. Focusing on CR of English pronouns, we leverage language differences and enrich the feature set of a standard monolingual CR system for English with features extracted from the Czech side of the bitext. Our work also includes a supervised pronoun aligner that outperforms a GIZA++ baseline in terms of both intrinsic evaluation and evaluation on CR. The final cross-lingual CR system has successfully outperformed both a monolingual CR and a cross-lingual projection system.

1 Introduction

Coreference resolution (CR) is a well-established task in the field of Natural Language Processing (NLP). The majority of papers published so far has focused on the monolingual CR, mostly experimenting on the English data. An important step towards multilingual CR was the CoNLL-2012 Shared Task in Modeling Multilingual Unrestricted Coreference in OntoNotes, where the participants were asked to build a CR system that could be applied on three typologically different languages contained in the OntoNotes corpus (Hovy et al., 2006): English, Chinese, and Arabic.

Same just as in other NLP tasks such as part-of-speech tagging or parsing, recent years have witnessed a rising interest in cross-lingual projection techniques, mostly aiming at under-resourced languages.

However, little attention is paid to leveraging cross-lingual information for CR in two resource-rich languages. This is probably due to lack of bilingual resources annotated with coreference since such techniques would require rich linguistic annotation on both sides of the bitext. Moreover, to solve this issue using a supervised learner, one needs the gold standard of coreference at least on the target side of the bitext. On the other hand, given such data, the typological differences in languages can be exploited to aid a CR system to perform better than if CR is performed independently for each language.

The motivation for solving this task is threefold. Firstly, even though Statistical Machine Translation (SMT) has been attracting interest of the community for years, most systems do not take information beyond the sentence boundary into account, leaving the issues of discourse coherence unresolved. Having a better-quality bitext with coreference resolved could drive research in discourse-aware SMT forward. Secondly, although inter-sentential relations are neglected in SMT, current phrase-based system unintentionally resolve some of the coreference links within the sentence, using just the power of phrases. This might be leveraged by using the SMT output instead of a human-translated output in a cross-lingual CR scenario. Finally, even monolingual CR may be improved by applying semi-supervised learning methods in a smart way on a large bilingual corpus with automatic rich annotations, such as CzEng 1.0 (Bojar et al., 2012).

Our work examines cross-lingual CR on the Czech-English language pair. We focus on CR of English pronouns, particularly the 3rd person *central pronouns*. Central pronouns is a term coined by Quirk (1985) embracing personal, possessive and reflexive pronouns. For the sake of simplicity, we will denote

Proceedings of COLING 2014, the 25th International Conference on Computational Linguistics: Technical Papers, pages 14–24, Dublin, Ireland, August 23-29 2014.

3rd person central pronouns by the word *pronouns* in the following. We ignore noun phrase coreference for two reasons. First, there has been no data set available for the Czech-English language pair with noun phrase coreference annotated, yet. Second, the language differences between languages show more clearly on pronouns than on nouns, as pronouns tend to be more constrained by various grammar rules across different languages.

Czech and English are typologically distant languages, which is also reflected in different behavior of pronouns. A cross-lingual CR system could substantially benefit from the necessity of the anaphor and its antecedent to agree in gender. Czech uses grammatical genders which are more evenly distributed among nouns than the notional genders[1] used in English, where male and female gender[2] are solely allocated to living objects. However, benefiting from the pronoun's gender becomes problematic for personal pronouns in subject position which are usually dropped from the surface representation in Czech. If their governing verb is in the past tense, the correct gender can be reconstructed from its form. With the verb in present or future tense, the pronoun's gender remains hidden. Possessive pronouns are used to a greater extent in English than in Czech. Same as articles, they play the role of determiners whereas in Czech, the determination and possession must be understood from the context. A missing Czech counterpart of an English possessive pronoun may indicate its antecedent to be in the same sentence. Moreover, Czech uses reflexive possessive pronouns, whose antecedent is easier to detect than for non-reflexive pronouns. On the other hand, English reflexive pronouns, unlike the Czech, carry gender and number information the resolver can benefit from.

In this work, we make to our knowledge a first attempt to leverage the language differences using a machine learning approach to improve CR on bitexts. To achieve this goal, we create a supervised CR model, proposing two sets of cross-lingual features: projected features used for Czech CR and an indicator feature of a projected Czech coreference link obtained by a Czech CR system. Note that for the latter set (actually comprising only a single feature), the Czech CR system would require gold annotation of Czech coreference. We did not consider new features that would address specific Czech-English correspondences.

The fact that a Czech counterpart is missing for many English pronouns has a negative effect on traditional unsupervised alignment approaches. We address this issue by a supervised aligner of pronouns that incorporates the result of the traditional aligner as a feature and adds other features that help detect the true Czech counterparts of English pronouns.

The structure of this paper is as follows: After introducing related work in Section 2 and describing the data used in experiments in Section 3, we present the design of a supervised approach to improve English pronoun alignment in Section 4. Section 5 describes the cross-lingual CR system and the experiments conducted with it. Finally, we discuss the main observations made in the experiments in Section 6 and conclude the paper in Section 7.

2 Related work

The task of coreference resolution has been studied for a few decades, with supervised systems dominating the field. The most popular approaches have been thoroughly summarized by Ng (2010).

The system for English CR we use has been built for automatic coreference annotation in the Czech-English parallel treebank CzEng 1.0 (Bojar et al., 2012). It is an implementation of the so-called mention ranking model, first introduced by Denis and Baldridge (2007).

Parallel bilingual data is often exploited to solve well-known tasks such as part-of-speech tagging (Das and Petrov, 2011), named entity recognition (Kim et al., 2012), name tagging (Li et al., 2012), and semantic role labeling (Zhuang and Zong, 2010). Undoubtedly, this approach is most popular with parsing. Joint parsing of both the source and the target text along with searching for the best alignment between the trees has been approached in a more (Burkett et al., 2010) or less (Smith and Smith, 2004; Burkett and Klein, 2008) integrated approach. However, much closer to our work is the research on

[1] "Nouns are classified semantically according to their coreferential relations with personal, reflexive and wh-pronouns." (Quirk et al., 1985, p.314)

[2] Quirk (1985) uses these terms instead of terms masculine and feminine related to grammatical gender.

bilingually-informed parsing by Haulrich (2012), in which English trees are used to enrich the feature set for a Danish parser and vice-versa. Rosa et al. (2012) explored the same approach on the Czech-English language pair. Moreover, they adapted this technique to parse the output of an SMT system.

As for coreference resolution in a bilingual scenario, most works focus on coreference projection (de Souza and Orsan, 2011; Rahman and Ng, 2012; Ogrodniczuk, 2013). Research on cross-lingual CR has been inhibited by the lack of coreference-annotated parallel corpora. There are only few such corpora, for instance an English-Romanian corpus containing full hand-annotated coreference chains including noun phrase coreference (Postolache et al., 2006) and two corpora with pronoun coreference annotations – Prague Czech-English Dependency Treebank 1.0 (Hajič et al., 2012, PCEDT) and the recently published English-German corpus ParCor 1.0 (Guillou et al., 2014).

However, the only attempts at cross-lingual CR date back to the time before these corpora were released. Harabagiu and Maiorano (2000) designed a CR system for English-Romanian bitexts while Mitkov and Barbu (2003) focused on the English-French language pair. Both extended their rule-based monolingual CR systems to apply some high-precision rules from one language to enhance the result in the other language. They both reported an improvement of about 4% in precision compared to the monolingual systems.

As concerns a machine learning approach, in the work by Veselovská et al. (2012), PCEDT was employed in related tasks – to identifying types of the English personal pronoun *it* and Czech types of the unexpressed subject. The tasks have been addressed by the isolated monolingual systems as well as by taking advantage of the features from the other language.

3 Main source of the data

As mentioned in Section 2, Czech is one of a few languages for which a coreference-annotated parallel corpus has been built – The Prague Czech-English Dependency Treebank (Hajič et al., 2012, PCEDT).[3]

PCEDT is a manually annotated Czech-English parallel treebank comprising over 1.2 million words for each language in almost 50,000 sentence pairs. The English part contains the entire Penn Treebank–Wall Street Journal Section (Linguistic Data Consortium, 1999) transformed into dependency trees, whereas the Czech part comprises the translations of all the texts from the English part. The data from both parts are annotated on three layers of linguistic description following the Prague tectogrammatics theory (Sgall, 1967; Sgall et al., 1986) – the morphological layer (where each token from the sentence gets a lemma and a POS tag), the analytical layer (surface syntax in the form of a dependency tree, where each node corresponds to a token in the sentence) and the tectogrammatical layer. Tectogrammatical representation of a sentence is a dependency tree, where only content words have their own nodes; on the other hand, it contains additional nodes, e.g., for pronouns unexpressed on the surface. This is also the layer where the coreference relations are annotated. PCEDT includes annotation of pronoun coreference and the so-called grammatical coreference[4] for Czech as well as English.

For the purpose of this work, we ignore all annotations originally provided by PCEDT. Annotations on the tectogrammatical layer, which is in the center of this work's attention, are mostly manual there. But to truly simulate the real-world scenario when given just a pair of parallel texts, we need to replace them with ones carried out in a fully automatic manner. The only two exceptions, where we employ the gold annotations, are the relations we aim to model, i.e. coreference links and our own annotation of alignment for English personal pronouns (see Section 4.1).

3.1 Fully Automatic Annotation

We have conducted automatic linguistic analysis on both the English and the Czech part of PCEDT, transforming the individual sentences into multi-layer dependency tree structures based on the Prague tectogrammatics theory. The analysis was carried out within the Treex framework (Popel and Žabokrtský, 2010).

[3] http://hdl.handle.net/11858/00-097C-0000-0015-8DAF-4

[4] Its antecedent is imposed by the grammar of the language, e.g. coreference of relative pronouns.

Treex is a multi-purpose open-source framework for NLP applications development, which integrates a wide range of modules, such as tools for sentence splitting, tokenization, morphological analysis, part-of-speech tagging, shallow and deep syntax parsing, named entity recognition, anaphora resolution, among others.

Moreover, we performed an unsupervised word alignment on the complete PCEDT using the MGIZA++ tool (Gao and Vogel, 2008), which is a multi-threaded version of the popular GIZA++ (Och and Ney, 2000) that supports applying a saved model on a new sentence pair. We used a model trained on CzEng 1.0, which is about 300 times bigger in terms of the number of sentence pairs. The resulting alignment of the `intersection` and `grow-diag-final-and` types was subsequently projected onto the tectogrammatical layer. Furthermore, a simple heuristic was applied to find the English counterparts for reconstructed Czech personal pronouns. We denote this alignment as the *original* in the following.

4 Supervised alignment

The alignment described in the previous section is sufficiently accurate for content words, such as verbs, nouns, and adjectives. However, errors become more frequent as we move to pronouns. Some reasons for this have already been outlined in Section 1, i.e. dropped subject personal pronouns and omitted possessive pronouns in Czech. In addition, English uses a pleonastic variant of the pronoun *it*, which also has no correspondence in Czech. Personal pronouns function in a sentence as a replacement of nouns. Thus, it is no exception if a pronoun is translated into a noun. And finally, the translation may be reworded to such an extent that the pronoun would carry no valuable information, and it disappears. All these cases are difficult for GIZA++ to tackle.

The pronoun correspondence problem has been already faced concerning the alignment of the personal pronoun *it* by Novák et al. (2013). The authors tried to find the Czech counterpart of *it* by taking the node that is aligned to the parent of *it* on the Czech side and picking the argument of the aligned node that agrees on the semantic role with the particular *it*. This approach assumed that the unsupervised alignment of the parent, which is likely to be a content word, is of higher quality than the alignment of *it* itself. Furthermore, it relied on high-accuracy semantic role labeling, which could only be justified because the experiments were conducted on data manually annotated with semantic roles.

As we are working with fully automatic annotations (i.e., much less reliable) and a wider range of words to align, we cannot just copy this rule-based approach. However, we can take a more robust approach of supervised machine learning and transform Novák et al.'s rule to one of the features in our alignment model.

In Section 4.1, we describe the manual annotation of alignment, then introduce the supervised model in Section 4.2, using features described in Section 4.3. Finally, we show the evaluation results of the alignment model in Section 4.4.

4.1 Manual Annotation of the Data

Supervised learning requires that the training data are manually labeled with a target variable. For this purpose, we set aside the section 19 of PCEDT. In this data, all occurrences of English personal pronouns have been coupled with its Czech counterpart by one human annotator. If no suitable Czech expression was found, the annotator identified a possible cause of the missing counterpart. The causes were then categorized into three classes – pleonastic *it*, missing possessive pronoun and missing correspondence due to translation rewording. So far, we do not distinguish these classes in our models and treat them in the same manner.

We managed to align 471 occurrences of personal pronouns, which account for over 50% of all occurrences in the section. The overall statistics of how English personal pronouns are translated into Czech is shown in Table 1.

It shows that more than 55% of English personal pronouns are dropped from the surface representation of the Czech sentence, though still present in its deep structure. In contrast, English pleonastic pronouns are not present even there. An interesting observation is that more than half of English possessives are either translated as reflexive possessives or completely missing in the Czech sentence. All these

CS\EN	personal	possessive	reflexive	Total

no possessive		38		38
Total	262	201	8	471

Table 1: The statistics on the correspondence of English personal pronouns to their Czech counterparts. The last three Czech categories indicate the reason why there is no corresponding word in Czech for an English pronoun.

phenomena might in the end be a source of helpful information to the CR system.

4.2 Model

The nature of the task of aligning a given English pronoun to its Czech counterpart is to pick the best-fitting one from a bunch of candidates. The set of candidates consists of all tectogrammatical nodes in the aligned Czech sentence. To allow the system to select no correspondence for a pronoun, we add a special candidate representing the null alignment.

We represent the candidate ranking task as a discriminative log-linear model trained in a cost-sensitive, one-against-all strategy with label-dependent features (`csoaa-ldf`) provided by the Vowpal Wabbit[5] machine learning toolkit. The feature weights are optimized by running stochastic gradient descent in 40 passes over the training data.

4.3 Features

The feature set consists of the following types of features, which consider an English pronoun and a Czech candidate from the corresponding Czech tree:

- **Original alignment features:** presumably the most valuable set of features. It indicates if there is a link between the two nodes in the original alignment and if there is any between their parents.

- **Graph features:** we designed these features to somehow reflect the distance between the nodes. The pair of aligned tectogrammatical trees is treated as a bipartite graph and a shortest path between the nodes is found using a sequence of dependency edges and a single alignment link. We applied the Dijkstra algorithm to find the shortest path. We ensure that it only uses a single alignment link by setting large weights to alignments and small weights to dependency edges, i.e., 100 and 1, respectively. The features then comprise the length of the shortest path and the sequence of edge labels (parent, child, alignment).

- **Grammatical features:** these include lemmas, part-of-speech tags, reflexivity indicators, semantic role labels both for each of the nodes individually and as a concatenation of the two.

- **Combined features:** these features combine selected features from the types mentioned above. The concatenation of parents' alignment and semantic role correspondence mimics the rule Novák et al. (2013) used to get better Czech counterparts for English *it* (see Section 4). Furthermore, features combining lemmas with direct alignment or alignment through parents are included.

Method	Train				Test			
	A	P	R	F	A	P	R	F
ORIGINAL	–	–	–	–	73.04	75.55	82.40	78.83
SUPERVISED	88.37	90.18	90.34	90.26	84.50	88.52	86.40	87.45

Table 2: Evaluation results of English-to-Czech pronoun alignment. The quality is measured in terms of accuracy (A), precision (P), recall (R), and F1-score (F).

4.4 Experiments and Results

The small amount of manually annotated data led us to evaluate alignment models by 10-fold cross-validation, with the results on the train and test partitions averaged over all folds.

We measured the quality of produced the alignment links in terms of both accuracy and F1-score, i.e., as the harmonic mean of precision and recall. While accuracy positively scores also the cases when a node is correctly labeled as having no alignment, precision and recall neglect these cases at all, thus describing how good a method is in finding the correct counterpart for a node.

Table 2 shows the performance of the supervised model with the best combination of features and learning method parameters and compares it to the original alignment described in Section 3.1. It shows an improvement of about 9% absolute in terms of both accuracy and F-score.

5 Cross-lingual coreference resolver for English

In this section, we describe cross-lingual coreference resolution. The CR system we use definitely does not aim to compete with current state-of-the-art systems. However, for the purpose of research on cross-lingual CR, it can be employed as a reasonable baseline.

In Section 5.1, we describe the supervised CR model trained and tested on the data described in Section 5.2. We elaborate more on the design of English and aligned features in Section 5.3 and Section 5.4, respectively. Finally, several variants of the CR system are evaluated and compared in Section 5.5.

5.1 Coreference model

Our resolver employs a supervised model denoted as *mention ranker* by Ng (2010). Its advantage lies in judging all antecedent candidates simultaneously, and then picking the candidate with the highest score as the predicted antecedent. However, it is unable to exploit features that describe already formed clusters of mentions belonging to the same entity. A typical issue related to ranking models is how to deal with non-anaphoric mentions. We use the approach introduced by Rahman and Ng (2009) – adding a special candidate that indicates no anaphor.

Since this work focuses only on the so-called pronoun resolution, all the anaphor candidates are English 3rd person central pronouns, i.e. personal, possessive and reflexive pronouns.

For every anaphor, we collect in the set of its antecedent candidates all semantic nouns[6] from the previous sentence and the part of the current sentence prior to the anaphor.

CR can be treated as a ranking task, so we represent it in the same way as we handled alignment in Section 3.1 – as a discriminative log-linear model trained in the `csoaa-ldf` strategy by the Vowpal Wabbit tool. The feature weights are optimized by running stochastic gradient descent in 20-80 passes (the number differs across the experiments) over the training data.

5.2 Data

Models for coreference were trained on data extracted from sections 00–18 of the automatically analyzed PCEDT (as described in Section 3). Sections 20–21 have been employed as development testing data and Sections 22–24 as evaluation testing data. The development set has been used to select the best configuration, which was subsequently tested on the evaluation set. The training, development, and evaluation set consist of 19,294, 1,988 and 2,591 instances with 86%, 67%, and 73% anaphoric instances, respectively.

[6]Semantic nouns are all nouns as well as pronouns acting as a noun.

5.3 English Features

A wide range of features used by us had already been proven to be beneficial for the task of CR in multiple prior works. The majority of the features presented here have already been used in the CR system for Czech (Nguy et al., 2009); we keep just the language-independent. Furthermore, several grammatical and positional features proposed by Charniak and Elsner (2009) have been added. Finally, the feature set has been enriched with the information on named entities and WordNet[7] classes. All the features disregard dependent members of a mention, describing just the head of the mention. They can be divided into several categories:

- **Distance features:** number of sentences, clauses, and words between the anaphor and the antecedent candidate; the order of the candidate,
- **Grammatical features:** morphological number and gender of both the anaphor and the antecedent candidate, agreement in gender and number; part-of-speech tag,
- **Function features:** they exploit dependency labels on the analytical layer and semantic roles on the tectogrammatical layer; they also include an indicator of whether the mention plays a role of an argument or an adjunct in the governing phrase,
- **Parent features:** the features of both nodes' parents, e.g. their lemmas or semantic roles, are compared; an indicator of whether a mention is in coordination,
- **Semantic features:** WordNet classes the head word is assigned to,
- **Named entity features:** the named entity category and subcategory returned by Stanford named entity recognizer.[8] This includes also the indicator of whether the mention is a name of a person,
- **Charniak features:** anaphor type (pronoun in subject position, in object position, possessive pronoun, reflexive pronoun, other); antecedent type (noun, pronoun, other); antecedent syntactic type (subject, object, prepositional phrase, other).

We denote this feature set as EN in all our experiments.

5.4 Alignment features

The features from the Czech nodes aligned to the given English anaphor and antecedent candidate are obtained by moving to the corresponding Czech nodes and extracting the features as though we are trying to resolve a Czech coreference link. As outlined in Section 1, we designed two sets of features: CS and CS-COREF.

The CS set consists of features introduced by Nguy et. al (2009). Most of them, namely the categories of distance, function, and parent features, are extracted in the same manner as the English ones in the previous section. Grammatical features also contain the full positional morphological tag as designed by Hajič (2004). Semantic features employ a different knowledge base, replacing WordNet by the Czech portion of EuroWordNet (Vossen, 1998). In addition to the features more or less shared with the English side, the Czech feature set includes a probability estimate of the antecedent candidate co-occurring with its governing verb. This statistics has been collected on Czech National Corpus (CNC, 2005).

The CS-COREF set consists of a single binary feature indicating if there is a coreference relation between the nodes predicted by the Czech CR system (Nguy et al., 2009), or not.

5.5 Experiments and Results

The different feature sets proposed in the previous sections suggest an obvious set of experiments. The system trained only on the monolingual EN features is put as a baseline.

The rest our experimental setups use alignment features, forming three combinations with EN features: EN + CS, EN + CS-COREF, and EN + CS + CS-COREF. Moreover, these three experiments can be run on the data provided either with the original or supervised alignment, which serves as extrinsic evaluation of alignment approaches. This allows us to confirm or deny the hypothesis that the alignment plays a significant role in cross-lingual CR (see Section 4).

For comparison, we also evaluated the system that simply projects coreference links obtained by the Czech CR system to English.

The performance of a CR system is usually measured by scores that treat CR as a clustering problem, e.g., MUC, B^3, CEAF. As this work focuses merely on a subset of coreference expressions – pronouns – and we only compare different feature sets trained in the same framework, we resorted to the simplest metrics with a sufficient expression power. For each English pronoun we test if its predicted antecedent hits any of the true antecedents within the window of the current and the previous sentence. Given this indicator we calculate precision, recall, and F1-score, which takes into account only the nodes for which a relation with another node exists – referential pronouns in this case (similarly to the alignment evaluation in Section 4.4). Likewise, in order to assess quality of detecting non-referential pronouns, accuracy is computed as well.

The final results are shown in Table 3. The overall higher numbers on the evaluation set than on the development set probably result from a different proportion of non-anaphoric pronouns (see Section 5.2). The smaller difference in F1-score than in accuracy also supports this explanation.

The coreference projection scores a great deal below the baseline, which suggests that this approach is worth using only if manual annotation for at least a small amount of target language data (English in our case) is extremely expensive.

As for the cross-lingual CR on the original alignment, all three feature set combinations have beaten the baseline. The EN + CS-COREF system confirmed the added value of the CS-COREF feature, which, unlike the CS feature set, conveys latent information on true Czech coreference links. Even the combination of all features performs worse than CS-COREF alone.

Moving to the experiments with supervised alignment, we can see the findings from Section 4.4 confirmed also in the extrinsic evaluation. All three systems outperform not only the baseline, but also all the systems working on the original alignment. Moreover, both accuracy and F1-score order the three feature combinations in the expected way, where the overall winner improves over the baseline in more than 1% absolute. This improvement is significant[9] at p-level $p \leq 0.1$ but not at p-level $p \leq 0.05$.

6 Discussion

Using information from Czech parallel texts in English CR led to an improvement in terms of automatic measures. To see what the main aspects in which the Czech text positively impacts the CR performance are, we compared the output of the system trained only on the EN features with systems working on the EN + CS and EN + CS-COREF feature sets. We used the results of the experiments run on the development set with supervised alignment for this comparison.

Out of 1988 coreference instances in the development set, the EN + CS system improved the output in 49 cases, while it worsened the output in 23 cases. The rest remained unchanged. Likewise, the EN + CS-COREF system scored better than the EN one in 63 instances, while it failed in 39 instances.

The inspection of 10% instances for which the systems differed revealed that the cases when the cross-lingual system scored better than the monolingual concur with the language differences described in Section 1. We found that in these cases, the pronoun is often a pleonastic *it* or a possessive pronoun with a Czech reflexive possessive counterpart. Finally, we noticed improvements in cases where the Czech antecedent is easier to determine due to agreement in gender and number.

[9] Significance has been calculated by bootstrap resampling using 100,000 samples.

Setup	Train				Dev				Eval			
	A	P	R	F	A	P	R	F	A	P	R	F

EN + CS + CS-COREF	80.75	81.52	87.61	84.46	62.27	61.33	80.96	69.79	64.03	63.59	79.57	70.69
Supervised alignment												
CS-COREF projection	30.74	49.91	24.87	33.20	36.60	41.38	27.61	33.12	33.60	41.85	23.98	30.49
EN + CS	83.19	83.98	89.73	86.76	62.27	61.42	80.60	69.72	64.53	64.13	79.09	70.83
EN + CS-COREF	79.27	80.20	85.89	82.95	62.17	61.27	81.11	69.81	64.65	64.11	79.67	71.05
EN + CS + CS-COREF	81.99	82.78	88.53	85.56	62.68	61.59	81.62	70.20	64.69	64.38	79.67	71.22

Table 3: Evaluation results of monolingual CR, CR via projection, and cross-lingual CR system trained and tested on the data with both the original and supervised alignment. Performance is measured in terms of accuracy (A), precision (P), recall (R) and F1-score (F).

We did not encounter an example of improvement for an English possessive pronoun having no Czech counterpart. We might have inspected too little data for it to appear. However, these cases may get covered after the features combining English and Czech features will be introduced.

7 Conclusion

This work introduced a largely unexplored task in the field of CR – cross-lingual CR. Given a Czech-English bitext, we sought to improve the performance of an English pronoun CR system by enriching the feature set with features from the aligned Czech text. Consistent improvements over the monolingual system confirmed that cross-language differences in pronoun behavior are big enough to affect the result. Furthermore, we have found that the quality of alignment is vital for this task.

In future work, we plan to apply this approach on a much larger parallel corpus and employ semi-supervised techniques to improve cross-lingual as well as monolingual CR. Moreover, human translation in the bitext can be replaced with the output of SMT system to see if we can produce valuable features for CR from the machine-translated source text.

Acknowledgments

Abstract

This papers presents a context-aware NLP approach to automatically detect noteworthy information in spontaneous mobile phone conversations. The proposed method uses a supervised modeling strategy which considers both features from the content of the conversation as well as contextual information from the call. We empirically analyze the predictive performance of features of different nature on a corpus of mobile phone conversations. The results of this study reveal that the context of the conversation plays a crucial role on boosting the predictive performance of the model.

1 Introduction

More than 6 billion people worldwide use their cellphones daily for a variety of purposes: contacting colleagues, relatives or friends, doing business, getting help in emergency situations, etc. Previous work (Carrascal et al., 2012) has shown that almost 40% of users frequently feel the need to recall bits of information from their phone conversations and that 27% of the users consider the recall task to be difficult, mainly because taking notes during a mobile phone call is not always possible (*e.g.* hands not free, lack of time or devices for note-taking). In a related user study, Cycyl *et al.* reveal that users are often engaged in concurrent tasks during mobile phone conversations (*e.g.* walking, jogging, driving, cooking, etc), which makes taking notes an unfeasible task (Cycil et al., 2013).

In this setting, information extraction techniques could be applied to automatically detect noteworthy information from mobile phone conversations. Related studies have focused on detecting noteworthiness from meeting transcripts (Banerjee and Rudnicky, 2009). However, very little work has been done to date to identify this kind of information in other types of human communication, such as spontaneous phone conversations.

In this paper, we present a data-driven information extraction approach aimed at automatically detecting fragments of phone conversations worth annotating for future recall, *i.e. noteworthy*. These *call notes* could then be presented to the users to enable fast browsing of their conversation history, and leveraged to design efficient information interaction techniques for supporting smart user interfaces.

Given the particular characteristics of mobile phone calls, detecting noteworthiness in them is challenging at many levels. First, the audio is captured in a natural environment rather than in controlled settings, which results in noisy signals, and consequently in noisy transcriptions. Second, the conversations are highly fragmented due to their spontaneous nature. Finally, at a conceptual level, judging which pieces of information are noteworthy is a very subjective task, as emerged in (Banerjee and Rudnicky, 2009), who investigated the feasibility of the task by conducting a Wizard of Oz-based user study.

Our noteworthiness modeling approach considers a supervised learning paradigm which takes into account two types of information: (1) Contextual information both from the call (*where, when, to whom,* ...) and the users (*gender, age,* ...); and (2) Content information of the conversation. The combination

* The work was conducted while the author was intern at Telefonica Research, Barcelona, Spain.

Proceedings of COLING 2014, the 25th International Conference on Computational Linguistics: Technical Papers, pages 25–36, Dublin, Ireland, August 23-29 2014.

of both sources of information enhances the flexibility of the model to accurately predict noteworthiness in different use scenarios.

The main contributions of this paper are:

i) We propose and evaluate a supervised machine learning model to automatically detect noteworthy segments of phone conversations. Our approach adopts a hybrid strategy to model conversations exploiting both *content* and *context*-related information.

ii) We propose a new set of content and context-based features specifically designed to detect noteworthy information in our corpus of real-world cellphone conversations, and compare their effectiveness

iii) We provide a discussion of the results, derived from our quantitative and qualitative analyses.

The paper is structured as follows. Relevant previous work is presented in Section 2. Section 3 describes the corpus of phone conversations and the annotations provided by the participants. In Section 4 we describe in-depth the extracted features. Our experimental validation and results are presented in Section 5. Finally, Section 6 summarizes our findings and highlights some lines of future research.

2 Related work

Noteworthiness detection in conversations can be considered to be a particular form of summarization: the aim is to summarize the conversation by keeping only the *relevant* pieces of information that the user would like to refer to at a later time. Although related, the main distinction between automatic summarization and detection of noteworthy information lays in the notion of *relevance*. The former aims at generating a comprehensive record of the conversation, while the latter considers only fragments worth registering for future recall.

Considerable research activity has recently been devoted to automatic text and speech summarization (Maskey and Hirschberg, 2003). Many approaches have been proposed in the literature, including cluster (Zhang et al., 2005) and graph-based methods (Garg et al., 2009; Wang and Liu, 2011) and machine learning techniques (Jian Zhang et al., 2007; Maskey and Hirschberg, 2006; Galley, 2006), where the task is tackled as a binary classification problem considering whether the sentence is a good candidate for a summary or not. In addition, different types of features have been used, including lexical, acoustic and structural characteristics (Xie et al., 2008; Maskey and Hirschberg, 2005). Recent works have been focused on adapting summarization to the social context, exploiting user generated contents associated with the documents (Yang et al., 2011; Hu et al., 2012). Implicit and explicit community feedback in online collaborative websites have also been leveraged to detect highlights of media assets (San Pedro et al., 2009).

However, few studies have focused on noteworthiness detection. Banerjee *et al.* investigate the feasibility of discovering noteworthy pieces of information in meetings by means of a Wizard of Oz-based user study where a human suggested notes to meeting participants during the meeting. The authors found that the human annotator obtained a precision of 35% and a recall of 41.5%. In the same work, Banerjee *et al.* reports a low inter annotator agreement (IAA) in noteworthiness discovery. In a related work –probably the most relevant prior-art to our work, the authors apply extractive meeting summarization techniques to automatically detect noteworthy utterances in meetings (Banerjee and Rudnicky, 2008). They train a Decision Tree classifier over a collection of 5 meetings, obtaining an F-score of 0.14. This result highlights the difficulty of the task at hand and motivates to explore alternative approaches.

To overcome the difficulties posed by this task we propose two main contributions: 1) the use of novel features engineered ad-hoc for this task, and 2) the use of contextual information. While the former adapts the document representation to the specific problem setting, the latter allows to enhance the representation with orthogonal information which many times provides a higher discriminative power. This approach has been used successfully in related fields; for instance, in information retrieval tasks rich multimodal queries have been shown to effectively boost the retrieval performance compared to pure textual queries (Yeh et al., 2011).

3 Corpus Collection

We used a corpus of cellphone conversations collected in a previous study (Carrascal et al., 2012). In this study, a large sample of mobile phone conversations was recorded, semi-automatically transcribed[1] and manually annotated for relevance by their participants. Over 64 days, 796 mobile phone conversations from 62 volunteering subjects (20 female) were recorded. All the participants were Spanish native speakers, and the conversations were recorded and transcribed in Spanish. Metadata about the call (*e.g.* duration, date, time) was also stored along with the actual conversation and its transcript. More details about the corpus collection process can be found in (Carrascal et al., 2012).

All the participants were first asked to fill out a pre-study questionnaire where they provided some personal information, including gender, marital status, education and income. Then they were asked to annotate what parts of their calls that they would like to take a note of: *i.e.* noteworthy fragments of conversations. To this end, participants used a Web-based interface that gave them access to their calls and allowed them to highlight with the mouse the parts of the transcript that they considered to be worth keeping for future reference.

We used these annotations as the ground truth for the studies presented in this paper, considering them as the ideal noteworthy parts of the calls. For privacy reasons, due to the sensible nature of the data (i.e. private phone conversations) we could not consider alternative ground truth generation schemes, for instance collecting annotations from users other than the callers themselves.[2]

Finally, the participants were asked to fill out a questionnaire after annotating each call, which was used to collect contextual information, including: location of the call (*i.e at work, at home, while commuting, while doing shopping, while exercising*), and category of the call (*i.e. discuss a topic, taking an appointment, give/receive information, asking a favor, social*).

3.1 Characteristics of the Corpus

The original conversation collection consists of a total of 796 conversations, of an average length of 178 seconds ($s = 384$ sec.). We pre-filtered this original set to exclude calls with problems in the transcript (*e.g.* empty transcript, only one speaker audible, etc). Out of the entire corpus we finally selected 659 conversations. We denote this subset of the corpus as the $\mathcal{G}$ dataset. The $\mathcal{G}$ dataset comprises $22,474$ turns, with an average of 34.10 ($s = 45$) turns per conversation. From these, only 671 are annotated as being noteworthy (2.98%), which represent an average of 1.02 turns ($s = 1.803$) per call. Given that the vast majority of turns (97.2%) are not annotated, this can be considered a highly unbalanced dataset, which makes the automatic modeling problem more challenging.

Hence, we considered a second dataset which included only the 295 calls from the $\mathcal{G}$ dataset containing at least one annotation. This second subset, denoted as $\mathcal{A}$ amounts for approximately 45% of the $\mathcal{G}$ dataset. The $\mathcal{A}$ dataset features $10,642$ turns, with an average of 36.07 ($s = 33$) turns per conversation. From these, again 671 (6.3%) are annotated, which represent an average of 2.275 ($s = 2.09$) per call. The $\mathcal{A}$ dataset is still highly unbalanced but significantly less than the $\mathcal{G}$ dataset. Table 1 summarizes the high level characteristics of each dataset.

		Turns		Annotated Turns	
	# Calls	Total	$avg.$ per call	Total	Fraction
$\mathcal{G}$	659	$22,474$	34.1 ($s = 45$)	671	2.9%
$\mathcal{A}$	295	$10,642$	36 ($s = 33$)	671	6.3%

Table 1: General statistics on $\mathcal{G}$ and $\mathcal{A}$ datasets.

Class	Annotations
I	*We are in front of the fruit shop*
RoA	*Tomorrow we go to look for the swimsuit*
RI	*Are you coming to eat? At what time*
O	*Sure, it's normal*

Table 2: Examples of annotations.

Given the complexity of the modeling problem, we studied the note taking behavior of participants to identify relevant patterns that would simplify the problem. To this end, we conducted a quantitative analysis of the note taking behavior of participants. We found that users tend to highlight complete

[1] Participants were given the opportunity to revise transcriptions during the annotation phase.

[2] Receivers of the calls were aware of the study and were given the possibility to not participate in the call, but were not directed involved in the study.

turns as relevant, instead of parts of the turns. On average, 66.57% ($s = 35.87$) of the words within an annotated turn are highlighted, with a median value of 80%. Hence, we decided to use *turns* –rather than individual words– as the unit to be automatically detected as noteworthy. Using this approach, a turn is considered to be noteworthy if it contains at least one annotated word.

3.2 Qualitative Analysis of the Corpus

Since our aim is to detect the noteworthy turns within a call, we conducted a preliminary qualitative analysis to understand the nature of the annotations entered by the participants in the study. We distinguished 4 types of annotations: *Giving Information (I)*, *Requesting Information (RI)*, *Reporting on an Action (RoA)* and *Other (O)*. Examples of these 4 types of annotations are presented in Table 2. We collected annotations from three collaborators of our lab for a total of 54 randomly selected turns from the $\mathcal{A}$ dataset (IAA, $Fleiss\ Kappa = 0.54$ (Fleiss, 1971)).

We found that 47% of the turns were classified as belonging to the *Giving Information* category, 22% of the turns to the *Request Information* category, 26% to the *Other* category, and only 3% were classified as *Report on an Action*. Intuitively, we had expected the *Giving Information* category to be the most common in the annotated turns. However, the results obtained show that the other types of annotations are also well represented in the data.

Two main interesting aspects emerge. First, while the vast majority of annotations correspond to turns where a piece of information is given (*e.g. We meet at 3pm*), turns where information is requested are also well represented in the sample. There are plausible explanations for this behavior, such as users trying to include more context in the annotations. Second, more than 25% of this manually annotated dataset was marked under the *Other* category, which includes turns with very diverse functionalities (*e.g.* greetings, statements of agreement). This reveals that participants tend to annotate turns with very diverse functional aspects, which poses a challenge to be added to the unbalanced nature of the dataset.

4 Feature Extraction

We follow a supervised machine learning approach to automatically detect noteworthy turns in conversations. In this section we describe the features that we compute to represent conversations and which have been engineered to capture information relevant to the problem at hand. We have divided the set of features into two categories: **C**ontent features, that we denote with the letter **C**, and conte**X**t features, that we denote with the letter **X**.

4.1 Content Features

Content features are computed by analyzing the content of the conversations. We use as input the textual information resulting from the semi-automatic transcription of the calls. Note that we do not make use of any conversational acoustic information. While the analysis of the acoustic signal may reveal additional cues useful for noteworthiness detection, it lies out of the scope of this work.

In order to extract features from the transcript, we first pre-proces the datasets (split in turns, lemmatized, PoS tagged). Also, we extract and classify Named Entities (NEs).[3] We extract 42 content-based features which include both variations of features previously used in the meeting summarization literature and novel features particularly adapted to our task. However, in contrast to related work on meeting summarization, we do not extract content features based on lexical similarity to the entire call or to the main topic of the call, under the intuition that the notion of noteworthiness depends on the user's needs rather than on the main topic of the conversation. In addition and for robusteness purposes, we decided not to rely on long distance dependency information (*e.g.* argument predicate relations) or deep syntactical parsing, which are sensitive to the quality of the transcription.

The resulting features are grouped into three main classes: **Turn-Based** (C-T), **Dynamic** (C-D), and **Conversational** (C-C). We compare them with a pure bag-of-words (BoW) representation. Table 3a provides a summary of all the content-based features used in our system. Where applicable, we experi-

[3] All pre-processing was performed using the Freeling Language Processing tools (Padro et al., 2010).

ment with two vector representations: binary and frequency-based. We will refer to these two different encoding schemes as **Bin** for the binary case, and **Freq** for the frequency case.

CONTENT FEATURES	
C-BoW (Bag of Words)	
BoW	BoW for all words (except hapax)
C-T (Turn-based)	
NE	Presence (or frequency) of NEs (Person, Location, Organization, Numbers, Dates, Misc.)
TLN	Turn length in # words normalized
PoS	PoS distribution
TF	Max and Mean term frequency
IDF	Max and Mean inverse document frequency
C-D (Dynamic)	
Rep	Repetition between t and t-1,t+1,t-2,t+2
Int	Presence (or total amount) of Int. pro./adj. in t-1
Q	Presence (or total amount) of question in t-1
C-C (Conversational)	
Dur	Duration of the call (# turns and # words)
Cent	Conversation centrality
Spk	Speaker
Dom	Speaker dominance

(a) Content Feature

CONTEXT FEATURES	
X-C (Call-based)	
X-C-T	Time of the call
X-C-Loc	Location of the call
X-C-Day	Day of the call
X-C-Obj	Objective of the call
X-U (User-based)	
X-U-G	Gender
X-U-A	Age
X-U -I	Income
X-U-E	Education
X-U-Ms	Marital Status

(b) Context Feature

Table 3: Content (a) and Context (b) based features.

4.1.1 Turn-Based Content features (C-T)

Turn-based content features take into account information related to individual turns. We distinguish lexical and non-lexical C-T.

Lexical content features: Lexical C-T features capture the lexical properties of a turn. We include NEs, such as *Locations, Organizations, Persons*, *Miscs* and *Numbers*, *Dates*, and temporal expressions. For each turn t, we detect the presence of any NE as well as the presence of individual classes of NEs. For each of these class of entities, we extract both a binary and a frequency feature vector. In the text summarization literature, the appearance of particular lexical phrases (*e.g. to summarize*) has been exploited to predict relevant sentences (Gupta and Lehal, 2010). In our study, attention has been given to the presence of temporal expressions under the intuition that temporal cues are good indicators of upcoming pieces of information (*e.g. The meeting is tomorrow*). We exploit temporal expressions, such as *today, tomorrow, etc*.[4]

Non-lexical content features: capture characteristics of the turn which do not involve lexical information, namely: turn length, Part-of-Speech (PoS) distributions and Tf-Idf descriptive statistics at the turn level.

In meeting summarization, the average length of a turn has been found to be a good feature to automatically create a summary of a meeting (Xie et al., 2008). In our dataset, preliminary analyses revealed that annotated turns tend to be longer in average. Hence, we include the turn length in the non-lexical content feature set. The turn length is given by the number of tokens per turn normalized over the average turn

[4]Note that, here and in the remainder of the paper, we report the English translations of the Spanish originals.

length (punctuation excluded). To further gauge discourse characteristics, we detect the distribution of PoS at the turn level: *i.e.* for each turn, the frequency of nouns, pronouns, adjectives, adverbs, interjections, verbs, prepositions and conjunctions is calculated. Finally, we compute the term frequency (Tf) and inverse document frequency (Idf) measures. In (Xie et al., 2008), authors report that Idf is among the most discriminative features in sentence selection for text summarization. We compute maximum and mean Tf and Idf values for each turn.

4.1.2 Dynamic content features (C-D)

Dynamic content features are designed to capture the semantic relationships between each turn and its precedent and subsequent turns. In particular we refer to relations such as lexical and topical cohesion, question-answer relationship, and the appearance of general cues that may anticipate relevant bits of information in the subsequent turn. We consider: *1)* the lexical and topical cohesion among consecutive turns (Repetitions); *2)* the appearance of general cues that may anticipate relevant bits of information in the subsequent turn (Interrogative Pronouns); *3)* the question-answer relationship among consecutive turns (Question).

Repetitions: words repeated by different speakers in consecutive turns. Participants of a conversation tend to align at several linguistic and paralinguistic levels in order to ease communication and increase mutual understanding (Pickering and Ferreira, 2008). This phenomenon has been investigated in terms of prosody, lexicon and syntax (Levitan and Hirschberg, 2011; Brennan, 1996; Bonin et al., 2013; Branigan et al., 2010). From a lexical point of view, the alignment mechanism, often referred to as priming, is realized by means of word repetitions among speakers. Many studies have investigated this phenomenon assessing correlation between priming and mutual understanding or dialogue success (Vogel, 2013; Reitter and Moore, 2007).

We exploit the priming phenomenon to detect concepts in the conversation that are considered important by both participants, relying on the fact that repeated words convey concepts that participants want to make sure they have been successfully communicated to their interlocutor. Given a dataset D, a turn in D, $t \in D$, and $t - i$ and $t + i$ turns in the context of t, we calculate the amount of repeated lemmas between t and $t-i$, and t and $t+i$ for $1 \leq i \leq 2$. In order to consider semantically meaningful repetitions, we take into account only content words (nouns, adjectives, adverbs, verbs) when they activate one of the C-T features described above. Being A the set of annotated turns, we noticed a significant difference in the amount of repeated lemmas between t,$t - i$ for $t \in A$ rather than for $t \notin A$. Find below an example of consecutive turns with repetitions:

```
Turn Utterance
  t-1: Starting at half past four.
  t:   Starting at half past four, yes.
```

Interrogative pronouns and questions: We also exploit indicators of an upcoming *giving information* act. As shown in Sec 3.2, 47% of the annotations were marked as *giving information*, which may have been triggered by a request of information in the precedent turn. Hence, in order to capture these cases, we identify linguistic elements that indicate a request of information in $t - 1$ (questions and interrogative pronouns/adjectives).

4.1.3 Conversational flow features (C-C)

They are designed to model information about the conversation's flow and speakers' interaction.

Centrality of the turn: Distance of a turn from the center of the conversation. This feature is inspired by the sentence location features used in text summarization (Chen et al., 2002). Chen *et al.* assign different weights to sentences in the first, middle and final part of a paragraph, in order to favor sentences that are in the central part of the paragraph as they are considered to be more informative for a summary. In our corpus, we noticed the tendency of users to annotate turns that are in the central portion of the conversation. Typically the first and the last quarters of the phone conversations are dedicated to social talk. Hence, we introduce a temporal feature, referred to as conversation centrality, that captures the distance of a turn from the center of the conversation. This distance is measured in terms of number of words, excluding punctuation.

Speaker: Who is uttering the turn (caller vs callee).

Conversation duration: Length of the conversation in number of turns and in number of words. The number of turns captures the dynamics of a dialogue (few longer turn vs a more dynamic exchange), while the number of words captures the overall duration.

Speaker dominance: We consider whether the speaker is the dominant speaker of the conversation, defining dominance in terms of amount of productions during the call. This is calculated by comparing the number of turns of speaker *a* vs speaker *b*, normalized over the total amount of turns per call.

4.1.4 Bag-of-Words (BoW)

Finally, we explore the performance of a naive bag-of-words scheme to represent the content at the turn level. Given the large vocabulary size of our corpus ($10,144$ tokens) and the sparsity organic to bag-of-word representations, we decided to use a trivial dimensionality reduction strategy filtering out the terms that appear only once in the corpus. We decided not to apply a stop-list of functional words for further reducing the feature space. This decision was based on the higher discrimintative power we observed when comparing classification accuracy with and without them. We discarded the use of more aggressive feature selection approaches (*e.g.* mutual information) to allow for a fair comparison of accuracy with the rest of feature representations described in the paper. In total, our BoW representation had $5,048$ dimensions in the $\mathcal{G}$ dataset, and $3,219$ dimensions in the $\mathcal{A}$ dataset.

4.2 Context Features

Context features are introduced under the assumption that noteworthy information may depend on the characteristics of the user and on the situation in which the call takes place. For example, people may not need to annotate pieces of information that are part of their daily lives. Whereas while taking an appointment, it is plausible the need to annotate the name of the doctor, in a social call with a friend, the name of the friend is part of the background knowledge of the user. Therefore, while from a content (and an NLP) point of view both names are Person NEs and carry the same amount of information, from the point of view of the user they might have different weight (no need of taking note vs need of taking note). Also, the current situation or location of the user may influence the necessity of taking notes: a user in a supermarket will not need to annotate to buy milk, (s)he will rather take it directly from the shelf. A user driving to the supermarket will need to keep in his/her mind the need to buy milk for later recall.

In line with this, we noted in Section 2 that pure NLP approaches applied to automatically detecting noteworthy information in meetings are able to achieve an F-score of only 0.14. This low F-score underlines the complexity of the task and the limitations of a pure content-based approach. Contextual cues may be used to increase the discriminative power of the classification model.

Since we consider the specific scenario of cellphone conversations, we can exploit contextual information derived from the use of the mobile network, such as geo-location, and temporal information. Other contextual features that we use, gathered during the pre-study questionaire, are organically much more challenging to infer. We still decided to consider these as a way to assess the potential of several types of contextual information with respect to the discriminative power of the classifier. We distinguish among Call-based (X-C) and User-based (X-U) contextual features. A schematic overview of these features is given in Table 3b.

4.2.1 Call-Based Features (X-C)

Call-based features are meant to capture contextual information at the call level. In particular, X-C features include information about *where*, *when* and *for what reason* a call is made, under the intuition that calls made, for example, during working hours may have different noteworthy information than calls made in the weekend. We distinguish six *location* categories: home, work place, while commuting, while exercising, while shopping, other. The location of the calls was provided by participants through the post-call questionnaire. However location information is typically available from the mobile network. In terms of *temporal* features, we consider the actual time of the call (over 24 hours). In addition, we classify the time in two classes: working vs non working hours, and the day in also two classes: weekday vs weekend. Finally, we also consider the *objective* of the call as described in Section 3. Note that,

although this information is not directly accessible from mobile data collected during the call, previous literature on conversation classification supports the feasibility of inferring this information from the content of the conversation (Koço et al., 2012).

4.2.2 User-Based Features (X-U)

Finally, we introduce a set of features that feed the model with information about the user. We exploit information that could be provided by users upon registration to such a *note-taking* service. We capture age, gender, educational level, income and marital status. Gender is represented as a binary feature, while age is categorized in 5 groups: below 20 years old, between 20 and 30, between 30 and 40, between 40 and 50 and above 50. The education status is represented by the following categories: Primary education, Secondary education, Bachelor degree or a Postgraduate education (Master or PhD). Yearly income is categorized by: up to 10k, 20k, 30k, 40k and more than 40k. Finally, marital status is categorized as: single, in a couple (married, with a stable partner), other.

5 Experiments

The goal of our system is to automatically identify information annotated by users in terms of its potential need for future recall. We frame this problem as a binary classification task (noteworthy or not) at the turn level. This task presents two main challenges. First, our dataset is extremely unbalanced, with less than 3% of the corpus labeled as relevant by the participants. Second, the subjectivity of the task leads to high variability of annotation behaviours, (see Sec. 3.2). In this section we describe the experimental setting that we used to empirically evaluate the performance of different features sets and present the results obtained using the ground truth data collected (Section 3) to provide classification performance scores. In order to fully investigate the predictive performance of the different feature sets, we conducted our experiments using both the entire corpus $\mathcal{G}$, which includes all the selected conversations, and its subset $\mathcal{A}$, which considers only the calls with at least one annotation. Both sets are described in Sec. 3. We experimented using both encoding schemes described in Section 4: binary based (**Bin**) and frequency based (**Freq**).

We used Support Vector Machines (SVMs) with RBF kernel, as this classification approach yielded the most consistent results throughout all the evaluated configurations. We used the same random split of training and test sets for all the experiments, accounting for 70% and 30% of the dataset respectively. We tune the hyperparameter C of the SVM model using a 3-fold cross-validation approach on the training data only, where we chose F-score as the quality metric to optimize. Given the nature of our task, recall is preferred to precision from a user-centric perspective: it is preferable to avoid missing any relevant information than to include some non-relevant fragments. For this reason, we also report precision and recall values.

5.1 Classification Results

This section presents the results obtained in our binary classification task (turns being noteworthy or not). We study the performance of different combinations of features and present the results obtained using only content information (C), and the combination of content and context information (CX).

5.1.1 Content features

We present a comparison of the different content feature sets using the naming scheme of Sec.4. We considered four classification scenarios: C-T only, C-D only, the combination of C-T and C-D (C-TD), and the combination of C-T, C-D and C-C (C-TDC). The results of these feature sets are shown in Tables 4a and 4b for the $\mathcal{G}$ and $\mathcal{A}$ collections, respectively.

As shown in Table 4a, the maximum F-score for the $\mathcal{G}$ dataset is achieved for the combination of all content features included the BoW. The low score ($F = 0.18$) is a direct consequence of the low precision obtained ($P = 0.11$). For the $\mathcal{A}$ dataset (Table 4b) we observe a better F-score ($F = 0.296$), still obtained by the combination of all content features, with a much higher precision ($P = 0.18$) due to the significant amount of noise removed by considering only annotated calls. Note that in both the $\mathcal{G}$ and the $\mathcal{A}$ datasets the C-TDC feature set outperforms the pure BoW approach ($F = 0.158$ vs. $F = 0.14$

Features	Precision		Recall		F-score	
Encoding	Bin	Freq	Bin	Freq	Bin	Freq
BoW	0.081	0.083	0.730	0.720	0.150	0.150
C-T	0.087	0.088	0.53	0.32	0.15	0.139
C-D	0.03	0.26	0.26	0.12	0.15	0.05
C-TD	0.087	0.09	**0.754**	0.33	0.1505	0.1419
C-TDC	0.09	0.093	0.58	0.37	0.158	0.149
C-TDC+BoW	**0.11**	**0.11**	0.52	0.51	**0.18**	**0.18**

(a) Results for the $\mathcal{G}$ dataset.

Features	Precision		Recall		F-score	
Encoding	Bin	Freq	Bin	Freq	Bin	Freq
BoW	0.14	0.14	0.54	0.54	0.22	0.22
C-T	0.135	0.147	0.56	0.555	0.218	0.23
C-D	0.149	0.11	0.24	0.15	0.18	0.12
C-TD	0.143	0.143	0.506	0.546	0.223	0.227
C-TDC	0.165	0.159	0.626	**0.693**	0.254	0.267
C-TDC+BoW	**0.188**	0.1659	0.57	0.568	0.283	**0.296**

(b) Results for the $\mathcal{A}$ dataset.

Table 4: Classification performance of Content features, BoW and their combination.

for $\mathcal{G}$ and $F = 0.267$ vs. $F = 0.22$ for $\mathcal{A}$), using a fraction (about 1%) of the number of BoW features, which leads to a considerably simpler model. On the other hand, the combination of C-TDC and BoW features improves the results up to $F = 0.18$ for $\mathcal{G}$ ($P = 0.11$, $R = 0.52$) and $F = 0.296$ ($P = 0.20$, $R = 0.57$) for the $\mathcal{A}$ subset. This result highlights how the lexical representation comprised by the BoW provides the model with orthogonal information to the one provided by the C-TDC features set.

To the best of our knowledge no previous work has been done in noteworthy detection from telephone conversations. For this reason, we report as a reference the results of the more similar prior art to our work, (Banerjee and Rudnicky, 2008), where the authors implement an SVM classifier for the detection of noteworthy information in meetings.[5] Although aware of the different nature of the dataset, these results are reported to get a sense of the potentiality of the system. The best performance of our model on the $\mathcal{A}$ dataset improves in 15% the F-score of $F = 0.14$ reported in (Banerjee and Rudnicky, 2008).

5.1.2 Combining Content and Context Features

In this section we report the performance of the model trained using both content and context features. For simplicity, in the remainder of this section we refer to the entire set of content features, (C-TDC) as C, to the entire set of context features as X, and to their combination as CX. When we test adding BoW features the *+BoW* naming is used. The results are shown in Table 5 and Figure 1. We observe that the fusion of content and context features (CX and CX+BoW) provides a noticeable overall increase in the F-score for both datasets. This increase is particularly high for the $\mathcal{G}$ dataset, where the F-score gets increased by almost a factor of 2, from $F = 0.18$ to $F = 0.28$. On the $\mathcal{A}$ dataset, the combination of content and context features improves the F-score from $F = 0.29$ to $F = 0.32$, given by a better precision ($P = 0.24$ vs $P = 0.18$) with similar recall.

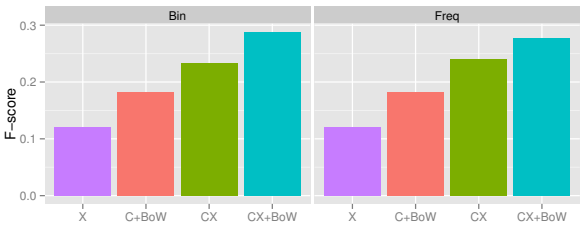
Features	Precision		Recall		F-score	
Rep.	B	F	B	F	B	F
C+BoW	0.11	0.11	0.52	0.51	0.18	0.18
X	0.068	0.068	**0.665**	**0.665**	0.124	0.124
CX	0.169	**0.20**	0.38	0.286	0.2354	0.2394
CX+BoW	0.189	0.1919	0.524	0.5022	**0.288**	0.277

(a) Results for the $\mathcal{G}$ dataset.

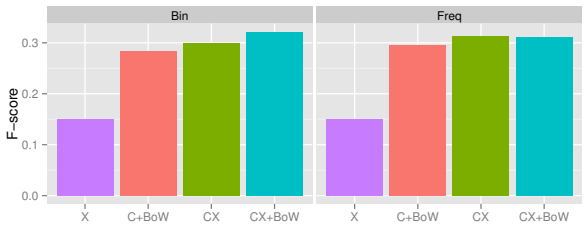
Features	Precision		Recall		F-score	
Rep.	B	F	B	F	B	F
C+BoW	0.188	0.1659	0.57	0.568	0.283	0.296
X	0.087	0.087	0.56	0.56	0.15	0.15
CX	0.2075	0.212	0.5866	**0.595**	0.3066	0.3130
CX+BoW	0.223	**0.2455**	0.573	0.426	**0.3212**	0.3116

(b) Results for the $\mathcal{A}$ dataset.

Table 5: Classification performance using the combination of context and context-based features



(a) Results for the $\mathcal{G}$ dataset.



(b) Results for the $\mathcal{A}$ dataset.

Figure 1: Classification performance using Content, Context features and their combination

This result gives empirical evidence that these two sets of features convey complementary information

[5] In their experimental settings all the meetings have at least one annotation as in our $\mathcal{A}$ scenario.

that is relevant for the task at hand. That is, the same words can carry different relevance depending on the contextual information of the conversation.

Note that the BoW features add discriminative information in the $\mathcal{G}$ scenario, but have a minimal effect in the less noisy $\mathcal{A}$ scenario where the combination of content and context features, without BoW, provides already an F-score of $F = 0.31$.

An interesting remark about this combined model is that the difference in performance between the $\mathcal{G}$ and the $\mathcal{A}$ dataset is vastly reduced. While in the pure content model the difference in F-score value between both datasets was 0.10, in the combined model this difference is just 0.03. This result shows that the combination of content and context features boosts considerably the results in the more noisy and realistic dataset $\mathcal{G}$, while its effect is weaker in the cleaner dataset.

5.2 Qualitative Analysis

In order to better understand the failure cases in our system, we carried out a qualitative analysis of both false positives, *i.e.* turns annotated by the system but not by the user, and false negatives, *i.e.* turns annotated by the user but not by the system. Table 6 illustrates a few representative examples. Note how the proposed system does not perform well when detecting a *request for information* as something worth annotating (*e.g. What are you doing?*). We noticed that in these cases, the model tended to annotate turns where the information was actually provided (*e.g.That is the package has arrived*). We can hypothesize that users annotate the *request for information* to give context to the a-priori more relevant information, *i.e.* the answer to the question. However, in some cases, participants did not annotate the answer as relevant. This counter-intuitive observation reflects the subjectivity and variability of the task.

False Positive	False Negative
I am leaving soon, I start at 3 o'clock or [..]	*How are you? Can you hear me?*

5.3 Comparative Analysis and Discussion

To the best of our knowledge there are no previous works of similar nature to the study presented in this paper. Yet, it is important to give a sense of the merits and limitations of the proposed approach in the context of the state-of-the-art. For this reason, we compare our results with (Banerjee and Rudnicky, 2009), which is the most similar prior art to our work. In (Banerjee and Rudnicky, 2009), Barnejee *et al.* perform a Wizard-of-Oz experiment and report a performance of the human annotator of $P = 0.35$ precision, $R = 0.42$ recall, leading to an F-score of $F = 0.38$. This result highlights the difficulty of the task, even for a human annotator. When comparing our proposed system with this Wizard-of-Oz experiment, we obtain an F-score of $F = 0.32$ against the human annotator's F-score of $F = 0.38$, with a significantly higher recall (0.57 vs 0.42) yet lower precision (0.245 vs 0.35). Given this human-based prediction performance, the proposed approach represents a good first step towards realizing an intelligent annotation system for mobile phone conversations.

6 Conclusions and Future Work

In this paper we have proposed and empirically evaluated a machine learning-based approach to automatically detect noteworthy information in spontaneous mobile phone conversations. The subjectivity of this task leads to a challenging classification problem even for human assessors. Our approach adopts a hybrid strategy that exploits the content and the context of the conversation. We have shown that information about the context of the conversation improves the predictive performance of the system over a pure content based approach.

In the future, we plan to extend the model by including acoustic features which could improve the performance by adding orthogonal information to the current model. To tackle the subjectivity of the task we also intend to investigate the performance of personalization techniques, creating individual models per user. Finally, we plan to conduct a study to evaluate our system from a user-centric perspective.

Hierarchical Topical Segmentation with Affinity Propagation

Abstract

We present a hierarchical topical segmenter for free text. Hierarchical Affinity Propagation for Segmentation (*HAPS*) is derived from a clustering algorithm Affinity Propagation. Given a document, *HAPS* builds a topical tree. The nodes at the top level correspond to the most prominent shifts of topic in the document. Nodes at lower levels correspond to finer topical fluctuations. For each segment in the tree, *HAPS* identifies a segment centre – a sentence or a paragraph which best describes its contents. We evaluate the segmenter on a subset of a novel manually segmented by several annotators, and on a dataset of Wikipedia articles. The results suggest that hierarchical segmentations produced by *HAPS* are better than those obtained by iteratively running several one-level segmenters. An additional advantage of *HAPS* is that it does not require the "gold standard" number of segments in advance.

1 Introduction

When an NLP application works with a document, it may benefit from knowing something about this document's high-level structure. Text summarization (Haghighi and Vanderwende, 2009), question answering (Oh et al., 2007) and information retrieval (Ponte and Croft, 1998) are some of the examples of such applications. Topical segmentation is a lightweight form of such structural analysis: given a sequence of sentences or paragraphs, split it into a sequence of *topical segments*, each characterized by a certain degree of topical unity. This is particularly useful for texts with little structure imposed by the author, such as speech transcripts, meeting notes or literature.

The past decade has witnessed significant progress in the area of text segmentation. Most of the topical segmenters (Malioutov and Barzilay, 2006; Eisenstein and Barzilay, 2008; Kazantseva and Szpakowicz, 2011; Misra et al., 2011; Du et al., 2013) can only produce single-level segmentation, a worthy endeavour in and of itself. Yet, to view the structure of a document linearly, as a sequence of segments, is in certain discord with most theories of discourse structure, where it is more customary to consider documents as trees (Mann and Thompson, 1988; Marcu, 2000; Hernault et al., 2010; Feng and Hirst, 2012) or graphs (Wolf and Gibson, 2006). Regardless of the theory, we hypothesize that it may be useful to have an idea about fluctuations of topic in documents beyond the coarsest level. It is the contribution of this work that we develop such a hierarchical segmenter, implement it and do our best to evaluate it.

The segmenter described here is *HAPS* – Hierarchical Affinity Propagation for Segmentation. It is closely based on a graphical model for hierarchical clustering called *Hierarchical Affinity Propagation* (Givoni et al., 2011). It is a similarity-based segmenter. It takes as input a matrix of similarities between atomic units of text in the sequence to be segmented (sentences or paragraphs), the desired number of levels in the topical tree and a preference value for each data point and each level. This value captures *a priori* belief about how likely it is that this data point is a segment centre at that level. The preference values also control the granularity of segmentation: how many segments are to be identified at each level. The output is a topical tree. For each segment at every level, *HAPS* also finds a segment centre, a data point which best describes the segment.

Proceedings of COLING 2014, the 25th International Conference on Computational Linguistics: Technical Papers, pages 37–47, Dublin, Ireland, August 23-29 2014.

The objective function maximized by the segmenter is net similarity – the sum of similarities between all segment centres and their children for all levels of the tree. This function is similar to the objective function of the well-known *k-means* algorithm, except that here it is computed hierarchically.

It is not easy to evaluate *HAPS*. We are not aware of comparable hierarchical segmenters other than that in (Eisenstein, 2009) which, unfortunately, is no longer publicly available. Therefore we compared the trees built by *HAPS* to the results of running iteratively two state-of-the-art flat segmenters. The results are compared on two datasets. A set of Wikipedia articles was automatically compiled by Carroll (2010). The other set, created to evaluate *HAPS*, consists of nine chapters from the novel *Moonstone* by Wilkie Collins. Each chapter was annotated for hierarchical structure by 3-6 people.

The evaluation is based on two metrics, *windowDiff* (Pevzner and Hearst, 2002) and *evalHDS* (Carroll, 2010). Both metrics are less then ideal. They do not give a complete picture of the quality of topical segmentations, but the preliminary results suggest that running a global model for hierarchical segmentation produces better results then iteratively running flat segmenters. Compared to the baseline segmenters, *HAPS* has an important practical advantage. It does not require the number of segments as an input; this requirement is customary for most flat segmenters.

We also made a rough attempt to evaluate the quality of the segment centres identified by *HAPS*. Using 20 chapters from several novels of Jane Austen, we compared the centres identified for each chapter against summaries produces by a recent automatic summarizer *CohSum* (Smith et al., 2012). The basis of comparison was the ROUGE metric (Lin, 2004). While far from conclusive, the results suggest that segment centres identified by *HAPS* are rather comparable with the summaries produced by an automatic summarizer.

A Java implementation of *HAPS* and the corpus of hierarchical segmentations for nine chapters of *Moonstone* are publicly available. We consider these to be the main contributions of this research.

2 Related work

Most work on topical text segmentation has been done for single-level segmentation. Contemporary approaches usually rely on the idea that topic shifts can be identified by finding shifts in the vocabulary (Youmans, 1991). We can distinguish between local and global models for topical text segmentation. Local algorithms have a limited view of the document. For example, TextTiling (Hearst, 1997) operates by sliding a window through the input sequence and computing similarity between adjacent units. By identifying "valleys" in similarities, TextTiling identifies topic shifts. More recently, Marathe (2010) used lexical chains and Blei and Moreno (2001) used Hidden Markov Models. Such methods are usually very fast, but can be thrown off by small digressions in the text.

Among global algorithms, we can distinguish generative probabilistic models and similarity-based models. Eisenstein and Barzilay (2008) model a document as a sequence of segments generated by latent topic variables. Misra et al. (2011) and Du et al. (2013) have similar models. Malioutov and Barzilay (2006) and (Kazantseva and Szpakowicz, 2011) use similarity-based representations. Both algorithms take as input a matrix of similarities between sentences of the input document; the former uses graph cuts to find cohesive segments, while the latter modifies a clustering algorithm to perform segmentation.

Research on hierarchical segmentation has been more scarce. Yaari (1997) produced hierarchical segmentation by agglomerative clustering. Eisenstein (2009) used a Bayesian model to create topical trees, but the system is regrettably no longer publicly available. Song et al. (2011) develop an algorithm for hierarchical segmentation which iteratively splits a document in two at a place where cohesion links are the weakest. A second pass transforms a deep binary tree into a shallow and broad structure.

Any flat segmenter can certainly be used iteratively to create trees of segments by subdividing each segment, but this may be problematic. Topical segmenters are not perfect, so running them iteratively is likely to compound the error. Most segmenters also require the number of segments as an input. This estimate is feasible for flat segmentation. To know in advance the number of segments and sub-segments at each level is not a realistic requirement when building a tree.

This work describes a hierarchical model of text segmentation. It takes a global view of the document and of the topical hierarchy. Each iteration attempts to find the best assignment of segments for the

whole tree. It does not need to know the exact number of segments. Instead, it takes a more abstract parameter, preference values, to specify the granularity of segmentation at each level. For each segment it also outputs a segment centre, a unit of text which best captures the contents of the segment.

3 Creating a corpus of hierarchical segmentations

Before embarking on the task of building a hierarchical segmenter, we wanted to study how people perform such a task. We also needed a benchmark corpus which could be used to evaluate the quality of segmentations produced by *HAPS*.

To this end, we annotated nine chapters of the novel *Moonstone* for hierarchical structure. We settled on these data because it is a subset of a publicly available dataset for flat segmentation (Kazantseva and Szpakowicz, 2012). In our study, each chapter was annotated by 3-6 people (4.8 on average). The annotators, undergraduate students of English, were paid $50 dollars each.

Procedure. The instructions asked the annotator to read the chapter and split it into top-level segments according to where there is a perceptible shift of topic. She had to provide a one-sentence description of what the segment is about. The procedure had to be repeated for each segment all the way down to the level of individual paragraphs. Effectively, the annotators were building a detailed hierarchical outline for each chapter.

Metrics. Two different metrics helped estimate the quality of our hierarchical dataset: *windowDiff* (Pevzner and Hearst, 2002) and *S* (Fournier and Inkpen, 2012).

windowDiff is computed by sliding a window across the input sequence and checking, for each window position, whether the number of reference breaks is the same as the number of breaks in the hypothetical segmentation. The number of erroneous windows is then normalized by the total number of windows. In Equation 1, N is the length of the input sequence and k is the size of the sliding window.

$$windowDiff \;=\; \frac{1}{N-k}\sum_{i=1}^{N-k}(|ref - hyp| \neq 0) \tag{1}$$

windowDiff is designed to compare sequences of segments, not trees. That is why we compute it for each level between each pair of annotators who worked on the same chapter. It should be noted that *windowDiff* is a penalty metric: higher values indicate less agreement (*windowDiff* $= 0$ corresponds to two identical segmentations).

The *S* metric allows us to compare trees and take into account situations when the segmenter places a boundary at a correct position but at a wrong level. *S* is an edit-distance metric. It computes the number of operations necessary to turn one segmentation into another. There are three types of editing operations: add/delete, transpose and substitute (change the level in the tree). The sum is normalized by the number of possible boundaries in the sequence. *S* has an unfortunate downside of being too optimistic, but it allows the breakdown of error types and it explicitly compares trees.

Unlike *windowDiff*, *S* is a similarity metric: higher values correspond to more similar segmentations. The value of *S* between two identical segmentations is 1.

$$S(bs_a, bs_b, n) = \frac{1 - |boundary\_distance(bs_a, bs_b, n)|}{pb(D)} \tag{2}$$

Here $boundary\_distance(bs_a, bs_b, n)$ is the total number of edit operations needed to turn a segmentation bs_a into bs_b, n is the threshold defining the maximum distance of transpositions. $pb(D)$ is the maximum possible number of edits. Segmentations bs_a and bs_a are represented as strings of sets of boundary positions. For example bs_a = ({2}, {1,2}, {1,2}) corresponds to a hierarchical segmentation of a three-unit sequence in the following manner: a segment boundary at level 1 after the first unit, segment boundaries at levels 1 and 2 after the second unit and the third unit.

Corpus Analysis. On average, the annotators took 3.5 hours to complete the task (σ = 1.6). The average depth of the tree is 3.00 levels (σ = 0.65), suggesting that the annotators prefer shallow but broad structures. Table 1 reports the average breadth of the tree at different levels. In the Table and further

in this paper we refer to the bottom level of the tree (i.e., the leaves of the tree or the most fine-grained level of segmentation) as level 1. In Table 1, level 4 refers to the top level of the tree (the coarsest segmentations). The values were computed using only the breaks explicitly specified by the annotators (*i.e.*, we did not assume that a break at a coarse level implies a break at a more detailed level).

The average breadth of the trees at the bottom (level 1) is lower than that at level 2, indicating that only a small percentage of the entire tree was annotated more than three levels deep. The table also shows the average values of *windowDiff* computed for each possible pair of annotators. The values worsen toward the bottom of the tree, suggesting that the annotators agree more about top-level segments and less and less about finer fluctuations of topic.

We hypothesize that these shallow broad structures are due to the fact that it is difficult for people to create deep recursive structures in their mental representations. We do not, however, have any hard data to support this hypothesis. Many of the annotators specifically commented on the difficulty of the task. 9 out of 23 people included comments ranging from notes about specific places to general comments about their lack of confidence. 4 annotators found several (specific) passages they had trouble with.

The average value of pairwise *S* is 0.79. We have noted earlier that the *S* metric tends to be optimistic (that is due to its normalization factor) but it provides a breakdown of disagreements between the annotators. According to *S*, 46.14% of disagreements are errors of omission (some of the annotators did not include segment breaks where others did), 47.56% are disagreements about the level of segmentation (the annotators placed boundaries in the same place but at different levels) and only 6.31% are errors of transposition (the annotators do not agree about the exact placement but place boundaries within 1 position of each other). This distribution is more interesting than the overall value of *S*. Among other things, it shows why it is so important to take into account adjacent levels when evaluating topical trees.

4 The *HAPS* algorithm[1]

4.1 Factor graphs

The *HAPS* segmenter is based on factor graphs, a unifying formalism for such graphical models as Markov or Bayesian networks. A factor graph is a bi-partite graph with two types of nodes, *factor* or *function nodes* and *variable nodes*. Each factor node is connected to those variable nodes which are its arguments. Running the well-known Max-Sum algorithm (Bishop, 2006) on a factor graph finds a configuration of variables which maximizes the sum of all component functions. This is a message-passing algorithm. All variable nodes send messages to their factor neighbours (functions in which those nodes are variables) and all factor nodes send messages to their variable neighbours (their arguments). A message $\mu_{x\to f}$ sent from a variable node x to a function node f is computed as a sum of all incoming messages to x, except the message from the recipient function f:

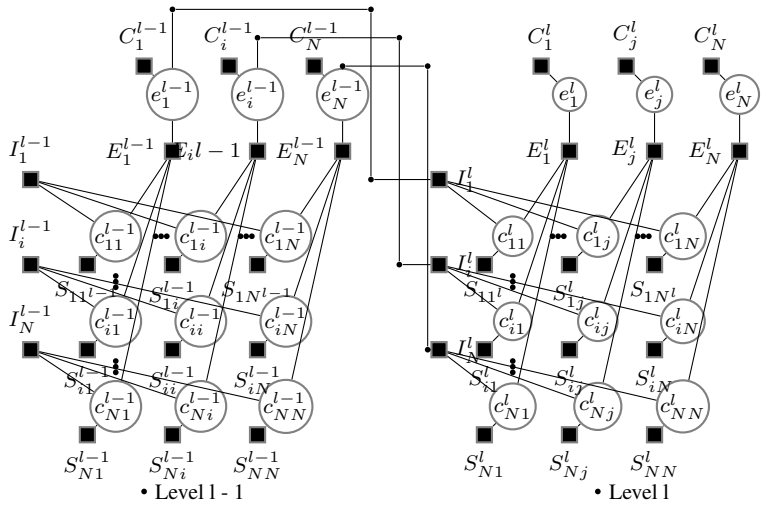
$$\mu_{x\to f} = \sum_{f'\in N(x)\setminus f} \mu_{f'\to x} \tag{3}$$

$N(x)$ is the set of all function nodes which are x's neighbours. Intuitively, the message reflects evidence about the distribution of x from all functions which have x as an argument, except the function corresponding to the receiving node f. A message $\mu_{f(x,\ldots)\to x}$ sent from the factor node $f(x,\ldots)$ to the

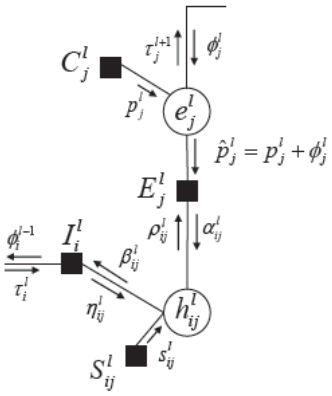
[1]The derivation of the *HAPS* algorithm, quite involved, is unlikely to interest many readers. We only present the bare minimum of facts about the algorithm, the framework of factor graphs and the derivation of *HAPS* from the underlying model of Affinity Propagation. A detailed account appears in (Kazantseva, 2014).

Table 1: Average breadth of manually created topical trees and *windowDiff* value across different levels

Level	Average breadth	*windowDiff*
4 (top)	6.53	0.35
3	17.55	0.46
2	17.63	0.47
1 (bottom)	8.80	0.50



(a) Fragment of the factor graph for levels $l-1$ and l



(b) Types of messages sent in the *HAPS* model

Figure 1: Factor graph for *HAPS* – Hierarchical Affinity Propagation for Segmentation

variable node x is computed as a maximum of the value of $f(x)$ plus all messages incoming to $f(x, ...)$ other than the message from the recipient node x:

$$\mu_{f \to x} = \max_{N(f) \setminus x} \left(f(x_1, \ldots, x_m) + \sum_{x' \in N(f) \setminus x} \mu_{x' \to f} \right) \tag{4}$$

$N(f)$ is the set of all variable nodes which are f's neighbours. The message reflects the evidence about the distribution of x from function f and its neighbours other than x.

4.2 Hierarchical Affinity Propagation for Segmentation

This work aims to build trees of topical segments. Each segment is characterized by a centre which best describes its content. The objective function is net similarity, the sum of similarities between all centres and the data points which they exemplify. The complete sequence of data points is to be segmented at each level of the tree, subject to the following constraint: centres at each level l, $l > 1$, must be a subset of the centres from the previous level $l-1$. Figure 1a shows a fragment of the factor graph describing *HAPS* corresponding to levels l and $l-1$. The tree has L levels, from the root ($l = L$) down to the leaves ($l = 1$). The superscripts of factor and variable nodes denote the level.

At each level, there are N^2 variable nodes c_{ij}^l and N variable nodes e_j^l (N is the number of data points in the sequence to segment). A variable's value is 0 or 1: $c_{ij}^l = 1 \Leftrightarrow$ the data point i at level l belongs to the segment centred around data point j; $e_j^l = 1 \Leftrightarrow$ there is a segment centred around j at level l.

Four types of factor nodes in Figure 1a are I, E, C and S. The I factors ensure that each data point is assigned to exactly one segment *and* that segment centres at level l are a subset of those from level $l-1$. The E nodes ensure that segments are centred around the segment centres in solid blocks (rather than unordered clusters). The values of I and E are 0 for valid configurations and -∞ otherwise. The S factors capture similarities between data points. $S_{ij}^l = sim(i,j)$ if $c_{ij}^l = 1$; $S_{ij}^l = 0$ if $c_{ij}^l = 0$.[2] The C factors handle preferences in an analogous manner. Running the Max-Sum algorithm on the factor graph in Figure 1a maximizes the net similarity between all segment centres and their children at all levels:

$$\max_{\{c_{ij}^l\},\{e_j^l\}} S(\{c_{ij}^l\},\{e_j^l\}) = \sum_{i,j,l} S_{i,j}^l(c_{ij}^l) + \sum_{i,l} I_i^l(c_{i1}^l, \ldots, c_{iN}^l, e_i^{l-1}) + \sum_{j,l} E_j^l(c_{1j}^l, \ldots, c_{Nj}^l, e_j^l) + \sum_{j,l} C_j^l(e_j^l) \tag{5}$$

[2]The value $sim(i,j)$ is specified in the input matrix.

Figure 1b shows a close-up view of the messages that must be sent to find the optimizing configuration of variables. Messages β, η, $\hat{\rho}$ do not need to be sent explicitly: their values are subsumed by other types of messages. We only need to compute explicitly and send four types of messages: α, ρ, ϕ and τ.

Algorithm 1 shows the pseudo-code for the *HAPS* algorithm.[3] Intuitively, different parts of the update messages in Algorithm 1 correspond to likelihood ratios between two hypotheses: whether a data point i is or is not part of a segment centred around another data point j at a given level l. For example, here is the availability (α) message sent from a potential segment centre j to itself at level l:

$$\alpha_{ij}^{l} = p_j^l + \phi_j^l + \max_{s=1}^{j}(\sum_{k=s}^{j-1}\rho_{kj}^l) \; + \; \max_{e=j}^{N}(\sum_{k=j+1}^{e}\rho_{kj}^l) \tag{6}$$

Here p_j^l incorporates the information about the preference value for the data point j at the level l. ϕ_j^l brings in the information from the coarser level of the tree. The summand $\max_{s=1}^{j}(\sum_{k=s}^{j-1}\rho_{kj}^l)$ encodes the likelihood that there is a segment starting before j given the values of responsibility messages for all data points i such that $i < j$ — hence the information from a more detailed level of the tree as well as the similarities between all data points i ($i < j$) and j. The summand $\max_{e=j}^{N}(\sum_{k=j+1}^{e}\rho_{kj}^l)$ does the same for the tail-end of the segment (all data points i such that $i > j$).

Complexity analysis. The *HAPS* model contains N^2 c_{ij}^l nodes at each level. In practice, however, the matrix of similarities $\mathcal{SIM}$ does not need to be fully specified. It is customary to compute this matrix with a large sliding window; the size should be at least twice the anticipated average length. On each iteration, we need to send *L*M*N* messages α and ρ, resulting in the complexity *O(L*M*N)*. Here L is the number of levels, N is the number of data points in the sequence and M ($M \leq N$) is the size of the sliding window used for computing similarities. The computation of ρ and α messages is independent for each row and column respectively, so the algorithm would be easy to parallelize.

Parameter settings. An important advantage of *HAPS* is that it does not require the number of segments in advance. Instead, the user needs to set the preference values for each level. However, *HAPS* is fairly resistant to changes in preferences and this generic parameter is a convenient knob for fine-tuning the desired granularity of segmentation, as opposed to specifying the exact number of segments at each level of the tree. In this work we set preferences uniformly, but it is possible to incorporate additional knowledge through more discriminative settings.

In all our experiments, preference values are set uniformly for each level of the tree, so effectively all data points are equally likely to be chosen as segment centres at each level. As a starting point, the preference value for the most detailed level of the tree should be about approximately equal to the median similarity value (as specified in the input matrix). A near-zero preference value tends to result in a medium number of segments and is thus suitable to the middle levels of the tree. A negative preference value results in a small number of segments and is appropriate for identifying the most pronounced segment breaks.

5 Experimental evaluation

In order to evaluate the quality of topical trees produced by *HAPS*, we ran the system on two datasets. We compared the results obtained by *HAPS* against topical trees obtained by iteratively running two high-performance single-level segmenters.

Datasets. We used the *Moonstone* corpus described in Section 2, and the Wikipedia dataset compiled by Carroll (2010). Created automatically from metadata on Web pages, the dataset consists of 66 Wikipedia entries on various topics; the annotations and the results concern sentences. In the *Moonstone* corpus we work with paragraphs. To simplify evaluation and interpretation, we produced three-tier trees. This is in line with the average depths of manual annotations in the *Moonstone* data.

[3] It is not possible to include a detailed derivation of the new update messages in the space allowed here. The interested reader can find these details in (Kazantseva, 2014). The derivation follows the same logic as (Givoni et al., 2011) and (Kazantseva and Szpakowicz, 2011).

Algorithm 1 Hierarchical Affinity Propagation for Segmentation

input: 1) L pairwise similarity matrices $\{\mathcal{SIM}^l(i,j)\}_{(i,j)\in\{1,\ldots,N\}^2}$; 2) L preferences p^l (one per level l) indicating *a priori* likelihood of point i being a segment centre at level l

initialization: $\forall i,j : \alpha_{ij} = 0$ (set all availabilities to 0)

repeat

iteratively update ρ, α, ϕ and τ messages

$$\forall i,l : \phi_i^{l-1} = \max[0, \alpha_{ii} - \max_{k\neq i}(s_{ik}^l + \alpha_{ik}^l)]$$

$$\forall i,j,l : \rho_{ij}^l = \begin{cases} \min(0, \tau_i^l) - \max_{k\neq i}(s_{ik}^l + \alpha_{ik}^l) & \text{if } i = j \\ s_{ij}^l + \min[\max(0, -\tau_i^l) - \alpha_{ii}^l, -\max_{k\notin i,j}(s_{ik}^l + \alpha_{ik}^l)] & \text{if } i \neq j \end{cases}$$

$$\forall i,j,l : \alpha_{ij}^l = \begin{cases} p_j^l + \phi_j^l + \max_{s=1}^{j}(\sum_{k=s}^{j-1}\rho_{kj}^l) \; + \; \max_{e=j}^{N}(\sum_{k=j+1}^{e}\rho_{kj}^l) & \text{if } i = j \\ \alpha_{ij,i<j}^l = \min[(\max_{s=1}^{i}\sum_{k=s}^{i-1}\rho_{kj}^l + \sum_{k=i+1}^{j}\rho_{kj}^l + \max_{e=j}^{N}\sum_{k=j+1}^{e}\rho_{kj}^l) + p_j^l + \phi_j^l, & \\ \quad \max_{s=1}^{i}\sum_{k=s}^{i-1}\rho_{kj}^l + \min_{s=i+1}^{j}\sum_{k=i+1}^{s-1}\rho_{kj}^l] & \text{if } i < j \\ \min[(\max_{s=1}^{j}\sum_{k=s}^{j-1}\rho_{kj}^l + \sum_{k=j}^{i-1}\rho_{kj}^l + \max_{e=i}^{N}\sum_{k=i+1}^{e}\rho_{kj}^l) + p_j^l + \phi_j^l, & \\ \quad \min_{e=j}^{i-1}\sum_{k=e+1}^{i-1}\rho_{kj}^l + \max_{e=i}^{N}\sum_{k=i+1}^{e}\rho_{kj}^l] & \end{cases}$$

$$\forall j,l : \tau_j^{l+1} = p^l(j) + \rho_{jj}^l + \max_{s=1}^{j}(\sum_{k=s}^{j-1}\rho_{kj}^l) \; + \; \max_{e=j}^{N}(\sum_{k=j+1}^{e}\rho_{kj}^l)$$

until convergence

compute optimal configuration: $\forall i,j$ i is in the segment centred around j iff $\rho_{ij} + \alpha_{ij} > 0$

output: segment centres and segment boundaries

Baselines. Regrettably, we are not aware of another publicly available hierarchical segmenter. That is why we used as baselines two recent flat segmenters: *MCSeg* (Malioutov and Barzilay, 2006) and *BSeg* (Eisenstein and Barzilay, 2008). Both were first run to produce top-level segmentations. Each segment thus computed was a new input document for segmentation. We repeated the procedure twice to obtain three-tiered trees. *MCSeg* cannot be run without knowing the number of segments in advance. Therefore, on each iteration, we had to specify the correct number of segments in the reference segmentation. *BSeg* does not need the exact number of segments, so we had two settings: with and without knowing the number of segments.

Evaluation metrics. We did our best to obtain a realistic picture of the results, but each metric has its shortcomings. We compared topical trees using *windowDiff* and *evalHDS* (Carroll, 2010). Both metrics are penalties: the higher the values, the worse the hypothetical segmentation. *evalHDS* computes *windowDiff* for each level of the tree in isolation and weighs the errors according to their prominence in

the tree. We computed *evalHDS* using the publicly available Python implementation (Carroll, 2010).[4]

When computing *windowDiff*, we treated each level of the tree as a separate segmentation and compared each hypothetical level against a corresponding level in the reference segmentation.

To ensure that evaluations are well-defined at all levels, we propagated the more pronounced reference breaks to lower levels (in both annotations and in the results). In effect, the whole sequence is segmented at each level – otherwise *windowDiff* would not be not well-defined. Conceptually this means that if there is a topical shift of noticeable magnitude (*e.g.,* at the top level), there must be at least a shift of less pronounced magnitude (*e.g.,* at an intermediate level).

The *Moonstone* dataset has on average 4.8 annotations per chapter. It is not obvious how to combine these multiple annotations. We evaluated separately each hypothetical segmentation against each available gold standard. We report the averages across all annotators – for both *evalHDS* and *windowDiff* – per level.

Preprocessing. The representations used by *HAPS* and the *MCSeg* are very similar. Both systems compute a matrix of similarities between atomic units of the document (sentences or paragraphs). Each unit was represented as a bag of words. The vectors were further weighted by the *tf.idf* value of the term and also smoothed in the same manner as in (Malioutov and Barzilay, 2006). We computed cosine similarity between vectors corresponding to each sentence or paragraph. We used tenfold cross-validation on the Wikipedia dataset and fourfold cross-validation on the smaller *Moonstone* data.

The quality of the segment centres. In addition to finding topical shifts, *HAPS* identifies segment centres – sentences or paragraphs which best capture what each segment is about. In order to get a rough estimate of the quality of the centres, we extracted paragraphs identified as segment centres at the second (middle) level of *HAPS* trees. These pseudo-summaries were then compared to summaries created by an automatic summarizer *CohSum*. We used ROUGE-1 and ROUGE-L metrics (Lin, 2004) as a basis for comparison. *CohSum* identifies the most salient sentences in a document by running a variant of the TextRank algorithm (Mihalcea and Tarau, 2004) on the entire document. In addition to using lexical similarity, the summarizer takes into account coreference links between sentences. We ran *CohSum* at 10% compression rate.

The summarization experiment was performed on the *Moonstone* corpus. We also collected 20 chapters from several other XIX century novels and used it in a separate experiment. The ROUGE package requires manually written summaries to compare with the automatically created ones. We obtained the summaries from the SparkNotes website.[5]

6 Results and discussion

Table 2 shows the results of comparing *HAPS* with two baseline segmenters using *windowDiff* and *evalHDS*. *HAPS* was run without knowing the number of segments. *MCSeg* required that the exact number be specified. *BSeg* was tested with and without that parameter. Therefore, rows 3 and 4 in Table 2 correspond to baselines considerably more informed than *HAPS*. This is especially true of the bottom levels where sometimes knowing the exact number of segments unambiguously determines the only possible segmentation.

The results suggest that *HAPS* performs well on the *Moonstone* data even when compared to more informed baselines. This applies to both metrics, *windowDiff* and *evalHDS*. *BSeg* performs slightly better at the bottom levels of the tree when it has the information about the exact number of segments. We hypothesize that the advantage may be due to this additional information, especially when segmenting already small segments at level 1 into a predefined number of segments. Another explanation may be that when using *windowDiff* as the evaluation metric, *HAPS* was fine-tuned so as to maximize the value of *windowDiff* at the top level, effectively disregarding lower levels of segmentation.

[4]When working with the *Moonstone* dataset, we realized that the software produces very low values, almost too good to be true. That is because the bottommost annotations are very fine-grained. Sometimes each paragraph corresponds to a separate segment. This causes problems for the software. So, when we report *evalHDS* values for the *Moonstone* dataset, we only consider two top levels of the tree, disregarding the leaves. We also remove the "too good to be true" outliers, though the "bad" tail is left intact. We applied the same procedure to all three segmenters, only for the *Moonstone* dataset.

	Level	*Moonstone windowDiff*	*Wikipedia windowDiff*	*Moonstone evalHDS*	*Wikipedia evalHDS*
HAPS	3 (top) 2 (middle) 1 (bottom)	0.337 (± 0.060) 0.422 (± 0.060) 0.556 (± 0.070)	0.421 (± 0.060) 0.447 (± 0.070) 0.617 (± 0.080)	0.353 (± 0.072)	0.450 (± 0.015)
MinCutSeg-iter. segm. known	3 (top) 2 (middle) 1 (bottom)	0.375 0.541 0.601	0.440 (± 0.075) 0.424 (± 0.064) 0.471 (± 0.057)	0.377 (± 0.002)	0.444 (± 0.002)
BayesSeg-iter. segm. known	3 (top) 2 (middle) 1 (bottom)	0.353 (± 0.071) 0.406 (± 0.053) 0.504 (± 0.064)	0.391 (± 0.070) 0.344 (± 0.033) 0.354 (± 0.033)	0.367 (± 0.089)	0.370 (± 0.019)
BayesSeg-iter. segm. unknown	3 (top) 2 (middle) 1 (bottom)	0.600 (± 0.071) 0.447 (± 0.053) 0.545 (± 0.064)	0.637 (± 0.070) 0.877 (± 0.033) 0.952 (± 0.033)	0.453 (± 0.089)	0.437 (± 0.022)

Table 2: Evaluation of *HAPS* and iterative versions of *APS*, *MCSeg* and *BSeg* using *windowDiff* per level (mean *windowDiff* and standard deviation for cross-validation)

	Moonstone corpus		Austen corpus	
	ROUGE-1	ROUGE-L	ROUGE-1	ROUGE-L
Segment centres	0.341 (0.312, 0.370)	0.321 (0.298, 0.346)	0.291 (0.272, 0.311)	0.301 (0.293, 0.330)
CohSum summaries	0.294 (0.243, 0.334)	0.269 (0.226, 0.306)	0.305 (0.290, 0.320)	0.307 (0.287, 0.327)

Table 3: *HAPS* segment centres compared to *CohSum* summaries: ROUGE scores and 95% confidence intervals

All segmenters perform worse on the Wikipedia dataset. Using that scale, informed *BSeg* performs the best, but it is interesting to note a significant drop in performance when the number of segments is not specified.

Overall, *HAPS* appears to perform better than, or comparably to, the more informed baselines, and much better than the baseline not given information about the number of segments.

We also made a preliminary attempt to evaluate the quality of segment centres by comparing them to the summaries created by the *CohSum* summarizer. In addition to working with the *Moonstone* corpus, we collected a corpus of 20 chapters from various novels by Jane Austen.

Table 3 shows the results. They are not conclusive because there is no evidence that ROUGE scores correlate with the quality of automatically created summaries for literature. According to the scores in Table 3, however, the summaries created by *CohSum* cannot be distinguished from simple summaries composed of segment centres identified by *HAPS*. We interpret this as a sign that the centres identified by *HAPS* are approximately as informative as those created by an automatic summarizer.

7 A brief conclusion

This paper presented *HAPS*, a hierarchical segmenter for free text. Given an input document, *HAPS* creates a topical tree and identifies a segment centre for each segment. One of the advantages of *HAPS* is that it does not require the exact number of segments in advance. Instead, it estimates the number of segments given information on generic preferences with regard to segmentation granularity. We also created a corpus of hierarchical segmentations which has been annotated by 3-6 people per chapter.

A Java implementation of *HAPS* and the *Moonstone* corpus are publicly available.[6]

Capturing Cultural Differences in Expressions of Intentions

Abstract

The intersection of psychology and computational linguistics is capable of providing novel automated insight into the language of everyday cognition through analysis of micro-blogs. While Twitter is often seen as banal or focused only on the who, $what$, $when$ or $where$ tweets can actually serve as a source for learning about the language people use to express complex cogntive states and their cultural identity. In this contribution we introduce a novel model which captures latent cultural dimensions through an individual's expressions of intentionality. We then show how these latent cultures can be used to create a culturally-sensitive model which provides enahnced detection of signals of intentionality in tweets. Finally, we demonstrate how these models reveal interesting cross-cultural differences in the goals and motivations of individuals from different cultures.

1 Introduction

Social media platforms have enabled new forms of discourse and have also provided enormous quantities of data on these communications. For instance, the popular microblogging service Twitter provides an exceptionally useful source of user-generated content which has attracted considerable interest from researchers in computational linguistics (Ritter et al., 2009; Gimpel et al., 2011). Most of the language processing on tweets has involved the identification of sentiment (Davidov et al., 2010), summarization (Sharifi et al., 2010), conversational models of Dialogue acts (Ritter et al., 2009), or lexical and semantic processing. In this effort we expand on these previous approaches and show how individuals express their cultural identity through expressions revealing their intentionality towards events and provide a way of capturing this information.

We define intentionality as the amount of effort an individual is willing to expend to achieve a goal(Ajzen, 1991). Goals represent future states or events which an individual wishes to happen. Accordingly, intentions are goals for which an individuals is willing to expend at least some minimal amount of effort to bring about. While people express goals throughout the day, intentions are the goals that they are willing to follow through with. Identifying when a goal is actually an intention requires the successful recognition of many distinct cognitive factors that can be revealed through the individual's use of language.

There is a long history of studies that have worked towards identifying a set of factors that underly an individual's intentions (Ajzen and Fishbein, 1977; Ajzen, 1991; Malle and Knobe, 1997; Sloman et al., 2012) of which, the setting of goals is one important factor. These studies have concentrated on identifying the factors that affect an individual's motivation. The studies have also identified a set of factors that people use to gauge the intentionality of other individuals. However, these factors have always been manually identified by an expert from an individual's speech or writing. It is not clear that these features can actually be detected automatically in language.

Intentions have also been considered in computational linguistics. In their seminal work entitled, "Attention, Intentions, and the Structure of Discourse" (Grosz and Sidner, 1986), Grosz and Sidner point out the fundamental role of intentions and their effect on the theory and processing of discourse structure. They even define a set of intentions that can be held by individuals that are relevant to discourse theory. In contrast, we focus on understanding intentions outside of the discourse. In addition, we work with a more general definition of intentions taken from psychology, defining intentionality as the amount of effort an individual is willing to expend to achieve a goal.

Culture refers to the set of beliefs, norms, and customs shared by a group of people. Beliefs and culture are inseparably tied to intentions and language (Ajzen and Fishbein, 1977; Tomasello et al., 2005). Culture affects an author's proclivity to have a particular intention, for example Hofstede's dimension of power distance (Hofstede, 1980) would suggest that individuals from high power-distance cultures have a lower likelihood of performing

Proceedings of COLING 2014, the 25th International Conference on Computational Linguistics: Technical Papers, pages 48–57, Dublin, Ireland, August 23-29 2014.

actions with the intention of overriding the actions of an individual of higher status. Culture can also affect the way in which individuals reason about other agents' intentions and the set of actions that are used to realize an individual's intentions. While considerable work has looked at the link between cultures and intentions, here we show how a latent representation of an individual's culture derived from their intentions can be utilized to explore the intersection between culture and intentions using the vast amount of written expressions present on Twitter.

In this contribution, instead of focusing on the discourse meaning of intentions, we look at how personal intentions can be understood through Twitter posts by focusing on the language of those posts contain. We briefly discuss previous work showing how it is possible to capture language that reveal cognitive factors of intentionality which could be used to capture broader intentions. Critically, we then augment the models of the cognitive factors of intentionality by accounting for the culture of the authors on Twitter. Twitter contains an immense number of authors covering a variety of different cultures definable at different levels, for example women, college-students, or fitness buffs.

We have evaluated the models on a very large set of over 7.5 million tweets which cover a sampling of Twitter from early 2011 to the middle of 2013. Our sample includes just over 900,000 authors. We found very promising results for identifying the factors of intentionality, but by considering culture we were able to provide a significant improvement of those results. We have shown that cognitive factors of intentionality, including goals, control and skill, and rewards can be recognized through the use of simple language models. Similarly, our cultural models were based on traditional techniques for latent variable modeling through principal component analysis enabling an understanding of the cultural distribution of intentions.

The remainder of the paper is organized as follows. We first present the cognitive factors of intentionality that we have used for this contribution. We then present a new cultural model of authors on Twitter and compare it to existing approaches in the literature. We then present a series of models which capture the cultural variation of the cognitive factors of intentionality. Finally, we present a look at some of the cultural differences identified through our approach.

2 Factors of Intentionality

While there are numerous factors that affect an individual's intentionality (Ajzen, 1991; Malle and Knobe, 1997; Sloman et al., 2012), in this contribution we focus on investigating the most historically central factors: goals, perceptions of control, and rewards. Below we provide brief examples of the three factors before detailing our approach for identification of latent cultures.

2.1 Factor 1: Goals

The first factor that we consider is evidence that an individual has a goal. Goals are expressions of a desire for a change of state or rewards which could require an action on the part of the individual. The setting of goals for both action and inaction have been linked to many different motivational and long-term outcomes (Albarracin et al., 2011; Locke, 1968). Examples of goals are

(1) I want to finish my paper

(2) I want to be famous

The first example of a goal expresses an intention to perform an action which could result in a positive reward for the individual, however it doees not mention the reward. In contrast, the second example expresses a clear expectation for a reward (fame), but does not describe the actions that will lead to that reward. Does the individual want to be President or the next Kardashian? Additionally, in contrast to explicit goals stated by an individual, goals can also be inferred by other people based on an analysis of actions (perceived intended events) carried out by the individual. For example, it is presumed that an individual has a goal to win the lottery when they buy a lottery ticket, or that the occupants of a car full of beach toys is headed to or from a beach. Goals represent the factor that has seen the most recent attention in terms of the creation of automatic methods for their recognition (Chen et al., 2013; Banerjee et al., 2012).

2.2 Factor 2: Perception of Control

Intentions are revealed not just through goals, but also through words expressing skill or a level of control. Individuals that feel that they have more control over a situation will expend more effort on their actions (Ajzen, 1991). Individuals are also perceived by others as having greater intentionality for actions that they have control over or exhibit skill at. We considered multiple ways in which an individual can express their perceived control over an event, subdividing this factor into three sub-factors. The first sub-factor captures expressions which indicate skill.

(3) Just helped some guy push his gas-less car to the garage #iamwoman #hearmeroar

Table 1: Example Hash Tags and Tweets.

Cognitive Factor	Sample Tags	Sample Tweets
F1: Goal	#goalinlife, #mywish	"3 more days of studying"
F2: Control	#dowhatisay, #kissmyfeet	"I defy the law of gravity"
F2: Skill	#madskillz, #iamapro	"you are flat out amazing to watch"
F2: Lack of Control	#oops, #cantstop	"cannot believe I said that"
F3: Negative Reward Self	#fml, #crap	"I just locked the keys in my car"
F3: Negative Reward Other	#worstdriverever, #awkward	"It does make me cringe"
F3: Positive Reward Self	#whyismile, #victoryismine	"my cats make me smile"
F3: Positive Reward Other	#ff, #thatsbadass	"Solar panels on the white house"

The second sub-factor captures expressions of control.

(4) I'm in control here!

The third sub-factor captures expressions of lack-of-control.

(5) i'm a little nervous for tomorrow

While several linguistic theories exist that could be utilized to create systems detecting control, such as agency (Dowty, 1991), there is no prominent work on automatically identifying control directly in an individual's expressions.

2.3 Factor 3: Reception of Rewards

Intentions can also be inferred when an individual receives a reward.

(6) I'm so proud of what I did

(7) Your work sucks!

Rewards can be positive (increasing the likelihood of the action being repeated, Example 6) or negative (decreasing the likelihood of the action in the future, Example 7). In addition, rewards can come from the individual (self-directed rewards, Example 6) or from other individuals (other-directed rewards, Example 7). This establishes four sub-factors for rewards. Knowing that an individual received a reward increases the likelihood that they had effortful participation in the event. In addition, evidence of negative rewards are strongly inferential for intentionality (Knobe, 2003). Interpretations of rewards are very culturally sensitive. For example, a comment such as "That is disgusting" would have a good chance of being interpreted as a positive reward when it was made as a comment to a user-generated contribution on the website DeviantArt.com. Additionally, the effect of rewards on motivation is not always clear-cut. Experts seek out and are actually motivated by criticism (Finkelstein and Fishbach, 2012).

2.4 Linking Hashtags and Factors of Intentionality

The factors and sub-factors described above capture expressions which can be used to infer an individual's intentionality towards a future action. In Tomlinson et al. (2014) we showed that it is possible to link particular hashtags used by people on Twitter to these cognitive factors. Our approach utilized two annotators. The first annotator, through trial and error, identified a large number of potential candidate tags for each sub-factor. The annotator then rated each hashtag for how well tweets containing that hashtag exhibited each sub-factor (on a scale of 1-5). The second annotator then separately rated each tag which scored a 4 or 5. The two annotators had an agreement rate of 87%. 178 tags in all were agreed to be a 4 or 5 by both annotators and considered representative of the particular sub-factor. Examples of the hashtags utilized and tweets with those tags are shown in Table 1. The tweets have been modified slightly to preserve anonymity.

3 Identification of Latent Cultures

In the preceding section we discussed examples of goals, control, and rewards, and discussed how hashtags are used on Twitter to mark a tweet expressing one of these factors. Some of these examples require cultural knowledge in order to correctly interpret. In this section we present the latent model of culture that is used for learning the cultural specific expressions of the factors of intentionality.

3.1 SVD-Model of Culture

A considerable amount of work has demonstrated how particular social characteristics of individuals can be identified on Twitter, such as gender, age, and political orientation (Zamal et al., 2012; Pennacchiotti and Popescu, 2011). While superb results can be obtained for identifying these characteristics of authors using a complex set of features, this approach does not neccesarily allow for generalization to other data sets. Therefore we settled on an approach utilizing a specially trained latent variable model. Instead of utilizing Latent-Dirichlet Allocation (LDA, Blei, Ng, and Jordan, 2003) as Pennacchiotti and Popescu we utilized a spectral analysis based on singular-value decomposition (SVD). This approach has been shown to be generally superior to LDA on the domain of topic modeling (Chen et al., 2011), but has not been tested for cultural modeling.

3.1.1 Data

We randomly sampled 1.6 million tweets from a Twitter dataset that had been generated by retrieving tweets that carried at least one of the hashtags linked to a cognitive factor of intentionality (and other posts by that author). In addition, we restricted the set to authors for which we had at least 20 posts in our dataset. For this dataset, all of the markup was left in the tweet (e.g. hashtags, urls, etc.).

3.1.2 Model

From our dataset we created a set of documents, $D = \{a_1, a_2, \ldots, a_A\}$. Where each a_i represents the entire collection of tweets for a single author that contain mentions of goals, skill/control, or rewards. This set of documents contains N words and hashtags. We then create a matrix, $X \in \Re^{N,A}$, where each author represents a row in the matrix and the columns are the number of times that the corresponding word or hashtag was used by that author. Then we perform a singular value decomposition of the matrix to solve

$$X = VSC^T \tag{1}$$

Where S is a $k\ x\ k$ matrix whose off-diagonal entries equal 0 and the on-diagonal entries are the k singular values for the matrix X. For our approach we set k equal to 100. V represents a mapping of the words into our reduced space $\Re^{n,k}$, and $C\ \Re^{i,k}$ contains a weighting for each author with respect to the k^{th} latent cultural dimension. The cultural model can be used to identify the culture of an unseen author through the creation of a projection matrix, P.

$$P = VS^{-1} \tag{2}$$

This matrix projects the tweets that make up the author into our latent cultural space C. This allows us to map each author in our complete data set into our latent space which can then be used for training and testing. The latent cultural space can be used to characterize the culture of an author as a distribution over the dimensions. Below we evaluate our latent cultures on the shared dataset provided by Zamal et al. 2012.

3.2 Evaluating the Latent Cultures

Culture is a system of shared beliefs and actions. Culture is often shared between individuals based on social similarity, this can be within a language, nation, gender, age-group or other social distinction. Thus, being able to identify an individual's culture should facilitate detection of socio-demographic information. To test this we looked at using the latent cultural dimensions to predict socio-demographics on Twitter. We looked at the systems ability to identify gender (male vs. female), age (young vs. old), and political orientation (Democrat vs. Republican) of individuals based on their exhibition of particular latent cultural dimensions. In this model we first represented an individual's tweets as a distribution over the latent dimensions. We then utilized two different statistical approaches to find associations between particular dimensions and the relevant socio-demographic information. For a comparison, we tested our SVD-culture model against a similarly trained LDA model and a model based on n-grams.

3.2.1 Data

We utilized the publicly available dataset from Zamal, Liu, and Ruths (2012). The dataset consisted of Twitter user names and associated meta-data identifying their gender (Male or Female), age (two classes, young and old), and political orientation (Liberal or Conservative). Unfortunately, many of the identified tweets were no longer available from the Twitter API, but we successfully retrieved 2.6 million tweets from authors identified in the dataset with 310 users identified for gender, 320 identified for their age, and 380 for their political affiliation. The tweets in our dataset are substantially different from the original dataset because of the time over which they were collected. Zamal, et al.'s tweets were from 2012 and before, whereas our tweets covered much of 2013. This suggests that comparisons of the raw numbers should be made with caution, particularly in the political area.

Table 2: Results for identifying user demographics based on latent cultural dimensions compared to linguistic style and an ensemble method utilized by Zamal et al (2012).

		Zamal et al.	N-Grams	LDA	SVD
	N	F	F	F	F
Gender	310	.80	.57	.71	.70
Age	320	.75	.63	.66	.67
Political Orientation	380	.89	.73	.66	.68

3.2.2 Modeling & Results

To provide a comprehensive view of the strengths and weakness of our approach we compared several models for their ability to correctly predict the cultural demographics of individuals on Twitter. We first established a base-line model which was an n-gram language model created from the language used by each individual in their tweets. This model learned to identify the cultural demographics based on the frequency with which individual's in that demographic used sequences of words, called n-grams. This approach is consistently ranked as one of the single best approaches to authorship identification and performs well on a large variety of datasets.

We also tested the SVD-Culture model introduced above on this dataset. For this experiment, we trained a logistic-regression based classifier to identify the demographic information of an author based on the vector created by projecting that author into our latent space.

Finally, to look for a difference in the performance between an SVD-based latent representation and one based on LDA (Pennacchiotti and Popescu, 2011), we also trained and tested an LDA-based Culture model. The model was trained on the same data as the SVD-based model and utilized the same number of dimensions.

All of the models were tested and trained utilizing 10-fold cross validation. It is very important to point out that the data sets used to generate the underlying latent representational models did not include any of the tweets from the data used for the 10-fold cross validation. That data was only utilized for the supervision of the logistic regression.

The results of the base model, the SVD model, the LDA model, and the original results presented by Zamal et al. (2012) are shown in Table 2. The latent models are clearly superior to the language model, on average outperforming it by a significant margin of 4%. As expected, the SVD-based model does outperform the LDA model on average, though it is only by 1%, on average.

The strength of this approach is in its simplicity. The latent cultural dimensions have been learned on a wholly different dataset than that used for testing, this supports good generalization performance. While the latent SVD-cultural model does not reach the performance of the system created by Zamal et al. (2012). Zamal et al.'s results were obtained using a plethora of different feature types, which were specifically trained to solve each individual problem. As pointed out in Cohen and Ruths (2013) this causes some issues on transfer to a novel dataset, because the selected features were not representative of differences between liberals and conservatives in the second dataset. In contrast, we suggest that the latent cultural model learns a more general representation utilizing only the set of features provided by the underlying latent cultural models, which were not trained on any of the data in the test set. Additionally, the latent SVD model is easy to implement and train.

Importantly, these results indicate that the latent cultural dimensions capture similarities in the ways in which individuals of similar socio-demographics express themselves on Twitter. The model is able to easily identify the gender, age, and political affiliation of individuals based on their tweets. In the next section we show how we can utilize these latent cultural dimensions to facilitate learning of expressions conveying factors of intentionality.

4 Cultural Sensitive Identification of Cognitive Factors of Intentionality in Language

Recognizing language that expresses factors of intentionality is complicated because of the wide variety of ways in which they can be expressed as shown in the examples in the previous section. While some work has explored automatic goal recognition, most recently by (Chen et al., 2013) and (Banerjee et al., 2012), little work has been done automatically characterizing the other factors, though work in detecting social implicatures in language is similar (Bracewell et al., 2012b). We first present a general framework for learning to model the content of tweets that express a given factor from our cognitive model, we then show how this approach can be enhanced with the addition of latent cultural dimensions.

4.1 Culture Agnostic Model

Here we introduce the $General\ Model$ that serves as the basis for the culture specific models. It is so named because it applies to all cultures. We utilized an n-gram based language model to identify the factors in tweets.

We first constructed a vocabulary of all n-grams between 2 and 4 words in length. Each tweet, j, which is labeled with a hashtag linked to a sub-factor f, is represented as a vector, X^j. Entries in X^j correspond to the number of occurrences in the tweet of the i^{th} n-gram from the vocabulary. We examined two different mathematical approaches to modeling the cognitive factors to gain a better understanding of the problem.

The first approach utilized a Naive-Bayes based classifier (NB) where

$$p(F = f|X) = \frac{p(F = f) \cdot \ p(X|F = f)}{p(X)} \tag{3}$$

The second approach utilized an L2-loss logistic regression model (L2):

$$p(F = f|X, W) = \frac{1}{1 + exp(w_0 + \sum_i w_i X_i)} \tag{4}$$

In which the weights, W, are learned by maximizing Equation (4)

$$\sum_{j}^{m_f} log\ p(y^j|X^j; W) - \alpha||W||_2^2 \tag{5}$$

where m_f represents a balanced training set created by randomly sampling the training tweets that are tied to sub-factor f and an equal number of tweets that express one of the other factors. For solving the maximization problem we utilized the LibLinear package (Fan et al., 2008).

4.2 Culture Sensitive Models

We compared two different methods for integrating the culture information from the SVD-based culture model into the models for identifying the cognitive factors of intentionality. Both models assume that the authors have been partitioned into a set of cultures, L, but differ in their modeling of the link between language and cognitive factors.

In order to identify the cultures of the authors we utilize a clustering of the latent dimensions produced by the SVD model, a spectral clustering (Kannan et al., 2004). We utilized a simple hierarchical clustering that capitalizes on the y largest singular values. We create a set of hierarchical clusters based on a median split of each of the first y columns in our latent space. When $y = 1$ we have two clusters where the authors have been split based on the median value of the first latent dimension, with $y = 2$ each cluster is then independently split by the author's value along the second latent dimension, giving four clusters, and so on.

4.2.1 Culture-Specific Model

Our first method, which we call the culture specific model uses a separate model of each factor for each latent culture, $l \in L$. We first identify a tweet x, as belonging to a given culture, l. We then determine whether or not the language it contains expresses a particular cognitive factor based on

$$p(F = f|x_l, L_l) \tag{6}$$

To learn the function we utilize a linear classifier, Logistic-Regression with an L2 regularization term, and limit the training data to authors that belong to the particular culture.

4.2.2 Joint-Culture Model

Our second model, which we call the joint culture model utilizes an ensemble based approach. For each tweet, x_l, we calculate both a culture specific view of the language in the tween $p(F = f|x_l, L_l)$ and a culture agnostic view $p(F = f|x_l)$, taking the classification is that is most confident. This joint approach utilizes the culture-agnostic model to smooth deficiencies caused by insufficient culture-specific data.

4.2.3 Number of Cultures

We explored settings of $y = \{2, 3, 4, 5\}$ latent dimensions which equates to $\{2, 4, 8, 16, 32\}$ latent cultures. Authors are first split according into their cultural group and then tweets from each culture are broken into a training and testing set. Because of the amount of data we utilized only a 5-fold cross validation procedure. In addition, we also tested a random culture model that randomly assigned authors to cultures instead of utilizing the spectral clustering. When creating these random cultures we balanced the number of authors in each random culture with the corresponding spectral cultures.

Table 3: Accuracies for modeling each sub-factor of intentionality. L2 represents results obtained using an L2-regularized linear regression, NB represents naive-Bayes, #Cultures signifies the number of latent cultural dimensions used for clustering.

	General		L2 - Culture Specific				L2 -Joint Culture				
#Cultures	NB-0	L2-0	2	3	4	5	2	3	4	5	NB-5
F1:Goals	79.8	80.9	81.1	80.9	79.8	78.8	82.1	**82.2**	82.1	82.0	79.1
F2:Control	70.1	75.5	75.5	75.3	74.4	73.8	76.4	**76.4**	76.4	76.4	72.3
F2:Lack of Control	69.1	73.7	75.2	74.9	74.1	72.9	**75.9**	75.7	75.8	75.6	71.6
F2:Skill	73.2	76.2	77.6	77.0	76.4	75.5	78.2	**78.2**	78.1	78.1	75.3
F3:Positive Other	78.3	82.9	84.3	84.1	83.7	83.4	**84.5**	84.4	84.4	84.5	81.9
F3:Positive Self	66.0	69.1	70.6	70.3	69.4	68.7	71.3	71.3	71.3	**71.4**	68.4
F3:Negative Other	68.7	72.3	73.6	73.4	72.5	71.6	74.1	74.0	**74.1**	74.0	70.8
F3:Negative Self	69.3	72.4	73.6	73.3	71.9	71.3	**74.4**	74.3	73.9	73.7	71.1

4.3 Data

Testing was done on a large number of tweets (7.5 million) that contained tweets from individuals that used any of the representative hashtags. In our collection hashtags exhibiting the sub-factor of control contained the largest number with approximately 575,000 tweets, while we only collected 110,000 tweets which were marked with a hashtags indicating positive rewards for the actions of other individuals. For training and testing purposes we removed all URLs, hashtags, and @users from the tweets. We then discarded tweets that were less than two words long. This approach is conservative, because we removed the classifier's ability to directly learn co-occurring hashtags, however we wanted to ensure that we would minimize deficient solutions and maximize the ability of the models to transfer from Twitter to other genres of text.

4.4 Results and Discussion

The accuracy of the classifiers for identifying each sub-factor are shown in Table 3. The accuracies reflect the classifiers ability to separate tweets that have a hashtag representing the given sub-factor from those that do not. The results suggest that all of the models are adequately capturing the differences between the cognitive factors. On average, the logistic regression based classifier achieves a 3.5 percent advantage in accuracy over the Naive-Bayes model, showing a clear advantage for the improved feature selection of the L2-loss logistic regression. Both models required a similar amount of time to train and test.

To conserve space Table 3 shows only the results for the 5-dimension Joint Culture Naive-Bayes model. The results for the Naive-Bayes model match the pattern exhibited by the logistic-regression Joint Culture model, except that the Naive-Bayes Joint-Culture model increases steadily as more groups are added with a maximum performance with 5 latent dimensions. With 5 latent dimension the gap between the two ML approaches shrinks to 2.8 percent (73.2 to 76.0).

On average the Joint Culture model shows a 1.8 percent improvement (74.3 to 76.1) over the culture neutral model for the L2-Logistic Regression, while it is a larger 2.2 percent for the Naive Bayes based approach (71.2 to 73.4). A comparison of the error reduction shows that the cultural integration is very promising. While the L2-loss logistic regression provides an 11 percent error reduction over the Naive-Bayes, the joint culture model achieves a comparable 7-9 percent reduction in error over the L2-loss regression and the Naive-Bayes model.

The improvements are strongest for positive self directed reward factor, skill factor, and lack of control factor. Interestingly, the models also exhibited considerable variation in accuracies across the different cultures, for example utilizing 3 dimensions positive rewards for others in one culture is recognized at 92 percent (this group contains 43,556 tweets), while for another culture of approximately the same size it is only recognized at 77 percent. Unfortunately, when moving to 4 dimension our clustering algorithm splits the group at 92 percent into two groups where the factor can only be recognized with an average of 88 percent accuracy. This suggests that more complex clusterings strategies within the latent space would be beneficial.

While not shown in the table for space reasons, we also tested the joint culture model utilizing a random assignment of authors to cultures, instead of relying on the assignment produced by the SVD-model. As expected the random model performed, on average, at approximately the same level as the general model, 74.6% compared to 74.5% respectively. Though the random culture model exhibited considerable variation in relation to the real joint culture model across the different factors. This evidence reinforces the idea that the latent cultures are coherent and that individuals within those cultures express the factors of intentionality in similar ways.

Table 4: Example cultures and the tags that are commonly associated with that factor.

Cultural Label	Cognitive Factor	Common Tags
Alterantive Medicine Health	Positive Rewards Self	#almond, #radish, #curd
Geek Interest	Positive Rewards Self	#theobroma, #freefiction, #nanotech
Teenagers	Positive Rewards Self	#bored, #me, #cute
Urban Hip/Hop	Positive Rewards Self	#bosslife, #teamfastfollow, #indiecharts
Martial Fitness	Goals	#healthynews, #fitnessimages, #fitso
Hip/Hop	Goals	#soundcloud, #support, #dl
General Religion	Goals	#singer, #jesus, #judas

Inspections of tweets where the cognitive factors have been discovered suggest that many times the hashtags are used sarcastically. Anecdotally, we also examined a list of the top hashtags associated with instances labeled by our approach and found good generalization to novel hashtags. We looked at a list of the hashtags based on the average confidence of the labels being applied to the tweets containing those tags, we found many reasonable candidate tags. For example, tweets containing the hashtags #day1 and #day2 were among the most likely to be labeled as exhibiting a goal even though neither were identified by our annotators initially. These two tags are used by individuals on the first and second day of pursuing a goal.

The results presented in this section suggest that breaking down the authors by culture before learning models linking the hashtags marking expressions of the cognitive factors of intentionality to language provides a significant benefit. It also hints at some interesting differences between the groups. In the next section we briefly explore some of those differences.

5 Investigating Cultural Differences in the Language of Intentionality

We investigated the cultural discriminations made by the model by looking at the hashtags that were the most popular for each culture. Two annotators provided labels for each of the cultures based on the most frequent hashtags for that culture. We found that some of the cultures could easily be labeled based on their differential use of topical hashtags. Many of the latent cultures reflected notions of distinctions between cultural (or sub-cultural) groups, such as along political orientation or socio-demographics (urban, hipster, university students, single mothers, and political activist). In addition to the latent cultures that weighed on group identity, some of the other clusters captured more topical information, such as being fitness oriented or discussions focused around sex.

The cultural distinctions allowed us to quantify the differences in the event and intentionality associations across the cultures and differences in expressions indicating cognitive factors of intentionality. For instance, activists and urban individuals were most likely to produce tweets expressing control over situations. There were also groups, such as the camaraderie group where individuals typically set goals that will benefit a group in some way as well as the individual. In most of these cases, the author is the member of a team or some other group that will be engaging in a cooperative or competitive activity. Some authors from this cultural group express goals of providing direct or moral support to specific teams or groups of which they are not members. Others have goals of attending group events or gatherings with no particular membership. In most cases, goals in this culture are associated with positive rewards or defeating an opponent.

Table 4 shows the most probable tags by cognitive factor for some of the more interesting groups. These lists were generated by first eliminating all tags from the culture that were not predictive of the culture. To do this, we generated an estimate of the mean and variance for each hashtag in our dataset across all of the different cultures. We then eliminated all tags where the probability of the tag given the culture was not significantly different than its estimate given the general population. This has the effect of removing that hashtags that signaled the cognitive factors because they had a fairly general distribution across the cultures.

6 Conclusion

In this paper we presented a novel approach for identifying factors of intentionality in tweets. Further, we showed how a latent cultural model could be used to enhance those identifications through an improved understanding of how these factors are expressed across the various cultures. The latent cultural dimensions identified by the model correspond well with real cultural demographic information.

This work presents several exciting possibilities, while Twitter is notoriously difficult for traditional natural language processing work because it doesn't follow established syntactic and semantic conventions, models learned over Twitter data are able to transfer to other types of social media, such as user-generated content sites (Tomlinson et al., 2014a). Hashtags provide a very interesting form of distant annotation that could reduce the amount of time and effort required to create models which capture a nuanced understanding of social or psychological pragmatics,

such as social acts (Bender et al., 2011; Bracewell et al., 2012a), thus making the exploration of a richer language understanding more tractable.

Lastly, we have also shown that the models provide an ability to look at differences between cultures in the how and when of their expressions of factors relating to intentionality. People express lots of goals, but what affects when they actually intent them. These models should be able to provide a novel view on the pulse of a city (Rios and Lin, 2013) or citizens' cognitive responses to events (Dodds et al., 2011). We can use these techniques to identify what events make people establish new goals or instill feelings of a loss of control?

Abstract

This study aims at retrieving tweets with an implicit topic, which cannot be identified by the current query-matching system employed by Twitter. Such tweets are relevant to a given query but do not explicitly contain the term. When these tweets are combined with a relevant tweet containing the overt keyword, the "serialized" tweets can be integrated into the same discourse context. To this end, features like reply relation, authorship, temporal proximity, continuation markers, and discourse markers were used to build models for detecting serialization. According to our experiments, each one of the suggested serializing methods achieves higher means of average precision rates than baselines such as the query matching model and the tf-idf weighting model, which indicates that considering an individual tweet within a discourse context is helpful in judging its relevance to a given topic.

1 Introduction

1.1 Limits of the Twitter Query-Matching Search

Twitter search was not a very crucial thing in the past (Stone, 2009a), at least for users in its early stages who read and wrote tweets only within their curated timelines real-time (Dorsey, 2007; Stone, 2009b; Stone, 2009c). Users' personal interests became one of the motivations to explore a large body of tweets only after commercial, political and academic demands, but it triggered the current extension of the Twitter search service. The domain of Twitter search was widened, for example, from tweets in the recent week to older ones (Burstein, 2013), and from accounts that have a specific term in their name or username to those that are relevant to that particular subject (Stone, 2007; Stone, 2008; Twitter, 2011; Kozak, Novermber 19, 2013). However, the standard Twitter search mechanism is based only on the presence of query terms.

Even though the Twitter Search API provides many operators, the current query matching search does not guarantee retrieving a complete list of all relevant tweets.[1][2] The 140-character limit sometimes forces a tweet not to contain a term, not because of its lack of relevance to the topic represented by the term, but due to one of the following:

Reduction the query term is written in an abbreviated form or in form of Internet slang,

Expansion the query term is in external text that can be expanded through other services such as TwitLonger (http://twitlonger.com) and twtkr (http://twtkr.olleh.com), while the part exceeding 140 characters is shown only as a link on twitter.com, or

Serialization the query term is contained as an antecedent in some previous tweet.

[2] "[T]he Search API is not meant to be an exhaustive source of Tweets." 7 March 2013. GET search/tweets https://dev.twitter.com/docs/api/1.1/get/search/tweets

Proceedings of COLING 2014, the 25th International Conference on Computational Linguistics: Technical Papers, pages 58–68, Dublin, Ireland, August 23-29 2014.

If these cases are frequent enough, the current query matching search in Twitter will get a low recall rate. Considering that tweets are usually used to obtain as various views on a topic as possible, in addition to accurate and reliable information about it, this setback would block attempts to collect diverse opinions in Twitter.

These three different cases require different approaches. First, *reduction*, one of the most significant characteristics of Twitter data in natural language processing, can be solved by building a dictionary of Internet slang terms or learning them. Second, in case of *expansion* tweets are always accompanied with short URLs (`http://tl.gd` for TwitLonger and `http://dw.am` for twtkr) and the full text is reachable through them. In these two cases, tweets correspond one-on-one with documents, whether reduced internally or expanded externally. This study will focus on the third case, *serialization*, where several tweets may be interpreted as a single document.

1.2 Serialization of Tweets: An Overlooked Aspect of Twitter

Though little reported before, serialization of tweets is frequently observed in Korean data.[3] Influential users like famous journalists, columnists and critics as well as ordinary users often publish multiple tweets over a short period of time instead of using other media such as blogs or web magazines. Types of tweets published in this way by Korean users include reports, reviews, and analysis on political or social affairs, news articles, books, films and dramas. The content users intend to express is longer than a tweet but shorter than a typical blog post. Examples from our dataset will be introduced in Section 3.

This study aims at retrieving tweets on a topic, which cannot be found by the current query-matching system. Such tweets are relevant to a given query but do not contain the necessary words. Under the hypothesis that a considerable number of these tweets not containing the query term are serialized with one containing it overtly, and that serialized segments are integrated into the same discourse context, we built a model that allows us, when given a tweet that includes a query or a mentioned topic, to find the other tweets serialized with it and count them as relevant to the topic. We primarily focused on Korean Twitter data, but we believe that the methods developed here are also applicable to other languages with similar phenomena.

2 Previous Studies

Our study is based on the observation that a tweet in a "serialization" does not necessarily correspond to a full document. In fact, it has already been reported (Hong and Davison, 2010; Weng et al., 2010; Mehrotra et al., 2013) that a single tweet is too short to be treated as an individual document, especially considering that word co-occurrence in a tweet is hardly found. Studies proved that performance of Latent Dirichlet Allocation (LDA) models for Twitter topic discovery can be improved by aggregating tweets into a document. In these studies, a "document " consists either of all tweets under the same authorship (Hong and Davison, 2010; Weng et al., 2010), all tweets published in a particular period, or all tweets sharing a hashtag (Mehrotra et al., 2013). These criteria are useful for finding topics, into which tweets can be classified, but our purpose requires a different degree of "documentness." Our study deals with a fixed topic and is interested in whether or not only tweets relevant to the topic can be pooled. All tweets merged into the same document as constructed in the previous studies are not necessarily coherent or related to the same topic because it is not usually expected that ordinary users devote their Twitter accounts to a single topic. In this study, we will develop more detailed criteria for the aggregation of tweets by combining authorship with time intervals and adopting features such as sentiment consistency and discourse markers.

A method of using discourse markers for microblog data was proposed by Mukherjee and Bhattacharyya (2012). They noted that a dependency parser, on which opinion analyses using discourse information (Somasundaran, 2010) are usually based, is inadequate for small microblog data, and instead used a "lightweight" discourse analysis, considering the existence of a discourse marker on each tweet. The list of discourse markers used in their study was based on the list of conjunctions representing discourse relations presented by Wolf et al. (2004). This method was successful for sentiment

[3] Some Korean users sarcastically call this a "saga" of tweets.

analysis on Twitter data assuming that the relevance of each tweet to a certain topic was already known. We will take a similar approach of using discourse markers, but with a different assumption and for a different purpose. In our study, we treat unknown topic relevance of tweets with missing query terms by aggregating them with a topic-marked tweet using discourse markers.

3 Features

3.1 Properties of Tweet Serialization

Multiple tweets are likely to be consistent with a topic if they form a discourse as in the following situations, with examples of tweets in Korean translated into English. In each tweet, topic words are in boldface.

Conversation This is the most typical case.

> **U1:** Wow the neighborhood theater is packed; will ***Snowpiercer*** hit ten million?
>
> **U2:** @U1 My parents and my boss are all gonna watch, and they watch only one film a year. This is the measure for ten million.

Comment after retweet Users retweet and comment.

> **U3** RT @U4: Today's quote. "It is stupid to concentrate on symbolic meaning in Wang Kar Wai's *Happy Together.* That would be like trying to find political messages and signs in ***Snowpiercer***." — Jung Sung-Il
>
> **U3** Master Jung's sarcasm.....☆

On-the-spot addition Because a published tweet cannot be edited, users can elaborate or correct it only by writing a new tweet or deleting the existing tweet.

> **U5** Is Curtis the epitome of **Director Bong**'s[4] sinserity
>
> **U5** Sincerity, shit

True (intentional) serialization Some users begin to write tweets with a text of more than 140 characters in mind. They arrive at the length limit and continue to write in a new tweet.

> **U6** (1) Watched ***Snowpiercer***. It was more interesting than I thought. It felt more like black comedy than SF. On another note, I was surprised by several oddities, making the film feel more like a Korean film with foreign actors in it rather than Director Bong's Hollywood debut.
>
> **U6** (2) In many ways the film was "nineties"... like watching *The City of Lost Children* all over again... and the trip from the tail-car to the first car, though I expected some kind of level-up for each car,
>
> **U6** (3) the world connected car to car was not an organic world (a sideways pyramid?) but worlds too separate car by car, and the front-car people were so lifeless that I was surprised. The scale of the "charge" after 17 years felt shrunken.

If this is a characteristic feature of Korean Twitter data, this may be due to reasons such as personal writing style, the writing system of the Korean language, and Korean Web platforms. First, it may be simply because these users prefer formal language and are reluctant to use short informal expressions even in Web writing. Second, it is possibly because CJK writing systems including Hangul, the Korean alphabet, have more information per character than the Roman alphabet (Neubig and Duh, 2013). Since a 140-character text in Hangul has generally more information than that in the Roman alphabet, a Korean (or Japanese) user can more readily tweet about content which an English (or other European) language user would consider too long to write about on Twitter. Third, for many Korean users Twitter is the most available medium for publishing their opinions online, as a number of standard blogs have been replaced

[4]Director of the film *Snowpiercer*

by microblogs. Some users divide a long public text into multiple length-limited tweets simply because they do not have a blog to write in.

While Internet slang and abbreviations are common in tweets, "Serializers" tend to use 1) fully-spelled forms (unlike "reducers"), 2) usually without hashtags and emoticons, 3) which are all visible on `twitter.com` itself (unlike "expanders"), so it is not guaranteed that all serialized tweets will contain the topic word, as in the examples above. This implies that some tweet segments in a single discourse may not be retrieved even if the discourse is relevant to a given query. Search results may include a partial document for which it is difficult the full version of which is difficult to find.

3.2 Extralinguistic Criteria

Two tweets are more likely to be a part of a larger document consisting of a series of tweets if

Reply-relation one of them is a reply to the other,

Temporal proximity they are published immediately one after the other, or

Continuation markers they share such markers as numbers, arrows >> and continuation marker '(continued).'

Figure 1 shows examples of each case.

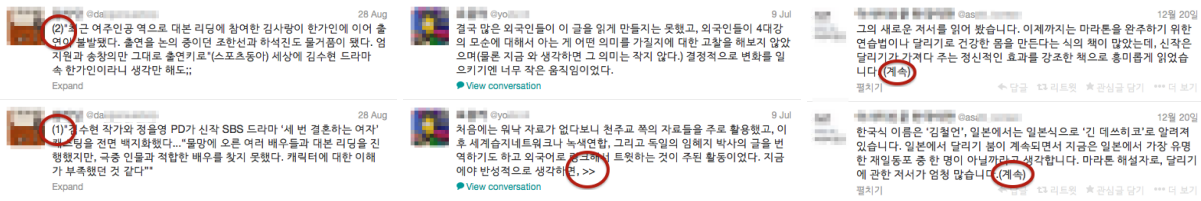

Figure 1: Serialized tweets with numbers, an arrow, or a continuation marker '(continued)'

3.3 Linguistic Clues

Semantic similarity to the query In order to determine the relatedness of two documents, the similarity between their term distributions is mainly considered. Based on this idea, one of our baseline methods will represent each tweet as a bag-of-words vector and retrieve a tweet containing no query term if its tf-idf weighted vector has a high cosine similarity with at least one vector from a tweet containing a query term.

Discourse markers Users may add a discourse marker when writing a new sentence in a new tweet. If a tweet begins with a marker that indicates continuation of a discourse, it is likely to be a part of a larger document. A sentiment analysis in Twitter by Mukherjee and Bhattacharyya (2012) adopted discourse relations from Wolf et al. (2004). In this paper, we use linguistic characteristics described by Kang (1999) in order to classify Korean texts, listing their English translations in Table 1. The *discourse marker* feature refers to whether or not any marker on the list occurs in the first N words (set $N = 5$) of the tweet.

4 Experiments

4.1 Data

We collected 173,271 tweets posted or retweeted by 105 Korean users, including film critics, film students, and amateur cinephiles from 27 July to 26 September 2013. Out of the 105 users, 17 users who had mentioned the film *Snowpiercer*[5] most often were singled out. In addition, the highest overall occurrence of the keyword was found to be between 1 to 15 August, probably due the film's release on 31

Conj-Coordinate	*and, nor*
Conj-Adversative	*but, yet, however, still, by contrast*
Conj-Discourse	*meanwhile, anyway, by the way*

Table 1: List of selected Korean discourse markers used for classifying text types in Kang (1999), translated into English

July in South Korea. Then we kept all 8,543 tweets posted by those 17 users from the period between 1 to 15 August 2013, in order to construct a labeled data set. This set includes 189 tweets that explicitly contain the word *Snowpiercer*. Each tweet in the filtered set was labeled as *related* or *not related* to the movie by three annotators who were Twitter users already following most of the above 17 users and thus aware of the context of most tweets, and a tweet was considered relevant if two or more of the annotators agreed. Inter-annotator agreement was evaluated by using Fleiss's kappa statistic flei:71, which was $\kappa = 0.749$ ($p \approx 0$). Table 2 shows the annotation results.

	Related	Not related	Total
Explicit	173	15	188
Not explicit	207	8,148	8,355
Total	380	8,163	8,543

Table 2: The number of annotated tweets classified by explicitness and relatedness

Table 2 shows that 8163/8543 = 95.55% of the tweets in the dataset are not relevant to the movie *Snowpiercer*. Additional topics are induced from 7–9 manually collected seed words among the 200 most frequently occurring nouns in the dataset, in which each tweet text was POS-tagged by the Korean morphological and POS tagger Hannanum[6]. Induced topics and their seed words are listed in Table 3.

Topic	Seed words
Movie	Movie, Snowpiercer, director, The Terror Live, actor, stage, audience, film, theater
Literature	Story, book, writing, author, novel, character, work
Gender/relationship	Men, women, female, marriage, male, wife, lover
Politics	Politics, state, Park Geun-hye, government, president, party, Ahn Cheol-soo

Table 3: Four topics from manually collected seed words

As described in 3.1, it should be noted again that hashtags are not always useful for finding information in Korean tweets, particularly in this dataset. Among the seed words above, only *Snowpiercer* was ever used as a hashtag, and happened only three times (twice in English and once in Korean). Only nine types of hashtags occurred more than twice in the full dataset (they are presented in Table 4 with their respective frequencies). This predicts that hashtag-based tweet aggregation would not be very useful to find tweets relevant to *Snowpiercer* or one of the four induced topics.

Table 5 shows the number of tweets containing seed words for each topic, where a tweet is allowed to belong to more than one topic. Since only 1853/8543 = 21.69% of the tweets explicitly contain a topic or seed word, it is not plausible that each of the remaining 80% tweets belongs to one of the four topics. Many of the tweets may be related to a topic which was of a too small portion to be induced, or to no topic at all. So, instead of classifying all of the tweets into the given topics, the experiment seeks to retrieve any tweet that is relevant to a certain topic, which allows each tweet to belong to more than one topic at once. In every experiment we regarded tweets that contain a topic or seed word as relevant to the topic, and restricted the test set to those tweets which did not contain them.

4.2 Measures

For all models, the authors judged the relevance of each of the retrieved tweets for induced topics until ten relevant tweets were retrieved. In the *Snowpiercer* case, precision scores were calculated for all recall scores. We built a ranking retrieval system for each model and evaluated its performance by average precision. For models including a randomizing process, we used the mean of average precisions over 1,000 replicated samples. Precision was computed at every percentile of recall levels for *Snowpiercer* case and after each retrieved relevant tweet (up to top 10) for induced topics. In sum, the performance of a model m was defined in two ways as

$$\text{meanAP@percent}(m) := \frac{1}{1000}\sum_{i=1}^{1000}\text{AP@percent}(m_i)$$

and

$$\text{meanAP@10}(m) := \frac{1}{1000}\sum_{i=1}^{1000}\text{AP@10}(m_i)$$

, where m has 1,000 replicates $m_1, \cdots m_{1000}$ whose measures are

$$\text{AP@percent}(m_i) := \frac{1}{100}\sum_{j=1}^{100}\text{prec@}j\%(m_i)$$

and

$$\text{AP@10}(m_i) := \frac{1}{10}\sum_{k=1}^{10}\text{prec@}k\%(m_i).$$

When m is a tf-idf model, which has a unique ranking without replication, average precision was used.

4.3 Baselines

Query matching method The most obvious baseline method for this study is the current Twitter search system that treats topic words and seed words as queries and finds documents, or tweets, that are relevant to the topic. Since only tweets not containing the query terms remained in the test set, there are no tweets matching them. As the set of retrieved tweets is empty, relevance rank is randomly assigned to each tweet of the test set.

Tf-idf weighting method One may predict that a tweet is likely to be relevant to a topic if it shows a similar word distribution to some explicitly relevant tweets. Under this assumption, we represented each tweet as a tf-idf weighted vector (Salton and Buckley, 1988) after removing all punctuation marks and user-mention markers (`@username`). Stopwords were not removed and tf-idf values were length-normalized. Relevance of each tweet in the test set was defined as the maximum of its cosine-similarities with all tweets containing a query term.

4.4 Tweet Serialization

Examples of Tweet Serialization in Section 3 indicate clues between related tweets other than distributional similarity. When 1) a tweet is a reply to another one, 2) two tweets are written one after another by the same user, 3) one tweet following another includes some discourse marker, or 4) two tweets share a marker, such as numbers, they can be considered to be serialized into a single document rather than being two separate ones. Tweets serialized together are treated as a single document, and if this document contains a a tweet with a query term, then all tweets lacking it but belonging to the same the same document are retrieved. All retrieved tweets are first ranked in random order, followed by the others also in random order.

We suggest four criteria for Tweet Serialization:

Reply Two tweets are serialized if one is a reply to the other.

Continuation markers Two tweets are serialized if they are written successively by the same user and share a marker, such as a number or a phrase "(cont.)"

Discourse markers Two tweets are serialized if they are written successively by the same user, the latter contains one of the discourse markers listed in Table 1 in its first 5 words, and neither of them is a reply to another user.

Time Two tweets are serialized if they are written successively by the same user within a given interval and neither of them is a reply to another user. The upper boundary for intervals is set in one of the following ways:

Constant 30 or 60 seconds

User-specific Users may show different densities in their tweets, depending on their tweeting environment. Distribution of time intervals between successive tweets over users is presented in Table 6. The smallest 5% and 15% quantiles were selected, corresponding to 30 and 60 seconds respectively.

Quantile	U1	U2	U3	U4	U5	U6	U7	U8	U9	U10	U11	U12	U13	U14	U15	U16	U17
0%	3	19	2	1	1	5	10	3	2	3	9	3	2	3	3	2	16
5%	20	42	18	16	13	30	21	18	13	8	43	23	18	15	13	12	110
10%	33	45	25	35	20	43	38	38	28	13	71	35	28	35	21	21	130
15%	47	52	33	57	30	56	67	57	40	23	89	51	37	61	27	40	161
20%	62	67	41	79	41	73	92	74	53	31	111	65	50	84	33	58	197
25%	81	86	55	100	55	92	145	95	69	43	138	84	68	105	38	77	275
50%	237	298	164	322	151	242	1060	297	167	159	297	317	178	258	90	266	725

Table 6: Time intervals (in seconds) by cumulative percentile between consecutive pairs of tweets for each user

For all criteria, Tweet Serialization is transitive, that is, if t_i and t_j are serialized and t_j and t_k are serialized, then t_i and t_k are serialized. Table 7 shows the distribution of serialization sizes (number of serialized tweets) over criteria. Time value of 60 seconds serializes most tweets, as many as (8543-6464)/8543=24.33%, while continuation markers serialize only (8543-8511)/8543 = .37%. Assuming all serializations are correct, the relevance of retrieved documents is judged.

4.5 Results

The average precision values of all models are summarized in Table 8 (means calculated over recall levels) and Figure 2 (means calculated over 1,000 replications). In both Tables 8 and 9, differences between the tf-idf weighting model and each of the Serialization methods were statistically significant according to t-test. Figure 2 compares the results of the serialization methods, among which *continuation marker* model has the highest precision over 0.8 at the 1% recall level, and *Time with 15% quantile* has the average precision score showing the slowest decrease. Even though for all serialization methods average precision values converge to zero as recall levels increase, each of the method gets higher precision rates than baselines until some part of relevant tweets are retrieved.

Size	Repl.	Disc.	Cohe.	T:30s	T:60s	T:5%	T:15%
1	8137	8169	8511	7314	6464	7845	6849

100%	.0268	.0556	.0434	.0322	.0375	.0666	.0628	.0669	**.0687**

Table 8: Means of average precision rates (at recall level up to 5%, 50%, and 100%) on various serialization criteria for the topic *Snowpiercer* (Results in boldface represent the best results among the methods.)

Serialization methods also perform better than the tf-idf baseline for induced topics, as shown in Figure 3 and Table 9. In particular, *Reply* and *Discourse markers*, which were far from the best for *Snowpiercer*, serve well for other topics such as *Movie* in general, *Politics*, and *Gender/Relationships*.

The precision of *Reply* for the topic *Movie* is exceptionally high, partly because the data were initially collected from users who were interested in films. *Reply relation* is dependent on the choice of the data, in that it is determined by interaction between users, not by a single user's tweets. If data are collected from users friendly with each other, *Reply* will serialize many tweets. On the contrary, if data contains some users while leaving out their friends, replies to these friends are not serialized by *Reply* criteria.

Discourse markers give a precision of higher than 50% for the topic *Politics*, which is likely to be discussed in more formal expressions using various conjunctions.

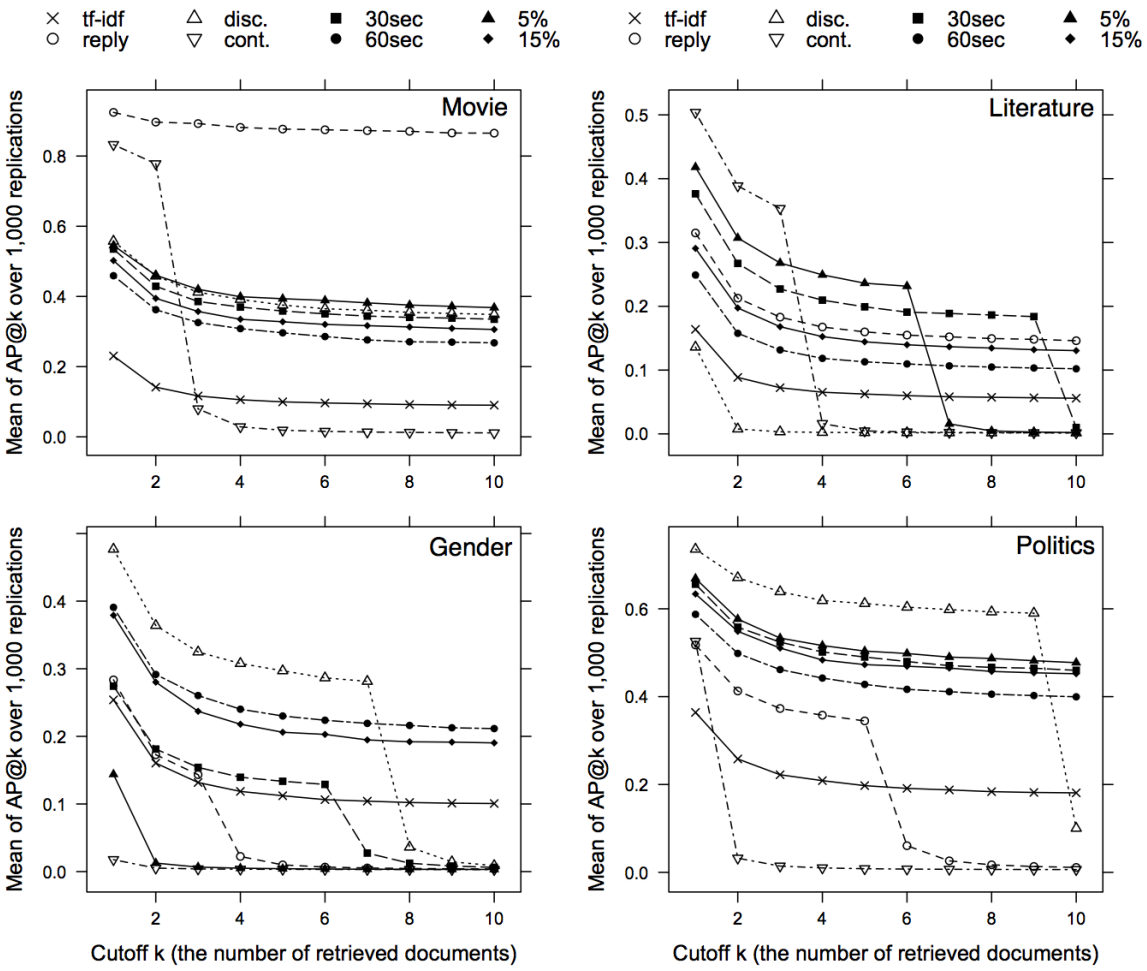

Figure 3: Means of average precision rates of all methods for the induced topics

	Baselines:		Repl.	Disc.	Cont.	Time difference threshold			
	Match	tf-idf	rela.	mark.	mark.	30sec	60sec	5%	15%
Mov.	.0134	.1139	**.8855**	.3925	.1791	.3787	.3123	.4161	.3435
Lit.	.0026	.0759	.1804	.0171	.1293	**.2005**	.1287	.1719	.1601
Gen.	.0048	.1287	.0653	.2424	.0050	.1092	**.2476**	.0187	.2297
Pol.	.0090	.2176	.2135	**.5762**	.0625	.5072	.4453	.5234	.4948

Table 9: Means of Average Precision rates at cutoff $k = 10$ of baselines and different serialization criteria for induced topics (Results in boldface represent the most accurate results of the topic among the methods.)

In the topics *Literature* and *Gender/Relationships*, average precision scores are at most 25%, which possibly results from the fact that the seed words for these topics consist of general terms only, while those of the other two topics include proper nouns such as movie titles or politicians' names. This is less a problem of the topic itself but rather one of data selection, which focused on users tweeting about films, and so the set of seed words will vary according to differences in data collection.

5 Conclusion

In this paper, we found that tweets with an implicit topic can be found more effectively by considering whether or not they are serialized with some tweet containing the overt keyword. Our experiments show that Tweet Serialization can be detected using various criteria such as reply relations between users, presence of discourse or continuation markers, and temporal proximity under the same authorship. Our

original purpose was to find as various opinions on a given topic as possible, but we expect the methods used here will be helpful for other tasks, including topic discovery and sentiment analysis, by setting more exact document boundaries in microblog data. The method we proposed is for Korean Twitter data, where tweet serialization is observed frequently, particularly among influential users, but it is also applicable to other languages with similar phenomena.

In future work, we will investigate methods for the evaluation of the results of Tweet Serialization and combine tf-idf methods with Tweet Serialization criteria. Furthermore, we aim at verifying the applicability of the results of this study with regard to more various users and more topics.

Abstract

Sentiment analysis of short texts such as single sentences and Twitter messages is challenging because of the limited contextual information that they normally contain. Effectively solving this task requires strategies that combine the small text content with prior knowledge and use more than just bag-of-words. In this work we propose a new deep convolutional neural network that exploits from character- to sentence-level information to perform sentiment analysis of short texts. We apply our approach for two corpora of two different domains: the Stanford Sentiment Treebank (SSTb), which contains sentences from movie reviews; and the Stanford Twitter Sentiment corpus (STS), which contains Twitter messages. For the SSTb corpus, our approach achieves state-of-the-art results for single sentence sentiment prediction in both binary positive/negative classification, with 85.7% accuracy, and fine-grained classification, with 48.3% accuracy. For the STS corpus, our approach achieves a sentiment prediction accuracy of 86.4%.

1 Introduction

The advent of online social networks has produced a crescent interest on the task of sentiment analysis for short text messages (Go et al., 2009; Barbosa and Feng, 2010; Nakov et al., 2013). However, sentiment analysis of short texts such as single sentences and and microblogging posts, like Twitter messages, is challenging because of the limited amount of contextual data in this type of text. Effectively solving this task requires strategies that go beyond bag-of-words and extract information from the sentence/message in a more disciplined way. Additionally, to fill the gap of contextual information in a scalable manner, it is more suitable to use methods that can exploit prior knowledge from large sets of unlabeled texts.

In this work we propose a deep convolutional neural network that exploits from character- to sentence-level information to perform sentiment analysis of short texts. The proposed network, named Character to Sentence Convolutional Neural Network (CharSCNN), uses two convolutional layers to extract relevant features from words and sentences of any size. The proposed network can easily explore the richness of word embeddings produced by unsupervised pre-training (Mikolov et al., 2013). We perform experiments that show the effectiveness of CharSCNN for sentiment analysis of texts from two domains: movie review sentences; and Twitter messages (tweets). CharSCNN achieves state-of-the-art results for the two domains. Additionally, in our experiments we provide information about the usefulness of unsupervised pre-training; the contribution of character-level features; and the effectiveness of sentence-level features to detect negation.

This work is organized as follows. In Section 2, we describe the proposed the Neural Network architecture. In Section 3, we discuss some related work. Section 4 details our experimental setup and results. Finally, in Section 5 we present our final remarks.

2 Neural Network Architecture

Given a sentence, CharSCNN computes a score for each sentiment label $\tau \in T$. In order to score a sentence, the network takes as input the sequence of words in the sentence, and passes it through

Proceedings of COLING 2014, the 25th International Conference on Computational Linguistics: Technical Papers, pages 69–78, Dublin, Ireland, August 23-29 2014.

a sequence of layers where features with increasing levels of complexity are extracted. The network extracts features from the character-level up to the sentence-level. The main novelty in our network architecture is the inclusion of two convolutional layers, which allows it to handle words and sentences of any size.

2.1 Initial Representation Levels

The first layer of the network transforms words into real-valued feature vectors (embeddings) that capture morphological, syntactic and semantic information about the words. We use a fixed-sized word vocabulary V^{wrd}, and we consider that words are composed of characters from a fixed-sized character vocabulary V^{chr}. Given a sentence consisting of N words $\{w_1, w_2, ..., w_N\}$, every word w_n is converted into a vector $u_n = [r^{wrd}; r^{wch}]$, which is composed of two sub-vectors: the *word-level embedding* $r^{wrd} \in \mathbb{R}^{d^{wrd}}$ and the *character-level embedding* $r^{wch} \in \mathbb{R}^{cl_u^0}$ of w_n. While word-level embeddings are meant to capture syntactic and semantic information, character-level embeddings capture morphological and shape information.

2.1.1 Word-Level Embeddings

Word-level embeddings are encoded by column vectors in an embedding matrix $W^{wrd} \in \mathbb{R}^{d^{wrd} \times |V^{wrd}|}$. Each column $W_i^{wrd} \in \mathbb{R}^{d^{wrd}}$ corresponds to the word-level embedding of the i-th word in the vocabulary. We transform a word w into its word-level embedding r^{wrd} by using the matrix-vector product:

$$r^{wrd} = W^{wrd} v^w \tag{1}$$

where v^w is a vector of size $\left|V^{wrd}\right|$ which has value 1 at index w and zero in all other positions. The matrix W^{wrd} is a parameter to be learned, and the size of the word-level embedding d^{wrd} is a hyper-parameter to be chosen by the user.

2.1.2 Character-Level Embeddings

Robust methods to extract morphological and shape information from words must take into consideration all characters of the word and select which features are more important for the task at hand. For instance, in the task of sentiment analysis of Twitter data, important information can appear in different parts of a hash tag (e.g., "*#SoSad*", "*#ILikeIt*") and many informative adverbs end with the suffix "*ly*" (e.g. "*beautifully*", "*perfectly*" and "*badly*"). We tackle this problem using the same strategy proposed in (dos Santos and Zadrozny, 2014), which is based on a convolutional approach (Waibel et al., 1989). As depicted in Fig. 1, the convolutional approach produces local features around each character of the word and then combines them using a max operation to create a fixed-sized character-level embedding of the word.

Given a word w composed of M characters $\{c_1, c_2, ..., c_M\}$, we first transform each character c_m into a character embedding r_m^{chr}. Character embeddings are encoded by column vectors in the embedding matrix $W^{chr} \in \mathbb{R}^{d^{chr} \times |V^{chr}|}$. Given a character c, its embedding r^{chr} is obtained by the matrix-vector product:

$$r^{chr} = W^{chr} v^c \tag{2}$$

where v^c is a vector of size $\left|V^{chr}\right|$ which has value 1 at index c and zero in all other positions. The input for the convolutional layer is the sequence of character embeddings $\{r_1^{chr}, r_2^{chr}, ..., r_M^{chr}\}$.

The convolutional layer applies a matrix-vector operation to each window of size k^{chr} of successive windows in the sequence $\{r_1^{chr}, r_2^{chr}, ..., r_M^{chr}\}$. Let us define the vector $z_m \in \mathbb{R}^{d^{chr} k^{chr}}$ as the concatenation of the character embedding m, its $(k^{chr} - 1)/2$ left neighbors, and its $(k^{chr} - 1)/2$ right neighbors[1]:

$$z_m = \left(r^{chr}_{m-(k^{chr}-1)/2}, ..., r^{chr}_{m+(k^{chr}-1)/2}\right)^T$$

[1]We use a special *padding character* for the characters with indices outside of the word boundaries.

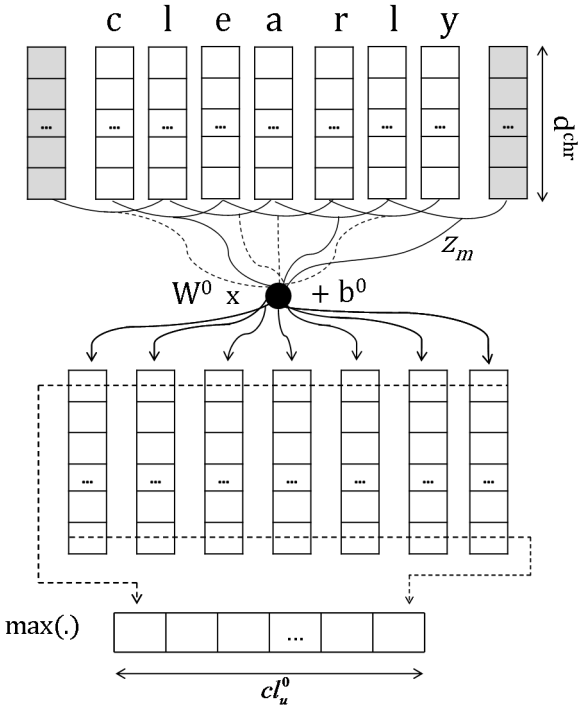

Figure 1: Convolutional approach to character-level feature extraction.

The convolutional layer computes the j-th element of the vector $r^{wch} \in \mathbb{R}^{cl_u^0}$, which is the character-level embedding of w, as follows:

$$[r^{wch}]_j = \max_{1<m<M} \left[W^0 z_m + b^0\right]_j \tag{3}$$

where $W^0 \in \mathbb{R}^{cl_u^0 \times d^{chr} k^{chr}}$ is the weight matrix of the convolutional layer. The same matrix is used to extract local features around each character window of the given word. Using the max over all character windows of the word, we extract a "global" fixed-sized feature vector for the word.

Matrices W^{chr} and W^0, and vector b^0 are parameters to be learned. The size of the character vector d^{chr}, the number of convolutional units cl_u^0 (which corresponds to the size of the character-level embedding of a word), and the size of the character context window k^{chr} are hyper-parameters.

2.2 Sentence-Level Representation and Scoring

Given a sentence x with N words $\{w_1, w_2, ..., w_N\}$, which have been converted to joint word-level and character-level embedding $\{u_1, u_2, ..., u_N\}$, the next step in CharSCNN consists in extracting a sentence-level representation r_x^{sent}. Methods to extract a sentence-wide feature set most deal with two main problems: sentences have different sizes; and important information can appear at any position in the sentence. We tackle these problems by using a convolutional layer to compute the sentence-wide feature vector r^{sent}. This second convolutional layer in our neural network architecture works in a very similar way to the one used to extract character-level features for words. This layer produces local features around each word in the sentence and then combines them using a max operation to create a fixed-sized feature vector for the sentence.

The second convolutional layer applies a matrix-vector operation to each window of size k^{wrd} of successive windows in the sequence $\{u_1, u_2, ..., u_N\}$. Let us define the vector $z_n \in \mathbb{R}^{(d^{wrd}+cl_u^0)k^{wrd}}$ as the concatenation of a sequence of k^{wrd} embeddings, centralized in the n-th word[2]:

$$z_n = \left(u_{n-(k^{wrd}-1)/2}, ..., u_{n+(k^{wrd}-1)/2}\right)^T$$

[2]We use a special *padding token* for the words with indices outside of the sentence boundaries.

The convolutional layer computes the j-th element of the vector $r^{sent} \in \mathbb{R}^{cl_u^1}$ as follows:

$$[r^{sent}]_j = \max_{1<n<N} \left[W^1 z_n + b^1\right]_j \tag{4}$$

where $W^1 \in \mathbb{R}^{cl_u^1 \times (d^{wrd} + cl_u^0)k^{wrd}}$ is the weight matrix of the convolutional layer. The same matrix is used to extract local features around each word window of the given sentence. Using the max over all word windows of the sentence, we extract a "global" fixed-sized feature vector for the sentence. Matrix W^1 and vector b^1 are parameters to be learned. The number of convolutional units cl_u^1 (which corresponds to the size of the sentence-level feature vector), and the size of the word context window k^{wrd} are hyper-parameters to be chosen by the user.

Finally, the vector r_x^{sent}, the "global' feature vector of sentence x, is processed by two usual neural network layers, which extract one more level of representation and compute a score for each sentiment label $\tau \in T$:

$$s(x) = W^3 h(W^2 r_x^{sent} + b^2) + b^3 \tag{5}$$

where matrices $W^2 \in \mathbb{R}^{hl_u \times cl_u^1}$ and $W^3 \in \mathbb{R}^{|T| \times hl_u}$, and vectors $b^2 \in \mathbb{R}^{hl_u}$ and $b^3 \in \mathbb{R}^{|T|}$ are parameters to be learned. The transfer function $h(.)$ is the hyperbolic tangent. The number of hidden units hl_u is a hyper-parameter to be chosen by the user.

2.3 Network Training

Our network is trained by minimizing a negative likelihood over the training set D. Given a sentence x, the network with parameter set θ computes a score $s_\theta(x)_\tau$ for each sentiment label $\tau \in T$. In order to transform these scores into a conditional probability distribution of labels given the sentence and the set of network parameters θ, we apply a softmax operation over the scores of all tags $\tau \in T$:

$$p\left(\tau | x, \theta\right) = \frac{e^{s_\theta(x)_\tau}}{\sum_{\forall i \in T} e^{s_\theta(x)_i}} \tag{6}$$

Taking the log, we arrive at the following conditional log-probability:

$$\log p\left(\tau | x, \theta\right) = s_\theta(x)_\tau - \log \left(\sum_{\forall i \in T} e^{s_\theta(x)_i} \right) \tag{7}$$

We use stochastic gradient descent (SGD) to minimize the negative log-likelihood with respect to θ:

$$\theta \mapsto \sum_{(x,y) \in D} -\log p(y | x, \theta) \tag{8}$$

where (x, y) corresponds to a sentence in the training corpus D and y represents its respective label.

The backpropagation algorithm is a natural choice to efficiently compute gradients of network architectures such as the one proposed in this work (Lecun et al., 1998; Collobert, 2011). In order to perform our experiments, we implement the proposed CharSCNN architecture using the *Theano* library (Bergstra et al., 2010). *Theano* is a versatile Python library that allows the efficient definition, optimization, and evaluation of mathematical expressions involving multi-dimensional arrays. We use *Theano*'s automatic differentiation capabilities in order to implement the backpropagation algorithm.

3 Related Work

There are a few works on neural network architectures for sentiment analysis. In (Socher et al., 2011), the authors proposed a semi-supervised approach based on recursive autoencoders for predicting sentiment distributions. The method learns vector space representation for multi-word phrases and exploits the recursive nature of sentences. In (Socher et al., 2012), it is proposed a matrix-vector recursive neural network model for semantic compositionality, which has the ability to learn compositional vector

representations for phrases and sentences of arbitrary length. The vector captures the inherent meaning of the constituent, while the matrix captures how the meaning of neighboring words and phrases are changed. In (Socher et al., 2013b) the authors propose the Recursive Neural Tensor Network (RNTN) architecture, which represents a phrase through word vectors and a parse tree and then compute vectors for higher nodes in the tree using the same tensor-based composition function. Our approach differ from these previous works because it uses a feed-forward neural network instead of a recursive one. Moreover, it does not need any input about the syntactic structure of the sentence.

Regarding convolutional networks for NLP tasks, in (Collobert et al., 2011), the authors use a convolutional network for the semantic role labeling task with the goal avoiding excessive task-specific feature engineering. In (Collobert, 2011), the authors use a similar network architecture for syntactic parsing. CharSCNN is related to these works because they also apply convolutional layers to extract sentence-level features. The main difference in our neural network architecture is the addition of one convolutional layer to extract character features.

In terms of using intra-word information in neural network architectures for NLP tasks, Alexandrescu et al. (2006) present a factored neural language model where each word is represented as a vector of features such as stems, morphological tags and cases and a single embedding matrix is used to look up all of these features. In (Luong et al., 2013), the authors use a recursive neural network (RNN) to explicitly model the morphological structures of words and learn morphologically-aware embeddings. Lazaridou et al. (Lazaridou et al., 2013) use compositional distributional semantic models, originally designed to learn meanings of phrases, to derive representations for complex words, in which the base unit is the morpheme. In (Chrupala, 2013), the author proposes a simple recurrent network (SRN) to learn continuous vector representations for sequences of characters, and use them as features in a conditional random field classifier to solve a character level text segmentation and labeling task. The main advantage of our approach to extract character-level features is it flexibility. The convolutional layer allows the extraction of relevant features from any part of the word and do not need handcrafted inputs like stems and morpheme lists (dos Santos and Zadrozny, 2014).

4 Experimental Setup and Results

4.1 Sentiment Analysis Datasets

We apply CharSCNN for two different corpora from two different domains: movie reviews and Twitter posts. The movie review dataset used is the recently proposed Stanford Sentiment Treebank (SSTb) (Socher et al., 2013b), which includes fine grained sentiment labels for 215,154 phrases in the parse trees of 11,855 sentences. In our experiments we focus in sentiment prediction of complete sentences. However, we show the impact of training with sentences and phrases instead of only sentences.

The second labeled corpus we use is the Stanford Twitter Sentiment corpus (STS) introduced by (2009). The original training set contains 1.6 million tweets that were automatically labeled as positive/negative using emoticons as noisy labels. The test set was manually annotated by Go et al. (2009). In our experiments, to speedup the training process we use only a sample of the training data consisting of 80K (5%) randomly selected tweets. We also construct a development set by randomly selecting 16K tweets from Go et al.'s training set. In Table 1, we present additional details about the two corpora.

Dataset	Set	# sentences / tweets	# classes
SSTb	Train	8544	5
	Dev	1101	5
	Test	2210	5
STS	Train	80K	2
	Dev	16K	2
	Test	498	3

Table 1: Sentiment Analysis datasets.

4.2 Unsupervised Learning of Word-Level Embeddings

Word-level embeddings play a very important role in the CharSCNN architecture. They are meant to capture syntactic and semantic information, which are very important to sentiment analysis. Recent work has shown that large improvements in terms of model accuracy can be obtained by performing unsupervised pre-training of word embeddings (Collobert et al., 2011; Luong et al., 2013; Zheng et al., 2013; Socher et al., 2013a). In our experiments, we perform unsupervised learning of word-level embeddings using the *word2vec* tool[3], which implements the *continuous bag-of-words* and *skip-gram* architectures for computing vector representations of words (Mikolov et al., 2013).

We use the December 2013 snapshot of the English Wikipedia corpus as a source of unlabeled data. The Wikipedia corpus has been processed using the following steps: (1) removal of paragraphs that are not in English; (2) substitution of non-western characters for a special character; (3) tokenization of the text using the tokenizer available with the Stanford POS Tagger (Manning, 2011); (4) and removal of sentences that are less than 20 characters long (including white spaces) or have less than 5 tokens. Like in (Collobert et al., 2011) and (Luong et al., 2013), we lowercase all words and substitute each numerical digit by a 0 (e.g., *1967* becomes *0000*). The resulting clean corpus contains about 1.75 billion tokens.

When running the *word2vec* tool, we set that a word must occur at least 10 times in order to be included in the vocabulary, which resulted in a vocabulary of 870,214 entries. To train our word-level embeddings we use *word2vec*'s skip-gram method with a context window of size 9. The training time for the English corpus is around 1h10min using 12 threads in a Intel® Xeon® E5-2643 3.30GHz machine.

In our experiments, we do not perform unsupervised pre-training of character-level embeddings, which are initialized by randomly sampling each value from an uniform distribution: $\mathcal{U}(-r, r)$, where $r = \sqrt{\frac{6}{|V^{chr}| + d^{chr}}}$. There are 94 different characters in the SSTb corpus and 453 different characters in the STS corpus. Since the two character vocabularies are relatively small, it has been possible to learn reliable character-level embeddings using the labeled training corpora. The raw (not lowercased) words are used to construct the character vocabularies, which allows the network to capture relevant information about capitalization.

4.3 Model Setup

We use the development sets to tune the neural network hyper-parameters. Many different combinations of hyper-parameters can give similarly good results. We spent more time tuning the learning rate than tuning other parameters, since it is the hyper-parameter that has the largest impact in the prediction performance. The only two parameters with different values for the two datasets are the learning rate and the number of units in the convolutional layer that extract sentence features. This provides some indication on the robustness of our approach to multiple domains. For both datasets, the number of training epochs varies between five and ten. In Table 2, we show the selected hyper-parameter values for the two labeled datasets.

Parameter	Parameter Name	SSTb	STS
d^{wrd}	Word-Level Embeddings dimension	30	30
k^{wrd}	Word Context window	5	5
d^{chr}	Char. Embeddings dimension	5	5
k^{chr}	Char. Context window	3	3
cl_u^0	Char. Convolution Units	10	50
cl_u^1	Word Convolution Units	300	300
hl_u	Hidden Units	300	300
λ	Learning Rate	0.02	0.01

Table 2: Neural Network Hyper-Parameters

[3] https://code.google.com/p/word2vec/

In order to assess the effectiveness of the proposed character-level representation of words, we compare the proposed architecture CharSCNN with an architecture that uses only word embeddings. In our experiments, SCNN represents a network which is fed with word representations only, i.e, for each word w_n its embedding is $u_n = r^{wrd}$. For SCNN, we use the same NN hyper-parameters values (when applicable) shown in Table 2.

4.4 Results for SSTb Corpus

In Table 3, we present the result of CharSCNN and SCNN for different versions of the SSTb corpus. Note that SSTb corpus is a sentiment treebank, hence it contains sentiment annotations for all phrases in all sentences in the corpus. In our experiments, we check whether using examples that are single phrases, in addition to complete sentences, can provide useful information for training the proposed NN. However, in our experiments the test set always includes only complete sentences. In Table 3, the column *Phrases* indicates whether all phrases (*yes*) or only complete sentences (*no*) in the corpus are used for training. The *Fine-Grained* column contains prediction results for the case where 5 sentiment classes (labels) are used (*very negative*, *negative*, *neutral*, *positive*, *very positive*). The *Positive/Negative* column presents prediction results for the case of binary classification of sentences, i.e, the neutral class is removed, the two negative classes are merged as well as the two positive classes.

Model	**Phrases**	**Fine-Grained**	**Positive/Negative**
CharSCNN	yes	**48.3**	**85.7**
SCNN	yes	**48.3**	85.5
CharSCNN	no	43.5	82.3
SCNN	no	43.5	82.0
RNTN (Socher et al., 2013b)	yes	45.7	85.4
MV-RNN (Socher et al., 2013b)	yes	44.4	82.9
RNN (Socher et al., 2013b)	yes	43.2	82.4
NB (Socher et al., 2013b)	yes	41.0	81.8
SVM (Socher et al., 2013b)	yes	40.7	79.4

Table 3: Accuracy of different models for fine grained (5-class) and binary predictions using SSTb.

In Table 3, we can note that CharSCN and SCNN have very similar results in both fine-grained and binary sentiment prediction. These results suggest that the character-level information is not much helpful for sentiment prediction in the SSTb corpus. Regarding the use of phrases in the training set, we can note that, even not explicitly using the syntactic tree information when performing prediction, CharSCNN and SCNN benefit from the presence of phrases as training examples. This result is aligned with Socher et al.'s (2013b) suggestion that information of sentiment labeled phrases improves the accuracy of other classification algorithms such as support vector machines (SVM) and naive Bayes (NB). We believe that using phrases as training examples allows the classifier to learn more complex phenomena, since sentiment labeled phrases give the information of how words (phrases) combine to form the sentiment of phrases (sentences). However, it is necessary to perform more detailed experiments to confirm this conjecture.

Regarding the fine-grained sentiment prediction, our approach provides an absolute accuracy improvement of 2.6 over the RNTN approach proposed by (Socher et al., 2013b), which is the previous best reported result for SSTb. CharSCN, SCNN and Socher et al.'s RNTN have similar accuracy performance for binary sentiment prediction. Compared to RNTN, our method has the advantage of not needing the output of a syntactic parser when performing sentiment prediction. For comparison reasons, in Table 3 we also report Socher et al.'s (2013b) results for sentiment classifiers trained with recursive neural networks (RNN), matrix-vector RNN (MV-RNN), NB, and SVM algorithms.

Initializing word-embeddings using unsupervised pre-training gives an absolute accuracy increase of around 1.5 when compared to randomly initializing the vectors. The *Theano* based implementation of CharSCNN takes around 10 min. to complete one training epoch for the SSTb corpus with all phrases

and five classes. In our experiments, we use 4 threads in a Intel® Xeon® E5-2643 3.30GHz machine.

4.5 Results for STS Corpus

In Table 4, we present the results of CharSCNN and SCNN for sentiment prediction using the STS corpus. As expected, character-level information has a greater impact for Twitter data. Using unsupervised pre-training, CharSCNN provides an absolute accuracy improvement of 1.2 over SCNN. Additionally, initializing word-embeddings using unsupervised pre-training gives an absolute accuracy increase of around 4.5 when compared to randomly initializing the word-embeddings.

In Table 4, we also compare CharSCNN performance with other approaches proposed in the literature. In (Speriosu et al., 2011), a label propagation (LProp) approach is proposed, while Go et al. (2009) use maximum entropy (MaxEnt), NB and SVM-based classifiers. CharSCNN outperforms the previous approaches in terms of prediction accuracy. As far as we know, 86.4 is the best prediction accuracy reported so far for the STS corpus.

Model	**Accuracy (unsup. pre-training)**	**Accuracy (random word embeddings)**
CharSCNN	**86.4**	81.9
SCNN	85.2	82.2
LProp (Speriosu et al., 2011)	84.7	
MaxEnt (Go et al., 2009)	83.0	
NB (Go et al., 2009)	82.7	
SVM (Go et al., 2009)	82.2	

Table 4: Accuracy of different models for binary predictions (positive/negative) using STS Corpus.

4.6 Sentence-level features

In figures 2 and 3 we present the behavior of CharSCNN regarding the sentence-level features extracted for two cases of negation, which are correctly predicted by CharSCNN. We choose these cases because negation is an important issue in sentiment analysis. Moreover, the same sentences are also used as illustrative examples in (Socher et al., 2013b). Note that in the convolutional layer, 300 features are first extracted for each word. Then the $\max$ operator selects the 300 features which have the largest values among the words to construct the sentence-level feature set r^{sent}. Figure 2 shows a positive sentence (left) and its negation. We can observe that in both versions of the sentence, the extracted features concentrate mainly around the main topic, *"film"*, and the part of the phrase that indicates sentiment (*"liked"* and *"did 'nt like"*). Note in the left chart that the word *"liked"* has a big impact in the set of extracted features. On the other hand, in the right chart, we can see that the impact of the word *"like"* is reduced because of the negation *"did 'nt"*, which is responsible for a large part of the extracted features.

In Figure 3 a similar behavior can be observed. While the very negative expression *"incredibly dull"* is responsible for 69% of the features extracted from the sentence in the left, its negation *"definitely not dull"*, which is somewhat more positive, is responsible for 77% of the features extracted from the sentence in the chart at right . These examples indicate CharSCNN's robustness to handle negation, as well as its ability to capture information that is important to sentiment prediction.

5 Conclusions

In this work we present a new deep neural network architecture that jointly uses character-level, word-level and sentence-level representations to perform sentiment analysis. The main contributions of the paper are: (1) the idea of using convolutional neural networks to extract from character- to sentence-level features; (2) the demonstration that a feed-forward neural network architecture can be as effective as RNTN (Socher et al., 2013a) for sentiment analysis of sentences; (3) the definition of new state-of-the-art results for SSTb and STS corpora.

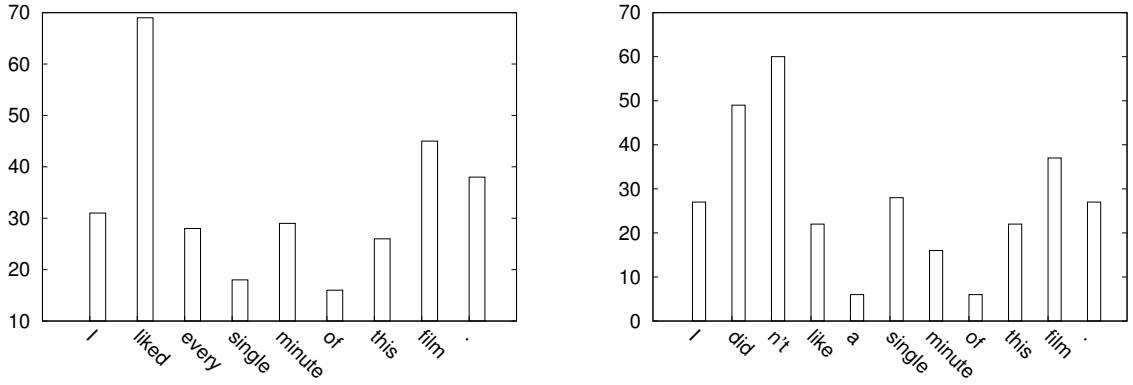

Figure 2: Number of local features selected at each word when forming the sentence-level representation. In this example, we have a positive sentence (left) and its negation (right).

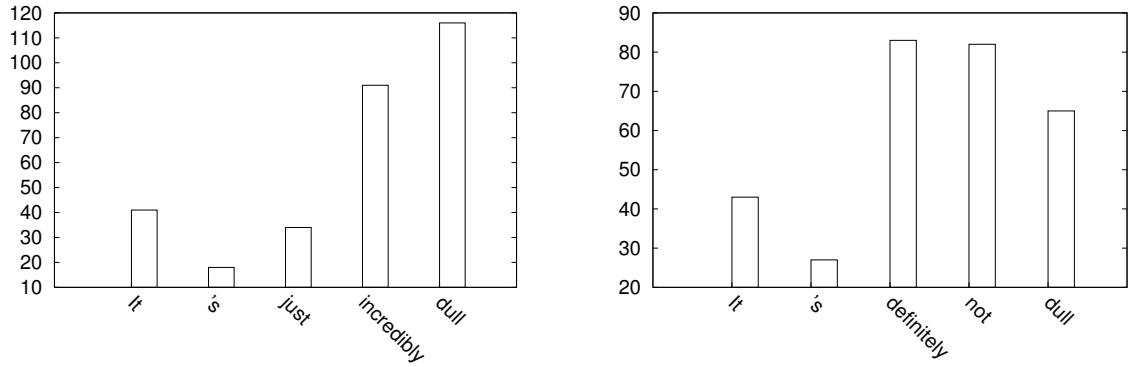

Figure 3: Number of local features selected at each word when forming the sentence-level representation. In this example, we have a negative sentence (left) and its negation (right).

As future work, we would like to analyze in more detail the role of character-level representations for sentiment analysis of tweets. Additionally, we would like to check the impact of performing the unsupervised pre-training step using texts from the specific domain at hand.

Abstract

This paper addresses implicit opinions expressed via inference over explicit sentiments and events that positively/negatively affect entities (*goodFor/badFor*, *gfbf* events). We incorporate the inferences developed by implicature rules into an optimization framework, to jointly improve sentiment detection toward entities and disambiguate components of gfbf events. The framework simultaneously beats the baselines by more than 10 points in F-measure on sentiment detection and more than 7 points in accuracy on gfbf polarity disambiguation.

1 Introduction

Previous work in NLP on sentiment analysis has mainly focused on explicit sentiments. However, as noted in (Deng and Wiebe, 2014), many opinions are expressed implicitly, as shown by this example:

> Ex(1) The reform would lower health care costs, which would be a tremendous positive change across the entire health-care system.

There is an explicit positive sentiment toward the event of "reform lower costs". However, in expressing this sentiment, the writer also implies he is negative toward the "costs", since he's happy to see the costs being decreased. Moreover, the writer may be positive toward "reform" since it contributes to the "lower" event. Such inferences may be seen as opinion-oriented *implicatures* (i.e., defeasible inferences)[1].

We develop a set of rules for inferring and detecting implicit sentiments from explicit sentiments and events such as "lower" (Wiebe and Deng, 2014). In (Deng et al., 2013), we investigate such events, defining a ***badFor (bf)*** event to be an event that negatively affects the theme and a ***goodFor (gf)*** event to be an event that positively affects the theme of the event.[2] Here, "lower" is a bf event. According to their annotation scheme, ***goodFor/badFor (gfbf)*** events have NP agents and themes (though the agent may be implicit), and the polarity of a gf event may be changed to bf by a ***reverser*** (and vice versa).

The ultimate goal of this work is to utilize gfbf information to improve detection of the writer's sentiments toward entities mentioned in the text. However, this requires resolving several ambiguities: (Q1) Given a document, which spans are gfbf events? (Q2) Given a gfbf text span, what is its polarity, gf or bf? (Q3) Is the polarity of a gfbf event being reversed? (Q4) Which NP in the sentence is the agent and which is the theme? (Q5) What are the writer's sentiments toward the agent and theme, positive or negative? Fortunately, the implicature rules in (Deng and Wiebe, 2014) define dependencies among these ambiguities. As in Ex(1), the sentiments toward the agent and theme, the sentiment toward the gfbf event (positive or negative), and the polarity of the gfbf event (gf or bf) are all interdependent. Thus, rather than having to take a pipeline approach, we are able to develop an optimization framework which exploits these interdependencies to jointly resolve the ambiguities.

Specifically, we develop local detectors to analyze the four individual components of gfbf events, (Q2)-(Q5) above. Then, we propose an Integer Linear Programming (ILP) framework to conduct global

[1]Specifically, we focus on *generalized conversational implicature* (Grice, 1967; Grice, 1989).

[2]Compared to (Deng et al., 2013), we change the term "object" to "theme" as the later is more appropriate for this task.

Proceedings of COLING 2014, the 25th International Conference on Computational Linguistics: Technical Papers, pages 79–88, Dublin, Ireland, August 23-29 2014.

inference, where the gfbf events and their components are variables and the interdependencies defined by the implicature rules are encoded as constraints over relevant variables in the framework. The reason we do not address (Q1) is that the gold standard we use for evaluation contains sentiment annotations only toward the agents and themes of gfbf events. We are only able to evaluate true hits of gfbf events. Thus, the input to the system is the set of the text spans marked as gfbf events in the corpus. The results show that, compared to the local detectors, the ILP framework improves sentiment detection by more than 10 points in F-measure and disambiguating gfbf polarity by more than 7 points in the accuracy, without any loss in accuracy for other two components.

2 Related Work

Most work in sentiment analysis focuses on classifying explicit sentiments and extracting explicit opinion expressions, holders and targets (Wiebe et al., 2005; Johansson and Moschitti, 2013; Yang and Cardie, 2013). There is some work investigating features that directly indicate implicit sentiments (Zhang and Liu, 2011; Feng et al., 2013). In contrast, we focus on how we can bridge between explicit and implicit sentiments via inference. To infer the implicit sentiments related to gfbf events, some work mines various syntactic patterns (Choi and Cardie, 2008), proposes linguistic templates (Zhang and Liu, 2011; Anand and Reschke, 2010; Reschke and Anand, 2011), or generates a lexicon of patient polarity verbs (Goyal et al., 2013). Different from their work, which do not cover all cases relevant to gfbf events, (Deng and Wiebe, 2014) defines a generalized set of implicature rules and proposes a graph-based model to achieve sentiment propagation between the agents and themes of gfbf events. However, that system requires all of the gfbf information (Q1)-(Q4) to be input from the manual annotations; the only ambiguity it resolves is sentiments toward entities. In contrast, the method in this paper tackles four ambiguities simultaneously. Further, as we will see below in Section 6, the improvement over the local detectors by the current method is greater than that by the previous method, even though it operates over the noisy output of local components automatically.

Different from pipeline architectures, where each step is computed independently, joint inference has often achieved better results. Roth and Yih (2004) formulate the task of information extraction using Integer Linear Programming (ILP). Since then, ILP has been widely used in various tasks in NLP, including semantic role labeling (Punyakanok et al., 2004; Punyakanok et al., 2008; Das et al., 2012), joint extraction of opinion entities and relations (Choi et al., 2006; Yang and Cardie, 2013), co-reference resolution (Denis and Baldridge, 2007), and summarization (Martins and Smith, 2009). The most similar ILP model to ours is (Somasundaran and Wiebe, 2009), which improves opinion polarity classification using discourse constraints in an ILP model. However, their work addresses discourse relations among explicit opinions in different sentences.

3 GoodFor/BadFor Event and Implicature

This work addresses sentiments toward, in general, states and events which positively or negatively affect entities. Deng et al. (2013) (hereafter DCW) identify a clear case that occurs frequently in opinion sentences, namely the gfbf events mentioned above. As defined in DCW, a *gf* event is an event that positively affects the theme of the event and a *bf* event is an event that negatively affects the theme. According to the annotation schema, *gfbf* events have NP agents and themes (though the agent may be implicit). In the sentence "President Obama passed the bill", the agent of the gf "passed" is "President Obama" and the theme is "the bill". In the sentence "The bill was denied", the agent of the bf "was denied" is implicit. The polarity of a gf event may be changed to bf by a *reverser* (and vice versa). For example, in "The reform will not worsen the economy," "not" is a reverser and it reverses the polarity from bf to gf.[3]

The constraints we encode in the ILP framework described below are based on implicature rules in (Deng and Wiebe, 2014). Table 1 gives two rule schemas, each of which defines four specific rules. In

[3]DCW also introduce *retainers*. We don't analyze retainers in this work since they do not affect the polarity of gfbfs, and only 2.5% of gfbfs have retainers in the corpus.

	s(gfbf)	gfbf	→	s(agent)	s(theme)		s(gfbf)	gfbf	→	s(agent)	s(theme)
1	positive	gf	→	positive	positive	3	positive	bf	→	positive	negative
2	negative	gf	→	negative	negative	4	negative	bf	→	negative	positive

Table 1: Rule Schema 1 & Rule Schema 3 (Deng and Wiebe, 2014)

the table, *s(*α*)* = β means that the **writer's** sentiment toward α is β, where α is a gfbf event, or the agent or theme of a gfbf event, and β is either *positive* or *negative*. P → Q means to infer Q from P.

Applying the rules to Ex(1): the writer expresses a positive sentiment ("positive") toward a bf event ("lower"), thus matching Case 3 in Table 1. We infer that the writer is positive toward the agent ("reform") and negative toward the theme ("costs"). Two other rule schemas (not shown) make the same inferences as Rule Schemas 1 and 3 but in the opposite direction. As we can see, if two entities participate in a gf event, the writer has the same sentiment toward the agent and theme, while if two entities participate in a bf event, the writer has opposite sentiments toward them. Later we use this observation in our experiments.

4 Global Optimization Framework

Optimization is performed over two sets of variables. The first set is *GFBF*, containing a variable for each gfbf event in the document. The other set is *Entity*, containing a variable for each agent or theme candidate. Each variable k in *GFBF* has its corresponding agent and theme variables, i and j, in *Entity*. The three form a triple unit, $\langle i, k, j \rangle$. The set *Triple* consists of each $\langle i, k, j \rangle$, recording the correspondence between variables in *GFBF* and *Entity*. The goal of the framework is to assign optimal labels to variables in *Entity* and *GFBF*. We first introduce how we recognize candidates for agents and themes, then introduce the optimization framework, and then define local scores that are input to the framework.

4.1 Local Agents and Theme Candidates Detector

We extract two agent candidates and two theme candidates for each gfbf event (one each will ultimately be chosen by the ILP model).[4] We use syntax, and the output of the SENNA (Collobert et al., 2011) semantic role labeling tool. SENNA labels the A0 (subject), A1 (object), and A2 (indirect object) spans for each predicate, if possible. To extract the *semantic agent* candidate: If SENNA labels a span as A0 of the gfbf event, we consider it as the semantic agent; if there is no A0 but A1 is labeled, we consider A1; if there is no A0 or A1 but A2 is labeled, we consider A2. To extract the *syntactic agent* candidate, we find the nearest noun in front of the gfbf span, and then extract any other word that depends on the noun according to the dependency parse. Similarly, to extract the *semantic theme* candidate, we consider A1, A2, A0 in order. To extract the *syntactic theme* candidate, the same procedure is conducted as for the syntactic agent, but the nearest noun should be after the gfbf. If there is no A0, A1 or A2, then there is only one agent candidate, *implicit* and only one theme candidate, *null*. We treat a *null* theme as an incorrect span in the later evaluations. If the two agent (theme) candidate spans are the same, there is only one candidate.

4.2 Integer Linear Programming Framework

We use Integer Linear Programming (ILP) to assign labels to variables. Variables in *Entity* will be assigned *positive* or *negative*, representing the writer's sentiments toward them. We may have two candidate agents for a gfbf and that we will choose between them. Thus, only one agent is assigned a *positive* or *negative* label; the other is considered to be an incorrect agent of the gfbf (similarly for the theme candidates). Each variable in *GFBF* will be assigned the label *gf* or *bf*. Optionally, it may also be assigned the label *reversed*. Label *gf* or *bf* is the polarity of the gfbf event; *reversed* is assigned if the polarity is reversed (e.g., for "not harmed", the labels are *bf* and *reversed*).

The objective function of the ILP is:

[4]This framework is able to handle any number of candidates. The methods we tried using more candidates did not perform as well - the gain in recall was offset by larger losses in precision.

$$\min_{u_{1gf},u_{1bf}\ldots}\Big(-1*\sum_{i\in GFBF\cup Entity}\sum_{c\in L_i}p_{ic}u_{ic}\Big)+\sum_{\langle i,k,j\rangle\in Triple}\xi_{ikj}+\sum_{\langle i,k,j\rangle\in Triple}\delta_{ikj} \tag{1}$$

subject to

$$u_{ic}\in\{0,1\},\forall i,c\qquad \xi_{ikj},\delta_{ikj}\in\{0,1\},\forall\langle i,k,j\rangle\in Triple \tag{2}$$

where L_i is the set of labels given to $\forall i \in$ ***GFBF*** $\cup$ ***Entity***. If $i \in$ ***GFBF***, L_i is {gf, bf, reversed} ({*gf, bf, r*}, for short). If $i \in$ ***Entity***, L_i is {positive, negative} ({*pos, neg*}, for short). u_{ic} is a binary indicator representing whether the label c is assigned to the variable i. When an indicator variable is 1, the corresponding label is selected. p_{ic} is the score given by local detectors, introduced in the following sections. Variables ξ_{ikj} and δ_{ikj} are binary slack variables that correspond to the gfbf implicature constraints of $\langle i,k,j\rangle$. When a given slack variable is 1, the corresponding triple violates the implicature constraints. Minimizing the objective function could achieve two goals at the same time. The first part ($-1*\sum_i\sum_c p_{ic}u_{ic}$) tries to select a set of labels that maximize the scores given by the local detectors. The second part ($\sum_{ikj}\xi_{ikj}+\sum_{ikj}\delta_{ikj}$) aims at minimizing the cases where gfbf implicature constraints are violated. Here we do not force each triple to obey the implicature constraints, but to minimize the violating cases. For each variable, we have defined constraints:

$$\sum_{c\in L_{GFBF'}}u_{kc}=1,\forall k\in GFBF \tag{3}$$

$$\sum_{\substack{i\in Entity\\ \langle i,k,j\rangle\in Triple}}\sum_{c\in L_{Entity}}u_{ic}=1,\forall k\in GFBF \tag{4}$$

$$\sum_{\substack{j\in Entity,\\ \langle i,k,j\rangle\in Triple}}\sum_{c\in L_{Entity}}u_{jc}=1,\forall k\in GFBF \tag{5}$$

where $L_{GFBF'}$ in Equation (3) is a subset of L_{GFBF}, consisting of {*gf*, *bf*}. Equation (3) means a gfbf must be either gf or bf. But it is free to choose whether it is being reversed. Recall that we have two agent candidates ($a1$,$a2$) for a gfbf. Thus we have four agent indicators in Equation (4): $u_{a1,pos}$, $u_{a1,neg}$, $u_{a2,pos}$ and $u_{a2,neg}$. Equation (4) ensures that three of them are 0 and one of them is 1. For instance, $u_{a1,pos}$ assigned 1 means that candidate $a1$ is selected to be the agent span and pos is selected to be its polarity. In this way, the framework disambiguates the agent span and sentiment polarity simultaneously. (Similar comments apply for the theme candidates in Equation (5).)

According to the implicature rules in Table 1 in Section 3, the writer has the same sentiment toward entities in a gf relation. Thus, for each triple unit $\langle i,k,j\rangle$, the gf constraints are applied via the following:

$$|\sum_{i,\langle i,k,j\rangle}u_{i,pos}-\sum_{j,\langle i,k,j\rangle}u_{j,pos}|+|u_{k,gf}-u_{k,r}|<=1+\xi_{ikj},\forall k\in GFBF \tag{6}$$

$$|\sum_{i,\langle i,k,j\rangle}u_{i,neg}-\sum_{j,\langle i,k,j\rangle}u_{j,neg}|+|u_{k,gf}-u_{k,r}|<=1+\xi_{ikj},\forall k\in GFBF \tag{7}$$

We use $|u_{k,gf}-u_{k,r}|$ to represent whether this triple is gf. In Equation (6), if this value is 1, then the triple should follow the gf constraints. In that case, $\xi_{ikj}=0$ means that the triple doesn't violate the gf constraints, and $|\sum_i u_{i,pos}-\sum_j u_{j,pos}|$ must be 0. Further, in this case, $\sum_i u_{i,pos}$ and $\sum_j u_{j,pos}$ are constrained to be of the same value (both 1 or 0) – that is, entities i and j must be both positive or both not positive. However, if $\xi_{ikj}=1$, Equation (6) does not constrain the values of the variables at all. If $|u_{k,gf}-u_{k,r}|$ is 0, representing that the triple is not gf, then Equation (6) does not constrain the values of the variables. Similar comments apply to Equation (7).

In contrast, the writer has opposite sentiments toward entities in a bf relation.

$$|\sum_{i,\langle i,k,j\rangle}u_{i,pos}+\sum_{j,\langle i,k,j\rangle}u_{j,pos}-1|+|u_{k,bf}-u_{k,r}|<=1+\delta_{ikj},\forall k\in GFBF \tag{8}$$

$$|\sum_{i,\langle i,k,j\rangle}u_{i,neg}+\sum_{j,\langle i,k,j\rangle}u_{j,neg}-1|+|u_{k,bf}-u_{k,r}|<=1+\delta_{ikj},\forall k\in GFBF \tag{9}$$

We use $|u_{k,bf}-u_{k,r}|$ to represent whether this triple is bf. In Equation (8), if a triple is bf and the constraints are not violated, then $|\sum_i u_{i,pos}+\sum_j u_{j,pos}-1|$ must be 0. Further, in this case, $\sum_i u_{i,pos}$

	u_{gf}	u_{bf}	u_r	$\lvert u_{gf} - u_r \rvert$	$\lvert u_{bf} - u_r \rvert$		u_{gf}	u_{bf}	u_r	$\lvert u_{gf} - u_r \rvert$	$\lvert u_{bf} - u_r \rvert$
A	1	0	0	1	0	C	0	1	0	0	1
B	0	1	1	1	0	D	1	0	1	0	1

Table 2: Truth table of being reversed or not (k is omitted)

and $\sum_j u_{j,pos}$ are constrained to be of the opposite value – that is, if entity i is positive then entity j must not be positive. Similar comments apply to Equation (9).

Note that above we use $|u_{k,gf} - u_{k,r}|$ and $|u_{k,bf} - u_{k,r}|$ to represent whether a triple is gf or bf. In Table 2, we show that they always take opposite values and that they are consistent with the actual polarities. In Table 2, Case A means the triple is gf and Case B means the triple is bf but it is reversed. In both cases, $|u_{gf} - u_r| = 1$, indicating that the triple should follow the gf constraints. Similarly for Case C and Case D to follow the bf constraints.

4.3 Local GoodFor/BadFor Score: $p_{k,gf}, p_{k,bf}$

We utilize a sense-level gfbf lexicon by (Choi et al., 2014). In total there are 6,622 gf senses and 3,290 bf senses. The gf lexicon covers 64% of the gf words in the corpus and the bf lexicon covers 42% of the bf words. We then look up the gfbf span k in the gfbf lexicon. If k only appears in the gf lexicon, then $p_{k,gf} = 1 - \epsilon$ and $p_{k,bf} = \epsilon$. Here $\epsilon = 0.0001$, to prevent there being any 0 scores in our computation. If k only appears in the bf lexicon, then $p_{k,bf} = 1 - \epsilon$ and $p_{i,gf} = \epsilon$. If k appears in both the gf and bf lexicon, and there are a senses in the gf lexicon and b senses in the bf lexicon, then $p_{k,gf} = a/(a+b)$ and $p_{k,bf} = b/(a+b)$. If k is not in either lexicon, then $p_{k,gf} = p_{k,bf} = \epsilon$. If there is more than one word in the gfbf span, we take the maximum score.

4.4 Local Reversed Score: $p_{k,r}$

As introduced in Section 3, a reverser changes the polarity of a gfbf. First, we build reverser lexicons from Wilson's shifter lexicon (2008), namely the entries labeled as *genshifter*, *negation*, and *shiftneg*. We create two lexicons: one with the verbs and the other with the non-verb entries, excluding nouns, adjectives, and adverbs, since most non-verb reversers are prepositions or subordinating conjunctions. There are 219 reversers in the entire corpus; 134 (61.19%) are instances of words in one of the two lexicons. Based on the lexicon, we categorize reversers into three classes. Examples are shown below.

Ex(2) They will **not** be able to water down your coverage.
Ex(3) ... how a massive new bureaucracy will cut costs **without** hurting the old and the helpless.
Ex(4) The new law includes new rules to **prevent** insurance companies from overcharging patients.

Negation: An instance in this category is "not" in Ex(2). If any word in the gfbf span has a *neg* dependency relation according to the Stanford dependency parser, then we consider the gfbf to be negated (i.e., reversed). In this case the path between the negator and the gfbf is labeled *neg* and the length of the path is one.

Other Non-Verb: This category consists of words such as "without" in Ex(3) (others are "never" and "few", etc). These words lower the extent of the gfbf event. We look in the sentence for instances of words in the non-verb reverser lexicon, which are not tagged as noun, verb, adj, or adv. For any found, we examine the path in the dependency parse between the potential reverser and the gfbf span. If the path has at least one of *advmod*, *pcomp*, *cc*, *xcomp*, *nsubj*, *neg* and the length of the path is less than four (learnt from development set), the event is considered to be reversed.

Verb: In Ex(4), the verb "prevent" stops the gfbf event "overcharging" from happening. We call such words *Verb* reverser (others are "prohibit" and "ban", etc). We look in the sentence for instances of words in the verb reverser lexicon. For any that appear before the gfbf span in the sentence, if the path has at least one of *xcomp*, *pcomp*, *obj* and the length of the path is less than four, then the event is reversed. For the triple ⟨companies, overcharging, patients⟩ in Ex(4), though it is reversed by "prevent", the agent of the reverser, which is "law", is different from the agent of the gfbf, which is "companies", so the bf

within the "overcharging" event is not reversed.[5] Though we extract the *Verb* reversers to evaluate the performance of recognizing a reverser, in the optimization framework, gfbf events with *Verb* reversers are not considered to be reversed, since almost all *Verb* reversers introduce new agents.

Different from other scores, $p_{k,r}$ could be negative. According to the heuristics above, the probability of a gfbf event being reversed decreases as the length of the path increases. We define $p_{k,r}$ so it is inversely proportional to the length of the path. Further, to make sense of a gfbf triple ⟨agent, gfbf, theme⟩, where, e.g., the local detectors label it ⟨pos, bf, pos⟩, the framework is choosing the smaller one from (a) $-1 * p_{k,r} * u_{k,r}$ (it has a reverser) versus (b) $1 * \xi_{ikj}$ (it is an exception to the rules). The framework assigns $u_{k,r} = 0$ and $\xi_{ikj} = 1$ if $-1 * p_{k,r} > 1$. It assigns $u_{k,r} = 1$ and $\xi_{ikj} = 0$ if $-1 * p_{k,r} <= 1$. For gfbf events which have *Negation* or *Other Non-verb* reversers, since we use the length four as a threshold in the heuristics above, we define $p_{k,r} = \frac{1}{d} - \frac{5}{4}$, so that $-1 * p_{k,r} = \frac{5}{4} - \frac{1}{d} > 1$ if $d > 4$. For gfbf events for which no reverser word appears in the sentence, or those which only have *Verb* reversers, $p_{k,r} = -1 * \frac{5}{4}$ (so $-1 * p_{k,r} > 1$), so that the framework chooses case (b) (choosing the gfbf event to be not reversed).

4.5 Local Sentiment Score: $p_{i,pos}, p_{i,neg}$

In the corpus of DCW, only the writer's sentiments toward the agents and the themes of gfbf events are annotated. Thus, since there are many false negatives of sentiments toward entities, the corpus does not support training a classifier. Therefore, we adopt the same local sentiment detector from (Deng and Wiebe, 2014), using available resources to detect writer's sentiments toward all agent and theme candidates.[6] The sentiment scores range from 0.5 to 1.

5 Co-reference In the Framework

So far the constraints in the framework are within a gfbf triple. Consider the following example:

Ex(5) **The reform** will decrease the healthcare costs and improve the medical qualify as expected.

The two gfbfs, "decrease" and "improve" have the same agent, "reform". Thus, if there is more than one gfbf in a sentence, and the path between the two gfbfs in dependency parse contains only *conj* or *xcomp*, and there is no other noun between the latter gfbf and the conjunction, we assume the two agents are the same and the sentiments toward them should be the same. Thus, for any $i, j \in$ *Entity*, if i, j co-refer[7], or they are the same agent as described above, $Coref(i, j) = 1$ (otherwise 0). We add two more constraints, similar to the gf constraints in Equations (6) and (7), as shown in Equation (10) and (11). where ν_{ij} is a slack variable, $e(i)$ is the set of agent/theme candidates linked to the same gfbf as i is. If $Coref(i, j) = 0$, Equations (10) and (11) do not constrain the variables. The objective function in Equation (12) is updated to incorporate these new constraints.

$$|\sum_{e(i)} u_{i,pos} - \sum_{e(j)} u_{j,pos}| + Coref(i,j) <= 1 + \nu_{ij}, \forall i, j \in Entity \tag{10}$$

$$|\sum_{e(i)} u_{i,neg} - \sum_{e(j)} u_{j,neg}| + Coref(i,j) <= 1 + \nu_{ij}, \forall i, j \in Entity \tag{11}$$

$$\min_{u_{1gf}, u_{1bf} \cdots} \left(-1 * \sum_{i \in GFBF \cup Entity} \sum_{c \in L_i} p_{ic} u_{ic} \right) + \sum_{\langle i,k,j \rangle \in Triple} \xi_{ikj} + \sum_{\langle i,k,j \rangle \in Triple} \delta_{ikj} + \sum_{i,j \in Entity} \nu_{ij} \tag{12}$$

6 Experiment and Performance

In this section we introduce the data we use, the baseline methods, the evaluations and the results. In addition, we give examples illustrating how opinion inference may improve performances.

[5] DCW defines here is a *triple chain*: ⟨law, prevent ⟨companies, overcharging, patients⟩⟩. The reverser is changing the polarity between "law" and "patients", but it does not change the polarity between "companies" and "patients".

[6] We use Opinion Extractor (Johansson and Moschitti, 2013) , opinionFinder (Wilson et al., 2005), MPQA subjectivity lexicon (Wilson et al., 2005), General Inquirer (Stone et al., 1966) and a connotation lexicon (Feng et al., 2013), to detect writer's sentiments toward all agent and theme candidates, and all gfbf events. We adopt Rule 1 and Rule 3 to infer from the sentiment toward event to the sentiment toward theme. Then we conduct a majority voting based on the results.

[7] We use the co-reference resolution system from (Stoyanov et al., 2010).

6.1 Experiment Data

We use the "Affordable Care Act" corpus of DCW, consisting of 134 online editorials and blogs. In total, there are 1,762 annotated triples, out of which 692 are gf or retainers and 1,070 are bf or reversers. From the writer's perspective, 1,495 noun phrases are annotated positive, 1,114 noun phrases are negative and the remaining 8 are neutral. This indicates that there are many opinions in the corpus. Out of 134 documents in the corpus, 3 do not have any annotation. 6 are used as a development set to develop the heuristics in Sections 4 and 5. We use the remaining 125 for the experiments.

6.2 Baseline Methods and Evaluation Metrics

We compare the output of the global optimization framework with the outputs of baseline systems built from the local detectors in Section 4. For the gfbf polarity and reverser ambiguities, the local detectors directly provide a disambiguation result. For the agent/theme span and sentiment ambiguities, the local sentiment detector assigns positive and negative scores to each candidate. The framework chooses among the combined options. Thus, for comparison, we build a baseline system that combines the outputs of the local agent/theme candidate detector and the local sentiment detector.

Recall from Section 4, a variable $k \in$ *GFBF* has two agent candidates, $a1$ and $a2 \in$ *Entity*. Together there are four binary indicator variables: $u_{a1,pos}$, $u_{a1,neg}$, $u_{a2,pos}$ and $u_{a2,neg}$. Among these indicator variables whose corresponding local scores (e.g., $p_{a1,pos}$ is the score of $u_{a1,pos}$) are larger than 0.5, the baseline system (denoted *Local*) chooses the one with the largest local sentiment score. If there is a tie, it prefers the variable representing the semantic candidate. If there is still a tie, it chooses the variable representing the majority polarity (positive). If all the local scores of the four variables are 0.5 (neutral), *Local* fails to recognize any sentiment for that entity, so it assigns 0 to all the indicator variables. *Local+coref* takes the maximum local score of the entities if they co-ref, and assigns each entity the maximum score before disambiguation.

Another baseline, *Majority*, always chooses the semantic candidate and the majority polarity.

To evaluate the performance in detecting sentiment, we use precision, recall, and F-measure. We do not take into account any agent or theme manually annotated as neutral (there are only 8).

$$\text{P} = \frac{\#(\text{auto=gold \& gold!=neutral})}{\#\text{auto!=neutral}} \qquad \text{Accuracy} = \text{R} = \frac{\#(\text{auto=gold \& gold!=neutral})}{\#\text{gold!=neutral}} \qquad \text{F} = \frac{2*\text{P}*\text{R}}{\text{P+R}} \tag{13}$$

In the equations, *auto* is the system's output and *gold* is the gold-standard label from annotations. Since we don't take into account any *neutral* agent or theme, *#gold!=neutral* equals to all nodes in the experiment set. Thus accuracy is equal to recall. We only report recall here. Here we have two definitions of *auto=gold*: (1) **Strict** evaluation means that, by saying *auto=gold*, the agent/theme must have the same polarity and must be the same NP as the gold standard, and (2) **Relaxed** evaluation means the agent/theme has the same polarity as the gold standard, regardless whether the span is correct or not.

Note that according to DCW, an implicit agent isn't annotated with any sentiment. Thus, for an implicit agent in *gold*, if *auto* outputs the span "implicit", we treat it as a correct span with correct polarity, regardless what sentiment *auto* gives to it. If *auto* outputs any span other than "implicit", we treat it as a wrong span with wrong polarity, regardless of its sentiment as well. For the theme span, if *auto* outputs a "null" theme candidate, we treat it as a wrong span but we evaluate its sentiment according to *gold*.

To evaluate extracting candidate span, we use accuracy. The baseline for this task always chooses the semantic candidate. To evaluate gfbf polarity and reverser, we also use accuracy.

Note that although we evaluate the performance in different tasks separately, the framework resolves all the ambiguities at the same time.

6.3 Results

We report the performance results for **(A) sentiment detection** in Table 3, on two sets. One is the subset containing the agents and themes where *auto* has the correct spans with *gold*. The other is the set of all agents and themes. As shown in Table 3, *ILP* significantly improves performance, approximately 10-20 points on F-measure over different baselines. Though *Local* has a competitive precision with

		correct span subset			whole set, strict eval			whole set, relaxed eval		
		P	R	F	P	R	F	P	R	F
1	ILP	0.6421	0.6421	0.6421	0.4401	0.4401	0.4401	0.5939	0.5939	0.5939
2	Local	0.6409	0.3332	0.4384	0.4956	0.2891	0.3652	0.5983	0.3490	0.4408
3	ILP+coref	0.6945	0.6945	0.6945	0.4660	0.4660	0.4660	0.6471	0.6471	0.6471
4	Local+coref	0.6575	0.3631	0.4678	0.5025	0.3103	0.3836	0.6210	0.3834	0.4741
5	Majority	0.5792	0.5792	0.5792	0.3862	0.3862	0.3862	0.5462	0.5462	0.5462

Table 3: Performances of sentiment detection

ILP, it has a much lower recall. That means the local sentiment detector cannot recognize implicit sentiments toward most entities. But *ILP* is able to recognize more entities correctly. By adding *coref*, performance improves for both *ILP* and *Local*. In comparison to (Deng and Wiebe, 2014), our current method improves more in F-measure (2.43 points more) over local sentiment detector than the earlier work, even though the earlier work takes the manual annotations of all the gfbf information as input.

In terms of the other tasks: For **(B) agent/theme span**, the baseline achieves 66.67% in accuracy, compared to 68.54% and 67.10% for *ILP* and *ILP+coref*, respectively. For **(C) gfbf polarity**, the baseline has an accuracy of 70.68%, whereas *ILP* achieves 77.25% and *ILP+coref* achieves 77.47%, respectively, both 7 points higher. This improvement is interesting because it represents cases in which the optimization framework is able to ***infer*** the correct polarity even though the gfbf span is not recognized by the local detector (i.e., the span isn't in the gfbf lexicon). For **(D) reverser**, the baseline is 88.07% in accuracy. *ILP* and *ILP+coref* are competitive with the baseline: 89% and 88.07% respectively. Note that both our local detector and *ILP* surpass the majority class (not reversed) which has an accuracy of 86.60%.

Following (Akkaya et al., 2009), since ILP is unsupervised without multiple runs, we adopt McNemar's test to measure statistical significance of our improvements (Dietterich, 1998). In Table 3, the improvements in recalls of Line 1 over 2, Line 3 over 4, and Lines 1&3 over 5 are statistically significant at the $p < .001$ level. The improvements of Line 3 over 1 are statistically significant at the $p < .005$ level. For accuracy of gfbf polarity, the improvement is significant at the $p < .001$ level.

6.4 Examples

This sections gives simplified examples to illustrate how the framework can improve over the local detectors. The explicit sentiment clues referred to in this section are from MPQA lexicon.

Ex(6) The reform would curb skyrocketing costs in the long run.

The local sentiment detector assigns "costs" *negative* due to the single sentiment clue, "skyrocketing". Since the agent and theme are in a bf triple, and the writer is *negative* toward that theme, we can infer the writer is *positive* toward the agent. This illustrates how we improve recall on sentiments.

Ex(7) The supposedly costly reform will curb skyrocketing costs in the long run.

In Ex(7), agent "reform" is labeled *negative* because "costly" is a negative clue in the lexicon. ("supposedly" is not in it.) However, in Ex(7), it is actually positive. The agent's negative score is 0.6, and its positive score is 0.5 due to the absence of a positive clue. Since the theme is *negative* too, by the bf constraints, we **expect** to see a positive agent. If we were to assign *negative* to the agent, the objective function would have -0.6 subjectivity score and +1 in violation penalty, together giving +0.4. If we assign *positive*, the subjectivity score is -0.5, and there is no violation, resulting in a total score of -0.5. Thus, the framework correctly chooses the positive label. This shows how we can improve precision on sentiments.

Ex(8) The great reform will curb skyrocketing costs in the long run.

In this case, the agent is positive and the theme is negative. If the gfbf word "curb" is not in the lexicon, we could still infer its polarity. Given that the entities in the triple have different sentiments, to not violate

the implicature rules, the framework will assign it *bf*, or assign it *gf* along with *reversed*. However, there is no reverser word in the sentence, so the reversed score $p_r = -\frac{5}{4}$. The framework will assign the reverser indicator $u_r = 0$, in order to avoid a gain in the objective function by $-1 * p_r * u_r$. Thus the framework assigns the label *bf* to "curb". This is how the framework can improve the accuracy of recognizing gfbf polarity.

7 Conclusion

The ultimate goal of this work is to utilize gfbf information to improve detection of the writer's sentiments toward entities mentioned in the text. Using an unsupervised optimization framework that incorporates gfbf implicature rules as constraints, our method improves over local sentiment recognition by almost 20 points in F-measure and over all sentiment baselines by over 10 points in F-measure. The global optimization framework jointly infers the polarity of gfbf events, whether or not they are reversed, which candidate NPs are the agent and theme, and the writer's sentiments toward them. In addition to beating the baselines for sentiment detection, the framework significantly improves the accuracy of gfbf polarity disambiguation. This work not only automatically utilizes gfbf information to improve sentiment detection, it also proposes a framework for jointly solving various ambiguities related to gfbf events.

Abstract

Community question answering (CQA) has become an important service due to the popularity of CQA archives on the web. A distinctive feature is that CQA services usually organize questions into a hierarchy of natural categories. In this paper, we focus on the problem of question retrieval and propose a novel approach, called group non-negative matrix factorization with natural categories (GNMFNC). This is achieved by learning the category-specific topics for each category as well as shared topics across all categories via a group non-negative matrix factorization framework. We derive an efficient algorithm for learning the factorization, analyze its complexity, and provide proof of convergence. Experiments are carried out on a real world CQA data set from Yahoo! Answers. The results show that our proposed approach significantly outperforms various baseline methods and achieves the state-of-the-art performance for question retrieval.

1 Introduction

Community question answering (CQA) such as Yahoo! Answers[1] and Quora[2], has become an important service due to the popularity of CQA archives on the web. To make use of the large-scale questions and their answers, it is critical to have functionality of helping users to retrieve previous answers (Duan et al., 2008). Typically, such functionality is achieved by first retrieving the historical questions that best match a user's queried question, and then using answers of these returned questions to answer the queried question. This is what we called *question retrieval* in this paper.

The major challenge for question retrieval, as for most information retrieval tasks, is the *lexical gap* between the queried questions and the historical questions in the archives. For example, if a queried question contains the word "company" but a relevant historical question instead contains the word "firm", then there is a mismatch and the historical question may not be easily distinguished from an irrelevant one. To solve the *lexical gap* problem, most researchers focused on translation-based approaches since the relationships between words (or phrases) can be explicitly modeled through word-to-word (or phrases) translation probabilities (Jeon et al., 2005; Riezler et al., 2007; Xue et al., 2008; Lee et al., 2008; Bernhard and Gurevych, 2009; Zhou et al., 2011; Singh, 2012). However, these existing methods model the relevance ranking without considering the category-specific and shared topics with natural categories, it is not clear whether this information is useful for question retrieval.

A distinctive feature of question-answer pairs in CQA is that CQA services usually organize questions into a hierarchy of natural categories. For example, Yahoo! Answers contains a hierarchy of 26 categories at the first level and more than 1262 subcategories at the leaf level. When a user asks a question, the user is typically required to choose a category label for the question from a predefined hierarchy. Questions in the predefined hierarchy usually share certain generic topics while questions in different categories have their specific topics. For example, questions in categories "Arts & Humanities" and "Beauty & Style" may share the generic topic of "dance" but they also have the category-specific topics of "poem" and "wearing", respectively.

[1] http://answers.yahoo.com/

[2] http://www.quora.com/

Proceedings of COLING 2014, the 25th International Conference on Computational Linguistics: Technical Papers, pages 89–98, Dublin, Ireland, August 23-29 2014.

Inspired by the above observation, we propose a novel approach, called group non-negative matrix factorization with natural categories (GNMFNC). GNMFNC assumes that there exists a set of category-specific topics for each of the category, and there also exists a set of shared topics for all of the categories. Each question in CQA is specified by its category label, category-specific topics, as well as shared topics. In this way, the large-scale question retrieval problem can be decomposed into small-scale subproblems.

In GNMFNC, questions in each category are represented as a term-question matrix. The term-question matrix is then approximated as the product of two matrices: one matrix represents the category-specific topics as well as the shared topics, and the other matrix denotes the question representation based on topics. An objective function is defined to measure the goodness of prediction of the data with the model. Optimization of the objective function leads to the automatic discovery of topics as well as the topic representation of questions. Finally, we calculate the relevance ranking between the queried questions and the historical questions in the latent topic space.

Past studies by (Cao et al., 2009; Cao et al., 2010; Ming et al., 2010; Cai et al., 2011; Ji et al., 2012; Zhou et al., 2013) confirmed a significant retrieval improvement by adding the natural categories into various existing retrieval models. However, all these previous work regarded natural categories individually without considering the relationships among them. On the contrary, this paper can effectively capture the relationships between the shared aspects and the category-specific individual aspects with natural categories via a group non-negative matrix factorization framework. Also, our work models the relevance ranking in the latent topic space rather than using the existing retrieval models. To date, no attempts have been made regarding group non-negative matrix factorization in studies of question retrieval, which remains an under-explored area.

The remainder of this paper is organized as follows. Section 2 describes our proposed group non-negative matrix factorization with natural categories for question retrieval. Section 3 presents the experimental results. In Section 4, we conclude with ideas for future research.

2 Group Non-negative Matrix Factorization with Natural Categories

2.1 Problem Formulation

In CQA, all questions are usually organized into a hierarchy of categories. When a user asks a question, the user is typically required to choose a category label for the question from a predefined hierarchy of categories. Hence, each question in CQA has a category label. Suppose that we are given a question collection $\mathcal{D}$ in CQA archive with size N, containing terms from a vocabulary $\mathcal{V}$ with size M. A question d is represented as a vector $\mathbf{d} \in \mathbb{R}^M$ where each entry denotes the weight of the corresponding term, for example tf-idf is used in this paper. Let $C = \{c_1, c_2, \cdots, c_P\}$ denote the set of categories (subcategories) of question collection $\mathcal{D}$, where P is the number of categories (subcategories). The question collection $\mathcal{D}$ is organized into P groups according to their category labels and can be represented as $\mathcal{D} = \{\mathbf{D}_1, \mathbf{D}_2, \cdots, \mathbf{D}_P\}$. $\mathbf{D}_p = \{\mathbf{d}_1^{(p)}, \cdots, \mathbf{d}_{N_p}^{(p)}\} \in \mathbb{R}^{M \times N_p}$ is the term-question matrix corresponding to category c_p, in which each row stands for a term and each column stands for a question. N_p is the number of questions in category c_p such that $\sum_{p=1}^{P} N_p = N$.

Let $\mathbf{U}_p' = [\mathbf{U}_s, \mathbf{U}_p] \in \mathbb{R}^{M \times (K_s + K_p)}$ be the term-topic matrix corresponding to category c_p, where K_s is the number of shared topics, K_p is the number of category-specific topics corresponding to category c_p, and $p \in [1, P]$. Term-topic matrix $\mathbf{U}_s$ can be represented as $\mathbf{U}_s = [\mathbf{u}_1^{(s)}, \cdots, \mathbf{u}_{K_s}^{(s)}] \in \mathbb{R}^{M \times K_s}$, in which each column corresponds to a shared topic. While the term-topic matrix $\mathbf{U}_p$ can be represented as $\mathbf{U}_p = [\mathbf{u}_1^{(p)}, \cdots, \mathbf{u}_{K_p}^{(p)}] \in \mathbb{R}^{M \times K_p}$. The total number of topics in the question collection $\mathcal{D}$ is $K = K_s + PK_p$. Let $\mathbf{V}_p = [\mathbf{v}_1^{(p)}, \cdots, \mathbf{v}_{N_p}^{(p)}] \in \mathbb{R}^{(K_s + K_p) \times N_p}$ be the topic-question matrix corresponding to category c_p, in which each column denotes the question representation in the topic space. We also denote $\mathbf{V}_p^T = [\mathbf{H}_p^T, \mathbf{W}_p^T]$, where $\mathbf{H}_p \in \mathbb{R}^{K_s \times N_p}$ and $\mathbf{W}_p \in \mathbb{R}^{K_p \times N_p}$ correspond to the coefficients of shared topics $\mathbf{U}_s$ and category-specific topics $\mathbf{U}_p$, respectively.

Thus, given a question collection $\mathcal{D} = \{\mathbf{D}_1, \mathbf{D}_2, \cdots, \mathbf{D}_P\}$ together with the category labels $C = \{c_1, c_2, \cdots, c_P\}$, our proposed GNMFNC amounts to modeling the question collection $\mathcal{D}$ with P group

simultaneously, arriving at the following objective function:

$$\mathcal{O} = \sum_{p=1}^{P} \left\{ \lambda_p \left\| \mathbf{D}_p - [\mathbf{U}_s, \mathbf{U}_p]\mathbf{V}_p \right\|_F^2 + R(\mathbf{U}_s, \mathbf{U}_p) \right\} \tag{1}$$

where $\lambda_p \triangleq \|\mathbf{D}_p\|_F^{-2}$. $R(\mathbf{U}_s, \mathbf{U}_p)$ is a regularization term used to penalize the "similarity" between the shared topics and category-specific topics through $\mathbf{U}_s$ and $\mathbf{U}_p$.

In this paper, we aim to ensure that matrix $\mathbf{U}_s$ captures only shared topics and matrix $\mathbf{U}_p$ captures only the category-specific topics. For example, if matrices $\mathbf{U}_s$ and $\mathbf{U}_p$ are mutually orthogonal, we have $\mathbf{U}_s^T\mathbf{U}_p = \mathbf{0}$. To impose this constraint, we attempt to minimize the sum-of-squares of entries of the matrix $\mathbf{U}_s^T\mathbf{U}_p$ (e.g., $\|\mathbf{U}_s^T\mathbf{U}_p\|_F^2$ which uniformly optimizes each entry of $\mathbf{U}_s^T\mathbf{U}_p$). With this choice, the regularization term of $R(\mathbf{U}_s, \mathbf{U}_p)$ is given by

$$R(\mathbf{U}_s, \mathbf{U}_p) = \sum_{p=1}^{P} \alpha_p \left\| \mathbf{U}_s^T\mathbf{U}_p \right\|_F^2 + \sum_{l=1, l\neq p}^{P} \beta_l \left\| \mathbf{U}_p^T\mathbf{U}_l \right\|_F^2 \tag{2}$$

where α_p and β_l are the regularization parameters, $\forall p \in [1, P]$, $\forall l \in [1, P]$.

Learning the objective function in equation (1) involves the following optimization problem:

$$\min_{\mathbf{U}_s, \mathbf{U}_p, \mathbf{V}_p \geq 0} \mathcal{L} = \mathcal{O} + \sigma_1 \left\| \mathbf{U}_s^T\mathbf{1}_M - \mathbf{1}_{K_s} \right\|_F^2 + \sigma_2 \left\| \mathbf{U}_p^T\mathbf{1}_M - \mathbf{1}_{K_p} \right\|_F^2 + \sigma_3 \left\| \mathbf{V}_p\mathbf{1}_{N_p} - \mathbf{1}_{K_s+K_p} \right\|_F^2 \tag{3}$$

where σ_1, σ_2 and σ_3 are the shrinkage regularization parameters. Based on the shrinkage methodology, we can approximately satisfy the normalization constraints for each column of $[\mathbf{U}_s, \mathbf{U}_p]$ and $\mathbf{V}_p^T$ by guaranteeing the optimization converges to a stationary point.

2.2 Learning Algorithm

We present the solution to the GNMFNC optimization problem in equation (3) as the following theorem. The theoretical aspects of the optimization are presented in the next subsection.

Theorem 2.1. *Updating $\mathbf{U}_s$, $\mathbf{U}_p$ and $\mathbf{V}_p$ using equations (4)∼(6) corresponds to category c_p will monotonically decrease the objective function in equation (3) until convergence.*

$$\mathbf{U}_s \leftarrow \mathbf{U}_s \circ \frac{\left[\sum_{p=1}^{P} \lambda_p \mathbf{D}_p\mathbf{H}_p^T \right]}{\left[\sum_{p=1}^{P} \lambda_p [\mathbf{U}_s, \mathbf{U}_p]\mathbf{V}_p\mathbf{H}_p^T + \alpha_p \mathbf{U}_p\mathbf{U}_p^T\mathbf{U}_s \right]} \tag{4}$$

$$\mathbf{U}_p \leftarrow \mathbf{U}_p \circ \frac{\left[\lambda_p \mathbf{D}_p\mathbf{W}_p^T \right]}{\left[\lambda_p [\mathbf{U}_s, \mathbf{U}_p]\mathbf{V}_p\mathbf{W}_p^T + \alpha_p \mathbf{U}_s\mathbf{U}_s^T\mathbf{U}_p + \sum_{l=1, l\neq p}^{P} \beta_l \mathbf{U}_l\mathbf{U}_l^T\mathbf{U}_p \right]} \tag{5}$$

$$\mathbf{V}_p \leftarrow \mathbf{V}_p \circ \frac{\left[\lambda_p \mathbf{D}_p^T [\mathbf{U}_s, \mathbf{U}_p] \right]}{\left[\lambda_p \mathbf{V}_p^T [\mathbf{U}_s, \mathbf{U}_p]^T [\mathbf{U}_s, \mathbf{U}_p] \right]} \tag{6}$$

where operator $\circ$ is element-wise product and $\frac{[\cdot]}{[\cdot]}$ is element-wise division.

Based on Theorem 2.1, we note that multiplicative update rules given by equations (4)∼(6) are obtained by extending the updates of standard NMF (Lee and Seung, 2001). A number of techniques can be used here to optimize the objective function in equation (3), such as alternating least squares (Kim and Park, 2008), the active set method (Kim and Park, 2008), and the projected gradients approach (Lin, 2007). Nonetheless, the multiplicative updates derived in this paper have reasonably fast convergence behavior as shown empirically in the experiments.

2.3 Theoretical Analysis

In this subsection, we give the theoretical analysis of the optimization, convergence and computational complexity.

Without loss of generality, we only show the optimization of $\mathbf{U}_s$ and formulate the Lagrange function with constraints as follows:

$$\mathcal{L}(\mathbf{U}_s) = \mathcal{O} + \sigma_1 \left\| \mathbf{U}_s^T \mathbf{1}_M - \mathbf{1}_{K_s} \right\|_F^2 + \mathrm{Tr}(\Psi_s \mathbf{U}_s^T) \tag{7}$$

where $\mathrm{Tr}(\cdot)$ denotes the trace of a matrix, $\Psi_s \in \mathbb{R}^{K_s \times K_s}$ is the Lagrange multiplier for the nonnegative constraint $\mathbf{U}_s \geq \mathbf{0}$.

The partial derivative of $\mathcal{L}(\mathbf{U}_s)$ w.r.t. $\mathbf{U}_s$ is

$$\begin{aligned} \bigtriangledown_{\mathbf{U}_s} \mathcal{L}(\mathbf{U}_s) = & -2 \sum_{p=1}^{P} \lambda_p \mathbf{D}_p \mathbf{H}_p^T + 2 \sum_{p=1}^{P} \lambda_p [\mathbf{U}_s, \mathbf{U}_p] \mathbf{V}_p \mathbf{H}_p^T \\ & + 2 \sum_{p=1}^{P} \alpha_p \mathbf{U}_p \mathbf{U}_p^T \mathbf{U}_s + 2\sigma_1 \mathbf{U}_s - 2\sigma_1 + \Psi_s \end{aligned} \tag{8}$$

Using the Karush-Kuhn-Tucker (KKT) (Boyd and Vandenberghe, 2004) condition $\Psi_s \circ \mathbf{U}_s = \mathbf{0}$, we obtain

$$\bigtriangledown_{\mathbf{U}_s} \mathcal{L}(\mathbf{U}_s) \circ \mathbf{U}_s = \left\{ \begin{array}{l} -\sum_{p=1}^{P} \lambda_p \mathbf{D}_p \mathbf{H}_p^T + \sum_{p=1}^{P} \lambda_p [\mathbf{U}_s, \mathbf{U}_p] \mathbf{V}_p \mathbf{H}_p^T \\ +\sum_{p=1}^{P} \alpha_p \mathbf{U}_p \mathbf{U}_p^T \mathbf{U}_s + \sigma_1 \mathbf{U}_s - \sigma_1 \end{array} \right\} \circ \mathbf{U}_s = \mathbf{0} \tag{9}$$

After normalization of $\mathbf{U}_s$, the terms $\sigma_1 \mathbf{U}_s$ and σ_1 are in fact equal. They can be safely ignored from the above formula without influencing convergence. This leads to the updating rule for $\mathbf{U}_s$ in equation (4). Following the similar derivations as shown above, we can obtain the updating rules for the rest variables $\mathbf{U}_p$ and $\mathbf{V}_p$ in GNMFNC optimization, as shown in equations (5) and (6).

2.3.1 Convergence Analysis

In this subsection, we prove the convergence of multiplicative updates given by equations (4)$\sim$(6). We first introduce the definition of auxiliary function as follows.

Definition 2.1. *$\mathcal{F}(\mathbf{X}, \mathbf{X}')$ is an auxiliary function for $\mathcal{L}(\mathbf{X})$ if $\mathcal{L}(\mathbf{X}) \leq \mathcal{F}(\mathbf{X}, \mathbf{X}')$ and equality holds if and only if $\mathcal{L}(\mathbf{X}) = \mathcal{F}(\mathbf{X}, \mathbf{X})$.*

Lemma 2.1. *(Lee and Seung, 2001) If $\mathcal{F}$ is an auxiliary function for $\mathcal{L}$, $\mathcal{L}$ is non-increasing under the update*

$$\mathbf{X}^{(t+1)} = \arg\min_{\mathbf{X}} \mathcal{F}(\mathbf{X}, \mathbf{X}^{(t)})$$

Proof. By Definition 2.1, $\mathcal{L}(\mathbf{X}^{(t+1)}) \leq \mathcal{F}(\mathbf{X}^{(t+1)}, \mathbf{X}^{(t)}) \leq \mathcal{F}(\mathbf{X}^{(t)}, \mathbf{X}^{(t)}) = \mathcal{L}(\mathbf{X}^{(t)})$ □

Theorem 2.2. *Let $\mathcal{L}(\mathbf{U}_s^{(t+1)})$ denote the sum of all terms in $\mathcal{L}$ that contain $\mathbf{U}_s^{(t+1)}$, the following function is an auxiliary function for $\mathcal{L}(\mathbf{U}_s^{(t+1)})$*

$$\mathcal{F}(\mathbf{U}_s^{(t+1)}, \mathbf{U}_s^{(t)}) = \mathcal{L}(\mathbf{U}_s^{(t)}) + (\mathbf{U}_s^{(t+1)} - \mathbf{U}_s^{(t)}) \bigtriangledown_{\mathbf{U}_s^{(t)}} \mathcal{L}(\mathbf{U}_s^{(t)}) + \frac{1}{2} (\mathbf{U}_s^{(t+1)} - \mathbf{U}_s^{(t)})^2 \mathcal{P}(\mathbf{U}_s^{(t)}) \tag{10}$$

$$\mathcal{P}(\mathbf{U}_s^{(t)}) = \frac{\sum_{ij} \left[\sum_{p=1}^{P} \lambda_p [\mathbf{U}_s^{(t)}, \mathbf{U}_p] \mathbf{V}_p \mathbf{W}_p^T + \alpha_p \mathbf{U}_p \mathbf{U}_p^T \mathbf{U}_s^{(t)} + \sigma_1 \mathbf{U}_s^{(t)} \right]_{ij}}{\sum_{ij} [\mathbf{U}_s^{(t)}]_{ij}}$$

where $\bigtriangledown_{\mathbf{U}_s^{(t)}} \mathcal{L}(\mathbf{U}_s^{(t)})$ is the first-order derivative of $\mathcal{L}(\mathbf{U}_s^{(t)})$ with respect to $\mathbf{U}_s^{(t)}$. Theorem 2.2 can be proved similarly to (Lee and Seung, 2001) by validating $\mathcal{L}(\mathbf{U}_s^{(t+1)}) \leq \mathcal{F}(\mathbf{U}_s^{(t+1)}, \mathbf{U}_s^{(t)})$, $\mathcal{L}(\mathbf{U}_s^{(t+1)}) = \mathcal{F}(\mathbf{U}_s^{(t+1)}, \mathbf{U}_s^{(t+1)})$, and the Hessian matrix $\bigtriangledown \bigtriangledown_{\mathbf{U}_s^{(t+1)}} \mathcal{F}(\mathbf{U}_s^{(t+1)}, \mathbf{U}_s^{(t)}) \succeq 0$. Due to limited space, we omit the details of the validation.

	addition	multiplication	division	overall
GNMFNC: $\mathbf{U}_s$	$P(3MN_pK_s + MN_pK_p + MK_s^2)$	$P(3MN_pK_s + MN_pK_p + MK_s^2)$	MK_s	$O(PMN_pK_{max})$
GNMFNC: $\mathbf{U}_p$	$3MN_pK_p + MN_pK_s + PM^2K'$	$3MN_pK_p + MN_pK_s + PM^2K'$	MK_p	$O(PMRK')$
GNMFNC: $\mathbf{V}_p$	$3MN_pK'$	$3MN_pK'$	N_pK'	$O(MN_pK')$

Table 1: Computational operation counts for each iteration in GNMFNC.

Based on Theorem 2.2, we can fix $\mathbf{U}_s^{(t)}$ and minimize $\mathcal{F}(\mathbf{U}_s^{(t+1)}, \mathbf{U}_s^{(t)})$ with respect to $\mathbf{U}_s^{(t+1)}$. When setting $\bigtriangledown_{\mathbf{U}_s^{(t+1)}} \mathcal{F}(\mathbf{U}_s^{(t+1)}, \mathbf{U}_s^{(t)}) = \mathbf{0}$, we get the following updating rule

$$\mathbf{U}_s^{(t+1)} \leftarrow \mathbf{U}_s^{(t)} \circ \frac{\left[\sum_{p=1}^{P} \lambda_p \mathbf{D}_p \mathbf{H}_p^T + \sigma_1\right]}{\left[\sum_{p=1}^{P} \lambda_p [\mathbf{U}_s^{(t)}, \mathbf{U}_p] \mathbf{V}_p \mathbf{W}_p^T + \alpha_p \mathbf{U}_p \mathbf{U}_p^T \mathbf{U}_s^{(t)} + \sigma_1 \mathbf{U}_s^{(t)}\right]} \tag{11}$$

which is consistent with the updating rule derived from the KKT conditions aforementioned.

By Lemma 2.1 and Theorem 2.2, we have $\mathcal{L}(\mathbf{U}_s^{(0)}) = \mathcal{F}(\mathbf{U}_s^{(0)}, \mathbf{U}_s^{(0)}) \geq \mathcal{F}(\mathbf{U}_s^{(1)}, \mathbf{U}_s^{(0)}) \geq \mathcal{F}(\mathbf{U}_s^{(1)}, \mathbf{U}_s^{(1)}) = \mathcal{L}(\mathbf{U}_s^{(1)}) \geq \cdots \geq \mathcal{L}(\mathbf{U}_s^{(Iter)})$, where $Iter$ is the number of iterations. Therefore, $\mathbf{U}_s$ is monotonically decreasing. Since the objective function $\mathcal{L}$ is lower bounded by 0, the correctness and convergence of Theorem 2.1 is validated.

2.3.2 Computational Complexity

In this subsection, we discuss the time computational complexity of the proposed algorithm GNMFNC. Besides expressing the complexity of the algorithm using big O notation, we also count the number of arithmetic operations to provide more details about running time. We show the results in Table 1, where $K_{max} = \max\{K_s, K_p\}$, $K' = K_s + K_p$ and $R = \max\{M, N_p\}$.

Suppose the multiplicative updates stop after $Iter$ iterations, the time cost of multiplicative updates then becomes $O(Iter \times PMRK')$. We set $Iter = 100$ empirically in rest of the paper. Therefore, the overall running time of GNMFNC is linear with respect to the size of word vocabulary, the number of questions and categories.

2.4 Relevance Ranking

The motivation of incorporating matrix factorization into relevance ranking is to learn the word relationships and reduce the "lexical gap" (Zhou et al., 2013a). To do so, given a queried question q with category label c_p from Yahoo! Answers, we first represent it in the latent topic space as $\mathbf{v}_q$,

$$\mathbf{v}_q = \arg\min_{\mathbf{v} \geq 0} \|\mathbf{q} - [\mathbf{U}_s, \mathbf{U}_p]\mathbf{v}\|_2^2 \tag{12}$$

where vector $\mathbf{q}$ is the tf-idf representation of queried question q in the term space.

For each historical question d (indexed by r) in question collection $\mathcal{D}$, with representation $\mathbf{v}_d = r$-th column of $\mathbf{V}$, we compute its similarity with queried question $\mathbf{v}_q$ as following

$$s_{topic}(q, d) = \frac{< \mathbf{v}_q, \mathbf{v}_d >}{\|\mathbf{v}_q\|_2 \cdot \|\mathbf{v}_d\|_2} \tag{13}$$

The latent topic space score $s_{topic}(q, d)$ is combined with the conventional term matching score $s_{term}(q, d)$ for final relevance ranking. There are several ways to conduct the combination. Linear combination is a simple and effective way. The final relevance ranking score $s(q, d)$ is:

$$s(q, d) = \gamma s_{topic}(q, d) + (1 - \gamma) s_{term}(q, d) \tag{14}$$

where $\gamma \in [0, 1]$ is the parameter which controls the relative importance of the latent topic space score and term matching score. $s_{term}(q, d)$ can be calculated with any of the conventional relevance models such as BM25 (Robertson et al., 1994) and LM (Zhai and Lafferty, 2001).

3 Experiments

3.1 Data Set and Evaluation Metrics

We collect the data set from Yahoo! Answers and use the *getByCategory* function provided in Yahoo! Answers API[3] to obtain CQA threads from the Yahoo! site. More specifically, we utilize the *resolved* questions and the resulting question repository that we use for question retrieval contains 2,288,607 questions. Each resolved question consists of four parts: "question title", "question description", "question answers" and "question category". We only use the "question title" and "question category" parts, which have been widely used in the literature for question retrieval (Cao et al., 2009; Cao et al., 2010). There are 26 first-level categories in the predefined natural hierarchy, i.e., each historical question is categorized into one of the 26 categories. The categories include "Arts & Humanities", "Beauty & Style", "Business & Finance", etc.

In order to evaluate our approach, we randomly select 2,000 questions as queried questions from the above data collection to construct the validation/test sets, and the remaining data collection as training set. Note that we select the queried questions in proportion to the number of questions and categories against the whole distribution to have a better control over a possible imbalance. To obtain the ground-truth, we employ the Vector Space Model (VSM) (Salton et al., 1975) to retrieve the top 10 results and obtain manual judgements. The top 10 results don't include the queried question itself. Given a returned result by VSM, an annotator is asked to label it with "relevant" or "irrelevant". If a returned result is considered semantically equivalent to the queried question, the annotator will label it as "relevant"; otherwise, the annotator will label it as "irrelevant". Two annotators are involved in the annotation process. If a conflict happens, a third person will make judgement for the final result. In the process of manually judging questions, the annotators are presented only the questions. As a result, there are in total 20,000 judged question pairs. We randomly split the 2,000 queried questions into validation/test sets, each has 1,000/1,000 queried questions. We use the validation set for parameter tuning and the test set for evaluation.

Evaluation Metrics: We evaluate the performance of question retrieval using the following metrics: Mean Average Precision (MAP) and Precision@N (P@N). MAP rewards methods that return relevant questions early and also rewards correct ranking of the results. P@N reports the fraction of the top-N questions retrieved that are relevant. We perform a significant test, i.e., a t-test with a default significant level of 0.05.

There are several parameters used in the paper, we tune these parameters on the validation set. Specifically, we set the number of category-specific topics per category and the number of shared topics in GNMFNC as $(K_s, K_p) = \{(5,2),(10,4),(20,8),(40,16),(80,32)\}$, resulting in $K = \{57, 114, 228, 456, 912\}$ total number of topics. (Note that the total number of topics in GNMFNC is $K_s + 26 \times K_p$, where 26 is the number of categories in the first-level predefined natural hierarchy[4]). Finally, we set $(K_s, K_p) = (20, 8)$ and $K = 228$ empirically as this setting yields the best performance.

For regularization parameters α_p and β_l, it is difficult to directly tune on the validation set, we present an alternative way by adding a common factor a to look at the objective function of optimization problem in equation (3) on the training data. In other words, we set $\alpha_p = \frac{a}{K_s \times K_p}$ and $\beta_l = \frac{a}{K_p \times K_l}$. Therefore, we tune the parameters α_p and β_l by alternatively adjusting the common factor a via grid search. As a result, we set $a = 100$, resulting in $\alpha_p = \beta_l = 0.625$ in the following experiments. The trade-off parameter γ in the linear combination is set from 0 to 1 in steps of 0.1 for all methods. We set $\gamma = 0.6$ empirically. For shrinkage regularization parameters, we empirically set $\sigma_1 = \sigma_2 = \sigma_3 = 1$.

3.2 Question Retrieval Results

In this experiment, we present the experimental results for question retrieval on the test data set. Specifically, for our proposed GNMFNC, we combine the latent topic matching scores with the term matching scores given by BM25 and LM, denoted as "BM25+GNMFNC" and "LM+GNMFNC". Table 2 shows

[3] http://developer.yahoo.com/answers

[4] Here we do not use the leaf categories because we find that it is not possible to run GNMFNC with such large number of topics on the current machines, and we will leave it for future work.

Table 2: Comparison with different methods for question retrieval.

#	Methods	MAP	P@10
1	BM25	0.243	0.225
2	LM	0.286	0.232
3	(Jeon et al., 2005)	0.327	0.235
4	(Xue et al., 2008)	0.341	0.238
5	(Zhou et al., 2011)	0.365	0.243
6	(Singh, 2012)	0.354	0.240
7	(Cao et al., 2010)	0.358	0.242

9	**BM25+GNMFNC**	**0.369**	**0.248**
10	**LM+GNMFNC**	**0.374**	**0.251**

Table 3: Comparison of matrix factorizations for question retrieval.

#	Methods	MAP	P@10
1	BM25	0.243	0.225
2	BM25+NMF	0.325	0.235
3	BM25+CNMF	0.344	0.239
4	BM25+GNMF	0.361	0.242
5	BM25+GNMFNC	0.369	0.248
6	LM	0.286	0.232
7	LM+NMF	0.337	0.237
8	LM+CNMF	0.352	0.240
9	LM+GNMF	0.365	0.243
10	LM+GNMFNC	0.374	0.251

the main retrieval performances under the evaluation metrics MAP, P@1 and P@10. Row 1 and row 2 are the baseline systems, which model the relevance ranking using BM25 (Robertson et al., 1994) and language model (LM) (Zhai and Lafferty, 2001) in the term space. Row 3 is word-based translation model (Jeon et al., 2005), and row 4 is word-based translation language model (TRLM) (Xue et al., 2008). Row 5 is phrase-based translation model (Zhou et al., 2011), and row 6 is the entity-based translation model (Singh, 2012). Row 7 to row 11 explore the natural categories for question retrieval. In row 7, Cao et al. (2010) employed the natural categories to compute the local and global relevance with different model combination, here we use the combination VSM + TRLM for comparison because this combination obtains the superior performance than others. In row 8, Cai et al. (2011) proposed a category-enhanced TRLM for question retrieval. There are some clear trends in the results of Table 2:

(1) BM25+GNMFNC and LM+GNMFNC perform *significantly* better than BM25 and LM respectively (t-test, p-value < 0.05, row 1 vs. row 9; row 2 vs. row 10), indicating the effective of GNMFNC.

(2) BM25+GNMFNC and LM+GNMFNC perform better than translation methods, some improvements are statistical significant (t-test, p-value < 0.05, row 3 and row 4 vs. row 9 and row 10). The reason may be that GNMFNC models the relevance ranking in the latent topic space, which can also effectively solve the the lexical gap problem.

(3) Capturing the shared aspects and the category-specific individual aspects with natural categories in the group modeling framework can *significantly* improve the performance of question retrieval (t-test, p-value < 0.05, row 7 and row 8 vs. row 9 and row 10).

(4) Natural categories are useful and effectiveness for question retrieval, no matter in the group modeling framework or existing retrieval models (row 3$\sim$ row 6 vs. row 7$\sim$row 10).

3.3 Comparison of Matrix Factorizations

We note that our proposed GNMFNC is related to non-negative matrix factorization (NMF) (Lee and Seung, 2001) and its variants, we introduce three baselines. The first baseline is NMF, which is trained on the whole training data. The second baseline is CNMF, which is trained on each category without considering the shared topics. The third baseline is GNMF (Lee and Choi, 2009; Wang et al., 2012), which is similar to our GNMFNC but there are no constraints on the category-specific topics to prevent them from capturing the information from the shared topics.

NMF and GNMF are trained on the training data with the same parameter settings in section 4.1 for fair comparison. For CNMF, we also train the model on the training data with the same parameter settings in section 4.1, except parameter K_s, as there exists no shared topics in CNMF.

Table 3 shows the question retrieval performance of NMF families on the test set, obtained with the best parameter settings determined by the validation set. From the results, we draw the following observations:

(1) All of these methods can *significantly* improve the performance in comparison to the baseline BM25 and LM (t-test, p-value < 0.05).

(2) GNMF and GNMFNC perform *significantly* better than NMF and CNMF respectively (t-test, p-value < 0.05), indicating the effectiveness of group matrix factorization framework, especially the use of shared topics.

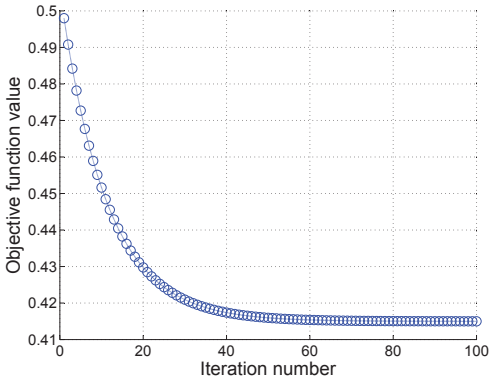

Figure 1: Convergence curve of GNMFNC.

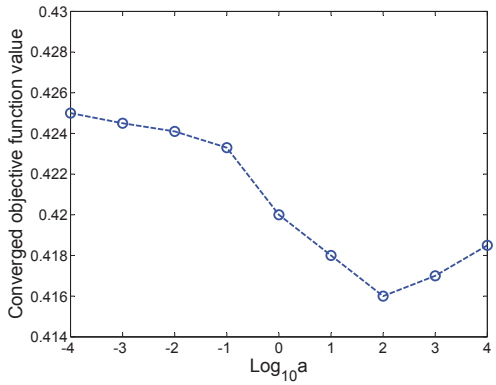

Figure 2: Objective function value vs. factor a.

(3) GNMFNC performs *significantly* better than GNMF (t-test, p-value < 0.05, row 4 vs. row 5; row 9 vs. row 10), indicating the effectiveness of the regularization term on the category-specific topics to prevent them from capturing the information from the shared topics.

From the experimental results reported above, we can conclude that our proposed GNMFNC is useful for question retrieval with high accuracies. To the best of our knowledge, it is the first time to investigate the group matrix factorization for question retrieval.

3.4 Convergence Behavior

In subsection 2.3.1, we have shown that the multiplicative updates given by equations (4)$\sim$(6) are convergent. Here, we empirically show the convergence behavior of GNMFNC.

Figure 1 shows the convergence curve of GNMFNC on the training data set. From the figure, y-axis is the value of objective function and x-axis denotes the iteration number. We can see that the multiplicative updates for GNMFNC converge very fast, usually within 80 iterations.

3.5 Regularization Parameters Selection

One success of this paper is to use regularized constrains on the category-specific topics to prevent them from capturing the information from the shared topics. It is necessary to give an in-depth analysis of the regularization parameters used in the paper. Consider the regularization term used in equation (2), each element in $\mathbf{U}_s^T\mathbf{U}_p$ and $\mathbf{U}_p^T\mathbf{U}_l$ has a value between 0 and 1 as each column of $\mathbf{U}_s$, $\mathbf{U}_p$ and $\mathbf{U}_l$ is normalized. Therefore, it is appropriate to normalize the term having $\|\mathbf{U}_s^T\mathbf{U}_p\|_F^2$ by K_sK_p since there are $K_s \times K_p$ elements in $\mathbf{U}_s^T\mathbf{U}_p$. Similarly, $\|\mathbf{U}_p^T\mathbf{U}_l\|_F^2$ is normalized by K_lK_p. Note that $K_l = K_p$ and $l \neq p$. As discussed in subsection 4.1, we present an alternative way by adding a common factor a and set $\alpha_p = \frac{a}{K_s \times K_p}$ and $\beta_l = \frac{a}{K_p \times K_l}$. The common factor a is used to adjust a trade-off between the matrix factorization errors and the mutual orthogonality, which cannot directly tune on the validation set. Thus, we look at the objective function of optimization problem in equation (3) on the training data and find the optimum value for a.

Figure 2 shows the objective function value vs. common factor a, where y-axis denotes the converged objective function value, and x-axis denotes $\text{Log}_{10}a$. We can see that the optimum value of a is 100. Therefore, the common factor a can be fixed at 100 for our data set used in the paper, resulting in $\alpha_p = \beta_l = 0.625$. Note that the optimum value of (K_s, K_p) are set as $(20, 8)$ in subsection 4.1. Due to limited space, we do not give an in-depth analysis for other parameters.

4 Conclusion and Future Work

In this paper, we propose a novel approach, called group non-negative matrix factorization with natural categories (GNMFNC). The proposed method is achieved by learning the category-specific topics for each category as well as shared topics across all categories via a group non-negative matrix factorization framework. We derive an efficient algorithm for learning the factorization, analyze its complexity, and

provide proof of convergence. Experiments show that our proposed approach significantly outperforms various baseline methods and achieves state-of-the-art performance for question retrieval.

There are some ways in which this research could be continued. First, the optimization of GNMFNC can be decomposed into many sub-optimization problems, a natural avenue for future research is to reduce the running time by executing the optimization in a distributed computing environment (e.g., MapReduce (Dean et al., 2004)). Second, another combination approach will be used to incorporate the latent topic match score as a feature in a learning to rank model, e.g., LambdaRank (Burges et al., 2007). Third, we will try to investigate the use of the proposed approach for other kinds of data sets with larger categories, such as categorized documents from ODP project.[5]

Abstract

Most web search results clustering (SRC) strategies have predominantly studied the definition of adapted representation spaces to the detriment of new clustering techniques to improve performance. In this paper, we define SRC as a multi-objective optimization (MOO) problem to take advantage of most recent works in clustering. In particular, we define two objective functions (compactness and separability), which are simultaneously optimized using a MOO-based simulated annealing technique called AMOSA. The proposed algorithm is able to automatically detect the number of clusters for any query and outperforms all state-of-the-art text-based solutions in terms of F_β-measure and F_{b^3}-measure over two gold standard data sets.

1 Introduction

Web search results clustering (SRC), also known as post-retrieval clustering or ephemeral clustering has received much attention for the past twenty years for easing up user's effort in web browsing. The key idea behind SRC systems is to return some meaningful labeled clusters from a set of web documents (or web snippets) retrieved from a search engine for a given query.

Recently, SRC strategies have been focusing on the introduction of external (exogenous) knowledge to better capture semantics between documents (Scaiella et al., 2012; Marco and Navigli, 2013). Although this research direction has evidenced competitive results, the proposed clustering techniques are based on a single cluster quality measure, which must reflect alone the goodness of a given partitioning. These techniques are usually referred to as single objective optimizations (SOO).

In this paper, we hypothesize that improved clustering can be achieved by defining different objective functions over well-known data representations. As such, our study aims to focus on new clustering issues for SRC instead of defining new representation spaces.

Recent studies (Maulik et al., 2011) have shown that clustering can be defined as a multi-objective optimization (MOO) problem. Within the context of SRC, we propose to define two objective functions (compactness and separability), which are simultaneously optimized using a MOO-based simulated annealing technique called AMOSA (Bandyopadhyay et al., 2008).

In order to draw conclusive remarks, we present an exhaustive evaluation where our MOO algorithm (*MOO-clus*) is compared to the most competitive text-based (endogenous) SRC algorithms: STC (Zamir and Etzioni, 1998), LINGO (Osinski and Weiss, 2005), OPTIMSRC (Carpineto and Romano, 2010) and GK-means (Moreno et al., 2013). Experiments are run over two different gold standard data sets (ODP-239 and MORESQUE) for two clustering evaluation metrics (F_β-measure and F_{b^3}-measure). Results show that *MOO-clus* outperforms all text-based solutions and approaches performances of knowledge driven strategies (Scaiella et al., 2012). In this paper, our main contributions are:

- The first[1] attempt to solve SRC by defining multiple objective functions,
- A new MOO clustering algorithm for SRC, which automatically determines the number of clusters,

[1] As far as we know.

Proceedings of COLING 2014, the 25th International Conference on Computational Linguistics: Technical Papers, pages 99–108, Dublin, Ireland, August 23-29 2014.

- An exhaustive evaluation of SRC algorithms with recent data sets and evaluation metrics over the most competitive state-of-the-art text-based SRC algorithms.

2 Related Work

2.1 SRC Algorithms

One of the most cited SRC solutions is the Suffix Tree Clustering (STC) algorithm proposed by (Zamir and Etzioni, 1998). They propose a monothetic clustering technique, which merges base clusters with high string overlap based on web snippets represented as compact tries. Their evaluation shows improvements over agglomerative hierarchical clustering, K-Means, Buckshot, Fractionation and Single-Pass algorithms, and is still a hard baseline to beat (Moreno and Dias, 2014).

Later, (Osinski and Weiss, 2005) proposed a polythetic solution called LINGO based on the same string representation as of (Zamir and Etzioni, 1998). They first extract frequent phrases based on suffix-arrays and match group descriptions with topics obtained with latent semantic analysis. Documents are then assigned straightforwardly to their corresponding groups. Their evaluation does not allow conclusive remarks but they propose an open source implementation, which is an important contribution.

More recently, (Carpineto and Romano, 2010) showed that the characteristics of the outputs returned by SRC algorithms suggest the adoption of a meta clustering approach. The underlying idea is that different SOO solutions lead to complementary results that must be combined. So, they introduce a novel criterion to measure the concordance of two partitions of objects into different clusters based on the information content associated to the series of decisions made by the partitions on single pairs of objects. The results of OPTIMSRC demonstrate that meta clustering is superior over individual clustering techniques.

The latest work, exclusively based on endogenous information (i.e. web snippets returned by the search engine), is proposed by (Moreno et al., 2013). They adapt the K-means algorithm to a third-order similarity measure and propose a stopping criterion to automatically determine the "optimal" number of clusters. Experiments are run over two gold standard data sets, ODP-239 (Carpineto and Romano, 2010) and MORESQUE (Navigli and Crisafulli, 2010), and show improved results over all state-of-the-art text-based SRC techniques so far.

A great deal of works have also proposed to include exogenous information to solve the SRC problem. One important work is proposed by (Scaiella et al., 2012) who use Wikipedia articles to build a bipartite graph and apply spectral clustering over it to discover relevant clusters. More recently, (Marco and Navigli, 2013) proposed to include word sense induction based on the Web1T corpus (Brants and Franz, 2006) to improve SRC. In this paper, we exclusively focus on endogenous solutions.

2.2 MOO-based Clustering

Many works have been proposed where the problem of clustering is posed as one of multi-objective optimization (Deb, 2009; Maulik et al., 2011). One important work is proposed by (Handl and Knowles, 2007) who define a multi-objective clustering technique with automatic K-determination called MOCK. Their algorithm outperforms several standard single-objective clustering algorithms (K-means, agglomerative hierarchical clustering and ensemble clustering) on artificial data sets.

In parallel, a multi-objective evolutionary algorithm for fuzzy clustering is proposed by (Bandyopadhyay et al., 2007) for clustering gene expressions. Here, two objectives are simultaneously optimized. The first one is the objective function optimized in the fuzzy C-means algorithm (Bezdek, 1981) and the other one is the Xie-Beni index (Xie and Beni, 1991).

Later, (Mukhopadhyay and Maulik, 2009) proposed a novel approach that combines the multi-objective fuzzy clustering method of (Bandyopadhyay et al., 2007) with a Support Vector Machines (SVM) classifier. Performance results are provided for remote sensing data.

As far as we know, within text applications, (Morik et al., 2012) is the first work, which formulates text clustering a multi-objective optimization problem. In particular, they express desired properties of frequent termset clustering in terms of multiple conflicting objective functions. The optimization is solved by a genetic algorithm and the result is a set of Pareto-optimal solutions. Note that this effort is

defined for large text colllections with high dimensional data, which is contradictory to the specific task of SRC (Carpineto et al., 2009)[2].

2.3 Our Motivation

Recent works have focused on the introduction of external (exogenous) knowledge to solve the SRC task. However, this research direction higly depends on existing resources, which are not available for a great deal of languages. Moreover, (Carpineto and Romano, 2010) has suggested an interesting research direction, which has still remained unexplored. Indeed, (Carpineto and Romano, 2010) showed that meta clustering leads to improved results in the context of text-based (endogenous) SRC. This suggests that better clustering can be obtained by combining different SOO solutions. However, their algorithm is casted to a SOO problem of the concordance between the clustering combination and a meta partition.

As a consequence, we hypothesize that improved performances can be obtained by defining the SRC task as a MOO clustering problem. For that purpose, we (1) take advantage of the recent advances in the field of multi-objective clustering (Saha and Bandyopadhyay, 2010), (2) define new objective functions in a non euclidean space and (3) adapt a MOO-based simulated annealing technique called AMOSA (Bandyopadhyay et al., 2008) to take into account third-order similarity metrics (Moreno et al., 2013).

3 Clustering as a MOO Problem

3.1 Formal Definition of MOO Clustering

Multi-objective optimization can be formally stated as finding the vector $\overline{x}^* = [x_1^*, x_2^*, \ldots, x_n^*]^T$ of decision variables that simultaneously optimize *M* objective function values $\{f_1(\overline{x}), f_2(\overline{x}), \ldots, f_M(\overline{x})\}$ while satisfying user-defined constraints, if any.

An important concept in MOO is that of domination. Within the context of a maximization problem, a solution $\overline{x_i}$ is said to dominate $\overline{x_j}$ if $\forall k \in 1, 2, \ldots, M,\ f_k(\overline{x_i}) \geq f_k(\overline{x_j})$ and $\exists k \in 1, 2, \ldots, M,$ such that $f_k(\overline{x_i}) > f_k(\overline{x_j})$.

Among a set of solutions R, the non-dominated set of solutions $R^{'}$ are those that are not dominated by any member of the set R and is called the globally Pareto-optimal set or Pareto front. In general, a MOO algorithm outputs a set of solutions not dominated by any solution encountered by it. These notions can be illustrated by considering an optimization problem with two objective functions (f_1 and f_2) with six different solutions, as shown in Figure 1. Here target is to maximize both objective functions f_1 and f_2.

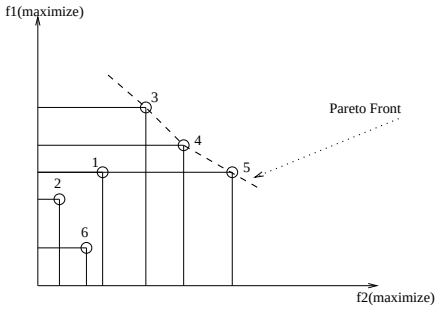

Figure 1: Example of dominance and Pareto optimal front.

In this example, solutions 3, 4 and 5 dominate all the other three solutions 1, 2 and 6. Solutions 3, 4 and 5 are nondominating to each other. Because 3 is better than 4 w.r.t. function f_1, but 4 is better than 3 w.r.t. f_2. Similarly 4 is better than 5 w.r.t. f_1 but 5 is better than 4 w.r.t. f_2. The same happens for solutions 3 and 5. So, the Pareto front is made of solutions 3, 4 and 5.

Within the specific context of clustering, two objective functions are usually defined, which must be optimized simultaneously. These functions are based on two intrinsic properties of the data space and are defined as follows.

[2]SRC is usually referred to as text clustering in the "small": i.e. small list of short text documents.

Compactness: This objective function measures the proximity among the various elements of a given cluster and must be maximized.

Separability: This objective function measures the similarity between two cluster centroids and must be minimized.

3.2 AMOSA Optimization Strategy

Clustering is viewed as a search problem, where optimal partitions satisfying the given set of objective functions must be discovered. As such, an optimization strategy must be defined. Here, we propose to use archived multi-objective simulated annealing (AMOSA) proposed by (Bandyopadhyay et al., 2008). AMOSA incorporates the concept of an archive where the non-dominated solutions seen so far are stored.

Two limits are kept on the size of the archive: a hard limit denoted by *HL* and a soft limit denoted by *SL*. Given $\gamma > 1$, the algorithm begins with the initialization of a number $(\gamma \times SL)$ of solutions each of which representing a state in the search space. Thereafter, the non-dominated solutions are determined and stored in the archive.

Then, one point is randomly selected from the archive. This is taken as the current point, or the initial solution, at temperature $T = T_{max}$. The current point is perturbed/mutated to generate a new solution named new-pt and its objective functions are computed. The domination status of the new-pt is checked w.r.t. the current point and the solutions in the archive. Based on domination status, different cases may arise: (i) accept the new-pt, (ii) accept the current-pt or (iii) accept a solution from the archive. In case of overflow of the archive, its size is reduced to *HL*.

The process is repeated *iter* times for each temperature that is annealed with a cooling rate of α ($<$1) till the minimum temperature T_{min} is attained. The process thereafter stops and the archive contains the final non-dominated solutions i.e. the Pareto front.

4 SRC as MOO Problem: MOO-clus

4.1 Archive Initialization

As we follow an endogenous approach, only the information returned by a search engine is used. In particular, we only deal with web snippets and each one is represented as a word feature vector. So, our solution called *MOO-clus* starts its execution after initializing the archive with some random solutions as archive members. Here, a particular solution refers to a complete assignment of web snippets (or data points) in several clusters. So, the first step is to represent a solution compatible with AMOSA, which represents each individual solution as a string. In order to encode the clustering problem in the form of a string, a center-based representation is used. Note that the use of a string representation facilitates the definition of individuals and mutation functions (Bandyopadhyay et al., 2008).

Let us assume that the archive member i represents the centroids of K_i clusters and the number of tokens in a centroid is p[3], then the archive member (or string) has length l_i where $l_i = p \times K_i$. To initialize the number of centroids K_i encoded in the string i, a random value between 2 and K_{max} is chosen and each K_i cluster centroid is initialized by randomly generated tokens from the global vocabulary.

4.2 Assignment of Web Snippets

As for any classical clustering algorithms, web snippets (or data points) must be assigned to their respective clusters. In *MOO-clus*, this assignment is computed as in (Moreno et al., 2013), to take advantage of recent advances in similarity measures. For two word feature vectors d_i and d_j, their similarity is evaluated by the similarity of their constituents as defined in Equation 1.

$$S(d_i, d_j) = \frac{1}{\|d_i\|\|d_j\|} \sum_{r=1}^{\|d_i\|} \sum_{b=1}^{\|d_j\|} SCP(w_i^r, w_j^b), \quad \text{with} \quad SCP(w_1, w_2) = \frac{P(w_1, w_2)^2}{P(w_1) \times P(w_2)} \tag{1}$$

[3] A centroid is represented by a p word feature vector $(w_k^1, w_k^2, w_k^3, \ldots, w_k^p)$.

Here, w_i^r (resp. w_j^b) corresponds to the token at the r^{th} (resp. b^{th}) position of the word feature vector d_i (resp. d_j). $\|d_i\|$ and $\|d_j\|$ respectively denote the total number of tokens in word feature vectors d_i and d_j. $SCP(w_i^r, w_j^b)$ is the Symmetric Conditional Probability (da Silva et al., 1999) where $P(.,.)$ is the joint probability of two tokens (w_1 and w_2) appearing in the same word feature vector and $P(.)$ is the marginal probability of any token appearing in a word feature vector.

Note that each cluster centroid is a word feature vector of varying number of tokens. Thus, Equation 2 is used to assign any data point (web snippet) d_j to a cluster t whose centroid has the maximum similarity value to d_j.

$$t = argmax_{k=1,...K} S(d_j, m_{\pi_k}) \tag{2}$$

K denotes the total number of clusters, d_j is the j^{th} web snippet, m_{π_k} is the centroid of the k^{th} cluster π_k and $S(d_j, m_{\pi_k})$ denotes similarity measurement between the point d_j and cluster centroid m_{π_k} defined in Equation 1.

4.3 Definition of Objective Functions

A string i represents a set of centroids to which web snippets can be assigned as seen in Section 4.2. As a consequence, each string i corresponds to a candidate partition of the data space. Now, in order to verify the domination of different solutions over other ones, objective functions must be defined. Compactness and separability are usually used in MOO clustering solutions. Here, compactness can be defined as the informational density of each cluster. This can be straightforwardly formulated as in Equation 3.

$$Compactness = \sum_{k=1}^{K} \sum_{d_i \in \pi_k} S(d_i, m_{\pi_k}) \tag{3}$$

Note that if tokens in a particular cluster are very similar to the cluster centroid then the corresponding $Compactness$ value would be maximized. Here our target is to form good clusters whose compactness in terms of similarity should be maximum.

The second objective function is cluster separability, which measures the dissimilarity between two cluster centroids. Indeed, the purpose of any clustering algorithm is to obtain compact similar typed clusters, which are dissimilar to each other. Here, we define separability as the minimization of the summation of similarities between each pair of cluster centroids. This is defined in Equation 4, where m_{π_k} and m_{π_o} are the centroids of clusters π_k and π_o, respectively.

$$Separability = \sum_{k=1}^{K} \sum_{o=k+1}^{K} S(m_{\pi_k}, m_{\pi_o}) \tag{4}$$

Finally, for a particular string, the following objectives $\{Compactness, \frac{1}{Separability}\}$ are maximized using the search capability of AMOSA.

4.4 Search Operators

In *MOO-clus*, AMOSA is used as the optimization strategy. For that purpose, three different types of mutation operations have been defined to suit the framework.

Mutation 1: This mutation operation is used to update the cluster center representation. Each token of cluster centroid is replaced by one token from the global vocabulary according to highest SCP similarity. This is applied individually to all tokens of a particular centroid if it is selected for mutation.

Mutation 2: This mutation operation is used to reduce the size of the string by 1. We randomly select a cluster centroid and thereafter all the tokens of this centroid are deleted from the string.

Mutation 3: This mutation is for increasing the size of string by 1 i.e. one new centroid is inserted in the string. For that purpose, we randomly choose p number of tokens from the global vocabulary and add it to the string.

Let be a string $< w_1\ w_2\ w_3\ w_4\ w_5\ w_6 >$ representing three cluster centroids (w_1, w_2), (w_3, w_4) and (w_5, w_6)[4]. For mutation 1, let position 2 be selected randomly. Each token of the word vector (w_3, w_4) will be changed by some token from the global vocabulary using SCP. Then, after change, the string will look like $< w_1\ w_2\ w_3^{new}\ w_4^{new}\ w_5\ w_6 >$. If mutation 2 is selected, a centroid will be removed from the string. Let centroid 3 be selected for deletion. The new string will look like $< w_1\ w_2\ w_3\ w_4 >$. In case of mutation 3, a new centroid will be added to the string. A new cluster centroid is generated choosing p=2 number of tokens from the global vocabulary. Let the randomly generated new cluster centroid to be added to the string be (w_7, w_8). After inclusion of this centroid, the string will be $< w_1\ w_2\ w_3\ w_4\ w_5\ w_6\ w_7\ w_8 >$. In our experiments, we have associated equal probability to each of these mutation operations. Thus, each mutation is applied in 33% cases of the cases.

5 Experimental Setup

5.1 Datasets

The main gold standards used for the evaluation of SRC algorithms are ODP-239 and MORESQUE[5]. In ODP-239 (Carpineto and Romano, 2010), each document is represented by a title and a web snippet and the subtopics are chosen from the top levels of DMOZ[6]. On the other hand, the subtopics in MORESQUE (Navigli and Crisafulli, 2010) follow a more natural distribution as they are defined based on the disambiguation pages of Wikipedia. As such, the subtopics cover most of the query-related senses. However, not all queries are Wikipedia related or ambiguous (e.g. "Olympic Games", which Wikipedia entry is not ambiguous, although there are many events related to this topic). As a consequence, it is clear that different results can be obtained from one data set to another. A quick summary of both data sets is presented in Table 1.

Dataset	# of queries	# of Subtopics Avg / Min / Max	# of Snippets
ODP-239	239	10 / 10 / 10	25580
MORESQUE	114	6.7 / 2 / 38	11402

Table 1: SRC gold standard data sets.

5.2 Evaluation Metrics

A successful SRC system must evidence high quality level clustering. Each query subtopic should ideally be represented by a unique cluster containing all the relevant web pages inside. However, determining a unique and complete metric to evaluate the performance of a clustering algorithm is still an open problem (Amigó et al., 2013).

In this paper, we propose to use the F_{b^3}-measure (Amigó et al., 2009) to explore the Pareto front. In particular, F_{b^3} has been defined to evaluate cluster homogeneity, completeness, rag-bag and size-vs-quantity constraints. F_{b^3} is a function of $Precision_{b^3}$ (P_{b^3}) and $Recall_{b^3}$ (R_{b^3}). All metrics are defined in Equation 5

$$F_{b^3} = \frac{2 * P_{b^3} * R_{b^3}}{P_{b^3} + R_{b^3}}, \quad P_{b^3} = \frac{1}{N}\sum_{i=1}^{K}\sum_{d_j \in \pi_i}\frac{1}{|\pi_i|}\sum_{d_l \in \pi_i} g^*(d_j, d_l), \quad R_{b^3} = \frac{1}{N}\sum_{i=1}^{K}\sum_{d_j \in \pi_i^*}\frac{1}{|\pi_i^*|}\sum_{d_l \in \pi_i^*} g(d_j, d_l) \qquad (5)$$

where π_i is i^{th} cluster, π_i^* is the gold standard of the category i, and $g^*(.,.)$ and $g(.,.)$ are defined as follows:

$$g^*(d_i, d_j) = \begin{cases} 1 \Leftrightarrow \exists l: & d_i \in \pi_l^* \wedge d_j \in \pi_l^* \\ 0 & \text{otherwise} \end{cases} \quad \text{and} \quad g(d_i, d_j) = \begin{cases} 1 \Leftrightarrow \exists l: & d_i \in \pi_l \wedge d_j \in \pi_l \\ 0 & \text{otherwise} \end{cases}.$$

[4] with p=2.

[5] AMBIENT has received less attention since the creation of ODP-239.

[6] http://www.dmoz.org [Last access: 14/03/2014].

Most SRC studies have also used the F_β-measure (F_β), which is defined in Equation 6.

$$F_\beta = \frac{(\beta^2+1)*P*R}{\beta^2*P+R}, \quad P = \frac{TP}{TP+FP}, \quad R = \frac{TP}{TP+FN} \tag{6}$$

where

$$TP = \sum_{i=1}^{K} \sum_{d_j \in \pi_i^*} \sum_{\substack{d_l \in \pi_i^* \\ l \neq j}} g(d_i, d_j), FP = \sum_{i=1}^{K} \sum_{d_j \in \pi_i} \sum_{\substack{d_l \in \pi_i \\ l \neq j}} (1 - g^*(d_i, d_j)), FN = \sum_{i=1}^{K} \sum_{d_j \in \pi_i^*} \sum_{\substack{d_l \in \pi_i^* \\ l \neq j}} (1 - g(d_i, d_j)).$$

6 Results and Discussion

In this evaluation, we used the open source framework GATE (Cunningham et al., 2013) without stopword removal for web snippet tokenization[7]. We executed *MOO-clus* over ODP-239 and MORESQUE. The parameters of *MOO-clus* are: $T_{min} = 0.01$, $T_{max} = 100$, $\alpha = 0.85$, $HL = 10$, $SL = 20$ and $iter = 15$. Note that, they have been determined after conducting a thorough sensitivity study. A first set of experiments have been conducted for different p values of tokens present in the centroid, namely in the range 2 to 5 in order to understand the behavior of *MOO-clus* w.r.t. centroid size[8]. Note that the partition with maximum F_{b^3} is choosen for each size of p[9]. Overall results are shown in Table 2.

	MORESQUE				ODP-239			
	MOO-clus				*MOO-clus*			
	2	3	4	5	2	3	4	5
$F_b{}^3$	0.477	0.491	0.497	**0.502**	0.478	0.481	**0.484**	0.481

Table 2: Evaluation results of *MOO-clus* over MORESQUE and ODP239 data sets.

Results show that for MORESQUE, *MOO-clus* obtains the highest F_{b^3} value for p=5. In particular, performance increases for higher values of p. For ODP-239, best results are reported for p=4, but evidence less sensitivity to the number of words in the centroids. Indeed, a marginal difference is obtained between all runs. In terms of F_β, the same behaviour is obtained for ODP-239. But, for MORESQUE, best results are provided for smaller values of p, namely p=3.

Two important comments must be pointed at. In the first place, F_{b^3} shows a steady behaviour compared to F_β when the data set changes. The conclusions drawn in (Amigó et al., 2009) reporting the superiority of F_{b^3} over F_β seem to be verified for the specific case of SRC. In the second place, *MOO-clus* evidences a marginal sensitivity to different p values. Indeed, for ODP-239, changing p between 2 and 5 words has a negligible impact on F_{b^3}. The figures show a different behaviour for MORESQUE but this can easily be explained. In MORESQUE, less queries are provided for test and the number of reference clusters varies between 2 and 38, with a majority of queries containing very few clusters (the average cluster size is 6.7). As such, small clustering errors may result in high deviations in the evaluation metrics. So, p can be seen as a non influent parameter for clustering purposes. In fact, increasing the value of p may exclusively allow a more descriptive power for cluster labeling.

We also compared *MOO-clus* to the current state-of-the-art text-based (endogenous) SRC algorithms: STC (Zamir and Etzioni, 1998), LINGO (Osinski and Weiss, 2005), OPTIMSRC (Carpineto and Romano, 2010), Bisecting Incremental K-means (BIK), GK-means (Moreno et al., 2013) and the combination STC-LINGO (Moreno and Dias, 2014). The results are illustrated in Table 3 where we provide values for all the metrics for open source implementations and reported values in the literature for the

[7]Note that keeping stop words is a challenging task as most methodologies withdraw these elements as they are hard to handle. This decision is supported by the fact that we aim to produce as much as possible language-independent solutions.

[8]Note that to ease the user effort in searching for information, the cluster label must be small and expressive. Typical configurations range between 3 to 5 to include multiword expressions.

[9]F_β metrics are calculated over the partition with highest F_{b^3} value.

other experiments i.e. OPTIMSRC, GK-means and STC-LINGO. In particular, the Min (resp. Max) column refers to the worst (resp. best) performance when varying p, the size of the centroid.

The results of Table 3 clearly show the performance improvements of our proposed methodology over existing text-based techniques for both data sets and most evaluation metrics. For ODP-239, *MOO-clus* attains the highest values with respect to F_1, F_2, F_5 and F_{b^3} metrics against all existing endogenous algorithms. For MORESQUE, our algorithm reaches highest performance over all state-of-the-art algorithms for F_1 and F_{b^3} metrics but marginally fails for F_2 and F_5 against GK-means.

		MOO-clus		*SOO SRC*				*Combination of SOO SRC*	
		Min	*Max*	GK-means	STC	LINGO	BIK	OPTIMSRC	STC-LINGO
MORESQUE	F_1	0.658	**0.675**	0.665	0.455	0.326	0.317	N/A	0.561
	F_2	0.742	0.768	**0.770**	0.392	0.260	0.269	N/A	N/A
	F_5	0.820	0.862	**0.872**	0.370	0.237	0.255	N/A	N/A
	${F_b}^3$	0.477	**0.502**	0.482	0.460	0.399	0.315	N/A	0.498
ODP-239	F_1	0.379	**0.384**	0.366	0.324	0.273	0.200	0.313	0.362
	F_2	0.534	**0.537**	0.416	0.319	0.167	0.173	0.341	N/A
	F_5	0.715	**0.720**	0.462	0.322	0.153	0.165	0.380	N/A
	${F_b}^3$	0.478	**0.484**	0.452	0.403	0.346	0.307	N/A	0.425

Table 3: Comparative results with respect to F_β and F_{b^3} metrics over the ODP-239 and MORESQUE datasets obtained by different SRC techniques.

It is important to notice that OPTIMSRC and STC-LINGO can be viewed as a combination of different SRC SOO solutions but still casted to a SOO solution. These previous results report interesting issues for SRC and confort the idea that the combination of different objective functions may lead to enhanced SRC algorithms. But, *MOO-clus* is capable to find better partitions than OPTIMSRC and STC-LINGO for all data sets and all evaluation metrics as reported in Table 3.

It is important to notice that the *MOO-clus* provides a set of partitions with automatic definition of the number of clusters. So, defining one unique solution is an important issue for SRC. So far, we have provided results for the best partition evaluated by F_{b^3}. However, deeper analysis of all the partitions on the Pareto front must be endeavoured. Results are reported for F_{b^3} only as all other metrics behave correspondingly and are reported in Table 4.

	MORESQUE				ODP-239			
	2	3	4	5	2	3	4	5
Min	0.428	0.464	0.464	0.462	0.396	0.401	0.403	0.408
Max	0.477	0.491	0.497	0.502	0.478	0.481	0.484	0.481
Avg.	0.454	0.479	0.482	0.486	0.443	0.447	0.448	0.449

Table 4: F_{b^3} evaluation results of the Pareto front.

Figures show the validity of each individual solution of the Pareto front. In the worst case, *MOO-clus* produces similar results compared to the hard baseline STC. On average, it reaches the results of GK-means and the highest performance values can be found on the Pareto front. The correct identification of the best partition is still an open issue and can be compared to the automatic selection of K clusters, which is a hard task as shown in recent studies (Scaiella et al., 2012; Marco and Navigli, 2013).

7 Conclusions

In this paper, we proposed the first attempt[10] to define the SRC task as a multi-objective problem. For that purpose, we defined two objective functions, which are simultaneously optimized through the archived multi-objective simulated annealing framework called AMOSA. A correct definition of the task allowed to take advantage of the most recent advances in terms of endogenous SRC algorithms as well as the most powerful techniques for multi-objective clustering. The performance of *MOO-clus* has been evaluated over two gold standard data sets, ODP-239 and MORESQUE for different evaluation metrics, F_1 and F_{b^3}.

[10] As far as we know.

Results showed that our proposal steadily outperforms all existing state-of-the-art text-based endogenous SRC algorithms and approaches recent knowledge-driven exogenous strategies (Scaiella et al., 2012), which reach F_1=0.413 for ODP-239[11].

As future works, we propose to use MOO clustering in a strict meta learning way, where any labeled-based SOO solution is defined by specific $Compactness$ and $Separability$ functions. Another research direction is the definition of the Dual representation proposed by (Moreno et al., 2014) as a MOO problem. Finally, new objective functions can be defined to measure the quality of the labels, which may integrate meaningful multiword expressions or named entities.

Query-by-Example Image Retrieval using Visual Dependency Representations

Desmond Elliott, Victor Lavrenko and **Frank Keller**

Abstract

Image retrieval models typically represent images as bags-of-terms, a representation that is well-suited to matching images based on the presence or absence of terms. For some information needs, such as searching for images of people performing actions, it may be useful to retain data about how parts of an image relate to each other. If the underlying representation of an image can distinguish between images where objects only co-occur from images where people are interacting with objects, then it should be possible to improve retrieval performance. In this paper we model the spatial relationships between image regions using Visual Dependency Representations, a structured image representation that makes it possible to distinguish between object co-occurrence and interaction. In a query-by-example image retrieval experiment on data set of people performing actions, we find an 8.8% relative increase in MAP and an 8.6% relative increase in Precision@10 when images are represented using the Visual Dependency Representation compared to a bag-of-terms baseline.

1 Introduction

Every day millions of people search for images on the web, both professionally and for personal amusement. The majority of image searches are aimed at finding a particular named entity, such as *Justin Bieber* or *supernova*, and a typical image retrieval system is well-suited to this type of information need because it represents an image as a bag-of-terms drawn from data surrounding the image, such as text, manual tags, and anchor text (Datta et al., 2008). It is not always possible to find useful terms in the surrounding data; the last decade has seen advances in automatic methods for assigning terms to images that have neither user-assigned tags, nor a textual description (Duygulu et al., 2002; Lavrenko et al., 2003; Guillaumin and Mensink, 2009). These automatic methods learn to associate the presence and absence of labels with the visual characteristics of an image, such as colour and texture distributions, shape, and points of interest, and can automatically generate a bag of terms for an unlabelled image.

It is important to remember that not all information needs are entity-based: people also search for images reflecting a mood, such as *people having fun at a party*, or an action, such as *using a computer*. The bag-of-terms representation is limited to matching images based on the *presence or absence* of terms, and not the *relation* of the terms to each other. Figures 1(a) and (b) highlight the problem with using unstructured representations for image retrieval: there is a person and a computer in both images but only (a) depicts a person actually using the computer. To address this problem with unstructured representations we propose to represent the structure of an image using the Visual Dependency Representation (Elliott and Keller, 2013). The Visual Dependency Representation is a directed labelled graph over the regions of an image that captures the spatial relationships between regions. The representation is inspired by evidence from the psychology literature that people are better at recognising and searching for objects when the spatial relationships between the objects in the image are consistent with our expectations of the world.(Biederman, 1972; Bar and Ullman, 1996). In an automatic image description task, Elliott

Proceedings of COLING 2014, the 25th International Conference on Computational Linguistics: Technical Papers, pages 109–120, Dublin, Ireland, August 23-29 2014.

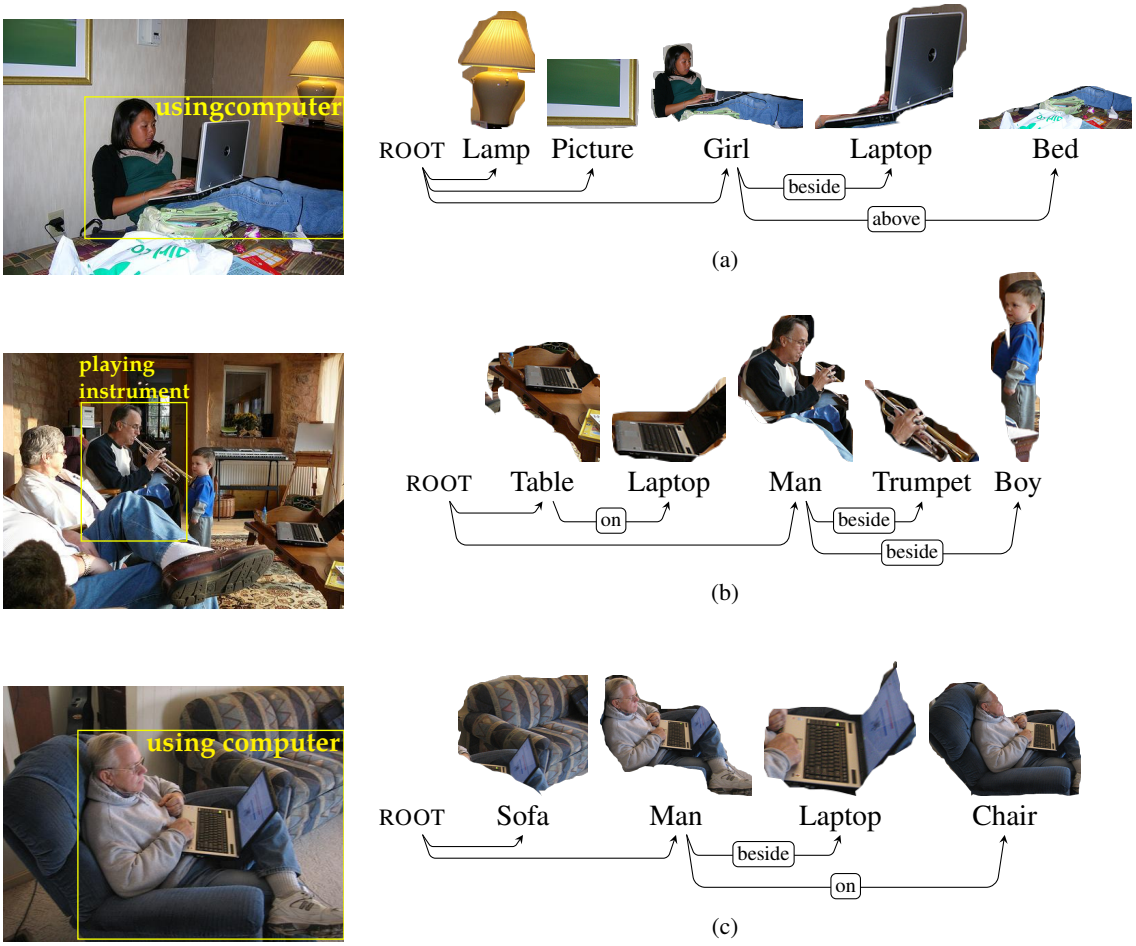

Figure 1: Three examples of images depicting a person and a computer, alongside a respective Visual Dependency Representation for each image. The bag-of-terms representation can be observed in the annotated regions of the Visual Dependency Representations. In (a) and (c) there is a person using a laptop, whereas in (b) the man is actually using the trumpet. The gold-standard action annotation is shown in the yellow bounding box.

and Keller (2013) showed that encoding the spatial relationships between objects in the Visual Dependency Representation helped to generate significantly better descriptions than approaches based on the spatial proximity of objects (Farhadi et al., 2010) or corpus-based models (Yang et al., 2011). In this paper we study whether the Visual Dependency Representation of images can improve the performance of query-by-example image retrieval models. The main finding is that encoding images using the Visual Dependency Representation leads to significantly better retrieval accuracy compared to a bag-of-terms baseline, and that the improvements are most pronounced for transitive verbs.

2 Related Work

2.1 Representing Images

A central problem in image retrieval is how to abstractly represent images (Datta et al., 2008). A bag-of-terms representation of an image is created by grouping visual features, such as color, shape (Shi and Malik, 2000), texture, and interest points (Lowe, 1999), in a vector or as a probability distribution over the features. Image retrieval can then be performed by trying to find the best matchings of terms across an image collection. Spatial Pyramid Matching is an approach to constructing low-level image representations that capture the relationships between features at differently sized partitions of the image (Lazebnik et al., 2006). This approach has proven successful for scene categorisation tasks. An alternative approach to representing images is to learn a mapping (Duygulu et al., 2002; Lavrenko et al.,

2003; Guillaumin and Mensink, 2009) between the bags-of-terms and object tags. An image can then be represented as a bag-of-terms and image retrieval is similar to text retrieval (Wu et al., 2012).

In this work, we represent an image as a directed acyclic graph over a set of labeled object region annotations. This representation captures the important spatial relationships between the image regions and makes it possible to distinguish between co-occurring regions and interacting regions.

2.2 Still-Image Action Recognition

One approach to recognizing actions is to learn appearance models for *visual phrases* and use these models to predict actions (Sadeghi and Farhadi, 2011). A visual phrase is defined as the people and the objects they interact with in an action. In this approach, a fixed number of visual phrase models are trained using the deformable parts object detector (Felzenszwalb et al., 2010) and used to perform action recognition.

An alternative approach is to model the relationships between objects in an image, and hence the visible actions, as a Conditional Random Field (CRF), where each node in the field is an object and the factors between nodes correspond to features that capture the relationships between the objects (Zitnick et al., 2013). The factors between object nodes in the CRF include object occurrence, absolute position, person attributes, and the relative location of pairs of objects. This model has been used to generate novel images of people performing actions and to retrieve images of people performing actions.

Most recently, actions have been predicted in images by selecting the most likely verb and object pair given a set of candidate objects detected in an image (Le et al., 2013a). The verb and object is selected amongst those that maximize the distributional similarity of the pair in a large and diverse collection of documents. This approach is most similar to ours but it relies on an external corpus and, depending on the text collections used to train the distributional model, will compound the problem of co-occurrence of objects instead of the relationships between the objects.

The work presented in this paper uses ground-truth annotation for region labels, an assumption similar to (Zitnick et al., 2013), but requires no external data to make predictions of the relationships between objects, unlike the approach of (Le et al., 2013a). The directed acyclic graph representation we propose for images can be seen as a latent representation of the depicted action in the image, where the spatial relationships between the regions capture the different types of actions.

3 Task and Baseline

In this paper we study the task of query-by-example image retrieval within the restricted domain of images depicting actions. More specifically, given an image that depicts a given action, such as *using a computer*, the aim of the retrieval model is to find all other images in the image collection that depict the same action. We define an action as an event involving one or more entities in an image, e.g., *a woman running* or *boy using a computer*, and assume all images have been manually annotated for objects. This assumption means we can explore the utility of the Visual Dependency Representation without the noise introduced by automatic computer vision methods. The data available to the retrieval models can be seen in Figure 1, and Section 5 provides further details about the different sources of data The action label - which is only used for evaluation - is shown in the labelled bounding box, and the Visual Dependency Representation - not used by the baseline model - is shown as a tree at the bottom of the figure.

The main hypothesis explored in this paper is that the accuracy of an image retrieval model will increase if the representation encodes information about the relationships between the objects in images. This hypothesis is tested by encoding images as either an unstructured bag-of-terms representation or as the structured Visual Dependency Representation. The Bag-of-Terms baseline represents the query image and the image collection as an unstructured bags-of-terms vector. All of the models used to test the main hypothesis use the cosine similarity function is to determine the similarity of the query image to other images in the collection, and thus to generate a ranked list from the similarity values.

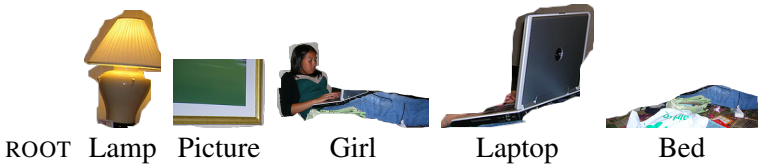
4 Visual Dependency Representation

The Visual Dependency Representation (VDR) is a structured representation of an image that captures the spatial relationships between pairs of image regions in a directed labelled graph. The Visual Dependency Grammar defines eight possible spatial relationships between pairs of regions, as shown in Table 1. The relationships in the grammar were designed to provide *sufficient* coverage of the types of spatial relationships required to describe the data, and are mathematically defined in terms of pixel overlap, distance between regions, and the angle between regions. The frame of reference for annotating spatial relationships is the image itself and not the object in the image, and angles and distance measurements are taken or estimated from the centroids of the regions. The VDR of an image is created by a trained human annotator in a two-stage process:

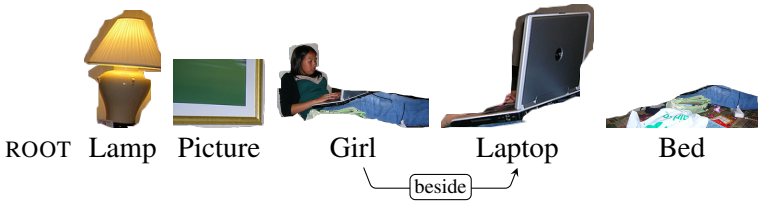
1. The annotator draws and labels boundaries around the parts of the image they think contribute to defining the action depicted in the image, and the context within which the action occurs;

2. The annotator draws labelled directed edges between the annotated regions that captures how the relationships between the image convey the action. In Section 4.1, we will explain how to automate the second stage of the process from a collection of labelled region annotations.

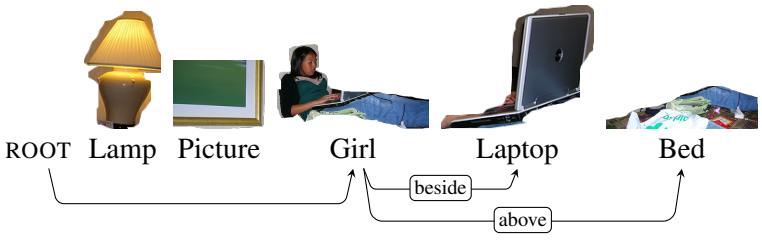
In addition to the annotated image regions, a VDR also contains a ROOT node, which acts as a placeholder for the image. In the remainder of this section we describe how a gold-standard VDR is created by a human annotator. The starting point for the VDR in Figure 1(a) is the following set of regions and the ROOT node:



First, the regions are attached to each other based on how the relationship between the objects contributes to the depicted action. In Figure 1(a), the Girl is *using* the Laptop, therefore a labelled directed edge is created from the Girl region to the Laptop region. The spatial relationship is labelled as BESIDE.



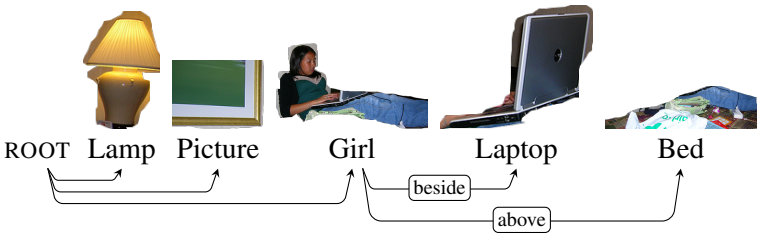
The Girl is also attached to the Bed because the bed supports her body. The spatial relation label is ABOVE because it expresses the spatial relationship between the regions, not the semantic relationship ON. ROOT is attached to the Girl without an edge label to symbolize that she is an actor in the image.



Now the regions that are not concerned with the depicted action are first attached to each other if there is a clear spatial relationship between them (for an example, see Figure 1(b), where the laptop is attached to the table because it is sitting on the table), and then to the ROOT node to signify that they do not play a part in the depicted action. In this example, neither the Lamp nor the Picture are related to the action of using the computer, so they are attached to the ROOT node.

 X $\overrightarrow{on}$ Y	More than 50% of the pixels of region X overlap with region Y.	 X $\overrightarrow{surrounds}$ Y	The entirety of region X overlaps with region Y.
 X $\overrightarrow{beside}$ Y	The angle between the centroid of X and the centroid of Y lies between 315° and 45° or 135° and 225°.	 X $\overrightarrow{opposite}$ Y	Similar to *beside*, but used when there X and Y are at opposite sides of the image.
 X $\overrightarrow{above}$ Y	The angle between X and Y lies between 225° and 315°.	 X $\overrightarrow{below}$ Y	The angle between X and Y lies between 45° and 135°.
 X $\overrightarrow{infront}$ Y	The Z-plane relationship between the regions is dominant.	 X $\overrightarrow{behind}$ Y	Identical to *infront* except X is behind Y in the Z-plane.

Table 1: Visual Dependency Grammar defines eight relations between pairs of annotated regions. To simplify explanation, all regions are circles, where X is the grey region and Y is the white region. All relations are considered with respect to the centroid of a region and the angle between those centroids.



This now forms a completed VDR for the image in Figure 1(a). This structured representation of an image captures the prominent relationship between the girl, the laptop, and the bed. There is no prominent relationship defined between the girl and either the lamp of the picture, in effect these regions have been relegated to background objects. The central hypothesis underpinning the Visual Dependency Representation is that images that contain similar VDR substructures are more likely to depict the same action than images that only contain the same set of objects. For example, the VDR for Figure 1(a) correctly captures the relationship between the people and the laptops, whereas this relationship is not present in Figure 1(b), where the person is playing a trumpet.

4.1 Predicting Visual Dependency Representations

We follow the approach of Elliott and Keller (2013) and predict the VDR y of an image over a collection of labelled region annotations $\mathbf{x}$. This task is framed as a supervised learning problem, where the aim is to construct a Maximum Spanning Tree from a fully-connected directed weighted graph over the labelled regions (McDonald et al., 2005). Reducing the fully-connected graph to the Maximum Spanning Tree removes the region–region edges that are not important in defining the prominent relationships between the regions in an image. The score of the VDR y over the image regions is calculated as the sum of the scores of the directed labelled edges:

$$score(\mathbf{x}, y) = \sum_{(a,b)\in y} \mathbf{w} \cdot \mathbf{f}(a, b) \quad (1)$$

where the score of an edge between image regions a and b is calculated using a vector of weighted feature functions $\mathbf{f}$. The feature functions characterize the image regions and the edge between pairs of regions, and include: the labels of the regions and the spatial relation annotated on the edge; the (normalized) distance between the centroids of the regions; the angle formed between the annotated regions, which is

mapped onto the set of spatial relations; the relative size of the region compared to the image; and the distance of the region centroid from the center of the image.

The model is trained over i instances of region-annotated images $\mathbf{x_i}$ associated with human-created VDR structures y_i, $I_{train} = \{\mathbf{x_i}, y_i\}$. The score of each edge a, b is calculated by applying the feature functions to the data associated with that edge, and this is performed over each edge in a VDR to obtain a score for a complete gold-standard structure. The parameters of the weight vector w are iteratively adjusted to maximise the score of the gold-standard structures in the training data using the Margin Infused Relaxation Algorithm (Crammer and Singer, 2002).

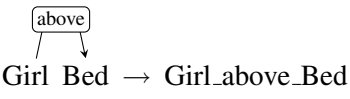
The test data contains i instances of region-annotated images with image regions $\mathbf{x_i}$, $I_{test} = \{\mathbf{x_i}\}$. The parsing model computes the highest scoring structure $\hat{y}_i$ for each instance in the test data by scoring each possible directed edge between pairs of regions in $\mathbf{x_i}$. This process forms a fully-connected graph over the image regions, from which the Maximum Spanning Tree is taken and returned as the predicted VDR.

We evaluate the performance of this VDR prediction model by comparing how well it can recover the manually created trees in the data set. This evaluation is performed on the development data in a 10-fold cross validation setting where each fold of the data is split 80%/10%/10%. Unlabelled directed accuracy means the model correctly proposes an edge between a pair of regions in the correct direction; Labelled directed accuracy means it additionally proposes the correct edge label. The baseline approach is to assume no latent image structure and attach all image regions to the ROOT node of the VDR; this achieves 51.6% labelled and unlabelled directed attachment accuracy. The accuracy of our automatic approach to VDR prediction is 61.3% labelled and 68.8% unlabelled attachment accuracy.

4.2 Comparing Visual Dependency Representations

It remains to define how to compare the Visual Dependency Representation of a pair of images. The most obvious approach is to use the labelled directed accuracy measurement used for the VDR prediction evaluation in the previous section, but we did not find significant improvements in retrieval accuracy using this method. We hypothesise that the lack of weight given to the edges between nodes in the Visual Dependency Representation results in this comparison function not distinguishing between object–object relationships that matter, such as PERSON $\overrightarrow{beside}$ BIKE, compared to ROOT $\rightarrow$ TREES. The former is a potential person–object relationship that explains the depicted event, whereas the latter is only a background object.

The approach we adopted in this paper is to compare Visual Dependency Representations of images by decomposing the structure into a set of labelled and a unlabelled parent–child subtrees in a depth-first traversal of the VDR. The decomposition process allows use to use the same similarity function as the Bag-of-Terms baseline model, removing the confound of choosing different similarity functions. The subtrees can be transformed into tokens and these tokens can be used as weighted terms in a vector representation. An example of a labelled transformation is shown below:



We now demonstrate the outcome of comparing images represented using either a vector that concatenates the decomposed transformed VDR and bag-of-terms, or a vector that contains only the bag-of-terms. In this demonstration, each term has a *tf-idf* weight of 1. The first illustration (*Similar*) compares images that depict the same underlying action: Figure 1 (a) and (c). The second illustration (*Dissimilar*) compares images that depict different actions: Figure 1 (a) and (b).

$$Similar : \cos(\text{VDR}_a, \text{VDR}_c) = 0.56 > \cos(\text{Bag}_a, \text{Bag}_c) = 0.52$$

$$Dissimilar : \cos(\text{VDR}_b, \text{VDR}_a) = 0.201 \ll \cos(\text{Bag}_b, \text{Bag}_a) = 0.4$$

It can be seen that when the images represent the same action, the decomposed VDR increases the similarity of the pair of images compared to the bag-of-terms representation; and when images do not

represent the same action, the decomposed VDR yields a lower similarity than the bag-of-terms representation. These illustrations confirm that Visual Dependency Representations can be used to distinguish the difference between presence or absence of objects, and the prominent relationships between objects.

5 Data

We use an existing dataset of VDR-annotated images to study whether modelling the structure of an image can improve image retrieval in the domain of action depictions. The data set of Elliott and Keller (2013) contains 341 images annotated with region annotations, three visual dependency representations per image (making a total of 1,023 instances), and a ground-truth action label for each image. An example of the annotations can be seen in Figure 1. The image collection is drawn from the PASCAL Visual Object Classification Challenge 2011 action recognition taster and covers a set of 10 actions (Everingham et al., 2011): riding a bike, riding a horse, reading, running, jumping, walking, playing an instrument, using a computer, taking a photo, and talking on the phone.

Image Descriptions

Each image is associated with three human-written descriptions collected from untrained annotators on Amazon Mechanical Turk. The descriptions do not form any part of the models presented in the current paper; they were used in the automatic image description task of Elliott and Keller (2013). Each description contains two sentences: the first sentence describes the action depicted in the image, and the second sentence describes other objects not involved in the action. A two sentence description of an image helps distinguish objects that are central to depicting the action from objects that may be distractors.

Region Annotations

The images contain human-drawn labelled region annotations. The annotations were drawn using the LabelMe toolkit, which allows for arbitrary labelled polygons to be created over an image (Russell et al., 2008). The annotated regions were restricted to those present in at least one of three human-written descriptions. To reduce the effects of label sparsity, frequently occurring equivalent labels were conflated, i.e., man, child, and boy $\rightarrow$ person; bike, bicycle, motorbike $\rightarrow$ bike; this reduced the object label vocabulary from 496 labels to 362 labels. The data set contains a total of 5,034 region annotations, with a mean of 4.19 ± 1.94 annotations per image.

Visual Dependency Representations

Recall that each image is associated with three descriptions, and that people were free to decide how to describe the action and background of the image. The differences between how people describe images leads to the creation of one Visual Dependency Representation per image–description pair in the data set, resulting in a total of 1,023 instances. The process for creating a visual dependency representation of an image is described in Section 4. The annotated dataset comprises a total of 5,748 spatial relations, corresponding to a mean of 4.79 ± 3.51 relations per image. Elliott and Keller (2013) report inter-annotator agreement on a subset of the data at 84% agreement for labelled directed attachments and 95.1% for unlabelled directed attachments.

Action Labels

The original PASCAL action recognition dataset contains ground truth action class annotations for each image. These annotations are in the form of labelled bounding boxes around the person performing the action in the image. The action labels are only used as the gold-standard relevance judgements for the query-by-example image retrieval experiments.

6 Experiments

In this section we present the results of a query-by-example image retrieval experiment to determine the utility of the Visual Dependency Representation compared to a bag-of-terms representation. In this

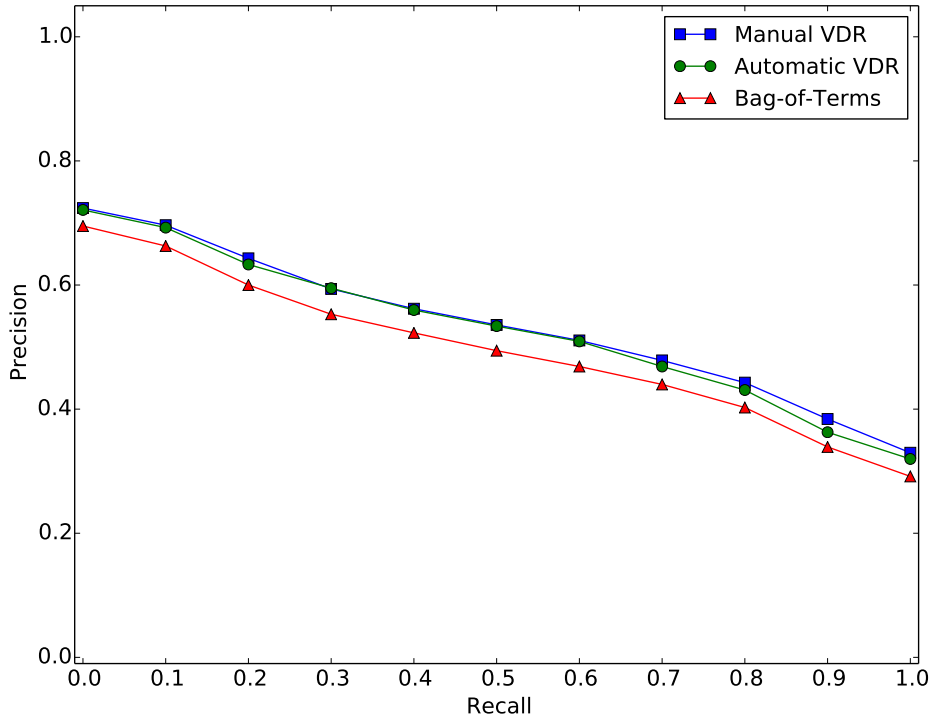


Figure 2: Average 11-point precision/recall curves show that the VDR-based retrieval models are consistently better than the Bag-of-Terms model.

experiment, a single image (the query image) is used to rank the images in the test collection, where the goal is to construct a ranking where the top images depict the same action as the query image.

6.1 Protocol

The image retrieval experiment is performed using 10-fold cross-validation in the following manner. The 341 images in the dataset are randomly partitioned into 80%/10%/10% splits, resulting in 1011 test queries[1]. For each query we compute average precision and Precision@10 of the ranked list, and use the resulting values to test the statistical significance of the results.

The *training set* is used to train the VDR prediction model and to estimate inverse document frequency statistics. During the training phase, the VDR-based models have access to region boundaries, region labels and three manually-created VDRs for each training image. In the *test set*, all models have access to the region boundaries and labels for each image. Each image in the test set forms a query and the models produce a ranked list of the remaining images in the test collection. Images are marked for relevance as follows: a image at rank r is considered *relevant* if it has the same action label as the query image; otherwise it is *non-relevant*. The *dev set* was used to experiment with different matching functions and to optimise the feature functions used in the VDR prediction model.

6.2 Models

We compare the retrieval accuracy of three approaches: Bag-of-Terms uses an unstructured representation for each image. A *tf-idf* weight is assigned to each region label in an image, and the cosine measure is used to calculate the similarity of images. This model allows us to compare the usefulness of a structured vs. unstructured image representation. Automatic VDR is a model using the VDR prediction method from Section 4.1, and Manual VDR uses the gold-standard data described in Section 5. Both

[1]Recall there are three Visual Dependency Representations for each image. The partitions are the same as those used in the VDR prediction experiment in Section 4.1

	MAP	P@10
Manual VDR	$0.514^{\star\dagger}$	$0.454^{\star}$
Automatic VDR	$0.508^{\star}$	$0.451^{\star}$
Bag-of-Terms	0.467	0.415

Table 2: Overall Mean Average Precision and Precision@10 images. The VDR-based models are significantly better than the Bag-of-Terms model, supporting the hypothesis that modelling the structure of an image using the Visual Dependency Representation is useful for image retrieval. $\star$: significantly different than Bag-of-Terms at $p < 0.01$; †: significantly different than Automatic VDR at $p < 0.01$.

of the VDR-based models have a tf-idf weight assigned to the transformed decomposed terms and the cosine similarity measure is used to calculate the similarity of images.

6.3 Results

Figure 2(a) shows the interpolated precision/recall curve and Table 2 shows the Mean Average Precision (MAP) and Precision at 10 retrieved images (P@10). The MAP of the Automatic VDR model increases by 8.8% relative to the Bag-of-Terms model, and a relative improvement up to 10.1% would possible if we had a better structure prediction model, as evidenced by Manual VDR. Furthermore, if we assume a user will only view the top results returned by the retrieval model, then P@10 increases by 8.6% when we model the structure of an image, relative to using an unstructured representation; a relative improvement of up to 9.4% would be possible if we had a better image parser.

To determine whether the differences are statistically significant, we perform the Wilcoxon Signed Ranks Test on the average precision and P@10 values over the 1011 queries in our cross-validation data set. The results support the main hypothesis of this paper: structured image representations allow us to find images depicting actions more accurately than the standard bag-of-terms representation. We find significant differences in average precision and P@10 between the Bag-of-Terms baseline and both Automatic VDR ($p < 0.01$) and Manual VDR ($p < 0.01$). This suggests that structure is very useful in the query-by-example scenario. We find a significant difference in average precision between Automatic VDR and Manual VDR ($p < 0.01$), but no difference in P@10 between Automatic VDR and Manual VDR ($p = 0.442$).

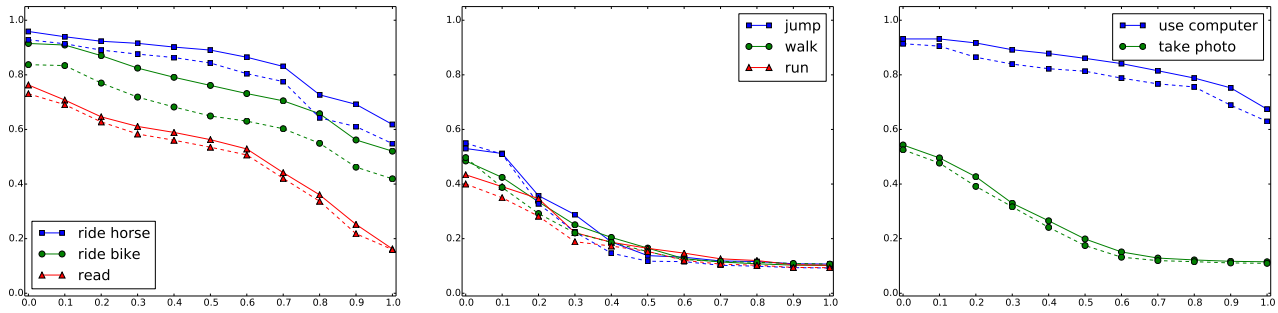
6.4 Retrieval Performance by Type of Action and Verb

We now analyse whether image structure is useful when the action does not require a direct object. The analysis presented here compares the Bag-of-Terms model against the Automatic VDR model because there was no significant difference in P@10 between the Automatic and Manual VDR models. Table 3 shows the MAP and Precision@10 per type of action. Figure 3 shows the precision/recall curves for (a) transitive verbs, (b) intransitive verbs, and (c) light verbs.

In Figure 3(a), it can be seen that the actions that can be classified as transitive verbs benefit from exploiting the structure encoded in the Visual Dependency Representation. The only exception is for the action *to read*, which frequently behaves as an intransitive verb: *the man reads on a train*. The consistent improvement in both the entirety of the ranked list and at the top of the ranked list can be seen in the MAP and P@10 results in Table 3.

Figure 3(b) shows that there is a small increase in retrieval performance for intransitive verbs compared to the transitive verbs. We conjecture this is because there are fewer objects to annotate in an image when the verb does not require a direct object. The summary results for the intransitive verbs in Table 3 confirm the small but insignificant increase in MAP and P@10.

Finally, the light verbs, shown in Figure 3(c), exhibit variable behaviour in retrieval performance. One reason for this could be that if the light verb encodes information about the object, as in *using a computer*, then the computer can be annotated in the image, and thus it acts as a transitive verb. Conversely, when



(a) (b) (c)

Figure 3: Precision/recall curves grouped by the type of verb. The solid lines represent the Automatic VDR model; the dashed lines represent the Bag-of-Terms model; y-axis is Precision, and the x-axis is Recall. (a) Images depicting transitive verbs benefit the most from the Visual Dependency Representation and are easiest to retrieve. (b) Intransitive verbs are difficult to retrieve and there is is a negligible improvement in performance when using Visual Dependency Representation. (c) Light verbs benefit from the Visual Dependency Representation depending on the type of the object involved in the action.

	MAP		P@10	
	VDR	Bag	VDR	Bag
Ride bike	0.721⋆	0.601	0.596⋆	0.513
Ride horse	0.833⋆	0.768	0.787⋆	0.726
Talk on phone	0.762⋆	0.679	0.666⋆	0.582
Play instrument	0.774⋆	0.705	0.634⋆	0.586
Read	0.483	0.454	0.498	0.475

Run	0.193	0.165	0.151	0.132
Jump	0.211	0.189	0.142	0.136
Use computer	0.814⋆	0.761	0.694⋆	0.648
Take photo	0.241	0.223	0.212	0.198

Table 3: Mean Average Precision and Precision@10 for each action in the data set, grouped into transitive (top), intransitive (middle), and light (bottom) verbs. VDR is the Automatic VDR model and Bag is the Bag-of-Terms model. It can be seen that the Automatic VDR retrieval model is consistently better than the Bag-of-Terms model on both MAP and Precision@10. ⋆: the Automatic VDR model is significantly different than Bag-of-Terms at $p < 0.01$.

the light verb conveys information about the outcome of the event, as in the action *take a photograph*, the outcome is rarely possible to annotate in an image, and so no improvements can be gained from structured image representations.

6.5 Discussion

In our experiments we observed that all models can achieve high precision at very low levels of recall. We found that this happens for testing images that are almost identical to the query image. For such images, objects that are unrelated to the target action form an effective context, which allows this image to be placed at the top of the ranking. However, near-identical images are relatively rare, and performance degrades for higher levels of recall.

It is surprising that image retrieval using automatically predicted VDR model is statistically indistinguishable from the manually crafted VDR model, given the relatively low accuracy of our VDR prediction model: 61.3% by the labelled dependency attachment accuracy measure. One possible explanation could be that not all parts of the VDR structure are useful for retrieval purposes, and our VDR prediction model does well on the useful ones. This observation also suggests that we are unlikely to achieve better retrieval performance by continuing to improve the accuracy of VDR prediction. We believe a more promising direction is refining the current formulation of the VDR, and exploring more sophisticated ways to measure the similarity of two structured representations.

7 Conclusion

In this paper we argued that a limiting factor of retrieving images depicting actions is the unstructured bag-of-terms representation typically used for images. In a bag-of-terms representation, images that share similar sets of regions are deemed to be related even when the depicted actions are different. We proposed that representing an image using the Visual Dependency Representation (VDR) can prevent this type of misclassification in image retrieval. The VDR of an image captures the region–region relationships that explain what is happening in an image, and it can be automatically predicted from a region-annotated image.

In a query-by-example image retrieval task, we found that representing images as automatically predicted VDRs resulted in statistically significant 8.8% relative improvement in MAP and 8.6% relative improvement in Precision@10 compared to a Bag-of-Terms model. There was a significant difference in MAP when using manually or automatically predicted image structures, but no difference in the Precision@10, suggesting that the proposed automatic prediction model is accurate enough for retrieval purposes. Future work will focus on using automatically generated visual input, such as the output of the image tagger (Guillaumin and Mensink, 2009), or an automatic object detector (Felzenszwalb et al., 2010), which will make it possible to tackle image ranking tasks (Hodosh et al., 2013). It would also be interesting to explore alternative structure prediction methods, such as predicting the relationships using a conditional random field (Zitnick et al., 2013), or by leveraging distributional lexical semantics (Le et al., 2013b).

Abstract

A significant portion of search engine queries mention business entities such as restaurants, cinemas, banks, and other places of interest. These queries are commonly known as "local search" queries, because they represent an information need about a place, often a place local to the user. A portion of these queries is not well served by the search engine because there is a mismatch between the query terms, and the terms representing the local business entity in the index. Business entities are frequently represented by their name, the category of entity (whether it is a restaurant, an airport, a grocery store, etc.) and other meta-data such as opening hours and price ranges. In this paper, we propose a method for representing business entities with a term distribution generated from web data and from social media that more closely aligns with user search query terms. We evaluate our system with the local search task of ranking businesses given a query, in both the U.S. and in Brazil. We show that augmenting entities with salient terms from social media and the Web improves precision at rank one for the U.S. by 18%, and for Brazil by 9% over a competitive baseline. For precision at rank three, the improvement for the U.S. is 19%, and for Brazil 15%.

1 Introduction

Search engine queries, particularly queries issued from mobile devices, often mention business entities such as restaurants, cinemas, banks, and other places of interest. These "local search" queries represent an information need about a place. Often there is a mismatch between the query terms, and the terms representing the local business entity in the index, making it difficult for the search engine to find results that satisfy the user. Local data consists largely of listings of businesses, annotated with metadata. This metadata includes the name of the location, category information (is the business a clothing retailer, or a Thai restaurant, for example), address and phone number, opening hours, and indicators such as price range, popularity, star ratings, etc. Figure 1 shows an example of the type of information available to local search systems.

Some local search queries are known item searches, where the user knows the name of a business and they seek other information about the place, such as the opening hours. Other local search queries are category searches where the user does not know the name of a specific business but is using the Internet in much the same way they might have used the Yellow Pages in pre-Internet days. An example of a category search is "Thai restaurants in Denver". There are also descriptive local queries such as "pizza delivery" or "romantic brunch in Seattle" where the user does not mention a category or a business name directly, but for which there is a closed class of businesses that will satisfy the user's need.

Descriptive queries such as "roasted chiles in Santa Fe" or "kid-friendly Caribbean resorts" pose a significant challenge to local search systems, as the information in the local index does not typically include terms that match the user's query. That is, the system may know businesses in Santa Fe, but not whether they sell roasted chiles.

Proceedings of COLING 2014, the 25th International Conference on Computational Linguistics: Technical Papers, pages 121–129, Dublin, Ireland, August 23-29 2014.

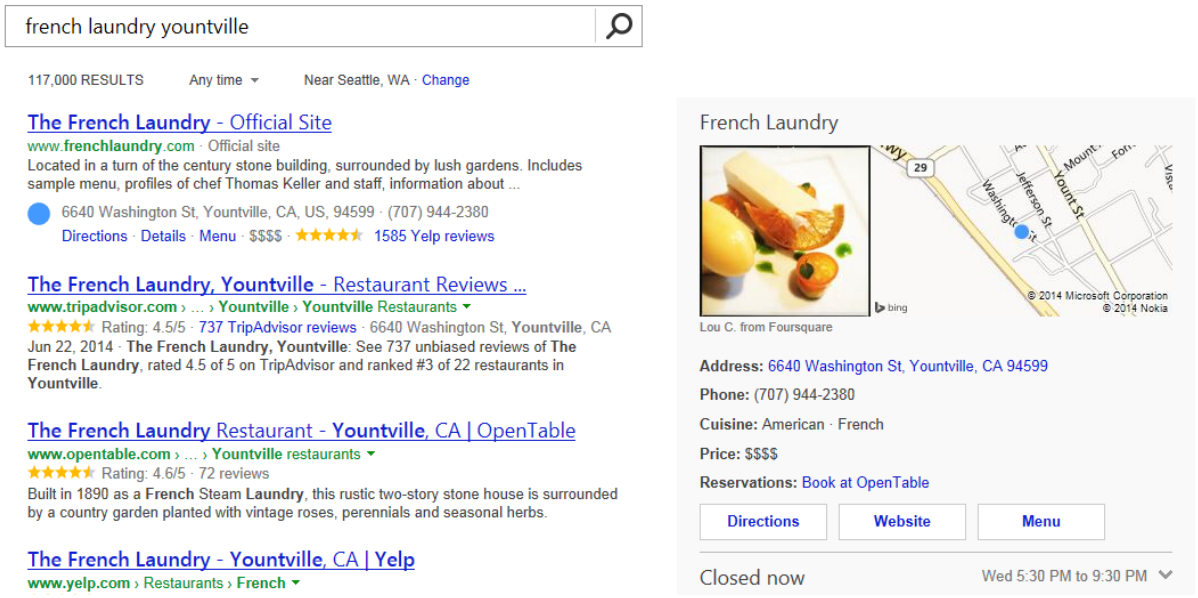

Figure 1: Example of the type of meta-data associated with a business entity, in this case a restaurant.

However, collectively people themselves know this type of information, and they frequently mention it in social media. The discussion of a local business in social media, such as Twitter[1], Flickr[2], Facebook[3] and Foursquare[4] may take the form of a simple check-in ("Drinking a Smog Rocket at @byronhamburgers") or a Facebook status caption to a photo ("Sea stars at the Seattle Aquarium"), or a Tweet ("the quad & the blonde both were good! The choc flavored one wasn't so much to my tastes..."), among others.

A growing number of users of social media attach geographic coordinates to their status updates, allowing the text of the updates to be associated to a location. Further, businesses use social networks as a publicity platform to widen their customer base. Today, Twitter has more than 500 million users.[5]

In this paper we augment business entities with salient terms describing the business. We extract the terms from Twitter, and from the Web. To determine which terms are salient, we compute the co-occurrence of terms with mentions of the business name (and name variants), for tweets issued within one kilometer of the business. Because some users are especially prolific on social media, and may dominate the tweets issued in that location, we estimate the term co-occurrence statistics with the user frequency of a term: the number of people using that term in a given location. We also extract salient terms from the Web pages of the business entity, but in this case the user frequency is not meaningful, so term co-occurrence is calculated with the term frequency.

We evaluate the term distributions describing a place in the context of local search for the U.S. and Brazil. We construct a corpus of search engine queries with local intent, and evaluate the retrieval of businesses in response to the queries. We compare several different strategies for augmenting the representation of the business to a baseline system described in Colombo et al. (2013). Augmenting with tweets improves precision at rank one for U.S. local search by 18%, and for Brazil by 9%. For precision at rank three, the improvement for the U.S. is 19%, and for Brazil 15%.

The rest of the paper is organized as follows: Section 2 surveys the related work. Section 3 details how salient terms are extracted from tweets and the Web. Section 4 illustrates the experimental setting and the evaluation of the impact of salient terms on retrieval. Section 5 presents a discussion of the results and Section 6 concludes the paper with remarks for future work.

2 Related Work

Modeling business entities from multiple sources like the Web and social media remains an open problem. Most of the work in this domain focuses on modeling locations and regions more generally (O'Hare and Murdock, 2013; Laere et al., 2012; Bennett et al., 2011), or on extracting mentions of business entities from text using NLP techniques (Rae et al., 2012). O'Hare and Murdock (2013) propose a statistical language modeling approach to characterize locations in text, based on user frequency. They utilize the geo-tagged public photos in Flickr. The primary difference between their work and ours is that they estimate the user frequency distribution, whereas we employ the user frequency in calculating the term co-occurrence. Also, the locations described in O'Hare and Murdock represent locations of one kilometer distance. They do not attempt to characterize specific points of interest or businesses.

There has been significant effort to leverage image content to characterize locations, due to the availability of geotagged Flickr photos. Much of the work uses Flickr photos and tag sets, and focuses on identifying the locations in photos. This is related, although not directly applicable, to work with Twitter. Ahern et al. (2007) identify geographically related tags by finding dense areas using geodesic distances between images. They rank the tags in these areas with $tf.idf$. In their subsequent work Kennedy et al. (2007) leverage tags that represent local events. Naaman et al. (2003) and Moxley et al. (2008) propose approaches for recommending tags to the user given a known location for an image. Some research efforts leverage image content to characterize locations. Crandall et al. (2009) employs image content and textual metadata to predict the location of a photograph at the city level and at the individual landmark level. Hays and Efros (2008) use visual features to predict geographic locations by nearest-neighbor classification.

Colombo et al. (2013) provide the baseline system for this paper, and it is described in more detail in Section 4.1. They use online reviews, comments and user tips about points of interest in location-based services like Yelp, Google+, and Qype to build a tag-based representation of a point of interest. They rank the tags by their $tf.idf$ score from a collection of location-based service related documents.

In terms of using geo-referenced information to represent locations, Rodrigues (2010) proposes to extract points of interest automatically from the Web, for example from Yahoo, Manta and Yellow Pages. He also infers points of interest based on geo-referenced content such as geo-tagged photos, blog posts and news feeds. They cluster content from multiple sources while building a language model for each cluster. Tags in each cluster are scored by $tf.idf$. This work is similar in spirit to the work proposed in this paper, although our work focuses more on obtaining the most unique and frequent tags associated with points of interest in tweets.

Hegde et al. (2013) assign tags to points of interest based on user interest profiles in online social networks and check-in logs of users at these places. They use probabilistic modeling to derive the point of interest tags followed by hierarchical clustering of most probable tags to filter out semantically irrelevant tags. Biancalana et al. (2013) use point of interest-related location-based service content to extract key phrases that could serve as tags characterizing each point of interest. The extracted phrases are weighted by user authority.

In terms of modeling locations from short microblog messages like tweets. Paradesi (2011) proposes TwitterTagger, a system that geo-tags tweets and shows them to users based on their current physical location. The tweets are geo-tagged by identifying the locations referenced in a tweet by part of speech tagging and a database of locations. Eisenstein et al. (2010) and Kinsella et al. (2011) present methods to identify the location of a user based on his or her tweets. Li et al. (2011) rank a set of candidate points of interest using language and temporal models. Given a query tweet, they build a unigram language model for each candidate point of interest and for the query tweet. Points of interest are then ranked by their KL-divergences with the tweet language model. Unlike our work, both approaches identify a location in tweets rather than modeling a certain location by the way it is mentioned in tweets.

3 Describing Businesses with Twitter and the Web

Salient terms are terms that uniquely characterize a place. As an overview, we extract terms from two sources namely geo-tagged tweets and business-related webpages. We extract terms from geo-tagged

tweets posted from locations within one kilometer of the business. We then identify the tweets about a given business from among the nearby tweets, by looking for mentions of the business name (along with naming variants). We compute the term co-occurrence between the business name, and the terms that occur in tweets mentioning the business.

We also extract terms from webpages related to the business entity. We issue a query with the business name to the Bing Search API.[6] We compute the term co-occurrence between the business name, and the terms that occur in these top three web pages resulting from Bing search.

There is no universal standard for representing locations. Some gazetteers are available for developers that represent places according to a hierarchy (such as Geonames[7] and Placemaker[8]). There is also proprietary data gathered by companies such as Nokia, YellowPages and Yelp, which provide some information about places like geo-location, address, and phone number. There are also open source data like Freebase and DBpedia. Both proprietary and open source data use structured representations for places.

There are three challenges with these representations. First, they do not provide a rich description of the place, as they are primarily designed to help users locate the place, via the name, address and phone number, or category ("restaurant" or "cinema," for example). However, the categories may be broad and in a language different from the language spoken by the user. Second, the coverage of points of interest and businesses focuses mostly on well-known places. Businesses are not usually well-represented because they are often relatively ephemeral. Finally, the data may be stale. For example, a restaurant that has closed, or moves location, should be flagged, and it may take time for the gazetteer to be updated. Social media provides fresh information about businesses, especially as more businesses promote themselves via these channels. Modeling businesses with tweets could complement the available data with fresh descriptions.

3.1 Text Pre-processing

We acquire geo-tagged tweets related to business entities in the United States and Brazil from the Twitter firehose, from January 1, 2013 to May 31, 2013. We chose these countries because of their high usage of Twitter, and to show that the approach is language agnostic. The tweets are primarily in English (in the U.S.) and in Portuguese (in Brazil).

We pre-process the tweets by removing stop words, using the Natural Language Toolkit (NLTK) library[9] and non-alphabetic characters. For our baseline implementation following Colombo (2013), we remove the non-English words using the English NLTK wordnet corpus. For removing non-Portuguese words in the baseline, we use the Enchant specll checking library.[10] In our proposed approach, we don't remove non-English and non-Portuguese words, but we rather remove twitter terms that did not appear in the Bing query logs in December 2013. Further, we remove tweets automatically generated by check-in services such as Foursquare by detecting the patterns "I'm at" and "mayor". We remove shortened URLs in the tweet text by detecting the pattern "http://t.co." URLs are removed as they do not carry salient terms. All text was lower-cased. All tweets are indexed in Solr,[11] an open-source search engine which allows for field search. The index carries the tweet text, geographic coordinates, time stamp, language, country, retweet count, source, URL and user information.

3.2 Computing Salient Terms

The business entities were submitted to the Solr index as queries, to retrieve the tweets related to the entity itself. We apply two sequential filters on the indexed tweets to obtain the relevant tweets. The first filter limits the search to those tweets whose geographic coordinates are within one kilometer of the business entity. This covers a wide range around the POI due to the small volume of geo-tagged tweets

[6] http://datamarket.azure.com/dataset/bing/search visited March 2014

[10] http://pythonhosted.org/pyenchant/ visited March 2014
[11] http://lucene.apache.org/solr/ visited March 2014

in general. Enlarging the range to one kilometer retains a reasonable volume although it does introduce more irrelevant tweets. The second filter eliminates irrelevant tweets by searching with the canonical name of the business along with naming variants. The indexed tweets are searched by name, 70% of the name, and the name fully concatenated with no spaces separating the multiple words, and with spaces replaced with an underscore. The resulting set of tweets are those that are relevant to the business entity since they have been posted within its vicinity and they mention the entity directly.

To extract the salient terms from Twitter, we compute the term co-occurrence of the entity name with the set of terms co-occurring in the associated tweets. Term co-occurrence is traditionally computed as the number of times term t and term w appear in the same tweet C, divided by the number of times term t appears in any tweet in the same one-kilometer vicinity, plus the number of times term w appears in any tweet in the same one-kilometer vicinity:

$$score(t, w) = \frac{count_C(t, w)}{count_C(t) + count_C(w)}. \quad (1)$$

Some users of twitter are extremely prolific, and may generate a lot of data in a small set of places. Term frequency may produce an estimate of the term distribution biased toward a particular user or set of users. To prevent a single prolific user from dominating the representation of a place, we estimate the term co-occurrence with the user frequency. That is, the term counts are the number of people who used a term in a place, rather than the number of times a term was applied. This has been shown to be a more reliable estimate of term distributions in other work using social media to model places (O'Hare and Murdock, 2013). Note that the baseline implementation is based on the term frequency, and uses tf.idf rather than term co-occurrence.

We also enrich the business entities with terms from the web pages. We issue a query to Bing Search API with the business name. We then extract salient terms from the content of the top three results. We pre-process the text according to Section 3.1 to get the unigram terms. We filter out the terms that are substrings of the business name, and single character terms. The terms are weighted according to the term frequency (tf) and the terms with $tf > 0.001$ are considered salient to the business entity. This threshold has been selected empirically.

4 Experimental Setting

In our experiments we evaluated the effect of expanding the business entities with salient terms within the context of local search. We examined whether adding tags such as "conchiglie" to the entity "French Laundry" will improve the retrieval results for a query with local intent like "conchiglie Napa Valley". For this purpose, we sampled a set of 30,000 businesses from a proprietary database of business listings in the United States and Brazil. We then chose 80 entities from the two countries to formulate the test set of search queries as illustrated below.

4.1 Baseline Approach

Colombo et al. (2013) suggested a method for filtering the salient terms extracted from a set of documents relevant to a place of interest. We used their method to filter the salient terms extracted from the geo-tagged tweets selected and pre-processed as described above in Section 3.1. The terms remaining after these filtration steps are weighted using $tf.idf$, where a background corpus of all tweets relating to any business within one kilometer of the entity in question is used to calculate the idf of each term. Finally, we kept only the terms with a $tf.idf$ greater than a threshold of 0.04 as the baseline salient terms for the business.

4.2 Building the Search Corpus

Our database of businesses contains metadata about each business including the name, phone number, website, street address, city, country, geographic coordinates, and category information that are a subset of a taxonomy of categories both in English and in the language of the country of the business. We appended the extracted salient terms for each business as a field in our database. We removed twitter

terms that escaped initial filtering by removing any terms that did not appear in the Bing query logs in December 2013. We also filtered out twitter terms that are included in the category taxonomy, as these tags will not add value to the existing data, and are unlikely to improve retrieval over the naive baseline.

Some businesses are very popular, and are likely to generate more social media traffic. To make sure that the system is as general as possible, and that we don't build in an inherent bias toward popular businesses (or national chains) we construct the search corpus to represent varying popularity levels. The popularity of a business is quantified by the number of unique users tweeting about it. We stratify the selection of the businesses from our database of 30000 businesses such that the search corpus contains 15,000 businesses from the U.S. and 15,000 businesses in Brazil, which are distributed across a range of popularity scores. Finally we indexed the search corpus using Solr.

4.3 Generating Search Queries

We formulate search queries by selecting 40 businesses in each market with their attributes and salient terms. We formulated query templates from the business name, location, category and terms selected by three judges from associated tweets and Web pages. The information is detailed in Table 1. The query templates are shown in Table 2, along with an illustrative example of each one.

Attribute	**Description**
Name	business name and variants
Location	city and country
Categories	categories provided by the database
Terms	term selected by judges from Twitter and Web pages

Table 1: Information included in the baseline queries

Query Template	**Example**
Name	"French Laundry"
Name + Location	"French Laundry in Yountville" or "French Laundry in California"
Name + Category	"French Laundry Restaurant"
Name + Term	"conchiglie French Laundry"
Term + location	"conchiglie Yountville" or "conchiglie California"
Category + location	"Restaurants in Yountville" or "Restaurants in California"

Table 2: Query templates with examples

Some of the automatically generated queries (such as "happy in california" and "week in Houston") don't have a local intent because of uninformative terms (such as "good", "happy", or "week") or because of malformed substrings of names and categories. To filter out these uninformative queries we issued the query to Bing Search API and kept only the queries that generated a direct answer. An example of a direct answer is shown in Figure 1. The Bing Search API returns a direct answer when the query has been classified as having local intent. We use the Bing API in this way as a black box, because building a local intent classifier is a significant undertaking, and is beyond the scope of this paper. The resulting test set consists of 1000 local queries representing 80 business entities in Brazil and the U.S., with an equal distribution of each of the query templates in Table 2.

4.4 Evaluation

Our primary evaluation is of query expansion for the class of queries for which a business listing is a relevant result. However, representing a business entity with a term distribution estimated from social

media has other applications as well. For this reason, we would like to know the quality of the expansion terms, independent of any task. To this end, we asked three judges to pick all the relevant terms from among an unordered set of extracted terms salient to a business, for 100 businesses in each country. We divided the terms among the three judges equally and each term has been judged by only one judge. The number of tags extracted from the web pages is an order of magnitude larger than the number of tags extracted from Twitter for a given business. We consider the tag accuracy to be proportion of "good" tags accounted for by a single data source. That is, for Twitter, it is the number of "good" Twitter tags, divided by the total number of "good" tags, whereas the accuracy of the Web tags is the number of "good" tags derived from the web, divided by the total number of "good" tags. Based on this assessment, the accuracy of the Twitter tags for the U.S. data was 0.22, and the accuracy of the Web tags was 0.78. For the data from Brazil, the accuracy of the Twitter terms was 0.15, and the accuracy of terms derived from the Web was 0.85.

The effect of the expansion strategies on the retrieval of business entities. As Solr allows for field search, we can limit the fields to the entity and its metadata, or the entity metadata and the twitter tags, etc. Tables 3 and 4 show the results for various retrieval from fields representing document expansion strategies on data from the U.S. and Brazil, respectively. The results are averaged over 500 queries (from the query formulations described above) for each country. In Tables 3 and 4 we see that nearly 60% of queries return the correct result at rank one, when the entity is represented only by its metadata. The results reported in the other rows also include the entity metadata. (The baseline in Tables 3 and 4 is described in Section 4.1.) Expanding the represnetation of the point of interest with terms from the Web and from social media shows a clear benefit.

Mobile devices are becoming ubiquitous, and local search represents an important class of search on mobile devices. Because the devices are small, real estate to show results is extremely limited. For this reason, we choose to evaluate precision @ k, for $k <= 3$ for this task. To create a truth set, the top three results were evaluated by judges to determine their relevance to the query. Each result is judged by one assessor. Because precision at one is binary, we do not apply a statistical significance test. Percent change is reported for precision at rank one, with respect to the baseline (row two). The fact that the precision at rank three is lower than precision at rank one is an artifact of their being a single relevant result in most cases.

	P@1	**P@3**	**% Change in P@1**
Entity metadata	0.595	0.353	(oracle)
Baseline	0.627	0.358	NA
Entity metadata + twitter tags	0.667	0.389	+6.4%
Entity metadata + web terms	0.686	0.396	+9.4%
Entity metadata + web terms + twitter tags	0.738	0.425	+18%

Table 3: Precision @ k for local search in the U.S.

	P@1	**P@3**	**% Change in P@1**
Entity metadata	0.618	0.436	(oracle)
Baseline	0.643	0.460	NA
Entity metadata + twitter tags	0.650	0.474	+1%
Entity metadata + web terms	0.700	0.517	+8.9%
Entity metadata + web terms + twitter tags	0.708	0.533	+10%

Table 4: Precision @ k for local search in the Brazil.

5 Discussion

Since the set of queries consists of the entity name plus attributes from the index such as the location and the category information, the resulting precision from search just on the entity metadata itself shows the degree to which the bias in the data accounts for the results. That is, if you have the correct entity name, location and category, just searching for a business with matching metadata gives a precision at rank one of 0.595 (0.618 for Brazil). This is a naive baseline. The baseline results show that it is a competitive baseline because it demonstrates that there is a benefit to expand the representation of a business entity with text, beyond the naive baseline above it in the table.

The gains in precision suggest that the extracted salient terms with co-occurrence statistics and user frequency from twitter and the web pages are of better quality than the terms extracted by the baseline in Colombo et al. (2013) with term frequency only. This is attributed to the fact that co-occurrence statistics and user frequency capture the terms that people frequently use when describing a place. Further, the quality of the salient terms extracted from the web pages exceeds the quality of the twitter terms. This is to be expected if the main search results for a business entity are reasonable, and the top three results are relevant to the query. Social media is notoriously noisy, so it is not surprising that the web pages produce more reliable expansion terms. Furthermore, comparing the terms expanded from the web, to the terms expanded from Twitter, we see the relative improvement with respect to the baseline of the Web expansion terms is greater than the Twitter expansion terms. The fact that both expanding from twitter and the Web produces results better than either individually shows that the two term distributions cover different slices of the vocabulary.

We experimented with the number of tweets required to improve the representation of the point of interest. We focused on the portion of the test set with queries of the form *term + location* like "conchiglie Yountville," as those are the queries that are not answered with relevant results in the absence of the proper salient terms. We found that 10 to 30 tweets mentioning the business were sufficient to improve the retrieval results for these queries, and there was no benefit to increasing the number of tweets to 50 or 100. In the Brazil data, the results for four of the queries of the form *term + location* were degraded when sampling terms from 10 tweets compared to more. However, the results were the same for 30, 50, 100 or more tweets, suggesting that there is no benefit to increasing the number of tweets beyond 30. This suggests that a smaller number of tweets is better, in terms of extracting salient terms. One possible reason for this is that adding more tweets increases the number of noise terms, relative to the number of salient terms.

6 Conclusion and Future Work

In this paper, we present an effective representation of business entities with a term distribution generated from web data and from social media that more closely aligns with user search query terms. We evaluate our system with the local search task of ranking businesses given a query, in both the U.S. and in Brazil. Our method uses co-occurrence statistics and user frequency to extract relevant salient terms. The results demonstrate the effectiveness of this approach when compared with a competitive baseline that uses term frequency to extract salient terms. Furthermore, we show that query expansion with salient terms improves retrieval in the common task of retrieving a business listing in response to a user query.

We leave to future work applying query expansion from social media to larger collections of local search queries, and other methods for formulating query templates based on the metadata available with business listings.

Abstract

Despite the overwhelming use of statistical language models in speech recognition, machine translation, and several other domains, few high probability guarantees exist on their generalization error. In this paper, we bound the test set perplexity of two popular language models – the n-gram model and class-based n-grams – using PAC-Bayesian theorems for unsupervised learning. We extend the bound to sequence clustering, wherein classes represent longer context such as phrases. The new bound is dominated by the maximum number of sequences represented by each cluster, which is polynomial in the vocabulary size. We show that we can still encourage small sample generalization by sparsifying the cluster assignment probabilities. We incorporate our bound into an efficient HMM-based sequence clustering algorithm and validate the theory with empirical results on the resource management corpus.

1 Introduction

The ability to predict unseen events from a few training examples is the holy grail of statistical language modeling (SLM). Although the final test for any language model is its contribution to the performance of a real system, task-independent metrics such as perplexity are popular for evaluating the general quality of a model. Standard algorithms therefore attempt to minimize perplexity on some previously unobserved test set, assumed to be drawn from the same distribution as the training set. This begets the question of how the test set perplexity is related to training set perplexity – every paper on SLM has an answer, with varying levels of theoretical and empirical justification.

The problem of data sparsity and generalization can be traced back to at least as early as Good (1953), and possibly Laplace, who recognizes that the maximum likelihood (ML) estimate of event frequencies (n-grams) cannot handle unseen events. Smoothing techniques such as the add-one estimator (Lidstone, 1920) and the Good-Turing estimator (Good, 1953) assign a non-zero probability to events that have never been observed in the training set. Recently, Ohannessian and Dahleh (2012) strengthened the theory by showing that Good-Turing estimation is consistent when the data generating process is heavy-tailed. In the context of this paper, smoothing was perhaps the first attempt to bound generalization error, in that it successfully guarantees a finite test set perplexity.

It is evident that smoothing of the n-gram estimate alone is not sufficient. Techniques that incorporate lower and higher order n-grams, such as Katz (1987) smoothing, Jelinek-Mercer (1980) interpolation, and Kneser-Ney (1995) smoothing, have become standard (Rosenfeld, 2000). Chen and Goodman (1999) provide a thorough empirical comparison of smoothing methods and uncover useful relationships between the test set cross-entropy (log perplexity) and the size of the training set, model order, etc. A Bayesian interpretation further explains why some of the techniques (don't) work. Teh (2006) discusses fundamental limitations of the Dirichlet process (Mackay and Peto, 1995) and proposes the hierarchical Pitman-Yor language model as a better way of generating the heavy-tailed (power law) distributions exhibited in natural language.

Proceedings of COLING 2014, the 25th International Conference on Computational Linguistics: Technical Papers, pages 130–140, Dublin, Ireland, August 23-29 2014.

Instead of directly modeling a heavy-tailed distribution over words, class-based models address data sparsity by estimating n-grams over clusters of words. Intuitively, clustering is a transformation of the event space from the space of word n-grams, in which most events are rare, to the space of class n-grams, which is more densely measured and therefore requires fewer training examples. Brown et al. (1992) show that the clustering function that maximizes the training data likelihood must also maximize mutual information between adjacent clusters; although several useful clustering algorithms are based on this principle, no provable guarantees currently exist. Moreover, word transitions are never completely captured by the underlying class transitions, and some tradeoff between accurate estimation of frequent events (word n-grams) and generalization to unseen events (class n-grams) is desired – class-based models are therefore often interpolated with word n-grams using some of the previously described Bayesian methods (Rosenfeld, 2000).

Our survey of SLM techniques and their treatment of generalization error has been rather brief and certainly not comprehensive. We focus primarily on n-grams and related models since they have dominated SLM over the last several decades (Rosenfeld, 2000), and therefore serve as a good starting point for further analysis. The existing literature suggests that apart from empirical validation and intuition, no provable guarantees exist on the generalization error of language models. Bayesian techniques work well only to the extent the prior assumptions are valid; in this paper, we present theoretical guarantees that hold irrespective of the correctness of the prior.

Model selection approaches such as the Akaike Information Criterion (AIC) (Akaike, 1973) and its variants (Burnham and Anderson, 2002) quantify the tradeoff between complexity and goodness of fit. In the context of a language model, it can be shown that test set cross entropy is approximately the training set cross entropy plus the number of model parameters. Unfortunately, such bounds are loose and do not provide significant algorithmic insight – at best, they recommend the smallest model that works well on the training set. Chen (2009) obtained a very accurate relationship for exponential language models by estimating the test set performance with linear regression. Although empirical, his approximation leads to better models based on $l_1 + l_2^2$ regularization. Exponential models are often motivated with the minimum discrimination information (MDI) principle, which roughly states that of all distributions satisfying a particular set of features, the exponential family is the centroid (minimizes distortion relative to the farthest possible true distribution) (Rosenfeld, 1996). This does not bound the generalization error in the manner we wish to, but it is nevertheless a useful property that complements Chen's observations.

In this paper, we strive for the best of both worlds – we present PAC-Bayesian theory as a powerful tool for deriving high probability guarantees as well as efficient and well-motivated algorithms. In the next section, we state some useful PAC-Bayesian theorems. In Section 3, we present our main results. We apply the PAC-Bayesian bounds to n-grams, class-based n-grams, and also sequence clustering, where classes represent longer context such as phrases. We show that for sequence clustering, the bound is dominated by the maximum number of sequences represented by each cluster, and consequently requires many more training examples than a class-based model over words. We address this issue by sparsifying the cluster assignment probabilities using the l_α norm, $0 < \alpha < 1$, an effective proxy for the intractable l_0 norm. In Section 4, we show how our bound can be incorporated into an HMM-based clustering algorithm. In Section 5, we validate the theory presented in this paper with some empirical results on the resource management corpus.

2 PAC-Bayesian Bounds

PAC-Bayesian theory is a useful framework for combining frequentist bounds with the notion of a prior. Probably approximately correct (PAC) learning bounds the worst case generalization error of the best hypothesis selected from a hypothesis space – and therefore treats all hypotheses uniformly (Valiant, 1984). PAC-Bayesian bounds, however, place a prior over the hypothesis space while making no assumptions on the data generating distribution (McAllester, 1998). Thus, PAC-Bayesian bounds can both 1) incorporate prior information, and 2) provide frequentist guarantees on the expected performance. They have been successfully applied to classification settings such as the support vector machine (SVM) (McAllester, 2003; Langford, 2005), yielding significantly tighter bounds. Seldin and Tishby (2010) extend the frame-

work to include unsupervised learning tasks such as density estimation and clustering. Since statistical language modeling at its core is a discrete density estimation problem, we focus on the bounds developed by Seldin and Tishby (2010) and summarize key results in the following subsection.

2.1 Unsupervised Learning

Given a d-dimensional product space $\mathcal{X}^{(1)} \times ... \times \mathcal{X}^{(d)}$ and a collection of N samples, S, independent and identically distributed (i.i.d.) according to some unknown distribution $p(x_1, ..., x_d)$ over the product space, we want to estimate $p(x_1, ..., x_d)$ with some model $q(x_1, ..., x_d)$. In the case of clustering (e.g. class-based models), we make the following assumption on $q(x_1, ..., x_d)$ [Note: we make no assumptions on the true distribution $p(x_1, ..., x_d)$]:

$$q(x_1, ..., x_d) = \sum_{c_1,...,c_d} q(c_1, ..., c_d) \prod_{i=1}^{d} q(x_i|c_i) \tag{1}$$

where $c_i = h_i(x_i)$ for some clustering function $h_i : \mathcal{X}^{(i)} \mapsto \mathcal{C}^{(i)}$. We refer to them collectively as a clustering function h, $h = \{h_i\}_{i=1}^{d}$; hence $h : \mathcal{X}^{(1)} \times ... \times \mathcal{X}^{(d)} \mapsto \mathcal{C}^{(1)} \times ... \times \mathcal{C}^{(d)}$. We assume that the original space $\mathcal{X}^{(1)} \times ... \times \mathcal{X}^{(d)}$ has finite cardinality, with $n_i = |\mathcal{X}^{(i)}|$, and likewise for the clustered space $\mathcal{C}^{(1)} \times ... \times \mathcal{C}^{(d)}$, where $m_i = |\mathcal{C}^{(i)}|$ is the number of clusters. We define a hypothesis space, $\mathcal{H}$, to be the space of all possible clustering functions $h \in \mathcal{H}$.

For $h \in \mathcal{H}$, we define the distributions $p_h(c_1, ..., c_d) = \sum_{x_1,...,x_d} p(x_1, ..., x_d) \prod_{i=1}^{d} \delta(h_i(x_i) = c_i)$ and $\hat{p}_h(c_1, ..., c_d) = \sum_{x_1,...,x_d} \hat{p}(x_1, ..., x_d) \prod_{i=1}^{d} \delta(h_i(x_i) = c_i)$, where $p(x_1, ..., x_d)$ is the unknown true distribution, and $\hat{p}(x_1, ..., x_d)$ is the empirical (maximum likelihood) estimate. The delta function, $\delta(arg)$, takes a value of 1 only when arg is true, and 0 otherwise. We can extend to the original space with the model assumption in Equation (1). For example, $p_h(x_1, ..., x_d) = \sum_{c_1,...,c_d} p_h(c_1, ..., c_d) \prod_{i=1}^{d} q(x_i|c_i)$.

The key difference between PAC learning and the PAC-Bayesian framework is the following notion of a random predictor, which is a distribution $\mathcal{Q}(h)$, learnt over the hypothesis space $\mathcal{H}$. Inference works as follows: for a new sample $(x_1, ..., x_d)$, we first draw a hypothesis h from $\mathcal{H}$ at random according to the distribution $\mathcal{Q}(h)$. We then return $q(x_1, ..., x_d)$ according to the model described by Equation (1) and the clustering function h. The PAC-Bayesian framework therefore allows for a second level of averaging over $\mathcal{Q}$, and we can define the induced distributions: $p_{\mathcal{Q}}(c_1, ..., c_d) = \sum_h \mathcal{Q}(h) p_h(c_1, ..., c_d)$ and $\hat{p}_{\mathcal{Q}}(c_1, ..., c_d) = \sum_h \mathcal{Q}(h) \hat{p}_h(c_1, ..., c_d)$. Again, we can extend to the original space with $p_{\mathcal{Q}}(x_1, ..., x_d)$ and $\hat{p}_{\mathcal{Q}}(x_1, ..., x_d)$ using the model assumption in Equation (1). Note that $p_{\mathcal{Q}}(x_1, ..., x_d)$ is unknown since $p(x_1, ..., x_d)$ is unknown; but the goal is to bound some notion of generalization error, such as the KL-divergence $\mathbb{KL}(\hat{p}_{\mathcal{Q}}(x_1, ..., x_d)||p_{\mathcal{Q}}(x_1, ..., x_d))$.

The **Change of Measure Inequality (CMI)** (Seldin and Tishby, 2010) is central to almost every PAC-Bayesian bound, so we briefly state it here. For any measurable function $\phi(h)$ on $\mathcal{H}$ and for any distributions $\mathcal{Q}(h)$ and $\mathcal{P}(h)$:

$$\mathbb{E}_{\mathcal{Q}(h)}[\phi(h)] \leq \mathbb{KL}(\mathcal{Q}||\mathcal{P}) + \ln \mathbb{E}_{\mathcal{P}(h)} \left[e^{\phi(h)} \right] \tag{2}$$

where $\mathbb{KL}(\mathcal{Q}||\mathcal{P}) = \mathbb{E}_{\mathcal{Q}(h)} \left[\ln \frac{\mathcal{Q}(h)}{\mathcal{P}(h)} \right]$ is the KL-divergence between $\mathcal{Q}$ and $\mathcal{P}$. The proof is fairly straightforward and is a direct consequence of rewriting $\phi(h)$ as $\ln \left(e^{\phi(h)} \frac{\mathcal{Q}(h)}{\mathcal{P}(h)} \frac{\mathcal{P}(h)}{\mathcal{Q}(h)} \right)$.

Seldin and Tishby (2010) apply the CMI with $\phi(h) = N \cdot \mathbb{KL}(\hat{p}_h(x_1, ..., x_d)||p_h(x_1, ..., x_d))$ and simplify the KL-divergence term by recognizing that 1) $\{q(c_i|x_i)\}_{i=1}^{d}$ defines a distribution over all possible clusterings, and hence $\mathcal{Q} = \{q(c_i|x_i)\}_{i=1}^{d}$; and 2) a specific $\mathcal{P}$, which they call the prior, can be defined without making any assumptions on the true distribution $p(x_1, ..., x_d)$. Note that $\mathcal{P}$ is not a prior in the Bayesian sense: 1) it indicates preference on the structure of the hypothesis, not an assumption on the data generating distribution, although the latter could be a consequence of the former; 2) the bound holds regardless of $\mathcal{P}$; and 3) the bound holds regardless of $\mathcal{Q}$, which is not necessarily the Bayes posterior.

The following prior on $\mathcal{H}$ makes no assumptions on $p(x_1, ..., x_d)$. We present a simplified version of the prior developed by Seldin and Tishby (2010):

$$\mathcal{P}(h) \geq \frac{1}{\exp\left[\sum_{i=1}^{d} m_i \ln n_i + n_i \ln m_i\right]} \tag{3}$$

The prior is based on a combinatorial argument. In order to select a clustering function h_i for some i, we first need to pick a cardinality profile (number of elements per cluster) for the m_i clusters; there are $n_i^{m_i}$ such profiles, hence the first term in the sum. Next, given a cardinality profile, we need to bound the number of ways in which each of the n_i elements can be assigned to the clusters given their sizes; there are at most $m_i^{n_i}$ possibilities, hence the second term in the sum. The CMI with $\phi(h) = N \cdot \mathbb{KL}(\hat{p}_h(x_1, ..., x_d)||p_h(x_1, ..., x_d))$, our modified prior, and a few information theoretic results lead to the following bound.

PAC-Bayesian Clustering: For any distribution p over $\mathcal{X}^{(1)} \times ... \times \mathcal{X}^{(d)}$ and an i.i.d. sample S of size N according to p, with probability at least $1-\delta$, for all distributions of cluster functions $\mathcal{Q} = \{q(c_i|x_i)\}_{i=1}^{d}$, the following holds:

$$\mathbb{KL}(\hat{p}_{\mathcal{Q}}(x_1, ..., x_d)||p_{\mathcal{Q}}(x_1, ..., x_d)) \leq \frac{\sum_{i=1}^{d} n_i \ln m_i + K_1}{N} \tag{4}$$

where $K_1 = \sum_{i=1}^{d} m_i \ln n_i + (M-1)\ln(N+1) + \ln\frac{d+1}{\delta}$, and $M = \prod_{i=1}^{d} m_i$. Although this shows convergence, in applications such as language modeling, we are interested in directly bounding the test set perplexity or cross-entropy. Seldin and Tishby (2010) smooth $\hat{p}_{\mathcal{Q}}(x_1, ..., x_d)$ to bound $\mathbb{E}_{p(x_1,...,x_d)}[-\ln \hat{p}_{\mathcal{Q}(x_1,...,x_d)}]$ and provide the following useful result based on Equation (4).

Bound on Cross-Entropy: For any probability measure p over $\mathcal{X}^{(1)} \times ... \times \mathcal{X}^{(d)}$ and an i.i.d. sample S of size N according to p, with probability $1-\delta$ for all distributions of cluster functions $\mathcal{Q} = \{q(c_i|x_i)\}_{i=1}^{d}$:

$$\mathbb{E}_{p(x_1,...,x_d)}[-\ln \hat{p}_{\mathcal{Q}}(x_1, ..., x_d)] \leq -I(\hat{p}_{\mathcal{Q}}(c_1, ..., c_d)) + \ln(M)\sqrt{\frac{\sum_{i=1}^{d} n_i \ln m_i + K_1}{2N}} + K_2 \tag{5}$$

where $\hat{p}_{\mathcal{Q}}(x_1, ..., x_d)$ is now the *smoothed* empirical estimate induced by $\mathcal{Q}$, $I(\hat{p}_{\mathcal{Q}}(c_1, ..., c_d)) = \sum_{i=1}^{d} H(\hat{p}_{\mathcal{Q}}(c_i)) - H(\hat{p}_{\mathcal{Q}}(c_1, ..., c_d))$ is the multi-information of the clustering, M and K_1 are as defined in Equation (4), and K_2 is an additional term, $K_2 \geq I(\hat{p}_{\mathcal{Q}}(c_1, ..., c_d))$, and the bound is non-negative.

3 Language Models

Since language modeling is yet another density estimation problem in which we want to minimize the test set perplexity, the bound in Equation (5) readily applies to both word n-grams and class-based n-grams. Note that the bounds are on cross-entropy, which is log perplexity, but we use the two terms almost interchangeably. We are now interested in estimating the unknown true distribution $p(v_1, ..., v_n)$ over the space $\mathcal{V}^n$, where $\mathcal{V}$ is some vocabulary consisting of $V = |\mathcal{V}|$ words. The degenerate case, $d = 1$, $\mathcal{X}^{(1)} = \mathcal{V}^n$, is the case of word n-grams and results in a bound that is dominated by $n_1 = |\mathcal{X}^{(1)}| = V^n$. This suggests that the number of training samples, N, must be on the same order as V^n for the bound (and hence the estimate) to be meaningful.

It is also clear why class-based models are favored whenever they work. In this case, $d = n$, $\mathcal{X}^{(i)} = \mathcal{V}$ for all $1 \leq i \leq d$, and the bound in Equation (5) reduces to something linear in V (since $\forall i$, $n_i = |\mathcal{X}^{(i)}| = V$). Moreover, the clustering function is the same for all i – that is, word clusters do not depend on the position in the n-gram. Assuming K word clusters, the number of training examples, N, only needs to be on the order of $K^n + nV$, achieving effective small sample generalization especially when $K << V$. In the following subsections, we extend the bound to sequences and present a unique approach to regularize the bound.

3.1 Sequence Clustering

We have discussed two extreme cases, namely $d = 1$ and $d = n$, that correspond to word n-grams and class-based n-grams, respectively. In practice, they are often interpolated to retain the advantages of both, as shown in the following model:

$$q(v_1, ..., v_n) = \alpha q(v_1, ..., v_n) + (1 - \alpha) \sum_{c_1,...,c_n} q(c_1, ..., c_n) \prod_{i=1}^{n} q(v_i|c_i) \tag{6}$$

for some $0 < \alpha < 1$. A Bayesian interpretation of the above model is to select between the n-gram and the class-based model with probabilities α and $1 - \alpha$, respectively. In other words, for each n-gram $(v_1, ..., v_n)$, we simply flip an α-biased coin to decide on one of the two models. In this paper, we interpolate across the entire spectrum, $1 \leq d \leq n$, instead of just the extreme cases – that is, we capture clusters over not just words, but also sequences of words (phrases). Previous results by Deligne and Bimbot (1995), Ries et al. (1996), and Justo and Torres (2007) indicate that clustering over phrases is practically useful and leads to significant improvements.

Suppose our goal is to estimate the probability of a trigram, for example, "the cat sat." In the case of $d = 1$, we directly estimate the joint probability $p(the, cat, sat)$. In the standard class-based model, where $d = 3$, we estimate with the model $p(the, cat, sat) = \sum_{c_1,c_2,c_3} p(c_1, c_2, c_3)p(the|c_1)p(cat|c_2)p(sat|c_3)$. The intermediate cases, such as $d = 2$ in this example, are often neglected. The theory we subsequently develop interpolates over all four segmentations, including the missing ones: $p(the, cat, sat) = \sum_{c_1,c_2} p(c_1, c_2)p(the\ cat|c_1)p(sat|c_2)$ as well as $p(the, cat, sat) = \sum_{c_1,c_2} p(c_1, c_2)p(the|c_1)p(cat\ sat|c_2)$.

In general, an n-gram has 2^{n-1} possible segmentations, as illustrated in the previous example. Suppose $f \in \mathcal{F}$ is a particular segmentation from the space of all possible segmentations, and we explicitly define it as the following mapping:

$$f : \mathcal{V}^n \mapsto \mathcal{X}^{(1)} \times ... \times \mathcal{X}^{(d)} \tag{7}$$

where $1 \leq d \leq n$ and f is simply a segmentation that does not modify the joint distribution; that is, $p(v_1, ..., v_n) = p(x_1, ..., x_d)$. If f is fixed *a priori*, we can immediately apply the bounds derived in Equation (5) over the segmented space $\mathcal{X}^{(1)} \times ... \times \mathcal{X}^{(d)}$. This is the case where we decide on a model, such as the standard class-based model ($d = n$), and simply use it.

An extension to the case of interpolated models is straightforward. We modify the hypothesis space $\mathcal{H}$ to not only include all possible clusterings, but also all possible segmentations. The new random prediction $\mathcal{Q}$ over $\mathcal{H}$ works as follows: given an n-gram $(v_1, ..., v_n)$, draw a segmentation $f \in \mathcal{F}$ according to the distribution $\pi = (\pi_1, ..., \pi_{2^{n-1}})$, where the segmentations are indexed by $j = 1, ..., 2^{n-1}$ (the ordering does not matter), and π_j is the probability of drawing segmentation j; pick a clustering as in the random classifier described in Equation (5) for the new segmented space; and estimate $q(v_1, ..., v_n)$ according to the model described by the previous steps. The bound, in terms of π, is given below.

PAC-Bayes Sequence Clustering: For any probability measure p over $\mathcal{V}^n$, and an i.i.d. sample S of size N drawn according to p, with probability $1 - \delta$ for all distributions of segmentations π and for all distributions of cluster functions $\mathcal{Q}$:

$$\mathbb{E}_{p(v_1,...,v_n)}[-\ln \hat{p}_{\mathcal{Q}}(v_1, ..., v_n)] \leq \sum_{j=1}^{2^{n-1}} \left(K_3(j) + \ln(M(j)) \sqrt{\frac{\sum_{i=1}^{d(j)} V^{a_i(j)} \ln m_i(j) + K_1(j)}{2N}} \right) \pi_j$$
$$K_3(j) = -I(\hat{p}_{\mathcal{Q}}(c_1, ..., c_{d(j)})) + K_2(j) \tag{8}$$

where $\forall j\ \forall i,\ 1 \leq a_i(j) \leq n$, and $\forall j,\ \sum_{i=1}^{d(j)} a_i(j) = n$, and $V^{a_i(j)}$ simply replaces n_i in Equation (5) for a given j. The term $K_2(j)$ is from Equation (5). Note that all terms such as $m_i(j)$, the number of clusters corresponding to the space, their product $M(j)$, and additional terms $K_1(j)$, $K_2(j)$ now depend on the segmentation j since $X^{(i)}$ and $d(j)$ depend on j.

We can favor certain segmentations (e.g. those that require few training examples), but note that the bound above is true regardless of the distribution over possible segmentations, π. Also, the bound is dominated by the exponent $a_i(j)$ and the constraint $\sum_{i=1}^{d(j)} a_i(j) = n$. Hence, the bound is polynomial in V for all segmentations except the standard class-based setting where $d(j) = n$, in which case $\forall i,\ a_i(j) = 1$. For example, if $d(j) = n - 1$ for some segmentation j, there exists some i such that $a_i(j) = 2$ and hence represents clusters of bigrams. If $d(j) = n - 2$, there exists some segmentation j, and a space i such that $a_i(j) = 3$, and so on until $d(j) = 1$, and this is the case of word n-grams where $a_1(j) = n$.

3.2 Bound Minimization

Imposing the restriction $\forall j\ \forall i,\ a_i(j) = 1$ is simple, and although it can guarantee the small-sample benefits of a standard class-based model, it is not a useful strategy for incorporating the constraint. Since $a_i(j)$ corresponds to the original space $\mathcal{X}^{(i)}$ for a given j, restricting $a_i(j)$ would restrict $\mathcal{X}^{(i)}$ to an *a priori*, fixed set of V elements. To learn the best possible set of V elements, however, we need to minimize the *effective* size of $\mathcal{X}^{(i)}$. For example, suppose we are estimating trigrams over $\mathcal{V}^3$ using the following segmentation: $\mathcal{X}^{(1)} = \mathcal{V}$ and $\mathcal{X}^{(2)} = \mathcal{V}^2$ – i.e. a bigram over clusters of words and clusters of word bigrams. The unconstrained bound is dominated by $\mathcal{X}^{(2)}$. We can restrict the *effective* size of $\mathcal{X}^{(2)}$ by assigning zero probability to the vast majority of its elements, by constraining the hypothesis space to consider only cluster assignment functions $q(x_i|c_i)$ in which $n_2 << V^2$ of the elements have nonzero probability. Thus, every word sequence in $\mathcal{V}^d$ can be generated by the $d = n$ segmentation, but every other segmentation is constrained to generate at most a subset of $\mathcal{V}^d$ with nonzero probability.

We achieve this by imposing the restriction on the random predictor $\mathcal{Q}$. By Bayes rule, $q(c_i|x_i) = \frac{q(x_i|c_i)q(c_i)}{q(x_i)}$ and we can alternatively define $\mathcal{Q}$ as $\mathcal{Q} = \{q(c_i), q(x_i), q(x_i|c_i)\}_{i=1}^{d}$. Our goal is to learn a $\mathcal{Q}$ that minimizes the RHS of Equation (5), which includes maximizing the multi-information term, as well as constraining n_i. As expected, $q(x_i)$ controls the absolute size of $\mathcal{X}^{(i)}$ and $q(x_i|c_i)$ controls the effective size based on the clustering. The dominant term in all of our bounds is n_i (or a_i, with $n_i = V^{a_i}$), which results from the second term in the prior defined in Equation (3), since it bounds the number of ways in which the n_i items can be assigned to the m_i clusters. Alternatively, we can represent this quantity with an upper bound, $\left(\sum_{c_i} \|q(x_i|c_i)\|_0\right) \ln m_i$. We can write $q(x_i) = \sum_{c_i} q(x_i|c_i)q(c_i)$, and $n_i = \|q(x_i)\|_0 = \|\sum_{c_i} q(x_i|c_i)q(c_i)\|_0$; by the triangle inequality and scale invariance of the l_0 norm, this is less than or equal to $\sum_{c_i} \|q(x_i|c_i)\|_0$. We therefore limit the upper bound, $\sum_{c_i} \|q(x_i|c_i)\|_0$, by sparsifying $q(x_i|c_i)$ for every cluster c_i.

The Optimization Problem: Given some segmentation, we want to find a random predictor $\mathcal{Q}$ – a class-based model over the fixed segmentation – such that the bound in Equation (5) is minimized, which is given by the following optimization problem:

$$\begin{aligned} \underset{\mathcal{Q}}{\text{maximize}} \quad & I(\hat{p}_{\mathcal{Q}}(c_1, ..., c_d)) \\ \text{subject to} \quad & \|q(x_i|c_i)\|_0 \leq V,\ \forall\, c_i \in \mathcal{C}^{(i)}, i = 1, \ldots, d \end{aligned} \tag{9}$$

Since such optimization problems are known to be NP-complete, we use a computationally tractable proxy. The standard practice is to use the l_1 norm instead of the l_0 norm; although non-convex, we resort to the l_α norm, $0 < \alpha < 1$, since $q(x_i|c_i)$ is a probability vector with a fixed l_1 norm. We therefore solve the following problem:

$$\begin{aligned} \underset{\mathcal{Q}}{\text{maximize}} \quad & I(\hat{p}_{\mathcal{Q}}(c_1, ..., c_d)) \\ \text{subject to} \quad & \|q(x_i|c_i)\|_\alpha \leq V,\ \forall\, c_i \in \mathcal{C}^{(i)}, i = 1, \ldots, d \end{aligned} \tag{10}$$

We have shown that one way to regularize the bound for a non-trivial sequence clustering problem, regardless of whether the segmentation is fixed or if we are interpolating across all segmentations, is to sparsify the cluster assignment probabilities for every cluster. There are many ways to sparsify a probability vector (Pilanci et al., 2012; Kyrillidis et al., 2013), and we select the l_α norm, $0 < \alpha <$

1, for its simplicity and success in other applications (Chartrand and Staneva, 2008). Our approach guarantees manageable bounds on the test set cross-entropy for a general class of SLMs, without making any assumptions on the true distribution $p(v_1, ..., v_n)$.

The Bayesian Connection A Bayesian interpretation of our regularization provides additional insight into other successful models, such as the hierarchical Pitman-Yor language model (HPYLM). In our approach, we impose the restriction $\|q(x_i|c_i)\|_\alpha \leq V$, $0 < \alpha < 1$, for every cluster c_i. It can be shown that this is equivalent to a sub-exponential prior on $q(x_i|c_i)$ (Hastie et al., 2009). Since $q(x_i) = \sum_{c_i} q(x_i|c_i)q(c_i)$ and we make the assumption that $q(x_i|c_i)$ is sub-exponential for every c_i, we are consequently assuming that $q(x_i)$ is also sub-exponential. Although the PAC-Bayesian bounds hold regardless of the true distribution, our regularization technique implicitly assumes that it is heavy-tailed.

The key to HPYLM's success within the Bayesian setting is a better prior that matches the heavy-tailed distribution of natural language (Teh, 2006) – the regularization approach developed in this paper reassuringly corresponds to the assumption that the true distribution is heavy-tailed (sub-exponential). On the other hand, it may be possible to derive provable guarantees for HPYLM within the context of our clustering model. The main difference between HPYLM and the less successful Dirichlet process (DP) is the Chinese restaurant process, which assigns new tables (clusters) to customers (samples) much more aggressively in the former model than in the latter (Teh, 2006). HPYLM therefore has far fewer customers (samples) per table (cluster) than DP, resulting in significantly sparser $q(x_i|c_i)$.

4 An Efficient HMM Algorithm

The hidden Markov model (HMM) is a popular tool for modeling sequences and has been used in several speech and language clustering tasks (Rabiner, 1989; Smyth, 1997; Li and Biswas, 1999). Over its rich history, several techniques, including regularization and sparsification of the HMM parameters, have been developed (Bicego et al., 2007; Bharadwaj et al., 2013). The goal of this section is to show how our bound easily fits into a well-established model such as the HMM.

We can rewrite the standard class-based model by making a Markov assumption on $q(c_1, ..., c_n)$:

$$q(x_1, ..., x_d, c_1, ..., c_d) = \prod_{i=1}^{d} q(x_i|c_i)q(c_i|c_{i-1}) \tag{11}$$

where $\{x_i\}_{i=1}^d$ is some segmentation of $(v_1, ..., v_n) \in \mathcal{V}^n$. The HMM literature refers to c_i as the hidden state, $q(x_i|c_i)$ as the observation probability, and $q(c_i|c_{i-1})$ as the state transition probability (Rabiner, 1989). If we consider each state of the HMM to be a cluster, then as before, $q(c_i|x_i) = q(x_i|c_i)\frac{q(c_i)}{q(x_i)}$ is a distribution over all possible clustering functions. To solve the optimization problem described in Equation (10), we need to maximize the multi-information $I(q(c_1, ..., c_n))$ while satisfying the constraint $\|q(x_i|c_i)\|_\alpha \leq V$. We can rewrite the constrained optimization problem as an unconstrained problem using a Lagrangian, and solve for $q(x_i|c_i)$ with an l_α regularized version of the expectation maximization (EM) algorithm, similar to Bharadwaj et al. (2013).

To maximize the multi-information term $I(q(c_1, ..., c_d))$ in Equation (10), we sparsify the state transition probabilities $q(c_i|c_{i-1})$. This provably works when we use l_α regularization, $0 < \alpha < 1$ for sparsifying $q(c_i|c_{i-1})$. The Renyi α-entropy of a random variable with some probability distribution q is defined to be $H_\alpha(q) = \frac{\alpha}{1-\alpha} \log \|q\|_\alpha$ and there are two useful results we use (Principe, 2010): 1) $\lim_{\alpha \to 1} H_\alpha(q) = H(q)$, where $H(q)$ is the Shannon entropy; and 2) $H_\alpha(q)$ is non-increasing in α. Thus, for $\alpha < 1$, $H_\alpha(q)$ is an upper bound on the Shannon entropy. Since l_α regularization minimizes the Renyi α-entropy, which for $0 < \alpha < 1$ is an upper bound on the Shannon entropy, it effectively maximizes the mutual information between c_i and c_{i-1}, given that $I(\hat{q}_\mathcal{Q}(c_i, c_{i-1})) = H(\hat{q}_\mathcal{Q}(c_i)) - H(\hat{q}_\mathcal{Q}(c_i|c_{i-1}))$.

Thus, we have shown that at least in the context of clustering, sparsifying both the observation probabilities and the state transition probabilities of an HMM using the l_α prior directly minimizes generalization error.

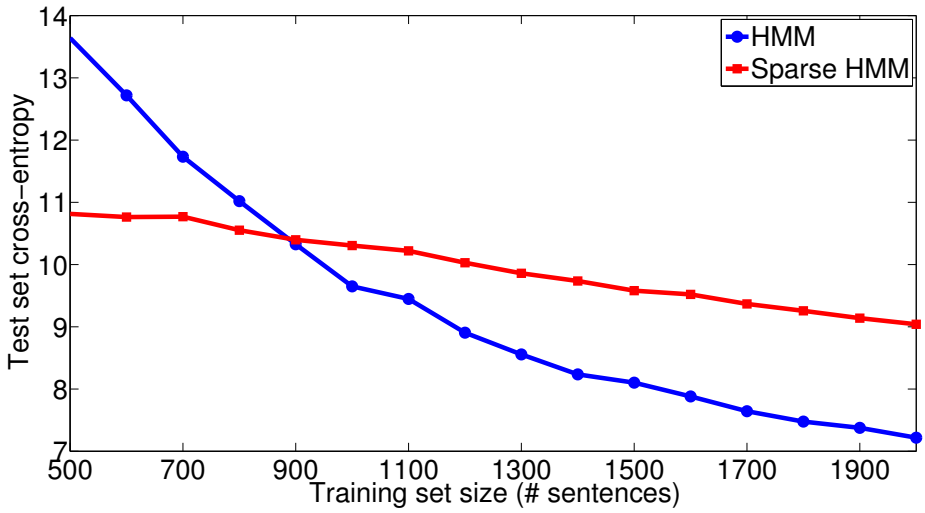

Figure 1: Test set cross-entropy of HMM vs l_α-regularized (sparse) HMM as a function of the number of training sentences

5 Experiments

We test our approach on a subset of the resource management (RM) corpus (Price et al., 1993), which consists of naval commands that span approximately $V = 1000$ words. First, we show that l_α regularization works. Figure 1 shows the estimated test set cross-entropy of an unregularized HMM and of an l_α-regularized HMM as a function of the number of training sentences. We vary the training set size from 10 to 2000 sentences and test the models on 800 sentences; Figure 1 reports the average cross-entropy on brackets of training sizes – 10-100, 110-200, and so on. The l_α-regularized HMM requires additional tunable parameters such as the value of α. To simplify the search on a separate 300 sentence development set, we make a (rather restrictive) assumption that α for both the transition and observation probabilities is the same, and that α is independent of the size of the training set. Our solutions are therefore not optimal, but adequate to demonstrate our claims. To ensure that the cross-entropy is bounded, we smooth all estimates with add-one smoothing. For small training datasets, the unregularized HMM learns models that assign near-zero likelihood to some of the test sentences; hence, we only present results for training set sizes greater than 500 sentences.

Like many other model selection results, Figure 1 suggests that model sparsity is essential when training datasets are small. In this example, about 900 sentences are required for the unregularized HMM to outperform the sparse HMM. In the context of the theory developed in earlier sections, it was shown that test set cross-entropy is proportional to $\frac{n_i}{N}$, where N is the number of training examples. In practical settings, N is fixed; hence, the only strategy for minimizing cross-entropy is to minimize n_i. Figure 1 confirms that l_α regularization successfully sparsifies $q(x_i|c_i)$, the observation probabilities of the HMM, thereby minimizing n_i.

We also compare how the test set cross-entropy improves as a function of the training set size for four different models: 1) a baseline bigram model estimated over words; 2) a baseline class-based model using Brown's algorithm (Brown et al., 1992) with $K = 20$ clusters, learnt over the entire dataset so that it is also representative of knowledge-based approaches in which the true clusters are known *a priori*; 3) l_α-regularized HMM with 20 ergodic states; and 4) a special case of 3) in which the state transitions are constrained to artificially form $m_1 = 10$ word clusters (10 states) and $m_2 = 5$ clusters that represent word bigrams (10 states, where the 5 clusters are modeled with 2 left-to-right states each); therefore, the model represents an interpolation between the standard class-based model and word bigrams, but is of the exact same complexity as 2) and 3).

Figure 2 shows the estimated test set cross-entropy for each of the four models. The values of α used in our experiments are $\alpha = 0.7$ for the words only case and $\alpha = 0.9$ for sequences. It is clear

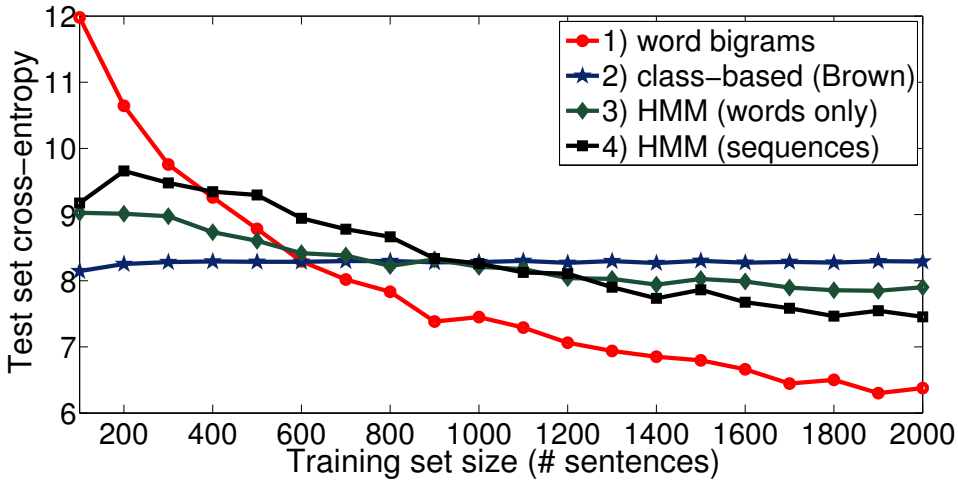

Figure 2: Test set cross-entropy as a function of the number of training sentences for the four settings

from Figure 2 that l_α regularization helps even in the case of a standard class-based model, the bound for which is already linear in V. With fewer than 100 sentences, l_α regularization can both learn the clusters and estimate their transitions reasonably well, and surpasses Brown for training set sizes of $N \geq 800$ sentences. Brown's algorithm in 2) finds clusters such that pairwise mutual information terms are maximized; in 3), we not only maximize the mutual information, but we also reduce the effective V by ensuring that each cluster (or state) specializes and represents as few words as possible. As the number of training examples increases, estimates of class transitions indeed improve, but the class-based assumption itself becomes too restrictive. In 4), which represents an interpolated model, we see the tradeoff achieved by incorporating sequences: for small training sets, the model achieves better generalization than word bigrams, but is worse than the class-based model; and for larger training sets, the interpolated model learns better representations of high frequency events and outperforms the class-based models represented by 2) and 3).

The value of α in 3) is 0.7, whereas α in 4) is 0.9; this seems counter-intuitive at first, but note that a smaller α does not necessarily imply sparser observation probabilities; however, it implies a heavier distribution in a Bayesian setting. A Bayesian interpretation therefore suggests that in 4), the model itself is better equipped to cope with heavy tails, whereas a more aggressive α is required in 3).

6 Conclusion

By defining a random clustering model (a model in which there is a distribution over possible cluster assignments, e.g. an HMM), it is possible to specialize published PAC-Bayesian cross-entropy bounds to the cases of n-gram and class-based n-gram estimation. A distribution over segmentations allows derivation of a cross-entropy bound on sequence clustering algorithms, which can be made useful by sparsifying the sequence cluster observation probabilities. An efficient l_α regularization technique can be used to maximize sparsity, thereby minimizing the test set cross-entropy.

Abstract

The techniques of using neural networks to learn distributed word representations (i.e., word embeddings) have been used to solve a variety of natural language processing tasks. The recently proposed methods, such as CBOW and Skip-gram, have demonstrated their effectiveness in learning word embeddings based on context information such that the obtained word embeddings can capture both semantic and syntactic relationships between words. However, it is quite challenging to produce high-quality word representations for rare or unknown words due to their insufficient context information. In this paper, we propose to leverage morphological knowledge to address this problem. Particularly, we introduce the morphological knowledge as both additional input representation and auxiliary supervision to the neural network framework. As a result, beyond word representations, the proposed neural network model will produce morpheme representations, which can be further employed to infer the representations of rare or unknown words based on their morphological structure. Experiments on an analogical reasoning task and several word similarity tasks have demonstrated the effectiveness of our method in producing high-quality words embeddings compared with the state-of-the-art methods.

1 Introduction

Word representation is a key factor for many natural language processing (NLP) applications. In the conventional solutions to the NLP tasks, discrete word representations are often adopted, such as the 1-of-v representations, where v is the size of the entire vocabulary and each word in the vocabulary is represented as a long vector with only one non-zero element. However, using discrete word vectors cannot indicate any relationships between different words, even though they may yield high semantic or syntactic correlations. For example, while *careful* and *carefully* have quite similar semantics, their corresponding 1-of-v representations trigger different indexes to be the hot values, and it is not explicit that *careful* is much closer to *carefully* than other words using 1-of-v representations.

To deal with the problem, neural network models have been widely applied to obtain word representations. In particular, they usually take the 1-of-v representations as the word input vectors in the neural networks, and learn new distributed word representations in a low-dimensional continuous embedding space. The principle of these models is that words that are highly correlated in terms of either semantics or syntactics should be close to each other in the embedding space. Representative works in this field include feed-forward neural network language model (NNLM) (Bengio et al., 2003), recurrent neural network language model (RNNLM) (Mikolov et al., 2010), and the recently proposed continues bag-of-words (CBOW) model and continues skip-gram (Skip-gram) model (Mikolov et al., 2013a).

However, there are still challenges for using neural network models to achieve high-quality word embeddings. First, it is difficult to obtain word embeddings for emerging words as they are not included in the vocabulary of the training data. Some previous studies (Mikolov, 2012) used one or more default indexes to represent all the unknown words, but such solution will lose information for the new words.

Proceedings of COLING 2014, the 25th International Conference on Computational Linguistics: Technical Papers, pages 141–150, Dublin, Ireland, August 23-29 2014.

Second, the embeddings for rare words are often of low quality due to the insufficient context information in the training data.

Fortunately, semantically or syntactically similar words often share some common morphemes such as roots, affixes, and syllables. For example, *probably* and *probability* share the same root, i.e., *probab*, as well as the same syllables, i.e., *pro* and *ba*. Therefore, morphological information can provide valuable knowledge to bridge the gap between rare or unknown words and well-known words in learning word representations. In this paper, we propose a novel neural network architecture that can leverage morphological knowledge to obtaining high-quality word embeddings. Specifically, we first segment the words in the training data into morphemes, and then employ the 1-of-v representations of both the words and their morphemes as the input to the neural network models. In addition, we propose to use morphological information as auxiliary supervision. Particularly, in the output layer of the neural network architecture, we predict both the words and their corresponding morphemes simultaneously. Moreover, we introduce extra coefficients into the network to balance the weights between word embeddings and morpheme embeddings. Therefore, in the back propagation stage, we will update the word embeddings, the morpheme embeddings, and the balancing coefficients simultaneously.

Our proposed neural network model yields two major advantages: on one hand, it can leverage three types of co-occurrence information, including co-occurrence between word and word (conventional), co-occurrence between word and morpheme (newly added), and co-occurrence between morpheme and morpheme (newly added); on the other hand, this new model allows to learn word embeddings and morpheme embeddings simultaneously, so that it is convenient to build the representations for unknown words from morpheme embeddings and enhance the representations for rare words. Experiments on large-scale public datasets demonstrate that our proposed approach can help produce improved word representations on an analogical reasoning task and several word similarity tasks compared with the state-of-the-art methods.

The rest of the paper is organized as follows. We briefly review the related work on word embedding using neural networks in Section 2. In Section 3, we describe the proposed methods to leverage morphological knowledge in word embedding using neural network models. The experimental results are reported in Section 4. The paper is concluded in Section 5.

2 Related Work

Neural Language Models (NLMs) (Bengio et al., 2003) have been applied in a number of NLP tasks (Collobert and Weston, 2008) (Glorot et al., 2011) (Mikolov et al., 2013a) (Mikolov et al., 2013b) (Socher et al., 2011) (Turney, 2013) (Turney and Pantel, 2010) (Weston et al.,) (Deng et al., 2013) (Collobert et al., 2011) (Mnih and Hinton, 2008) (Turian et al., 2010). In general, they learn distributed word representations in a continuous embedding space. For example, Mikolov et al. proposed the continuous bag-of-words model (CBOW) and the continuous skip-gram model (Skip-gram) (Mikolov et al., 2013a). Both of them assume that words co-occurring with the same context should be similar. Collobert et al. (Collobert et al., 2011) fed their neural networks with extra features such as the capital letter feature and the part-of-speech (POS) feature, but they still met the challenge of producing high-quality word embeddings for rare words.

Besides using neural network, many different types of models were proposed for estimating continuous representations of words, such as the well-known Latent Semantic Analysis (LSA) and Latent Dirichlet Allocation (LDA). However, Mikolov et al. (Mikolov et al., 2013c) have shown that words learned by neural networks are signicantly better than LSA for preserving linear regularities while LDA becomes computationally expensive on large datasets.

There were a lot of previous attempts to include morphology in continuous models, especially in the speech recognition field. Represent works include Letter n-gram (Sperr et al., 2013) and feature-rich DNN-LMs (Mousa et al., 2013). The first work improves the letter-based word representation by replacing the 1-of-v word input of restricted Boltzman machine with a vector indicating all n-grams of order n and smaller that occur in the word. Additional information such as capitalization is added as well. In the model of feature-rich DNN-LMs, the authors expand the inputs of the network to be a mixture of

selected full words and morphemes together with their features such as morphological tags. Both of these works intend to capture more morphological information so as to better generalize to unknown or rare words and to lower the out-of-vocabulary rate.

There are some other related works that consider morphological knowledge when learning the word embeddings, such as factored NLMs (Alexandrescu and Kirchhoff, 2006) and csmRNN (Luong et al., 2013), both of which are designed to handle rare words. In factored NLMs, each word is viewed as a vector of shape features (e.g., affixed, capitalization, hyphenation, and classes) and a word is predicted based on several previous vectors of factors. Although they made use of the co-occurrence of morphemes and words, the context information is lost after chopping the words and feeding the neural network with morphemes. In our model, we also utilize the co-occurrence information between morphemes, which has not been investigated before. In csmRNN, Luong *et al* proposed a hierarchical model considering the knowledge of both morphological constitutionality and context. The hierarchical structure looks more sophisticated, but the relatedness of words with morphological similarity are weaken by layers when combining morphemes into words. In addition, the noise accumulated in the hierarchical structure in building a word might be propagated to the context layer. In our model, the morphological and contextual knowledge are combined in parallel, and their contributions to the input vector are decided by a pair of learned tradeoff coefficients.

3 The Morpheme powered CBOW Models

In this section, we introduce the architecture of our proposed neural network model based on the CBOW model. In CBOW (see Figure 1), a sliding window is employed on the train text stream to obtain the training samples. In each sliding window, the model aims to predict the central word using the surrounding words as the input. Specifically, the input words are represented in the 1-of-v format. In the feed-forward process, these input words are first mapped into the embedding space by the same weight matrix M, and then the embedding vectors are summed up to a combined embedding vector. After that, the combined embedding vector is mapped back to the 1-of-v space by another weight matrix M', and the resulting vector is used to predict the central word after conducting softmax on it. In the back-propagation process, the prediction errors are propagated back to the network to update the two weight matrices. After the

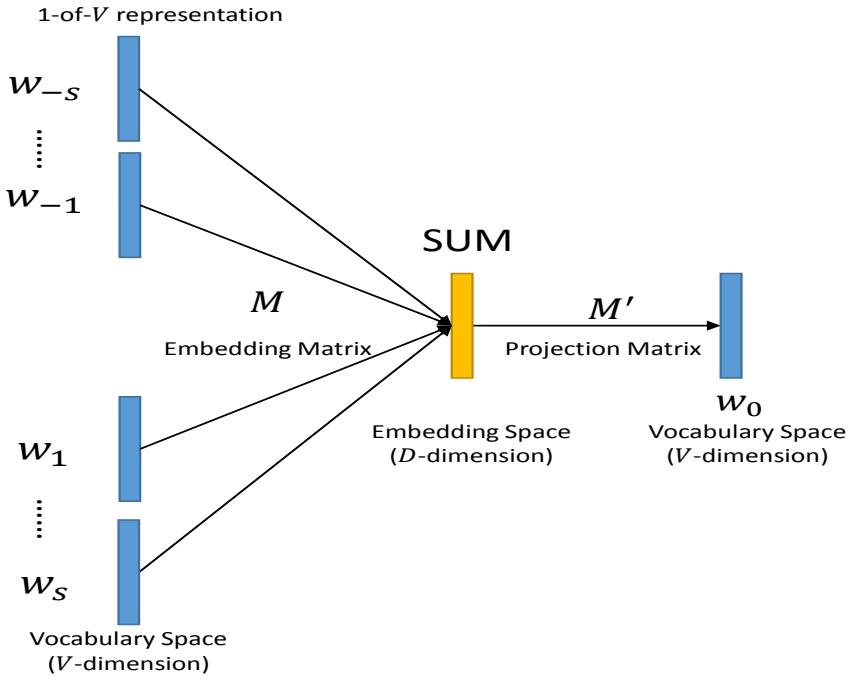

Figure 1: The CBOW model.

In our proposed model, we address the challenge of producing high-quality word embeddings for rare words and unknown words by leveraging the three types of co-occurrence information between words and morphemes.

On the input side, we segment the words into morphemes and put both the words and the morphemes as input. That is, the vocabulary for the 1-of-v representation contains both words and morphemes. As shown in Figure 2, the surrounding words in the sliding window are $w_{-s}, \cdots, w_{-1}, w_1, \cdots, w_s$ and their corresponding morphemes are $m_{-s,1}, m_{-s,2}, \cdots, m_{-s,t_{-s}}; \cdots; m_{-1,1}, m_{-1,2}, \cdots, m_{-1,t_{-1}}; m_{1,1}, m_{1,2}, \cdots, m_{1,t_1}; \cdots; m_{s,1}, m_{s,2}, \cdots, m_{s,t_s}$, where $2s$ is the number of the surrounding words and t_i is the number of morphemes for w_i $(i = -s, \cdots, -1, 1, \cdots, s)$. Note that t_i depends on the formation of w_i so that it may vary from word to word. If a word is also a morpheme, there will be two embedding vectors which are tagged differently. We use v_{w_i} and $v_{m_{i,j}}$ to represent the 1-of-v vectors of word w_i and morpheme $m_{i,j}$ respectively. On the input side, both the words and their morphemes are mapped into the embedding space by the same weight matrix M, and then the weighted sum v_I of the combination of word embeddings and the combination of morpheme embeddings is calculate as below,

$$v_I = \phi_w \cdot \sum_{\substack{i=-s \\ i \neq 0}}^{s} v_{w_i} + \phi_m \cdot \sum_{\substack{i=-s \\ i \neq 0}}^{s} \sum_{j=1}^{t_i} v_{m_{i,j}},$$

where ϕ_w and ϕ_m are the tradeoff coefficients between the combination of word embeddings and the combination of morpheme embeddings.

On the output side, we map the combined embedding vector v_I back to the 1-of-v space by another weight matrix M' to do the prediction. We have four settings of the structure. In the first setting, we only predict the central word w_0, and we name the model under this setting as *MorphemeCBOW*. In the second setting, we predict both the central word w_0 and its morphemes $m_{0,1}, m_{0,2}, \cdots, m_{0,t_0}$, and we name this setting as *MorphemeCBOW+*. In the above two settings, the tradeoff weights ϕ_w and ϕ_m are fixed. If we update the two weights in the learning process of *MorphemeCBOW*, we will get the third setting and we name it as *MorphemeCBOW**, while updating the two weights in *MorphemeCBOW+* yields the forth setting named *MorphemeCBOW++* .

Take *MorphemeCBOW+* as example, the objective is to maximize the following conditional co-occurrence probability,

$$\log(P(w_0 \mid \{w_i\}, \{m_{i,j}\})) + \log(\sum_{j=1}^{t_0} P(m_{0,j} \mid \{w_i\}, \{m_{i,j}\})), \tag{1}$$

where $\{w_i\}, \{m_{i,j}\}$ represent the bag of words and bag of morphemes separately. The conditional probability in the above formula is defined using the softmax function,

$$P(w_0 \mid \{w_i\}, \{m_{i,j}\}) = \frac{\exp(v'^T_{w_0} \cdot v_I)}{\sum_{v' \in V_O} \exp(v'^T \cdot v_I)} \quad , \quad P(m_{0,j} \mid \{w_i\}, \{m_{i,j}\}) = \frac{\exp(v'^T_{m_{0,j}} \cdot v_I)}{\sum_{v' \in V_O} \exp(v'^T \cdot v_I)}, \tag{2}$$

where V_O is the set of the output representations for the whole vocabulary; v' is used to differentiate with input representations; and $v'_{w_0}, v'_{m_{0,j}}$ represent the output embedding vectors of w_0 and $m_{0,j}$ respectively.

Usually, the computation cost for Formula (2) is expensive since it is proportional to the vocabulary size. In our model, we use negative sampling discussed in (Mikolov et al., 2013b) to speed up the computation. Particularly, we random select k negative samples $u_1, u_2, \cdots, u_k$ for each prediction target (word or morpheme). By using this technique, Formula (1) can be equally written as,

$$G(v_I) \equiv \log \sigma(v'^T_{w_0} \cdot v_I) + \sum_{j=1}^{t_0} \log \sigma(v'^T_{m_{0,j}} \cdot v_I) + \sum_{\substack{i=1 \\ u_i \neq w_0 \\ u_i \neq \forall m_{0,j}}}^{k} E_{u_i \sim P_n(u)}[\log \sigma(-v'^T_{u_i} \cdot v_I)],$$

where σ denotes the logistic function, and $P_n(u)$ is the vocabulary distribution used to select the negative samples. $P_n(u)$ is set as the 3/4rd power of the unigram distribution $U(u)$[1]. The negative samples should not be the same as any of the prediction targets w_0 and $m_{0,j}$ $(j = 1, \cdots, t_0)$. By using negative sampling, the training time spent on summing up the whole vocabulary in Formula (2) is greatly reduced so that it becomes linear with the number of the negative samples. Thus, we can calculate the gradient of $G(v_I)$ as below,

$$\frac{\partial G(v_I)}{\partial v_I} = (1 - \sigma(v'^T_{w_0} \cdot v_I)) \cdot \frac{\partial (v'^T_{w_0} \cdot v_I)}{\partial v_I} + \sum_{j=1}^{t_0} (1 - \sigma(v'^T_{m_{0,j}} \cdot v_I)) \cdot \frac{\partial (v'^T_{m_{0,j}} \cdot v_I)}{\partial v_I} - \sum_{\substack{i=1 \\ u_i \neq w_0 \\ u_i \neq \forall m_{0,j}}}^{k} [\sigma(v'^T_{u_i} \cdot v_I) \cdot \frac{\partial (v'^T_{u_i} \cdot v_I)}{\partial v_I}].$$

In the back-propagation process, the weights in the matrices M and M' are updated. When the training process converges, we take the matrix M as the learned word embeddings and morpheme embeddings.

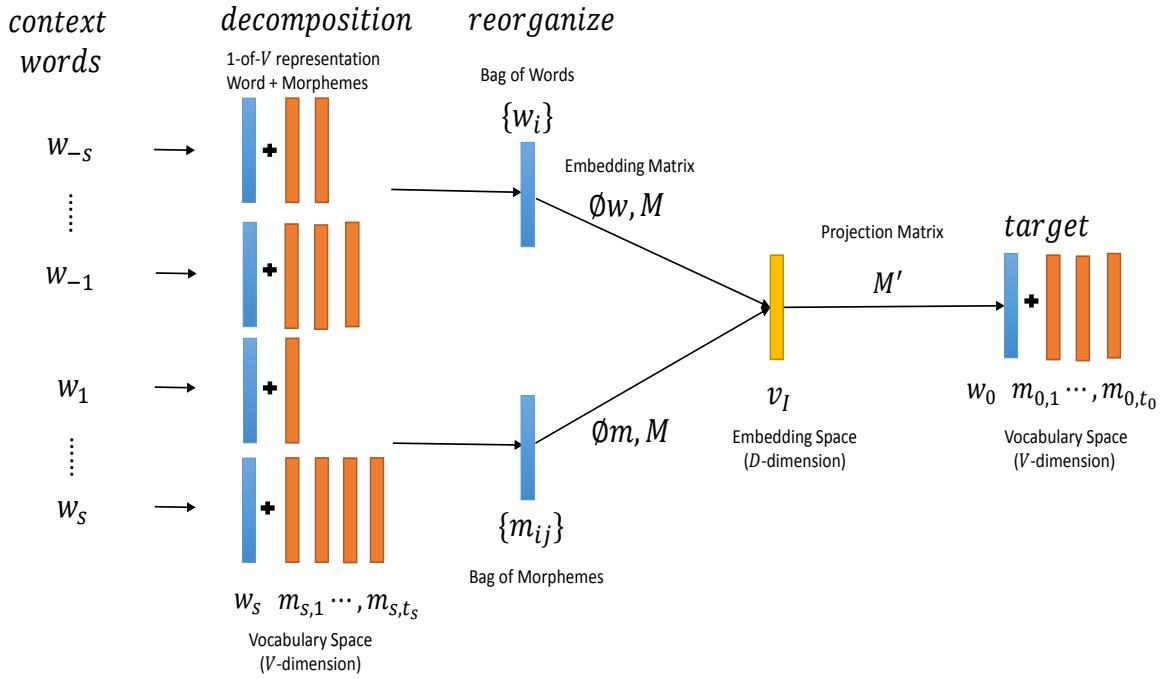

Figure 2: The proposed neural network model.

4 Experimental Evaluation

In this section we test the effectiveness of our model in generating high-quality word embeddings. We first introduce the experimental settings, and then we report the results on one analogical reasoning task and several word similarity tasks.

4.1 Datasets

We used two datasets for training: *enwiki9*[2] and *wiki2010*[3].

[1] http://www.cs.bgu.ac.il/~yoavg/publications/negative-sampling.pdf
[2] http://mattmahoney.ent/dc/enwik9.zip
[3] http://www.psych.ualberta.ca/~westburylab/downloads/westburylab.wikicorp.download.html

- The *enwiki9* dataset contains about 123.4 million words. We used Matt Mahoney's text pre-processing script[4] to process the corpus. Thus, we removed all non-Roman characters and mapped all digits to English words. In addition, words occurred less than 5 times in the training corpus were discarded. We used the learned word embeddings from *enwiki9* to test an analogical reasoning task described in (Mikolov et al., 2013a).

- The *wiki2010* dataset contains about 990 million words. The learned embeddings from this dataset were used on word similarity tasks as it was convenient to compare with the csmRNN model (Luong et al., 2013). We did the same data pre-processing as csmRNN did. That is, we removed all non-Roman characters and mapped all digits to zero.

4.2 Settings

In the analogical reasoning task, we used the CBOW model as the baseline. In both CBOW and our proposed model, we set the context window size to be 5, and generated three dimension sizes (100, 200, and 300) of word embeddings. We used negative sampling (Mikolov et al., 2013b) in the output layer and the number of negative samples is chosen as 3.

In the word similarity tasks, we used the csmRNN model as the baseline. The context window size of our model was set to be 5. To make a fair comparison with the csmRNN model, we conducted the same settings in our experiments as csmRNN. First, as csmRNN used the *Morfessor* (Creutz and Lagus, 2007) method to segment words into morphemes, we also used *Morfessor* as one of our word segmentation methods to avoid the influence caused by the segmentation methods. Second, as csmRNN used two existing embeddings C&W[5] (Collobert et al., 2011) and HSMN[6] (Huang et al., 2012) to initialize the training process, we also used the two embeddings as the initial weights of M in our experiments. Third, we set the dimension of the embedding space to 50 as csmRNN did.

In our model, we employed three methods to segment a word into morphemes. The first method is called *Morfessor*, which is a public tool implemented based on the minimum descriptions length algorithm (Creutz and Lagus, 2007). The second method is called *Root*, which segments a word into roots and affixes according to a predefined list in Longman Dictionaries. The third method is called *Syllable*, which is implemented based on the hyphenation tool proposed by Liang (Liang, 1983). Besides, the architecture of the proposed model can be specified into four types: *MorphemeCBOW*, *MorphemeCBOW**, *MorphemeCBOW+*, and *MorphemeCBOW++*. For the model *MorphemeCBOW* and *MorphemeCBOW+* with fixed tradeoff coefficients, we set the weights ϕ_w and ϕ_m to be 0.8 and 0.2 respectively; while for the other two models with updated tradeoff weights, the weights ϕ_w and ϕ_m are initialized as 1. These weight settings are chosen empirically.

4.3 Evaluation Tasks

4.3.1 Analogical reasoning task

The analogical reasoning task was introduced by Mikolov et al (Mikolov et al., 2013a). All the questions are in the form "a is to b is as c is to ?", denoted as $a : b \rightarrow c : ?$. The task consists of 19,544 questions involving semantic analogies (e.g., England: London $\rightarrow$ China: Beijing) and syntactic analogies (e.g., amazing: amazingly $\rightarrow$ unfortunate: unfortunately). Suppose that the corresponding vectors are $\overrightarrow{a}$, $\overrightarrow{b}$, and $\overrightarrow{c}$, we will answer the question by finding the word with the representation having the maximum cosine similarity to vector $\overrightarrow{b} - \overrightarrow{a} + \overrightarrow{c}$, i.e,

$$\max_{x \in V, x \neq b, x \neq c} (\overrightarrow{b} - \overrightarrow{a} + \overrightarrow{c})^T \overrightarrow{x}$$

where V is the vocabulary. Only when the computed word is exactly the answer word in evaluation set can the question be regarded as answered correctly.

[4] http://mattmahoney.net/dc/textdata.html
[5] http://ronan.collobert.com/senna/
[6] http://ai.stanford.edu/~ehhuang/

4.3.2 Word similarity task

The word similarity task was tested on five evaluation sets: WS353 (Finkelstein et al., 2002), SCWS* (Huang et al., 2012), MC (Miller and Charles, 1991), RG (Rubenstein and Goodenough, 1965) and RW (Luong et al., 2013), which contain 353, 1,762, 30, 65 and 2,034 pairs of words respectively. Table 1 shows some statistics about the datasets. Furthermore, the words in WS353, MC, RG are mostly frequent words, while SCWS* and RW have much more rare words and unknown words (i.e., unseen words in the training corpus) than the first three sets. The word distributions of these datasets are shown in Figure 3, from which we can see that RW contains the largest number of rare and unknown words. For the unknown words, we segmented them into morphemes, and calculated their word embeddings by summing up their corresponding morpheme embeddings. Each word pair in these datasets is associated with several human judgments on similarity and relatedness on a scale from 0 to 10 or 0 to 4. For example, (*cup*, *drink*) received an average score of 7.25, while (*cup*, *substance*) received an average score of 1.92. To evaluate the quality of the learned word embeddings, we computed Spearman's ρ correlation between the similarity scores calculated on the learned word embeddings and the human judgments.

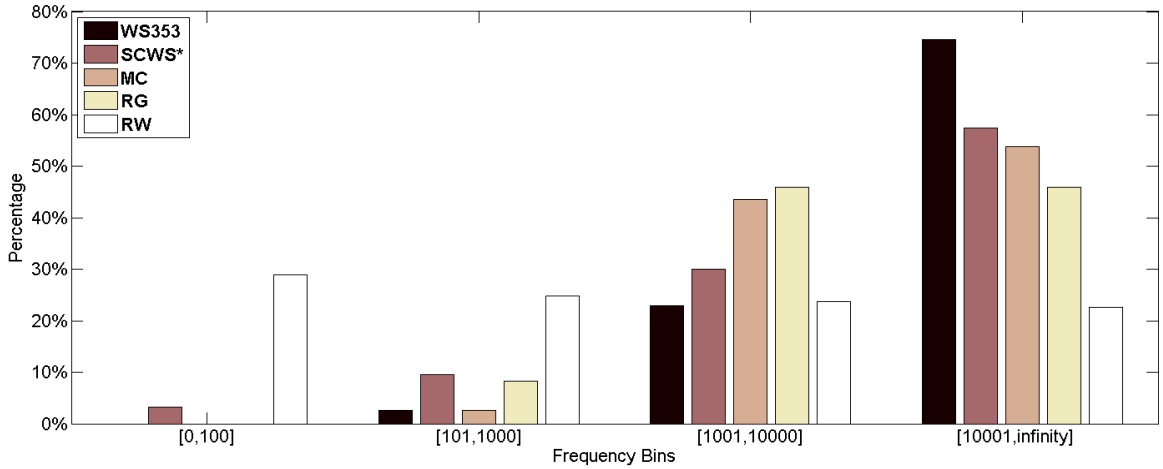

Figure 3: **Word distribution by frequency**. Distinct words in each test dataset are grouped according to frequencies. The figure shows the percentage of words in each bin.

Table 1: Statistics on the word similarity evaluation sets.

Dataset	Number of pairs	Number of words	Percentage of multi-segments words by *Morfessor*
WS353	353	437	28.15%
SCWS*	1726	1703	34.00%
RW	2034	2951	69.06%

4.4 Experimental Results

4.4.1 Results on analogical reasoning task

The experimental results on the analogical reasoning task are shown in Table 2, including semantic accuracy, syntactic accuracy, and total accuracy of all competition settings. Semantic/syntactic accuracy refers to the number of correct answers over the total number of all semantic/syntactic questions. From the results, we have the following observations:

- In MorphemeCBOW, we used the surrounding words and their morphemes to predict the central word. The total accuracies are all improved compared with baseline using the three word segmentation methods across three different dimensions of the embedding space. Generally, the improvements on semantic accuracies are less than those on syntactic accuracies. The reason is that the morphological information favors more for the syntactic tasks than the semantic tasks. Further-

more, the *Root* method achieved the best among the three segmentation methods, showing that the roots and affixes from the dictionary can help produce a high-quality morpheme segmentation tool.

- In MorphemeCBOW*, we predicted the central word, and updated the tradeoff coefficients in the learning process. We can see that the results are comparable or slightly better than MorphemeCBOW using the three word segmentation methods across three different dimensions of the embedding space, showing that updating the tradeoff coefficients may further boost the model performance under some specific settings.

- In MorphemeCBOW+, we predicted both the central word and its morphemes. MorphemeCBOW+ can provide slightly better results compared with MorphemeCBOW and MorphemeCBOW*, indicating that putting morphemes (especially roots) in the output layer can do extra help in generating high-quality word embeddings.

- In MorphemeCBOW++, we predicted the central word and its morphemes, and updated the tradeoff coefficients in the learning process. The performance under all of the three word segmentation methods got further improved compared with MorphemeCBOW+. It tells that the contributions from words and morphemes are different to the analogical reasoning task. According to our observations, the weight for words is usually higher than that for morphemes.

- By comparing MorphemeCBOW with MorphemeCBOW* as well as MorphemeCBOW+ with MorphemeCBOW++, we can observe that updating the weights of tradeoff coefficients seem to essentially boost syntactic accuracy by trading off a bit of semantic accuracy. As introduced in Section 4.2, in the fixed weight model the ratio of weight of morphemes to the weight of word is 0.25; while our experiment records show that the averaged ratio are 0.43 if the two weights are updated, meaning that the weight of the combination of morphemes increases and the contribution of the original word to the final combined embedding decreased. As a result, the syntactic accuracy which largely reflected in the morphological structure of a word increased, but the semantic accuracy hurts a little.

4.4.2 Results on word similarity task

Experimental results on the word similarity tasks are shown in Table 3[7],where the labels of C&W + csmRNN and HSMN + csmRNN mean that using C&W and HSMN to initialize csmRNN model as what had been introduced in the paper of Luong et al. In our experiments, the architecture of MorphemeCBOW* performs the best, so we only show the results related to MorphemeCBOW* in the table. We have the following observations from the results:

- On WS353, MC, RG, and SCWS*, MorphemeCBOW* performs consistently better than the csmRNN model, showing that our model can achieve better representations for common words.

[7]csmRNN embeddings are available on `http://www-nlp.stanford.edu/~lmthang/morphoNLM/`, Performances are tested based on the two embeddings.

MorphemeCBOW*	63.45	53.40	77.40	63.78	32.88

- On RW, MorphemeCBOW* performs better than the csmRNN model when using the HSMN embeddings as the initialization. When using the C&W embeddings as the initialization, the performance of MorphemeCBOW* is also comparable with that of csmRNN. In particular, if we do not use any pre-trained embeddings to initialize our mode, it performed the best (32.88%), and it even beats the best performance of csmRNN with initializations (31.77%)[8]. The initialization is very important to a neural network. Suitable initialization will help increase the embedding quality which works like training with multi-epochs. However, as there are two matrix M and M' in our network structure, the initialization of both of them are more sensible. Furthermore, considering that the recursive structure of csmRNN will bring higher computation complexity, we can conclude that our model has excellent ability in learning the embeddings of rare words from pure scratch.

- The improvement on RW is more significant than those on the other four datasets. Considering that RW contains more rare and unknown words (See Figure 3), we verified our idea that leveraging morphological information will especially benefit the embedding of low-frequency words. More specifically, without sufficient context information for the rare words in the training data, building connections between words using morphemes will provide additional evidence for the model to generate effective embeddings for these rare words; and, by combining the high-quality morpheme embeddings to obtain the representations of the unknown words, the model does a good job in dealing with the new emerging words.

5 Conclusions and Future Work

We proposed a novel neural network model to learn word representations from text. The model can leverage several types of morphological information to produce high-quality word embeddings, especially for rare words and unknown words. Empirical experiments on an analogical reasoning task and several word similarity tasks have shown that the proposed model can generate better word representations compared with several state-of-the-art approaches.

For the future work, we plan to separate words and morphemes into several buckets according to their frequencies. Different buckets will be associated with different coefficients, so that we can tune the coefficients to approach even better word embeddings. We also plan to run our model on more training corpus to obtain the embedding vectors for rare words, especially those new words invented out recently. These emerging new words usually do not exist in standard training corpus such as Wikipedia, but exists in some noisy data such as news articles and web pages. How well our model performs on these new training corpus is an interesting question to explore.

Abstract

Distributed word representations have been widely used and proven to be useful in quite a few natural language processing and text mining tasks. Most of existing word embedding models aim at generating only one embedding vector for each individual word, which, however, limits their effectiveness because huge amounts of words are polysemous (such as *bank* and *star*). To address this problem, it is necessary to build multi embedding vectors to represent different meanings of a word respectively. Some recent studies attempted to train multi-prototype word embeddings through clustering context window features of the word. However, due to a large number of parameters to train, these methods yield limited scalability and are inefficient to be trained with big data. In this paper, we introduce a much more efficient method for learning multi embedding vectors for polysemous words. In particular, we first propose to model word polysemy from a probabilistic perspective and integrate it with the highly efficient continuous Skip-Gram model. Under this framework, we design an Expectation-Maximization algorithm to learn the word's multi embedding vectors. With much less parameters to train, our model can achieve comparable or even better results on word-similarity tasks compared with conventional methods.

1 Introduction

Distributed word representations usually refer to low dimensional and dense real value vectors (a.k.a. word embeddings) to represent words, which are assumed to convey semantic information contained in words. With the exploding text data on the Web and fast development of deep neural network technologies, distributed word embeddings have been effectively trained and widely used in a lot of text mining tasks (Bengio et al., 2003) (Morin and Bengio, 2005) (Mnih and Hinton, 2007) (Collobert et al., 2011) (Mikolov et al., 2010) (Mikolov et al., 2013b).

While word embedding plays an increasingly important role in many tasks, most of word embedding models, which assume one embedding vector for each individual word, suffer from a critical limitation for modeling tremendous polysemous words (e.g. *bank*, *left*, *doctor*). Using the same embedding vector to represent the different meanings (we will call *prototype* of a word in the rest of the paper) of a polysemous word is somehow unreasonable and sometimes it even hurts the model's expression ability.

To address this problem, some recent efforts, such as (Reisinger and Mooney, 2010) (Huang et al., 2012), have investigated how to obtain multi embedding vectors for the respective different prototypes of a polysemous word. Specifically, these works usually take a two-step approach: they first train single prototype word representations through a multi-layer neural network with the assumption that one word only yields single word embedding; then, they identify multi word embeddings for each polysemous word by clustering all its context window features, which are usually computed as the average of single prototype embeddings of its neighboring words in the context window.

Compared with traditional single prototype model, these models have demonstrated significant improvements in many semantic natural language processing (NLP) tasks. However, they suffer from a

Proceedings of COLING 2014, the 25th International Conference on Computational Linguistics: Technical Papers, pages 151–160, Dublin, Ireland, August 23-29 2014.

crucial restriction in terms of scalability when facing exploding training text corpus, mainly due to the deep layers and huge amounts of parameters in the neural networks in these models. Moreover, the performance of these multi-prototype models is quite sensitive to the clustering algorithm and requires much effort in clustering implementation and parameter tuning. The lack of probabilistic explanation also refrains clustering based methods from being applied to many text mining tasks, such as language modeling.

To address these challenges, in this work, we propose a new probabilistic multi-prototype model and integrate it into a highly efficient continuous Skip-Gram model, which was recently introduced in the well-known Word2Vec toolkit (Mikolov et al., 2013b). Compared with conventional neural network language models which usually set up a multi-layer neural network, Word2Vec merely leverages a three-layer neural network to learn word embeddings, resulting in greatly decreased number of parameters and largely increased scalability. However, similar to most of existing word embedding models, Word2Vec also assumes *one embedding for one word*. We break this limitation by introducing a new probabilistic framework which employs hidden variables to indicate which prototype each word belongs to in the context. In this framework, the conditional probability of observing word w_O conditioned on the presence of neighboring word w_I (i.e. $P(w_O|w_I)$) can be formulated as a mixture model, where *mixtures* corresponds to w_I's different *prototypes*. This is a more natural way to define $P(w_O|w_I)$, since it has taken the polysemy of word w_I into consideration. After defining the model, we design an efficient Expectation-Maximization (EM) algorithm to learn various word embedding vectors corresponding to each of w_I's prototypes. Evaluations on widely used word similarity tasks demonstrate that our algorithm produces comparable or even better word embeddings compared with either clustering-based multi-prototype models or the original Skip-Gram model. Furthermore, as a unified way to obtain multi word embeddings, our proposed method can effectively avoid the sensitivity to the clustering algorithm applied by previous multi-prototype word embedding approach.

The following of the paper is organized as follows: we introduce related work in Section 2. Then, Section 3 describes our new model and algorithm in details and conducts a comparison in terms of complexity between our algorithm and the previous method. We present our experimental results in Section 4. The paper is concluded in Section 5.

2 Related Work

Since the initial work (Bengio et al., 2003), there have been quite a lot of neural network based models to obtain distributed word representations (Morin and Bengio, 2005) (Mnih and Hinton, 2007) (Mikolov et al., 2010) (Collobert et al., 2011) (Mikolov et al., 2013b). Most of these models assume that one word has only one embedding, except the work of Eric Huang (Huang et al., 2012), in which the authors propose to leverage global context information and multi-prototype embeddings to achieve performance gains in word similarity task. To obtain multi-prototype word embeddings, this work conducts clustering on a word's all context words' features in the corpus. The features are the embedding vectors trained previously via a three-layer neural network. Each cluster's centroid is regarded as the embedding vector for each prototype. Their reported experimental results verify the importance of considering multi-prototype models.

Note that (Reisinger and Mooney, 2010) also proposes to deal with the word polysemy problem by assigning to each prototype a real value vector. However their embedding vectors are obtained through a tf-idf counting model, which is usually called as distributional representations (Turian et al., 2010), rather than through a neural network. Therefore, we do not regard their paper as very related to our work. The similar statement holds for other works on vector model for word meaning in context such as (Erk and Padó, 2008) (Thater et al., 2011) (Reddy et al., 2011) (Van de Cruys et al., 2011).

Our model is mainly based on the recent proposed Word2Vec model, more concretely, the continuous Skip-Gram model (Mikolov et al., 2013a) (Mikolov et al., 2013b). The continuous Skip-Gram model specifies the probability of observing the context words conditioned on the central word w_I in the window via a three-layer neural network. With less parameters to train (thus higher scalability), Word2Vec discovers interesting analogical semantic relations between words like *Japan - Tokyo = France - Paris*.

3 Model Description

In this section, we introduce our algorithm for learning multi-prototype embeddings in details. In particular, since our new model is based on the continuous Skip-Gram model, we first make a brief introduction to the Skip-Gram model. Then, we present our new multi-prototype algorithm and how we integrate it into the Skip-Gram model. After that, we propose an EM algorithm to conduct the training process. We also conduct a comparison on the number of parameters between the new EM algorithm and the state-of-the-art multi-prototype model proposed in (Huang et al., 2012), which can illustrate the efficiency superior of our algorithm.

3.1 Multi-Prototype Skip-Gram Model

In contrast to the conventional ways of using context words to predict the next word or the central word, the Skip-Gram model (Mikolov et al., 2013b) aims to leverage the central word to predict its context words. Specifically, assuming that the central word is w_I and one of its neighboring word is w_O, $P(w_O|w_I)$ is modeled in the following way:

$$P(w_O|w_I) = \frac{exp(V_{w_I}^T U_{w_O})}{\sum_{w \in W} exp(V_{w_I}^T U_w)}, \tag{1}$$

where W denotes the dictionary consisting of all words, $U_w \in R^d$ and $V_w \in R^d$ represent the d-dimensional 'output' and 'input' embedding vectors of word w, respectively. Note that all the parameters to be learned are the input and output embedding vectors of all words, i.e. $U = \{U_w | w \in W\}$ and $V = \{V_w | w \in W\}$. This corresponds to a three-layer neural network, in which U and V denote the two parameter matrices of the neural network. Compared with the conventional neural networks employed in the literature which yield at least four layers (including the look-up table layer), the Skip-Gram model greatly reduces the number of parameters and thus gives rise to a significant improvement in terms of training efficiency.

Our proposed Multi-Prototype Skip-Gram model is similar to the original Skip-Gram model in that it also aims to model $P(w_O|w_I)$ and uses two matrices (the input and output embedding matrices) as the parameters. The difference lies in that given word w_I, the occurrence of word w_O is described as a finite mixture model, in which each mixture corresponds to a prototype of word w_I. To be specific, suppose that word w has N_w prototypes and it appears in its h_w-th prototype, i.e., $h_w \in \{1, \cdots, N_w\}$ is the index of w's prototype. Then $P(w_O|w_I)$ is expanded as:

$$p(w_O|w_I) = \sum_{i=1}^{N_{w_I}} P(w_O|h_{w_I} = i, w_I) P(h_{w_I} = i|w_I) \tag{2}$$

$$= \sum_{i=1}^{N_{w_I}} \frac{exp(U_{w_O}^T V_{w_I,i})}{\sum_{w \in W} exp(U_w^T V_{w_I,i})} P(h_{w_I} = i|w_I), \tag{3}$$

where $V_{w_I,i} \in R^d$ refers to the embedding vector of w_I's i-th prototype. This equation states that $P(w_O|w_I)$ is a weighted average of the probabilities of observing w_O conditioned on the appearance of w_I's every prototype. The probability $P(w_O|h_{w_I} = i, w_I)$ takes the similar softmax form to equation (1) and the weight is specified as a prior probability of word w_I falls in its every prototype.

The general idea behind the Multi-Prototype Skip-Gram model is very intuitive: the surrounding words under different prototypes of the same word are usually different. For example, when the word *bank* refers to the side of a river, it is very possible to observe the corresponding context words such as *river*, *water*, and *slope*; however, when *bank* falls into the meaning of the financial organization, the surrounding word set is likely to be comprised of quite different words, such as *money*, *account*, and *investment*.

The probability formulation in (3) brings much computation cost because of the linear dependency of $|W|$ in the denominator $\sum_{w \in W} exp(U_w^T V_{w_I,i})$. To address this issue, several efficient methods have been proposed such as Hierarchical Softmax Tree (Morin and Bengio, 2005) (Mnih and Kavukcuoglu, 2013) and Negative Sampling (Mnih and Kavukcuoglu, 2013) (Mikolov et al., 2013b). Taking Hierarchical

Softmax Tree as an example, through a binary tree in which every word is a leaf node, word w_O is associated with a binary vector $b^{(w_O)} \in \{-1,+1\}^{L_{w_O}}$ specifying a path from the root of the tree to leaf w_O, where L_{w_O} is the length of vector $b^{(w_O)}$. Then the conditional probability is described as

$$P(w_O|h_{w_I}=i,w_I)=\prod_{t=1}^{L_{w_O}}P\left(b_t^{(w_O)}|w_I,h_{w_I}=i\right)=\prod_{t=1}^{L_{w_O}}\varsigma\left(b_t^{(w_O)}U_{w_O,t}^T V_{w_I,i}\right), \tag{4}$$

where $\varsigma(x)=1/(1+exp(-x))$ is the sigmoid function, and $U_{w_O,t}$ specifies the d-dimensional parameter vector associated with the t-th node in the path from the root to the leaf node w_O. Substituting (4) into (2) to replace the large softmax operator in (3) leads to a much more efficient probability form.

3.2 EM Algorithm

In this section, we describe the EM algorithm adopted to train the Multi-Prototype Skip-Gram model. Without loss of generality, we will focus on obtaining multi embeddings for a specified word $w \in W$ with N_w prototypes. Word w's embedding vectors are denoted as $V_w \in R^{d\times N_w}$. Suppose there are M word pairs for training: $\{(w_1,w),(w_2,w),\cdots,(w_M,w)\}$, where all the inputs words (i.e., word w) are the same, and the set of output words to be predicted are denoted as $\mathbb{X}=\{w_1,w_2,\cdots,w_M\}$. That is, $\mathbb{X}$ are M surrounding words of w in the training corpus.

For ease of reference and without loss of generality, we make some changes to the notations in Section 3.1. We will use h_m as the index of w's prototype in the pair (w_m,w), $m\in\{1,2,\cdots,M\}$. Besides, some new notations are introduced: $P(h_w=i|w_I)$ is simplified as π_i, and $\gamma_{m,k}$, where $m\in\{1,2,\cdots,M\}$, $k\in\{1,2,\cdots N_w\}$, are the hidden binary variables indicating whether the m-th presence of word w is in its k-th prototype, i.e. $\gamma_{m,k}=1_{h_m=k}$, where 1 is the indicator function. Other notations are the same as before: $V_{w,i}\in R^d$ is the embedding vector for word w's i-th prototype, $U_{w,t}\in R^d$ is the embedding vector for the t-th node on the path from the tree root to the leaf node representing word w, and $b_t^{(w)}\in\{-1,1\}$ is the t-th bit of the binary coding vector of word w along its corresponding path on the Hierarchical Softmax Tree.

Then the parameter set we aim to learn is $\Theta=\{\pi_1,\cdots,\pi_{N_w};U;V_w\}$. The hidden variable set is $\Gamma=\{\gamma_{m,k}|m\in(1,2,\cdots,M),k\in(1,2,\cdots,N_w)\}$. Considering equation (2) and (4), we have the log likelihood of $\mathbb{X}$ as below:

$$\begin{aligned}\log P(\mathbb{X},\Gamma|\Theta)&=\sum_{m=1}^{M}\sum_{k=1}^{N_w}\gamma_{m,k}\big(\log\pi_k+\log P(w_m|h_m=k,w)\big)\\&=\sum_{m=1}^{M}\sum_{k=1}^{N_w}\gamma_{m,k}\big(\log\pi_k+\sum_{t=1}^{L_{w_m}}\log\varsigma(b_t^{(w_m)}U_{w_m,t}^T V_{w,k})\big).\end{aligned} \tag{5}$$

With equation (5), the E-Step and M-Step are:

E-Step:

The conditional expectation of hidden variable $\gamma_{m,k}$, denoted as $\hat{\gamma}_{m,k}$, is:

$$\hat{\gamma}_{m,k}=P(\gamma_{m,k}=1|\mathbb{X},\Theta)=\frac{\pi_k P(w_m|h_m=k,w)}{\sum_{i=1}^{N_w}\pi_i P(w_m|h_m=i,w)}. \tag{6}$$

The Q function w.r.t. the parameters at the i-th iteration $\theta^{(i)}$ is written as:

$$\begin{aligned}Q(\theta,\theta^{(i)})&=\sum_{k=1}^{N_w}\sum_{m=1}^{M}\hat{\gamma}_{m,k}\left(\log\pi_k+\log P(w_m|h_m=k,w)\right)\\&=\sum_{m=1}^{M}\sum_{k=1}^{N_w}\hat{\gamma}_{m,k}\big(\log\pi_k+\sum_{t=1}^{L_{w_m}}\log\varsigma(b_t^{(w_m)}U_{w_m,t}^T V_{w,k})\big).\end{aligned} \tag{7}$$

M-Step:

π can be updated by

$$\pi_k = \frac{\sum_{m=1}^{M} \hat{\gamma}_{m,k}}{M}, \quad k = 1, 2 \cdots, N_w. \tag{8}$$

We leave the detailed derivations for equation (6), (7), and (8) to the appendix of the paper. Then we discuss how we obtain the update of the embedding parameters $U_{w_m,t}$ and $V_{w,k}$. Note that the optimization problem is non-convex, and it is hard to compute the exact solution of $\frac{\partial Q}{\partial U_{w_m,t}} = 0$ and $\frac{\partial Q}{\partial V_{w,k}} = 0$. Therefore, we use gradient ascent to optimize in the M-step. The gradients of Q function w.r.t. embedding vectors are given by:

$$\frac{\partial Q}{\partial U_{w_m,t}} = \sum_{k=1}^{N_w} \hat{\gamma}_{m,k} b_t^{(w_m)} \big(1 - \varsigma(b_t^{(w_m)} U_{w_m,t}^T V_{w,k})\big) V_{w,k}, \tag{9}$$

$$\frac{\partial Q}{\partial V_{w,k}} = \sum_{m=1}^{M} \hat{\gamma}_{m,k} \sum_{t=1}^{L_{w_m}} b_t^{(w_m)} \big(1 - \varsigma(b_t^{(w_m)} U_{w_m,t}^T V_{w,k})\big) U_{w_m,t}. \tag{10}$$

Iterating between **E-Step** and **M-Step** till the convergence of the value of function Q makes the EM algorithm complete.

In order to enhance the scalability of our approach, we propose a fast computing method to boost the implementation of the EM algorithm. Note that the most expensive computing operations in both the E-Step and M-Step are the inner product of the input and output embedding vectors, as well as the sigmoid function. However, if we take the Hierarchical Softmax Tree form as shown in Equation (4) to model $P(w_m|h_m = i, w)$, and perform only one step gradient ascent in M-Step, the aforementioned two expensive operations in M-Step will be avoided by leveraging the pre-computed results in the E-Step. Specifically, since the gradient of the function $f(x) = \log \varsigma(x)$ is given by $f'(x) = 1 - \varsigma(x)$, the sigmoid values computed in the E-Step to obtain $P(w_m|h_m = i, w)$ (i.e. the term $\varsigma(b_t^{(w_m)} U_{w_m,t}^T V_{w,k})$ in equation (5), (9), and (10)) can be re-used to derive the gradients in the M-Step.

However, such enhanced computation method cannot benefit the second order optimization methods in the M-Step such as L-BFGS and Conjugate Gradient, since they usually rely on multiple iterations to converge. In fact, we tried these two optimization methods in our experiments but they have brought no improvement compared with simple one-step gradient ascent method.

3.3 Model Comparison

To show that our model is more scalable than the former multi-prototype model in (Huang et al., 2012) (We denote it as EHModel in the rest of the paper), we conduct a comparison on the number of parameters with respect to each of these two models in this subsection.

We use $n_{embedding}$ and n_{window} to denote the numbers of all word embedding vectors and context window words, respectively. It is clear that $n_{embeddings} = \sum_{w \in W} N_w$. EHModel aims to compute two scores, i.e., the local score and the global score, both with hidden layer node activations. We denote the hidden layer node number as h_l and h_g for these two scores. The parameter numbers are listed in Table 1.

Model	EHModel	Our Model
#parameters	$dn_{words} + dn_{embeddings} + (dn_{window} + 1)h_l + (2d + 1)h_g$	$dn_{words} + dn_{embeddings}$

Table 1: Comparison of parameter numbers of two models

Note that d in Table 1 denotes the embedding vector size. It can be observed that EHModel has $(dn_{window} + 1)h_l + (2d + 1)h_g$ more parameters than our model, which is mainly because EHModel has one more layer in the neural network and it considers global context. In previous study (Huang et al., 2012), d, n_{window}, h_l, and h_g are set to be 50, 10, 100, 100, respectively, which greatly increases the gap of parameter numbers between the two models.

4 Experiments

In this section, we will present our experimental settings and results. Particularly, we first describe the data collection and the training configuration we used in the experiments; then, we conduct a qualitative case study followed by quantitative evaluation results on a public word similarity task to demonstrate the performance of our proposed model.

4.1 Experimental Setup

Dataset: To make a fair comparison with the state-of-the-art methods, we employ a publicly available dataset, which is used in (Huang et al., 2012), to train word embeddings in our experiments. Particularly, this training corpus is a snapshot of Wikipedia at April, 2010 (Shaoul, 2010), which contains about 990 million tokens. We removed the infrequent words from this corpus and kept a dictionary of about 1 million most frequent words. Similar to Word2Vec, we removed pure digit words such as *2014* as well as about 100 stop words like *how*, *for*, and *we*.

Training Configuration: In order to boost the training speed, we take advantage of the Hierarchical Softmax Tree structure. More concretely, we use the Huffman tree structure, as introduced in Word2Vec, to further increase the training speed. All the embedding size, including both word embedding vectors and the Huffman tree node embedding vectors, are set to be 50, which is the same as the size used in (Huang et al., 2012). To train word embedding, we set the context window size as 10, i.e., for a word w, 10 of the closest neighboring words to w are regarded as ws contexts. For the numbers of word prototypes, i.e., N_w introduced in Section 3.2, we set the top 7 thousand frequent words as multi-prototype words by experience, with all of them having 10 prototypes (i.e. $N_w = 10$).

During the training process, we used the same strategy to set the learning rate as what Word2Vec did. Specifically, we set the initial learning rate to 0.025 and diminished the value linearly along with the increasing number of training words. Our experimental results illustrate that this learning rate strategy can lead to the best results for our algorithm.

For the hyper parameters of the EM algorithm, we set the batch size to 1, i.e. $M = 1$ in Section 3.2, since our experimental results reveal that smaller batch size can result in better experimental results. The reason is explained as the following. Our optimization problem is highly non-convex. Smaller batch size yields more frequent updates of parameters, and thus avoids trapping in local optima, while larger batch size, associated with more infrequent parameter updating, may cause higher probability to encounter local optima. In our experiments, we observe that only one iteration of E-Step and M-Step can reach the embedding vectors with good enough performance on the word similarity task, whereas increasing the iteration number just leads to slight performance improvement with much longer training time. Under the above configuration, our model runs about three times faster than EHModel.

4.2 Case Study

This section gives some qualitative evaluations of our model by demonstrating how our model can effectively identify multi-prototype word embeddings on some specific cases. In Table 2, we list several polysemous words. For each word, we pick some of their prototypes learned by our model, including the prototype prior probability (i.e. π_i introduced in Section 3.2) and three of the most similar words with each prototype, respectively. The similarity is calculated by the cosine similarity score between the embedding vectors.

From the table we can observe some interesting results of the multi-prototype embedding vectors produced by our model:

- For a polysemous word, its different embedding vectors represent its different semantic meanings. For example, the first embedding vector of the word *apple* corresponds to its sense as a kind of fruit, whereas the second one represents its meaning as an IT company.

- The prior probability reflects the likelihood of the occurrence of various prototypes to some extent. For example, the word *cell* is more likely to represent the meaning of the smallest part of living structure (with probability 0.81), than to be used as the meaning of *cellphone* (with probability

Word	Prior Probability	Most Similar Words
apple_1	0.82	strawberry, cherry, blueberry
apple_2	0.17	iphone, macintosh, microsoft
bank_1	0.15	river, canal, waterway
bank_2	0.6	citibank, jpmorgan, bancorp
bank_3	0.25	stock, exchange, banking
cell_1	0.09	phones, cellphones, mobile
cell_2	0.81	protein, tissues, lysis
cell_3	0.01	locked, escape, handcuffed

Table 2: Most similar words with different prototypes of the same word

0.09) or *prisoned* (with probability 0.01). Note that the three prior probability scores of *cell* do not sum to 1. The reason is that there are some other embeddings not presented in the table which are found to have high similarities with the three embeddings. We do not present them due to the space limitation.

- By setting the prototype number to a fairly large value (e.g. $N_w = 10$), the model tends to learn more fine-grained separations of the word's different meanings. For example, we can observe from Table 2 that the second and the third prototypes of the word *bank* seem similar to each other as both of them denote a financial concept. However, there are subtle differences between them: the second prototype represents concrete banks, such as citibank and jpmorgan, whereas the third one denotes what is done in the banks, since it is most similar to the words *stock*, *exchange*, and *banking*. We believe that such a fine-grained separation will bring more expressiveness to the multi-prototype word embeddings learned by our model.

4.3 Results on Word Similarity in Context Dataset

In this subsection, we give quantitative comparison of our method with conventional word embedding models, including Word2Vec and EHModel (Huang et al., 2012).

The task we perform is the word similarity evaluation introduced in (Huang et al., 2012). Word similarity tasks evaluate a model's performance by calculating the Spearman's rank correlation between the ranking of ground truth similarity scores (given by human labeling) and the ranking based on the similarity scores produced by the model. Traditional word similarity tasks such as WordSim353 (Finkelstein et al., 2001) and RG (Rubenstein and Goodenough, 1965) are not suitable for evaluating multi-prototype models since there is neither enough number of polysemous words in these datasets nor context information to infer the prototype index. To address this issue, a new word similarity benchmark dataset including context information was released in (Huang et al., 2012). Following (Luong et al., 2013), we use SCWS to denote this dataset. Similar to WordSim353, SCWS contains some word pairs (concretely, 2003 pairs), together with human labeled similarity scores for these word pairs. What makes SCWS different from WS353 is that the words in SCWS are contained in sentences, i.e., there are 2003 pairs of sentences containing these words, while words in WS353 are not associated with sentences. Therefore, the human labeled scores are based on the meanings of the words in the context. Given the presence of the context, the word similarity scores, especially those scores depending on polysemous words, are much more convincing for evaluating different models' performance in our experiments.

Then, we propose a method to compute the similarity score for a pair of words $\{w_1, w_2\}$ in the context based on our model. Suppose that the context of a word w is defined as all its neighboring words in a $T+1$ sized window, where w is the central word in the window. We use $Context_1 = \{c_1^1, c_2^1, \cdots, c_T^1\}$ and $Context_2 = \{c_1^2, c_2^2, \cdots, c_T^2\}$ to separately denote the context of w_1 and w_2, where c_t^1 and c_t^2 are the t-th context word of w_1 and w_2, respectively. According to Bayesian rule, we have that for $i \in \{1, 2, \cdots, N_{w_1}\}$:

$$\begin{aligned} P(h_{w_1} = i | Context_1, w_1) &\propto P(Context_1 | h_{w_1} = i, w_1) P(h_{w_1} = i | w_1) \\ &= \prod_{t=1}^{T} P(c_t^1 | h_{w_1} = i, w_1) P(h_{w_1} = i | w_1), \end{aligned} \tag{11}$$

where $P(c_t^1|h_{w_1}=i,w_1)$ can be calculated by equation (4) and $P(h_{w_1}=i|w_1)$ is the prior probability we learned in the EM algorithm (equation (8)). The similar equation holds for word w_2 as well. Here we make an assumption that the context words are independent with each other given the central word. Furthermore, suppose that the most likely prototype index for w_1 given $Context_1$ is $\hat{h}_{w_1}$, i.e., we denote $\hat{h}_{w_1} = \arg\max_{i\in\{1,2,\cdots,N_{w_1}\}} P(h_{w_1}=i|Context_1,w_1)$. Similarly, $\hat{h}_{w_2}$ is denoted as the corresponding meaning for w_2.

We calculate two similarity scores base on equation (11), i.e., MaxSim Score and WeightedSim Score:

$$MaxSim(w_1,w_2) = Cosine(V_{w_1,\hat{h}_{w_1}}, V_{w_2,\hat{h}_{w_2}}), \tag{12}$$

$$WeightedSim(w_1,w_2) = \sum_{i=1}^{N_{w_1}}\sum_{j=1}^{N_{w_2}} P(h_{w_1}=i|Context_1,w_1)P(h_{w_2}=j|Context_2,w_2)Cosine(V_{w_1,i},V_{w_2,j}). \tag{13}$$

In the above similarity scores, $Cosine(x,y)$ denotes the cosine similarity score of vector x and y, and $V_{w,i} \in R^d$ is the embedding vector for the word w's i-th prototype.

The detailed experimental results are listed in Table 3, where ρ refers to the Spearman's rank correlation. The higher value of ρ indicates the better performance. The performance score of EHModel is borrowed from its original paper (Huang et al., 2012). For Word2Vec model, we use Hierarchical Huffman Tree rather than Negative Sampling to do the acceleration. Our **Model_M** uses the MaxSim score in testing and our **Model_W** uses the WeightedSim score. All of these models are run on the same aforementioned Wikipedia corpus, with the dimension of the embedding space to be 50.

From the table, we can observe that our **Model_W** (65.4%) outperforms the original Word2Vec model (61.7%), and achieves almost the same performance with the state-of-the-art EHModel (65.7%). Among the two similarity measures used in testing, the WeightedSim score performs better (65.4%) than the MaxSim score (63.6%), indicating that the overall consideration of all prototype probabilities are more effective.

Model	$\rho \times 100$
Word2Vec	61.7
EHModel	65.7
Model_M	63.6
Model_W	65.4

Table 3: Spearman's rank correlations on SCWS dataset.

5 Conclusion

In this paper, we introduce a fast and probabilistic method to generate multiple embedding vectors for polysemous words, based on the continuous Skip-Gram model. On one hand, our method addresses the drawbacks of the original Word2Vec model by leveraging multi-prototype word embeddings; on the other hand, our model yields much less complexity without performance loss compared with the former clustering based multi-prototype algorithms. In addition, the probabilistic framework of our method avoids the extra efforts to perform clustering besides training word embeddings.

For the future work, we plan to apply the proposed probabilistic framework to other neural network language models. Moreover, we would like to apply the multi-prototype embeddings to more real world text mining tasks, such as information retrieval and knowledge mining, with the expectation that the multi-prototype embeddings produced by our model will benefit these tasks.

6 Appendix

6.1 Derivations for the EM Algorithm

We give detailed derivations for the updating rules used in the EM algorithms in Section 3.2., i.e., the derivations for equation (6), (7), and (8).

According to the properties of conditional probability, we have

$$\begin{aligned}\hat{\gamma}_{m,k} = P(\gamma_{m,k}=1|\mathbb{X},\Theta) &= \frac{P(\gamma_{m,k}=1,\mathbb{X}|\Theta)}{\sum_{i=1}^{N_w} P(\gamma_{m,i}=1,\mathbb{X}|\Theta)} \\ &= \frac{P(\gamma_{m,k}=1|\Theta)P(\mathbb{X}|\gamma_{m,k}=1,\Theta)}{\sum_{i=1}^{N_w} P(\gamma_{m,i}=1|\Theta)P(\mathbb{X}|\gamma_{m,i}=1,\Theta)} \\ &= \frac{\pi_k P(w_m|h_m=k,w)}{\sum_{i=1}^{N_w}\pi_i P(w_m|h_m=i,w)}.\end{aligned} \tag{14}$$

From equation (7), the Q function is calculated as:

$$\begin{aligned}Q(\theta,\theta^{(i)}) &= E[\log P(\mathbb{X},\Gamma|\Theta)|\Theta^{(i)}] \\ &= \sum_{k=1}^{N_w}\sum_{m=1}^{M} E[\gamma_{m,k}|\Theta^{(i)}]\big(\log\pi_k + \sum_{t=1}^{L_{w_m}} \log\varsigma(b_t^{(w_m)} U_{w_m,t}^T V_{w,k})\big) \\ &= \sum_{k=1}^{N_w}\sum_{m=1}^{M} \hat{\gamma}_{m,k}\big(\log\pi_k + \sum_{t=1}^{L_{w_m}} \log\varsigma(b_t^{(w_m)} U_{w_m,t}^T V_{w,k})\big) \\ &= \sum_{m=1}^{M}\sum_{k=1}^{N_w} \hat{\gamma}_{m,k}\big(\log\pi_k + \sum_{t=1}^{L_{w_m}} \log\varsigma(b_t^{(w_m)} U_{w_m,t}^T V_{w,k})\big).\end{aligned} \tag{15}$$

Then we give the derivations for π's updating rule, i.e., equation (8). Note that for parameters π_k, $k=\{1,2,\cdots,N_w\}$, they need to satisfy the condition that $\sum_{k=1}^{N_w}\pi_k = 1$. From equation (7) (or equivalently equation (15)), the loss with regard to π is:

$$L_{[\pi]} = \sum_{m=1}^{M}\sum_{k=1}^{N_w} \hat{\gamma}_{m,k}\log\pi_k + \lambda\big(\sum_{k=1}^{N_w}\pi_k - 1\big), \tag{16}$$

where λ is the Language multiplier. Letting $\frac{\partial L_{[\pi]}}{\partial \pi} = 0$, we obtain:

$$\pi_k \propto \sum_{m=1}^{M} \hat{\gamma}_{m,k}. \tag{17}$$

Further considering the fact that $\sum_{k=1}^{N_w}\sum_{m=1}^{M}\hat{\gamma}_{m,k} = M$, we have $\pi_k = \frac{\sum_{m=1}^{M}\hat{\gamma}_{m,k}}{M}$.

Learning Task-specific Bilexical Embeddings

Abstract

We present a method that learns bilexical operators over distributional representations of words and leverages supervised data for a linguistic relation. The learning algorithm exploits low-rank bilinear forms and induces low-dimensional embeddings of the lexical space tailored for the target linguistic relation. An advantage of imposing low-rank constraints is that prediction is expressed as the inner-product between low-dimensional embeddings, which can have great computational benefits. In experiments with multiple linguistic bilexical relations we show that our method effectively learns using embeddings of a few dimensions.

1 Introduction

We address the task of learning functions that compute compatibility scores between pairs of lexical items under some linguistic relation. We refer to these functions as bilexical operators. As an instance of this problem, consider learning a model that predicts the probability that an adjective modifies a noun in a sentence. In this case, we would like the bilexical operator to capture the fact that some adjectives are more compatible with some nouns than others. For example, a bilexical operator should predict that the adjective *electronic* has high probability of modifying the noun *device* but little probability of modifying the noun *case*.

Bilexical operators can be useful for multiple NLP applications. For example, they can be used to reduce ambiguity in a parsing task. Consider the following sentence extracted from a weblog: *Vynil can be applied to electronic devices and cases, wooden doors and furniture and walls*. If we want to predict the dependency structure of this sentence we need to make several decisions. In particular, the parser would need to decide (1) Does *electronic* modify *devices*? (2) Does *electronic* modify *cases*? (3) Does *wooden* modify *doors*? (4) Does *wooden* modify *furniture*? Now imagine that in the corpus used to train the parser none of these nouns have been observed, then it is unlikely that these attachments can be resolved correctly. However, if an accurate noun-adjective bilexical operator were available most of the uncertainty could be resolved. This is because a good bilinear operator would give high probability to the pairs *electronic-device*, *wooden-door*, *wooden-furniture* and low probability to the pair *electronic-case*.

The simplest way of inducing a bilexical operator is to learn it from a training corpus. That is, assuming that we are given some data annotated with a linguistic relation between a modifier and a head (e.g. adjective and noun) we can simply build a maximum likelihood estimator for $\Pr(m \mid h)$ by counting the occurrences of modifiers and heads under the target relation. For example, we could consider learning bilexical operators from sentences annotated with dependency structures. Clearly, this model can not generalize to head words not present in the training data.

To mitigate this we could consider bilexical operators that can exploit lexical embeddings, such as a distributional vector-space representation of words. In this case, we assume that for every word we can compute an n-dimensional vector space representation $\phi(w) \rightarrow \mathbb{R}^n$. This representation typically captures distributional features of the context in which the lexical item can occur. The key point is that

Proceedings of COLING 2014, the 25th International Conference on Computational Linguistics: Technical Papers, pages 161–171, Dublin, Ireland, August 23-29 2014.

we do not need a supervised corpus to compute the representation. All we need is a large textual corpus to compute the relevant statistics. Once we have the representation we can exploit operations in the induced vector space to define lexical compatibility operators. For example we could define a bilexical operator as:

$$\Pr(m \mid h) = \frac{\exp\{\langle \phi(m), \phi(h) \rangle\}}{\sum_{m'} \exp\{\langle \phi(m'), \phi(h) \rangle\}} \quad (1)$$

where $\langle \phi(x), \phi(y) \rangle$ denotes the inner-product. Alternatively, given an initial high-dimensional distributional representation computed from a large textual corpus we could first induce a projection to a lower k dimensional space by performing truncated singular value decomposition. The idea is that the lower dimensional representation will be more efficient and it will better capture the relevant dimensions of the distributional representation. The bilexical operator would then take the form of:

$$\Pr(m|h) = \frac{\exp\{\langle U\phi(m), U\phi(h) \rangle\}}{\sum_{m'} \exp\{\langle U\phi(m'), U\phi(h) \rangle\}} \quad (2)$$

where $U \in \mathbb{R}^{k \times n}$ is the projection matrix obtained via SVD. The advantage of this approach is that as long as we can estimate the distribution of contexts of words we can compute the value of the bilexical operator. However, this approach has a clear limitation: to design a bilinear operator for a target linguistic relation we must design the appropriate distributional representation. Moreover, there is no clear way of exploiting a supervised training corpus.

In this paper we combine both the supervised and distributional approaches and present a learning algorithm for inducing bilexical operators from a combination of supervised and unsupervised training data. The main idea is to define bilexical operators using bilinear forms over distributional representations: $\phi(x)^\top W \phi(y)$, where $W \in \mathbb{R}^{n \times n}$ is a matrix of parameters. We can then train our model on the supervised training corpus via conditional maximum-likelihood estimation. To induce a low-dimensional representation, we first observe that the implicit dimensionality of the bilinear form is given by the rank of W. In practice controlling the rank of W can result in important computational savings in cases where one evaluates a target word x against a large number of candidate words y: this is because we can project the representations $\phi(x)$ and $\phi(y)$ down to the low-dimensional space where evaluating the function is simply an inner-product. This setting is in fact usual, for example for lexical retrieval applications (e.g. given a noun, sort all adjectives in the vocabulary according to their compatibility), or for parsing (where one typically evaluates the compatibility between all pairs of words in a sentence).

Consequently with these ideas, we propose to regularize the maximum-likelihood estimation using a nuclear norm regularizer that serves as a convex relaxation to the rank function. To minimize the regularized objective we make use of an efficient iterative proximal method that involves computing the gradient of the function and performing singular value decompositions.

We test the proposed algorithm on several linguistic relations and show that it can predict modifiers for unknown words more accurately than the unsupervised approach. Furthermore, we compare different types of regularizers for the bilexical operator W, and observe that indeed the low-rank regularizer results in the most efficient technique at prediction time.

In summary, the main contributions of this paper are:

- We propose a supervised framework for learning bilexical operators over distributional representations, based on learning bilinear forms W.
- We show that we can obtain low-dimensional compressions of the distributional representation by imposing low-rank constraints to the bilinear form. Combined with supervision, this results in lexical embeddings tailored for a specific bilexical task.
- In experiments, we show that our models generalize well to unseen word pairs, using only a few dimensions, and outperforming standard unsupervised distributional approaches. We also present an application to prepositional phrase attachment.

2 Bilinear Models for Bilexical Predictions

2.1 Definitions

Let $\mathcal{V}$ be a vocabulary, and let $x \in \mathcal{V}$ denote a word. Let $\mathcal{H} \subseteq \mathcal{V}$ be a set of head words, and $\mathcal{M} \subseteq \mathcal{V}$ be a set of modifier words. In the noun-adjective relation example, $\mathcal{H}$ is the set of nouns and $\mathcal{M}$ is the set of adjectives.

The task is as follows. We are given a training set of l tuples $\mathcal{D} = \{(m,h)^1, \ldots, (m,h)^l\}$, where $m \in \mathcal{M}$ and $h \in \mathcal{H}$ and we want to learn a model of the conditional distribution $\Pr(m \mid h)$. We want this model to perform well on all head-modifier pairs. In particular we will test the performance of the model on heads that do not appear in $\mathcal{D}$.

We assume that we are given access to a distributional representation function $\phi : \mathcal{V} \rightarrow \mathbb{R}^n$, where $\phi(x)$ is the n-dimensional representation of x. Typically, this function is computed from an unsupervised corpus. We use $\phi(x)_{[i]}$ to refer to the i-th coordinate of the vector.

2.2 Bilinear Model

Our model makes use of the bilinear form $W : \mathbb{R}^n \times \mathbb{R}^n \rightarrow \mathbb{R}$, where $W \in \mathbb{R}^{n \times n}$, and evaluates as $\phi(m)^\top W \phi(h)$. We define the bilexical operator as:

$$\Pr(m \mid h) = \frac{\exp\left\{\phi(m)^\top W \phi(h)\right\}}{\sum_{m' \in \mathcal{M}} \exp\left\{\phi(m')^\top W \phi(h)\right\}} \tag{3}$$

Note that the above model is nothing more than a conditional log-linear model defined over n^2 features $f_{i,j}(m,h) = \phi(m)_{[i]}\phi(h)_{[j]}$ (this can be seen clearly when we write the bilinear form as $\sum_{i=1}^n \sum_{j=1}^n f_{i,j}(m,h) W_{i,j}$. The reason why it is useful to regard W as a matrix will become evident in the next section.

Before moving to the next section, let us note that the unsupervised SVD model in Eq. (2) is also a bilinear model as defined here. This can be seen if we set $W = UU^\top$, which is a bilinear form of rank k. The key difference is in the way W is learned using supervision.

3 Learning Low-rank Bilexical Operators

3.1 Low-rank Optimization

Given a training set $\mathcal{D}$ and a feature function $\phi(x)$ we can do standard conditional max-likelihood optimization and minimize the negative of the log-likelihood function, $\log \Pr(\mathcal{D})$:

$$\sum_{(m,h) \in \mathcal{D}} \phi(m)^\top W \phi(h) - \log \sum_{m' \in \mathcal{M}} \exp\left\{\phi(m')^\top W \phi(h)\right\} \tag{4}$$

We would like to control the complexity of the learned model by including some regularization penalty. Moreover, like in the low-dimensional unsupervised approach we want our model to induce a low-dimensional representation of the lexical space. The first observation is that the bilinear form computes a weighted inner product in some space. Consider the singular value decomposition: $W = U\Sigma V$. We can write the bilinear form as: $[\phi(m)^\top U]\ \Sigma\ [V\phi(h)]$, thus we can regard $\tilde{m} = \phi(m)^\top U$ as a projection of m and $\tilde{h} = V\phi(h)$ as a projection of h. Then the bilinear form can be written as: $\sum_{i=1}^n \Sigma_{[i,i]}\ \tilde{m}_{[i]}\ \tilde{h}_{[i]}$. The rank of W defines the dimensionality of the induced space. It is easy to see that if W has rank k it can be factorized as $U\Sigma V$ where $U \in \mathbb{R}^{n \times k}$ and $V \in \mathbb{R}^{k \times n}$.

Since the rank of W determines the dimensionality of the induced space, it would be reasonable to add a rank minimization penalty in the objective in (4). Unfortunately this would lead to a non-convex regularized objective. Instead, we propose to use as a regularizer a convex relaxation of the rank function, the nuclear norm $\|W\|_*$ (the ℓ_1 norm of the singular values of W). Putting it all together, our learning algorithm minimizes:

$$\sum_{(m,h) \in \mathcal{D}} -\log \Pr(m \mid h)) + \lambda \|W\|_* \tag{5}$$

Here λ is a constant that controls the trade-off between fitting the data and the complexity of the model. This objective is clearly convex since both the objective and the regularizer are convex. To minimize it we use the a proximal gradient algorithm which is described next.

3.2 A Proximal Algorithm for Bilexical Operators

We now describe the learning algorithm that we use to induce the bilexical operators from training data. We are interested in minimizing the objective (5), or in fact a more general version where we can replace the regularizer $\|W\|_*$ by standard ℓ_1 or ℓ_2 penalties. For any convex regularizer $r(W)$ (namely ℓ_1, ℓ_2 or the nuclear norm) the objective in (5) is convex. Our learning algorithm is based on a simple optimization scheme known as *forward-backward splitting (FOBOS)* (Duchi and Singer, 2009).

This algorithm has convergence rates in the order of $1/\epsilon^2$, which we found sufficiently fast for our application. Many other optimization approaches are possible, for example one could express the regularizer as a convex constraint and utilize a projected gradient method which has a similar convergence rate. Proximal methods are slightly more simple to implement and we chose the proximal approach.

The FOBOS algorithm works as follows. In a series of iterations $t = 1 \dots T$ compute parameter matrices W_t as follows:

1. Compute the gradient of the negative log-likelihood, and update the parameters

$$W_{t+0.5} = W_t - \eta_t g(W_t)$$

   where $\eta_t = \frac{c}{\sqrt{t}}$ is a step size and $g(W_t)$ is the gradient of the loss at W_t.

2. Update $W_{t+0.5}$ to take into account the regularization penalty $r(W)$, by solving

$$W_{t+1} = \operatorname*{argmin}_W ||W_{t+0.5} - W||_2^2 + \eta_t \lambda r(W)$$

   For the regularizers we consider, this step is solved using the *proximal operator* associated with the regularizer. Specifically:

   - For ℓ_1 it is a simple thresholding:

$$W_{t+1}(i,j) = \text{sign}(W_{t+0.5}(i,j)) \cdot \max(W_{t+0.5}(i,j) - \eta_t \lambda, 0)$$

   - For ℓ_2 it is a simple scaling:

$$W_{t+1} = \frac{1}{1 + \eta_t \lambda} W_{t+0.5}$$

   - For nuclear-norm, perform SVD thresholding. Compute the SVD to write $W_{t+0.5} = USV^\top$ with S a diagonal matrix and U, V orthogonal matrices. Denote by σ_i the i-th element on the diagonal of S. Define a new matrix $\bar{S}$ with diagonal elements $\bar{\sigma}_i = \max(\sigma_i - \eta_t \lambda, 0)$. Then set

$$W_{t+1} = U\bar{S}V^\top$$

Optimizing a bilinear model using nuclear-norm regularization involves the extra cost of performing SVD of W at each iteration. In our experiments the dimension of W was $2,000 \times 2,000$ and computing SVD was fast, much faster than computing the gradient, which dominates the cost of the algorithm. The optimization parameters of the method are the regularization constant λ, the step size constant c and the number of iterations T. In our experiments we ran a range of λ and c values for 200 iterations, and used a validation set to pick the best configuration.

4 Related Work

Research in learning representations for natural language processing can be broadly classified into two different paradigms based on the learning setting: unsupervised representation learning and semi-supervised representation learning. Unsupervised representation learning does not require any supervised training data, while semi-supervised representation learning requires the presence of supervised training data with the potential advantage that it can adapt the representation to the task at hand.

Unsupervised approaches to learning representations mainly involve representations that are learned not for a specific task, rather a variety of tasks. These representations rely more on the property of abstractness and generalization. Further, unsupervised approaches can be roughly categorized into (a) clustering-based approaches that make use of clusters induced using a notion of distributed similarity, such as the method by Brown et al. (1992); (b) neural-network-based representations that focus on learning multilayer neural network in a way to extract features from the data (Morin and Bengio, 2005; Mnih and Hinton, 2007; Bengio and Sénécal, 2008; Mnih and Hinton, 2009); (c) pure distributional approaches that principally follow the distributional assumption that the words which share a set of contexts are similar (Sahlgren, 2006; Turney and Pantel, 2010; Dumais et al., 1988; Landauer et al., 1998; Lund et al., 1995; Väyrynen et al., 2007).

We also induce lexical embeddings, but in our case we employ supervision. That is, we follow a semi-supervised paradigm for learning representations. Semi-supervised approaches initially learn representations typically in an unsupervised setting and then induce a representation that is jointly learned for the task with a labeled corpus. A high-dimensional representation is extracted from unlabeled data, while the supervised step compresses the representation to be low-dimensional in a way that favors the the task at hand.

Collobert and Weston (2008) present a neural network language model, where given a sentence, it performs a set of language processing tasks (from part of speech tagging, chunking, extracting named entity, extracting semantic roles and decisions on the correctness of the sentence) by using the learned representations. The representation itself is extracted from unlabeled corpora, while all the other tasks are jointly trained on labeled corpus.

Socher et al. (2011) present a model based on recursive neural networks that learns vector space representations for words, multi-word phrases and sentences. Given a sentence with its syntactic structure, their model assings vector representations to each of the lexical tokens of the sentence, and then traverses the syntactic tree bottom-up, such that at each node a vector representation of the corresponding phrase is obtained by composing the vectors associated with the children.

Bai et al. (2010) use a technique similar to ours, using bilinear forms with low-rank constraints. In their case, they explicitly look for a low-rank factorization of the matrix, making their optimization non-convex. As far as we know, ours is the first convex formulation, where we employ a relaxation of the rank (i.e. the nuclear norm) to make the objective convex. They apply the method to document ranking, and thus optimize a max-margin ranking loss. In our application to bilexical models, we perform conditional max-likelihood estimation. Hutchinson et al. (2013) propose an explicitly sparse and low-rank maximum-entropy language model. The sparse plus low rank setting is learned in such a way that the low rank component learns the regularities in the training data and the sparse component learns the exceptions like multiword expressions etc.

Chechik et al. (2010) also learned bilinear operators using max-margin techniques, with pairwise similarity as supervision, but they did not consider low-rank constraints.

One related area where bilinear operators are used to induce embeddings is distance metric learning. Weinberger and Saul (2009) used large-margin nearest neighbor methods to learn a non-sparse embedding, but these are computationally intensive and might not be suitable for large-scale tasks in NLP.

5 Experiments on Syntactic Relations

We conducted a set of experiments to test the ability of our algorithm to learn bilexical operators for several linguistic relations. As supervised training data we use the gold standard dependencies of the WSJ training section of the Penn Treebank (Marcus et al., 1993). We consider the following relations:

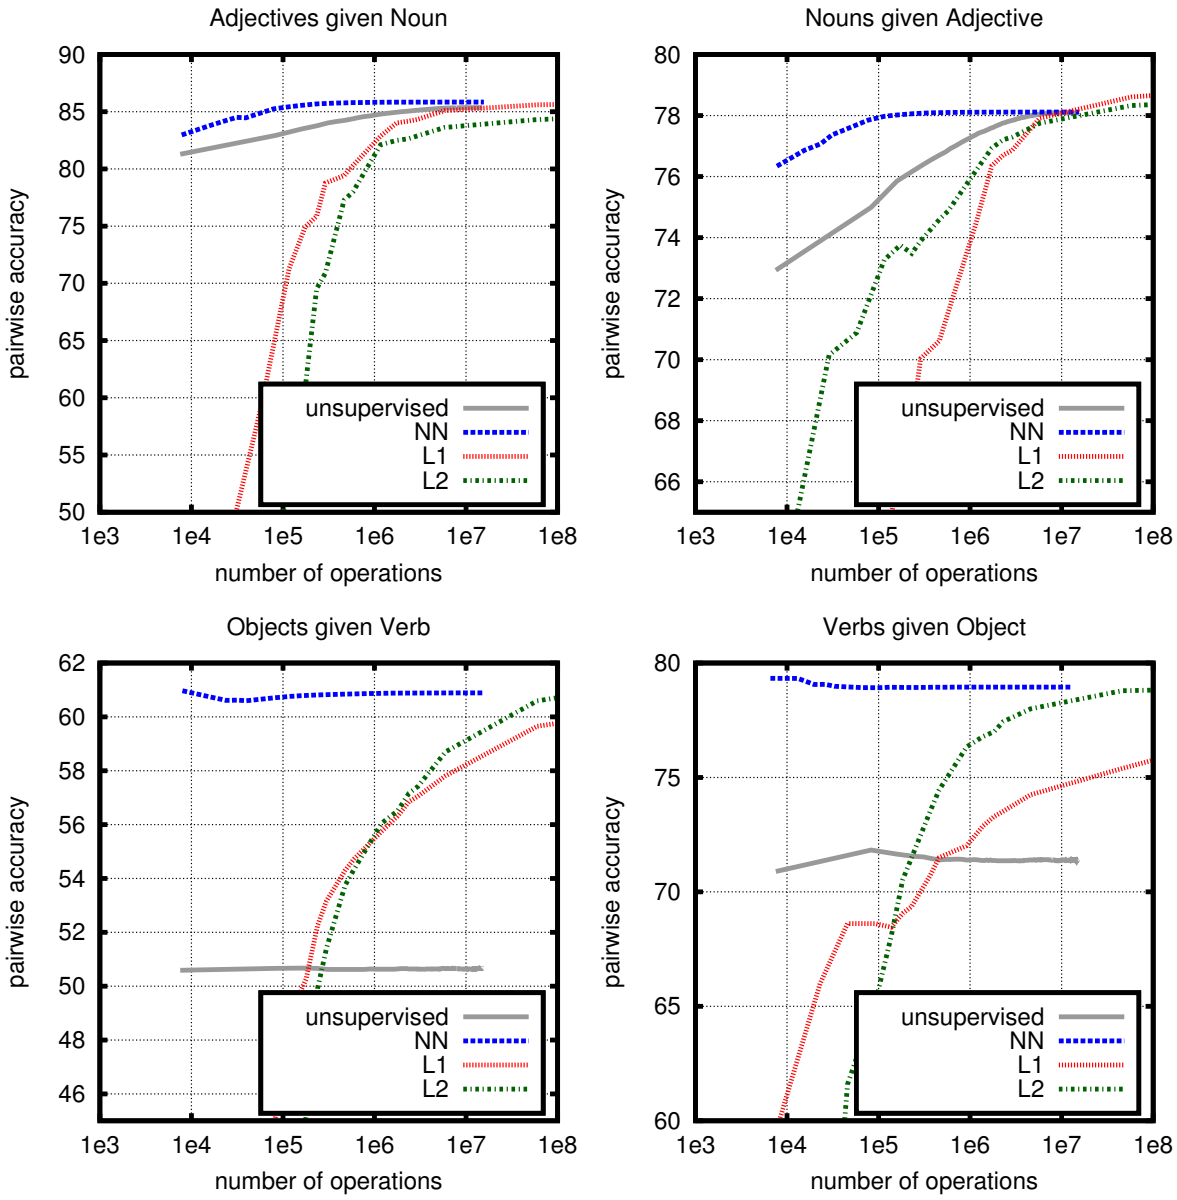

Figure 1: Pairwise accuracy with respect to the number of double operations required to compute the distribution over modifiers for a head word. Plots for noun-adjective and verb-object relations, in both directions.

- Noun-Adjective: we model the distribution of adjectives given a noun; and a separate distribution of nouns given an adjective.
- Verb-Object: we model the distribution of object nouns given a verb; and a separate distribution of verbs given an object.
- Prepositions: in this case we consider bilexical operators associated with a preposition, which model the probability of a head noun or verb above the preposition *given* the noun below the preposition. We present results for prepositional relations given by "with", "for", "in" and "on".

The distributional representation $\phi(x)$ was computed using the BLLIP corpus (Charniak et al., 2000). We compute a bag-of-words representation for the context of each lexical item, that is $\phi(w)_{[i]}$ corresponds to the frequency of word i appearing in the context of w. We use a context window of size 10 and restrict our bag-of-words vocabulary to contain only the 2,000 most frequent words present in the corpus. Vectors were normalized.

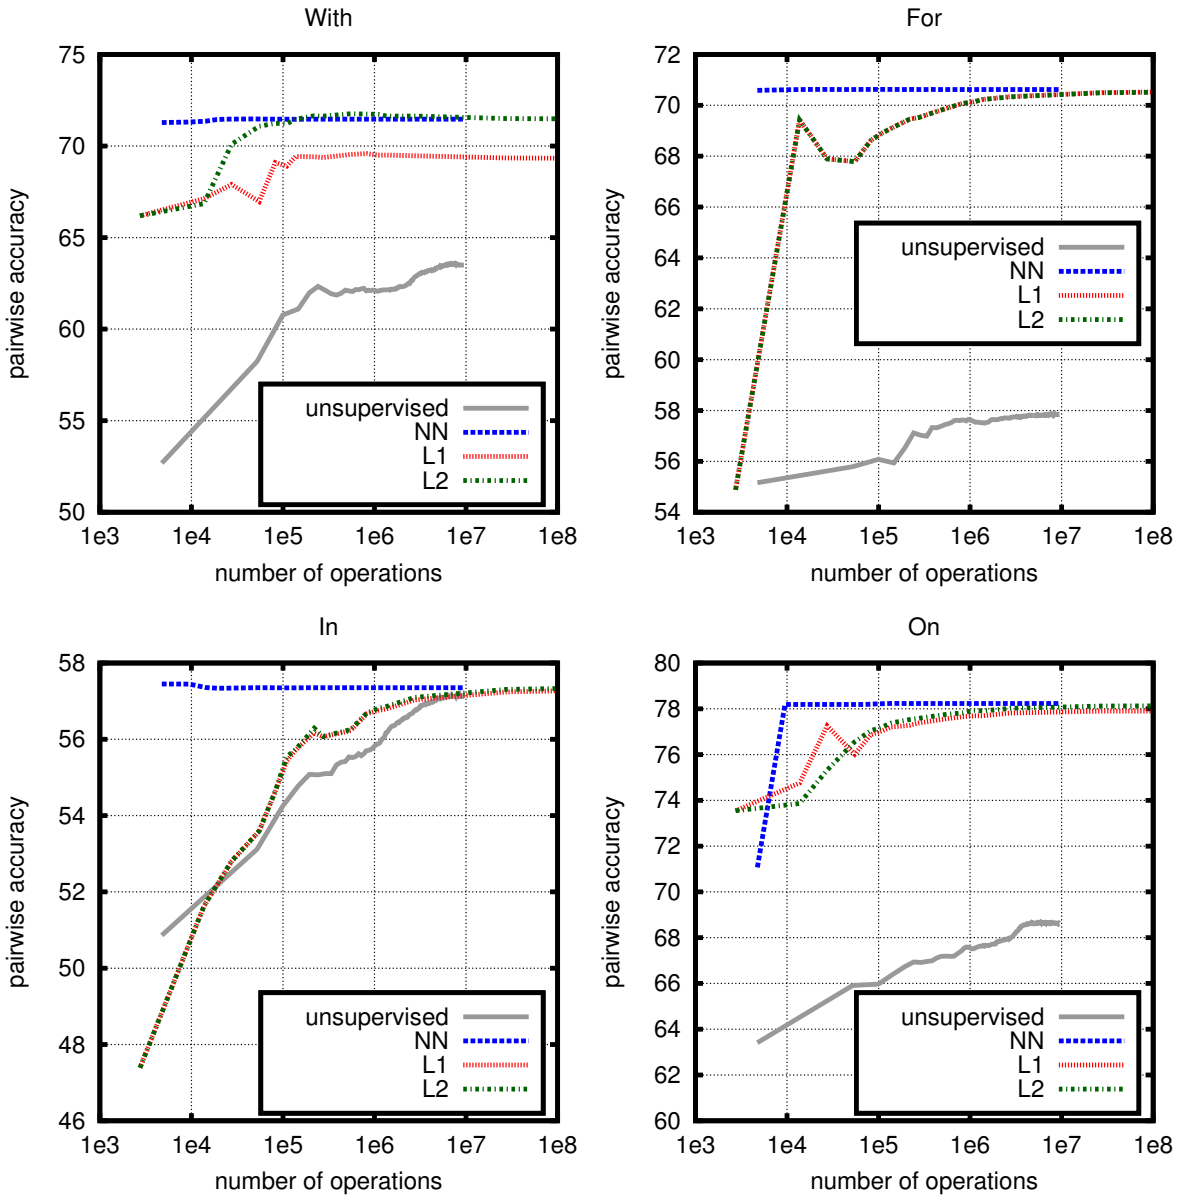

Figure 2: Pairwise accuracy with respect to the number of double operations required to compute the distribution over modifiers for a head word. Plots for four prepositional relations: with, for, in, on. The distributions are of verbs and objects above the preposition given the noun below the preposition.

To test the performance of our algorithm for each relation we partition the set of heads into a training and a test set, 60% of the heads are use for training, 10% of the heads are used for validation and 30% of the heads are used for testing. Then, we consider all observed modifiers in the data to form a vocabulary of modifier words. The goal of this task is to learn conditional distribution over all these modifers given a head word without context. In our experiments, the number of modifiers per relation ranges from 2,500 to 7,500 words. For each head word, we create a list of *compatible* modifiers from the annotated data, by taking all modifiers that occur at least once with the head. Hence, for each head the set of all modifiers is partitioned into compatible and non-compatible. For testing, we measure a *pairwise accuracy*, the percentage of compatible/non-compatible pairs of modifiers where the former obtains higher probability. Let us stress that none of the test head words has been observed in training, while the list of modifiers is the same for training, validation and testing.

We compare the performance of the bilexical model trained with nuclear norm regularization (NN) with other regularization penalties (L1 and L2). We also compare these supervised methods with an

Noun	Predicted Adjectives
president	executive, senior, chief, frank, former, international, marketing, assistant, annual, financial
wife	former, executive, new, financial, own, senior, old, other, deputy, major
shares	annual, due, net, convertible, average, new, high-yield, initial, tax-exempt, subordinated
mortgages	annualized, annual, three-month, one-year, average, six-month, conventional, short-term, higher, lower
month	last, next, fiscal, first, past, latest, early, previous, new, current
problem	new, good, major, tough, bad, big, first, financial, long, federal
holiday	new, major, special, fourth-quarter, joint, quarterly, third-quarter, small, strong, own

Table 1: 10 most likely adjectives for some test nouns.

unsupervised model: a low-dimensional SVD model as in Eq. (2), which corresponds to an inner product as in Eq. (1) when all dimensions are considered.

To report performance, we measure pairwise accuracy with respect to the capacity of the model in terms of number of active parameters. To measure the capacity of a model we consider the number of double operations that are needed to compute, given a head, the scores for all modifiers in the vocabulary (we exclude the exponentiations and normalization needed to compute the distribution of modifiers given a head, since this is a constant cost for all the models we compare, and is not needed if we only want to rank modifiers). Recall that the dimension of $\phi(x)$ is n, and assume that there are m total modifiers in the vocabulary. In our experiments $n = 2,000$ and m ranges from $2,500$ to $7,500$. The correspondances with operations are:

- Assume that the L1 and L2 models have k non-zero weights in W. Then the number of operations to compute a distribution is km.
- Assume that the NN and the unsupervised models have rank k. We assume that the modifier vectors are alredy projected down to k dimensions. For a new head, one needs to project it and perform m inner products, hence the number of operations is $kn + km$.

Figure 1 shows the performance of models for noun-adjective and verb-object relations, while Figure 2 shows plots for prepositional relations. [1] The first observation is that supervised approaches outperform the unsupervised approach. In cases such as noun-adjetive relations the unsupervised approach performs close to the supervised approaches, suggesting that the pure distributional approach can sometimes work. But in most relations the improvement obtained by using supervision is very large. When comparing the type of regularizer, we see that if the capacity of the model is unrestricted (right part of the curves), all models tend to perform similarly. However, when restricting the size, the nuclear-norm model performs much better. Roughly, 20 hidden dimensions are enough to obtain the most accurate performances (which result in $\sim 140,000$ operations for initial representaions of $2,000$ dimensions and $5,000$ modifier candidates). As an example of the type of predictions, Table 1 shows the most likely adjectives for some test nouns.

6 Experiments on PP Attachment

We now switch to a standard classification task, prepositional phrase attachment, that we frame as a bilexical prediction task. We start from the formulation of the task as a binary classification problem by Ratnaparkhi et al. (1994): given a tuple $x = \langle v, o, p, n \rangle$ consisting of a verb v, noun object o, preposition

[1] To obtain curves for each model type with respect to a range of number of operations, we first obtained the best model on validation data and then forced it to have at most k non-zero features or rank k by projecting, for a range of k values.

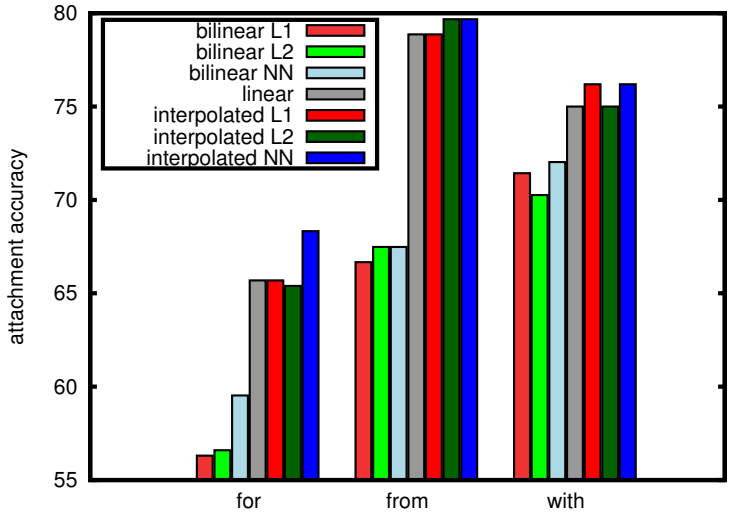

Figure 3: Attachment accuracies of linear, bilinear and interpolated models for three prepositions.

p and noun n, decide if the prepositional phrase p-n attaches to v ($y = \text{V}$) or to o ($y = \text{O}$). For example, in $\langle$ `meet,demand,for,products` $\rangle$ the correct attachment is O.

Ratnaparkhi et al. (1994) define a linear maximum likelihood model of the form $\Pr(y \mid x) = \exp\{\langle w, f(x,y)\rangle\} * Z(x)^{-1}$, where $f(x,y)$ is a vector of d features, w is a parameter vector in $\mathbb{R}^d$, and $Z(x)$ is the normalizer summing over $y = \{\text{V}, \text{O}\}$. Here we define a bilexical model of the form that uses a distributional representation ϕ:

$$\Pr(\text{V}|\langle v,o,p,n\rangle) = \frac{\exp\{\phi(v)^\top W^p_\text{V}\, \phi(n)\}}{Z(x)} \qquad \Pr(\text{O}|\langle v,o,p,n\rangle) = \frac{\exp\{\phi(o)^\top W^p_\text{O}\, \phi(n)\}}{Z(x)} \tag{6}$$

The bilinear model is parameterized by two matrices W_V and W_O per preposition, each of which captures the compatibility between nouns below a certain preposition and heads of V or O prepositional relations, respectively. Again $Z(x)$ is the normalizer summing over $y = \{\text{V}, \text{O}\}$, but now using the bilinear form. It is straighforward to modify the learning algorithm in Section 3 such that the loss is a negative log-likelihood for binary classification, and the regularizer considers the sum of norms of the model matrices.

We ran experiments using the data by Ratnaparkhi et al. (1994). We trained separate models for different prepositions, focusing on the prepositions that are more ambiguous: `for, from, with`. We compare to a linear "maxent" model following Ratnaparkhi et al. (1994) that uses the same feature set. Figure 3 shows the test results for the linear model, and bilinear models trained with L1, L2, NN regularization penalties. The results of the bilinear models are significantly below the accuracy of the linear model, suggesting that some of the non-lexical features of the linear model (such as prior weighting of the two classes) might be difficult to capture by the bilinear model over lexical representations. To check if the bilinear model might complement the linear model or just be worse than it, we tested simple combinations based on linear interpolations. For a constant $\lambda \in [0,1]$ we define:

$$\Pr(y \mid x) = \lambda \Pr_\text{L}(y \mid x) + (1-\lambda) \Pr_\text{B}(y \mid x) \qquad . \tag{7}$$

We search for the best λ on the validation set, and report results of combining the linear model with each of the three bilinear models. Results are shown also in Figure 3. Interpolation models improve over linear models, though only the improvement for `for` is significant (2.6%). Future work should exploit finer combinations between standard linear features and distributional bilinear forms.

7 Conclusions

We have presented a model for learning bilexical operators that can leverage both supervised and unsupervised data. The model is based on exploiting bilinear forms over distributional representations. The

learning algorithm induces a low-dimensional representation of the lexical space by imposing low-rank constraints on the parameters of the bilinear form. By means of supervision, our model induces two low-dimensional lexical embeddings, one on each side of the bilexical linguistic relation, and computations can be expressed as an inner-product between the two embeddings. This factorized form of the model can have great computational advantages: in many applications one needs to evaluate the function multiple times for a fixed set of lexical items, for example in dependency parsing. Hence, one can first project the lexical items to their embeddings, and then compute all pairwise scores as inner-products. In experiments, we have shown that the embeddings we obtain in a number of linguistic relations can be modeled with a few hidden dimensions.

As future work, we would like to apply the low-rank approach to other model forms that can employ lexical embeddings, specially when supervision is available. For example, dependency parsing models, or models of predicate-argument structures representing semantic roles, exploit bilexical relations. In these applications, being able to generalize to word *pairs* that are not observed during training is essential.

We would also like to study how to combine low-rank bilexical operators, which in essence induce a task-specific representation of words, with other forms of features that capture class or contextual information. One desires that such combinations can preserve the computational advantages behind low-rank embeddings.

Abstract

In this paper, we propose to build large-scale sentiment lexicon from Twitter with a representation learning approach. We cast sentiment lexicon learning as a phrase-level sentiment classification task. The challenges are developing effective feature representation of phrases and obtaining training data with minor manual annotations for building the sentiment classifier. Specifically, we develop a dedicated neural architecture and integrate the sentiment information of text (e.g. sentences or tweets) into its hybrid loss function for learning sentiment-specific phrase embedding (**SSPE**). The neural network is trained from massive tweets collected with positive and negative emoticons, without any manual annotation. Furthermore, we introduce the Urban Dictionary to expand a small number of sentiment seeds to obtain more training data for building the phrase-level sentiment classifier. We evaluate our sentiment lexicon (**TS-Lex**) by applying it in a supervised learning framework for Twitter sentiment classification. Experiment results on the benchmark dataset of SemEval 2013 show that, TS-Lex yields better performance than previously introduced sentiment lexicons.

1 Introduction

A sentiment lexicon is a list of words and phrases, such as "*excellent*", "*awful*" and "*not bad*", each of which is assigned with a positive or negative score reflecting its sentiment polarity and strength. Sentiment lexicon is crucial for sentiment analysis (or opining mining) as it provides rich sentiment information and forms the foundation of many sentiment analysis systems (Pang and Lee, 2008; Liu, 2012; Feldman, 2013). Existing sentiment lexicon learning algorithms mostly utilize propagation methods to estimate the sentiment score of each phrase. These methods typically employ parsing results, syntactic contexts or linguistic information from thesaurus (e.g. WordNet) to calculate the similarity between phrases. For example, Baccianella et al. (2010) use the glosses information from WordNet; Velikovich et al. (2010) represent each phrase with its context words from the web documents; Qiu et al. (2011) exploit the dependency relations between sentiment words and aspect words. However, parsing information and the linguistic information from WordNet are not suitable for constructing large-scale sentiment lexicon from Twitter. The reason lies in that WordNet cannot well cover the colloquial expressions in tweets, and it is hard to have reliable tweet parsers due to the informal language style.

In this paper, we propose to build large-scale sentiment lexicon from Twitter with a representation learning approach, as illustrated in Figure 1. We cast sentiment lexicon learning as a phrase-level classification task. Our method contains two part: (1) a representation learning algorithm to effectively learn the continuous representation of phrases, which are used as features for phrase-level sentiment classification, (2) a seed expansion algorithm that enlarge a small list of sentiment seeds to collect training data for building the phrase-level classifier. Specifically, we learn sentiment-specific phrase embedding (**SSPE**), which is a low-dimensional, dense and real-valued vector, by encoding the sentiment information and

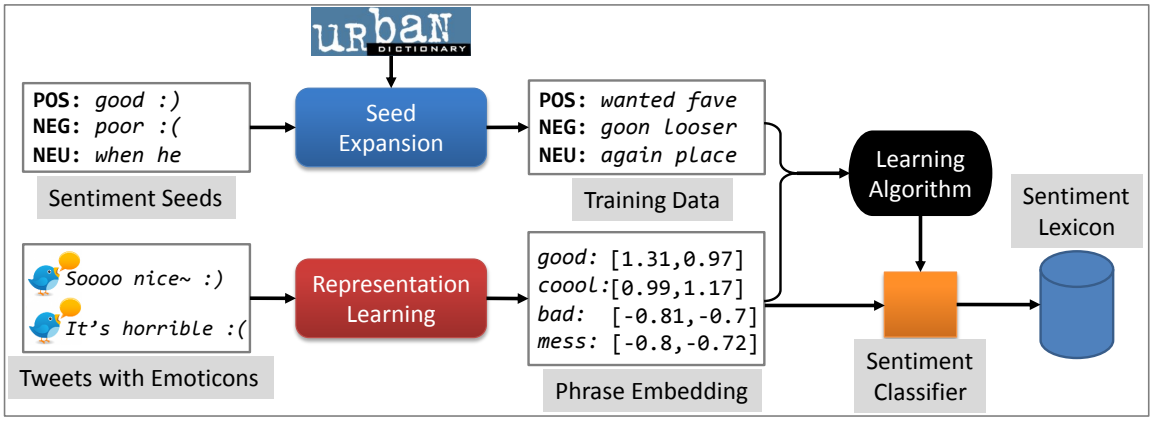

Figure 1: The representation learning approach for building Twitter-specific sentiment lexicon.

syntactic contexts into the continuous representation of phrases [1]. As a result, the nearest neighbors in the embedding space of SSPE are favored to have similar semantic usage as well as the same sentiment polarity. To this end, we extend the existing phrase embedding learning algorithm (Mikolov et al., 2013b), and develop a dedicated neural architecture with hybrid loss function to incorporate the supervision from sentiment polarity of text (e.g. tweets). We learn SSPE from tweets, leveraging massive tweets containing positive and negative emoticons as training set without any manual annotation. To obtain more training data for building the phrase-level sentiment classifier, we exploit the similar words from Urban Dictionary [2], which is a crowd-sourcing resource, to expand a small list of sentiment seeds. Finally, we utilize the classifier to predict the sentiment score of each phrase in the vocabulary of SSPE, resulting in the sentiment lexicon.

We evaluate the effectiveness of our sentiment lexicon (**TS-Lex**) by applying it in a supervised learning framework (Pang et al., 2002) for Twitter sentiment classification. Experiment results on the benchmark dataset of SemEval 2013 show that, TS-Lex yields better performance than previously introduced lexicons, including two large-scale Twitter-specific sentiment lexicons, and further improves the top-performed system in SemEval 2013 by feature combination. The quality of SSPE is also evaluated by regarding SSPE as the feature for sentiment classification of the items in existing sentiment lexicons (Hu and Liu, 2004; Wilson et al., 2005). Experiment results show that SSPE outperforms existing embedding learning algorithms. The main contributions of this work are as follows:

- To our best knowledge, this is the first work that leverages the continuous representation of phrases for building large-scale sentiment lexicon from Twitter;
- We propose a tailored neural architecture for learning the sentiment-specific phrase embedding from massive tweets selected with positive and negative emoticons;
- We report the results that our lexicon outperforms existing sentiment lexicons by applying them in a supervised learning framework for Twitter sentiment classification.

2 Related Work

In this section, we give a brief review about building sentiment lexicon and learning continuous representation of words and phrases.

2.1 Sentiment Lexicon Learning

Sentiment lexicon is a fundamental component for sentiment analysis, which can be built manually (Das and Chen, 2007), through heuristics (Kim and Hovy, 2004) or using machine learning algorithms (Turney, 2002; Li et al., 2012; Xu et al., 2013). Existing studies typically employ machine learning methods

[1] Word/unigram is also regarded as phrase in this paper.
[2] http://www.urbandictionary.com/

and adopt the propagation method to build sentiment lexicon. In the first step, a graph is built by regarding each item (word or phrase) as a node and their similarity as the edge. Then, graph propagation algorithms, such as pagerank (Esuli and Sebastiani, 2007), label propagation (Rao and Ravichandran, 2009) or random walk (Baccianella et al., 2010), are utilized to iteratively calculate the sentiment score of each item. Under this direction, parsing results, syntactic contexts or linguistic clues in thesaurus are mostly explored to calculate the similarity between items. Wiebe (2000) utilize the dependency triples from an existing parser (Lin, 1994). Qiu et al. (2009; 2011) adopt dependency relations between sentiment words and aspect words. Esuli and Sebastiani (2005) exploit the glosses information from Wordnet. Hu and Liu (2004) use the synonym and antonym relations within linguistic resources. Velikovich et al. (2010) represent words and phrases with their syntactic contexts within a window size from the web documents. Unlike the dominated propagation based methods, we explore the classification framework based on representation learning for building large-scale sentiment lexicon from Twitter.

To construct the Twitter-specific sentiment lexicon, Mohammad et al. (2013) use pointwise mutual information (PMI) between each phrase and hashtag/emoticon seed words, such as *#good*, *#bad*, *:)* and *:(*. Chen et al. (2012) utilize the Urban Dictionary and extract the target-dependent sentiment expressions from Twitter. Unlike Mohammad et al. (2013) that only capture the relations between phrases and sentiment seeds, we exploit the semantic and sentimental connections between phrases through phrase embedding and propose a representation learning approach to build sentiment lexicon.

2.2 Learning Continuous Representation of Word and Phrase

Continuous representation of words and phrases are proven effective in many NLP tasks (Turian et al., 2010). Embedding learning algorithms have been extensively studied in recent years (Bengio et al., 2013), and are dominated by the syntactic context based algorithms (Bengio et al., 2003; Collobert et al., 2011; Dahl et al., 2012; Huang et al., 2012; Mikolov et al., 2013a; Lebret et al., 2013; Sun et al., 2014). To integrate the sentiment information of text into the word embedding, Maas et al. (2011) extend the probabilistic document model (Blei et al., 2003) and predict the sentiment of a sentence with the embedding of each word. Labutov and Lipson (2013) learn task-specific embedding from an existing embedding and sentences with gold sentiment polarity. Tang et al. (2014) propose to learn sentiment-specific word embedding from tweets collected by emoticons for Twitter sentiment classification. Unlike previous trails, we learn sentiment-specific phrase embedding with a tailored neural network. Unlike Mikolov et al. (2013b) that only use the syntactic contexts of phrases to learn phrase embedding, we integrate the sentiment information of text into our method. It is worth noting that we focus on learning the continuous representation of words and phrases, which is orthogonal with Socher et al. (2011; 2013) that learn the compositionality of sentences.

3 Methodology

In this section, we describe our method for building large-scale sentiment lexicon from Twitter within a classification framework, as illustrated in Figure 1. We leverage the continuous representation of phrases as features, without parsers or hand-crafted rules, and automatically obtain the training data by seed expansion from Urban Dictionary. After the classifier is built, we employ it to predict the sentiment distribution of each phrase in the embedding vocabulary, resulting in the sentiment lexicon. To encode the sentiment information into the continuous representation of phrases, we extend an existing phrase embedding learning algorithm (Mikolov et al., 2013b) and develop a tailored neural architecture to learn sentiment-specific phrase embedding (**SSPE**), as described in subsection 3.1. To automatically obtain more training data for building the phrase-level sentiment classifier, we use the similar words from Urban Dictionary to expand a small list of sentiment seeds, as described in subsection 3.2.

3.1 Sentiment-Specific Phrase Embedding

Mikolov et al. (2013b) introduce Skip-Gram to learn phrase embedding based on the context words of phrases, as illustrated in Figure 2(a).

Given a phrase w_i, Skip-Gram maps it into its continuous representation e_i. Then, Skip-Gram utilizes

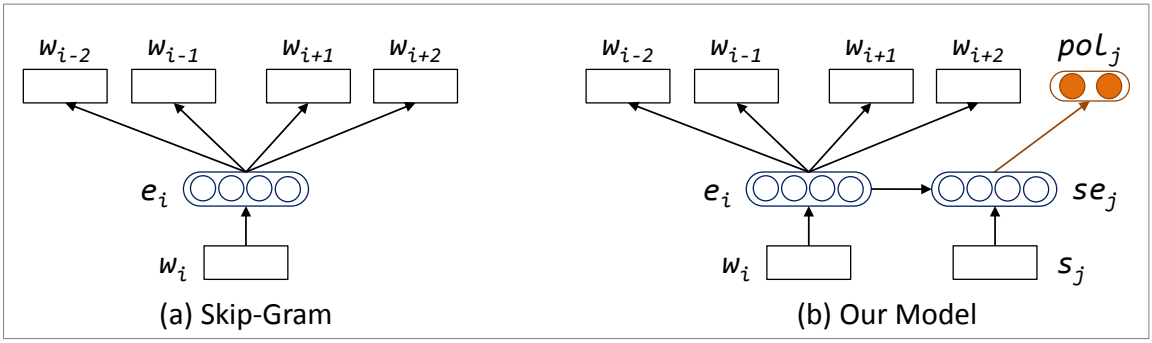

Figure 2: The traditional Skip-Gram model and our neural architecture for learning sentiment-specific phrase embedding (SSPE).

e_i to predict the context words of w_i, namely w_{i-2}, w_{i-1}, w_{i+1}, w_{i+2}, et al. Hierarchical softmax (Morin and Bengio, 2005) is leveraged to accelerate the training procedure because the vocabulary size of phrase table is typically huge. The objective of Skip-Gram is to maximize the average log probability:

$$f_{syntactic} = \frac{1}{T}\sum_{i=1}^{T}\sum_{-c\leq j\leq c, j\neq 0} log\ p(w_{i+j}|e_i) \tag{1}$$

where T is the occurrence of each phrase in the corpus, c is the window size, e_i is the embedding of the current phrase w_i, w_{i+j} is the context words of w_i, $p(w_{i+j}|e_i)$ is calculated with hierarchical softmax. The basic $softmax$ unit is calculated as $softmax_i = exp(z_i)/\sum_k exp(z_k)$. We leave out the details of hierarchical softmax (Morin and Bengio, 2005; Mikolov et al., 2013b) due to the page limit. It is worth noting that, Skip-Gram is capable to learn continuous representation of words and phrases with the identical model (Mikolov et al., 2013b).

To integrate sentiment information into the continuous representation of phrases, we develop a tailored neural architecture to learn SSPE, as illustrated in Figure 2(b). Given a triple $\langle w_i, s_j, pol_j\rangle$ as input, where w_i is a phrase contained in the sentence s_j whose gold sentiment polarity is pol_j, our training objective is to (1) utilize the embedding of w_i to predict its context words, and (2) use the sentence representation se_j to predict the gold sentiment polarity of s_j, namely pol_j. We simply average the embedding of phrases contained in a sentence as its continuous representation (Huang et al., 2012). The objective of the sentiment part is to maximize the average of log sentiment probability:

$$f_{sentiment} = \frac{1}{S}\sum_{j=1}^{S} log\ p(pol_j|se_j) \tag{2}$$

where S is the occurrence of each sentence in the corpus, $\sum_k pol_{jk} = 1$. For binary classification between positive and negative, the distribution of [0,1] is for positive and [1,0] is for negative. Our final training objective is to maximize the linear combination of the syntactic and sentiment parts:

$$f = \alpha \cdot f_{syntactic} + (1-\alpha)\cdot f_{sentiment} \tag{3}$$

where α weights the two parts. Accordingly, the nearest neighbors in the embedding space of SSPE are favored to have similar semantic usage as well as the same sentiment polarity.

We train our neural model with stochastic gradient descent and use AdaGrad (Duchi et al., 2011) to update the parameters. We empirically set embedding length as 50, window size as 3 and the learning rate of AdaGrad as 0.1. Hyper-parameter α is tuned on the development set. To obtain large-scale training corpus, we collect tweets from April, 2013 through TwitterAPI. After filtering the tweets that are too short ($<$ 5 words) and removing *@user* and *URLs*, we collect 10M tweets (5M positive and 5M negative) with positive and negative emoticons [3], which is are utilized as the training data to train our neural model. The vocabulary size is 750,000 after filtering the 1$\sim$4 grams through frequency.

[3]We use the emoticons selected by Hu et al. (2013), namely :) :) :-) :D =) as positive and :(: (:-(as negative ones.

3.2 Seed Expansion with Urban Dictionary

Urban Dictionary is a web-based dictionary that contains more than seven million definitions until March, 2013 [4]. It was intended as a dictionary of slang, cultural words or phrases not typically found in standard dictionaries, but it is now used to define any word or phrase. For each item in Urban Dictionary, there is a list of similar words contributed by volunteers. For example, the similar words of "*cooool*" are "*cool*", "*awesome*", "*coooool*", et al [5] and the similar words of "*not bad*" are "*good*", "*ok*" and "*cool*", et al [6]. These similar words are typically semantically close to and have the same sentiment polarity with the target word. We conduct preliminary statistic on the items of Urban Dictionary from "*a*" to "*z*", and find that there are total 799,430 items containing similar words and each of them has about 10.27 similar words on average.

We utilize Urban Dictionary to expand little sentiment seeds for collecting training data for building the phrase-level sentiment classifier. We manually label the top frequent 500 words from the vocabulary of SSPE as positive, negative or neutral. After removing the ambiguous ones, we obtain 125 positive, 109 negative and 140 neutral words, which are regarded as the sentiment seeds [7]. Afterwards, we leverage the similar words from Urban Dictionary to expand the sentiment seeds. We first build a k-nearest neighbors (KNN) classifier by regarding the sentiment seeds as gold standard. Then, we employ the KNN classifier on the items of Urban Dictionary containing similar words, and predict a three-dimensional discrete vector $[knn_{pos}, knn_{neg}, knn_{neu}]$ for each item, reflecting the hits numbers of sentiment seeds with different sentiment polarity in its similar words. For example, the vector value of "*not bad*" is $[10, 0, 0]$, which means that there are 10 positive seeds, 0 negative seeds and 0 neutral seeds occur in its similar words. To ensure the quality of the expanded words, we set threshold for each category to collect the items with high quality as expanded words. Take the positive category as an example, we keep an item as positive expanded word if it satisfies $knn_{pos} > knn_{neg} + threshold_{pos}$ and $knn_{pos} > knn_{neu} + threshold_{pos}$ simultaneously. We empirically set the thresholds of positive, negative and neutral as 6,3,2 respectively by balancing the size of expanded words in three categories. After seed expansion, we collect 1,512 positive, 1,345 negative and 962 neutral words, which are used as the training data to build the phrase-level sentiment classifier. We also tried the propagation methods to expand the sentiment seeds, namely iteratively added the similar words of sentiment seeds from Urban Dictionary into the expanded word collection. However, the quantity of expanded words is less than the KNN-based results and the quality is relatively poor.

After obtaining the training data and feature representation of phrases, we build the phrase-level classifier with $softmax$, whose length is two for the positive *vs* negative case:

$$\mathbf{y}(w) = softmax(\theta \cdot e_i + b) \tag{4}$$

where θ and b are the parameters of classifier, e_i is the embedding of the current phrase w_i, $\mathbf{y}(w)$ is the predicted sentiment distribution of item w_i. We employ the classifier to predict the sentiment distribution of each phrase in the vocabulary of SSPE, and save the phrases as well as their sentiment probability in the positive (negative) lexicon if the positive (negative) probability is larger than 0.5.

4 Experiment

In this section, we conduct experiments to evaluate the effectiveness of our sentiment lexicon (**TS-Lex**) by applying it in the supervised learning framework for Twitter sentiment classification, as given in subsection 4.1. We also directly evaluate the quality of SSPE as it forms the fundamental component for building sentiment lexicon. We use SSPE as the feature for sentiment classification of items in existing sentiment lexicons, as described in subsection 4.2.

[6] http://www.urbandictionary.com/define.php?term=not+bad
[7] We will publish the sentiment seeds later.

4.1 Twitter Sentiment Classification

Experiment Setup and Dataset We conduct experiments on the benchmark Twitter sentiment classification dataset (message-level) from SemEval 2013 (Nakov et al., 2013). The training and development sets were completely released to task participants. However, we were unable to download all the training and development sets because some tweets were deleted or not available due to modified authorization status. The statistic of the positive and negative tweets in our dataset are given in Table 1(b). We train positive *vs* negative classifier with LibLinear (Fan et al., 2008) with default settings on the training set, tune parameters *-c* on the dev set and evaluate on the test set. The evaluation metric is Macro-F1.

(a) Sentiment Lexicons

Lexicon	Positive	Negative	Total
HL	2,006	4,780	6,786
MPQA	2,301	4,150	6,451
NRC-Emotion	2,231	3,324	5,555
TS-Lex	**178,781**	**168,845**	**347,626**
HashtagLex	216,791	153,869	370,660
Sentiment140Lex	480,008	260,158	740,166

(b) SemEval 2013 Dataset

	Positive	Negative	Total
Train	2,642	994	3,636
Dev	408	219	627
Test	1,570	601	2,171

Table 1: Statistic of sentiment lexicons and Twitter sentiment classification datasets.

Results and Analysis We compare TS-Lex with *HL*[8] (Hu and Liu, 2004), *MPQA*[9] (Wilson et al., 2005), *NRC-Emotion*[10] (Mohammad and Turney, 2012), *HashtagLex* and *Sentiment140Lex*[11] (Mohammad et al., 2013). The statistics of TS-Lex and other sentiment lexicons are illustrated in Table 1(a). *HL*, *MPQA* and *NRC-Emotion* are traditional sentiment lexicons with a relative small lexicon size. *HashtagLex* and *Sentiment140Lex* are Twitter-specific sentiment lexicons. We can find that, TS-Lex is larger than the traditional sentiment lexicons.

We evaluate the effectiveness of TS-Lex by applying it as the features for Twitter sentiment classification in the supervised learning framework (Pang et al., 2002). We conduct experiments in two settings, namely only utilizing the lexicon features (*Unique*) and appending lexicon feature to existing feature sets (*Appended*). In the first setting, we design the lexicon features as same as the top-performed Twitter sentiment classification system in SemEval2013 [12] (Mohammad et al., 2013). For each sentiment polarity (positive *vs* negative), the lexicon features are:

- total count of tokens in the tweet with score greater than 0;
- the sum of the scores for all tokens in the tweet;
- the maximal score;
- the non-zero score of the last token in the tweet;

In the second experiment setting, we append the lexicon features to the existing basic feature. We use the feature sets of Mohammad et al. (2013) excluding the lexicon feature as the basic feature, including bag-of-words, pos-tagging, emoticons, hashtags, elongated words, etc. Experiment results of the *Unique* features and *Appended* features from different sentiment lexicons on Twitter sentiment classification are given in Table 2(a).

From Table 2(a), we can find that TS-Lex yields best performance in both *Unique* and *Appended* feature sets among all sentiment lexicons, including two large-scale Twitter-specific sentiment lexicons. The reason is that the classifier for building TS-Lex utilize (1) the well developed feature representation of phrases (SSPE), which captures the semantic and sentiment connections between phrases, and (2) the enlarged sentiment words through web intelligence as training data. *HashtagLex* and *Sentiment140Lex*

(a)

Lexicon	Unique	Appended
HL	60.49	79.40
MPQA	59.15	76.54
NRC-Emotion	54.81	76.79
HashtagLex	65.30	76.67
Sentiment140Lex	72.51	80.68
TS-Lex	**78.07**	**82.36**

(b)

Lexicon	Unique
Seed	57.92
Expand	60.69
Lexicon(seed)	74.64
TS-Lex	**78.07**

Table 2: Macro-F1 on Twitter sentiment classification with different lexicon features.

only utilize the relations between phrases and hashtag/emoticon seeds, yet do not well capture the connections between phrases. In the *Unique* setting, the performances of the traditional lexicons (*HL*, *MPQA* and *NRC-Emotion*) are lower than large-scale Twitter-specific lexicons (*HashtagLex*, *Sentiment140Lex* and our lexicon). The reason is that, tweets have the informal language style and contain slangs and diverse multi-word phrases, which are not well covered by the traditional sentiment lexicons with a small size. After incorporating the lexicon feature of TS-Lex into the top-performs system (Mohammad et al., 2013), we further improve the macro-F1 from 84.70% to 85.65%.

Effect of Seed Expansion with Urban Dictionary To verify the effectiveness of seed expansion through Urban Dictionary, we conduct experiments by applying (1) sentiment seeds (*Seed*), (2) words after expansion (*Expand*), (3) sentiment lexicon generated from the classifier only utilizing sentiment seeds as training data (*Lexicon(seed)*), (4) the final lexicon (*TS-Lex*) exploiting the expanded words as training data to build sentiment classifier, to produce lexicon features, and only use them for Twitter sentiment classification (*Unique*). From Table 2(b), we find that the performance of sentiment seeds and expanded words are relatively poor due to their low coverage. Under this scenario, seed expansion yields 2.77% improvement (from 57.92% to 60.69%) on macro-F1. By utilizing the expanded words as training data to build the phrase-level sentiment classifier, TS-Lex obtains 3.43% improvements on Twitter sentiment classification (from 74.64% to 78.07%), which verifies the effectiveness of seed expansion through Urban Dictionary. In addition, we find that only using a small number of sentiment seeds as the training data, we can obtain superior performance (74.64%) than all baseline lexicons. This indicates that the representation learning approach effectively capture the semantic and sentimental connections between phrases through SSPE, and leverage them for building the sentiment lexicon.

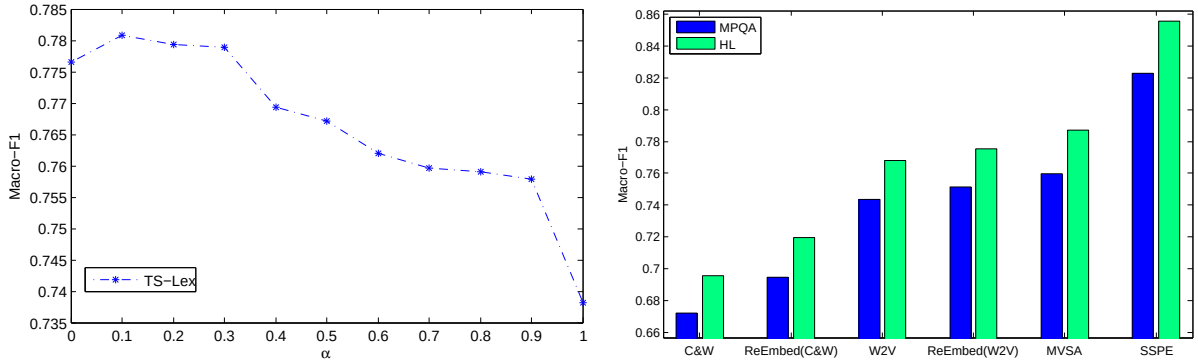
Effect of α in SSPE We tune the hyper-parameter α of SSPE on the development set of SemEval 2013, and study its influence on the performance of Twitter sentiment classification by applying the generated lexicon as features. We utilize the expanded words as training data to train $softmax$ and only utilize the lexicon features (*Unique*) for Twitter sentiment classification. Experiment results with different α are illustrated in Figure 3(a).

From Figure 3(a), we can see that that SSPE performs better when α is in the range of [0.1, 0.3], which is dominated by the sentiment information. The model with $\alpha = 1$ stands for Skip-Gram model. The sharp decline at $\alpha = 1$ indicates the importance of sentiment information in learning sentiment-specific phrase embedding for building sentiment lexicon.

Discussion In the experiment, we do not apply TS-Lex into the unsupervised learning framework for Twitter sentiment classification. The reason is that the lexicon-based unsupervised method typically require the sentiment lexicon to have high precision, yet our task is to build large-scale lexicon (TS-Lex) with broad coverage. We leave this as the future work, although we may set higher threshold (e.g. larger than 0.5) to increase the precision of TS-Lex and loose the recall.

4.2 Evaluation of Different Representation Learning Methods

Experiment Setup and Dataset We conduct sentiment classification of items in two traditional sentiment lexicons, *HL* (Hu and Liu, 2004) and *MPQA* (Wilson et al., 2005), to evaluate the effective of the



(a) SSPE with different α on the development set for Twitter sentiment classification.

(b) Sentiment classification of lexicons with different embedding learning algrithms.

Figure 3: Experiment results with different settings.

sentiment-specific phrase embedding (SSPE). We train the positive *vs* negative classifier with LibLinear (Fan et al., 2008). The evaluation metric is the macro-F1 of 5-fold cross validation. The statistics of *HL* and *MPQA* are listed in Table 1(a).

Baseline Embedding Learning Algorithms We compare SSPE with the following embedding learning algorithms:

(1) *C&W*. C&W is one of the most representative embedding learning algorithms (Collobert et al., 2011) for learning word embedding, which has been proven effective in many NLP tasks.

(2) *W2V*. Mikolov et al. (2013a) introduce Word2Vec for learning the continuous vectors for words and phrases. We utilize Skip-Gram as it performs better than CBOW in the experiments.

(3) *MVSA*. Maas et al. (2011) learn word vectors for sentiment analysis with a probabilistic model of documents utilizing the sentiment polarity of documents.

(4) *ReEmbed*. Lebret et al. (2013) learn task-specific embedding from existing embedding and task-specific corpus. We utilize the training set of Twitter sentiment classification as the labeled corpus to re-embed words. *ReEmbed(C&W)* and *ReEmbed(W2V)* stand for the use of different embedding results as the reference word embedding.

The embedding results of the baseline algorithms and SSPE are trained with the same dataset and parameter sets.

Results and Analysis Experiment results of the baseline embedding learning algorithms and SSPE are given in Figure 3(b). We can see that SSPE yields best performance on both lexicons. The reason is that SSPE effectively encode the sentiment information of tweets as well as the syntactic contexts of phrases from massive data into the continuous representation of phrases. The performances of *C&W* and *W2V* are relatively low because they only utilize the syntactic contexts of items, yet ignore the sentiment information of text, which is crucial for sentiment analysis. *ReEmbed(C&W)* and *ReEmbed(W2V)* achieve better performance than *C&W* and *W2V* because the sentiment information of sentences are incorporated into the continuous representation of phrases. There is a gap between *ReEmbed* and SSPE because SSPE leverages more sentiment supervision from massive tweets collected by positive and negative emoticons.

5 Conclusion

In this paper, we propose building large-scale Twitter-specific sentiment lexicon with a representation learning approach. Our method contains two parts: (1) a representation learning algorithm to effectively learn the embedding of phrases, which are used as features for classification, (2) a seed expansion algorithm that enlarge a small list of sentiment seeds to obtain training data for building the phrase-level sentiment classifier. We introduce a tailored neural architecture and integrate the sentiment information of tweets into its hybrid loss function for learning sentiment-specific phrase embedding (**SSPE**). We learn SSPE from the tweets collected by positive and negative emoticons, without any manual annota-

tion. To collect more training data for building the phrase-level classifier, we utilize the similar words from Urban Dictionary to expand a small list of sentiment seeds. The effectiveness of our sentiment lexicon (**TS-Lex**) has been verified through applied in the supervised learning framework for Twitter sentiment classification. Experiment results on the benchmark dataset of SemEval 2013 show that, TS-Lex outperforms previously introduced sentiment lexicons and further improves the top-perform system in SemEval 2013 with feature combination. In future work, we plan to apply TS-Lex into the unsupervised learning framework for Twitter sentiment classification.

Abstract

This paper describes an approach for political tendency identification of Twitter users. We define some metrics that take into account the polarity of the political entities in the tweets of each user. To obtain this polarities we present the sentiment analysis system developed. The evaluation was performed on the general corpus developed at TASS2013 workshop for Spanish. To our knowledge, the results obtained for the sentiment analysis task and the political tendency identification task are the best results published until now using this data set.

1 Introduction

Social media are usually used to express opinions and feelings about companies, products, services, hobbies, politics, etc. Therefore, enterprises, organizations, governments, and different groups in general have shown interest in the opinions that users have for their activities. They are also interested to known the way users use these media, the communication behaviour, and some users attributes such as gender, age, geographical location, political orientation, etc. In general, the main aim is to provide personalized services, particularized offers, or simply to know what people think about something in order to improve their activities.

The scientific community has made a great effort to provide effective solutions to analyse, structure, and process the large amount of on-line reviews in social media. A wide set of techniques of Sentiment Analysis (SA) are used in micro-blogging texts to extract the polarity (positive, negative, mixed or neutral) that users express in these texts. In this respect, Twitter has become a popular micro-blogging site in which users express their opinions on a variety of topics in real time. The texts used in Twitter are called tweets, which are short texts of a maximum of 140 characters and a language that does not have any restriction on the form and content. The nature of these texts poses new challenges for researchers in Natural Language Processing (NLP). In some cases, the tweets are written with ungrammatical sentences with a lot of emoticons, abbreviations, specific terminology, slang, etc. Therefore, the usual techniques of NLP must be adapted to these characteristics of the language, and new approaches must be proposed in order to successfully address this problem. NLP tools like POS taggers, parsers, or Named Entity Recognition (NER) tools usually fail when processing tweets because they generally are trained on grammatical texts and they perform poorly in micro-blogging texts.

In this work we present a system for addressing the task of political tendency identification of Twitter users based on SA techniques. For each user, we collect all their tweets and we extract all the entities related to the political subject. Then, we automatically assign a polarity to these entities and we define a political tendency metric that uses this entity polarity information combined with another tendency metric for classifying the political tendency of each user in four categories: *Left*, *Right*, *Center*, or *Undefined*. The evaluation of our system is performed on the General Corpus, a corpus of Spanish tweets provided by the organization of the TASS2013 workshop.

The paper is organized as follows. In section 2 we present relevant works for Twitter user classification and Sentiment Analysis. In Section 3 we present a description of the corpus used to evaluate our user

Proceedings of COLING 2014, the 25th International Conference on Computational Linguistics: Technical Papers, pages 183–192, Dublin, Ireland, August 23-29 2014.

political tendency system. This system is based on SA techniques. A description of our SA system is described in section 4. In Section 5 we describe the way we classify users according to their political leading. The evaluation and discussion of the results obtained are presented in section 6. Finally, in section 7 we present some conclusions and possible directions for future works.

2 Related works

The different approaches for estimating the political leaning of Twitter users explore features that range from *text content*, *users behavior* (taking into account the tweets and retweets information) and the *Twitter structure* (by considering the followers users, following users, etc.). An interesting study of some useful features to classify latent users attributes (gender, age, regional origin, and political orientation) is presented in (Rao et al., 2010). In (Conover et al., 2011a; Conover et al., 2011b) and study of the political alignment of Twitter users is performed by analyzing the way users communicates by means of retweets and user mentions. In (O'Connor et al., 2010a) SA techniques are used to determine the positive and negative polarity of Twitter messages. They also study the connexion between these polarities and the public opinion derived from traditional polling in order to substitute or complement them. (Pennacchiotti and Popescu, 2011) present a machine learning approach to Twitter user classification in democrats or republicans. With respect to the linguistic content they considered prototypical words and hashtags that are common in democrats or republicans users which provides clues for the classification. They also use SA tecniques based on lexicons for the classification task. In (Boutet et al., 2012) polical leading of users is performed by counting the amount of tweets related to political parties analysing the hashtags. They also consider the interaction among parties by analyzing the retweets and mentions. Users interaction by analysing tweets and retweets is also the main idea of the work presented in (Wong et al., 2013).

In (Cohen and Ruths, 2013) previous works on political orientation of Twitter users are analyzed to conclude that the accuracy results reported are overstimated do to the way the data sets are constructed. When these approaches are applied to normal Twitter users accuracy results significantly decrease.

Sentiment Analysis (SA) has been widely studied in the last decade in multiple domains. Most work focuses on classifying the polarity of the texts as positive, negative, mixed, or neutral. The pioneering works in this field used supervised (Pang et al., 2002) or unsupervised (knowledge-based) (Turney, 2002) approaches. In (Pang et al., 2002), the performance of different classifiers on movie reviews was evaluated. In (Turney, 2002), some patterns containing POS information were used to identify subjective sentences in reviews to then estimate their semantic orientation.

The construction of polarity lexicons is another widely explored field of research. Opinion lexicons have been obtained for English language (Liu et al., 2005) (Wilson et al., 2005) and also for Spanish language (Perez-Rosas et al., 2012). A good presentation of the SA problem and a description of the state-of-the-art of the more relevant approaches to SA can be found in (Liu, 2012). An overview of the current state of different approaches to the subjectivity and SA task is presented in (Montoyo et al., 2012).

Research works about SA on Twitter are much more recent. Twitter appeared in the year 2006 and the early works in this field are from 2009 when Twitter started to achieve popularity. Some of the most significant works are (Barbosa and Feng, 2010), (Jansen et al., 2009), and (O'Connor et al., 2010b). A survey of the most relevant approaches to SA on Twitter can be see in (Martínez-Cámara et al., 2012) , (Vinodhini and Chandrasekaran, 2012). The SemEval2013 competition has also dedicated a specific task for SA on Twitter (Wilson et al., 2013), which shows the great interest of the scientific community in this field. The TASS2013 workshop has proposed different tasks for SA and political tendency identification focused on the Spanish language (Villena-Román and García-Morera, 2013).

3 The Corpus

The General Corpus of TASS2013[1](Villena-Román and García-Morera, 2013) contains approximately 68000 Twitter messages (*tweets*) written in Spanish (between November 2011 and March 2012) by 158 well-known personalities of the world of politics, economy, communication, mass media, and culture.

[1]This corpus is freely available on the web page of TASS2013 (http://www.daedalus.es/TASS2013).

The corpus is encoded in XML. Each tweet includes its ID (*tweetid*), the creation date (*date*), and the user ID (*user*). It is tagged with its global polarity using N and N+ labels for negative polarity with different intensity, P and P+ labels for positive polarity with different intensity, and the NEU label for neutral polarity. Label NONE was used to represent tweets with no polarity at all. Moreover, the polarity to the entities that are mentioned in the tweet was also included. The level of agreement of the expressed sentiment is annotated both for global and entity level. Also, a selection of a set of topics was made based on the thematic areas covered by the corpus, such as politics, soccer, literature, entertainment, etc. Each message is also assigned to one or several of these topics.

	N	N+	NEU	NONE	P	P+
training	1,335 (18.49%)	847 (11.73%)	670 (9.28%)	1,483 (20.54%)	1,232 (17.07%)	1,652 (22.88%)
test	11,287 (18.56%)	4,557 (7.50%)	1,305 (2.15%)	21,416 (35.22%)	1,488 (2.45%)	20,745 (34.12%)

Table 1: The distribution of the polarity of the tweets in the corpus.

Table 1 shows the distribution of tweets per polarity in the corpus. It is divided into two sets: training (about 10%, 7219 tweets) and test (about 90%, 60798 tweets). It can be observed that this distribution is not balanced for the different polarities. Finally, each user from the test set of the General corpus is labeled with their political tendency in four possible values: $Left$, $Right$, $Centre$, and $Undefined$.

4 Description and Evaluation of the Sentiment Analysis System

Figure 1 shows an overview of our system for the SA problem. The system consists of 4 modules. The first module is the Pre-processing module, which performs the tokenization, lemmatization, and Named Entities recognition of the input tweet. A lemma reduction and a POS tagging process is also carried out in this module. The second module is optional. It allows us to obtain the polarity of the entities contained in the tweet. If we omitted this step the global polarity of the tweet is obtained. The third module is the Feature Extraction module, which selects the features from the pre-processed tweet (or from the segments of tweets) and obtains a feature vector. Some features require the use of a polarity lexicon of lemmas and words. To determine the best features, a tuning process is required during the training phase. The fourth module is the Polarity Classifier module, which uses a classifier (learned from feature vectors of the training set) to assign a polarity label to the tweet.

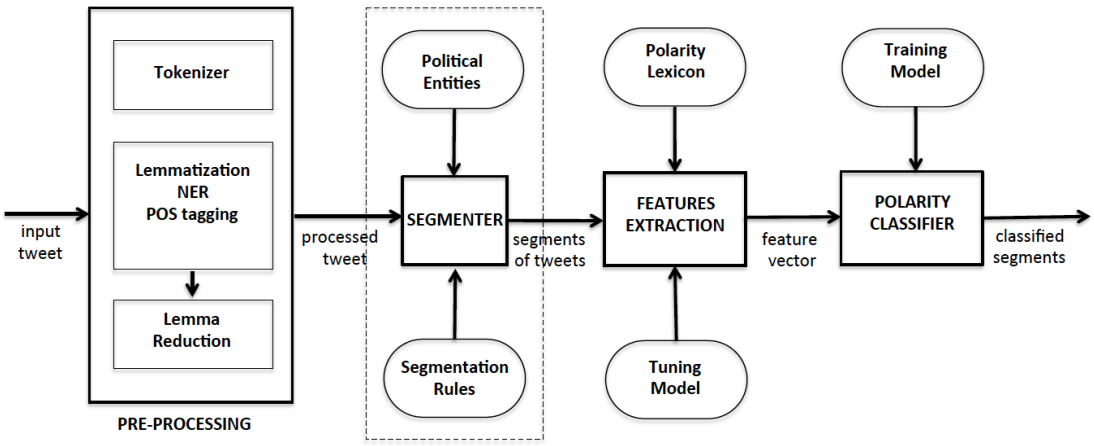

Figure 1: Sentiment Analysis System Overview

4.1 Pre-processing of Tweets

Before addressing the SA task, it is necessary to make a proper tokenization of the tweets. Although there are a lot of tokenizers available on the web, they need to be adapted in order to address the segmentation of tokens of a tweet. Furthermore, most of these resources are for the English language, which adds a degree of difficulty for their use in processing Spanish tweets.

Moreover, the use of NLP resources such as stemmers, POS taggers, parsers, NER systems, Word Sense Disambiguation (WSD) systems, etc. are impractical if the characteristics of the tweets are not taken into account. Therefore, an adjustment and adaptation must be made for the Twitter domain.

In our system, we decided to use and adapt available tools for tokenization, lemmatization, NER, and POS tagging. We adapted the package *Tweetmotif* [2] that is described in (O'Connor et al., 2010b) to process Spanish tweets. We also used *Freeling* [3] (Padró and Stanilovsky, 2012) (with the appropriate modifications for handling Twitter messages) for stemming, Named Entity Recognition, and POS tagging.

We added some functions to process special tokens (e.g., grouping all *hashtags* into a single token, grouping all *web* addresses into a single token or grouping all *url* into a single token). We also grouped the *dates* into a single token, the *numbers* into a single token, and the *punctuation* marks into a single token.

4.2 The Segmenter

For the proposed approach we need to determine the polarity of political entities that contains a tweet. It is because the polarity of each entity could be different of the global polarity of the tweet. In the tweet of the corpus[4]: *"Rajoy's government goes up the pensions. PSOE cuts back all things except the unemployment."* we have two entities, *Rajoy* (the president of Spanish government from the right-wing party PP) and *PSOE* (a Spanish left-wing party). This tweet is labeled with a neutral global polarity, but each entity have a different polarity (ENTITY (Rajoy): *Positive*. ENTITY (PSOE): *Negative*).

Even for tweets with only one entity we must decide what fragments of text refers to that entity. In the example: *"Rajoy already has been talking for an hour. Not saving anywhere only expenses, all reforms cost a lot of money. Did he tell us something at the end?"*, to determine the polarity of entity Rajoy, we must take into account all the tweet, because the two last sentences references to *ENTITY(Rajoy)*. In contrast, in the example: *"Today 349 members attending to the formation of the lower house. Only the AMAIUR deputy for Navarra is missing"*, only the sentence containing the AMAIUR entity is being required to determine its polarity.

Obtaining the polarity at entity level is a hard problem and introduces additional complexity because the part of the tweet refers to each of the entities must be determined. To resolve this problem it should make a deep parsing of the tweet and perform a study of such dependencies. This is not a solved problem in NLP even considering normative texts and is further aggravated in Twitter texts. Besides, in many cases, the dependencies are between different sentences, and problems such as coreference must be taking into account in order to determine, for example, which pronoun refers to a certain entity. Other problems such as synonyms and acronyms of certain entities can make this problem harder.

We have chosen a more simple and practice approach that consists in defining a set of heuristics to determine which segment of the tweet refers to each of the entities present on it. We defined some rules to do this segmentation. If the tweet contains only one entity the context considered was all the tweet. We evaluated other alternatives, but due to the short length of tweets, with that decision the best global results were obtained. If the tweet contains two entities, the casuistry is greater. If both entities are placed together at the beginning or the end of the tweet all the tweet is considered as a context for both entities. By contrast, if separate, and has sufficient context, the tweet is segmented by defining the context of each entity. Next, we show some examples and the segmentation produced by the defined rules.

Example 1 is the easier case due the two entities are in separated sentences. When both entities are in the same sentence, in Example 2 the rule applied determines that the context for the first entity is from the beginning until the second entity, and the rest of the sentence is the context for the second entity. Example 3 is more difficult, and the rules applied produce segmentations like this *[On March 25 we elect between the immobility of the @PSOE] [and the renovation and the hope of the @ppandaluz.])*, that are not correct but can be useful for determining the polarity of each entity. In addition, due to the short length of the tweets, the context of an entity is often so small that it does not contain information enough

[2] https://github.com/brendano/tweetmotif.

[3] http://nlp.lsi.upc.edu/freeling/

[4] All the exemples have been translated to English.

Example 1
*[***Rajoy***'s government goes up the pensions.] [***PSOE** *cuts back all things except the unemployment.]*
GLOBAL POLARITY: *NEU*. ENTITY (Rajoy): *Positive*. ENTITY (PSOE): *Negative*
Example 2
[As **IU** *gains confidence in Andalucía] [***PP** *loses members.]*
GLOBAL POLARITY: *NEU*. ENTITY (IU): *Positive*. ENTITY (PP): *Negative*
Example 3
On March 25 we elect between [the immobility of the **@PSOE***] and [the renovation and the hope of the* **@ppandaluz.]**
GLOBAL POLARITY: *NEU*. ENTITY (@PSOE): *Negative*. ENTITY (@ppandaluz): *Positive*

to correctly classify the polarity of the entity. In such case, the option that was chosen is to establish a threshold of context, and if it is below than this threshold, it was assigned the same polarity to all the entities of the tweet. When the number of entities is greater than two in much cases we assigned the same polarity to all the entities of the tweet because we had not enough context.

4.3 Feature Selection

The feature selection process was performed by cross validation (10-fold validation) using the training set to select the set of relevant features.

We considered the following set of features: unigrams and bigrams of lemmas obtained in the preprocessing of the tweets that belong to a set of selected POS. We considered only the lemmas of a minimum frequency (*f*) in the training set. We unified all *hashtags*, *user references*, *dates*, *punctuations* as a single feature. We classified the emoticons in the following categories: *happy, sad, tongue, wink, and other*. Finally, we used external polarity lexicons of lemmas and words.

Some of the features required further adjustment. For the POS feature we selected the lemas that belongs to the *nouns, verbs, adjectives, and adverbs* POS and also *exclamations* and *emoticons*. We estimated the minimum frequency of the lemmas to be selected (*f =2*). Finally, we selected the external lexicons to be used. One of the lexicons used was originally for English language (Wilson et al., 2005) that was translated into Spanish automatically, and other (Perez-Rosas et al., 2012) lexicon was a list of words that was originally in Spanish. Then, we combined these two resource with the lexicon presented in (Saralegi and San Vicente, 2013).

4.4 Polarity Classifier

The task was addressed as a classification problem that consisted of determining the polarity of each tweet. We used WEKA[5], which is a tool that includes (among other utilities) a collection of machine-learning algorithms that can be used for classification tasks. Specifically, we used a SVM-based approach because it is a well-founded formalism, that has been successfully used in many classification problems. In the SA task, SVM has shown it ability to handle large feature spaces and to determine the relevant features (Joachims, 1998).

We used the NU-SVM algorithm (Schölkopf et al., 2000) from an external library called *LibSVM*[6], which is very efficient software for building SVM classifiers. It is easy to integrate this software with WEKA thus allowing us to use all of WEKA's features. We used the *bag_of_words* approach to represent each tweet as a feature vector that contains the frequency of the selected features of the training set.

4.5 Evaluation of the Sentiment Analysis System

We evaluated our system on the SA tasks defined at the TASS2013 workshop. Two different sub-tasks called *5-level* and *3-level* were proposed. Both sub-tasks differ only in the polarity granularity considered. The *5-leve*l sub-task uses the labels *N*, *N+*, *P*, *P+*, and *NEU*. The *3-level* sub-task uses the labels *N*, *P*, and *NEU*. In both sub-tasks, an additional label (*NONE*) was used to represent tweets with no polarity.

The accuracy results obtained on the unseen data test were: 62.88%±0.38% for *5-level* task and 70.25%±0.36% for *3-level task*. This results outperformed all the approaches at TASS2013 workshop with statistical significance (with a 95% level of confidence). The official results ranged from 61.6% to 13.5% for the *5-level* task and from 66.3% to 38.8% for the *3-level* task. The F_1 result obtained in the

[5]http://www.cs.waikato.ac.nz/ml/weka/
[6]http://www.cs.iastate.edu/~ yasser/wlsvm/

Sentiment Analysis at Entity level task was worse (F_1=0.40), but it still is the best result reported in the sentiment analysis at entity level task at TASS2013 competition.

5 Political tendency identification

The objective of this task is to estimate the political tendency of each user from the test set of the General corpus in four possible values: $Left$, $Right$, $Centre$, and $Undefined$. Next, we describe the approach we proposed for this task. This approach uses the SA system previously described in section 4.

To perform the classification of users we assume the following hypothesis: the positive opinions on a political party is a political orientation similarly to the user performing the review for this party, on the contrary, a negative opinion about a party is a political orientation opposite to that shown by this party.

In this way, to classify users by their political orientation, first we identify entities associated with political parties and secondly we analyze the polarity of these entities in the tweets of each user.

We consider three types of entities: entities labeled by *Freeling* as proper names (i.e., comité_del_pp_de_madrid), Twitter users (i.e., @38congresopsoe), and Twitter hashtags (i.e., #upyd). Among all possible entities we selected those containing the acronym for a political party or the name of a political leader. A total of 864 entities related to political parties and political leaders were detected. Table 2 shows the parties and political leaders considered and some examples of the selected entities.

Party	**Tendency**	**Examples of Entities**
PP	right	#17congesoPP, congreso_nacional_pp, ppopular, congresopp, #ppfachas
PSOE	left	elpsoe, #adiosalpsoeenandalucia, #38congresopsoe
IU	left	asamblea_de_iu, iumalaga, diputados_de_iu, #iu
UPyD	centre	upydeuskadi, #demagogiaupyd, #mareamagenta, upyd_asturias
CiU	right	ciu+tripartito, #ciu, ciu-mintiendo-crujen

Political Leader	**Party**	**Examples of Entities**
Rajoy	PP	#rajoynoeslasolución, españa_de_rajoy, irpf_de_rajoy
González Pons	PP	@gonzalezpons, rajoy_para_gonzález_pons
Rubalcaba	PSOE	#rubalcabaenlaser, @conrubalcaba, rubalcaba_para_el_psoe
Zapatero	PSOE	nueva_via_de_zapatero, presidente_zapatero, zapatero_tv
Cayo Lara	IU	@cayo_lara, cayo_lara, cayo

Table 2: Tendency of political parties and political leaders.

We defined a tendency measure $Tendency$ that assigned a value of -1 to those entities related to left parties, a value of $+1$ to entities related to right parties and a value of 0 to the entities related to centre parties.

Next we show how has been numerically calculated the political orientation of users. For each user U_i of the General corpus we obtain the set T_i that includes all of their tweets that contain political entities. For users who do not have any tweet that contain political entities the *Undefined* label is assigned.

For each tweet $T_{i_j} \in T_i$, $j = 1 \cdots |T_i|$, we identify the political entities that are contained on it. Let E_{i_j} be the set of entities of the tweet T_{i_j}. We denote each of the entities contained in E_{i_j} as $E_{i_{j_k}} \in E_{i_j}, k = 1 \cdots |E_{i_j}|$.

We obtained the polarity of each entity by using the system described in section 4. After that, we assigned a numerical value to each polarity. In this respect, we assigned $Polarity = +1$ to the entities with positive polarity (label P), $Polarity = -1$ to the entities with negative polarity (label N) and finally, $Polarity = 0$ to the entities without polarity, that is, to the NEU and NONE labels.

We combined[7] the $Tendency$ and $Polarity$ measures previously presented to define a new measure ($Political\_Tendency$) to obtain the political orientation of each user.

[7]We have considered multiple combination strategies, in this work we present the combination with the best results.

$$Political\_Tendency(U_i) = \frac{\sum_{j=1\cdots|T_i|} \sum_{k=1\cdots|E_{i_j}|} Polarity(E_{i_{j_k}}) \cdot Tendency(E_{i_{j_k}})}{\sum_{j=1\cdots|T_i|} |E_{i_j}|} \quad (1)$$

From the $Political\_Tendency$ values obtained for each user, we classified the user tendency tanking into account the following: users without political entities in their tweets are classified as $Undefined$; users with $Political\_Tendency$ between -0.05 and +0.05 are classified as $Centre$; users with $Political\_Tendency$ lower than -0.05 are classified as $Left$; and users with $Political\_Tendency$ greater than +0.05 are classified as $Right$.

6 Experimental Evaluation of the Political Identification System

The measures selected to evaluate our approach were the Precision, the Recall, and the F-measure for $\beta = 1$ (F_1). Table 3 summarizes the experimental results of our proposal. The table includes both the overall results (*Global*) and the results for each one of the political tendencies (*Left*, *Right*, *Centre*, and *Undefined*). It also includes the distribution of the tendencies in the gold-standard (%Ref). For the global result, the precision and the recall are the same since each user in the test set had a tendency assigned and the task consist to assign a tendency to all the users.

Tendency	%Ref	Precision	Recall	F_1
Left	21.5	0.658	0.735	0.694
Centre	17.7	0.478	0.393	0.431
Right	39.9	0.786	0.698	0.739
Undefined	20.9	0.780	0.970	0.865
Global	100	0.709	0.709	0.709

Table 3: Experimental results obtained in the political tendency identification task of TASS2013.

The result obtained by our system (0.709) is the best result reported so far for this corpus, to our knowledge. The tendency for what we get better results is the *Undefined* (F_1=0.865). We consider the political tendency of a user to be *Undefined* if he did not have any tweet that references any of the majority parties. This assumption may be too strict for common users, but it seems reasonable for the well-know users that form the test corpus.

The tendency that our system had more trouble identifying was *Centre* (F_1=0.431). The tendency of a user can be identified as *Centre* when he expressed -in his tweets- opinions about entities related to centre parties, even when these opinions were negative. This is because the neutral value of *Centre* entities. In addition, users with opinions on right and left parties with the same polarity may be identified as *Centre*, which can be wrong in many cases.

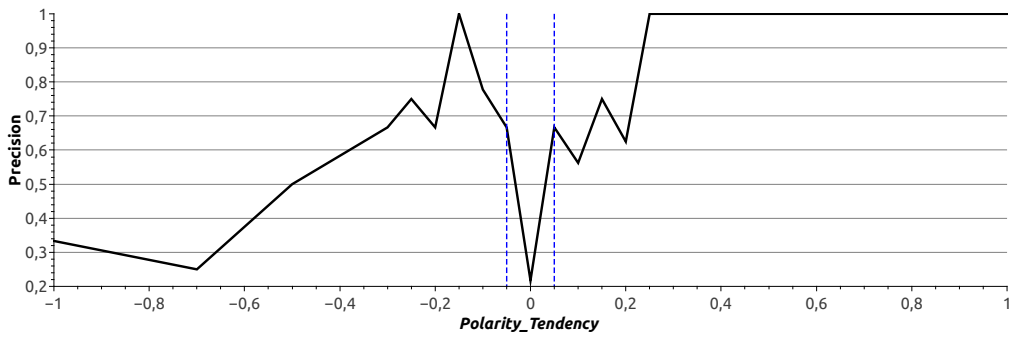

Figure 2: Precision results depending on the $Political\_Tendency$ assigned by the system.

Although it seems that the ability of our system to identify *Left* and *Right* tendencies was similar (F_1=0.694 for *Left* and F_1=0.739 for *Right*), analyzing the results considering the values of *Political_Tendency* some significant differences can be observed. Figure 2 shows the results, in terms of Precision, considering the value of *Political_Tendency* assigned to each user by our system, from a value of -1 (the maximum value for *Left*) to a value of +1 (the maximum for *Right*).

As expected, most identification errors occurred for *Political_Tendency* value near zero, should remember that values between -0.05 and 0.05 were considered *Centre*. Considering the *Right* tendency, all users that obtained *Political_Tendency* value greater than 0.25 were correctly identified as *Right*, performed better than would be expected. However, the behavior of the *Left* tendency was not symmetrical. It seems that values between -0.3 and -0.1 were better to determine correctly this tendency.

Although we have no clear explanation for this behavior, it could be due to multiple factors, including: the simplicity of the proposal, labeling errors in the polarity of certain entities, or the greater difficulty of numerically identify the *Left* tendency (at least in this corpus).

7 Conclusions

We have described our approach for political tendency identification of Twitter users. We have defined a metric, called *Political_Tendency*, that takes into account the polarity of entities related to political parties that appear in the tweets of the user. The Sentiment Analysis system developed in order to obtain the polarity of these entities was also presented.

The evaluation was performed using a corpus of Spanish tweets developed at TASS2013 workshop. This corpus was used for a specific political tendency identification task at this workshop. To our knowledge, the results obtained by our system are the best results published until now using this corpus.

We are very interested in SA tasks and in identifying tendencies in social media. In this sense, we have several ideas on how to improve our approach to identifying the political tendency in Twitter.

It would be interesting to test our approach using a larger corpus of tweets from normal user. We think that the characteristics of the users of the test corpus -figures of culture, journalism and politics in Spain- made the task a little easier. Perhaps the political tendency of ordinary users would be more difficult to identify. Moreover, the political spectrum would be more diverse and should increase the catalog of political parties. Moreover, the political spectrum would be more varied and, consequently, the catalog of political parties should be increased.

It should be emphasized the difficulty of building an annotated corpus of tweets that could be used to evaluate and compare different alternative systems. A great effort of acquisition of the tweets and a subsequent manual labeling process is required. In addition, a validation process is needed to correct the errors introduced by manual labeling. Even using crowdsourcing-based solutions it is a very expensive task both in money and time. In this context, to have a labeled corpus as the one provided by TASS2013 is a great help for the scientific community.

On the portability of the system, we think that it will be easy to adapt our proposal to another political context. This adaptation should focus on two different aspects. First, the Sentiment Analysis System should be adapted to a new language. In the case of languages with linguistic resources freely available the adaptation would be very simple. Second, political entities should be changed to fit the political context where we want to test the system. It would be sufficient to identify the most relevant parties and their leaders and classify them according to their political tendency. However, it is possible that in other political contexts different to Spanish, the *Left*, *Centre*, and *Right* tendencies also need to be adapted.

Finally, we have interest in using Machine Learning techniques for the task of identifying political tendency on twitter. On this point, we are working on a system in which *Political_Tendency*, as defined in this paper, will be a feature within a wider classification system. In this new system, we want to include additional information (not available in the TASS2013 corpus) about user behavior and Twitter structure in order to improve our approach.

Abstract

This paper presents an empirical study on using syntactic and semantic information for Concept Segmentation and Labeling (CSL), a well-known component in spoken language understanding. Our approach is based on reranking N-best outputs from a state-of-the-art CSL parser. We perform extensive experimentation by comparing different tree-based kernels with a variety of representations of the available linguistic information, including semantic concepts, words, POS tags, shallow and full syntax, and discourse trees. The results show that the structured representation with the semantic concepts yields significant improvement over the base CSL parser, much larger compared to learning with an explicit feature vector representation. We also show that shallow syntax helps improve the results and that discourse relations can be partially beneficial.

1 Introduction

Spoken Language Understanding aims to interpret user utterances and to convert them to logical forms, or, equivalently, database queries, which can then be used to satisfy the user's information needs. This process is known as Concept Segmentation and Labeling (CSL): it maps utterances into meaning representations based on semantic constituents. The latter are basically sequences of semantic entities, often referred to as concepts, attributes or semantic tags. Traditionally, grammar-based methods have been used for CSL, but more recently machine learning approaches to semantic structure computation have been shown to yield higher accuracy. However, most previous work did not exploit syntactic/semantic structures of the utterances, and the state-of-the-art is represented by conditional models for sequence labeling, such as Conditional Random Fields (Lafferty et al., 2001) trained with simple morphological and lexical features. In our study, we measure the impact of syntactic and discourse structures by also combining them with innovative features. In the following subsections, we present the application context for our CSL task and then we outline the challenges and the findings of our research.

1.1 Semantic parsing for the "restaurant" domain

We experiment with the dataset of McGraw et al. (2012), containing spoken and typed questions about restaurants, which are to be answered using a database of free text such as reviews, categorical data such as names and locations, and semi-categorical data such as user-reported cuisines and amenities.

Semantic parsing, in the form of sequential segmentation and labeling, makes it easy to convert spoken and typed questions such as "cheap lebanese restaurants in doha with take out" into database queries. First, a language-specific semantic parser tokenizes, segments and labels the question:

[*Price* cheap] [*Cuisine* lebanese] [*Other* restaurants in] [*City* doha] [*Other* with] [*Amenity* take out]

Then, label-specific normalizers are applied to the segments, with the option to possibly relabel mislabeled segments; at this point, discourse history may be incorporated as well.

[*Price* low] [*Cuisine* lebanese] [*City* doha] [*Amenity* carry out]

[*] Iman Saleh (iman.saleh@fci-cu.edu.eg) is affiliated to Faculty of Computers and Information, Cairo University.

Proceedings of COLING 2014, the 25th International Conference on Computational Linguistics: Technical Papers, pages 193–202, Dublin, Ireland, August 23-29 2014.

Finally, a database query is formed from the list of labels and values, and is then executed against the database, e.g., MongoDB; a backoff mechanism may be used if the query does not succeed.

```
{$and [{cuisine:"lebanese"}, {city:"doha"},  {price:"low"},  {amenity:"carry out"}]}
```

1.2 Related work on CSL

Pieraccini et al. (1991) used Hidden Markov Models (HMMs) for CSL, where the observations were word sequences and the hidden states were meaning units, i.e, *concepts*. In subsequent work (Rubinstein and Hastie, 1997; Santafé et al., 2007; Raymond and Riccardi, 2007; De Mori et al., 2008), other generative models were applied, which model the joint probability of a word sequence and a concept sequence, as well as discriminative models, which directly model a conditional probability over the concepts in the input text.

Seneff (1989) and Miller et al. (1994) used stochastic grammars for CSL. In particular, they applied stochastic Finite State Transducers (FST) for recognizing constituent annotations. FSTs describe local syntactic structures with a sequence of words, e.g., noun phrases or even constituents. Papineni et al. (1998) proposed and evaluated exponential models, but, nowadays, Conditional Random Fields (Lafferty et al., 2001) are considered to be the state-of-the-art. More recently, Wang et al. (2009) illustrated an approach for CSL that is specific to query understanding for web applications. A general survey of CSL approaches can be found in (De Mori et al., 2008). CSL is also connected to a large body of work on shallow semantic parsing; see (Gildea and Jurafsky, 2002; Màrquez et al., 2008) for an overview.

Another relevant line of research with a considerable body of work is reranking in NLP. Tree kernels for reranking syntactic parse trees were first proposed in (Collins and Duffy, 2002). Some variants used explicit spaces (Kudo et al., 2005), and feature vector approaches were proposed in (Koo and Collins, 2005). Other reranking work using tree kernels regards predicate argument structures (Moschitti et al., 2006) and named entities (Nguyen and Moschitti, 2012). In (Dinarelli et al., 2011), we rerank CSL hypotheses using structures built on top of concepts, words and features that are simpler than those studied in this paper. The work of Ge and Mooney (2006) and Kate and Mooney (2006) is also similar to ours, as it models the extraction of semantics as a reranking task using string kernels.

1.3 Syntactic and semantic structures for CSL

The related work has highlighted that automatic CSL is mostly based on powerful machine learning algorithms and simple feature representations based on word and tag n-grams. In this paper, we study the impact of more advanced linguistic processing on CSL, such as shallow and full syntactic parsing and discourse structure. We use a reranking approach to select the best hypothesis annotated with concepts derived by a local model, where the hypotheses are represented as trees enriched with semantic concepts similarly to (Dinarelli et al., 2011). These tree-based structures can capture dependencies between sentence constituents and concepts. However, extracting features from them is rather difficult as their number is exponentially large. Thus, we rely on structural kernels (e.g., see (Moschitti, 2006)) for automatically encoding tree fragments, which represent syntactic and semantic dependencies from words and concepts, and we train the reranking functions with Support Vector Machines (e.g., see (Joachims, 1999)). Additionally, we experiment with several types of kernels and newly designed feature vectors.

We test our models on the above-mentioned *Restaurant* domain. The results show that *(i)* the basic CRF model, in fact semi-CRF (see below), is very accurate, achieving more than 83% in F_1-score, which indicates that improving over the semi-CRF approach is very hard; *(ii)* the upper-bound performance of the reranking approach is very high as well, i.e., the correct annotation is generated in the first 100 hypotheses in 98.72% of the cases; *(iii)* our feature vectors show improvement only when all feature groups are used together; otherwise, we only observe marginal improvement; *(iv)* structural kernels yield a 10% relative error reduction from the semi-CRF baseline, which is more than double the feature vector result; *(v)* syntactic information significantly improves on the best model, but only when using shallow syntax; and finally, *(vi)* although, discourse structures provide good improvement over the semi-CRF model, they perform lower than shallow syntax (thus, a valuable use of discourse features is still an open problem that we plan to pursue in future work).

2 CSL reranking

Reranking is based on a list of N annotation hypotheses, which are generated and sorted by probability using local classifiers. Then a reranker, typically a meta-classifier, tries to select the best hypothesis from the list. The reranker can exploit global information, and, specifically, the dependencies between the different concepts that are made available by the local model. We use semi-CRF as our local model since it yields the highest accuracy in CSL (when using a single model), and preference reranking with kernel machines to rerank the N hypotheses generated by the semi-CRF.

2.1 Basic parser using semi-CRF

We use a semi-Markov CRF (Sarawagi and Cohen, 2004), or semi-CRF, a variation of a linear-chain CRF (Lafferty et al., 2001), to produce the N-best list of labeled segment hypotheses that serve as the input to reranking. In a linear-chain CRF, with a sequence of tokens x and labels y, we approximate $p(y|x)$ as a product of factors of the form $p(y_i|y_{i-1}, x)$, which corresponds to features of the form $f_j(y_{i-1}, y_i, i, x)$, where i iterates over the token/label positions. This supports a Viterbi search for the approximate N best values of y. With M label values, if for each label y_m we know the best N sequences of labels $y_1, y_2, \ldots, y_{i-1} = y_m$, then we can use $p(y_i|y_{i-1}, x)$ to get the probability for extending each path by each possible label $y_i = y'_m$. Then for each label y'_m, we will have MN paths and scores, one from each of the paths of length $i-1$ ending with y_m. For each y'_m, we pick the N best extended paths.

With semi-CRF, we want a labeled segmentation s rather than a sequence of labels. Each segment $s_i = (y_i, t_i, u_i)$ has a label y_i as well as a starting and ending token position for the segment, t_i and u_i respectively, where $u_i + 1 = t_{i+1}$. We approximate $p(s|x)$, with factors of the form $p(s_i|s_{i-1}, x)$, which we simplify to $p(y_i, u_i|y_{i-1}, t_i)$, so features take the form $f_j(y_{i-1}, y_i, t_i, u_i)$, i.e., they can use the previous segment's label and the current segment's label and endpoints. The Viterbi search is extended to search for a pair of label and segment end. Whereas for M labels we kept track of MN paths, we must keep track of MLN paths, where L is the maximum segment length.

We use token n-gram features relative to the segment boundaries, n-grams within the segment, token regular expression and lexicon features within a segment. Each of these features also includes the labels of the previous and current segment, and the segment length.

2.2 Preference reranking with kernel machines

Preference reranking (PR) uses a classifier $\mathcal{C}$ of pairs of hypotheses $\langle H_i, H_j \rangle$, which decides if H_i is better than H_j. Given each training question Q, positive and negative examples are generated for training the classifier. We adopt the following approach for example generation: the pairs $\langle H_1, H_i \rangle$ constitute positive examples, where H_1 has the lowest error rate with respect to the gold standard among the hypotheses for Q, and vice versa, $\langle H_i, H_1 \rangle$ are considered as negative examples. At testing time, given a new question Q′, $\mathcal{C}$ classifies all pairs $\langle H_i, H_j \rangle$ generated from the annotation hypotheses of Q′: a positive classification is a vote for H_i, otherwise the vote is for H_j. Also, the classifier score can be used as a weighted vote. H_k are then ranked according to the number (sum) of the (weighted) votes they get.

We build our reranker with kernel machines. The latter, e.g., SVMs, classify an input object o using the following function: $\mathcal{C}(o) = \sum_i \alpha_i y_i K(o, o_i)$, where α_i are model parameters estimated from the training data, o_i are support objects and y_i are the labels of the support objects. $K(\cdot, \cdot)$ is a kernel function, which computes the scalar product between the two objects in an implicit vector space. In the case of the reranker, the objects o are $\langle H_i, H_j \rangle$, and the kernel is defined as follow:

$K(\langle H_1, H_2 \rangle, \langle H'_1, H'_2 \rangle) = S(H_1, H'_1) + S(H_2, H'_2) - S(H_1, H'_2) - S(H_2, H'_1)$.

Our reranker also includes traditional feature vectors in addition to the trees. Therefore, we define each hypothesis H as a tuple $\langle T, \vec{v} \rangle$ composed of a tree T and a feature vector $\vec{v}$. We then define a structural kernel (similarity) between two hypotheses H and H' as follows: $S(H, H') = S_{\text{TK}}(T, T') + S_{\text{v}}(\vec{v}, \vec{v}')$, where S_{TK} is one of the tree kernel functions defined in Section 3.1, and S_{v} is a kernel over feature vectors (see Section 3.3), e.g., linear, polynomial, gaussian, etc.

3 Structural kernels for semantic parsing

In this section, we briefly describe the kernels we use in $S(H, H')$ for preference reranking. We engineer them by combining three aspects: *(i)* different types of existing tree kernels, *(ii)* new syntactic/semantic structures for representing CSL, and *(iii)* new feature vectors.

3.1 Tree kernels

Structural kernels, e.g., tree and sequence kernels, measure the similarity between two structures in terms of their shared substructures. One interesting aspect is that these kernels correspond to a scalar product in the fragment space, where each substructure is a feature. Therefore, they can be used in the training and testing algorithms of kernel machines (see Section 2.2). Below, we briefly describe different types of kernels we tested in our study, which are made available in the SVM-Light-TK toolkit (Moschitti, 2006).

Subtree Kernel (K0) is one of the simplest tree kernels, as it only generates complete subtrees, i.e., tree fragments that, given any arbitrary starting node, necessarily include all its descendants.

Syntactic Tree Kernel (K1), also known as a subset tree kernel (Collins and Duffy, 2002), maps objects in the space of all possible tree fragments constrained by the rule that the sibling nodes cannot be separated from their parents. In other words, substructures are composed of atomic building blocks corresponding to nodes, along with all of their direct children. In the case of a syntactic parse tree, these are complete production rules for the associated parser grammar.

Syntactic Tree Kernel + BOW (K2) extends ST by allowing leaf nodes to be part of the feature space. The leaves of the trees correspond to words, i.e., we allow bag-of-words (BOW).

Partial Tree Kernel (K3) can be effectively applied to both constituency and dependency parse trees. It generates all possible connected tree fragments, e.g., sibling nodes can be also separated and be part of different tree fragments. In other words, a fragment is any possible tree path from whose nodes other tree paths can depart. Thus, it can generate a very rich feature space.

Sequence Kernel (K4) is the traditional string kernel applied to the words of a sentence. In our case, we apply it to the sequence of concepts.

3.2 Semantic/syntactic structures

As mentioned before, tree kernels allow us to compute structural similarities between two trees without explicitly representing them as feature vectors. For the CSL task, we experimented with a number of tree representations that incorporate different levels of syntactic and semantic information.

To capture the structural dependencies between the semantic tags, we use a basic tree (Figure 1a) where the words of a sentence are tagged with their semantic tags. More specifically, the words in the sentence constitute the leaves of the tree, which are in turn connected to the pre-terminals containing the semantic tags in BIO notation ('B'=*begin*, 'I'=*inside*, 'O'=*outside*). The BIO tags are then generalized in the upper level, and so on. The basic tree does not include any syntactic information.

However, part-of-speech (POS) and phrasal information could be informative for both segmentation and labeling in semantic parsing. To incorporate this information, we use two extensions of the basic tree: one that includes the POS tags of the words (Figure 1e), and another one that includes both POS tags and syntactic chunks (Figure 1c). The POS tags are children of the semantic tags, whereas the chunks (i.e., phrasal information) are included as parents of the semantic tags.

We also experiment with full syntactic trees (Figure 1d) to see the impact of deep syntactic information. The semantic tags are attached to the pre-terminals (i.e., POS tags) in the syntactic tree. We use the Stanford POS tagger and syntactic parser and the Twitter NLP tool[1] for the shallow trees.

A sentence containing multiple clauses exhibits a coherence structure. For instance, in our example, the first clause *"along my route tell me the next steak house"* is *elaborated* by the second clause *"that is within a mile"*. The relations by which clauses in a text are linked are called *coherence* relations (e.g., *Elaboration, Contrast*). Discourse structures capture this coherence structure of text and provide additional semantic information that could be useful for the CSL task (Stede, 2011). To build the discourse structure of a sentence, we use a state-of-the-art discourse parser (Joty et al., 2012) which generates discourse trees in accordance with the Rhetorical Structure Theory of discourse (Mann and Thompson, 1988), as exemplified in Figure 1b. Notice that a text span linked by a coherence relation can be either a *nucleus* (i.e., the core part) or a *satellite* (i.e., a supportive one) depending on how central the claim is.

3.3 New features

In order to compare to the structured representation, we also devoted significant effort towards engineering a set of features to be used in a flat feature-vector representation; they can be used in isolation or in combination with the kernel-based approach (as a composite kernel using a linear combination):

CRF-based: these include the basic features used to train the initial semi-CRF model (cf. Section 2.1).

n-gram based: we collected 3- and 4-grams of the output label sequence at the level of concepts, with artificial tags inserted to identify the start ('S') and end ('E') of the sequence.[2]

Probability-based: two features computing the probability of the label sequence as an average of the probabilities at the word level $p(l_i|w_i)$ (i.e., assuming independence between words). The *unigram* probabilities are estimated by frequency counts using maximum likelihood in two ways: *(i)* from the complete 100-best list of hypotheses; *(ii)* from the training set (according to the gold standard annotation).

DB-based: a single feature encoding the number of results returned from the database when constructing a query using the conjunction of all semantic segments in the hypothesis. Three possible values are considered by using a threshold t: 0 (if the query result is void), 1 (if the number of results is in $[1, t]$), and 2 (if the number of results is greater than t). In our case, t is empirically set to 10,000.

4 Experiments

The experiments aim at investigating which structures, and thus which linguistic models and combination with other models, are the most appropriate for our reranker. We first calculate the *oracle* accuracy in order to compute an upper bound of the reranker. Then we present experiments with the feature vectors, tree kernels, and representations of linguistic information introduced in the previous sections.

4.1 Experimental setup

In our experiments, we use questions annotated with semantic tags in the restaurant domain,[3] which were collected by McGraw et al. (2012) through crowdsourcing on Amazon Mechanical Turk.[4] We split the dataset into training, development and test sets. Table 1 shows statistics about the dataset and about the size of the parts we used for training, development and testing (see the semi-CRF line).

We subsequently split the training data randomly into ten folds. We generated the N-best lists on the training set in a cross-validation fashion, i.e., iteratively training on nine folds and annotating the remaining fold. We computed the 100-best hypotheses for each example.

[1] Available from *http://nlp.stanford.edu/software/index.shtml* and *https://github.com/aritter/twitter_nlp*, respectively.

[2] For instance, if the output sequence is *Other-Rating-Other-Amenity* the 3-gram patterns would be: S-*Other-Rating, Other-Rating-Other, Rating-Other-Amenity*, and *Other-Amenity*-E.

[3] *http://www.sls.csail.mit.edu/downloads/restaurant*

[4] We could not use the datasets used by Dinarelli et al. (2011), because they use French and Italian corpora for which there are no reliable syntactic and discourse parsers.

	Train	Devel.	Test	Total
semi-CRF	6,922	739	1,521	9,182
Reranker	28,482	3,695	7,605	39,782

Table 1: Number of instances and pairs used to train the semi-CRF and rerankers, respectively.

N	1	2	**5**	10	100
F_1	83.03	87.76	**92.63**	95.23	98.72

Table 2: Oracle F_1-score for N-best lists of different lengths.

We used the development set to experiment and tune the hyper-parameters of the reranking model. The results on the development set presented in Section 4.2 were obtained by semi-CRF and reranking models learned on the training set. The results on the test set were obtained by models trained on the training plus development sets. Similarly, the N-best lists for the development and test sets were generated using a single semi-CRF model trained on the training set and the training+development sets, respectively.

Each generated hypothesis is represented using a semantic tree and a feature vector (explained in Section 3) and two extra features accounting for *(i)* the semi-CRF probability of the hypothesis, and *(ii)* the hypothesis reciprocal rank in the N-best list. SVM-Light-TK[5] is used to train the reranker with a combination of tree kernels and feature vectors (Moschitti, 2006; Joachims, 1999). Although we tried several parameters on the validation set, we observed that the default values yielded the highest results. Thus, we used the default c (trade-off) and tree kernel parameters and a linear kernel for the feature vectors. Table 1 shows the sizes of the train, the development and the test sets used for the semi-CRF as well as the number of pairs generated for the reranker. As a baseline, we picked the best-scored hypothesis in the list, according to the semi-CRF tagger. The evaluation measure used in all the experiments is the harmonic mean of precision and recall, i.e., the F_1-score (van Rijsbergen, 1979), computed at the token level and micro-averaged over the different semantic types.[6] We used paired t-test to measure the statistical significance of the improvements: we split the test set into 31 equally-sized samples and performed t-tests based on the F_1-scores of different models on the resulting samples.

4.2 Results

Oracle accuracy. Table 2 shows the oracle F_1-score for N-best lists of different lengths, i.e., which can be achieved by picking the best candidate of the N-best list for various values of N. We can see that going to 5-best increases the oracle F_1-score by almost ten points absolute. Going down to 10-best only adds 2.5 extra F_1 points absolute, and a 100-best list adds 3.5 F_1 points more to yield a respectable F_1-score of 98.72. This high result can be explained considering that the size of the complete hypothesis set is smaller than 100 for most questions. Thus, we can conclude that the N-best lists do include many good options and do offer quite a large space for potential improvement. We can further observe that going to 5-best lists offers a good balance between the length of the list and the possibility to improve F_1-score: generally, we do not want too long N-best lists since they slow down computation and also introduce more opportunities to make the wrong choice for a reranker (since there are just more candidates to choose from). In our experiments with larger N, we observed improvements only for 10 and only on the development set; thus, we will focus on 5-best lists in our experiments below.

	K0	K1	K2	K3	K4
Dev	84.21	82.92	83.07	**85.07**	83.78
Test	84.08	83.19	83.20	**84.61**	82.93

Table 3: Results for using different tree kernels on the basic tree (BT) representation.

Choosing the best tree kernel. We first select the most appropriate tree kernel to limit the number of experiment variables. Table 3 shows the results of different tree kernels using the basic tree (BT) representation (see Figure 1a). We can observe that for both the development set and the test set, kernel K3 (see Section 3.1) yields the highest F_1-score.

Impact of feature vectors. Table 4 presents the results for the feature vector experiments in terms of F_1-scores and relative error reductions (row RER). The first column shows the baseline, when no reranking is used; the following four columns contain the results when using vectors including different

[5] http://disi.unitn.it/moschitti/Tree-Kernel.htm

[6] 'Other' is not considered a semantic type, thus 'Other' tokens are not included in the F_1 calculation.

	RER	7.5	**9.6**	**7.4**	2.8	3.9	10.6	**10.7**	9.1
Test	83.03	84.61	**84.63**	**84.07**	83.81	83.86	84.67	**84.79**	84.76
	RER	9.3	**9.4**	**6.1**	4.5	4.8	9.6	**10.2**	10.2
	p.v.	0.00049	0.0002	0.012	0.032	0.00018	0.00028	0.00004	0.000023

Table 5: Tree kernel experiments: F_1-score, relative error reduction (in %), and p-values.

kinds of features: *(i)* n-gram features, *(ii)* all features used by the semi-CRF, *(iii)* count features, and *(iv)* database (DB) features. In each case, we include two additional features: the semi-CRF score (i.e., the probability) and the reciprocal rank of the hypothesis in the N-best list. Among *(i)–(iv)*, only the semi-CRF features seem to help; the rest either show no improvements or degrade the performance. However, putting all these features together (AllFeat) yields sizable gains in terms of F_1-score and a relative error reduction of 4-5%; the improvement is statistically significant, and it is slightly larger on the test dataset compared to the development dataset.

Impact of structural kernels and combinations. Table 5 shows the results when experimenting with various tree structures (see columns 2-5): *(i)* the basic tree (BT), *(ii)* the basic tree augmented with part-of-speech information (BTP), *(iii)* shallow syntactic tree (ShT), and *(iv)* syntactic tree (ST). We can see that the basic tree works rather well, yielding +1.6 F_1-score on the test dataset, but adding POS information can help a bit more, especially for the tuning dataset. Interestingly, the syntactic tree kernels, ShT and ST, perform worse than BT and BTP, especially on the test dataset. The last three columns in the table show the results when we combine the AllFeat feature vector (see Table 4) with BT and ShT. We can see that combining AllFeat with ShT works better, on both development and test sets, than combining it with BT or with both ShT and BT. Also note the big jump in performance from AllFeat to AllFeat+ShT. Overall, we can conclude that shallow syntax has a lot to offer over AllFeat, and it is preferable over BT in the combination with AllFeat. The improvements reported in Tables 5 and 6 are statistically significant when compared to the semi-CRF baseline as shown by the p.v. (value) row. Moreover, the improvement of AllFeat + ShT over BT is also statistically significant (p.v.$<$0.05).

	Baseline	DS	Combining AllFeat and +DS	+DS +BT	+DS +ShT

	p.v.	0.0005	0.0001	0.00066	0.00015

Table 6: Experiments with discourse kernels: F_1 score, relative error reduction (in %), and p-values.

Discourse structure. Finally, Table 6 shows the results for the discourse tree kernel (DS), which we designed and experimented with for the first time in this paper. We see that DS yields sizable improvements over the baseline. We also see that further gains can be achieved by combining DS with AllFeat, and also with BT and ShT, the best combination being AllFeat+DS+ShT (see last column). However, comparing to Table 5, we see that it is better to use just AllFeat+ShT and leave DS out. We would like to note though that the discourse parser produced non-trivial trees for only 30% of the hypotheses (due to the short, simple nature of the questions); in the remaining cases, it probably hurt rather than helped. We conclude that discourse structure has clear potential, but how to make best use of it, especially in the case of short simple questions, remains an open question that deserves further investigation.

Tag ID		Other	Rating	Restaurant	Amenity	Cuisine	Dish	Hours	Location	Price

Table 7: Confusion matrix for the output of the best performing system.

4.3 Error analysis and discussion

Table 7 shows the confusion matrix for our best-performing model *AllFeat+ShT* (rows = gold standard tags; columns = system predicted tags). Given the good results of the semantic parser, the numbers in the diagonal are clearly dominating the weight of the matrix. The largest errors correspond to missed (first column) and over-generated (first row) entity tokens. Among the proper confusions between semantic types, *Dish* and *Cuisine* tend to mislead each other most. This is due to the fact that these two tags are semantically similar, thus making them hard to distinguish. We can also notice that it is difficult to identify *Amenity* correctly, and the model mistakenly tags many other tags as *Amenity*. We looked into some examples to further investigate the errors. Our findings are as follow:

Inaccuracies and inconsistencies in human annotations. Since the annotations were done in Mechanical Turk, they have many inaccuracies and inconsistencies. For example, the word *good* with exactly the same sense was tagged as both *Other* and *Rating* by the Turkers in the following examples:

Gold: [$_{Other}$ any good] [$_{Price}$ cheap] [$_{Cuisine}$ german] [$_{Other}$ restaurants] [$_{Location}$ nearby]
Model: [$_{Other}$ any] [$_{Rating}$ good] [$_{Price}$ cheap] [$_{Cuisine}$ german] [$_{Other}$ restaurants] [$_{Location}$ nearby]

Gold: [$_{Other}$ any place] [$_{Location}$ along the road] [$_{Other}$ has a] [$_{Rating}$ good] [$_{Dish}$ beer] [$_{Other}$ selection that also serves] ...

Requires lexical semantics and more coverage. In some cases our model fails to generalize well. For instance, it fails to correctly tag *establishments* and *tameles* for the following examples. This suggests that we need to consider other forms of semantic information, e.g., distributional and compositional semantics computed from large corpora and/or using Web resources such as Wikipedia.

Gold: [$_{Other}$ any] [$_{Location}$ dancing establishments] [$_{Other}$ with] [$_{Price}$ reasonable] [$_{Other}$ pricing]
Model: [$_{Other}$ any] [$_{Amenity}$ dancing] [$_{Other}$ establishments] [$_{Other}$ with] [$_{Price}$ reasonable] [$_{Other}$ pricing]

Gold: [$_{Other}$ any] [$_{Cuisine}$ mexican] [$_{Other}$ places have a] [$_{Dish}$ tameles] [$_{Amenity}$ special today]
Model: [$_{Other}$ any] [$_{Cuisine}$ mexican] [$_{Other}$ places have a] [$_{Amenity}$ tameles] [$_{Other}$ special] [$_{Hours}$ today]

5 Conclusions

We have presented a study on the usage of syntactic and semantic structured information for improved Concept Segmentation and Labeling (CSL). Our approach is based on reranking a set of N-best sequences generated by a state-of-the-art semi-CRF model for CSL. The syntactic and semantic information was encoded in tree-based structures, which we used to train a reranker with kernel-based Support Vector Machines. We empirically compared several variants of syntactic/semantic structured representations and kernels, including also a vector of manually engineered features.

The first and foremost conclusion from our study is that structural kernels yield significant improvement over the strong baseline system, with a relative error reduction of $\sim 10\%$. This more than doubles the improvement when using the explicit feature vector. Second, we observed that shallow syntactic information also improves results significantly over the best model. Unfortunately, the results obtained using full syntax and discourse trees are not so clear. This is probably explained by the fact that user queries are rather short and linguistically not very complex. We also observed that the upper bound performance for the reranker still leaves large room for improvement. Thus, it remains to be seen whether some alternative kernel representations can be devised to make better use of discourse and other syntactic/semantic information. Also, we think that some innovative features based on analyzing the results obtained from our database (or the Web) when querying with the segments represented in each hypotheses have the potential to improve the results. All these concerns will be addressed in future work.

Abstract

The task of recommending hashtags for microblogs has been received considerable attention in recent years, and many applications can reap enormous benefits from it. Various approaches have been proposed to study the problem from different aspects. However, the impacts of temporal and personal factors have rarely been considered in the existing methods. In this paper, we propose a novel method that extends the translation based model and incorporates the temporal and personal factors. To overcome the limitation of only being able to recommend hashtags that exist in the training data of the existing methods, the proposed method also incorporates extraction strategies into it. The results of experiments on the data collected from real world microblogging services by crawling demonstrate that the proposed method outperforms state-of-the-art methods that do not consider these aspects. The relative improvement of the proposed method over the method without considering these aspects is around 47.8% in F1-score.

1 Introduction

Over the past few years, social media services have become one of the most important communication channels for people. According to the statistic reported by the Pew Research Center's Internet & American Life Project in Aug 5, 2013, about 72% of adult internet users are also members of at least one social networking site. Hence, microblogs have also been widely used as data sources for public opinion analyses (Bermingham and Smeaton, 2010; Jiang et al., 2011), prediction (Asur and Huberman, 2010; Bollen et al., 2011), reputation management (Pang and Lee, 2008; Otsuka et al., 2012), and many other applications (Sakaki et al., 2010; Becker et al., 2010; Guy et al., 2010; Guy et al., 2013). In addition to the limited number of characters in the content, microblogs also contain a form of metadata tag (hashtag), which is a string of characters preceded by the symbol (#). Hashtags are used to mark the keywords or topics of a microblog. They can occur anywhere in a microblog, at the beginning, middle, or end. Hashtags have been proven to be useful for many applications, including microblog retrieval (Efron, 2010), query expansion (A.Bandyopadhyay et al., 2011), sentiment analysis (Davidov et al., 2010; Wang et al., 2011). However, only a few microblogs contain hashtags provided by their authors. Hence, the task of recommending hashtags for microblogs has become an important research topic and has received considerable attention in recent years.

Existing works have studied discriminative models (Ohkura et al., 2006; Heymann et al., 2008) and generative models (Krestel et al., 2009; Blei and Jordan, 2003; Ding et al., 2013) based on textual information from a single microblog. However, from a dataset containing 282.2 million microblogs crawled from Sina Weibo[1], we observe that different users may have different perspectives when picking hashtags, and the perspectives of users are impacted by their own interests or the global topic trend. Meanwhile,the global topic distribution is likely to change over time. To better understand how the topics vary over time, we aggregate the microblog posts published in a month as a document. Then, we use a Latent Dirichlet Allocation (LDA) to estimate their topics. Figure 1 illustrates an example, where ten active topics are selected. We can observe that the topics distribution varies greatly over time.

[1]http://www.weibo.com. It is one of the most popular microblog services in China.

Proceedings of COLING 2014, the 25th International Conference on Computational Linguistics: Technical Papers, pages 203–212, Dublin, Ireland, August 23-29 2014.

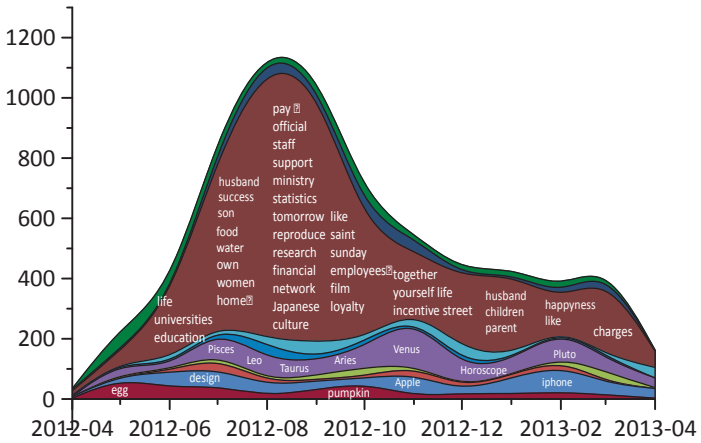

Figure 1: An example of the topics of retweets in each month. Each colored stripe represents a topic, whose height is the number of words assigned to the topic. For each topic, the top words of this topic in each month are placed on the stripe.

Motivated by the methods proposed to handle the vocabulary gap problem for keyphrase extraction (Liu et al., 2012) and hashtag suggestion (Ding et al., 2013), in this work, we also assume that the hashtags and textual content in a microblog are parallel descriptions of the same thing in different languages. To model the document themes, in this paper, we adopt the topical translation model to facilitate the translation process. Topic-specific word triggers are used to bridge the gap between the words and hashtags. Since existing topical translation models can only recommend hashtags learned from the training data, we also incorporate an extraction process into the model.

This work makes three main contributions. First, we incorporate temporal and personal factors into considerations. Most of the existing works on hashtag recommendation tasks have focused on textual information. Second, we adopt a topical translation model to combine extraction and translation methods. This makes it possible to suggest hashtags that are not included in the training data. Third, to evaluate the task, we construct a large collection of microblogs from a real microblogging service. All of the microblogs in the collection contain textual content and hashtags labeled by their authors. This can benefit other researchers investigating the same task or other topics using author-centered data.

The remaining part of this paper is structured as follows: We briefly review existing methods in related domains in Section 2. Section 3 gives an overview of the proposed generation model. Section 4 introduces the dataset construction, experimental results and analyses. In Section 5, we will conclude the paper.

2 Related Works

Due to the usefulness of tag recommendation, many methods have been proposed from different perspectives (Heymann et al., 2008; Krestel et al., 2009; Rendle et al., 2009; Liu et al., 2012; Ding et al., 2013). Heymann et al. (Heymann et al., 2008) investigated the tag recommendation problem using the data collected from social bookmarking system. They introduced an entropy-based metric to capture the generality of a particular tag. In (Song et al., 2008), a Poisson Mixture Model based method is introduced to achieve the tag recommendation task. Krestel et al. (Krestel et al., 2009) introduced a Latent Dirichlet Allocation to elicit a shared topical structure from the collaborative tagging effort of multiple users for recommending tags. Based on the the observation that similar webpages tend to have the same tags, Lu et al. proposed a method taking both tag information and page content into account to achieve the task (Lu et al., 2009). Ding et al. proposed to use translation process to model this task (Ding et al., 2013). They extended the translation based method and introduced a topic-specific translation model to process the various meanings of words in different topics. In (Tariq et al., 2013), discriminative-term-weights were used to establish topic-term relationships, of which users' perception were learned to suggest suitable hashtags for users. To handle the vocabulary problem in keyphrase extraction task, Liu et al. proposed a

topical word trigger model, which treated the keyphrase extraction problem as a translation process with latent topics (Liu et al., 2012).

Most of the works mentioned above are based on textual information. Besides these methods, personalized methods for different recommendation tasks have also been paid lots of attentions (Liang et al., 2007; Shepitsen et al., 2008; Garg and Weber, 2008; Li et al., 2010; Liang et al., 2010; Rendle and Schmidt-Thieme, 2010). Shepitsen et al. (2008) proposed to use hierarchical agglomerative clustering to take into account personalized navigation context in cluster selection. In (Garg and Weber, 2008), the problem of personalized, interactive tag recommendation was also studied based on the statics of the tags co-occurrence. Liang et al. (2010) proposed to the multiple relationships among users, items and tags to find the semantic meaning of each tag for each user individually and used this information for personalized item recommendation.

From the brief descriptions given above, we can observe that most of the previous works on hashtag suggestion focused on textual information. In this work, we propose to incorporate temporal and personal information into the generative methods. Further more, to over the limitation that translation based method can only recommend hashtags learned from the training data, we also propose to incorporate an extraction process into the model.

3 The Proposed Methods

In this section, we firstly introduce the notation and generation process of the proposed method. Then, we describe the method used for learning parameters. Finally, we present the methods of how do we apply the learned model to achieve the hashtag recommendation task.

3.1 The Generation Process

We use D to represent the number of microblogs in the given corpus, and the microblogs have been divided into T epoches. Let $t = 1, 2, ..., T$ be the index of an epoches, θ^t is the topic distribution of the epoch t. Each microblog is generated by a user u_i, where u_i is an index between 1 and U, and U is the total number of users. A microblog is a sequence of N_d words denoted by $w_d = \{w_{d1}, w_{d2}, ..., w_{dN_d}\}$. Each microblog contains a set of hashtags denoted by $h_d = \{h_{d1}, h_{d2}, ..., h_{dM_d}\}$. A word is defined as an item from a vocabulary with W distinct words indexed by $w = \{w_1, w_2, ..., w_W\}$. Each hashtag is from the vocabulary with V distinct hashtags indexed by $h = \{h_1, h_2, ..., h_V\}$. The notations in this paper are summarized in Table 1.

The original LDA assumes that a document is contains a mixture of topics, which is represented by a topic distribution, and each word has a hidden topic label. Although, it is sensible for long document, due to the limitations of the length of characters in a single microblog, it tends to be about a single topic. Hence, we associate a single hidden variable with each microblog to indicate its topic. Similar idea of assigning a single topic to a short sequence of words has also been used for modeling Twitters (Zhao et al., 2011)

The hashtag recommendation task is to discover a list of hashtags for each unlabeled microblog, In our method, we first learn a topical translation model, and then we estimate the latent variables for each microblog, finaly recommending hashtags accord to the learned model.

Fig. 2 shows the graphical representation of the generation process. The generative story for each microblog is as follows:

3.2 Learning

To learn the parameters of our model, we use collapsed Gibbs sampling (Griffiths and Steyvers, 2004) to sample the topics assignment $\mathbf{z}$, latent variables assignment $\mathbf{x}$ and $\mathbf{y}$.

Given the current state of all but the variable x_d and z_d for the dth microblog, we can jointly sample

1. Draw $\pi \sim Beta(\delta)$, $\eta \sim Beta(\lambda)$
2. Draw background word distribution $\phi^B \sim Dirichlet(\beta^w)$
3. Draw global trendy topic distribution $\theta^t \sim Dirichlet(\alpha)$ for each time epoch $t = 1, 2, ..., T$
4. Draw personal topic distribution $\psi^u \sim Dirichlet(\alpha)$ for each user $u = 1, 2, ..., U$
5. Draw word distribution $\phi^z \sim Dirichlet(\beta^w)$ for each topic $z = 1, 2, ..., K$
6. Draw hashtag distribution $\varphi_{z,w} \sim Dirichilet(\beta^h)$ for each topic $z = 1, 2, ..., K$ and each word $w = 1, 2, ..., W$
7. For each microblog $d = 1, 2, ..., D$

   a. Draw $x_d \sim Bernoulli(\eta)$

   b. If $x_d = 0$ then

   Draw a topic $z_d \sim Multinomial(\psi^u)$

   End if

   If $x_d = 1$ then

   Draw a topic $z_d \sim Multinomial(\theta^t)$

   End if

   c. For each word $n = 1, ..., N_d$

   i. Draw $y_{dn} \sim Bernoulli(\pi)$

   ii. If $y_{dn} = 0$ then

   Draw a word $w_{dn} \sim Multinomial(\phi^B)$

   End if

   If $y_{dn} = 1$ then

   Draw a word $w_{dn} \sim Multinomial(\phi^{z_d})$

   End if

   d. For each hashtag $m = 1, ..., M_d$

   i. Draw $h_{dm} \sim P(h_{dm}|w_d, z_d, \varphi_{z_d,w_d})$

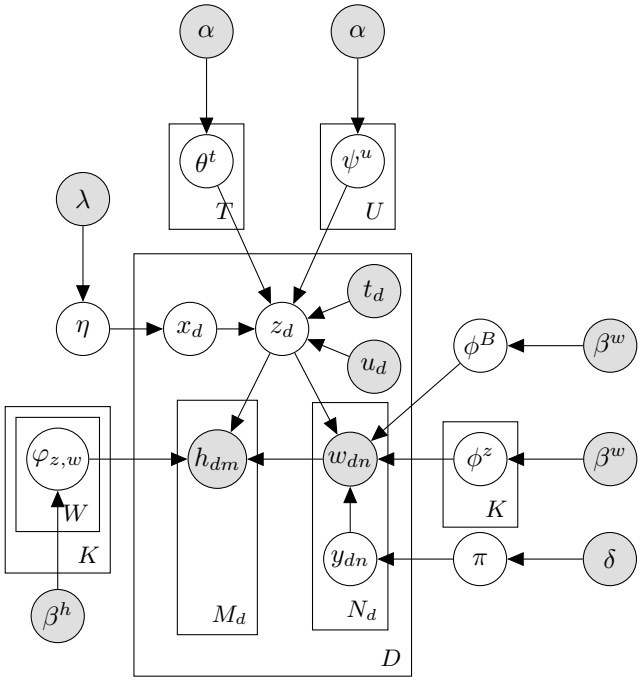

Figure 2: The graphical representation of the proposed model. Shaded circles are observations or constants. Unshaded ones are hidden variables.

Table 1: The notations used in this work.

D	The number of training data set
W	The number of unique word in the corpus
V	The number of unique hashtag in the corpus
K	The number of topics
T	The total number of time epoches
U	The total number of users
N_d	The number of words in the dth microblog
M_d	The number of hashtags in the dth microblog
z_d	The topic of the dth microblog
x_d	The latent variable decided the distribution category of z_d
y_{dn}	The latent variable decided the distribution category of w_{dn}
π	The distribution of latent variable y_{dn}
η	The distribution of latent variable x_d
ϕ^z	The distribution of topic words
ϕ^B	The distribution of background words
θ^t	The distribution of topics for time epoch t
ψ^u	The distribution of topics for user u
t_d	The time epoch for microblog d
u_d	The user of the microblog d
φ	The topic-specific word alignment table between word and hashtag or itself

x_d and z_d, the conditional probability of $x_d = p$,$z_d = k$ is calculated as follows:

$$\begin{aligned} &Pr(x_d = p, z_d = k|\mathbf{z}_{\neg\mathbf{d}}, \mathbf{x}_{\neg\mathbf{d}}, \mathbf{y}, \mathbf{w}, \mathbf{h}) \\ &\propto \frac{N_p^\eta + \lambda}{N_{(.)}^\eta + 2\lambda} \cdot \frac{N_k^l + \alpha}{N_{(.)}^l + K\alpha} \cdot \prod_{n=1}^{N_d} \frac{N_{w_{dn}}^k + \beta^w}{N_{(.)}^k + W\beta^w} \cdot \prod_{m=1}^{M_d} \sum_{n=1}^{N_d} \frac{M_{\neg d,k}^{w_{dn},h_{dm}} + \beta^h}{M_{\neg d,k}^{w_{dn},(.)} + V\beta^h}, \end{aligned} \tag{1}$$

where $l = u_d$ when $p = 0$ and $l = t_d$ when $p = 1$. N_0^η is the number of microblog generated by personal interests, while N_1^η is the number of microblog coming from global topical trends, $N_{(.)}^\eta = N_0^\eta + N_1^\eta$. $N_k^{u_d}$ is the number of microblogs generated by user u_d and under topic k. $N_{(.)}^{u_d}$ is the total number of microblogs generated by user u_d. $N_k^{t_d} = \sum_{t'=1}^{t_d} e^{\frac{-t'}{\rho}} N'^{t-t'}_k$, $N'^{t-t'}_k$ is the number of microblogs assigned to topic k at time epoch $t - t'$, $e^{\frac{-t'}{\rho}}$ is decay factory, and $N_{(.)}^{t_d} = \sum_{k=1}^K N_k^{t_d}$. $N_{w_{dn}}^k$ is the times of word w_{dn} assigned to topic k, $N_{(.)}^k$ is the times of all the word assigned to topic k, $M_{\neg d,k}^{w_{dn},h_{dm}}$ is the number of occurrences that word w_{dn} is translated to hashtag h_{dm} given topic k. All the counters mentioned above are calculated with the dth microblog excluded.

We sample y_{dn} for each word w_{dn} in the dth microblog using the following equation:

$$Pr(y_{dn} = q|\mathbf{z}, \mathbf{x}, \mathbf{y}_{\neg\mathbf{dn}}, \mathbf{w}, \mathbf{h}) \propto \frac{N_q^\pi + \delta}{N_{(.)}^\pi + 2\delta} \cdot \frac{N_{w_{dn}}^l + \beta^w}{N_{(.)}^l + W\beta^w}, \tag{2}$$

where $l = B$ when $q = 0$ and $l = z_d$ when $q = 1$. N_0^π is the number of words assigned to background words and N_1^π is the number of words under any topic respectively. $N_{(.)}^\pi = N_0^\pi + N_1^\pi$, $N_{w_{dn}}^B$ is a count of word w_{dn} occurs as a background word. $N_{w_{dn}}^{z_d}$ is the number of word w_{dn} is assigned to topic z_d, and $N_{(.)}^{z_d}$ is the total number of words assigned to topic z_d. All counters are calculated with taking no account of the current word w_{dn}.

In many cases, hashtag dose not appear in the training data, to solve this problem, we assume that each word in the microblog can translate to a hashtag in the training data or itself. We assume that each word

have aligned σ (we set $\sigma = 1$ in this paper after trying some number) times with itself under the specific topic. After all the hidden variables become stable, we can estimate the alignment probability as follows:

$$\varphi_{h,w,z} = \begin{cases} \frac{N^h_{z,w}+\beta^h}{N^{(.)}_{z,w}+\sigma+(V+1)\beta^h} & \text{if } h \text{ is a hashtag in the training data} \\ \frac{\sigma+\beta^h}{N^{(.)}_{z,w}+\sigma+(V+1)\beta^h} & \text{if } h \text{ is the word itself} \end{cases} \tag{3}$$

where $N^h_{z,w}$ is the number of the hashtag h co-occurs with the word w under topic z in the microblogs.

For the probability alignment φ between hashtag and word, the potential size is $W \cdot V \cdot K$. The data sparsity poses a more serious problem in estimating φ than the topic-free word alignment case. To remedy the problem, we use interpolation smoothing technique for φ. In this paper, we emplogy smoothing as follows:

$$\varphi^*_{h,w,z} = \gamma\varphi_{h,w,z} + (1-\gamma)P(h|w), \tag{4}$$

where $\varphi^*_{h,w,z}$ is the smoothed topical alignment probabilities, $\varphi_{h,w,z}$ is the original topical alignment probabilities. $P(h|w)$ is topic-free word alignment probability. Here we obtain $P(h|w)$ by exploring IBM model-1 (Brown et al., 1993). γ is trade-off of two probabilities ranging from 0.0 to 1.0. When $\gamma = 0.0$, $\varphi^*_{h,w,z}$ will be reduce to topic-free word alignment probability; and when $\gamma = 1.0$, there will be no smoothing in $\varphi^*_{h,w,z}$. For the word itself there are no smoothing, because it is a pseudo-count.

3.3 Hashtag Extraction

We perform hashtag extraction as follows. Suppose given an unlabeled dataset, we perform Gibbs Sampling to iteratively estimate the topic and determine topic/background words for each microblog. The process is the same as described in Section 3.2. After the hidden variables of topic/background words and the topic of each microblog become stable, we can estimate the distribution of topics for the dth microblog in unlabeled data by:$\chi^*_{dk} = \frac{p(k)p(w_{d1}|k)\ldots p(w_{dN_d}|k)}{Z}$ where $p(w_{dn}|k) = \frac{N^\pi_1+\delta}{N^\pi_{(.)}+2\delta} \cdot \frac{N^k_{w_{dn}}+\beta^w}{N^k_{(.)}+W\beta^w}$ and $N^k_{w_{dn}}$ is the number of words w_{dn} that are assigned to topic k in the corpus, and $p(k) = \frac{N^\eta_0+\lambda}{N^\eta_{(.)}+2\lambda} \cdot \frac{N^u_k+\alpha}{N^u_{(.)}+K\alpha} + \frac{N^\eta_1+\lambda}{N^\eta_{(.)}+2\lambda} \cdot \frac{N^t_k+\alpha}{N^t_{(.)}+K\alpha}$ is regarded as a prior for topic distribution, Z is the normalized factor. With topic distribution χ^* and topical alignment table φ^*, we can rank hashtags for the dth microblog in unlabeled data by computing the scores:

$$P(h_{dm}|w_d, \chi^*_d, \varphi^*) \propto \sum_{z_d=1}^{K}\sum_{n=1}^{N_d} P(h_{dm}|z_d, w_{dn}, \varphi^*) \cdot P(z_d|\chi^*_d) \cdot P(w_{dn}|w_d), \tag{5}$$

where h_{dm} can be a hashtag in the training data or a word in the dth microblog, $p(w_{dn}|w_d)$ is the weight of the word w_{dn} in the microblog, which can be estimated by the IDF score of the word. According to the ranking scores, we can suggest the top-ranked hashtags for each microblog to users.

4 Experiments

In this section, we introduce the experimental results and the data collection we constructed for training and evaluation. Firstly, we describe how do we construct the collection and statics of it. Then we introduce the experiment configurations and baseline methods. Finally, the evaluation results and analysis are given.

4.1 Data Collection

We use a dataset collected from Sina Weibo to evaluate the proposed approach and alternative methods. We random select 166,864 microblogs from Aug. 2012 to June 2013. The unique number of hashtags in the corpus is 17,516. We use the microblogs posted from Aug. 2012 to May 2013 as the training data. The other microblogs are used for evaluation. The hashtags marked in the original microblogs are considered as the golden standards.

Figure 3: Precision-recall curves of different methods on this task.

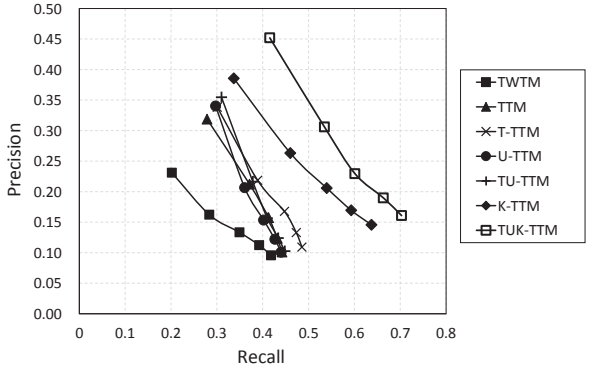

Table 2: Evaluation results of different methods on the evaluation collection.

Methods	Precision	Recall	F_1
TWTM	0.231	0.202	0.215
SVM	0.418	0.366	0.390
TTM	0.319	0.279	0.297
T-TTM	0.338	0.301	0.319
U-TTM	0.341	0.307	0.323
K-TTM	0.386	0.337	0.360
TU-TTM	0.355	0.310	0.331
TUK-TTM	**0.452**	**0.415**	**0.433**

4.2 Experiment Configurations

We use precision (P), recall (R), and F1-score (F_1) to evaluate the performance. Precision is calculated based on the percentage of "hashtags truly assigned" among "hashtags assigned by system". Recall is calculated based on the "hashtags truly assigned" among "hashtags manually assigned". F1-score is the harmonic mean of precision and recall. We do 500 iterations of Gibbs sampling to train the model. For optimize the hyperparmeters of the proposed method and alternative methods, we use 5-fold cross-validation in the training data to do it. The number of topics is set to 70. The other settings of hyperparameters are as follows: $\alpha = 50/K$, $\beta^w = 0.1$, $\beta^h = 0.1$, $\lambda = 0.01$, and $\delta = 0.01$. The smoothing factor γ in Eq.(3) is set to 0.6. For estimating the translation probability without topical information, we use GIZA++ 1.07 to do it (Och and Ney, 2003).

For baselines, we compare the proposed model with the following alternative models.

- **TWTM**: Topical word trigger model (TWTM) was proposed by Liu et al. for keyphrase extraction using only textual information (Liu et al., 2012). We implemented the model and used it to achieve the task.

- **TTM**: Ding et al. (2013) proposed the topical translation model (TTM) for hash tag extraction. We implemented and extended their method for evaluating it on the corpus constructed in this work.

4.3 Experimental Results

Table 2 shows the comparisons of the proposed method with the state-of-the-art methods on the constructed evaluation dataset. "TUK-TTM" denotes the method proposed in this paper. "T-TTM" and "U-TTM" represent the methods incorporating temporal and personal information respectively. "K-TTM" represents the method incorporating the extraction factor. From the results, we can observe that the proposed method is significantly better than other methods at 5% significance level (two-sided). Comparing to results of the TTM, we can observe that the temporal information, personal information and extraction strategy can all benefit the task. Among the three additional factors, the extraction strategy achieves the best result. The limitation of only being able to recommend hashtags that exist in the training data can be overcome in some degree by the proposed method. The relative improvement of proposed TUK-TTM over TTM is around 47.8% in F1-score.

Table 3 shows the comparisons of the proposed method with the method "K-TTM" in two corpus NE-Corpus and E-Corpus. NE-Corpus include microblogs whose hashtags are not contained in the training data. E-Corpus include the microblogs whose hashtags appear in the training data. We can observe that the proposed method significantly better than "K-TTM" in the E-Corpus. Another observation is that the method incorporating the extraction factor achieves better performances on the NE-Corpus than E-Corpus. We think that the reason is that the fewer times hashtag appear, the greater weight it has. Hence, we can extract this kind of hashtags more easier.

Figure 3 shows the precision-recall curves of TWTW, TTM, T-TTM, U-TTM, TU-TTM, K-TTM, and TUK-TTM on the evaluation dataset. Each point of a precision-recall curve represents extracting

Table 3: Evaluation results of two different corpus.

Corpus	Methods	P	R	F
NE-Corpus	K-TTM	0.631	0.553	0.589
	TUK-TTM	0.641	0.561	0.598
E-Corpus	K-TTM	0.172	0.162	0.167
	TUK-TTM	0.288	0.271	0.279

Table 4: The influence of the number of topics K of TUK-TTM.

K	Precision	Recall	$\mathbf{F}_1$
10	0.410	0.382	0.396
30	0.435	0.380	0.406
50	0.448	0.413	0.430
70	**0.452**	**0.415**	**0.433**
100	0.439	0.404	0.421

Table 5: The influence of the smoothing parameter γ of TUK-TTM.

γ	Precision	Recall	$\mathbf{F}_1$
0.0	0.379	0.354	0.366
0.2	0.405	0.372	0.388
0.4	0.433	0.398	0.415
0.6	**0.452**	**0.415**	**0.433**
0.8	0.426	0.386	0.405
1.0	0.423	0.381	0.401

different number of hashtags ranging from 1 to 5 respectively. In the figure, curves which are close to the upper right-hand corner of the graph indicate the better performance. From the results, we can observe that the performance of TUK-TTM is in the upper right-hand corner. It also demonstrates that the proposed method achieves better performances than other methods.

From the description of the proposed model, we can know that there are several hyperparameters in the proposed TUK-TTM. To evaluate the impacts of them, we evaluate two crucial ones, the number of topics K and the smoothing factor γ. Table 4 shows the influence of the number of topics. From the table, we can observe that the proposed model obtains the best performance when K is set to 70. And performance decreases with more number of topics. We think that data sparsity may be one of the main reasons. With much more topic number, the data sparsity problem will be more serious when estimating topic-specific translation probability. Table 5 shows the influence of the translation probability smoothing parameter γ. When γ is set to 0.0, it means that the topical information is omitted. Comparing the results of $\gamma = 0.0$ and other values, we can observe that the topical information can benefit this task. When γ is set to 1.0, it represents the method without smoothing. The results indicate that it is necessary to address the sparsity problem through smoothing.

5 Conclusions

In this paper, we propose a novel method which incorporates temporal and personal factors into the topical translation model for hashtag recommendation task. Since existing translation model based methods for this task can only recommend hashtags that exist in the training data of the topical translation model, we also incorporate extraction strategies into the model. To evaluate the proposed method, we also construct a dataset from real world microblogging services. The results of experiments on the dataset demonstrate that the proposed method outperforms state-of-the-art methods that do not consider these aspects.

Abstract

This paper presents a machine learning approach to sarcasm detection on Twitter in two languages – English and Czech. Although there has been some research in sarcasm detection in languages other than English (e.g., Dutch, Italian, and Brazilian Portuguese), our work is the first attempt at sarcasm detection in the Czech language. We created a large Czech Twitter corpus consisting of 7,000 manually-labeled tweets and provide it to the community. We evaluate two classifiers with various combinations of features on both the Czech and English datasets. Furthermore, we tackle the issues of rich Czech morphology by examining different preprocessing techniques. Experiments show that our language-independent approach significantly outperforms adapted state-of-the-art methods in English (F-measure 0.947) and also represents a strong baseline for further research in Czech (F-measure 0.582).

1 Introduction

Sentiment analysis on social media has been one of the most targeted research topics in NLP in the past decade, as shown in several recent surveys (Liu and Zhang, 2012; Tsytsarau and Palpanas, 2012). Since the goal of sentiment analysis is to automatically detect the polarity of a document, misinterpreting irony and sarcasm represents a big challenge (Davidov et al., 2010).

As there is only a weak boundary in meaning between irony, sarcasm and satire (Reyes et al., 2012), we will use only the term sarcasm in this paper. Bosco et al. (2013) claim that "even if there is no agreement on a formal definition of irony, psychological experiments have delivered evidence that humans can reliably identify ironic text utterances from an early age in life." We have thus decided to rely on the ability of our human annotators to manually label sarcastic tweets to train our classifiers. Sarcasm generally reverses the polarity of an utterance from positive or negative into its opposite, which deteriorates the results of a given NLP task. Therefore, correct identification of sarcasm can improve the performance.

The issue of automatic sarcasm detection has been addressed mostly in English, although there has been some research in other languages, such as Dutch (Liebrecht et al., 2013), Italian (Bosco et al., 2013), or Brazilian Portuguese (Vanin et al., 2013). To the best of our knowledge, no research has been conducted in Czech or other Slavic languages. These languages are challenging for many NLP tasks because of their rich morphology and syntax. This has motivated us to focus our current research on both English and Czech.

Majority of the existing state-of-the-art techniques are language dependent, which rely on language-specific lexical resources. Since no such resources are available for Czech, we adapt some language-independent methods and also apply various preprocessing steps for sentiment analysis proposed by Habernal et al. (2013).

This paper focuses on document-level sarcasm detection on Czech and English Twitter datasets using supervised machine learning methods. The Czech dataset consists of 7,000 manually labeled tweets,

Proceedings of COLING 2014, the 25th International Conference on Computational Linguistics: Technical Papers, pages 213–223, Dublin, Ireland, August 23-29 2014.

the English dataset consists of a balanced distribution and an imbalanced distribution, each containing 100,000 tweets, where hashtag #sarcasm was used as an indicator of sarcastic tweets. We provide both datasets under Creative Commons BY-NC-SA licence[1] at http://liks.fav.zcu.cz/sarcasm/.

Our research questions were the following: (1) To what extent can the language-independent approach compete with methods based on lexical language-dependent resources? (2) Is it possible to reach good agreement on annotating sarcasm and what typical text properties on Twitter are important for sarcasm detection? (3) What is the best preprocessing pipeline that can boost performance on highly-flective Czech language and what types of features and classifiers yield the best results?

The rest of this article is organized as follows. Section 2 describes the related work. In section 3, we outline our approach to sarcasm detection and describe the selection of features in our approach. Section 4 thoroughly describes the datasets and the annotation process. Section 5 describes and discusses the experimental results. Finally we conclude in Section 6.

2 Related Work

Experiments with semi-supervised sarcasm identification on a Twitter dataset (5.9 million tweets) and on 66,000 product reviews from Amazon were conducted in (Davidov et al., 2010) and (Tsur et al., 2010). They used 5-fold cross validation on their kNN-like classifier and obtained an F-measure of 0.83 on the product reviews dataset and 0.55 on the Twitter dataset. For acquiring the Twitter dataset they used hashtag #sarcasm as an indicator of sarcastic tweets. They further created a balanced evaluation set of 180 tweets using 15 human annotators via Amazon Mechanical Turk[2] and achieved an inter-annotator agreement 0.41 (Fleiss' κ).

González-Ibáñez et al. (2011) experimented with Twitter data divided into three categories (sarcastic, positive sentiment and negative sentiment), each containing 900 tweets. They used the #sarcasm and #sarcastic hashtags to identify sarcastic tweets. They used two classifiers – support vector machine (SVM) with sequential minimal optimization (SMO) and logistic regression. They tried various combinations of unigrams, dictionary-based features and pragmatic factors (positive and negative emoticons and user references), achieving the best result (accuracy 0.65) for sarcastic and non-sarcastic classification with the combination of SVM with SMO and unigrams. They employed 3 human judges to annotate 180 tweets (90 sarcastic and 90 non-sarcastic). The human judges achieved Fleiss' $\kappa = 0.586$, demonstrating the difficulty of sarcasm classification. Another experiment included 50 sarcastic and 50 non-sarcastic (25 positive, 25 negative) tweets with emoticons annotated by two judges. The automatic classification and human judges achieved the accuracy of 0.71 and 0.89 respectively. The inter-annotator agreement (Cohen's κ) was 0.74.

Reyes et al. (2012) proposed features to capture properties of a figurative language such as ambiguity, polarity, unexpectedness and emotional scenarios. Their corpus consists of five categories (humor, irony, politics, technology and general), each containing 10,000 tweets. The best result in the classification of irony and general tweets was F-measure 0.65.

In (Reyes et al., 2013) they explored the representativeness and relevance of conceptual features (signatures, unexpectedness, style and emotional scenarios). These features include punctuation marks, emoticons, quotes, capitalized words, lexicon-based features, character n-grams, skip-grams, (Guthrie et al., 2006), and polarity skip-grams. Their corpus consists of four categories (irony, humor, education and politics), each containing 10,000 tweets. Their evaluation was performed on two distributional scenarios, balanced distribution and imbalanced distribution (25% ironic tweets and 75% tweets from all three non-ironic categories) using the Naive Bayes and decision trees algorithms from the Weka toolkit (Witten and Frank, 2005). The classification by the decision trees achieved an F-measure of 0.72 on the balanced distribution and an F-measure of 0.53 on the imbalanced distribution.

The work of Riloff et al. (2013) identifies one type of sarcasm: contrast between a positive sentiment and negative situation. They used a bootstrapping algorithm to acquire lists of positive sentiment phrases

[1] http://creativecommons.org/licenses/by-nc-sa/3.0/

[2] http://www.mturk.com

and negative situation phrases from sarcastic tweets. They proposed a method which classifies tweets as sarcastic if it contains a positive predicative that precedes a negative situation phrase in close proximity. Their evaluation on a human-annotated dataset[3] of 3000 tweets (23% sarcastic) was done using the SVM classifier with unigrams and bigrams as features, achieving an F-measure of 0.48. The hybrid approach that combines the results of the SVM classifier and their contrast method achieved an F-measure of 0.51.

Sarcasm and nastiness classification in online dialogues was also explored in (Lukin and Walker, 2013) using bootstrapping, syntactic patterns and a high precision classifier. They achieved an F-measure of 0.57 on their sarcasm dataset.

3 Our Approach

This paper presents the first attempt at sarcasm detection in the Czech language, in which we focus on supervised machine learning approaches and evaluate their performance. We selected various n-grams, including unigrams, bigrams, trigrams with frequency greater than three (Liebrecht et al., 2013), and a set of language-independent features, including punctuation marks, emoticons, quotes, capitalized words, character n-grams and skip-grams (Reyes et al., 2013) as our baselines.

3.1 Classification

Our evaluation was performed using the Maximum Entropy (MaxEnt) and Support Vector Machine (SVM) classifiers. We used *Brainy* – a Java framework for machine learning (Konkol, 2014) – with default settings (the linear kernel for SVM). All experiments were conducted in the 5-fold cross validation manner similar to (Davidov et al., 2010; González-Ibáñez et al., 2011). Our motivation to test multiple classifiers stemmed also from related works which mostly test more than one classifier. On the other hand, the choice between state-of-the-art linear classifiers might not be much of importance, as the most important is the feature engineering.

3.2 Features

For our evaluation we used the most promising language-independent features from the related work and POS related features. Feature sets used in our evaluation are described in Table 1.

Group	Features	Description
N-gram	Character n-gram	We used character n-gram features (Blamey et al., 2012). We set the minimum occurrence of a particular character n-gram to either 5 or 50, in order to prune the feature space. Our character feature set contains 3-grams to 6-grams.
	N-gram	We used word unigrams, bigrams and trigrams as binary features. The feature space is pruned by the minimum n-gram occurrence set to 3 (Liebrecht et al., 2013).
	Skip-bigram	Instead of using sequences of adjacent words (n-grams) we used skip-grams (Guthrie et al., 2006), which skip over arbitrary gaps. Reyes et al. (2013) consider skip-bigrams with 2 or 3 word skips and remove skip-grams with a frequency ≤ 20.
Pattern	Pattern	Patterns composed of high frequency words (HFWs)[4] and content words (CWs)[5] used by (Davidov et al., 2010). Pattern must contain at least one high frequency word. The patterns contain 2-6 HFWs and 1-6 CWs. We set the minimum occurrence of a particular pattern to 5.
	Word-shape pattern	We tried to improve pattern features by using word-shape classes for content words. We assign words into one of 24 classes[6] similar to the function specified in (Bikel et al., 1997).
POS	POS characteristics	We implemented various POS features, e.g., the number of nouns, verbs, and adjectives (Ahkter and Soria, 2010), the ratio of nouns to adjectives and verbs to adverbs (Kouloumpis et al., 2011), and number of negative verbs obtained from POS tags.

[3]They used three annotators. Each annotator was given the same 100 tweets with the sarcasm hashtag and 100 tweets without the sarcasm hashtag (the hashtags were removed). On these tweets the pairwise inter-annotator scores were computed (Cohen's Kappa $\kappa_1 = 0.80, \kappa_2 = 0.81$ and $\kappa_3 = 0.82$). Then each annotator labeled additional 1000 tweets.

[4]A word whose corpus frequency is more than 1000 words per million plus all punctuation characters.

[5]A word whose corpus frequency is less than 1000 words per million.

[6]We use edu.stanford.nlp.process.WordShapeClassifier with the WORDSHAPECHRIS1 setting.

	POS word-shape	Unigram feature consisting of POS and word-shape (see Word-shape pattern). The feature space is pruned by the minimum occurrence set to 5.
	POS n-gram	Direct use of POS n-grams has not shown any significant improvement in sentiment analysis but it may improve the results of sarcasm detection. We experimented with 3-grams to 6-grams with the minimum n-gram occurrence set to 5.
Others	Emoticons	We used two lists of positive and negative emoticons (Montejo-Ráez et al., 2012). The feature captures the number of occurrences of each class of emoticons within the text.
	Punctuation-based	We adapted punctuation-based features proposed by (Davidov et al., 2010). This feature set consists of number of words, exclamation marks, question marks, quotation marks and capitalized words normalized by dividing them by the maximal observed value multiplied by the averaged maximal value of the other feature groups.
	Pointedness	Pointedness was used by (Reyes et al., 2013) to distinguish irony. It focuses on explicit marks which should reflect a sharp distinction in the information that is transmitted. The presence of punctuation marks, emoticons, quotes and capitalized words has been considered.
	Extended Pointedness	This feature captures the number of occurrences of punctuation marks and emoticons as well as the number of words, exclamation marks, question marks, quotation marks and capitalized words normalized by maximal observed value.
	Word-case	We implemented various word-case features that include, e.g., the number of upper cased words, number of words with first letter capital normalized by number of words and number of upper cased characters normalized by number of words.

Table 1: Descriptions of used feature sets.

4 Evaluation Datasets

We collected datasets using *Twitter Search API* and *Java Language Detector*[7]. We collected 140,000 Czech and 780,000 English tweets, respectively. Due to lack of support for the Czech language on Twitter, we used the *Twitter Search API* parameter *geocode* to acquire tweets posted near Prague. For the English dataset we also collected tweets with the #sarcasm hashtag. Czech users generally don't use the sarcasm ("`#sarkasmus`") or irony ("`#ironie`") hashtag variants[8] thus we had to annotate the Czech dataset manually. The final label distribution in datasets is shown in Table 4.

4.1 Filtering and Normalization

All user, URL and hashtag references in tweets have been replaced by "user", "link" and "hashtag" respectively. We also removed all tweets starting with "RT" because they refer to previous tweets and tweets containing just combinations of user, link, "RT" and hashtags without any additional words.

Tokenization of tweets requires proper handling of emoticons and other special character sequences typical on Twitter. The *Ark-tweet-nlp tool* (Gimpel et al., 2011) offers precisely that and although it was developed and tested in English, it yields satisfactory results in Czech as well.

Czech is a highly flective language and uses a lot of diacritics. However some Czech users type only the unaccented characters.[9] Preliminary experiments showed that removing diacritics yields better results, thus we removed diacritics from all tweets.

4.2 Czech Dataset Annotation

Firstly we conducted an experiment to determine whether to annotate the original data or the normalized data. We selected two sample sets of 50 tweets containing Czech sarcasm (`#sarkasmus`) and irony (`#ironie`) hashtags and other tweets. One annotator obtained the original data while the other got the normalized data from the first sample set. We then tried to give both annotators the original data from the first sample set and finally we gave them both the normalized data from the second sample set. Table 2 shows the difficulty of sarcasm identification without the knowledge hidden in hashtags, user and links.

[7] `http://code.google.com/p/jlangdetect/`

[8] We found only 10 tweets with sarcasm hashtag ("`#sarkasmus`") and 100 tweets with irony hashtag ("`#ironie`") in 140,000 collected tweets.

[9] Approximately 10% of collected tweets were without any diacritics.

Normalized	Normalized

"Basic" pipe	**Pipe 2**	**Pipe 3**
Tokenizing: ArkTweetNLP		
POS tagging: PDT		
–	**Stem:** no (Sn) / light (Sl) / HPS (Sh)	
–	**Stopwords removal**	
–	–	**Phonetic:** eSpeak (Pe)

Table 3: The preprocessing pipes for Czech (top-down). Combinations of methods are denoted using the appropriate labels, e.g. "Sn" means *1. tokenizing, 2. POS-tagging, 3. no stemming and 4. removing stopwords*. eSpeak stands for a phonetic transcription to International Phonetic Alphabet, which should reduce the effects of grammar mistakes and misspellings.

The most promising results come from the annotation of the original data, thus the rest of the data are annotated in this manner.

We randomly selected 7,000 tweets from the collected data for annotation. The annotators were given just simple instructions without an explicit sarcasm definition (see Section 1): *"A tweet is considered sarcastic when its content is intended ironically / sarcastically without anticipating further information. Offensive utterances, jokes and ironic situations are not considered ironic / sarcastic."*

The complete dataset of 7,000 tweets was independently annotated by two annotators. The inter-annotator agreement (Cohen's κ) between the two annotators is 0.54. They disagreed on 403 tweets. To resolve these conflicts we used a third annotator.

The third annotator has been instructed the same way as the other two. The final κ agreement was measured between the first two annotators, thus it was not affected by the third annotator. Kappa agreements measured on the conflicted states (403 tweets) were 0.4 (annotator 1 vs. annotator 3) and 0.6 (annotator 2 vs. annotator 3).

Preprocessing

Preprocessing steps for handling social media texts in Czech were explored in (Habernal et al., 2013). The preprocessing diagram and its variants is depicted in Table 3. Overall, there are various possible preprocessing "pipe" configurations including "Basic" pipeline consisting of tokenizing and POS-tagging only. We adapted all their preprocessing pipelines. However, as the number of combinations would be too large, we report only the settings with better performance.

4.3 English Dataset

We collected 780,000 (130,000 sarcastic and 650,000 non-sarcastic) tweets in English. The `#sarcasm` hashtag was used as an indicator of sarcastic tweets. From this corpus we created two distributional scenarios based on the work of (Reyes et al., 2013). Refer to Table 4 for the final statistics of the dataset. Part of speech tagging was done using the *Ark-tweet-nlp tool* (Gimpel et al., 2011).

5 Results

For each preprocessing pipeline (refer to table 3) we assembled various sets of features and employed two classifiers. Accuracy (micro F-measure) tends to prefer performance on dominant classes in highly

Dataset \ Tweets	Sarcastic	Non-sarcastic

Table 5: Results on the Czech dataset with the MaxEnt classifier. Macro F-measure, 95% confidence interval $\approx \pm 1.2$. Best results are in bold. **B2**: character n-gram (3-5, min. occurrence > 50) + skip-bigram + pointedness; **FS1**: character n-gram (3-6, min. occurrence > 5) + extended pointedness; **FS2**: POS word-shape + pattern + POS characteristics + emoticons + word-case.

unbalanced datasets (Manning et al., 2008), thus we chose macro F-measure as the evaluation metric (Forman and Scholz, 2010), as it allows us to compare classification results on different datasets. For statistical significance testing, we report confidence intervals at α 0.05. Another applicable methods would be, i.e., two-matched-samples t Test or McNemar's test (Japkowicz and Shah, 2011).

5.1 Czech

Tables 5 and 6 show the results on the Czech dataset. The best result (F-measure 0.582) was achieved by the SVM classifier and a feature set enriched with patterns, utilizing stopwords removal and phonetic transcription in the preprocessing step.

The importance of the appropriate preprocessing techniques for Czech is evident from the improvement of results for various feature sets, e.g., the best result for "Basic" pipeline (see line "B2 + pattern"). Both baselines show improvement on most preprocessing pipelines. The most significant difference is visible on the second baseline with the MaxEnt classifier and the "Sl" pipeline where the F-measure is 0.018 higher than the "Basic" pipeline with no additional preprocessing. The n-gram baseline was significantly outperformed by the SVM classifier with feature sets "B1 + POS characteristics + Emoticons + Word-case" and "B1 + extended pointedness" on the "SnPe" pipeline.

Error Analysis

To get a better understanding of the limitations of our approach, we inspected 100 random tweets from the Czech dataset, which were wrongly classified by the SVM classifier with the best feature combination.

Feature Set \ Pipeline	Basic	Sh	ShPe	Sl	SlPe	Sn	SnPe
Baseline 1 (B1): n-gram	55.8	54.6	54.5	54.6	55.5	56.0	53.9

Table 6: Results on the Czech dataset with the SVM classifier. Macro F-measure, 95% confidence interval $\approx \pm 1.2$. Best results are in bold. **B2**: character n-gram (3-5, min. occurrence > 50) + skip-bigram + pointedness; **FS1**: character n-gram (3-6, min. occurrence > 5) + extended pointedness; **FS2**: POS word-shape + pattern + POS characteristics + emoticons + word-case.

We found 48 false positives and 52 false negatives. The annotators disagreed upon 10% of these tweets.

Non-sarcastic tweets were often about news, reviews, general information and user status updates. In most of the difficult cases of true negatives, the tweet contains a question, insult, opinion or wordplay.

Understanding sarcasm in some tweets was often bound with broader common knowledge (e.g., about news or celebrities), the context known only to the author or authors opinion. Another difficulty poses subtle or sophisticated expression of sarcasm such as *"I'm not sure whether you didn't overdo a bit the first part of the renovation - the demolition. :)"*[10] or *"Conservatism, once something is in the school rules, it must be followed, forever, otherwise anarchy will break out and traditional values will die."*[11]

5.2 English

The results on both balanced and imbalanced English datasets are presented in Table 7. In most cases the MaxEnt classifier significantly outperforms the SVM classifier. The combination of majority of features ("B2 + FS1 + FS2") with the MaxEnt classifier yields the best results for both balanced and imbalanced dataset distributions. This suggests that these features are coherent. While no single feature captures the essence of sarcasm, all features together provide useful linguistic information for detecting sarcasm at textual level.

Balanced distribution Both baselines were surpassed by various combinations of feature sets with the MaxEnt classifier, although in some cases very narrowly ("B1 + punctuation-based" and "B1 + pointedness" feature sets). Although the SVM classifier has slightly worse results, it still performs reasonably, and we even recorded significant improvement over the baseline for "B1 + POS word-shape". The best results were achieved using the MaxEnt classifier with "B2 + FS1 + FS2" (F-measure 0.947) and "B1 + word-shape pattern " (F-measure 0.943) feature sets.

[10] "Jestli jste tu první část rekonstrukce - demolici - trochu nepřehnali . :)"

[11] "Konzervatismus , když je to jednou ve školním řádu , tak se to musí dodržovat , a to navždy , jinak vypukne anarchie a tradiční hodnoty zemřou ."

Table 7: Results on the English dataset with the MaxEnt and SVM classifiers. Macro F-measure (Fm) and 95% confidence interval (CI) are in %. Best results are in bold. **B2**: character n-gram (3-5, min. occurrence > 50) + skip-bigram + pointedness; **FS1**: character n-gram (3-6, min. occurrence > 5) + extended pointedness; **FS2**: POS word-shape + pattern + POS characteristics + emoticons + word-case.

Imbalanced distribution However, data in the real world do not necessarily resemble the balanced distribution. Therefore we have also performed the evaluation on an imbalanced distribution. The MaxEnt classifier clearly achieves the best results. This experiment indicates that combinations of features "B2 + FS1 + FS2" (F-measure 0.924) and "B1, word-shape pattern" (F-measure 0.920) yields the best results for both balanced and imbalanced dataset distribution.

5.3 Discussion

To explain the huge difference in the performance between English and Czech, we conducted an additional experiment in English. We sampled the "big-data" English corpus (100k Tweets) to obtain the same distribution as on the "small-data" Czech corpus (325 sarcastic and 6,675 non-sarcastic Tweets). Feature combination "B2 + FS1 + FS2" achieves an F-measure of 0.734 ± 0.01 (MaxEnt classifier) and 0.729 ± 0.01 (SVM). This performance drop shows that the amount of training data plays a key role (≈ 0.92 on "big-data" vs. ≈ 0.73 on "small-data"). However, these results are still significantly better than in Czech (≈ 0.58). This demonstrates that Czech is a challenging language in sarcasm detection, as in other NLP tasks.

In addition, we also experimented with the Naive Bayes classifier and with delta TF-IDF feature variants (Martineau and Finin, 2009; Paltoglou and Thelwall, 2010) in both languages. However, the performance was not satisfactory in comparison with the reported results.

6 Conclusions

We investigated supervised machine learning methods for sarcasm detection on Twitter. As a pilot study for sarcasm detection in the Czech language, we provide a large human-annotated Czech Twitter dataset containing 7,000 tweets with inter-annotator agreement $\kappa = 0.54$. The novel contributions of our work include the extensive evaluation of two classifiers with various combinations of feature sets on both the Czech and English datasets as well as a comparison of different preprocessing techniques for the

Czech dataset. Our approaches significantly outperformed both baselines adapted from related work[12] in English and achieved F-measure of 0.947 and 0.924 on the balanced and imbalanced datasets, respectively.[13] The best result on the Czech dataset was achieved by the SVM classifier with the feature set enriched with patterns yielding F-measure 0.582. The whole project is available to the community under GPL license at `http://liks.fav.zcu.cz/sarcasm/`. We believe that our findings will contribute to the research outside the mainstream languages and may be applied to sarcasm detection in other Slavic languages, such as Slovak or Polish.

6.1 Future work

We approached the problem mainly from the data-driven perspective (annotation, feature engineering, error analysis). However, we feel that elaborating deep linguistic insights would be helpful to better understand the phenomena of sarcasm on social media (Averbeck, 2013; Averbeck and Hample, 2008; Ivanko et al., 2004; Jorgensen, 1996).

There are also possible extensions to the lexical/morphological features – either in the direction of semi-supervised learning and adding for example features based on latent semantics, topic models, or graphical models popular in the sentiment analysis field (Habernal and Brychcín, 2013; Brychcín and Habernal, 2013), or the direction of deeper linguistic processing in terms of, e.g., syntax/dependecy parsing (but this has limitation given the nature of Twitter data as well as unavailability of such tools for Czech). These deserve further investigation and are planned in future work.

A Three-Step Transition-Based System for Non-Projective Dependency Parsing

Ophélie Lacroix and **Denis Béchet**

Abstract

This paper presents a non-projective dependency parsing system that is transition-based and operates in three steps. The three steps include one classical method for projective dependency parsing and two inverse methods predicting separately the right and left non-projective dependencies. Splitting the parsing allows to increase the scores on both projective and non-projective dependencies compared to state-of-the-art non-projective dependency parsing. Moreover, each step is performed in linear time.

1 Introduction

Dependency parsing is a particularly studied task and could be a significant step in various natural language processes. That is why dependency parsers should tend to get speed and precision. In recent years, various methods for dependency parsing were proposed (Kübler et al., 2009). Among these methods, transition-based systems are particularly suitable.

The first methods developed for transition-based parsers proposed to produce projective dependency structures (including no crossing dependencies). Then, extended methods were developed to handle the non-projective cases. The non-projective dependency structures admit non-projective dependencies (a dependency is non-projective if at least one word located between the head and the dependent of the dependency does not depend directly or inderectly on the head, see Figure 1 for example). Handling the non-projective cases has been the foundation of the first work concerning the dependency representations (Tesnière, 1959; Melcuk, 1988). Moreover, it is important to successfully parse the non-projective sentences which can be very helpful in processes such as question-answering.

The transition-based parsers achieve interesting overall results for both projective and non-projective analyses. But, in practice, the non-projective methods achieve far lower and variable scores on non-projective dependencies than on projective dependencies. Finding these dependencies is more difficult because the non-projective dependencies are often distant ones. It is then essential to achieve descent scores on non-projective dependencies as well as on projective ones because some languages contain a high rate of non-projective dependencies.

Here we propose to predict separately the projective dependencies from the non-projective ones. Using a mixed dependency representation including both projective and non-projective dependency annotations in one representation, we aim at predicting the projective dependencies in a first step. Taking advantage of the good results of projective dependency parsing, we aim at predicting the non-projective dependencies in a second step.

The formal dependency representation on which we base our work results from the formalism of categorial dependency grammars (CDG) (Dekhtyar and Dikovsky, 2008). It allows to handle the discontinuities of the natural languages. The dependency representation induced is mixed: it associates projective and non-projective dependencies to represent complementary syntactic information in one dependency

Proceedings of COLING 2014, the 25th International Conference on Computational Linguistics: Technical Papers, pages 224–232, Dublin, Ireland, August 23-29 2014.

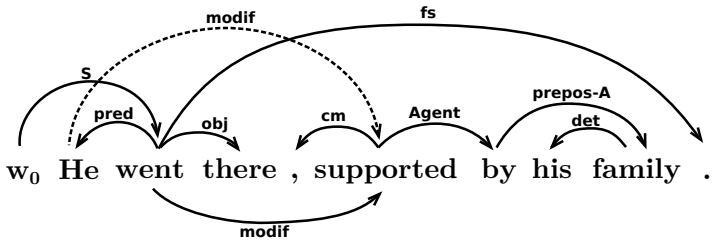

Figure 1: Dependency structure of the sentence "He went there, supported by his family." Anchors are shown below the sentence. Non-projective dependencies appear using a dash line. The other dependencies are plain projective dependencies.

structure. In this representation, each non-projective dependency is paired with a projective one called an anchor. From any dependency structure a projective tree[1] can be extracted.

Our approach is to predict the projective dependency trees first, using a standard and efficient method for projective dependency parsing. In a second step, we use the information (the projective/anchor labelled dependencies) given by the projective parsing to predict the non-projective dependencies. This second step is split into two inverse methods which predict independently the right and left non-projective dependencies. The advantage of the splitting is to perform the parsing in linear time and achieve better scores on non-projective dependencies.

Finally, in order to evaluate the efficiency of our method, we apply it on data annotated according to the formalism of the categorial dependency grammar. The data consists on a treebank containing both projective and non-projective trees associated with sentences of French.

2 Related Work

Our approach is similar to a post-processing method for retrieving the non-projective dependencies. In a way, our work is then analogous to the work of Hall and Novák (2005) who apply a post-processing method after converting constituency trees into dependency ones since the conversion can not automatically recover the non-projective relations.

Moreover, taking advantage of the efficiency of projective dependency methods to predict the non-projective dependencies is a technique used by Nivre and Nilsson (2005) in their pseudo-projective method. They projectivize the dependency trees before parsing in order to apply a projective method first and apply an inverse transformation to retrieve the non-projective dependencies. For our method, we do not need to projectivize the trees since the dependency representation we use includes both projective and non-projective annotations in one representation. But we can employ the projectivization method to build such data adding the generated projective dependencies to the non-projective structure as if they were artificial anchors. Consequently, our approach can be applied on treebank containing standard non-projective trees.

The advantage of our method is that the information that is useful for retrieving the non-projective dependencies is not predicted during the projective parsing which makes the projective and non-projective steps completely independent from each other. Moreover, the non-projective steps are data-driven and remain linear.

3 Representation and Formalism

Our work is based on dependency structures combining projective and non-projective annotations in one representation. In such a representation the projective dependencies bring both local and syntactic information while the non-projective dependencies bring only syntactic information (i.e. the relation shared by the dependents). Thus, each non-projective dependency is paired with a projective relation (called anchor) determining the position of the dependent in the sentence. Figure 1 presents a non-projective dependency structure of a sentence which illustrates the use of a projective relation (anchor)

[1] Composed of projective dependencies and anchors of non-projective dependencies, see Section 3.

and a non-projective dependency to represent a discontinuous relation: "supported" is a modifier for the pronoun "he".

The dependency representation is induced by a particular formalism: the class of the categorial dependency grammars (CDG). The categories of the grammars correspond to the dependency labels. The rules $\mathbf{L}^1$, $\mathbf{I}^1$ and $\mathbf{\Omega}^1$, presented in Table 1, are the classical left elimination rules of categorial grammars. Only the left rules are shown but there are symmetrical right rules. These rules allow to define the projective dependencies and anchors. Moreover, CDGs are classical categorial grammars in which the notion of polarized valencies was added. Each of the three first rules includes the concatenation of potentials (such as P, P_1, P_2) which are lists of polarized valencies. The polarized valencies are label names associated with a polarity (south-west $\swarrow$, north-west $\nwarrow$, north-east $\nearrow$ and south-east $\searrow$). They represent the ends of the non-projective dependencies. The south polarities indicate an incoming non-projective dependency and the north valencies indicate an outgoing non-projective dependency. The rule $\mathbf{D}^1$ allows the elimination of dual pairs of polarized valencies, following the **FA** principle.

First Available (FA) principle: the closest dual polarized valencies with the same name are paired.

Thus, the elimination of the dual pairs $(\swarrow C)$ $(\nwarrow C)$ and $(\nearrow C)$ $(\searrow C)$ defines respectively left and right non-projective dependencies labelled by C.

$\mathbf{L}^1$	$C^{P_1}\,[C\backslash\beta]^{P_2} \vdash [\beta]^{P_1P_2}$
$\mathbf{I}^1$	$C^{P_1}\,[C^*\backslash\beta]^{P_2} \vdash [C^*\backslash\beta]^{P_1P_2}$
$\mathbf{\Omega^1}$	$[C^*\backslash\beta]^{P} \vdash [\beta]^{P}$
$\mathbf{D}^1$	$\alpha^{P_1(\swarrow C)P(\nwarrow C)P_2} \vdash \alpha^{P_1PP_2}$, if $(\swarrow C)(\nwarrow C)$ satisfies the **FA** principle

Table 1: (Left) Rules of the categorial dependency grammars.

4 Method

We conduct a three-step transition-based parsing. We choose the arc-eager method of Nivre (2008) to perform the first step. Note that any projective method for dependency parsing would also be appropriate to perform this step. The second and third steps are methods which go through the sentence (respectively from left to right and from right to left) in order to find the non-projective dependencies.

4.1 Projective Dependency Parsing

The arc-eager method is an efficient transition-based method for projective dependency parsing. A transition system is composed of a set of configurations (states), a set of transitions (operations on the configurations), an initial configuration and a set of terminal configurations. The transition-based parsing consists in applying a sequence of transitions to configurations in order to build a dependency structure. For the arc-eager method, a configuration is a triplet $\langle \sigma, \beta, A \rangle$ where:

- σ is a stack of partially treated words;
- β is a buffer of non-treated words;
- A is a set of dependencies (the partially built dependency structure).

The dependencies are described by triplets such as (k, l, i) where k is the position of the head, l is the label of the dependency and i is the position of the dependent. The set of transitions includes three transitions which are evolutions of the standard transitions of the system of Yamada and Matsumoto (2003) plus the Reduce transition which allows to delete the first word of the stack when this one shares no dependency with the first word of the buffer. The standard Right-Arc and Left-Arc are renamed respectively as Local-Right and Local-Left since these transitions only add local dependencies (whitout distinction between projective ones and anchors). The Shift transition pops the first word from the buffer

Transition	Application	Condition
Local-Left(l)	$(\sigma \mid w_i, w_j \mid \beta, A) \Rightarrow (\sigma, w_j \mid \beta, A \cup \{(j, l, i)\})$	$i \neq 0 \wedge \neg\exists k \exists l'(k, l', i) \in A$
Local-Right(l)	$(\sigma \mid w_i, w_j \mid \beta, A) \Rightarrow (\sigma \mid w_i w_j, \beta, A \cup \{(i, l, j)\})$	$\neg\exists k \exists l'(k, l', j) \in A$
Reduce	$(\sigma \mid w_i, \beta, A) \Rightarrow (\sigma, \beta, A)$	$\exists k \exists l(k, l, i) \in A$
Shift	$(\sigma, w_i \mid \beta, A) \Rightarrow (\sigma \mid w_i, \beta, A)$	

Table 2: Transitions of the arc-eager method.

and pushes it into the stack. The Reduce transition pops the first word from the stack. The effects of the transitions on configurations are detailed in Table 2.

For a given sentence $W = w_1...w_n$, the initial configuration of the transition-based system is defined as follows: $([w_0], [w_1, ..., w_n], \emptyset)$ where w_0 is the root of the structure. And any terminal configuration is of the form: $([w_0], [], A')$ where A' contains the fully projective dependency/anchor structure for the sentence W[2].

This step should produce the projective dependency structure of Figure 2 for the sentence "Il y est allé, soutenu par sa famille" (french equivalent of the sentence seen in Figure 1).

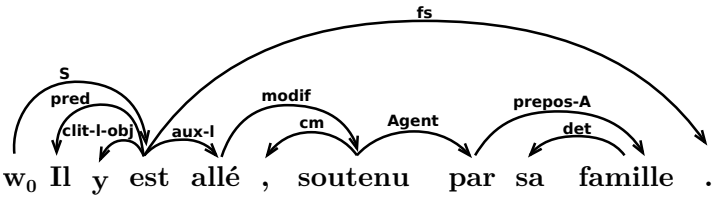

Figure 2: Projective dependency structure of the sentence "Il y est allé, soutenu par sa famille".

4.2 Adding Non-Projective Dependencies

With the aim of retrieving non-projective dependencies we propose two inverse methods also inspired by transition-based systems. For these methods, the configuration is a quadruplet $\langle \sigma, \beta, \theta, A \rangle$ where σ, β and A are the same stack, buffer and set of arcs as those defined for projective parsing in the previous subsection and θ is a list of polarized valencies. The valencies have the same role here as in the formalism of the categorial dependency grammars (detailed in section 3). They define the ends of the non-projective dependencies. Therefore, our idea is to go through the sentence in order to predict, for each word, whether a non-projective dependency could end on the word (by adding valency $\swarrow l$ or $\searrow l$ in the list θ) or should start from it (by adding valency $\nwarrow l$ or $\nearrow l$ in the list θ). As soon as dual valencies are collected in θ, they are removed from it (according to the **FA** principle) and the corresponding non-projective dependency is added to the set of dependencies.

In the second step, the valencies associated with the left dependencies are computed, i.e. the valencies of the form $\swarrow l$ and $\nwarrow l$. The sentence is linearly covered from left to right, as in the previous projective step. Details of the transitions are presented in Table 3. The Shift transition is the same as during the previous step and allows to cover the sentence classically from left to right. The PutValency transition makes possible to predict, for the first word of the buffer, exactly one southwest valency $\swarrow l$, which means that a left dependency labelled l can end on this word. In addition, the valency is concatenated at the end

Transition	Application	Condition
PutValency($\swarrow l$)	$(\sigma, w_i \mid \beta, \theta, A) \Rightarrow (\sigma \mid w_i, \beta, \theta \swarrow l^i, A)$	$\swarrow l^i \notin \theta$
Dist-Left($\nwarrow l$)	$(\sigma, w_j \mid \beta, \theta_1 \swarrow l^i \theta_2, A) \Rightarrow (\sigma, w_j \mid \beta, \theta'_1\theta'_2, A \cup \{(j, l, i)\})$	$\swarrow l \notin \theta_2 \wedge \forall k \swarrow k^i \notin \theta'_1\theta'_2$
Shift	$(\sigma, w_i \mid \beta, \theta, A) \Rightarrow (\sigma \mid w_i, \beta, \theta, A)$	

Table 3: Transitions of the left non-projective method.

[2]The words which were not attached during the parsing are automatically attached to the root node w_0.

of θ. The transition Dist-Left is applied when the first word of the buffer receives the dual valency (i.e. a valency of the form $\nwarrow l$). If at least one valency $\swarrow l$ belongs to θ then the last one is removed from θ and the non-projective dependency corresponding to the pair of dual valencies $\swarrow l \nwarrow l$ (left non-projective labelled l) is added to A.

Therefore, for a given sentence, the initial configuration of this system is $([w_0], [w_1, ..., w_n], (), A')$ where A' is the projective dependency structure predicted by the arc-eager method. And the terminal configuration is a quadruplet of the form $([w_0, ..., w_n], [], \theta', A'')$ where θ' could contain southwest valencies which did not match with their dual and A'' is a partially non-projective dependency structure.

The third step uses the inverse method of the previous step and allows to predict right non-projective dependencies. In this method, the sentence is linearly covered from right to left. The initial configuration $([w_0, .., w_{n-1}], [w_n], (), A'')$ contains the partial dependency structure A'' produced by the last method and the terminal configuration $([w_0], [w_1, ..., w_n], \theta'', A''')$ contains the fully non-projective dependency structure A'''. The transitions used here are presented in Table 4. This time, the PutValency transition adds only southeast valencies ($\searrow l$) at the beginning of θ and pops the first word of σ to push it into β. The Dist-Right transition adds a right non-projective dependency in the set of arcs by predicting a dual valency of the form $\nearrow l$. Finally, the RShift transition pops the first word of σ to push it in β.

Transition	**Application**	**Condition**
PutValency($\searrow l$)	$(\sigma \mid w_i, \beta, \theta, A) \Rightarrow (\sigma, w_i \mid \beta, \searrow l^i \theta, A)$	$\searrow l^i \notin \theta$
Dist-Right($\nearrow l$)	$(\sigma \mid w_j, \beta, \theta_1 \searrow l^i \theta_2, A) \Rightarrow (\sigma \mid w_j, \beta, \theta'_1 \theta'_2, A \cup \{(j, l, i)\})$	$\searrow l \notin \theta_1 \wedge \forall k \searrow k^i \notin \theta'_1 \theta'_2$
RShift	$(\sigma \mid w_i, \beta, \theta, A) \Rightarrow (\sigma, w_i \mid \beta, \theta, A)$	

Table 4: Transitions of the right non-projective method.

The splitting of the non-projective dependencies prediction on two different methods is essential to find the right non-projective dependencies as well as the left ones. Practically, finding the head (i.e. the $\nearrow l$ and $\nwarrow l$ valencies) of a non-projective dependency is easier once the dependent (i.e. the $\searrow l$ and $\swarrow l$ valencies) has been previously predicted. Indeed, the prediction system benefits of information about the presence of the head valency in θ to predict the dual valency. Moreover, the heads are predicted more efficiently whether the projective dependency associated with the word was predicted with the right label during the first parsing step. The next section presents the prediction system and the features needed to proceed good transition predictions.

The application of these two steps on the sentence seen in Figure 2 are shown on Table 5. The

Transition	**Configuration**			
	([w$_0$],	[Il,...,.],	(),	A)
Shift	$\Rightarrow$ ([w$_0$,Il],	[y,...,.],	(),	A)

4.3 Oracle

The transition-based systems are particularly interesting for deterministic data-driven parsing. Associated with a statistical method, such as a probabilistic graphical model or a linear classifier, and suitable features, the prediction of the transitions is very efficient. It ensures a deterministic parsing in linear time for both the projective arc-eager method and our two non-projective post-processing methods.

Previous work such as (Yamada and Matsumoto, 2003) shows that support vector machines (SVM) allow to achieve good scores on dependency parsing when associated with a transition-based system. Therefore, we chose to use this classifier to predict the transitions of our two post-processing methods. Moreover, the arc-eager method (i.e. *nivreeager*) being already successfully implemented and optimized, we decided to use the MaltParser (Nivre et al., 2007) to perform the projective dependency parsing.

For this projective step, the features are composed of classical features such as the word forms, POS-tags and dependency labels of the current words (the first elements of the stack and the buffer), their neighbors and their attached dependents. For the two non-projective steps the feature pattern includes in addition some features on the projective head of the first word of the buffer and the list of the valencies remaining in θ. The feature pattern is presented in Table 6. Nevertheless, the SVM model bears only numerical features. And each feature must be converted into a binary feature determining its absence or presence. For the valencies, the features denotes the absence or presence of each possible valency label in θ.

Feature Pattern	
• Word forms:	• POS-tags:
$w_{\{i-1,i+1\}}$	$t_{\{i-2,i+2\}}$
w_j	t_j
• Labels:	• Valencies:
l_j (projective dependency label)	$(v_0, ..., v_k)$ (the list of valencies in θ)
$(l_{j_1}, ..., l_{j_n})$ (the list of dependency labels)	

Table 6: Features for the prediction of transition in the two inverse methods. i is the position of the first word in β, j is the position of the head of w_i, the list of dependency labels is the list of labels of the right or left dependents of the head (depending on the right or left method).

5 Evaluation

In order to evaluate the efficiency of our approach, we decided to experiment on a dependency treebank for which the data were annotated following the formalism of the categorial dependency grammars[3]. We call this treebank the CDG Treebank 1. Moreover, in order to evaluate the adaptation of our method

[3]The treebank is not yet publicly available. But the authors have made it available to us.

to standard treebanks we would like to perform the method on data for which the anchors would have been artificially created. Therefore, we build a second treebank from the first one, which we call the CDG Treebank 2, in which the original anchors are replaced by artificial anchors generated by the projectivization step of the pseudo-projective method of Nivre and Nilsson (2005).

5.1 Non-Projective Dependency Treebank

The CDG Treebank 1 contains 3030 sentences of French, each paired with a dependency structure. The dependency structures are composed of both projective and non-projective dependencies. Out of the 37580 dependencies (excluding the anchor ones), 3.8% are non-projective. Hence, 41% of the dependency structures of the treebank contain at least one non-projective dependency.

The data were annotated semi-automatically using the CDG Lab (Alfared et al., 2011), a development environment dedicated to large scale grammar and treebank development. Thus, the annotations followed the formalism proposed by the categorial dependency grammar of French (Dikovsky, 2011). The labels of the dependencies are the 117 categories used by the grammar. Most of the dependency labels (89) are exclusively associated with projective dependencies. 23 labels can be associated both with projective and non-projective dependencies. Among these ones the most frequent are clitics, negatives, objects, reflexives and copredicates. In most of the cases, clitics, negatives and reflexives are associated with short dependencies (generally, one or two words separate the head from the dependent) whereas copredicates or apposition are often associated with distant dependencies (the heads and dependents can be located at the opposite ends of the sentence). Four dependency labels are exclusively associated with non-projective dependencies, they are particular cases of aggregation, copula, comparison and negation.

The grammar and the treebank were developed simultaneously. Consequently, a large part of the sentences were used to develop the grammar and were chosen to cover as much as possible the syntactic phenomenon of French. The treebank contains sentences from newspaper, 19^{th} and 20^{th} century literary works and plain language.

To build the CDG Treebank 2, we removed the anchors of the dependency structures of the CDG Treebank 1 and added the projective dependencies generated by projectivization[4]. Note that, 90.9% of the anchors are the same between the two CDG treebanks.

5.2 Experimental Settings

We evaluate our method through a 10-fold cross-validation on the non-projective dependency treebank. First, we train the prediction models (the MaltParser training model and the SVM model) on each training set containing 90% sentences of the treebank. Second, each fold of our testing data sets is tagged with Part-Of-Speech tags using Melt (Denis and Sagot, 2009), a POS-tagger that achieves high score on French. Then the sentences are parsed.

In order to estimate the benefit of our method, our results are compared with those obtained by the methods proposed by the MaltParser. The table shows the results of the methods that give the best results among the non-projective ones and the best results among the projective ones (associated with the pseudo-projective method (Nivre and Nilsson, 2005)):

- the *covnonproj* (non-projective) method inspired by Covington (2001);
- the *nivreeager* (projective) method associated with the pseudo-projective method.

For a fair comparison, the scores are computed on the same data for each experiments, i.e. on the non-projective structures minus the anchors and the dependencies combined with punctuations.

Moreover, in order to demonstrate that our method can be applied successfully on standard treebanks, the experiments are performed on the CDG Treebank 1 an 2. The comparison scores that are used in these experiments are:

[4]The labels of the artificial anchors do not contain additional encoded information. They are identical to the labels of the non-projective dependencies.

- the label accuracy (LA), i.e. the percentage of words for which the correct label is assigned;
- the unlabelled attachment score (UAS), i.e. the percentage of words for which the correct dependency is assigned;
- the labelled attachment score (LAS), i.e. the percentage of words for which the correct labelled dependency is assigned.

5.3 Experimental Results

The results of the experiments are presented in Table 7. First, we notice that the scores relating to projective dependencies of our method, both for CDG Treebank 1 (3) and CDG Treebank 2 (4), are better than those obtained by the covnonproj method (1) and equivalent to the pseudo-projective method (2). We assume that finding non-projective dependencies at the same time as the projective ones is more difficult than finding projective dependencies only. Moreover, the scores on non-projective dependencies

	All dependencies			**Projective Dep.**			**Non-projective Dep.**		
	LA	UAS	LAS	LA	UAS	LAS	LA	UAS	LAS
(1) covnonproj	82.2	85.5	78.0	82.8	86.2	78.7	68.7	68.7	62.7
(2) pseudoproj [5]	83.6	85.9	78.7	**84.1**	**87.0**	**79.7**	73.5	56.9	53.5
(3) non-projLR (CDGTbk1)	**83.7**	**86.3**	**79.1**	**84.1**	86.9	79.6	**75.5**	70.2	66.3
(4) non-projLR (CDGTbk2)	**83.7**	86.2	79.0	**84.1**	86.9	79.5	**75.5**	**70.5**	**66.7**

Table 7: Results of the non-projective dependency parsing comparing the MaltParser methods (1) and (2) with ours (3).

are particularly interesting. Our method achieves far better scores on non-projective dependencies than the other two. The label accuracy (LA) achieves significantly better scores (+6.8) than the covnonproj method. Indeed, the projective step allows to find the anchors which are a kind of projective dependencies, so there are easier to predict than the non-projective dependencies. Thus, the label accuracy of the non-projective dependencies takes advantage of the good results of the anchors which were not paired with a non-projective dependency during the second and third parsing steps. Concerning the attachment scores, our method still outperforms the two others. Globally, our method allows to recover the head of the non-projective dependencies more successfully.

The non-projective dependencies can be also compared depending on their direction. The left non-projective dependencies achieve far better scores (75.0% LAS) than the right non-projective dependencies (42.7% LAS). We know that the non-projective step performed from right to left is essential to recover the right non-projective dependencies. In fact, finding the right non-projective dependencies by performing the non-projective step from left to right seems almost infeasible because it is essential to find the dependent first. Therefore, the problem comes essentially from the bad prediction of the anchors during the projective step. Indeed, only 51.4% of the words associated with a right non-projective dependency receive the correct label (LA), compared with 84.2% for those associated with left non-projective dependencies. The under-representation of the right non-projective dependencies (25% of the non-projective dependencies) in the treebank is a first explanation. But, even the more frequent labels (associated with right non-projective dependencies) achieve low scores. Moreover, we noticed that even the right projective dependencies always achieve lower scores than the left projective dependencies. This problem may suggest that the use of a left-to-right projective method is not appropriate to predict the right dependencies.

Furthermore, we note that our method achieve equivalent scores on CDG Treebank 1 and CDG Treebank 2, and even slightly better for non-projective dependencies with the use of artificial anchors. This suggest that our method could be succesfully applied to standard treebanks in which artificial anchors would have been added.

[5] The pseudo-projective method were applied with the option "path" for projectivization and deprojectivization.

6 Conclusion

We propose a three-step method retrieving separately the projective dependencies and anchors, the left non-projective dependencies and the right non-projective dependencies through the use of a mixed dependency representation. The projective step and the two non-projective steps are performed in linear time and allow to outperform state-of-the-art transition-based scores on non-projective dependencies. The method needs a learning corpus that associate to each non-projective dependency a projective anchor. Thus the method is well adapted to CDG treebanks. But we showed that the method can be applied to standard treebanks by adding artificial anchors with the use of a method of projectivization.

One of the advantages of our method is a significant improvement on the label accuracy for the non-projective dependencies. The efficiency of the two non-projective methods depends on the good results of the projective parsing. Moreover, performing the non-projective parsing from left-to-right and from right-to-left raises interesting questions on how to recover the right and left dependencies for both projective and non-projective methods.

Acknowledgement

We want to thank Danièle Beauquier and Alexander Dikovsky for giving us the CDG Treebank on which we experimented our system. Moreover, we want to thank all our reviewers : the anonymous reviewers of Coling for their accurate reviews, and the members of the team TALN of the University of Nantes (Colin de la Higuera, Florian Boudin and the master students) who reviewed our work with a fresh eye.

Abstract

With a large amount of complex network data available from multiple data sources, how to effectively combine these available data with existing auxiliary information such as item content into the same recommendation framework for more accurately modeling user preference is an interesting and significant research topic for various recommender systems. In this paper, we propose a novel hierarchical Bayesian model to integrate multiple social network structures and content information for item recommendation. The key idea is to formulate a joint optimization framework to learn latent user and item representations, with simultaneously learned social factors and latent topic variables. The main challenge is how to exploit the shared information among multiple social graphs in a probabilistic framework. To tackle this challenge, we incorporate multiple graphs probabilistic factorization with two alternatively designed combination strategies into collaborative topic regression (CTR). Experimental results on real dataset demonstrate the effectiveness of our approach.

1 Introduction

Many real-life data have representations in the form of multiple views (Liu et al., 2013). For example, web pages usually consist of both text content and hyperlink information; images on the web have relevant tags associated with their content. In addition, it is also common that in real networks comprising multiple types of nodes are connected by multiple types of links, forming heterogeneous information networks (HIN) (Huang et al., 2012). For example, in scientific community, various types of links are formed for different types of objects, i.e., author writes paper, venue publishes paper, reader labels tag, and so on. Therefore, with a large amount of complex network data available from multiple data sources, how to effectively combine this kind of rich structure with other auxiliary information such as content information into the same recommendation framework is an interesting and significant research topic for various recommender systems. This paper aims to model multiple social graphs into a principled hierarchy Bayesian framework to improve recommending performance.

The basic idea in this paper is inspired by multi-view learning approach (Liu et al., 2013), i.e., leveraging the redundancy and consistency among distinct views (Kumar et al., 2011) to strengthen the overall performance. We extend this idea (Liu et al., 2013) originally for clustering problem to deal with rating scarcity problem when modeling user preference for recommendation. Just as in general multi-view learning, each view of objective function is assumed to be capable of correctly classifying labeled examples separately. Then, they are smoothed with respect to similarity structures in all views. Similarly, in this paper, we assume that our individual views of multiple user social relations are similar and complementary with a shared latent structure.

However, different from multi-view clustering problem, our goal is to recover a sparse rating matrix with a large number of missing user-item pairs rather than merely exploiting cluster structure with full task information. Thus, the straightforward multi-view representation of the objective (rating matrix) is

*Corresponding author

not available. Instead, we use side information (user social graphs) to exploit multi-view learning for improving collaborative filtering (CF). As a result, collaborative topic regression (CTR) (Wang and Blei, 2011) is employed as our basic learning framework with side information. Recently, CTR has gained considerable attention due to its well-defined mathematical framework and strong performance on user behavior prediction for various real-world applications, such as document recommendation (Li et al., 2013), tag recommendation (Wang et al., 2013), music recommendation (Purushotham et al., 2012), celebrity recommendation (Ding et al., 2013) and vote prediction (Kang and Lerman, 2013). However, all the extensions above merely focus on a single view of user or item relation. In reality, a large amount of diverse social graphs data are widely existed and particularly valuable for mutually reinforcing each other. Therefore, it should be well considered. Taking this into consideration, we extend CTR with multiple social graphs factorization for recommender systems.

The main challenge of incorporating multiple relations into CTR is how to exploit the shared information among multiple social networks and how to further deal with it to recover sparse rating matrix in a probabilistic framework. Previous efforts, purely to address the first issue for clustering problem, are usually to seek a weak consensus (Liu et al., 2013) learnd from data jointly with clustering process. Intuitively, consensus can be seen as a latent cluster structure shared by different views. Thus, it means that learning from different views should be softly regularized towards a common latent structure. However, it is not easy to directly formulate it in a probabilistic framework, because weak consensus modeling can not be separated from a joint higher task, i.e., recovering spare rating matrix, in our case.

To tackle this challenge, we propose a novel hierarchical Bayesian model with multiple social graphs factorization. We exploit two ways of modeling shared information for multi-view based recommendation. One is for heterogeneous network by directly modeling different view specific latent structures with consensus for user representation. The other is for homogeneous case, which can be used as a transformed version of heterogeneous relations. In contrast with the first strategy, we model the latter using a shared latent social structure for all views but with different user representations. Thus, we can relax strong consensus assumption in our heterogeneous case, through linear combination of each sub-latent user with maintained sharing mechanism. The multiple graphs factorization process in the proposed model can be seen as a regularization approach on each latent user for better uncovering user-item latent structures. Although, regularization technique for modeling multiple heterogeneous networks is a hot research topic, in clustering study from an algebra view (Liu et al., 2013; Kumar et al., 2011), not much is known on using it for collaborative recommendation problems in a more complex probabilistic setting.

The following sections will discuss those in details and we use the terms network and graph interchangeably throughout this paper.

2 Preliminaries

In this section, we briefly review collaborative topic regression (CTR) (Wang and Blei, 2011), as the foundation of our proposed model. Figure 1 (left) shows the graphical representation of CTR, which combines the merits of traditional collaborative filtering and probabilistic topic modeling. Specifically, the key mechanism of CTR is that using topic vectors learned from LDA (Blei et al., 2003) jointly controls the prior distribution of latent items in original matrix factorization process of CF. The generative process is described as follows:

- For each user i,
  - draw user latent vector $u_i \sim N(0, \lambda_u^{-1} I)$, multivariate Gauss distribution with zero mean.
- For each item j,
  - draw topic proportions $\theta_j \sim Dirichlet(\alpha)$, Dirichlet distribution.
  - draw item latent offset vector $\epsilon_j \sim N(0, \lambda_v^{-1} I)$, and set the item latent vector as $v_j = \epsilon_j + \theta_j$.
  - For each word w_{jn}
    - draw topic assignment $z_{jn} \sim Mult(\theta)$, Multinomial distribution.
    - draw word $w_{jn} \sim Mult(\beta_{z_{jn}})$, Multinomial distribution.
- For each user-item pair (i, j),

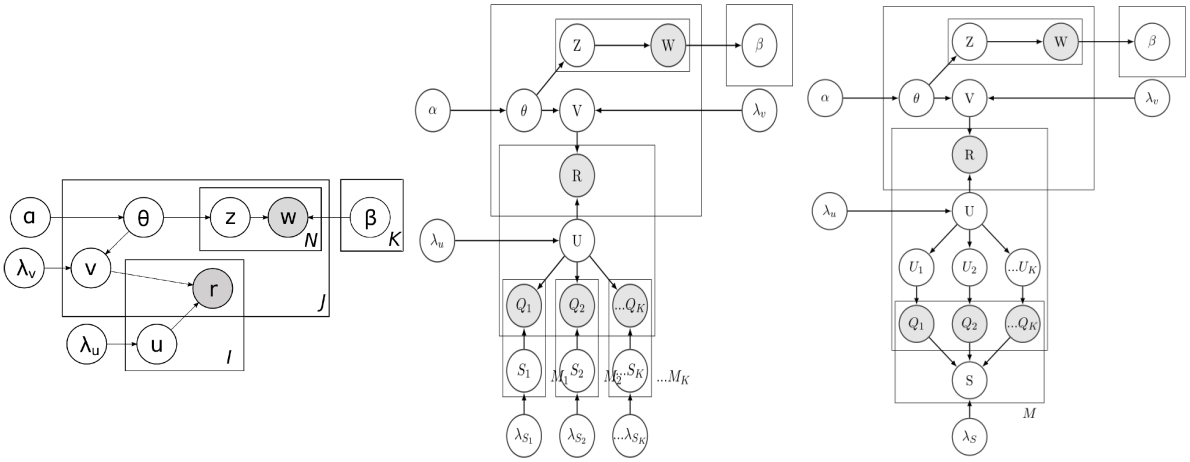

Figure 1: CTR (left), heterogeneous CTR-MGF (middle), homogeneous CTR-MGF (right).

– draw the response $r_{ij} \sim N(u_i^T v_j, c_{ij}^{-1})$, univariate Gauss distribution, where c_{ij} is a confidence parameter for rating r_{ij}, $a > b$. $c_{ij} = a$ (higher confidence), if $r_{ij} = 1$, and $c_{ij} = b$, if $r_{ij} = 0$.

However, CTR does not take the complex social network information, which is available and crucial in many real-world applications, into consideration.

3 CTR-MGF: Collaborative Topic Regression with Multiple Graphs Factorization

In this section, we discuss our proposed method, called CTR with multiple graphs factorization (CTR-MGF). Our model is a generalized hierarchical Bayesian model which jointly learns latent user, item and multiple latent social factor spaces. Different from previous approaches, our method extends CTR to multiple complex networks setting instead of one particular type of relation for user or item. Moreover, we consider two real general contexts in various practical applications. One is the context of heterogeneous networks. The other is the context of homogeneous networks. It is noted that, for relative simplicity, in this paper we only consider user oriented complex network. The graphical representation of our models in Figure 1 (middle and right) takes $K = 3$ networks as illustration, which can be arbitrary in our derivation. It is also easy to see that Purushotham et al. (2012) is a special case of our proposed model, which is not equipped with graph sharing mechanism.

3.1 Model Notations

Each social matrix Q corresponds to a social network structure $G = \{V, E\}$, where users and their social relations are represented as vertex set V and edge set E in network structure G, respectively. The element q_{im} in Q denotes the binary relation between user 'i' and graph specific feature 'm' in heterogeneous network or the relation between two users 'i' and 'm' in homogeneous network.

3.2 CTR-MGF for Heterogeneous Networks

Heterogeneous network is formed by multiple types of nodes being connected by multiple types of links. The key characteristic of heterogeneous network is that the sizes of feature dimensions are different among multiple social graphs. For example, in a social music sharing system such as LastFM, each user has multiple heterogeneous relations associated with the interested music, i.e., user-artist, user-tag, and so on. Our model can handle all these relations in the proposed framework, CTR-MGF. Specifically, the generative process of CTR-MGF for heterogeneous networks is listed as follows:

- For each item j,
  - draw topic proportions $\theta_j \sim Dirichlet(\alpha)$, Dirichlet distribution.
  - draw item latent offset $\epsilon_j \sim N(0, \lambda_v^{-1} I)$, multivariate Gauss distribution and set the item latent vector as $v_j = \epsilon_j + \theta_j$.

- For each word w_{jn}
  - $*$ draw topic assignment $z_{jn} \sim Mult(\theta)$.
  - $*$ draw word $w_{jn} \sim Mult(\beta_{z_{jn}})$.

- For each heterogeneous social graph k,
  - For each social graph specific feature m
    - $*$ draw graph factor-specific latent feature vector $s_m^k \sim N(0, \lambda_{s_{km}}^{-1} I)$.
- For each user i,
  - draw the shared latent user vector among multiple social graphs $u_i \sim N(0, \lambda_{u_i}^{-1} I)$.
  - For each heterogeneous social graph k
    - $*$ For each social graph specific feature m
      - $\cdot$ draw graph specific user heterogeneous relation pair $q_{im}^k \sim N(u_i^{\mathrm{T}} s_m^k, c_{k,q_{im}}^{-1})$.
- For each user-item pair (i, j),
  - draw the response $r_{ij} \sim N(u_i^{\mathrm{T}} v_j, c_{ij}^{-1})$.

In the above generative process, the joint likelihood of data, i.e., $R, Q_{k=1,\ldots,K}, W$, and the latent factors $U, V, S_{k=1,\ldots,K}$ under the full model is:

$$\begin{aligned} & p(R, U, V, S_{k=1,\ldots,K}, Q_{k=1,\ldots,K}, W, \theta | \lambda_\bullet) \\ & = p(R|U,V) \cdot p(W, \theta|\beta) \cdot p(U|\lambda_U) \cdot p(V|\lambda_V) \cdot \prod_k^K p(Q_k|U, S_k, \lambda_{Q_k}) \cdot \prod_k^K p(S_k|\lambda_{S_k}) \end{aligned} \tag{1}$$

For learning the parameters, we develop an EM-style algorithm similar to CTR. In our model, finding the MAP is equivalent to maximizing the following log likelihood obtained by substituting univariate and multivariate Gaussian pdfs in Eq. 1:

$$\begin{aligned} L = & \sum_j \sum_n log(\sum_z \theta_{jz} \beta_{z_{jn}}) - \sum_{k=1}^K \frac{\lambda_{S_k}}{2} \sum_m (s_m^k)^{\mathrm{T}} s_m^k - \sum_{k=1}^K \sum_i \sum_m \frac{c_{k,q_{im}}}{2} (q_{im}^k - u_i^{\mathrm{T}} s_m^k)^2 \\ & - \frac{\lambda_U}{2} \sum_i u_i^{\mathrm{T}} u_i - \frac{\lambda_V}{2} \sum_j (v_j - \theta_j)^{\mathrm{T}} (v_j - \theta_j) - \sum_i \sum_j \frac{c_{ij}}{2} (r_{ij} - u_i^{\mathrm{T}} v_j)^2 \end{aligned} \tag{2}$$

We employ coordinate ascent (CA) approach alternatively optimizing latent factor variables u_i, v_j, $s_m^{k=1,2,\ldots,K}$ and the simplex variables θ_j as topic proportions. Specifically, the following update rules in CA are obtained by setting the derivative of L with respect to u_i, v_j, and $s_m^{k=1,2,\ldots,K}$ to zero.

$$u_i = (\lambda_U I + V^{\mathrm{T}} D_{c_i} V + \sum_k^K S_k^{\mathrm{T}} D_{q_i}^k S_k)^{-1} \cdot (V^{\mathrm{T}} D_{c_i} R_i + \sum_k^K S_k^{\mathrm{T}} D_{q_i}^k Q_i^k) \tag{3}$$

$$v_j = (\lambda_V I + U^{\mathrm{T}} D_{c_j} U)^{-1} \cdot (\lambda_V \theta_j + U^{\mathrm{T}} D_{c_j} R_j) \tag{4}$$

$$s_m^{k=1,2,\ldots,K} = (\lambda_{S_k} I + U^{\mathrm{T}} D_{q_m}^k U)^{-1} \cdot (U^{\mathrm{T}} D_{q_m}^k Q_m^k) \tag{5}$$

where K is the total number of graphs. I is an identity matrix of the same dimension as that of latent space. U and V are matrices with rows as latent users and latent items, respectively. S_k is a matrix with rows as social factor-specific latent feature vectors for graph k. R_i is a column vector with values $[r_{i1}, \ldots, r_{iJ}]^{\mathrm{T}}$. Similarly, $R_j = [r_{1j}, \ldots, r_{Ij}]^{\mathrm{T}}$. For graph k, $Q_i^k = [q_{i1}^k, \ldots, q_{iM}^k]^{\mathrm{T}}$ and $Q_m^k = [q_{1m}^k, \ldots, q_{Im}^k]^{\mathrm{T}}$ respectively. Likewise, $D_{q_i}^k$, and $D_{q_m}^k$ are similarly defined with diagonal elements $c_{k,q_{i\cdot}}$ and $c_{k,q\cdot m}$, respectively. D_{c_i} is a diagonal matrix with values $diag(c_{i1}, \ldots, c_{iJ})$. $D_{c_j} = diag(c_{1j}, \ldots, c_{Ij})$. In addition, c_{ij} and $c_{k,q_{im}}$ are also seen as the confidence parameters for r_{ij} and q_{im}^k, respectively. The high confidence value a is set to the observed interactive pairs and the low confidence value b is set to the unobserved interactive pairs, where $a > b > 0$.

For our brevity, the remaining update rules for θ and β, can be obtained using the same way as described in CTR (Wang and Blei, 2011). Please see that for details.

It is worth noting that through our assumption and the derivation above, we have theoretically proved that our modeling in this case is equivalent to first concatenating features of different views together and then applying Purushotham et al. (2012) for recommendation.

3.3 CTR-MGF for Homogeneous Networks

In this section, we further extend the basic CTR to the context of homogeneous networks. In fact, any user specific homogeneous networks can be obtained through transforming corresponding heterogeneous networks. For example, in LastFM, we can construct two user-user homogeneous networks by computing the similarities of user-tag and user-artist from original heterogeneous networks. The goal of this transformation is to further exploit weak consensus modeling scheme based on Section 3.2. Different from the graph sharing mechanism presented in last section, we relax the restriction that all users have the same representation. Specifically, we assume each latent user has multiple sub-graph specific representations.

However, it is nontrivial to model the relaxed assumption directly from original perspective. To achieve this more weaker sharing mechanism, we are towards its transformed perspective, i.e., sacrificing heterogeneous characteristic, because we need to exploit shared information from latent graph specific feature perspective. Thus, we require equal dimensions of different graphs, which motivates us to investigate the homogeneous case.

The key differences between our model in this section and that in last section are the strategies of latent user modeling and its social factor modeling. More specifically, we model each latent user as a linear combination of all sub-latent users associated with multiple homogeneous networks. All these sub-latent homogeneous users are associated with a shared social factor feature space. Thus, the shared information among multiple graphs can be exploited and it is more flexible to adjust the contribution of each sub-latent user to the final latent user representation. The generative process of CTR-MGF for homogeneous networks is listed as follows:

- For each item j,
  - draw topic proportions $\theta_j \sim Dirichlet(\alpha)$, Dirichlet distribution.
  - draw item latent offset $\epsilon_j \sim N(0, \lambda_v^{-1} I)$, multivariate Gauss distribution and set the item latent vector as $v_j = \epsilon_j + \theta_j$.
  - For each word w_{jn}
    - draw topic assignment $z_{jn} \sim Mult(\theta)$.
    - draw word $w_{jn} \sim Mult(\beta_{z_{jn}})$.
- For each social graph specific feature m, regarding to all related homogeneous social graphs
  - draw a shared factor-specific latent feature vector across multiple graphs $s_m \sim N(0, \lambda_{s_m}^{-1} I)$.
- For each user i,
  - For each homogeneous social graph k
    - draw a social graph specific latent user $u_i^k \sim N(0, (\lambda_{u_i}^k)^{-1} I)$.
    - For each social graph specific feature m
      - draw graph specific user homogeneous relation pair $q_{im}^k \sim N((u_i^k)^{\mathrm{T}} s_m, c_{k,q_{im}}^{-1})$.
  - draw a final latent user $u_i \sim N(\sum_{k=1}^K T_k u_i^k, \lambda_{u_i}^{-1} I)$.
- For each user-item pair (i, j),
  - draw the response $r_{ij} \sim N(u_i^{\mathrm{T}} v_j, c_{ij}^{-1})$.

In the above generative process, the joint likelihood of data, i.e. R, $Q_{k=1,\ldots,K}$ and W, and the latent factors $U, U_{k=1,\ldots,K}, V$ and S under the full model is:

$$p(R, U, V, S, U_{k=1,\ldots,K}, Q_{k=1,\ldots,K}, W, \theta | \lambda_\bullet) = p(R|U, V) \cdot p(W, \theta|\beta) \cdot$$
$$(\prod_{k=1}^K p(Q_k|U_k, S, \lambda_{Q_k})) \cdot p(S|\lambda_S) \cdot (\prod_{k=1}^K p(U_k|\lambda_{U_k})) \cdot p(V|\lambda_V) \cdot p(U|\lambda_U) \cdot p(U|U_{k=1,\ldots,K}, \lambda_C) \tag{6}$$

Similarly to last section, we develop an EM-style algorithm to find the MAP solutions, which is equivalent to maximizing the following log likelihood by substituting univariate and multivariate Gaussian pdfs in Eq. 6:

$$
\begin{aligned}
L = & \sum_j \sum_n log(\sum_z \theta_{jz} \beta_{z_{jn}}) - \sum_{k=1}^{K} \frac{\lambda_{U_k}}{2} \sum_i (u_i^k)^{\mathrm{T}} u_i^k - \frac{\lambda_S}{2} \sum_m s_m^{\mathrm{T}} s_m \\
& - \sum_{k=1}^{K} \sum_i \sum_m \frac{c_{k,q_{im}}}{2} (q_{im}^k - (u_i^k)^{\mathrm{T}} s_m)^2 - \frac{\lambda_V}{2} \sum_j (v_j - \theta_j)^{\mathrm{T}} (v_j - \theta_j) \\
& - \sum_i \sum_j \frac{c_{ij}}{2} (r_{ij} - u_i^{\mathrm{T}} v_j)^2 - \frac{\lambda_C}{2} \sum_i (u_i - \sum_{k=1}^{K} T_k u_i^k)^{\mathrm{T}} (u_i - \sum_{k=1}^{K} T_k u_i^k) - \frac{\lambda_U}{2} \sum_i u_i^{\mathrm{T}} u_i
\end{aligned} \tag{7}
$$

We employ coordinate ascent (CA) approach as previous section alternatively optimizing latent factor variables and simplex variables as topic proportions. Then we acquire the update rules by setting the derivative of L with respect to the following variables to zero.

$$
u_i^{k=1,2,\ldots,K} = (\lambda_{U_k} I + \lambda_C T_k^2 I + S^{\mathrm{T}} D_{q_i}^k S)^{-1} \cdot (\lambda_C u_i T_k - (\sum_{p \neq k}^{K} T_p u_i^p) \lambda_C T_k + S^{\mathrm{T}} D_{q_i}^k Q_i^k) \tag{8}
$$

$$
u_i = (\lambda_U I + \lambda_C I + V^{\mathrm{T}} D_{c_i} V)^{-1} \cdot (V^{\mathrm{T}} D_{c_i} R_i + \lambda_C \sum_{k}^{K} T_k u_i^k) \tag{9}
$$

$$
v_j = (\lambda_V I + U^{\mathrm{T}} D_{c_j} U)^{-1} \cdot (U^{\mathrm{T}} D_{c_j} R_j + \lambda_V \theta_j) \tag{10}
$$

$$
s_m = (\lambda_S I + \sum_{k=1}^{K} U_k^{\mathrm{T}} D_{q_m}^k U_k)^{-1} \cdot (\sum_{k=1}^{K} U_k^{\mathrm{T}} D_{q_m}^k Q_m^k) \tag{11}
$$

where K is the total number of graphs. I is an identity matrix of the same dimension as that of latent space. U and V are matrices with rows as latent users and latent items, respectively. S is a matrix with rows as the shared social factor-specific latent feature vectors for all graphs. T is the graph selection weight, $\sum_{k=1}^{K} T_k = 1, T_k >= 0$. $R_i = [r_{i1}, \ldots, r_{iJ}]^{\mathrm{T}}$ and $R_j = [r_{1j}, \ldots, r_{Ij}]^{\mathrm{T}}$. For graph k, $Q_i^k = [q_{i1}^k, \ldots, q_{iM}^k]^{\mathrm{T}}$, $Q_m^k = [q_{1m}^k, \ldots, q_{Im}^k]^{\mathrm{T}}$ and U_k is a matrix with rows as the social graph k specific latent user vectors. Likewise, $D_{q_i}^k$, and $D_{q_m}^k$ are similarly defined with diagonal elements $c_{k,q_{i\cdot}}$ and $c_{k,q_{\cdot m}}$, respectively. $D_{c_i} = diag(c_{i1}, \ldots, c_{iJ})$ and $D_{c_j} = diag(c_{1j}, \ldots, c_{Ij})$. In addition, c_{ij} and $c_{k,q_{im}}$ are also seen as the confidence parameters for r_{ij} and q_{im}^k, respectively. The high confidence value a is set to the observed interactive pairs and the low confidence value b is set to the unobserved interactive pairs, where $a > b > 0$.

For our brevity, the remaining update rules for θ and β, can be obtained using the same way as described in CTR (Wang and Blei, 2011). Please see that for details.

3.4 Prediction

Using the learned parameters above, we can make in-matrix and out-of-matrix predictions defined in Wang and Blei (2011). For in-matrix prediction, it refers to the case where those items have been rated by at least one user in the system. To compute predicted rating, we use

$$
r_{ij}^* \approx (u_i^*)^T v_j^*. \tag{12}
$$

For out-of-matrix prediction, it refers to the case where those items have never been rated by any user in the system. To compute predicted rating, we use

$$
r_{ij}^* \approx (u_i^*)^T \theta_j^*, \tag{13}
$$

where the corresponding θ_j^* is defined as topic proportion in Section 3.2 and 3.3.

3.5 Computational Issue

To reduce computational costs when updating u_i, v_j and other variables with similar structure in update rule, we adopt the same strategy of matrix operation shown in Hu et al. (2008). Specifically, directly computing $V^{\mathrm{T}} D_{c_i} V$ and $U^{\mathrm{T}} D_{c_j} U$ requires time $O(L^2 J)$ and $O(L^2 I)$ for each user and item, where J and I are the total number of items and users respectively, L is the dimension of latent representation space. Instead, we rewrite $U^{\mathrm{T}} D_{c_j} U = U^{\mathrm{T}}(D_{c_j} - bI)U + bU^{\mathrm{T}}U$. Then, $bU^{\mathrm{T}}U$ can be pre-computed and $D_{c_j} - bI$ has only I_r non-zeros elements, where I_r refers to the number of users who rated item j and empirically $I_r \ll I$. For other similar structures, i.e., $V^{\mathrm{T}} D_{c_i} V$, $S^{\mathrm{T}} D_{q_i}^k S$, and so on, they are similar. Therefore, we can significantly speed up computation by this sparsity property.

4 Experiments

4.1 Data

We evaluate our proposed method on real life dataset [1] from LastFm. LastFm[2] is an online music catalogue, powered by social music discovery service for personalized recommendation. This dataset (Cantador et al., 2011) is challenging. Though it contains 92,834 pairs of observed ratings with 1892 users and 17,632 items, the sparseness is quite low, i.e., merely 0.2783% , which is much lower than that of the well-known Movielens dataset with the sparseness 4.25%. On average, each user has 44.21 items in the play list, ranging from 0 to 50, and each item appears in 4.95 users libraries, ranging from 0 to 611. For each item, the tag information is used as bag-of-word representation. After text processing, 11,946 distinct words are remained in the corpus. In addition, we further remove noisy users which have no items. We also construct two additional social graphs for our experiments. One is user-tag network extracted from user-tag-item relations in original dataset. The other is user-user network through transforming the constructed user-tag network. The relation in all graphs is binary, i.e., the available denoted as 1 and the unavailable denoted as 0.

Table 1: Original dataset description

Dataset	users	items	tags	user-user relations	user-tags-items	user-items relations
LastFm	1892	17632	11946	25434	186479	92834

4.2 Metrics

Two metrics for evaluating the recommendation performance are employed, i.e., Recall and NDCG. Measure for plain relevance:

$$Recall@k = \frac{\sharp relevance}{k}, \tag{14}$$

where $\sharp relevance$ denotes the total relevant papers in returned top-*k* result. Measure for ranking-based relevance:

$$NDCG@k = \frac{\sum_{i=1}^{k} \frac{2^{rel_i}-1}{log_2(1+i)}}{IDCG}, \tag{15}$$

where rel_i denotes the relevant degree which is binary in our task and $IDCG$ is the optimal score computed using the same form in numerator but with optimal ranking known in advance.

4.3 Experimental Design

In this paper, we expect the proposed model 'Our-Homo' in Section 3.2 and 'Our-Heter' in Section 3.3 can jointly provide a general and systematic solution to handling the following cases of using multiple graphs for recommendation:

- **Case 1**:(Heterogeneous networks with noise) Network data or the extraction process is usually imprecise or noisy in practice. Transform it into homogeneous case and then use 'Our-Homo'.

[1] Data available at http://grouplens.org/datasets/hetrec-2011/

[2] http://www.last.fm/

- **Case 2**:(Homogeneous networks) 'Our-Homo' can be directly employed as the tool for case 1.
- **Case 3**:(Heterogeneous networks with high quality) 'Our-Heter' might be directly employed. It is not needed to be further transformed into Homogeneous case.

The detail experiments in the following sections are presented to justify the effectiveness of our methods for the three cases above.

4.4 Experiments for Case 1 and Case 2

In this section, we mainly focus on the most complex and common case 1 with case 2 in practice.

4.4.1 Baselines

We compare our proposed two models, the model in Section 3.2 denoted as Our-Heter and the model in Section 3.3 denoted as Our-Homo, with some state-of-the-art algorithms.

- **CTR**: This method, described in Wang and Blei (2011), combines both item content information and user-item ratings for CF.
- **PMF**: This method, described in Salakhutdinov and Mnih (2007), is a well-known matrix factorization method for CF, only using interactive rating information.
- **SMF-1**: This method, described in Purushotham et al. (2012), exploits single user's social network structure combined with item's content information for CF. SMF-1 denotes using our extracted user-tag relation.
- **SMF-2**: The same SMF method, described in (Purushotham et al., 2012). SMF-2 denotes using original user-user relation.
- **Our-Heter**: Our model for heterogeneous networks, proposed in Section 3.2, uses our extracted user-tag network and original user-user network.
- **Our-Homo**: Our model for homogeneous networks, proposed in Section 3.3, uses two homogeneous networks, i.e., 1) the transformed user-user network through our extracted user-tag relation, and 2) original user-user network.

4.4.2 Settings

For a fair comparison, we use the similar settings as prior work in Purushotham et al. (2012). Specifically, to well judge the influence of multiple social network structures, we fix the effects of content information to the same level that is optimal in SMF, $\lambda_v = 0.1$. We randomly split the dataset into two parts, training (90%) and test datasets (10%), with constraint that users in test dataset have more than half of the average number of rated items, i.e., 20. This expands the range of performance analysis for our evaluation compared with Purushotham et al. (2012). The optimal parameters are obtained on a small held-out dataset. For PMF, we set $\lambda_v = 100, \lambda_u = 0.01$. For all CTR-based methods, we set $a = 1, b = 0.01, \lambda_v = 0.1$. Specifically, for CTR, we set $\lambda_u = 0.01$. For SMF-1 and SMF-2, we set $\lambda_u = 0.01$. For Our-Homo, we set $\lambda_u = 0.01, \lambda_{u1} = \lambda_{u2} = \lambda_s = 100, \lambda_c = 0.01$. For Our-Heter, we set $\lambda_u = 0.01, \lambda_{s1} = \lambda_{s2} = 100$. The remaining paramters are varied for experiment analysis.

It is noted that the task of out-of-matrix prediction is originally designed for evaluating item content modeling in CTR rather than user social graphs as in CTR-smf. Thus, we followed the same setting in baseline CTR-smf (Purushotham et al., 2012), not considering this task.

4.4.3 Performance Comparison with State-of-the-Art Methods

Figure 2 shows the recall and NDCG results of all the methods when the number of latent factor is fixed to 200 (optimal for the baselines). The proposed model 'Our-Homo' consistently outperforms the baselines and 'Our-Heter' model under both recall and NDCG measures. This finding demonstrates that (1) using multiple graphs for CTR is a necessary for improving recommendation performance from both ranking and plain accuracy perspectives. (2) strong consensus for modeling shared information undermines the performance for multiple graphs factorization as designed in Our-Heter. (3) For heterogeneous case, we address that through simply transforming the heterogeneous network to homogeneous one and then use

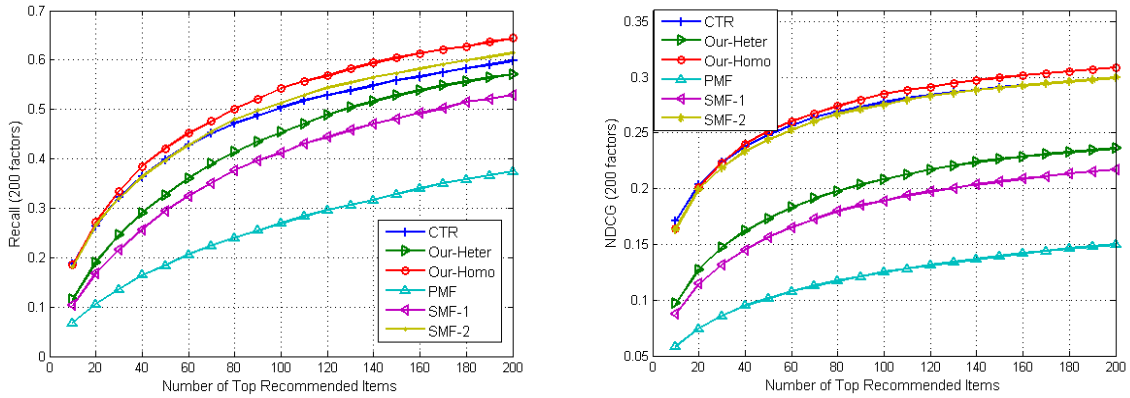

Figure 2: Our model comparison with the state-of-the-art methods, for Recall and NDCG.

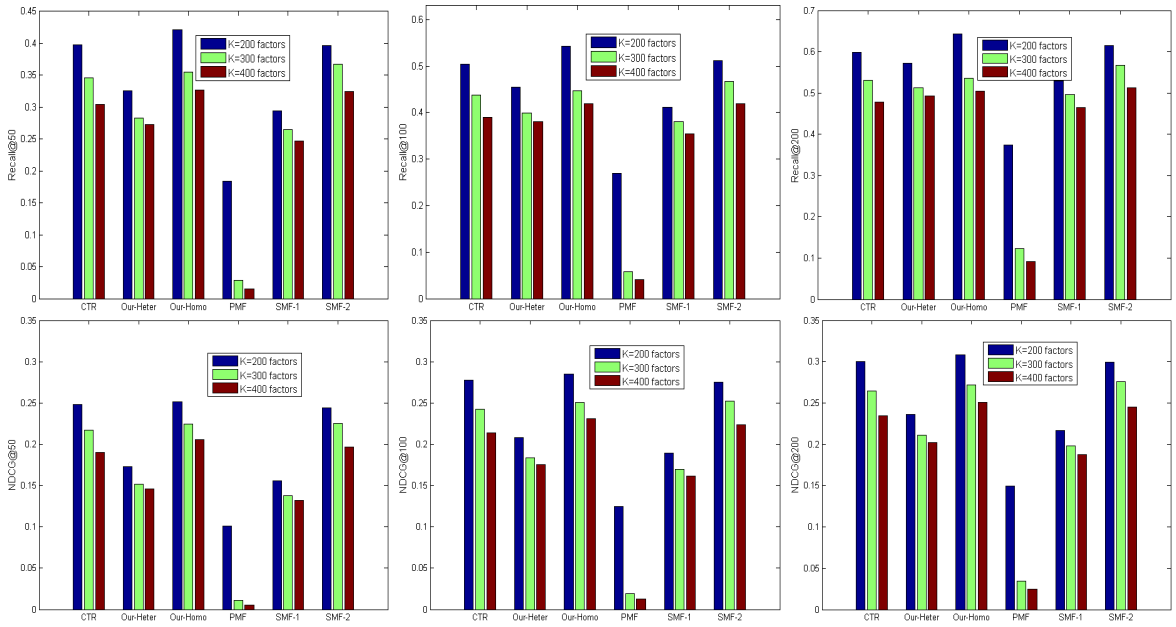

Figure 3: Performance comparison for different latent factors (K=200,300,400) @ top (50,100,200).

'Our-Homo'. This is natural but the opposite is hard. Thus, our solution 'Our-Homo' for modeling weak consensus is effective for both homogeneous and heterogeneous cases.

In addition, we can see that CTR-smf (Purushotham et al., 2012) is sensitive to the quality of graph (SMF-1 with low quality and SMF-2 with high quality as shown in Figure 2). In contrast, we can use the low quality noisy graph (SMF-1) to improve the overall performance by this transformation process. In fact, why Our-Heter does not perform well is mainly due to the noisy graph-1. 'Transformation' can be seen as a 'denoising' process.

4.4.4 Performance Analysis with Different Latent Factors

Figure 3 shows the results of the compared algorithms, with different number of latent factors for varied top recommended item. It shows that $K = 200$ factors is optimal for all baselines compared with other choices of the number of latent factors. This justifies our fire choice of 200 latent factors reported in Figure 3 (Other factor choices are omitted here due to page constraint, which is not optimal for our baselines) and suggests that the choice of latent factor number is crucial for all algorithms especially for PMF. In contrast, the proposed 'Our-Homo' is more stable compared with PMF and outperforms the other baselines in an overall performance as reported in Figure 2.

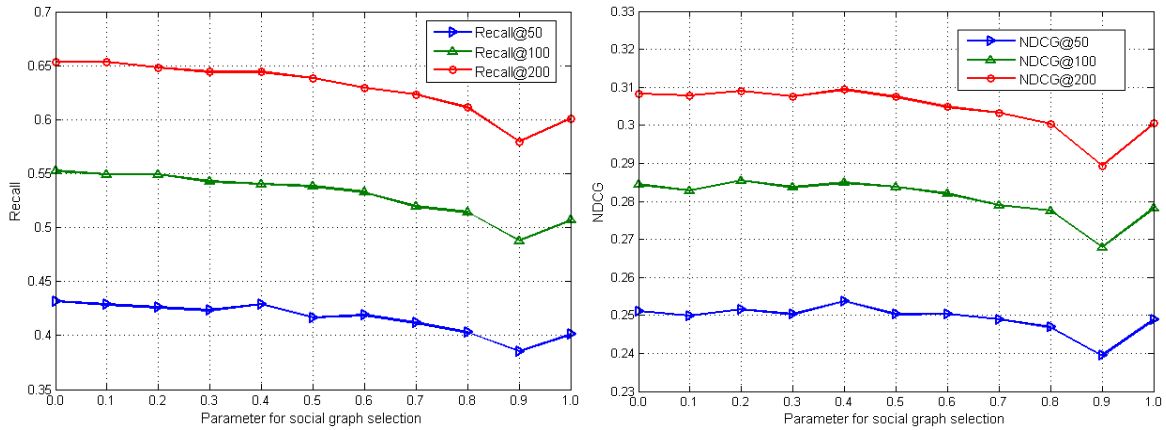

Figure 4: Parameter analysis of graph selection for our weak consensus modeling, i.e., Our-Homo.

4.4.5 Impact of the Parameter for Graph Selection

Next, we examine how our algorithm 'Our-Homo' is influenced by the graph-selection weights. In Figure 4, the horizontal axis shows the graph proportion weight T_1 for graph-1 (user-tag network). In our case, two social graphs are considered. The weight for second graph is $T_2 = 1 - T_1$, which is not shown in Figure 4. Figure 4 clearly proves the effectiveness of our weak consensus modeling. Specifically, we can see that 0.0 seemingly means that the first graph is not selected due to the weight of the first graph $T_1 = 0.0$ and that of second graph $T_2 = 1$ (fully selected). However, due to our weak consensus modeling scheme, though the graph-1 weight is 0.0, it does not mean that the first graph is removed. In fact, the effect of graph-1 is also active through the shared variable 's' in Figure 1 (right). This further can be investigated from the Equation 9. Apparently, the case of 0.0 weight for graph-1, u is only relevant to u_1, but from Equation 8, we can see that u_1 is also influenced by u_2 via the shared social graph factors s. Thus, this also explains why 0.0 weight for graph-1 is not equal to the result of SMF-2 as shown in Figure 2, which only uses graph-2, original user-user graph in SMF-2.

In addition, the 'valley' in Figure 4 might be explained that in the extreme cases (0.0 and 1.0), the denoising effect of weak consensus is slightly strengthened because only one specific graph (higher quality smf-2 or lower quality smf-1 shown in Fig.2) is directly associated with final latent user combined with shared variable. Therefore, the extreme case (1.0) is towards a relative higher performance.

4.5 Experiments for Case 3

Though the proposed 'Our-Homo' is more effective than CTR and CTR-smf, it does not mean that the proposed another method 'Our-Heter' is useless. In this section, we show how the case 3 will be justified.

4.5.1 Baselines

- **Our-Heter(N)**: Our model for heterogeneous networks, proposed in Section 3.2, uses our modified high quality user-tag network as described in Section 4.5.2 and original user-user social network as SMF-2 in Section 4.4.1.
- **SMF-1(N)**: The same SMF method with single social network, described in Purushotham et al. (2012). SMF-1 (N) denotes using our modified high quality user-tag network as described in Section 4.5.2.
- **Our-Homo(O)**: The result of this method is the same as that reported in Section 4.4.3.
- **CTR(O)**: The result of this method (Wang and Blei, 2011) is the same as that reported in Section 4.4.3.

4.5.2 Settings

We want to investigate whether Our-Heter will outperform Our-Homo in the case where the heterogeneous networks with less noise are available, compared with previous results in Figure 2. The settings

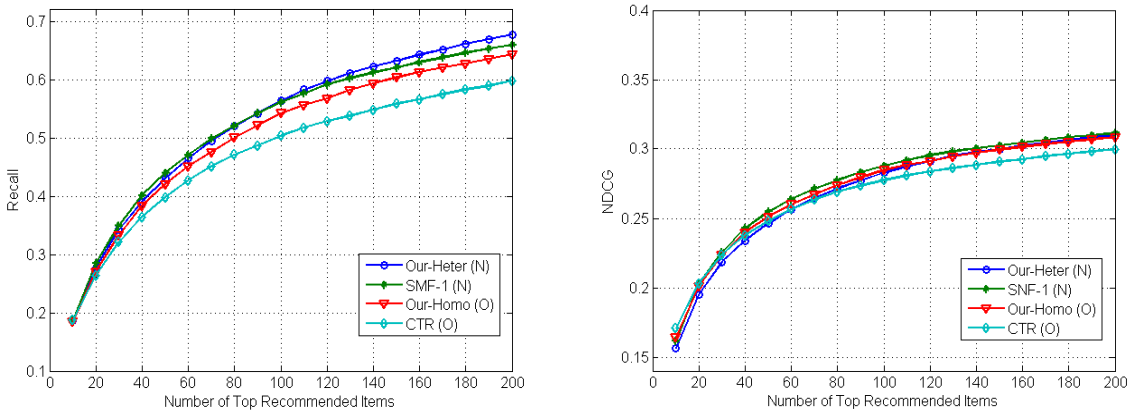

Figure 5: Our model comparison with the state-of-the-art methods (case 3), for Recall and NDCG.

in case 3 are the same as that in Section 4.4.2 except for the refined user-tag graph. In this case, we construct a less noisy user-tag network by selecting top-10% tags according to $tf * idf$ value. The optimal latent factor number is set to 100 for Our-Heter (N) through a small held-out dataset. The remaining parameters are kept as the same values in Section 4.4.2. For notations in baselines Section, 'O' denotes old setting and 'N' denotes new setting with updated user-tag network presented in this section.

4.5.3 Performance Comparison with State-of-the-Art Methods

Figure 5 shows Our-Heter (N) can achieve improved performance compared with baselines without transformation, for the case where high quality graphs are available. Specifically, for recall measure, Our-Heter (N) produces the best result with the increasing number of top recommended items. In addition, we observe that modeling multiple graphs is necessary to further improve recommending performance, while multiple high quality heterogeneous graphs are available.

For NDCG measure, Our-Heter (N) is comparable to our baselines. Since recall measure is only considered for several reasons in previous work (Wang and Blei, 2011; Purushotham et al., 2012), NDCG is introduced as a plus compared with primarily focused recall. Therefore, Our-Heter (N) is also competitive in overall performance in case 3.

In fact, as discussed in Kang and Lerman (2013), CTR-smf (Purushotham et al., 2012) is not always superior to CTR (Wang and Blei, 2011) and vice versa due to different contexts. Likewise, our model is under the multi-view assumption as discussed in Section 1 that should be checked in practice.

5 Conclusions

In this paper, we propose a general recommendation framework with multiple data sources based on CTR. It is a principled hierarchy Bayesian framework with multiple social graphs factorization for recommender systems. In this framework, two ways of consensus modeling are exploited. Specifically, the proposed models Our-Homo and Our-Heter can jointly provide a general and systematic solution to handling three real cases of using multiple graphs with item content information for recommendation: case 1) Heterogeneous networks with noise; case 2) Homogeneous networks; case 3) Heterogeneous networks with high quality. Experimental results on real dataset demonstrate the effectiveness of our approach. While this framework is used for modeling multiple user social graphs, it can be easily extended to exploiting other side information such as multiple complex relations for items in various applications.

Abstract

In this paper, we present a machine learning approach for word sense alignment (WSA) which combines distances between senses in the graph representations of lexical-semantic resources with gloss similarities. In this way, we significantly outperform the state of the art on each of the four datasets we consider. Moreover, we present two novel datasets for WSA between Wiktionary and Wikipedia in English and German. The latter dataset in not only of unprecedented size, but also created by the large community of Wiktionary editors instead of expert annotators, making it an interesting subject of study in its own right as the first crowdsourced WSA dataset. We will make both datasets freely available along with our computed alignments.

1 Introduction

Lexical-semantic resources (LSRs) are an important foundation for numerous natural language processing (NLP) tasks such as word sense disambiguation (WSD) or information extraction (IE). However, large-scale LSRs are only available for a few languages. The Princeton WordNet (Fellbaum, 1998) is commonly used for English, but for most languages such resources are small or missing altogether. Another problem is that, even for English, there is no single LSR which is suitable for all different application scenarios, because the resources contain different words, senses or even information types. Recently, it has been argued that collaboratively constructed resources (e.g. Wiktionary (Meyer and Gurevych, 2012))) are a viable alternative, especially for smaller languages (Matuschek et al., 2013), but there are still considerable drawbacks in coverage which make their usage challenging.

These observations have led to the insight that word sense alignment (WSA), i.e. linking at the level of word senses, is key for the efficient exploitation of LSRs, and it was shown that the usage of linked resources can indeed yield performance improvements. Examples include WSD using aligned WordNet and Wikipedia (Navigli and Ponzetto, 2012a), semantic role labeling using PropBank, VerbNet and FrameNet (Palmer, 2009), the construction of a semantic parser using FrameNet, WordNet, and VerbNet (Shi and Mihalcea, 2005) and IE using WordNet and Wikipedia (Moro et al., 2013). Cholakov et al. (2014) address the special task of verb sense disambiguation. They use the large-scale resource UBY (Gurevych et al., 2012) which contains nine resources in two languages, mapped to a uniform representation using the LMF standard for interoperability (Eckle-Kohler et al., 2012), and also (among others) sense alignments between WordNet, FrameNet, VerbNet and Wiktionary which are exploited in their approach.

However, WSA is challenging because of word ambiguities, different sense granularities and information types (Navigli, 2006), so that past efforts mostly focused on specific resources or applications, where expert-built resources such as WordNet played a central role in most cases. Approaches which aim at being more generic (i.e. applicable to a wider range of LSRs) usually focused on only one information source for the alignment (e.g. glosses or graph structures) without combining them in an elaborate way.

Proceedings of COLING 2014, the 25th International Conference on Computational Linguistics: Technical Papers, pages 245–256, Dublin, Ireland, August 23-29 2014.

In this paper, we want to go beyond this previous work in two ways: i) For the first time, we present an alignment between the large-scale collaboratively constructed resources Wiktionary and Wikipedia. While both LSRs have been extensively used in NLP and especially WSA (see Section 2), no attempt has been made to combine them, although Wiktionary was explicitly designed to complement the encyclopedic knowledge in Wikipedia with linguistic knowledge. Apart from already established tasks like WSD, the strong multilingual focus of both resources makes their combination especially promising for applications such as knowledge-based machine translation or computer-assisted translation where additional background knowledge and translation options can be crucial (Matuschek et al., 2013). To fill this gap in the body of research, we present two new evaluation datasets for English and German, where the latter is not only of remarkable size, but also directly extracted from Wiktionary in a novel approach, making it the first crowdsourced WSA dataset. ii) Also for the first time, we jointly model different aspects of sense similarity by applying machine learning techniques to WSA. However, unlike previous approaches, we do not engineer our features towards a specific resource pair, rendering the approach powerful but proprietary. Instead, we aim to combine generic features which are applicable to a variety of resources, and we show that combining them leads to state-of-the-art WSA performance. In particular, we employ distances calculated with Dijkstra-WSA (Matuschek and Gurevych, 2013), an algorithm which works on graph representations of resources, as well as gloss similarity values. This lets us take advantage of both (orthogonal) ways of identifying equivalent senses and yields a very robust and flexible WSA framework.

The rest of this paper is structured as follows: In Section 2 we discuss related work, in Section 3 we describe our approach and introduce the resources and datasets we use in our experiments, in Section 4 we evaluate our results, and we conclude in Section 5 with some directions for future work.

2 Related Work

There are two main approaches to WSA which have been applied: Similarity-based and graph-based ones. To our knowledge, there exists no previous work which effectively combines both approaches in a unified framework, and only few works which combine both kinds of features for different purposes.

2.1 Similarity-based Approaches

WordNet was aligned to Wikipedia (Niemann and Gurevych, 2011) and Wiktionary (Meyer and Gurevych, 2011) using a framework based on gloss similarity, in spirit of the earliest work in WSD presented by Lesk (1986). In both cases, cosine and personalized PageRank (PPR) similarity (Agirre and Soroa, 2009) were calculated, and a simple machine learning approach was used to classify each pair of senses (see Section 3.3). This idea was also applied to cross-lingual alignment between WordNet and the German part of OmegaWiki (Gurevych et al., 2012), using machine translation as an intermediate component. Henrich et al. (2011) use a similar approach for aligning GermaNet and Wiktionary, but with word overlap as the similarity measure. De Melo and Weikum (2010) report an alignment of WordNet synsets to Wikipedia articles which is also based on word overlap. We later report results based on gloss similarity as one of our baselines (Tables 2 and 3).

2.2 Graph-based Approaches

In one of the earliest structure-based works, Daudé et al. (2003) map different versions of WordNet based on the synset hierarchy. Navigli (2009) disambiguates WordNet glosses, i.e. sense markers are assigned to all non-stopwords in each WordNet gloss. The approach is based on finding circles in the WordNet relation graph to identify disambiguations. In later work, this idea was applied to the disambiguation of translations in a bilingual dictionary (Flati and Navigli, 2012). While this "alignment" of dictionary entries is related to our problem, it was not discussed how this idea could be applied to word sense alignment of two resources. Laparra et al. (2010) use a shortest path algorithm (SSI-Dijkstra+) to align FrameNet lexical units (LUs) with WordNet synsets. They align monosemous LUs first and then search for the closest synset in WordNet for the other LUs in the same frame. The LUs are, however, considered as mere texts to be disambiguated; there is no attempt made to exploit the graph structure of FrameNet.

Ponzetto and Navigli (2009) use a graph-based method for aligning WordNet synsets and Wikipedia categories. Using semantic relations, they build subgraphs of WordNet for each category and then align senses to categories based on the structural features. In our own previous work, we presented Dijkstra-WSA, a graph-based approach working with shortest paths (Matuschek and Gurevych, 2013). It achieves state-of-the-art precision, but recall is an issue if the graphs are sparse (i.e. in case of only few semantic relations). As Dijkstra-WSA distances are one of the features we use for our machine learning approach, we will present this approach in more detail in section 3.2.2 and also report results for Dijkstra-WSA on our evaluation datasets for comparison.

2.3 Hybrid Approaches

In later work, Navigli and Ponzetto (2012a) also align WordNet with the full Wikipedia. Besides using bag-of-words overlap to compute gloss similarity, they also build a graph structure for the senses in both resources by using WordNet semantic relations. The goal is to determine which WordNet sense is closest to the Wikipedia sense to be aligned. However, the graph structure of Wikipedia is disregarded, as is the global structure of WordNet, as just a locally restricted subset of WordNet relations is used. In the same context of BabelNet, Navigli and Ponzetto (2012b) also present BabelRelate, an approach which relies on translations to compute cross-lingual semantic similarity; however, they do not apply it to WSA. Dijkstra-WSA was enhanced by using a backoff, by means of performing a graph-based alignment first, and in cases where no alignment target sense can be found, a decision is made based on the similarity of glosses (Matuschek and Gurevych, 2013). While this simple two-step approach increases recall substantially, it comes at the expense of lower precision. However, the overall F-measure achieved state-of-the-art performance on every considered dataset (0.65–0.87). We also report the results for this hybrid approach as a baseline (Tables 2 and 3). De Melo and Weikum (2008) use a machine learning approach with a combination of structural and content-based features of WordNet, but for building new wordnets in other languages, not aligning existing ones.

In summary, the different approaches to compute similarity have mostly been used in isolation, or combined in a shallow or restricted way. More complex approaches usually require resource-specific feature engineering, which makes their transferability to other resources or languages difficult. Thus, we present a framework which combines different similarity measures in a generic and flexible way and enables state-of-the-art WSA performance on a variety of resources with modest effort.

3 The Alignment Procedure

The basic steps of our alignment algorithm are:

1. For each sense in one resource, all possible candidates in the other resource are retrieved. Candidates are senses which have the same attached lemma and part of speech. For instance, for the *programming* sense of *Java* in one resource, their might exist senses for *programming*, *island* or *coffee* in the other one which are all possible alignment targets.

2. For each candidate pair, we calculate a set of features describing their similarity in different ways.

3. For a set of word senses (the gold standard), the alignment decision is made by human annotators.

4. A machine learning classifier is trained on this gold standard, and an alignment decision is made for the remainder of the candidate pairs to produce a complete alignment of the resources. In our setup, we use 10-fold cross validation to train the classifier.

The different datasets and steps of the algorithm are explained in more detail in the following sections.

3.1 Resources and Datasets

We use four different WSA evaluation datasets, two of which are presented for the first time. To ensure compatibility with previous work, we use the same versions of the resources as reported in (Gurevych et al., 2012) and (Matuschek and Gurevych, 2013).

Pair	Pos.	Neg.	Polysemy	One cand.	F_1	A_0	Composition
WordNet-OmegaWiki	210	473	1.50	75.2%	0.84	0.85	random
WordNet-Wiktionary	313	2 110	4.76	18.6%	0.78	0.93	manual
Wiktionary-Wikipedia (En)	75	292	1.27	87.6%	0.79	0.95	automatic
Wiktionary-Wikipedia (De)	21 855	9 953	1.47	77.6%	0.85	0.89	crowd

Table 1: Characteristics of the gold standards used in the evaluation. The degree of polysemy (i.e. the number of possible alignment targets per sense) hints towards the difficulty of the task, as does the number of senses with only one alignment candidate. WordNet-Wiktionary stands out as it was manually composed and is not representative of the full alignment (Meyer and Gurevych, 2011). The inter-annotator agreements A_0 and F_1 can be considered as upper bounds for automatic alignment accuracy and F-measure. Note that for the Wiktionary-Wikipedia datasets, due to the nature of their creation, the agreement was originally not available; we estimated it by manually re-annotating a sample of 100 examples with two annotators.

3.1.1 Resources

WordNet (Fellbaum, 1998) is a computational lexicon for English created at Princeton University. It is organized in sets of synonyms (synsets), each expressing a distinct concept. Synsets are represented by textual definitions (so-called glosses). A hierarchical organization is encoded via semantic relations such as hyponymy.

Wikipedia is a collaboratively created online encyclopedia available in almost 300 languages. The current English version contains around 4 400 000 articles, and the German one around 1 700 000 articles, each usually describing a particular concept. Due to its encyclopedic nature, Wikipedia mostly covers nouns, while the other LSRs discussed also cover verbs, adjectives, etc. Articles are connected via hyperlinks in the article text (implying a graph structure), and the first paragraph usually gives a short summary of the topic, serving as a gloss for our purposes. Articles are also linked to the equivalent articles in other languages.

Wiktionary is a dictionary "side project" of Wikipedia, available in over 500 languages. Currently, the English Wiktionary contains over 500 000 lexical entry pages, while the German one contains around 350 000 ones. For a word, multiple senses can be encoded, and these are usually represented by glosses. Wiktionary also contains hyperlinks to synonyms, hypernyms, etc. and translations into other languages.

OmegaWiki is a freely editable online dictionary like Wiktionary. However, instead of distinct language editions, OmegaWiki contains language-independent concepts ("Defined Meanings") which carry lexicalizations in different languages. These concepts are connected via semantic relations. OmegaWiki contains over 46 000 concepts and lexicalizations in almost 500 languages.

3.1.2 Datasets

WordNet–OmegaWiki: The first alignment between these LSRs based on the German part of OmegaWiki was reported in (Gurevych et al., 2012). As OmegaWiki Defined Meanings are multilingual, we used the same dataset for monolingual WSA in later work (Matuschek and Gurevych, 2013). Table 1 presents details about this and the other evaluation datasets.

WordNet–Wiktionary: Meyer and Gurevych (2011) originally used this dataset for similarity-based alignment. While we could not improve upon this using Dijkstra-WSA on its own (Matuschek and Gurevych, 2013), the backoff approach yielded a significant improvement. This dataset was manually composed according to specific criteria, hence it differs from the others and is not fully representative of the full alignment.

Wiktionary–Wikipedia (English): No evaluation dataset (let alone a full alignment) has been reported for this resource pair yet. However, as the datasets for WordNet-Wiktionary (Meyer and Gurevych, 2011) and WordNet-Wikipedia (Niemann and Gurevych, 2011) are lexically overlapping, we were able to automatically create a gold standard for Wiktionary-Wikipedia by exploiting the transitivity of the alignment relation, i.e. by using WordNet as a pivot. Note that, unlike Wiktionary, Word-

Net synsets have multiple lexicalizations for the same meaning, introducing alignment candidates from Wikipedia which might not be applicable to a particular Wiktionary sense. Hence, we decided to filter the examples where the lexeme of the Wiktionary sense and the Wikipedia article title did not match. An effect of this process was that words not contained in all three resources were filtered out, and many examples were left with few or only one candidate, leading to a low polysemy. We also manually checked the derived gold standard and corrected a small number of wrong annotations introduced through the automatic process. The resulting dataset is thus considerably smaller than the others, but it still turned out to be sufficient for machine learning experiments.

Wiktionary–Wikipedia (German): Same as for the English editions, neither a gold standard nor an alignment was previously reported for this pair. We were able to create a gold standard in a novel way by exploiting the fact that many German Wiktionary senses contain links to the corresponding Wikipedia articles, inducing a sense alignment between the two LSRs manually validated by the Wiktionary community. However, we were unable to extract such an alignment for English, as Wikipedia articles are attached to the lexical entry page in this version and not to a specific sense.

In the German Wiktionary, a large portion of the senses is linked in this way, and even after aggressively filtering out invalid link targets (e.g. disambiguation pages or pages with a non-matching title), we retained over 20 000 alignments between Wiktionary senses and Wikipedia pages, a sample of which we manually confirmed to be correct. Of course, this only yields positive examples; to also include cases of non-alignment, we extracted the other candidate (i.e. lexically matching) Wikipedia articles for each aligned Wiktionary sense, assuming that Wiktionary editors also considered and discarded them before eventually creating a link. Interestingly, the number of negative examples derived in this way is relatively low in comparison to the other datasets. An analysis revealed that a large fraction of the linked Wiktionary senses are either scientific terms (e.g. from biology) or named entities such as cities. Both types of senses tend to have few alternative candidates in Wikipedia due to their specificity, and it seems logical that Wiktionary users predominantly link these senses to the explanatory Wikipedia articles which are not familiar to the majority of users.

In the end, this process yielded a WSA dataset with unprecedented characteristics: It was not only created and validated by a crowd of editors rather than a handful of annotators, but it is also an order of magnitude larger than previously reported datasets (Table 1). This enables us to assess the performance of our WSA approach in a scenario which is close in size to a full alignment task, allowing a more well-grounded statement about its effectiveness.

3.2 Feature Engineering

The selection of features for our machine learning approach was driven by the premise to keep the framework as generic and resource-agnostic as possible, in order to ensure applicability to many different LSRs without additional engineering effort. Thorough analysis of existing resources and approaches revealed that two types of information are available for the vast majority of LSRs: i) Glosses, or more general, textual descriptions of concepts, and ii) Relationships between concepts inducing a graph, given through semantic relations, links, or other means. We also evaluated some features which are specific to a smaller subset of resources (see Section 3.2.3).

3.2.1 Gloss Similarity

Cosine similarity (COS) calculates the cosine of the angle between a vector representation of two senses s_1 and s_2. For the vector representation of a sense, we use a bag-of-words approach, i.e., a vector $\mathrm{BoW}(s)$ contains the term frequencies of all words in the description of s. In this work, we only rely on the textual definition of a sense to keep the approach as generic as possible, while the usage of example sentences, related words, synonyms etc. would also be possible.

Personalized PageRank similarity (PPR) (Agirre and Soroa, 2009) measures the semantic relatedness between two word senses s_1 and s_2 by comparing semantic vectors which can be derived in different ways; we utilize the variant introduced by Niemann and Gurevych (2011). The idea is to identify senses of words in a sense's gloss which are central for describing its meaning. These senses (represented in a graph derived from an LSR such as WordNet) should have a high PageRank score (i.e. a high centrality).

3.2.2 Dijkstra-WSA Distance

Dijkstra-WSA (Matuschek and Gurevych, 2013) is the graph-based WSA algorithm we use to calculate a distance-based similarity measure between word senses. We will briefly explain its two steps.

Graph construction: The *resource graph* is comprised of a set of nodes V which represents the senses of an LSR and a set of edges $E \subseteq V \times V$ which expresses semantic relatedness between them. One can use semantic relations, hyperlinks, or other relatedness indicators. For sparse LSRs, it is advisable to add edges between senses s_1 and s_2 if a monosemous term t with sense s_2 is included in the gloss of s_1. For example, one can link a sense of *Java* to *programming language* if the latter term is included in the former's definition text. This *monosemous linking* enhances the graph density (and hence, the recall) significantly.

Computing sense alignments: First, trivial alignments between the two resource graphs A and B are created. Alignments are trivial if two senses have the same attached lexeme in A and B and this lexeme is also unique in either resource. Intuitively, these alignments serve as "bridges" between highly related regions of A and B. Next, for each remaining sense $s \in A$, the set of possible target senses $T \subset B$ is retrieved in a similar fashion as for our approach, and for each of them the shortest path is computed using Dijkstra's algorithm (Dijkstra, 1959). While Dijkstra-WSA then goes on to directly align the sense which is closest to the source sense, we save the distance for each candidate sense and directly use it as a feature, expressing semantic relatedness based on the structure of both underlying resources. When no distance can be computed (in case of a disconnected graph), we assume infinite distance.

3.2.3 Other Features

We also experimented with other features which were accessible directly from the resources, i.e. without the need for external knowledge or extensive computational effort; these were usually not available for every resource pair. Features we tried were the part of speech (Wiktionary, OmegaWiki, WordNet), the sense index, i.e. the position in the sense list for a lexeme (WordNet, Wiktionary), similarity of example sentences (WordNet, Wiktionary), overlap of translations into other languages (Wikipedia, Wiktionary, cf. (Bond and Foster, 2013)) and overlap of domain labels (Wikipedia, Wiktionary, WordNet, OmegaWiki). However, for none of these features we could observe any significant[1] impact on the results, mostly due to sparsity of the respective features. Thus, we do not report them, but on the other hand we consider this an indicator that gloss similarity and distance in the resource graph already sufficiently capture the similarity between senses.

3.3 Machine Learning Classifiers

We experimented with different machine learning classifiers using WEKA (Hall et al., 2009). While a detailed discussion of these classifiers is beyond the scope of this work, we will at least give a short description of the ones we eventually used. For more details, please refer to textbooks such as (Murphy, 2012). We used WEKA's standard configuration in every case.

Threshold-based classifiers work by simply trying to learn a numeric boundary value which separates positive examples from negative ones. Although this approach is rather naive, it has been successfully used in previous WSA efforts (Meyer and Gurevych, 2011; Niemann and Gurevych, 2011).

A **Naive Bayes** classifier assumes that features are independent (i.e. the value of one feature is unrelated to any other feature), and is thus able to learn reliable classification probabilities on relatively small training sets. While the independence assumption can be considered an oversimplification, the algorithm is widely used due to its efficiency and good precision.

Bayesian Networks (or *belief networks*) also classify based on probabilities learned from training data, however, they offer the advantage of modeling dependencies between features, hence allowing a more accurate representation of the data. Technically, such a network is a directed acyclic graph modeling the conditional dependencies between variables.

A **Perceptron** is a classifier which maps a real-valued input vector to a binary output, by means of an artificial neural network. It is commonly used for pattern recognition, also in NLP (Collins, 2002).

[1] All significance claims in this paper are based on McNemar's test at a confidence level of 1%.

Support Vector Machines (SVMs) construct a hyperplane in a multi-dimensional space which yields a good separation between positive and negative training examples, represented as data points.

Decision Trees are built from training input by iteratively splitting the set of samples based on attribute values so that the resulting subset is as homogeneous as possible with regard to the class label. Unseen examples can be classified by testing the attribute values and following different branches of the tree. One of the main advantages (e.g. in comparison to SVMs) is that this approach is easily interpretable.

4 Experimental Results and Analysis

Baselines For reference, we report six different baselines: i) *Random*: A random sense from the set of candidates is chosen in each case, ii) *1:1*: An alignment is always made if and only if there is exactly one candidate, iii) *1st*: The first of the candidate senses is always selected[2], iv) *SIM*: A similarity threshold is learned for gloss similarity values as suggested by Meyer and Gurevych (2011), cf. Section 3.2.1, v) *DWSA*: The closest candidate sense in the resource graph is aligned as we suggested in (Matuschek and Gurevych, 2013), cf. Section 3.2.2, vi) *HYB*: A hybrid approach of using *DWSA* first and then *SIM* as a backoff, also suggested by us (Matuschek and Gurevych, 2013). The latter approach represents state-of-the-art performance for WSA. Note that for the two Wiktionary-Wikipedia datasets, no previous results were available, so we created similarity-based and Dijkstra-WSA alignments ourselves, based on the same versions of the resources as in the previous work. For the other datasets, we used the numbers reported in the original papers (Matuschek and Gurevych, 2013; Meyer and Gurevych, 2011).

Overview Tables 2 and 3 present the results for all setups. Although the best classifiers for each dataset always outperform the previous state of the art and the baselines by a significant margin, there is no consistent pattern in the results across different LSRs and classifiers. One reason for this is that the range of feature values varies substantially between different datasets. For instance, Dijkstra-WSA distances tend to be greater when Wikipedia is involved simply by its virtue of being larger than the other LSRs, and gloss similarities also differ depending on the average length of the glosses and the language. Another factor are the gold standards, which are quite different in terms of size and composition (see Table 1). Thus, no classifier is the undisputed "winner", but Bayesian Networks proved most robust in our experiments, showing competitive results in every case. As training them is also computationally cheap (compared to SVMs, for instance), we would generally recommend this kind of classifier for WSA tasks. In the following, we also provide a more detailed discussion of the results for each individual dataset.

WordNet-OmegaWiki In this case, the precision of the alignment is satisfactory for every classifier, while both previously reported approaches struggle for different reasons (Gurevych et al., 2012; Matuschek and Gurevych, 2013). The strength of the machine learning becomes apparent especially in comparison with the *HYB* approach: While the latter merely combines independent alignment decisions, hence achieving better recall but failing to improve precision (cf. Section 2.3), the joint usage of features leads to a massive improvement. Analysis of the decision tree classifier shows that, as we suspected, the "edge cases" are explicitly reflected in the learned model, i.e. examples with high gloss similarity but also a high Dijkstra-WSA distance (or vice versa) are ruled out with higher confidence. This observation generally also holds for the other datasets. As an example, the two senses of *genome* in biology (*"The non-redundant genetic information stored in DNA sequences that defines an individual organism"*) and algorithmics (*"In the context of a genetic algorithm, the information that defines an individual entity"*) have similar glosses; they are, however, quite far apart in the graph and thus not aligned. The Bayesian Network achieves the best results as it comprehensively models this interdependence of features. The SVM achieves the best precision, but the distribution of feature values does not lend itself well to linear separation in this case, leading to unsatisfactory recall.

WordNet-Wiktionary For this dataset, the results look similar to WordNet-OmegaWiki as far as the improvement of precision is concerned, as the joint usage of features helps to make a correct decision on

[2]While this corresponds to the most frequent sense baseline in other setups, note that no explicit frequency information is available for OmegaWiki, Wiktionary and Wikipedia, so that the first sense baseline is only a rough approximation.

We report precision, recall, F-measure (the harmonic mean of both) and accuracy. Best results for each value and dataset are marked in bold. The inter-annotator agreements A_0 and F_1 are given as upper bounds.

borderline examples. However, in this case the recall is also substantially improved, especially for the Bayesian classifiers. This was an issue in the original Dijkstra-WSA results (Matuschek and Gurevych, 2013) due to the low connectivity of the English Wiktionary graph. The combination of distances and gloss similarities is able to alleviate this shortcoming of Wiktionary to some extent, as examples with missing Dijkstra-WSA distance can still be aligned in case of sufficient gloss similarity. SVMs also show the best precision here, but are challenged by the suboptimal separability of the feature space.

Wiktionary-Wikipedia (English) The low connectivity of Wiktionary is not as much an issue here as for WordNet-Wiktionary, mostly due to the different composition of the gold standard – higher-frequency words tended to be retained (see Section 3.1.2), which in turn are better connected within Wiktionary. This leads to reasonable results for Dijkstra-WSA alone. The hybrid approach reaches the best recall, but due to the relatively low precision of the *SIM* alignment, the overall result leaves room for improvement. This improvement is again achieved via joint modeling of features. As for the datasets discussed above, the precision is improved significantly; this is especially true for the Bayesian Network classifier. Precision and recall for the SVM classifier are also satisfactory in this case (due to the better linear separability of the feature space), making it the best overall classifier along with the Perceptron.

Wiktionary-Wikipedia (German) On this dataset, the naive baselines are very strong, due to the disproportionately large number of positive examples – this is especially true for the *1:1* setup which reaches perfect precision. In other words, whenever there is only one alignment candidate, it is already the correct one. The *HYB* approach also yields good results thanks to the high precision of its two components, but recall is an issue for gloss similarity due to the richer morphology and different formation of compounds in German. We did not use a compound splitter (an obvious extension for future work), so that, for instance *"Kinderspiel"* and *"Spiel für Kinder"* (both meaning *"a game for children"*) could not be lexically matched. However, when machine learning is applied, the recall can again be significantly improved at only a negligible expense of precision. Here, as for the WordNet-Wiktionary dataset, the joint modeling of distance and gloss similarity allows to correctly align more borderline examples. While the strong bias towards positive examples might make this dataset not fully representative of a full alignment task (which is the eventual goal of WSA), the results still beat the strong baselines in terms of F-measure and thus indicate that WSA, and especially our approach, works well on such a large-scale dataset.

Table 3: Results for Wiktionary-Wikipedia alignment in English and German: Using baselines (top), approaches from previous work (middle) and different machine learning classifiers (bottom). We report precision, recall, F-measure (the harmonic mean of both) and accuracy. Best results for each value and dataset are marked in bold. The inter-annotator agreements A_0 and F_1 are given as upper bounds.

Error analysis Error sources for our system are mostly the same as for the previously reported approaches – if equivalent concepts are described very differently (known as the "lexical gap", e.g. the senses *"divulge confidential information"* and *"to confess under interrogation"* of the verb *to sing*) and happen to be not very close in the resource graph, i.e. both similarity measures fail at once, they are likely not aligned (false negatives). On the other hand, false positives occur for examples such as *Brand*, which is the name of districts in two different German cities (Aachen and Zwickau). The sense descriptions are very much alike, and the senses are also located in similar regions of the resource graphs (roughly speaking, *German geography*), which makes the distinction hard. Addressing these issues might be possible by computing more sophisticated gloss similarity measures (e.g. using lexical expansion (Iida et al., 2008)) or enhancing the graph construction process. In general, however, there are no discernible systematic errors made by our system.

5 Conclusions and future work

We have shown that through joint modeling of different similarity measures for WSA the overall alignment quality in terms of F-measure can be significantly improved over the state of the art for each and every of the considered four datasets. This proves that such a joint usage of global structure as well as the content of the LSRs is indeed preferable over using either of them in isolation or combining them in a simple backoff approach, since it effectively utilizes both ways of calculating similarity.

Apart from substantially improving WSA performance, we also present two new datasets for Wiktionary-Wikipedia alignment in English and German which fill a considerable gap in the previous work on WSA. One of Wiktionary's explicit purposes is to complement the knowledge in Wikipedia, so that an alignment between these widely used resources seems a natural and important extension to the body of work in this field. Especially for (semi-) automatic translation tasks, this resource combination seems extremely promising due to the abundant multilingual content in both resources (see Section 3.1.1). We suggested a comparable combination of Wiktionary and OmegaWiki in the past (Matuschek et al., 2013), but the much larger Wikipedia is bound to hold even more potential. Moreover, the German dataset is of unprecedented size, allowing more credible statements about the performance of WSA algorithms in a full alignment scenario. Another interesting aspect is that this dataset was derived from links created by the crowd of Wiktionary editors, not by expert annotators; thus, it can be considered the first crowdsourced WSA dataset. This type of dataset creation is also one aspect of future work. We want to investigate in more detail to what extent these alignments are trustworthy, what steps are necessary

to improve the dataset's size and quality, and how negative examples (i.e. non-alignments) can be more reliably derived. We also plan to find out if such datasets could be created for other Wiktionary language editions.

The fact that the achieved results are close to the human agreement suggests that, for the datasets considered, there is not much room for improvement. Thus, we plan to apply and adapt the algorithm to LSRs with different properties than the ones considered here, such as the more syntax-focused FrameNet (Ruppenhofer et al., 2010) which only recently has received research attention in automatic WSA (Hartmann and Gurevych, 2013). The usage of syntactic features to express sense similarity has not been thoroughly explored yet, and it seems a promising direction to make further progress in WSA. Usage of more elaborate textual similarity features (e.g. covering semantic similarity or using lexical expansion) as it was suggested for text reuse detection (Bär et al., 2012) would be another direction worth exploring.

Inspired by the semi-automatic construction of the Wiktionary-Wikipedia gold standard for English from existing datasets, we also want to investigate whether an alignment of more than two resources at once (n-way alignment) is feasible, using joint knowledge from all LSRs involved. For instance, the information that two senses in resources A and B share a strong resemblance to a sense in another resource C could be expressed by an additional feature.

Abstract

We present a multi-view annotation framework for Chinese treebanking, which uses dependency structures as the base view and supports conversion into phrase structures with minimal loss of information. A multi-view Chinese treebank was built under the proposed framework, and the first release (PMT 1.0) containing 14,463 sentences is be made freely available. To verify the effectiveness of the multi-view framework, we implemented an arc-standard transition-based dependency parser and added phrase structure features produced by the phrase structure view. Experimental results show the effectiveness of additional features for dependency parsing. Further, experiments on dependency-to-string machine translation show that our treebank and parser could achieve similar results compared to the Stanford Parser trained on CTB 7.0.

1 Introduction

Phrase structures (PS) and dependency structures (DS) are two of the most popular grammar formalisms for statistical parsing (Collins, 2003; Charniak, 2000; McDonald et al., 2005; Nivre, 2006; Petrov and Klein, 2007; Zhang and Clark, 2008). While DS trees emphasize the grammatical relation between heads and dependents, PS trees stress the hierarchical constituent structures of sentences. Several researchers have explored DS and PS simultaneously to enhance the quality of syntactic parsing (Wang and Zong, 2010; Farkas and Bohnet, 2012; Sun and Wan, 2013) and tree-to-string machine translation (Meng et al., 2013), showing that the two types of information complement each other for NLP tasks.

Most existing Chinese and English treebanks fall into the phrase structure category, and much work has been done to convert PS into DS (Magerman, 1994; Collins et al., 1999; Collins, 2003; Sun and Jurafsky, 2004; Johansson and Nugues, 2007; Duan et al., 2007; Zhang and Clark, 2008). Research on statistical dependency parsing has frequently used dependency treebanks converted from phrase structure treebanks, such as the Penn Treebank (PTB) (Marcus et al., 1993) and Penn Chinese Treebank (CTB) (Xue et al., 2000). However, previous research shows that dependency categories in converted treebanks are simplified (Johansson and Nugues, 2007), and the widely used head-table PS to DS conversion approach encounters ambiguities and uncertainty, especially for complex coordination structures (Xue, 2007). The main reason is that the PS treebanks were designed without consideration of DS conversion, leading to inherent ambiguities in the mapping, and loss of information in the resulting DS treebanks. To minimize information loss during treebank conversions, a treebank could be designed by considering PS and DS information simultaneously; such treebanks have been proposed as *multi-view* treebanks (Xia et al., 2009). We develop a multi-view treebank for Chinese, which treats PS and DS as different views of the same internal structures of a sentence.

We choose the DS view as the base view, from which PS would be derived. Our choice is based on the effectiveness of information transfer rather than convenience of annotation (Rambow, 2010; Bhatt and Xia, 2012). Research on Chinese syntax (Zhu, 1982; Chen, 1999; Chen, 2009) shows that the phrasal category of a constituent can be derived from the phrasal categories of its immediate subconstituents and

v, iv, im, jv, lv, Vg, vd, vi, vl, vq,vu, vx, vt,kv	v (verb)
w, wd, wf, wj, wk, wky, wkz, wm,wp, ws, wt, wu, ww, wy, wyy, wyz	w (punctuation)

Table 1: Mapping from PKU POS to our POS.

the dependency categories between them (for terminal words, parts-of-speech can be used as phrasal categories). Consequently, in Chinese, the canonical PS, containing information of constituent hierarchies and phrasal categories, can be derived naturally from the canonical DS. As Xia et al. (2009) stated, a rich set of dependency categories should be designed to ensure lossless conversion from DS to PS. When the information of PS has been represented in DS explicitly or implicitly, we can convert DS to PS without ambiguity (Rambow et al., 2002).

Given our framework, a multi-view Chinese treebank, containing 14,463 sentences and 336K words, is constructed. This main corpus is based on the Peking University People's Daily Corpus. We name our treebank the Peking University Multi-view Chinese Treebank (PMT) release 1.0. To verify the usefulness of the treebank for statistical NLP, a transition-based dependency parser is implemented to include PS features produced in the derivation process of phrasal categories. We perform a set of empirical evaluations, with experimental results on both dependency parsing and dependency-to-string machine translation showing the effectiveness of the proposed annotation framework and treebank. We make the treebank, the DS to PS conversion script and the parser freely available.

2 Annotation Framework

2.1 Part-of-speech Tagset

Our part-of-speech (POS) tagset is based on the Peking University (PKU) People's Daily corpus, which consists of over 100 tags (Yu et al., 2003). We simplify the PKU tagset by syntactic distribution. The simplified tagset contains 33 POS tags. The mapping from the original PKU POS to our simplified POS is shown in Table 1. For instance, *Ag* (adjective morpheme), *ad* (adjective acting as an adverb), *ia* (adjective idioms), *ja* (adjective abbreviation) and *la* (temporary phrase acting as an adjective) are all mapped to one tag *a* (adjective). A set of basic PKU POS tags, including *c* (conjunction), *e* (interjection), *f* (localizer), *g* (morpheme), *h* (prefix), *i* (idiom), *j* (abbreviation), *k* (suffix), *l* (temporary phrase), *nr* (personal name), *nrf* (family name), *nrg* (surname), *ns* (toponym), *nt* (organization name), *nx* (non-Chinese noun), *nz* (other proper noun), *o* (onomonopeia), *p* (preposition), *q* (measure word), *r* (pronoun), *s* (locative), *x* (other non-Chinese word), *y* (sentence final particle), *z* (state adjective), are left unchanged.

2.2 Dependency Category Tagset

In a DS, the modifier is tagged with a dependency category, which denotes the role the modifier plays with regard to its head. The root word of a sentence is dependent on a virtual root node *R* and tagged with the dependency category *HED*. Table 2 lists the 32 dependency categories used in our annotation guideline. These categories are designed in consideration of PS conversion with minimal ambiguities, and can be classified according to the following criteria:

(1) whether the head dominates a compound clause (i.e. has an IC modifier) in the PS view. According to this, dependency categories can be *cross-clause* or *in-clause*. For instance, in Figure 1, the last punctuation (。) is labeled with the *cross-clause* tag *PUS*, and its head dominates an *IC* modifier. (2) the relative position of the modifier to the head. According to this, dependency categories can be *left*, *right* or *free*. For instance, the *LAD, SBV, ADV, COS, DE and ATT* labels in Figure 1 are all *left*. The *VOB* label

Tag	Description	Tag	Description
ACT	action object	LAD	left additive
ADV	adverbial	MT	modality and time
APP	appositive element	NUM	number
ATT	attribute	POB	propositional object
CMP	complement	PUN	punctuation
COO	other coordination element	PUS	cross-clause punctuation
COS	share-right-child coordination element	QUC	post-positional quantity
DE	de (modifier of 的(special function word))	QUCC	non-shared post-positional quantity
DEI	dei (modifier of 得(special function word))	QUN	quantity
DI	di (modifier of 地(special function word))	RAD	right additive
FOC	focus	RADC	non-shared right additive
HED	root of a sentence	RED	reduplicate element
IC	independent clause	SBV	subject
IOB	indirect object	TPC	topic
IS	independent structure	VOB	direct object
ISC	non-shared independent structure	VV	serial verb construction

Table 2: Proposed dependency category set.

is *right*, while the *PUS, PUN, IC* labels are *free* and can lie on both sides. (3) whether the modifiers of a head follows the right-to-left order when combined with the head for deriving the PS structure. According to this, dependency categories can be *special* (not following the right-to-left order) or *common*. For instance, in Figure 1, the word "观察 (observe)" was labeled with the *special left* tag *COS*, because it is combined with its head "体贴 (consider)" before "体贴 (consider)"'s VOB modifier on the right.

Combining the three perspectives, the 32 dependency categories can be classified into 8 classes. Categories in different classes have different priorities when attached to the head word during PS conversion.

(1) *Special left* (2 labels): COS and RED. If there is a word tagged with the special left category, all the words between this word and its head word should be taken as *special left*.

(2) *Common left* (13 labels): ADV, APP, ATT, DE, DI, FOC, NUM, QUN, SBV, TPC, VV, PUN and IS. For instance, "就要 (must)" in Figure 1 is labeled with the *common left* tag ADV and follows the right-to-left order, being combined with its head "善于 (be good at)" after "体贴 (consider)".

(3) *Common left cross-clause* (5 labels): ADV, SBV, LAD, TPC and IS. A *common left cross-clause* modifier can also act like common left in-clause, but not vice versa.

(4) *Common right* (7 labels): ACT, CMP, DEI, IOB, MT, POB and VOB. For instance, the word "心理 (psychology)" in Figure 1 is labeled with *VOB* and follows the right-to-left order.

(5) *Special right* (4 labels): QUC, RAD, PUN, IS. In particular, PUN and IS are common categories when appearing on the left side but special categories on the right side of the head.

(6) *Special right* (attached before COO) (3 labels): QUCC, RADC and ISC. These categories differ from those in the previous class in that they would be combined to the head before COO modifiers.

(7) *Free cross-clause* (2 labels): IC, PUS. IC is a clausal category and so can be used to connect two clauses. PUS denotes cross-clause punctuations.

(8) *Common left coordination* (2 labels): COO and LAD.

2.3 Rules for Annotating Punctuations

To resolve the ambiguity of finding the head of a punctuation, we make the following rules.

(1) Coupled punctuations (e.g. brackets and quotation marks) take the head word of the phrase between the two punctuations as their head.

(2) Full stops, question marks, exclamatory marks and semicolons take the topmost head word (without violating projectivity) on their left as their heads.

(3) Commas take the nearest word on the right with HED or IC, or the topmost head words on the right (if there is no right node tagged with HED or IC), or the nearest words on their left tagged with HED or IC as their heads, all under the condition of not breaking projectivity.

(4) Colons take the topmost head word (without violating projectivity) on their right as their heads.

(5) Slight-pause marks (、) take the head of the COO or COS constituent on their left as their heads.

3 Automatic Derivation of Phrase Function and Hierarchy

In our treebank, DS is represented explicitly and PS implicitly. The conversion from DS to PS consists of two steps. First, a binary PS hierarchy is generated bottom-up according to the DS. Second, each non-terminal node in the hierarchy is tagged with a phrasal tag (e.g. NP, VP) based on manual rules. We adopt the PS tagset of the CTB (Xue et al., 2000) for our treebank.

3.1 Derivation of Phrase Hierarchy

3.1.1 Derivation Algorithm

The PS trees in our grammar are binary-branching, making the derivation of hierarchical PS from DS relatively straightforward. With leaf nodes being pre-terminals, a PS is derived bottom-up by recursive combinations of neighbouring spans according to the dependency links in a sentence. In this process, a head word is always combined with the nearest modifier that is currently not in the constituents it dominates. The only ambiguities lie in the orders in which neighbouring PS are combined to form a larger PS, which can be denoted as (A (B C)) versus ((A B) C), with A, B, and C being three neighbouring spans. For the above ambiguity to exist, the head word for each span must bare the dependency links ($A \curvearrowleft B \curvearrowright C$), with the head word of B being the head of those of A and C.

In most cases, the (A (B C)) structure is chosen. An intuitive example is that a verb is first combined with the object (VOB, a *common right* category) to form a VP, before being combined with the subject (SBV, a *common left* category) to form an IP. One example of ((A B) C) structures is the coordination structure shown in Figure 1, where the spans headed by "观察 (observe)" and "心理 (psychology)" are combined after those by "观察 (observe)" and "体贴 (consider)", due to the fact that "心理 (psychology)" is a shared object to the coordinated verbs, linked by a COS (a *special left* category) arc. In general, the modifiers of a given head are attached according the following priorities:

(1) the *special left* category $>$ (2) the *common right* category $>$ (3) the *common left* category $>$ (4) the *special right* category before COO $>$ (5) the *common left* coordination category $>$ (6) the other *special right* category $>$ (7) the *free cross-clause* clausal category (IC) $>$ (8) the *common left cross-clause* category $>$ (9) the *free cross-clause* punctuations (PUS).

3.1.2 A Case Study: Generating the Hierarchy of Coordination Structure

We take coordination structures as an example to illustrate the PS hierarchy generation process. Typically, researchers treat the rightmost conjunct as the head of a coordinate structure. However, doing so introduces modifier scope ambiguities when modifiers are also attached to the rightmost head. Vice versa, treating the leftmost conjunct as the head will lead to ambiguities when modifiers attached to the left head (Che et al., 2012). Another choice is treating the conjunction as the head (Huang et al., 2000; Xue, 2007). However, this is usually not preferred since it makes parsing more difficult and a choice still has to be made between the left and right elements when there is no conjunction in a coordinate structure (Xue, 2007). Our strategy is as follows: (1) Choose the rightmost conjunct as the head to eliminate the ambiguities when the modifiers are attached to the left; (2) Classify coordinate structures into common coordinate structures (COO) and sharing-right-child coordinate structures (COS). COO words are taken as *common left* nodes (as shown in Figure 2), while COS words are *special left* nodes (as shown in Figure 1). Doing so avoids the aforementioned scope ambiguities for modifiers.

3.2 Derivation of Phrasal Category

Several Chinese linguists discuss the issue of deriving phrasal categories from the syntactic categories of the PS and DS context. Both Zhu (1982) and Chen (1999) state that if two phrases have constituents with the same phrasal categories and the dependency types between them are also the same, the phrasal categories of their combinations must be the same. Consequently, it is natural to derive the category of a phrase from the phrasal categories of the immediate constituents and the dependency type between the constituents. We make a set of rules for the derivation, each being a DS pattern/phrasal type pair. The DS pattern is a modifier-head link with associated information such as the dependency category (DepCate)

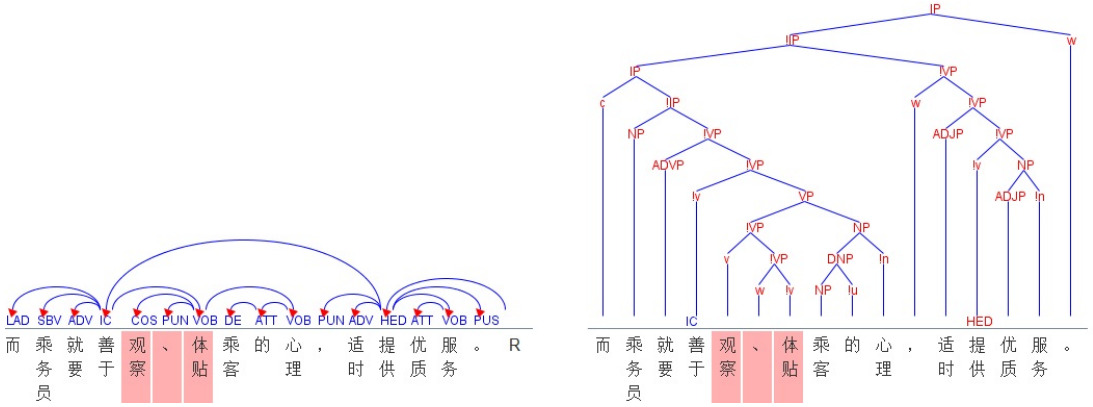

Figure 1: An instance of DS-PS conversion (而 (moreover) 乘务员 (crew) 就要 (must) 善于 (be good at) 观察 (observe) 体贴 (consider) 乘客 (passenger) 的 ('s) 心理 (psychology)， 适时 (timely) 提供 (provide) 优质 (quality) 服务 (service)). "!" denotes the head constituent.

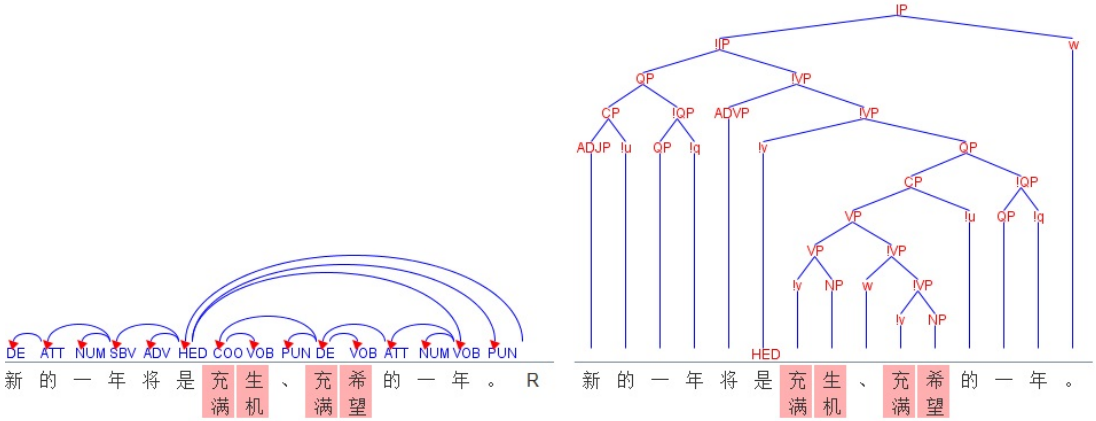

Figure 2: A second instance of DS-PS conversion (新 (new) 的 (de, an auxiliary word) 一 (one) 年 (year) 将 (will) 是 (be) 充满 (be full of) 生机 (vitality) 、 充满 (be full of) 希望 (hope) 的 (de, an auxiliary word) 一 (one) 年 (year)). "!" denotes the head constituent.

and the phrasal categories (POS tags for terminial nodes) of the subphrases that the modifier and head dominates. Some high-frequency rules are listed in Table 3.

For instance, the phrasal category of 充满 (be full of) 生机 (vitality) in Figure 2 is *VP* using the rule (v-NP-VOB, VP). Executing the derivation algorithms in Section 3.1 and derivation rules in Section 3.2, a DS in the proposed framework can be converted into corresponding PS, as shown in Figure 1 and 2.

4 The Annotation Process of PMT

According to the proposed schema, we constructed the multi-view Chinese treebank (PMT), version 1.0, which contains about 14,463 sentences and 336K words, and supports both the PS view and DS view. Our treebanking is based on the work of Yu et al. (2003), who built a segmented and POS-tagged Chinese corpus (the PFR Corpus), and released a sub-corpus containing about 1.1M words for free[1]. We choose the previous 14,463 sentences from the corpus, follow the original word segmentation standard but simplify the POS tagset according to the mapping rules described in Section 2.1. Then each sentence is annotated into a projective dependency tree according to the annotation framework described in this paper.

To speed up the annotation, a statistical dependency parser is used to give automatic parse trees and annotators are required to check each tree on a visualized annotation platform, which supports detecting

invalid derivation from DS to PS.

For quality control, a detailed annotation guideline is provided with abundant instances for different types of syntactic structures in Mandarin Chinese. More information of the guideline can be found in an extended version of this paper. In addition, we adopt the annotation strategy for the construction of the Penn Chinese Treebank (Xue et al., 2000) — one annotator examines an automatic parse tree first, and a second annotator verifies the annotation of the first annotator.

5 A Transition-Based Parser for Multi-view Treebank

In order to demonstrate the usefulness of our treebank in comparison with existing Chinese treebanks, we perform empirical analysis to the treebank, by the statistical dependency parsing and dependency-to-string machine translation tasks. Several researchers explored joint DS and PS information to enhance the quality of syntactic parsing (Wang and Zong, 2010; Farkas and Bohnet, 2012; Sun and Wan, 2013). Most tried to combine the outputs of constituent and dependency parsers by stacking or bagging. Since our treebank is multi-view, it is possible to combine DS features and PS features directly in the decoding process.

We implemented an arc-standard transition-based dependency parser (Nivre, 2008) based on the arc-eager parser of Zhang and Nivre (2011), which is a state-of-the-art transition-based dependency parser (Zhang and Nivre, 2012). It is more reasonable to derive the phrasal category of a phrase after the complete subtree (phrase) rather than partial subtree headed by a word has been built. The arc-standard parser differs from the arc-eager parser in that it postpones the attachment of right-modifiers until the complete subtrees headed by the modifiers themselves have been built. Because of this, we add PS features into an arc-standard parser rather than an arc-eager one.

The parser processes a sentence from left to right, using a stack to maintain partially built derivations and a queue to hold next incoming words. Three transition actions (LEFT, RIGHT and SHIFT) are defined to consume input words from the queue and construct arcs using the stack (Nivre, 2008):

LEFT pops the second top item off the stack, and adds it as a modifier to the top of the stack;

RIGHT pops the top item off the stack, and adds it as a modifier to the second top of the stack;

SHIFT removes the front of the queue and pushes it onto the top of the stack.

Table 4 show the feature templates of our parser, most of which are based on those of Zhang and Nivre (2011). The contextual information consists of the top four nodes of the stack (S_3, S_2, S_1 and S_0), the next three input words (N_0, N_1 and N_2), the left and right children (ld, rd) of these nodes, and the distance between S_0 and S_1. Word and POS information from the context are manually combined.

Due to the multi-view nature of our treebank, the DS parser can be extended naturally to incorporate PS information. Further, because our PS is binary branching, each constituent corresponds to a dependency link. In the decoding process, we derive the phrasal category c of a subtree whenever a dependency link

features of stack top	$S_0wt; S_0w; S_0t; S_1wt; S_1w; S_1t; S_2wt; S_2w; S_2t; S_3wt; S_3w; S_3t; N_0wt;$
features of next input	$N_0w; N_0t; N_1wt; N_1w; N_1t; N_2wt; N_2w; N_2t;$
bigram features	$S_0wS_1w; S_0wS_1t; S_0tS_1w; S_0tS_1t; S_0wN_0w; S_0wN_0t; S_0tN_0w; S_0tN_0t;$

is established, using the derivation rules in Table 3. Using *c* and its combination with other features, we can produce several PS features, as shown in Table 4. By this simple extension of features, we arrive at an efficient linear-time joint DS and PS parser.

6 Experiments

6.1 Syntactic Parsing

PMT 1.0 contains all the articles of People's Daily from January 1st to January 10th, 1998. Sentences 12001-13000 and 13001-14463 are used as the development and test set, respectively. The remaining sentences are used as training data.

Several state-of-the-art statistical parsers, including Mate-tools (Bohnet, 2010)[2], BerkeleyParser (Petrov and Klein, 2007)[3], ZPar-dep (Zhang and Nivre, 2011) and ZPar-con (Zhang and Clark, 2009; Zhu et al., 2013)[4] are used for comparison. We used the gold segmentation, and the Stanford POS tagger (Toutanova et al., 2003) (version 3.3.1) to provide automatic POS tags for all the experiments. The POS tagger was trained on the PKU corpus (Yu et al., 2003) containing articles of People's Daily from January 2000 to June 2000. It achieved a 95.78% precision on the PMT. In the baseline parser (Ours-standard), the feature templates in Table 4 except the PS features are used. We refer to the parser after adding PS features as Ours-PS. The results of dependency (ZPar-eager, Ours-standard, Ours-PS and Mate-tools) and constituent parsers (BerkeleyParser and ZPar-con) are measured by the unlabeled accuracy score (UAS), labeled accuracy score (LAS) and bracketing f-measure (BF), respectively.

We display the parsing results in Table 5. Our dependency parser (Ours-PS) outperforms the baseline parser (Ours-standard) with a 0.47% increase in UAS. For additional evaluation, we also converted the DS trees parsed by the dependency parsers to PS using the conversion procedure in Section 3, in order to compare the results of dependency parsers and constituent parsers. The three ZPar-based dependency parsers gave higher accuracies than the two state-of-the-art constituent parsers. In particular, the DS2PS outputs of Ours-PS parser outperforms the PS outputs of Berkeley Parer with 0.62% higher BF.

Both Zhang and Clark (2011) and Petrov and McDonald (2012) show that DS trees converted from the outputs of PS parsers outperform those produced directly by DS parsers trained on DS conversions of the CTB. Interestingly, our evaluation on the PMT gave results in the opposite direction: parsers trained on the DS treebank outperforms parsers trained on the PS conversion. One possible reason is that parser errors can be hidden in the conversion process. Take the sentence in Figure 3 for example. Figure 3(a) shows the correct PS while Figure 3(b) shows an incorrect parser output. In particular, "黎明 (dawn)" is put under the incorrect constituent. When converted into DS, both lead to the correct link, with "黎明 (dawn)" being the SBV modifier of "降临 (come)" (Figure 3(c)). As a result, the PS parser error is erased in the conversion into DS. The same can happen in DS to PS conversion.

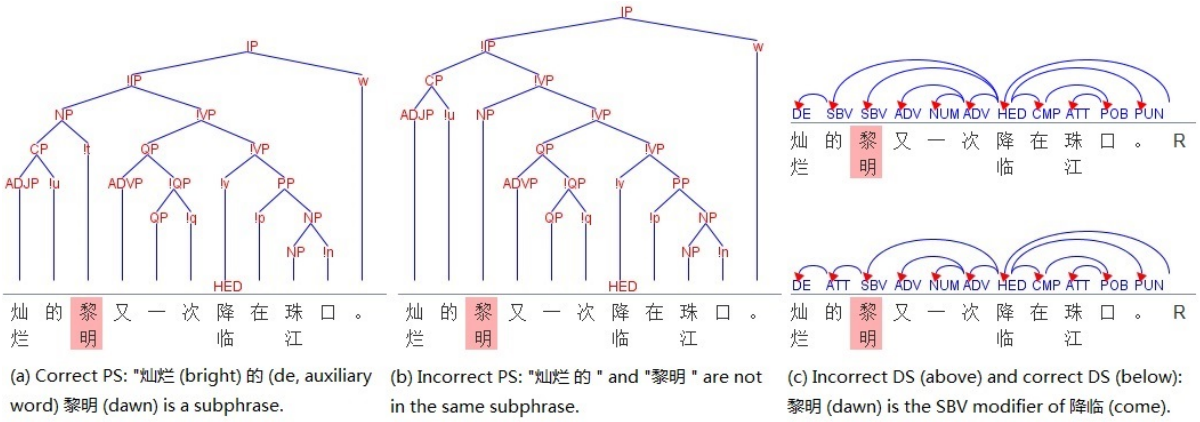
6.2 Dependency-to-string Machine Translation

We compare the effects of our treebank and the Stanford dependencies converted from CTB on machine translation, using the dependency-to-string system of Xie et al. (2011). Our training corpus consists of

[2]https://code.google.com/p/mate-tools/

[3]http://code.google.com/p/berkeley-parser-analyser/

[4]http://sourceforge.net/projects/zpar/



(a) Correct PS: "灿烂 (bright) 的 (de, auxiliary word) 黎明 (dawn) is a subphrase.

(b) Incorrect PS: "灿烂 的 " and "黎明 " are not in the same subphrase.

(c) Incorrect DS (above) and correct DS (below): 黎明 (dawn) is the SBV modifier of 降临 (come).

Figure 3: An instance where PS parser error is erased in the PS to DS conversion (灿烂 (bright) 的 (de, an auxiliary word) 黎明 (dawn) 又 (again) 一 (one) 次(time) 降临 (come) 在 (in) 珠江 (the Pearl River) 口 (estuary)). "!" denotes the head constituent.

Dependency Parsing			Constituent Parsing		Constituent Parsing(DS2PS)	
Parsers	**UAS**	**LAS**	**len<=40 words**	**Unlimited**	**len<=40 words**	**Unlimited**
Mate-tools	82.98	79.37	/	/	84.77	83.43
ZPar-dep	82.73	80.20	/	/	85.47	84.33
Ours-standard	82.81	80.04	/	/	85.53	84.47
Ours-PS	**83.28**	**80.50**	/	/	**85.92**	**84.84**
Berkeley Parser	/	/	85.25	84.22	/	/
ZPar-con	/	/	85.02	84.12	/	/

Table 5: Parsing results on our treebank using automatic POS-tags.

31K Chinese-English sentence pairs from the Xinhua Corpus (Liu et al., 2006), and we used NIST MT Evaluation 2006 test set as the development set, and the NIST 2003 (MT03), 2004 (MT04) and 2005 (MT05) test sets as the test sets. For Stanford dependency trees, we parsed the source sentences with the Stanford Parser (Chang et al., 2009) (version 3.3.1), which was trained on CTB 7.0. For the PMT treebank, we used the Ours-PS parser, trained with 14000 sentences (the last 463 sentences are used as development data for the parser). All the MT configurations are the same as Xie et al. (2011).

The results are shown in Table 6. The Chinese-English translation outputs using our parser and treebank are slightly lower but comparable to those using the Stanford Parser. Note that our treebank contains 336K words on People's Daily, while the CTB 7.0 contains about 1.19M words, most on Xinhua, the source of the MT training and test data. This result to some degree demonstrates the usefulness of our treebank for NLP applications, in comparison with a well-established treebank.

7 Related Work

PS Treebanks and DS Conversion PTB (Marcus et al., 1993) and CTB (Xue et al., 2000) are the most widely used treebanks for English and Chinese in the literature. Both are in PS. For conversion from PS to DS, a head-table approach (Magerman, 1994; Collins, 2003; Yamada and Matsumoto, 2003; Sun and Jurafsky, 2004; Nivre, 2006; Johansson and Nugues, 2007; Duan et al., 2007; Zhang and Clark, 2008) is widely used. However, the reliability of head tables has been questioned (Xue, 2007). Xue (2007) proposed a novel approach that better exploits the structural information in the CTB and pointed out that the results of the approach and the widely used Penn2Malt tools[5] agree only 60.6% in terms of unlabeled dependency. The coordination structures, in particular, are not properly converted by Penn2Malt.

DS Treebanks and PS Conversion An existing DS treebank for Chinese is the Chinese Dependency Treebank (Che et al., 2012), which is not designed as a multi-view treebank. For conversion from DS to PS, Xia and Palmer (2001) compare three algorithms. These algorithms do not use a rich set of

Table 6: Results of dependency-to-string machine translation.

dependency categories, only distinguishing arguments and modifiers. Xia et al. (2009) propose a DS-to-PS algorithm, which assumes that a given DS is identical to a flattened version of the desired PS, and then introduce a set of conversion rules. Their error analysis show that coordination and punctuation amount to about 32.1% of conversion errors, while other errors fall into missing content in DS and inconsistency in the target treebank (PTB). This analysis demonstrates that coordination and punctuation should be tackled carefully for the conversion between PS and DS, which we do in the design of our treebank. Bhatt et al. (2011) presented three scenarios arising in the conversion of DS into PS. Bhatt and Xia (2012) further described 7 phenomena of incompatibility in the conversion from DS to PS, mainly involving the annotation of empty categories, yet coordination structure and punctuation were not discussed.

Multi-view Treebanks The Tiger (Brants et al., 2002) and TüBa-D/Z (Telljohann et al., 2003) treebanks for German seek to explicitly represent both PS and DS by labeling both nodes and edges in the syntactic tree. For these treebanks, both dependency categories and phrasal categories have been annotated explicitly. The English side of the Czech-English parallel corpus is annotated and linked also as both PS (original PTB annotation) and DS (Hajic et al., 2012), while the DS is a conversion of the original PS. Our multi-view treebank is different in that dependency categories and phrasal categories derive from each other. The Hindi/Urdu treebank (Xia et al., 2009; Palmer et al., 2009; Bhatt et al., 2009) can be taken as a multi-view treebank. Its PS view is derived automatically from the DS. However, the converted PS is not a PS with a full hierarchy but a flattened one (Xia et al., 2009).

8 Conclusion

We presented an DS-based multi-view annotation framework, and built a Chinese treebank according to the framework and an arc-standard transition-based dependency parser that exploits the multi-view nature of the treebank. We used SMT as an example to demonstrate the usefulness of our treebank for NLP applications. Experiments showed that the proposed treebank and parser can give similar results to the Stanford Parser trained on CTB 7.0. We make our treebank (PMT 1.0) (`http://klcl.pku.edu.cn/ResourceList.aspx`), the DS to PS conversion script and the proposed parser (`http://sourceforge.net/projects/zpar/`) freely available.

Acknowledgments

We gratefully acknowledge the invaluable assistance of Jun Xie in helping us make experiments on dependency-to-string machine translation. We thank Ji Ma for helpful suggestions and comments, and Yijia Liu for providing a generic arc-standard dependency parser. We also thank all the students from Ludong University and Leshan Normal University for annotating the large-scale treebank. Abstract

We present a novel approach for rapidly developing a corpus with discourse annotations using crowdsourcing. Although discourse annotations typically require much time and cost owing to their complex nature, we realize discourse annotations in an extremely short time while retaining good quality of the annotations by crowdsourcing two annotation subtasks. In fact, our experiment to create a corpus comprising 30,000 Japanese sentences took less than eight hours to run. Based on this corpus, we also develop a supervised discourse parser and evaluate its performance to verify the usefulness of the acquired corpus.

1 Introduction

Humans understand text not by individually interpreting clauses or sentences, but by linking such a text fragment with another in a particular context. To allow computers to understand text, it is essential to capture the precise relations between these text fragments. This kind of analysis is called discourse parsing or discourse structure analysis, and is an important and fundamental task in natural language processing (NLP). Systems for discourse parsing are, however, available only for major languages, such as English, owing to the lack of corpora with discourse annotations.

For English, several corpora with discourse annotations have been developed manually, consuming a great deal of time and cost in the process. These include the Penn Discourse Treebank (Prasad et al., 2008), RST Discourse Treebank (Carlson et al., 2001), and Discourse Graphbank (Wolf and Gibson, 2005). Discourse parsers trained on these corpora have also been developed and practically used. To create the same resource-rich environment for another language, a quicker method than the conventional time-consuming framework should be sought. One possible approach is to use crowdsourcing, which has actively been used to produce various language resources in recent years (e.g., (Snow et al., 2008; Negri et al., 2011; Hong and Baker, 2011; Fossati et al., 2013)). It is, however, difficult to crowdsource the difficult judgments for discourse annotations, which typically consists of two steps: finding a pair of spans with a certain relation and identifying the relation between the pair.

In this paper, we propose a method for crowdsourcing discourse annotations that simplifies the procedure by dividing it into two steps. The point is that by simplifying the annotation task it is suitable for crowdsourcing, but does not skew the annotations for use in practical discourse parsing. First, finding a discourse unit for the span is a costly process, and thus we adopt a clause as the discourse unit, since this is reliable enough to be automatically detected. We also limit the length of each target document to three sentences and at most five clauses to facilitate the annotation task. Secondly, we detect and annotate clause pairs in a document that hold logical discourse relations. However, since this is too complicated to assign as one task using crowdsourcing, we divide the task into two steps: determining the existence of logical discourse relations and annotating the type of relation. Our two-stage approach is a robust method in that it confirms the existence of the discourse relations twice. We also designed the tagset of discourse relations for crowdsourcing, which consists of two layers, where the upper layer contains the following three classes: "CONTINGENCY," "COMPARISON" and "OTHER." Although the task

Proceedings of COLING 2014, the 25th International Conference on Computational Linguistics: Technical Papers, pages 269–278, Dublin, Ireland, August 23-29 2014.

settings are simplified for crowdsourcing, the obtained corpus and knowledge of discourse parsing could be still useful in general discourse parsing.

In our experiments, we crowdsourced discourse annotations for Japanese, for which there are no publicly available corpora with discourse annotations. The resulting corpus consists of 10,000 documents, each of which comprises three sentences extracted from the web. Carrying out this two-stage crowdsourcing task took less than eight hours. The time elapsed was significantly shorter than the conventional corpus building method.

We also developed a discourse parser by exploiting the acquired corpus with discourse annotations. We learned a machine learning-based model for discourse parsing based on this corpus and evaluated its performance. An F1 value of 37.9% was achieved for contingency relations, which would be roughly comparable with state-of-the-art discourse parsers on English. This result indicates the usefulness of the acquired corpus. The resulting discourse parser would be effectively exploited in NLP applications, such as sentiment analysis (Zirn et al., 2011) and contradiction detection (Murakami et al., 2009; Ennals et al., 2010).

The novel contributions of this study are summarized below:

- We propose a framework for developing a corpus with discourse annotations using two-stage crowdsourcing, which is both cheap and quick to execute, but still retains good quality of the annotations.
- We construct a Japanese discourse corpus in an extremely short time.
- We develop a discourse parser based on the acquired corpus.

The remainder of this paper is organized as follows. Section 2 introduces related work, while Section 3 describes our proposed framework and reports the experimental results for the creation of a corpus with discourse annotations. Section 4 presents a method for discourse parsing based on the corpus as well as some experimental results. Section 5 concludes the paper.

2 Related Work

Snow et al. (2008) applied crowdsourcing to five NLP annotation tasks, but the settings of these tasks are very simple. There have also been several attempts to construct language resources with complex annotations using crowdsourcing. Negri et al. (2011) proposed a method for developing a cross-lingual textual entailment (CLTE) corpus using crowdsourcing. They tackled this complex data creation task by dividing it into several simple subtasks: sentence modification, type annotation and sentence translation. The creative CLTE task and subtasks are quite different from our non-creative task and subtasks of discourse annotations. Fossati et al. (2013) proposed FrameNet annotations using crowdsourcing. Their method is a single-step approach to only detect frame elements. They verified the usefulness of their approach through an experiment on a small set of verbs with only two frame ambiguities per verb. Although they seem to be running a larger-scale experiment, its result has not been revealed yet. Hong and Baker (2011) presented a crowdsourcing method for selecting FrameNet frames, which is a part of the FrameNet annotation process. Since their task is equivalent to word sense disambiguation, it is not very complex compared to the whole FrameNet annotation process. These FrameNet annotations are still different from discourse annotations, which are our target. To the best of our knowledge, there have been no attempts to crowdsource discourse annotations.

There are several manually-crafted corpora with discourse annotation for English, such as the Penn Discourse Treebank (Prasad et al., 2008), RST Discourse Treebank (Carlson et al., 2001), and Discourse Graphbank (Wolf and Gibson, 2005). These corpora were developed from English newspaper articles. Several attempts have been made to manually create corpora with discourse annotations for languages other than English. These include the Potsdam Commentary Corpus (Stede, 2004) for German (newspaper; 2,900 sentences), Rhetalho (Pardo et al., 2004) for Portuguese (scientific papers; 100 documents; 1,350 sentences), and the RST Spanish Treebank for Spanish (da Cunha et al., 2011) (several genres; 267 documents; 2,256 sentences). All of these consist of relatively small numbers of sentences compared with the English corpora containing several tens of thousands sentences.

In recent years, there have been many studies on discourse parsing on the basis of the above hand-annotated corpora (e.g., (Pitler et al., 2009; Pitler and Nenkova, 2009; Subba and Di Eugenio, 2009; Hernault et al., 2010; Ghosh et al., 2011; Lin et al., 2012; Feng and Hirst, 2012; Joty et al., 2012; Joty et al., 2013; Biran and McKeown, 2013; Lan et al., 2013)). This surge of research on discourse parsing can be attributed to the existence of corpora with discourse annotations. However, the target language is mostly English since English is the only language that has large-scale discourse corpora. To develop and improve discourse parsers for languages other than English, it is necessary to build large-scale annotated corpora, especially in a short period if possible.

3 Development of Corpus with Discourse Annotations using Crowdsourcing

3.1 Corpus Specifications

We develop a tagged corpus in which pairs of discourse units are annotated with discourse relations. To achieve this, it is necessary to determine target documents, discourse units, and a discourse relation tagset. The following subsections explain the details of these three aspects.

3.1.1 Target Text and Discourse Unit

In previous studies on constructing discourse corpora, the target documents were mainly newspaper texts, such as the Wall Street Journal for English. However, discourse parsers trained on such newspaper corpora usually have a problem of domain adaptation. That is to say, while discourse parsers trained on newspaper corpora are good at analyzing newspaper texts, they generally cannot perform well on texts of other domains.

To address this problem, we set out to create an annotated corpus covering a variety of domains. Since the web contains many documents across a variety of domains, we use the Diverse Document Leads Corpus (Hangyo et al., 2012), which was extracted from the web. Each document in this corpus consists of the first three sentences of a Japanese web page, making these short documents suitable for our discourse annotation method based on crowdsourcing.

We adopt the clause as a discourse unit, since spans are too fine-grained to annotate using crowdsourcing and sentences are too coarse-grained to capture discourse relations. Clauses, which are automatically identified, do not need to be manually modified since they are thought to be reliable enough. Clause identification is performed using the rules of Shibata and Kurohashi (2005). For example, the following rules are used to identify clauses as our discourse units:

- clauses that function as a relatively strong boundary in a sentence are adopted,
- relative clauses are excluded.

Since workers involved in our crowdsourcing task need to judge whether clause pairs have discourse relations, the load of these workers increases combinatorially as the number of clauses in a sentence increases. To alleviate this problem, we limit the number of clauses in a document to five. This limitation excludes only about 5% of the documents in the original corpus.

Our corpus consists of 10,000 documents corresponding to 30,000 sentences. The total number of clauses in this corpus is 39,032, and thus the average number of clauses in a document is 3.9. The total number of clause pairs is 59,426.

3.1.2 Discourse Relation Tagset

One of our supposed applications of discourse parsing is to automatically generate a bird's eye view of a controversial topic as in Statement Map (Murakami et al., 2009) and Dispute Finder (Ennals et al., 2010), which identify various relations between statements, including contradictory relations. We assume that expansion relations, such as elaboration and restatement, and temporal relations are not important for this purpose. This setting is similar to the work of Bethard et al. (2008), which annotated temporal relations independently of causal relations. We also suppose that temporal relations can be annotated separately for NLP applications that require temporal information. We determined the tagset of discourse relations

Upper type	Lower type	Example
CONTINGENCY	Cause/Reason	【ボタンを押したので】【お湯が出た。】 [since (I) pushed the button] [hot water was turned on]
	Purpose	【試験に受かるために】【必死に勉強した。】 [to pass the exam] [(I) studied a lot]
	Condition	【ボタンを押せば】【お湯が出る。】 [if (you) push the button] [hot water will be turned on]
	Ground	【ここにカバンがあるから】【まだ社内にいるだろう。】 [here is his/her bag] [he/she would be still in the company]
COMPARISON	Contrast	【あのレストランは寿司はおいしいが】【ラーメンは普通だ。】 [at that restaurant, sushi is good] [ramen is so-so]
	Concession	【あのレストランは確かにおいしいが】【値段は高い。】 [that restaurant is surely good] [the price is high]
OTHER	(Other)	【家に着いてから】【雨が降ってきた。】 [After being back home] [it began to rain]

Table 1: Discourse relation tagset with examples.

by referring to the Penn Discourse Treebank. This tagset consists of two layers, where the upper layer contains three classes and the lower layer seven classes as follows:

- CONTINGENCY
  - Cause/Reason (causal relations and not conditional relations)
  - Purpose (purpose-action relations where the purpose is not necessarily accomplished)
  - Condition (conditional relations)
  - Ground (other contingency relations including pragmatic cause/condition)
- COMPARISON (same as the Penn Discourse Treebank)
  - Contrast
  - Concession
- OTHER (other weak relation or no relation)

Note that we do not consider the direction of relations to simplify the annotation task for crowdsourcing. Table 1 shows examples of our tagset.

Therefore, our task is to annotate clause pairs in a document with one of the discourse relations given above. Sample annotations of a document are shown below. Here, clause boundaries are shown by "::" and clause pairs that are not explicitly marked are allocated the "OTHER" relation.

Cause/Reason 気がつけば::梅雨も明けてました。::毎日暑い日が続きますね。::【父の手術も無事に終わり、】::【少しだけほっとしてます。】
... [the surgery of my father ended safely] [(I) am relieved a little bit]

Contrast 今日とある企業のトップの話を聞くことが出来た。::経営者として何事も全てビジネスチャンスに変えるマインドが大切だと感じた。::【生きていく上で追い風もあれば、】::【逆風もある。】
... [There is tailwind to live,] [there is also headwind.]

3.2 Two-stage Crowdsourcing for Discourse Annotations

We create a corpus with discourse annotations using two-stage crowdsourcing. We divide the annotation task into the following two subtasks: determining whether a clause pair has a discourse relation excluding "OTHER," and then, ascertaining the type of discourse relation for a clause pair that passes the first stage.

Probability	Number
$= 1.0$	64
> 0.99	554
> 0.9	1,065
> 0.8	1,379
> 0.5	2,655
> 0.2	4,827
> 0.1	5,895
> 0.01	9,068
> 0.001	12,277
> 0.0001	15,554

Table 2: Number of clause pairs resulting from the judgments of discourse relation existence.

3.2.1 Stage 1: Judgment of Discourse Relation Existence

This subtask determines whether each clause pair in a document has one of the following discourse relations: Cause/Reason, Purpose, Condition, Ground, Contrast, and Concession (that is, all the relations except "OTHER"). Workers are shown examples of these relations and asked to determine only the existence thereof.

In this subtask, an item presented to a worker at a particular time consists of all the judgments of clause pairs in a document. By adopting this approach, each worker considers the entire document when making his/her judgments.

3.2.2 Stage 2: Judgment of Discourse Relation Type

This subtask involves ascertaining the discourse relation type for a clause pair that passes the first stage. The result of this subtask is one of the seven lower types in our discourse relation tagset. Workers are shown examples of these types and then asked to select one of the relations. If a worker chooses "OTHER," this corresponds to canceling the positive determination of the existence of the discourse relation in stage one.

In this subtask, an item is the judgment of a clause pair. That is, if a document contains more than one clause pair that must be judged, the judgments for this document are divided into multiple items, although this is rare.

3.3 Experiment and Discussion

We conducted an experiment of the two-stage crowdsourcing approach using Yahoo! Crowdsourcing.[1] To increase the reliability of the produced corpus, we set the number of workers for each item for each task to 10. The reason why we chose this value is as follows. While Snow et al. (2008) claimed that an average of 4 non-expert labels per item in order to emulate expert-level label quality, the quality of some tasks increased by increasing the number of workers to 10. We also tested hidden gold-standard items once every 10 items to examine worker's quality. If a worker failed these items in serial, he/she would have to take a test to continue the task.

We obtained judgments for the 59,426 clause pairs in the 10,000 documents of our corpus in the first stage of crowdsourcing, i.e., the subtask of determining the existence of discourse relations. We calculated the probability of each label using GLAD[2] (Whitehill et al., 2009), which was proved to be more reliable than the majority voting. This probability corresponds to the probability of discourse relation existence of each clause pair. Table 2 lists the results. We set a probability threshold to select those clause pairs whose types were to be judged in the second stage of crowdsourcing. With this threshold set to 0.01, 9,068 clause pairs (15.3% of all the clause pairs) were selected. The threshold was set fairly low to allow low-probability judgments to be re-examined in the second stage.

Lower type	All	prob > 0.8
Cause/Reason	2,104	1,839 (87.4%)
Purpose	755	584 (77.4%)
Condition	1,109	925 (83.4%)
Ground	442	273 (61.8%)
Contrast	437	354 (81.0%)
Concession	80	49 (61.3%)
Sum of the above discourse relations	4,927	4,024 (81.7%)
Other	4,141	3,753 (90.6%)
Total	9,068	7,777 (85.8%)

Table 3: Results of the judgments of lower discourse relation types.

Upper type	All	prob > 0.8
CONTINGENCY	4,439	3,993 (90.0%)
COMPARISON	516	417 (80.8%)
Sum of the above discourse relations	4,955	4,410 (89.0%)
OTHER	4,113	3,753 (91.2%)
Total	9,068	8,163 (90.0%)

Table 4: Results of the judgments of upper discourse relation types.

The discourse relation types of the 9,068 clause pairs were determined in the second stage of crowdsourcing. We extended GLAD (Whitehill et al., 2009) for application to multi-class tasks, and calculated the probability of the labels of each clause pair. We assigned the label (discourse relation type) with the highest probability to each clause pair. Table 3 gives some statistics of the results. The second column in this table denotes the numbers of each discourse relation type, while the third column gives the numbers of each type of clause pair with a probability higher than 0.80. Table 4 gives statistics of the results when the lower discourse relation types are merged into the upper types. Table 5 shows some examples of the resulting annotations.

Carrying out the two separate subtasks using crowdsourcing took approximately three hours and five hours with 1,458 and 1,100 workers, respectively. If we conduct this task at a single stage, it would take approximately 33 (5 hours / 0.153) hours. It would be four times longer than our two-stage approach. Such single-stage approach is also not robust since it does not have a double check mechanism, with which the two-stage approach is equipped. We spent 111 thousand yen and 113 thousand yen (approximately 1,100 USD, respectively) for these subtasks, which would be extremely less expensive than the projects of conventional discourse annotations.

For the examples in Table 5, we confirmed that the discourse relation types of the top four examples were surely correct. However, we judged the type (Contrast) of the bottom example as incorrect. Since the second clause is an instantiation of the first clause, the correct type should be "Other." We found such errors especially in the clause pairs with a probability lower than 0.80.

4 Development of Discourse Parser based on Acquired Discourse Corpus

To verify the usefulness of the acquired corpus with discourse annotations, we developed a supervised discourse parser based on the corpus, and evaluated its performance. We built two discourse parsers using the annotations of the lower and upper discourse relation types, respectively. From the annotations in the first stage of crowdsourcing (i.e., judging the existence of discourse relations), we assigned annotations with a probability less than 0.01 as "OTHER." Of the annotations acquired in the second stage (i.e., judging discourse relation types), we adopted those with a probability greater than 0.80 and discarded the rest. After this preprocessing, we obtained 58,135 (50,358 + 7,777) instances of clause pairs for the lower-type discourse parser and 58,521 (50,358 + 8,163) instances of clause pairs for the upper-type

Prob	# W	Type	Document
1.00	6/10	Cause/Reason	ツツジ科・ツツジ属。【花が陰暦五月に咲くため】【「皐月」と呼ばれている。】市制２０年を記念して、１９７９年１１月３日に制定された。 ... [Since the flower blooms in the fifth lunar month] [it is called "Satsuki."] ...
0.99	4/10	Condition	【↓マップ上の吹き出しをクリックすると】【おすすめルートがご覧になれます。】市町村名をクリックすると「見どころ・体験・食」の情報がご覧になれます。緑色の表記は各スポットの写真がご覧になれます。 [If you click the balloon on the map] [you can see the recommended route] ...
0.81	3/10	Purpose	ダイランティアはマナによって支えられた世界。しかし、人類の繁栄と共に世界樹が３年に一度結実させる「大いなる実り」だけでは人類の繁栄を支えることができなくなってしまった。【そして「大いなる実り」を求めて】【各国が戦争を繰り広げていく。】 ... [And seeking "Great harvest"] [each country is engaged in a war]
0.61	2/10	Cause/Reason	スケールは（一部を除き）１／３２とされている。これは単３形乾電池２本が入りやすいようにしたサイズである。動力は単３形乾電池２本とＦＡ－１３０サイズのモーター１個で、【ギヤーとシャフトの組み合わせにより動力を前後の車軸に伝達し、】【４輪を駆動する。】 ... [by transmitting power to the front and rear axle with the combination of gears and shafts] [(it) drives the four wheels.]
0.54	3/10	Contrast	来年春には、阪急百貨店が新博多駅に東急ハンズと共にお目見えする。そうなると【百貨店による顧客の奪い合いが厳しくなる。】【そこに浮上するのが、三越福岡の閉鎖の可能性である。】 ... [a scramble for customers by department stores would be severe.] [What comes out is the possibility of the closure of Fukuoka Mitsukoshi.]

Table 5: Examples of Annotations. The first column denotes the estimated label probability and the second column denotes the number of workers that assigned the designated type. In the fourth column, the clause pair annotated with the type is marked with 【】 ([ ] in English translations).

discourse parser. Of these, 4,024 (6.9%) and 4,410 (7.5%) instances, respectively, had one of the types besides "OTHER." We conducted experiments using five-fold cross validation on these instances.

To extract features of machine learning, we applied the Japanese morphological analyzer, JUMAN,[3] and the Japanese dependency parser, KNP,[4] to the corpus. We used the features listed in Table 6, which are usually used for discourse parsing.

We adopted Opal (Yoshinaga and Kitsuregawa, 2010)[5] for the machine learning implementation. This tool enables online learning using a polynomial kernel. As parameters for Opal, we used the passive-aggressive algorithm (PA-I) with a polynomial kernel of degree two as a learner and the extension to multi-class classification (Matsushima et al., 2010). The numbers of classes were seven and three for the lower- and upper-type discourse parsers, respectively. We set the aggressiveness parameter C to 0.001, which generally achieves good performance for many classification tasks. Other parameters were set to the default values of Opal.

To measure the performance of the discourse parsers, we adopted precision, recall and their harmonic mean (F1). These metrics were calculated as the proportion of the number of correct clause pairs to the

Type	Precision	Recall	F1
CONTINGENCY	0.625 (1,084/1,735)	0.272 (1,084/3,993)	0.379
COMPARISON	0.412 (7/17)	0.017 (7/417)	0.032
OTHER	0.942 (53,454/56,769)	0.988 (53,454/54,111)	0.964

Table 8: Performance of our upper-type discourse parser.

number of all recognized or gold-standard ones for each discourse relation type. Tables 7 and 8 give the accuracies for the lower- and upper-type discourse parsers, respectively.

From Table 8, we can see that our upper-type discourse parser achieved an F1 of 37.9% for contingency relations. It is difficult to compare our results with those in previous work due to the use of different data set and different languages. We, however, anticipate that our results would be comparable with those of state-of-the-art English discourse parsers. For example, the end-to-end discourse parser of Lin et al. (2012) achieved an F1 of 20.6% – 46.8% on the Penn Discourse Treebank.

We also obtained a low F1 for comparison relations. This tendency is similar to the previous results on the Penn Discourse Treebank. The biggest cause of this low F1 is the lack of unambiguous explicit discourse connectives for these relations. Although there are explicit discourse connectives in Japanese, many of them have multiple meanings and cannot be used as a direct clue for discourse relation detection (e.g., as described in Kaneko and Bekki (2014)). As reported in Pitler et al. (2009) and other studies, the identification of implicit discourse relations are notoriously difficult. To improve its performance, we need to incorporate external knowledge sources other than the training data into the discourse parsers. A promising way is to use large-scale knowledge resources that are automatically acquired from raw corpora.

5 Conclusion

We presented a rapid approach for building a corpus with discourse annotations and a discourse parser using two-stage crowdsourcing. The acquired corpus is made publicly available and can be used for research purposes.[6] This corpus can be used not only to build a discourse parser but also to evaluate its performance. The availability of the corpus with discourse annotations will accelerate the development and improvement of discourse parsing. In the future, we intend integrating automatically acquired knowledge from corpora into the discourse parsers to further enhance their performance. We also aim to apply our framework to other languages without available corpora with discourse annotations.

Chinese Word Ordering Errors Detection and Correction for Non-Native Chinese Language Learners

Shuk-Man Cheng, Chi-Hsin Yu, Hsin-Hsi Chen
Department of Computer Science and Information Engineering
National Taiwan University, Taipei, Taiwan
{smcheng,jsyu}@nlg.csie.ntu.edu.tw; hhchen@ntu.edu.tw

Abstract

Word Ordering Errors (WOEs) are the most frequent type of grammatical errors at sentence level for non-native Chinese language learners. Learners taking Chinese as a foreign language often place character(s) in the wrong places in sentences, and that results in wrong word(s) or ungrammatical sentences. Besides, there are no clear word boundaries in Chinese sentences. That makes WOEs detection and correction more challenging. In this paper, we propose methods to detect and correct WOEs in Chinese sentences. Conditional random fields (CRFs) based WOEs detection models identify the sentence segments containing WOEs. Segment point-wise mutual information (PMI), inter-segment PMI difference, language model, tag of the previous segment, and CRF bigram template are explored. Words in the segments containing WOEs are reordered to generate candidates that may have correct word orderings. Ranking SVM based models rank the candidates and suggests the most proper corrections. Training and testing sets are selected from HSK dynamic composition corpus created by Beijing Language and Culture University. Besides the HSK WOE dataset, Google Chinese Web 5-gram corpus is used to learn features for WOEs detection and correction. The best model achieves an accuracy of 0.834 for detecting WOEs in sentence segments. On the average, the correct word orderings are ranked 4.8 among 184.48 candidates.

1 Introduction

Detection and correction of grammatical errors are practical for many applications such as document editing and language learning. Non-native language learners usually encounter problems in learning a new foreign language and are prone to generate ungrammatical sentences. Sentences with various types of errors are written by language learners of different backgrounds. In the HSK corpus, which contains compositions of students from different countries who study Chinese in Beijing Language and Culture University (http://nlp.blcu.edu.cn/online-systems/hsk-language-lib-indexing-system.html), there are 35,884 errors at sentence level. The top 10 error types and their occurrences are listed below: Word Ordering Errors (WOE) (8,515), Missing Component (Adverb) (3,244), Missing Component (Predicate) (3,018), Grammatical Error ("Is … DE") (2,629), Missing Component (Subject) (2,405), Missing Component (Head Noun) (2364), Grammatical Error ("Is" sentence) (1,427), Redundant Component (Predicate) (1,130), Uncompleted Sentence (1,052), and Redundant Component (Adverb) (1,051). WOEs are the most frequent type of errors (Yu and Chen, 2012).

The types of WOEs in Chinese are different from those in English. A Chinese character has its own meaning in text, while individual characters are meaningless in English. Learners taking Chinese as a foreign language often place character(s) in the wrong places in sentences, and that results in wrong word(s) or ungrammatical sentences. Besides, there are no clear word boundaries in Chinese sentences.

Proceedings of COLING 2014, the 25th International Conference on Computational Linguistics: Technical Papers, pages 279–289, Dublin, Ireland, August 23-29 2014.

Word segmentation is fundamental in Chinese language processing (Huang and Zhao, 2007). WOEs may result in wrong segmentation. That may make WOEs detection and correction more challenging.

This paper aims at identifying the positions of WOEs in the text written by non-native Chinese language learners, and proposes candidates to correct the errors. It is organized as follows. Section 2 surveys the related work. Section 3 gives an overview of the study. Section 4 introduces the dataset used for training and testing. Sections 5 and 6 propose models to detect and correct Chinese WOEs, respectively. Section 7 concludes this study and propose some future work.

2 Related Work

There are only a few researches on the topic of detection and correction of WOEs in Chinese language until now. We survey the related work from the four aspects: (1) grammatical errors made by non-native Chinese learners, (2) word ordering errors in Chinese language, (3) computer processing of grammatical errors in Chinese language, and (4) grammatical error correction in other languages.

Leacock et al. (2014) give thorough surveys in automated grammatical error detection for language learners. Error types, available corpora, evaluation methods, and approaches for different types of errors are specified. Several shared tasks on grammatical error correction in English have been organized in recent years, including HOO 2011 (Dale and Kilgarriff, 2011), HOO 2012 (Dale et al., 2012) and CoNLL 2013 (Ng et al., 2013). Different types of grammatical errors are focused: (1) HOO 2011: article and preposition errors, (2) HOO 2012: determiner and preposition errors, and (3) CoNLL 2013: article or determiner errors, preposition errors, noun number errors, verb form errors, and subject-verb agreement errors. In Chinese, spelling check evaluation was held at SIGHAN Bake-off 2013 (Wu et al., 2013). However, none of the above evaluations deals with word ordering errors.

Wang (2011) focuses on the Chinese teaching for native English-speaking students. He shows the most frequent grammatical errors made by foreigners are missing components, word orderings and sentence structures. One major learning problem of foreign learners is the influence of negative transfer of mother tongue. Lin (2011) studies the biased errors of word order in Chinese written by foreign students in the HSK corpus. Sun (2011) compares the word orderings between English and Chinese to figure out the differences in sentence structures. Yu and Chen (2012) propose classifiers to detect sentences containing WOEs, but they do not deal with where WOEs are and how to correct them.

Wagner et al. (2007) deal with common grammatical errors in English. They consider frequencies of POS n-grams and the outputs of parsers as features. Gamon et al. (2009) identify and correct errors made by non-native English writers. They first detect article and preposition errors, and then apply different techniques to correct each type of errors. Huang et al. (2010) propose a correction rule extraction model trained from 310,956 sets of erroneous and corrected pairwise sentences. Some studies related to word orderings are specific to the topic of pre-processing or post-processing of statistical machine translation, such as Galley and Manning (2008), Setiawan et al. (2009), and DeNero and Uszkoreit (2011).

The major contributions of this paper cover the following aspects: (1) application aspect: detecting and correcting a common type of Chinese written errors of foreign learners with HSK corpus; (2) language aspect: considering the effects of words and segments in Chinese sentences; and (3) resource aspect: exploring the feasibility of using a Chinese web n-gram corpus in WOE detection/correction.

3 Overview of a Chinese Word Ordering Detection and Correction System

Figure 1 sketches an overview of our Chinese WOE detection and correction system. It is composed of three major parts, including dataset preparation, WOE detection, and WOE correction. At first, a corpus is prepared. Sentences containing WOEs are selected from the corpus and corrected by two Chinese native speakers. This corpus will be used for training and testing. Then, a sentence is segmented into a sequence of words, and chunked into several segments based on punctuation marks. Regarding words and segments as fundamental units reduce the number of reordering and limit the reordering scope. The segments containing WOEs are identified by using CRF-based models. Finally, the candidates are generated by reordering and ranked by Ranking SVM-based models. To examine the performance of WOE correction, two datasets, C_{ans} and C_{sys}, consisting of error segments labelled by human and detected by our system, respectively, are employed.

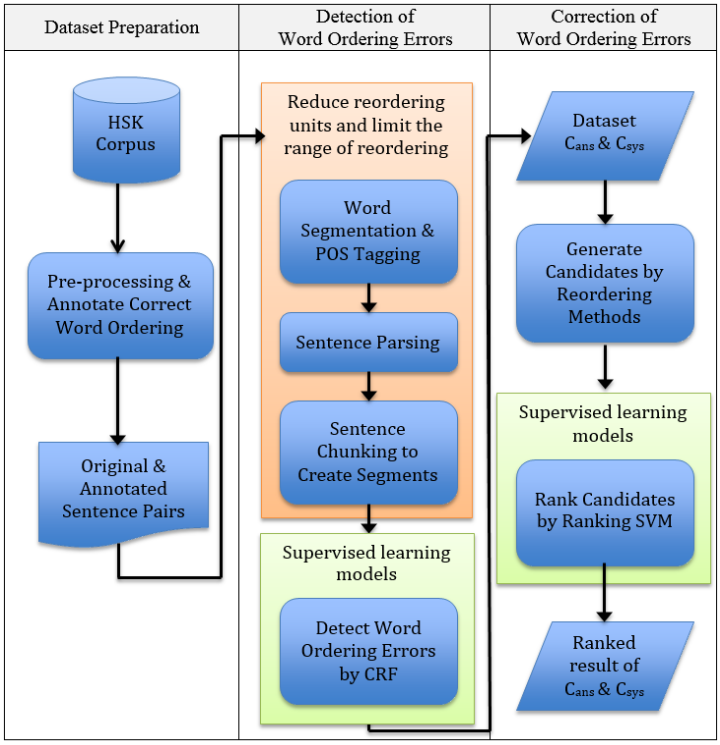

Figure 1: Overview of word ordering error detection and correction.

The example shown below demonstrates the major steps. This sentence is composed of three segments. The second segment contains a WOE, i.e., 今年夏天毕业了大学 (Graduated college this summer). The correct sentence should be 今年夏天大学毕业了 (Graduated from college this summer).

(1) Reduce the number of reordering units in a sentence by using word segmentation.

我	叫	王大安	，	今年	夏天	毕业	了	大学	，	现在	找	工作	。

(I / am /Wang Daan/ , /this /summer /graduated/le /college /, /now /look for/job /.)

(2) Chunk a sentence into segments by punctuation marks.

我	叫	王大安	，	今年	夏天	毕业	了	大学	，	现在	找	工作	。

(3) Detect the possible segments containing WOEs in a sentence by CRF-based methods.

我	叫	王大安	，	今年	夏天	毕业	了	大学	，	现在	找	工作	。

(4) Reorder words in an erroneous segment and generate candidates.

我	叫	王大安	，	今年	夏天	毕业	大学	了	，	现在	找	工作	。

…

我	叫	王大安	，	今年	夏天	大学	毕业	了	，	现在	找	工作	。

(5) Rank candidates and suggest correct word ordering by Ranking SVM-based methods.

我	叫	王大安	，	今年	夏天	大学	毕业	了	，	现在	找	工作	。

…

4 A Word Ordering Errors (WOEs) Corpus

HSK dynamic composition corpus created by Beijing Language and Culture University is adopted. It contains the Chinese composition articles written by non-native Chinese learners. There are 11,569 articles and 4.24 million characters in 29 composition topics. Composition articles are scanned into text and annotated with tags of error types ranging from character level, word level, sentence level, to discourse level. There are 35,884 errors at sentence level, and WOEs are the most frequent type at this level. Total 8,515 sentences are annotated with WOEs. We filter out sentences with multiple error types and remove duplicate sentences. Total 1,150 error sentences with WOEs remain for this study.

Two Chinese native speakers are asked to correct the 1,150 sentences. Only reordering operation is allowed during correction. A dataset composed of 1,150 sets of original sentence S and its two corrections A1 and A2 is formed for training and testing in the experiments. A1 may be different from A2. The following shows an example. Without context, either A1 or A2 is acceptable.

S: 她我们兄弟姊妹鼓励学音乐和外语。
(She we encouraged to study music and foreign languages.)
A1: 我们兄弟姊妹鼓励她学音乐和外语。
(We encouraged her to study music and foreign languages.)
A2: 她鼓励我们兄弟姊妹学音乐和外语。
(She encouraged us to study music and foreign languages.)

In some cases, A1 and/or A2 may be equal to S. That is, the annotators may think S is correct. That may happen when context is not available. Finally, 327 of 1,150 sets contain different corrections. Both A1 and A2 are equal to S in 27 sets. Total 47 sentences corrected by one annotator are the same as the original sentences, and total 65 sentences corrected by another annotator are the same as the original sentences. This corpus is available at http://nlg.csie.ntu.edu.tw/nlpresource/woe_corpus/.

Figure 2 shows the Damerau Levenshtein distance between the original sentences S and the corrections A1 and A2. It counts the minimum number of operations needed to transform a source string into a target one. Here the operation is the transposition of two adjacent characters. Total 823 sets of A1 and A2 have a distance of 0. It means 71.5% of sentences have the same corrections by the two Chinese native speakers. The distances between S and A1 are similar to those between S and A2. Total 850 sets of original sentences and the corrections have a distance below 10 characters and 1,014 sets of sentences have a distance below 20. We can also observe that the number of sentences with even distances is larger than that of sentences with odd distances because most of the Chinese words are composed of two characters.

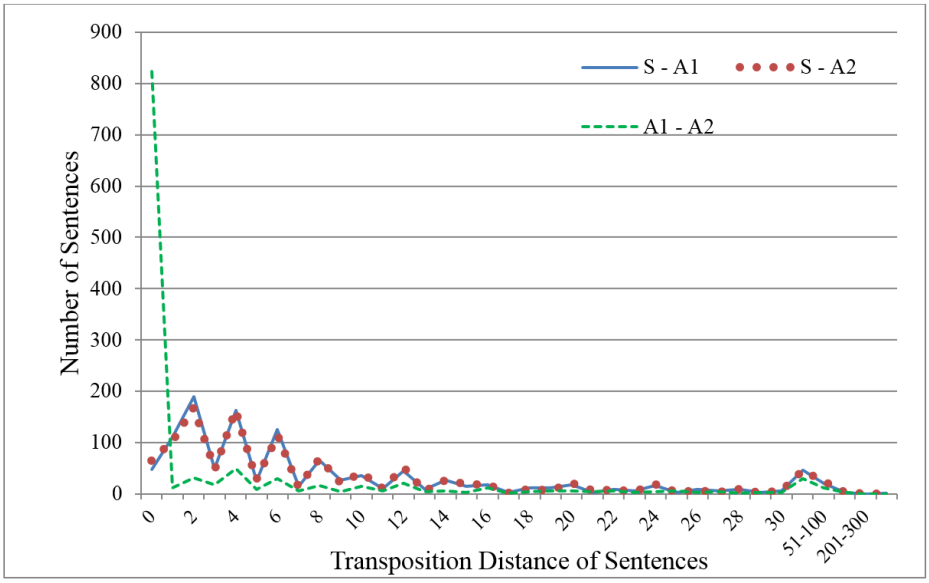

Figure 2: Transposition distance among the original sentences and two corrections.

5 Detection of Word Ordering Errors

This section first defines the fundamental units for error detection, then introduces the error detection models along with their features, and finally presents and discusses the experimental results.

5.1 Fundamental Units for Reordering

Permutation is an intuitive way to find out the correct orderings, but its cost is very high. Unrestrictive permutation will generate too many candidates to be acceptable in computation time. What units to be reordered in what range under what condition has be considered. Chinese is different from English in that characters are the smallest meaningful units, and there are no clear word boundaries. Computation cost and segmentation performance is a trade-off to select character or word as a reordering unit. On the one hand, using words as the reordering units will reduce the number of candidates generated. On the other hand, word segmentation results will affect the performance of WOE detection and correction. The following two examples show that reordering the words cannot generate the correct answers. In these two examples, a word in the original sentence (S) is segmented into two words in the correct sentence (A). These words are underlined. Because a word is regarded as a unit for reordering, the correct sentence cannot be generated by word reordering only in these two cases.

S: 他 / 教给 / 学生们 / 英语 /。
(He / teach to / students / English / .)
A: 他 / 给 / 学生们 / 教 / 英语 / 。
(He / for / students / teach / English / .)
S: 最近 / 我 / 开始 / 学 / 中国 / 的 / 做菜。
(Recently / I / start to / learn / China / ‘s / cooking cuisine.)
A: 最近 / 我 / 开始 / 学 / 做 / 中国 / 的 / 菜。
(Recently / I / start to / learn / cooking / China / ‘s /cuisine.)

Total 76 sets of sentences belong to such cases. They occupy 6% of the experimental dataset. Considering the benefits of words, we still adopt words as reordering units in the following experiments.

To prevent reordering all the words in the original sentences, we further divide a sentence into segments based on comma, caesura mark, semi-colon, colon, exclamation mark, question mark, and full stop. Sentence segments containing WOEs will be detected and words will be reordered within the segments to generate the candidates for correction. In our dataset, there are only 31 sets of sentences (i.e., 2.7%) with WOEs across segments. The following shows two examples. The underlined words are moved to other segments.

S: 其实，我还是做事情的时候，不怎么老实。
(In fact, when I am still working, I am not honest.)
A: 其实，我做事情的时候，还是不怎么老实。
(In fact, when I am working, I am still not honest.)
S: 所以有绝对的导游工作经验，无须再培训。
(Therefore we have absolute guide work experience, we do not need retraining.)
A: 有绝对的导游工作经验，所以无须再培训。
(We have absolute guide work experience, therefore we do not need retraining.)

In summary, the upper bound of the correction performance would be 91.3%. That is, 6%+2.7% of sentences cannot be resolved.

5.2 Word Ordering Errors Detection Models

Conditional random fields (CRFs) (Lafferty, 2001) are used to implement the WOE detection in sentence segments. Segments with WOEs are labelled with answer tags before training. The original sentence S written by non-native Chinese learner is compared with the annotated correct sentence A. Characters are compared from the start and the end of sentences, respectively. The positions are marked ERR_{start} and ERR_{end} once the characters are different. All words within ERR_{start} and ERR_{end} are marked ERR_{range}. The longest common subsequence (LCS) within ERR_{range} of S and ERR_{range} of A are excluded from ERR_{range} and the remaining words are marked ERR_{words}. Figure 3 shows an example. We use BIO encoding (Ramshaw and Marcus, 1995) to label segments with WOEs. Segments contain-

ing words in ERR_{words} are defined to be segments with WOEs. The leftmost segment with WOEs is tagged B, and the following segment with WOEs are tagged I. Those segments without WOEs are tagged O.

Figure 3: An example for ERR_{range} and ERR_{words}.

Table 1 lists the distribution of B, I and O segments. Recall that two Chinese native speakers are asked to correct the 1,150 sentences, thus we have two sets of B-I-O tagging.

Tagging→	B Tag		I Tag		O Tag		Total
Statistics→	#Segments	Percentage	#Segments	Percentage	#Segments	Percentage	Segments
Annotator 1	1111	40.6%	53	1.9%	1572	57.5%	2736
Annotator 2	1097	40.1%	59	2.2%	1580	57.7%	2736

Table 1: Distribution of B, I, and O segments.

Five features are proposed as follows for CRF training. Google Chinese Web 5-gram corpus (Liu, Yang and Lin, 2010) is adopted to get the frequencies of Chinese words for f_{PMI}, f_{Diff} and f_{LM}.

(1) Segment Pointwise Mutual Information (f_{PMI})
$PMI(Seg_i)$ defined below measures the coherence of a segment Seg_i by calculating PMI of all word bigrams in Seg_i. To avoid the bias from different lengths, the sum of PMI of all word bigrams is divided by n-1 for normalization, where n denotes the segment length. The segment PMI values are partitioned into intervals by equal frequency discretization. Feature f_{PMI} of the segment Seg_i reflects the label of the interval to which $PMI(Seg_i)$ belongs.

$$PMI(Seg_i) = \frac{1}{n-1}\sum_{k=1}^{n-1} log\frac{P(w_k, w_{k+1})}{P(w_k)P(w_{k+1})}$$

(2) Inter-segment PMI Difference (f_{Diff})
Feature f_{Diff} captures the PMI difference between two segments Seg_{j-1} and Seg_j. It aims to measure the coherence between segments. The feature setting is also based on equal frequency discretization.

(3) Language Model (f_{LM})
Feature f_{LM} uses bigram language model to measure the log probability of the words in a segment defined below. Labels of interval are also determined by equal frequency discretization.

$$LM(Seg_i) = log\ [P(w_1)\prod_{k=1}^{n-1}\frac{P(w_k,w_{k+1})}{P(w_k)}] = log\,P(w_1) + \sum_{k=1}^{n-1} log\frac{P(w_k,w_{k+1})}{P(w_k)}$$

(4) Tag of the previous segment (f_{Tag})
Feature f_{Tag} reflects the tag B, I or O of the previous segment.

(5) CRF bigram template (f_B)
Feature f_B is a bigram template given by SGD-CRF tool[1]. Bigram template combines the tags of the previous segment and current segment, and generates $T*T*N$ feature functions, where T is number of tags and N is number of strings expanded with a macro.

[1] http://leon.bottou.org/projects/sgd

5.3 Results and Discussion

WOE detection models will annotate the segments of a sentence with labels B, I or O. These labels will determine which segments may contain WOEs. In the experiments, we use 5-fold cross-validation to evaluate the proposed models. Performance for detecting WOEs is measured at the segment and the sentence levels, respectively. The metrics at the segment level are defined as follows. Here set notation is adopted. The symbol $|S|$ denotes the number of elements in the set S which is derived by the logical formula after vertical bar. $TAG_{pred}(SEG)$ and $TAG_{ans}(SEG)$ mean the labels of segment SEG tagged by WOE detection model and human, respectively. The symbol m denotes total number of segments in the test set.

$$Accuracy = \frac{|\{\, SEG \mid TAG_{pred}(SEG) = TAG_{ans}(SEG) \,\}|}{m}$$

$$Recall = \frac{|\{\, SEG \mid TAG_{pred}(SEG) \in (\mathrm{B},\mathrm{I}) \cap TAG_{ans}(SEG) \in (\mathrm{B},\mathrm{I}) \,\}|}{|\{\, SEG \mid TAG_{ans}(SEG) \in (\mathrm{B},\mathrm{I}) \,\}|}$$

$$Precision = \frac{|\{\, SEG \mid TAG_{pred}(SEG) \in (\mathrm{B},\mathrm{I}) \cap TAG_{ans}(SEG) \in (\mathrm{B},\mathrm{I}) \,\}|}{|\{\, SEG \mid TAG_{pred}(SEG) \in (\mathrm{B},\mathrm{I}) \,\}|}$$

$$F1 - Score = \frac{2 * Precision * Recall}{Precision + Recall}$$

The metrics at the sentence level are defined as follows:

$$Accuracy = \frac{|\{\, SENT \mid \forall\, SEG \in SENT,\ TAG_{pred}(SEG) = TAG_{ans}(SEG) \,\}|}{1150}$$

$$Correctable\ Rate = \frac{|\{\, SENT \mid \nexists\, SEG \in SENT,\ TAG_{pred}(SEG) = \mathrm{O}\ AND\ TAG_{ans}(SEG) \in (\mathrm{B},\mathrm{I}) \,\}|}{1150}$$

Accuracy and F1-score measure whether the models can find out segments with WOEs. *Correctable Rate* of sentences measures whether it is possible that the candidates of the correct word order can be generated by the WOE correction models. If a segment without WOEs is misjudged to be erroneous, the word order still has a chance to be kept by the WOE correction models. However, if a segment with WOEs is misjudged to be correct, words in the misjudged segment will not be reordered in the correction part because the error correction module is not triggered. A sentence is said to be "correctable" if no segments in it are misjudged as "correct". The ratio of the "correctable" sentences is considered as a metric at the sentence level.

Table 2 shows the performance of WOE detection. Five models are compared. We regard tagging all the segments with the labels B and O respectively as two baselines. Clearly, the recall at the segment level and the correctable rate at the sentence level are 1 by the all-tag-B baseline. However, its accuracy at the segment and the sentence levels are low. The all-tag-O baseline has better accuracy at the segment level than the all-tag-B baseline, but has very bad F1-score, i.e., 0. The proposed models are much better than the two baselines. Among the feature combinations, $f_{PMI}f_{Diff}f_{Tag}f_{B}$ show the best performance. The accuracy at the segment level is 0.834, and the correctable rate is 0.883. The best detection result will be sent for further correction.

Model	Segment				Sentence	
	Accuracy	Recall	Precision	F1-Score	Accuracy	Correctable Rate
Baseline (*all tag B*)	0.404	1.000	0.424	0.595	0.271	1.000
Baseline (*all tag O*)	0.576	0.000	0.000	0.000	0.074	0.074
$f_{PMI}f_{LM}f_{Tag}f_{B}$	0.830	0.781	0.802	0.791	0.787	0.862
$f_{PMI}f_{Diff}f_{Tag}f_{B}$	**0.834**	**0.795**	0.805	**0.800**	**0.788**	**0.883**
$f_{PMI}f_{Diff}f_{LM}f_{Tag}f_{B}$	0.831	0.769	**0.823**	0.795	0.777	0.850

Table 2: Performance of word ordering error detection

6 Correction of Word Ordering Errors

This section deals with generating and ranking candidates to correct WOEs. Two datasets, C_{ans} and C_{sys}, are explored in the experiments. We evaluate the optimal performance of the WOE correction models with the C_{ans} dataset, and evaluate WOE detection and correction together with the C_{sys} dataset.

6.1 Candidate Generation

Instead of direct permutation, we consider three strategies shown as follows to correct the error sentences. The complexity of generating candidates by permutation is O(n!). The complexity of using these three strategies decreases to O(n^2).

(1) Reorder single unit (R_{single})
R_{single} strategy reorders only one reordering unit (i.e., a word) to n-1 positions within a segment containing n words. Total $(n\text{-}1)^2$ candidates can be generated by this strategy. The following shows an example.

S: 今天 / 学校 / 去
(Today / school / go to)
A: 今天 / 去 / 学校
(Today / go to / school)

(2) Reorder bi-word ($R_{bi\text{-}word}$)
$R_{bi\text{-}word}$ is similar to R_{single}, but two reordering units are merged into a new word before reordering. Because n-1 bi-words can be generated in a segment and n-2 positions are available for each merged bi-word, $(n\text{-}1)(n\text{-}2)$ candidates are generated by $R_{bi\text{-}word}$. The following shows an example.

S: 早/就/一家/公司/找/我/工作
(before / already / one / company / employ / me / work)
A: 一家/公司/早/就/找/我/工作
(one / company / before / already / employ / me / work)

(3) Reorder tri-word ($R_{tri\text{-}word}$)
$R_{tri\text{-}word}$ works similarly to $R_{bi\text{-}word}$, but three reordering units are merged before reordering. Total $(n\text{-}2)(n\text{-}3)$ candidates are generated by $R_{tri\text{-}word}$. The following shows an example.

S: 我/需要/工作/的/经验/在/您/的/公司。
(I / need / working / (de) / experience / in / your / (de) / company.)
A: 我/需要/在/您/的/公司/工作/的/经验。
(I / need / in / your / (de) / company / working / (de) / experience.)

Table 3 shows the recall rate of each candidate generation strategy. With the C_{ans} dataset, correct word ordering can be generated for 85.8% of the original sentences by fusing R_{single}, $R_{bi\text{-}word}$ and $R_{tri\text{-}word}$. The candidates generated by using the C_{sys} dataset cover 69.7% of the correct word orderings. The difference would probably be due to the error propagation of word ordering error detection specified in Section 5.3. Furthermore, 6% of correct word orderings are unable to be generated by using the reordering units due to the word segmentation issue as mentioned in Section 5.1. We can also find that 72.3% of sentences with WOEs can be corrected by the R_{single} strategy using the C_{ans} dataset. It means most of the WOEs made by non-native Chinese learners can be corrected by moving only one word.

Strategy\Dataset	C_{ans}	C_{sys}
R_{single}	0.723	0.577
$R_{bi\text{-}word}$	0.365	0.308
$R_{tri\text{-}word}$	0.239	0.217
$R_{single} \cup R_{bi\text{-}word} \cup R_{tri\text{-}word}$	**0.858**	**0.697**

Table 3: Recall of candidate generation strategies

6.2 Candidate Ranking

We use Ranking SVM (Joachims, 2002) for candidates ranking. Because WOEs may produce abnormal POS sequence, POS bigrams and POS trigrams are considered as features for Ranking SVM. We

use a *k*-tuple feature vector for each candidate sentence, where *k* is the number of features. In each dimension, binary weight is assigned: 1 if the feature exists in a candidate, and 0 otherwise. Score for each candidate is assigned by a binary classifier: 1 if the candidate is the same as either of the annotated corrections, and 0 otherwise.

6.3 Results and Discussion

Mean Reciprocal Rank (MRR) defined below is used for performance evaluation. The reciprocal rank is the multiplicative inverse of the rank of the first correct answer. MRR is the mean of reciprocal rank for all sentences *S*, value from 0 to 1. The larger MRR means the correct answer more closes to the top ranking.

$$MRR = \frac{1}{|S|}\sum_{i=1}^{|S|}\frac{1}{rank_1}$$

Percentage of answers having rank 1 is another metric. Five-fold cross-validation is used for training and testing. In the C_{ans} and C_{sys} datasets, 182.03 and 184.48 candidates are proposed by the approach of fusing the results of R_{single}, $R_{bi\text{-}word}$, and $R_{tri\text{-}word}$ on the average. Experimental results are listed in Table 4. The proposed candidate ranking method achieves an MRR of 0.270 in the C_{ans} dataset. It means the correct candidates are ranked 3.7 on the average. In contrast, the MRR by using the C_{sys} dataset is 0.208. It means the correct candidates are ranked 4.8 on the average when error detection and correction are performed in pipelining.

Metric\Dataset	C_{ans}	C_{sys}
MRR	0.270	**0.208**
% of rank 1	0.195	**0.144**

Table 4: Performance of candidate ranking

There are some major types of errors shown as follows in WOE correction.

(1) Word ordering errors across segments
Section 5.1 mentions there are 31 sets of sentences (i.e., 2.7%) with WOEs across segments. Our algorithm cannot capture such kinds of sentences.

(2) Propagation errors from candidate generation
Table 3 shows the recall of word ordering error detection using the C_{ans} dataset is 0.858. Besides, 6% of sentences mentioned in Section 5.1 cannot be reordered to correct word ordering due to word segmentation issue.

(3) Limitation of our models
In the fused n-gram models, only one n-gram can be moved. It reduces the number of candidates to be generated, but some types of reorderings are missed. An example is shown as follows. The 2-gram 出生 / 于 (was born in) and the unigram 于 (on) have to be exchanged.

S：我 / 出生 / 于 / 1968 年 10 月 25 日 / 在 / 维也纳。
(I / was born / in / 25 October 1968 / on / Vienna.)
A：我 / 在 / 1968 年 10 月 25 日 / 出生 / 于 / 维也纳。
(I / on / 25 October 1968 / was born / in / Vienna.)

7 Conclusion

In this paper, we consider words as the reordering units in WOE detection and correction. Sentences are chunked into segments based on punctuation marks and the CRF technique is used to detect segments that possibly contain WOEs. The best error detection model achieves an accuracy of 0.834. Three reordering strategies are further proposed to generate candidates with correct word ordering and reduce the numerous number of candidates generated by permutation. If the segments containing WOEs are known, 85.8% of correct sentences can be generated by our approach. Finally, Ranking SVM orders the generated candidates based on POS bigrams and POS trigrams features, and achieves an MRR of 0.270 when all erroneous segments are given and an MRR of 0.208 when both detection and correction modules are considered.

Using words as the reordering unit reduces the cost to generate numerous candidates, but 6% of sentences are unable to reorder due to the word segmentation issue. How to balance the trade-off has to be investigated further. In the candidate ranking, selection of proper weights for POS bigram and trigram features may improve the ranking performance. Since the corpus of WOEs in Chinese is still in a limited size, expanding the related corpus for further research is also indispensable.

Abstract

NLP methods for automatic information access to rich technological knowledge sources like patents are of great value. One important resource for accessing this knowledge is the technical terminology of the patent domain. In this paper, we address the problem of automatic terminology acquisition (ATA), i.e., the problem of automatically identifying all technical terms in a document. We analyze technical terminology in patents and define the concept of technical term based on the analysis. We present a novel method for labeling large amounts of high-quality training data for ATA in an unsupervised fashion. We train two ATA methods on this training data, a term candidate classifier and a conditional random field (CRF), and investigate the utility of different types of features. Finally, we show that our method of automatically generating training data is effective and the two ATA methods successfully generalize, considerably increasing recall while preserving high precision relative to a state-of-the-art baseline.

1 Introduction

A large part of our technological knowledge is encoded in patents. Methods for automatically finding information in patents and inferring information from patents are thus of great value. An important step in getting access to patent information is identification of technical terminology, i.e., finding the linguistic expressions that denote the technical concepts of a patent: the methods, processes, substances and objects that are part of the invention or modified by it. In the example "The present invention relates to a **charging apparatus** of a **bicycle dynamo**", the bolded compound nouns are the main content words and refer to specific technological concepts. We call such linguistic expressions *(technical) terms* or TERMS and their totality the *(technical) terminology* of a document or domain.

We address the task of *automatic terminology acquisition* (ATA), the task of finding technical TERMS in texts without reliance on existing resources that list TERMS of the domain. In contrast to this stands *automatic terminology recognition* (ATR), which we define as finding *known* TERMS and their variants (Jacquemin and Bourigault, 2003). ATA provides input to downstream components like automatic summarization, machine translation, ontology building, information extraction and retrieval. TERMS extracted by ATA can be semantically classified or mapped to entries in a semantic database (Krauthammer and Nenadic, 2004), but we focus on identifying them without further classification in this paper.

Our main contributions are as follows. (i) We present a method for automatically labeling large amounts of training data for ATA. (ii) We show that two types of statistical classifiers trained on this training data beat a state-of-the-art baseline, indicating that the automatic labeling is of high quality. (iii) We study different feature types for ATA and investigate how much they contribute to good performance. We investigate a semi-supervised setting in which features are selected based on a manually labeled evaluation set and a completely unsupervised setting where the feature selection is performed on an automatically produced set. (iv) Finally, we show that performance strongly depends on correct identification of the boundaries of TERMS and could be enhanced considerably by improving candidate identification.

The paper is organized as follows. Section 2 gives a definition of technical terminology and provides a brief analysis of TERMS in patents. Section 3 presents related work. Section 4 describes the architecture of our ATA system: preprocessing, linguistic filtering, automatic labeling of training data, feature selection and postprocessing. Section 5 reports evaluation results and analyzes selected features and errors. Section 6 presents our conclusions.

Proceedings of COLING 2014, the 25th International Conference on Computational Linguistics: Technical Papers, pages 290–300, Dublin, Ireland, August 23-29 2014.

2 Problem Description

Let $w_{1...k}$ be a sequence of words $w_1, w_2, \ldots, w_k$ and w_k a head noun. $w_{1...k}$ is a TERM of domain D iff (i) the head noun w_k is unmodified ($k = 1$) or (for $k > 1$) is modified by sequences of other nouns ("disk controller"), adjectives ("secondary controller") or present participles ("writing controller") and (ii) it denotes a concept specific to D.

(i) and (ii) describe the syntactic and semantic properties of a TERM, respectively. Part (i) restricts TERMS to parts of noun phrases. This is a reasonable restriction that covers most technical terms (Daille et al., 1996) and it has been frequently made in the computational terminology literature. We exclude comparatives and superlatives as modifying adjectives because they are rarely used attributively in patents and usually modify quantities or qualities of TERMS(e.g., "*higher* shunt currents"); in other words, only "positive" (base-form) adjectives are included in our definition. Note that the number of tokens per TERM is not restricted by the definition. Our approach aims to find TERMS of arbitrary length.

Part (ii) of the definition restricts TERMS to be specific to a domain D. We can set D to a general domain like 'electricity' and be on a par with many prior definitions (Ananiadou, 1994; Georgantopoulos and Piperidis, 2000; Zhang and Fang, 2010), but we can also set D to a narrow domain like 'emergency protective circuit arrangements' (IPC code[1] H02H).

Here, we choose the most general technical domain possible: the domain of all technical subjects. This is a good setting for many downstream tasks, e.g., information retrieval should benefit from a broad coverage of D. It also makes annotation easier: Non-experts can carry it out with good agreement (Section 5.1) because they simply look for all technical expressions.

The syntactic and semantic parts of our definition of TERM correspond to the concepts of *unithood* and *termhood*, respectively. Unithood is the degree to which a sequence of tokens is a linguistic unit; and termhood the degree to which a linguistic unit is a TERM of a domain (Kageura and Umino, 1996). Both aspects have to be covered by ATA systems.

Terms in Patents

In addition to traditional TERMS like simple nouns (1, "voltage"), modified nouns (2, "secondary arm") and nouns modified by prepositional phrases (3, "trajectory of the lever"), patents provide also coordinations (4, "constant and variable current") and complex constructions (5, "storage device storing a target temperature value which a battery is intended to reach").

For ATA, it seems advisable to exclude infrequent and complex nominal expressions from the definition of TERM, both from a terminological and a computational point of view. Most nominal expressions that are generally viewed as terms are single nouns, compound nouns, and nouns with an adjectival modifier (Daille et al., 1996); our syntactic definition covers these three types. Nominal expressions like (5) tend to be long; if we were to count such cases as TERMS, then it would be unclear where the TERM ends. When analyzing (5), our first take might be that there is a nucleus ("storage device") which is modified by a verbal phrase ("storing a target temperature value") and that the rest of the phrase is not part of the TERM. But it turns out that the *whole phrase* appears multiple times in its patent; it is a stable way of denoting a part of the invention. However, the underlying concept is also denoted by simpler constructions like the nucleus itself, or synonymous TERMS like "control circuit"; these simpler constructions are covered by our definition.

Coordinations like (4) mix multiple concepts (here, "constant current" and "variable current") without making this explicit on the surface. It is difficult to identify "constant current" as a potential TERM because it is non-contiguous and is only indicated by an adjective. Our treatment of coordinations in this paper is to only consider sequences satisfying the syntactic definition (i.e., "variable current") to be TERMS and discard other parts (i.e., "constant"). Of course, if both conjuncts are complete TERMS and satisfy the syntactic definition, both will be identified as TERMS.

Finally, prepositional phrases like (3) are rather infrequent compared to terms covered by our syntactic definition. They also tend to be highly ambiguous and the underlying concept is often expressed by terms covered by our definition ("lever trajectory").

3 Related Work

Previous work on ATA either employs *filtering* or *sequence models*. Filtering combines linguistic and statistical criteria for (i) *extracting a list of candidates* (typically word n-grams) based on simple linguistic criteria, (ii) *computing candidate statistics* and (iii) using ranking, classification or some other mechanism for *producing a pruned list of* TERMS *as output*. Because variation of the surface form of TERMS is limited,

[1] `wwwcms10.wipo.int/classifications/ipc/en/`

it makes sense to use word n-grams as the basis for candidate identification – even though there are cases that cannot be found this way, e.g., "constant current" or alternations like "pressure regulating valve" vs. "valve regulating pressure".

The main difference between ATA methods that rely on filtering is in how they accomplish the ranking/pruning of the candidate list. See Kageura and Umino (1996), Jacquemin (2001) and Pazienza et al. (2005) for an overview. In this paper, we accomplish this by training a statistical model to classify TERM candidates. We also run experiments with a sequence model. Our main innovation is that these models are trained on automatically labeled training data.

It is difficult to directly compare computational terminology systems because of differences in domain, language, application and task definition. As an example consider Takeuchi and Collier (2005) who report an F_1 of .742. However, their task definition includes assigning terms to pre-defined categories such as DNA and protein as opposed to simply identifying TERMS. In addition, terminologies in the biomedical and technological domains are different. In biomedicine, categories like DNA and protein dominate. For these TERMS, shape features are informative – in contrast to TERMS in patents. Another difference is that TERMS in patents tend to be long whereas DNA and proteins are often single-token abbreviations.

3.1 Training Data Collection

One of our main contributions is unsupervised training data generation (Section 4.3). Prior work has used automatically recognized training data for computational terminology, specifically for ATR (Craven and Kumlien, 1999; Hatzivassiloglou et al., 2001; Morgan et al., 2003; Zhang et al., 2010) in the biomedical domain. Given large precompiled TERM lists they search for occurrences of list elements, e.g., genes, in texts and use the occurrences they find as training examples. This is similar to *distant supervision* (Mintz et al., 2009) which also uses pre-existing resources such as gazetteers for, e.g., relation extraction.

In contrast, our method is applied to ATA for the technological domain and does not rely on precompiled resources – we make use of figure references, which are an inherent part of patents. Our method can be characterized as training data *identification*: we exploit given conditions in patents for our search of training data. In contrast, training data *recognition* methods need precompiled resources as input and search for instances of resource elements in texts.

3.2 Learning Algorithms and Features

Different learning algorithms and feature sets have been used for computational terminology. Foo and Merkel (2010) use Ripper (Cohen, 1995) with a variety of features to classify uni- and bigram TERM candidates. Hatzivassiloglou et al. (2001) compare C4.5 (Quinlan, 1993) and Naive Bayes (Duda and Hart, 1973). Zhang et al. (2010) acquire novel TERMS using CRFs and syntactic features. Takeuchi and Collier (2005) find that more training data results in higher F scores. Large training sets have the same positive effect in our experiments. Our approach has the added advantage that the training sets are generated completely automatically.

4 Approach

As discussed in the introduction, we address the problem of ATA. We use the abbreviation ATAS (automatic terminology acquisition system) to refer to our approach in general as well as to the specific implementation we evaluate in this paper.

ATAS consists of three parts: (i) training set generation, (ii) parameter selection and training of the TERM candidate classifier (ATAS-TC) and the CRF (ATAS-CRF) and (iii) identification of terminology in documents.

Processing in step (iii) is document by document because some of our features are document-based. ATAS takes a document as input and identifies all TERMS in the document, using the TERM candidate classifier or the CRF learned in (ii).

The TERM candidate classifier (ATAS-TC) decides on entire (multi-token) candidates while the CRF decides on single tokens. ATAS-TC heavily relies on candidate computation and its decisions are mutually independent, which is clearly incorrect. In contrast, ATAS-CRF is less dependent on candidate computation and models dependence of decisions correctly; but it lacks the more 'global' view of ATAS-TC on entire candidates. We want to investigate which approach is more suited for ATA.

In what follows we describe how we preprocess patents, the linguistic filters used to implement our syntactic definition of TERM, automatic labeling of training data (step (i) of ATAS), training of TERM candidate classifier and CRF (step (ii) of ATAS), features and feature selection.

4.1 Preprocessing

The preprocessing pipeline consists of the ANNIE tokenizer, OpenNLP sentence splitter, Mate POS tagger (Bohnet (2010), retrained for patents) and Mate lemmatizer. Preprocessing has a big influence on computational terminology because special domain text poses problems for off-the-shelf components. For example, patents tend to use common language words in rare functions or meanings, e.g., "said" as a de facto determiner in contexts such as "the structure of said component". Other problems are the use of special language words, e.g., substances like "triphenylphosphine" and acronyms like "AC". Such properties pose serious problems to POS taggers. Patent citations, acronyms and even product names can include punctuation, confusing sentence splitters. Chemical formulas may confuse tokenizers.

We adapted our POS tagger and sentence splitter for patent language to deal with unusual punctuation and POS tags – especially unusual POS tags of common-language words like "said". This adaptation involves training on a manually labeled training set of patent text and some other adjustments; e.g., we only allow the tag NN for the acronyms "AC", "DC" and "A/D".

4.2 Filter

We now describe how we find TERM candidates that satisfy the syntactic definition; recall that only (possibly modified) nouns can be TERMS (Section 2).

In general, candidate identification strategies using linguistic knowledge perform better. There are two different strategies of this type: (i) parsing the sentence, extracting nominal chunks from the parse and further processing the nominal chunks and (ii) POS tagging the sentence and extracting word sequences that satisfy a set of predefined POS patterns. Because many patent sentences are long and difficult to parse, we adopt the POS pattern approach in this paper. To this end, we define two simple POS-based rules for finding term candidates.[2]

PREMODS. This rule defines a modifier *sequence*. It matches a sequence of noun pre-modifiers: (JJ|"/"|VBG|RB|N(N|P))*.[3] We include RB because the POS tagger sometimes misclassifies JJ as RB. We include "/" because the tokenizer splits abbreviations containing it.

CANDIDATE. This rule defines a TERM candidate. It matches either a single noun or PREMODS followed by a noun: (PREMODS N(N|P)). The last noun must be longer than two characters. We add a flag indicating if the candidate comes before a figure reference. A figure reference consists of an optional keyword (e.g., "Figure", "Fig.") and a sequence of numbers and letters, optionally enclosed in parentheses.

We select the longest match in case of overlapping matches and the first longest match in case of overlapping matches of the same length.

These simple rules will find all TERMS – as well as many non-terms that we will train ATAS to identify – with two exceptions. First, due to POS errors some candidates are spurious. Second, unwanted modifiers may be part of candidates. E.g., the rules will only identify "same battery" as a candidate and not "battery". But only "battery" is a valid TERM. To address the latter, we manually compiled a stop list of 67 modifiers, mostly numerals ("first") and adjectives in anaphoric function ("above-mentioned"). These modifiers are removed from TERM candidates.

4.3 Automatic Labeling of Training Data

We view ATA as either a binary classification task where a TERM candidate classifier decides if a candidate is a TERM or not, or as a sequence labeling task where a CRF decides if a token (word) belongs to a TERM or not.

Large training sets are needed to train such models. Usually, these sets are produced by expensive human labeling. We present a method for generating high quality training data in an unsupervised way without the necessity of precompiled resources. In principle, our method can be used for any language for which machine-readable patents are available.

Our starting point is that patents typically contain figure references, i.e., pointers to drawings illustrating the invention or its parts. Consider the example: "...so that first **clamp-holding secondary arms** (1) ..." Here, the figure reference ("(1)") points to the illustration "Figure 1" and is preceded by the illustrated TERM ("clamp-holding secondary arms"). Illustrated TERMS may be concrete, as in this example, or abstract, e.g., a diagram illustrating properties of a method.

We call a TERM candidate that precedes a figure reference a *basic figure reference term candidate* (bFRTC). In a manual inspection of bFRTCs in 12 patents we found that almost 95% of bFRTCs were

[2] JJ, VBG, and RB are POS tags for positive adjectives, gerunds/present participles, and adverbs, respectively.
[3] '*' is the Kleene star, '?' denotes optionality, and '|' denotes alternation.

TERMS. Thus, bFRTCs can be used as positive training examples because they usually denote technical concepts; they have the advantage of being identifiable with high precision using simple patterns.

Once the bFRTCs have been identified, there is a simple way to further increase the size of the training data: we add all *extended FRTCs* (eFRTCs) to the training set, where we define an eFRTC as a TERM candidate whose suffix is a bFRTC. E.g., if we have identified "shunt current" as a bFRTC, then "AC shunt current" is an eFRTC. eFRTCs typically are hyponyms since the modifiers added at the beginning restrict the bFRTC to a more specific meaning. This kind of hyponymy is a special case of term derivation, a modification where a base term is further specified by prefixes (Daille et al., 1996). The strategy of identifying eFRTCs can also be applied to free word order languages because figure references tend to have a local and fixed occurrence pattern similar to English. We use the term FRTC to refer to both bFRTCs and eFRTCs.

We identify all FRTCs and add them as positive examples to the training set. We also add the 5% most frequent candidates as positive examples; most of them are FRTCs, so that this step usually adds few new training examples.

We label the following candidates as negative training examples: candidates appearing only once in a patent; patent citations; and measurements. Citations and measurements ("3 cm") are clear non-terms. We identify them using regular expressions. Many singletons are non-terms because they denote common language (i.e., nontechnical) concepts, e.g., "time". These heuristics for finding negative training examples are not applied to a candidate if it has the same head as a positive training example.

We exclude from the training set candidates that do not satisfy any positive or negative criteria.

4.4 Classifiers

We use the L2-regularized logistic regression of LIBLINEAR (Fan et al., 2008) as our TERM candidate classifier. We use LIBLINEAR's default normalization for continuous-valued attributes (normalization to range $[0, 1]$) and the default representation for categorical attributes. As LIBLINEAR cannot handle missing values, we replace them with their means and modes. We set the regularization parameter $c = 1$. Our sequence model is CRF++[4], order 1, with default parameters. The CRF features are adapted from the ATAS-TC features, e.g., TERM-level features (e.g., TFIDF) are propagated down to the individual tokens of the TERM. We also include word trigrams. We discretize numeric features to three values.

4.5 Features

We developed a set of 74 features for ATA. Some of these features are taken from the literature, some are specific to our approach and make use of the concept of FRTC and some exploit other properties of patents (e.g., the importance of the title and the claims in patents). A final group consists of other novel features that we designed in the course of developing our system. We now provide an overview. c refers to a TERM candidate.

Corpus and document statistics. This feature type captures termhood and unithood of c as well as the position of c's first occurrence in the document. We use a corpus of technical text C_T and a general language corpus C_G. For every $c \in C_T$ we collect the number of patents it appears in, its frequency and its FRTC frequency, i.e., the number of its occurrences that are FRTCs. Features that are intended to indicate termhood include simple frequencies and distributional characteristics (in C_T or in a single patent). Finally, we define a measure of frequency deviation (or 'keywordness') of $h(c)$, the head of c:

$$\text{bias}(h(c)) = \frac{f_{C_G}(h(c))}{|C_G|}|C_T| - f_{C_T}(h(c))$$

f_{C_G} (resp., f_{C_T}) are the frequencies in C_G (resp., C_T), $|X|$ is the sum of frequencies of all $x \in X$. $\text{bias}(h(c))$ measures the deviation between expected frequency of the head of c (estimated on C_G) and its actual frequency. The intuition here is that the frequency of a general language noun like "time" will be similar over text types, resulting in a lower bias.

Context. This feature type captures unigrams and bigrams adjacent to c as well as their POS tags.

Part-of-speech. This feature type captures the POS sequence of c.

A patent usually focuses on a narrow technological subdomain. As a result, many of its TERMS are semantically related to each other. We would like to include features that directly capture semantic similarity to other TERMS because a candidate that is semantically similar to several other already recognized TERMS is likely to be a TERM itself.

Our goal in this paper is to address ATA using simple and efficient methods. For this reason, we approximate semantic similarity using string similarity because a subset of semantically similar terms are

also similar on the surface. E.g., the semantic similarity between "AC power supply source" and "AC supply source" also manifests itself as string similarity.

String similarity. When designing a similarity measure, we wanted it to satisfy the following criteria: (i) more words in common should result in higher scores and (ii) words in common *towards the end* of the two strings should be weighted higher than words in common at the beginning. The motivation for (ii) is that candidates differing only in initial modifiers are often cohyponyms and highly related; conversely, candidates with different heads are often not related.

To implement this, we represent a candidate c as a vector $\vec{c}$ in $|V|$-dimensional space where V is the vocabulary. $\vec{c}_i$ is set to the position of word w_i in c if it occurs and 0 otherwise. The string similarity between c and c' is then defined as the cosine of $\vec{c}$ and $\vec{c'}$. Example: for "AC power supply source" and "AC supply source", we get the vectors $(1, 2, 3, 4)$ and $(1, 0, 2, 3)$ and the cosine .927; comparing the first string with "AC power supply" with the vector $(1, 2, 3, 0)$ we get the cosine .683.

Features in our initial set of 74 that make use of this semantic similarity are: maximum similarity of c to any FRTC, average similarity of c to all FRTCs in the patent and similarity of c to the rightmost TERM candidate in the title.

Frantzi and Ananiadou (1997) define *C-value(c)* as:

$$\text{C-value}(c) = \log_2 |c|(f(c) - \frac{1}{|T_c|}\sum_{b \in T_c} f(b))$$

where T_c is the set of TERM candidates containing c and f is frequency in C_T. C-value is high for TERM candidates that are frequent and occur as parts of many other TERM candidates – this is a good indicator of termhood.

5 Experiments and Evaluation

5.1 Data Sets

We hired three students with a bachelor degree in computer science to annotate 16 patents. The test set $\mathcal{T}^{\text{l}}_{\text{test}}$ consists of 5 patents annotated by all three students. We used majority voting to produce the final gold annotations. The devset $\mathcal{T}^{\text{l}}_{\text{dev}}$ consists of the remaining 11 patents. Each $\mathcal{T}^{\text{l}}_{\text{dev}}$ sentence was annotated by one student.

Inter-annotator agreement on $\mathcal{T}^{\text{l}}_{\text{test}}$ was .76 (Fleiss' κ). Most disagreements concern *modifiers* or *common nouns* (e.g., the TERM "battery" was often not annotated). More extensive training of the annotators should reduce these problems considerably.

As unlabeled data we randomly selected 390 technology patents. We use 365 as $\mathcal{T}^{\text{u}}_{\text{tdg}}$ for training data generation and 25 as $\mathcal{T}^{\text{u}}_{\text{sel}}$ for unsupervised feature selection. We made sure the 390 documents are not

in $\mathcal{T}^{\mathrm{l}}_{\mathrm{dev}}$ and $\mathcal{T}^{\mathrm{l}}_{\mathrm{test}}$. We excluded chemical patents because standard preprocessing components often fail for chemical formulas. Table 1 gives data set statistics.

As our technical corpus C_T we use $\mathcal{T}^{\mathrm{u}}_{\mathrm{tdg}}$ and as our general corpus C_G all nouns in the 2000 most frequent English words from Project Gutenberg[5]. This list contains many general nouns which also appear in patents (e.g., "time") without containing many technical terms (e.g., "battery"); this way, C_T and C_G give us a good contrast between technical and non-technical vocabularies (cf. Section 4.5).

One obstacle to comparing systems for ATA in the technical domain is the lack of publicly available evaluation benchmarks. We are making our data sets and the annotation guidelines available[6].

5.2 Baselines

We define the *FRTC baseline* as the system that labels all FRTCs and only FRTCs as TERMS. Almost all FRTCs are TERMS, but many TERMS are not FRTCs; thus, the FRTC baseline has high precision and low recall. Our goal is to preserve high precision while considerably increasing recall, or to generalize well from FRTCs to other TERMS.

Our state of the art baseline is Z-CRF, a reimplementation of the CRF described in (Zhang et al., 2010). Its feature representation includes POS tags, unigrams, bigrams and syntactic information, e.g., the number of times a particular token is used in a syntactic function like subject in the training set. Syntactic information is extracted with Mate (Bohnet, 2010). Z-CRF is trained on $\mathcal{T}^{\mathrm{u}}_{\mathrm{tdg}}$, just as ATAS.

Our last baseline is the well-known C-value (Frantzi and Ananiadou, 1997). Like our first baseline, it needs no training data. In contrast to our first baseline, it was specifically designed for terminology acquisition. It combines observations about statistical and linguistic properties of TERMS, i.e., a candidate is preferred as a term if it is long and frequently appears as substring of other candidates. Following Frantzi and Ananiadou (1997) we regard a candidate as TERM if its C-value it not zero; unlike them, we do not restrict the length of TERMS because the computation of long terms did not pose computational problems for us.

5.3 Evaluation Setup

We evaluate ATAS using precision, recall and F_1. Evaluation is based on candidate tokens (as opposed to candidate types or word tokens); e.g., each instance of a candidate TERM that is incorrectly classified as a TERM is a false positive. Evaluation is strict in the sense that a TERM is counted as a false positive if there is a single token that is added or missed.

We evaluate ATAS in two settings. In the system (S) setting, the ATAS pipeline described in Section 4 (ATAS-TC or ATAS-CRF) is used to identify TERM candidates. This is the real-world setting since errors in TERM candidate identification – misplaced boundaries, missing candidates, etc. – are a major source of error in ATA.

We would also like to evaluate candidate classification on *gold boundaries* (manually verified boundaries of TERM candidates); this allows us to quantify by how much performance can be improved if candidate identification is perfect. However, since gold boundary annotation is expensive, we instead approximated it: (i) We run automatic TERM candidate identification. (ii) We remove all TERM candidates that overlap with gold (manually annotated) TERMS. (iii) The set of gold TERM candidates is then the union of all remaining automatically identified candidates and the manually annotated TERMS.

In the gold boundary (G) setting, we provide these gold TERM candidates to the ATAS pipeline. This allows us to evaluate the performance of TERM/non-term classification separately from TERM candidate identification.

5.4 Feature Selection

For our feature set of 74, we perform forward feature selection for the TERM candidate classifier by selecting the feature in each step that maximizes system F_1. We perform feature selection (i) on the manually labeled set $\mathcal{T}^{\mathrm{l}}_{\mathrm{dev}}$ (to gauge performance for an optimal or close-to-optimal feature set) and (ii) on the automatically labeled set $\mathcal{T}^{\mathrm{u}}_{\mathrm{sel}}$ (to gauge the performance in a completely unsupervised setting). In the following we explain both settings in more detail.

Table 2 gives the features selected in **supervised feature selection**, i.e., when features are optimized on $\mathcal{T}^{\mathrm{l}}_{\mathrm{dev}}$. Precision remains stable, except for a drop on line 3. Recall rises steadily from .797 to .893. F_1 increases from .748 to .798.

The best feature (line 1) is the mean string similarity of a TERM candidate c to all FRTCs in a document (Section 4.5). Together with the next best feature (frequency of c as an FRTC in C_T) and feature 5 (is

Table 3: System (S) and gold boundary (G) results with supervised (S-SEL) and unsupervised (U-SEL) feature selection. *: significantly lower than corresponding ATAS-TC and ATAS-CRF scores.

c followed by a figure reference?) this supports our intuition for using FRTCs for automatic training set generation because they are indeed strong indicators for termness. Additionally, feature 9 indicates that candidates occurring often with FRTCs in sentences are probably TERMS. Feature 4 (is c uppercase?) is selected because uppercase TERM candidates are often abbreviations and TERMS.

Feature 3 (TFIDF of c) hurts precision, but increases recall, resulting in increased F_1. This feature models the hypothesis that a TERM is frequent in some patents but does not occur in many patents. Patent writers often invent novel TERMS rather than using standard ones to make finding a patent hard. Thus, a TERM candidate that occurs often in a few patents could be such an obfuscating TERM.

TFIDF is low for TERMS with small term frequency. Features 6 (TFIDF of $h(c)$) and 10 (C-value of c) can help correctly identify such TERM candidates as TERMS.

Features 8 and 11 incorporate information from the general purpose corpus C_G. Feature 8 contrasts the frequency of c in C_G with its frequency in C_T – frequencies of TERMS are higher in C_T, frequencies of non-terms are similar in both corpora. Feature 11 is complementary to this. It makes it more probable that c is a non-term if its head appears more often in C_G. Additionally, string similarity with the patent's title is an effective feature.

Unsupervised feature selection, i.e., selection on $\mathcal{T}^{u}_{sel}$, selected seven features that are similar to those selected by supervised selection and that we will discuss now. The best unsupervised feature (*maximum* string similarity, 1) and the best supervised feature (*mean* string similarity) both capture partial string overlap of c and FRTCs. For similar reasons, the feature "string similarity of c and rightmost NP in patent title" (2) – which exploits the importance of the title in analogy to the importance of figure references – is selected.

Other selected features (relative patent frequency of c and its head (3, 4), number of patent sentences in which c occurs with FRTCs (5), patent frequency of $c = 1?(6)$) are also similar to the features selected in the supervised setting. They capture frequency distributions of c. However, while many features in the supervised setting capture distributions of c in C_T, in the unsupervised setting, distributions of c in the patent are more important. The reason may be that C_T-based features (which use all technical text as opposed to the relevant patent in question) are harder to recognize as good predictors if the set used for selection is automatically labeled and hence noisier.

The last unsupervised feature captures the length of c in tokens (7). Manual inspection revealed that on average TERMS have more tokens than non-terms (1.9 vs. 1.3).

5.5 ATAS Results

Table 3 gives evaluation results for ATA on $\mathcal{T}^{l}_{dev}$ and $\mathcal{T}^{l}_{test}$. We report results for the ATAS versions (ATAS-TC, ATAS-CRF) and for the baselines (Z-CRF, C-value, FRTC) as well as for using supervised (S-SEL) and unsupervised feature selection (U-SEL) in system setting (S) and gold boundary setting (G).

Differences in F_1 between ATAS and baselines (marked with a †) are significant at $p < .01$.[7] If not stated otherwise, numbers below are for the system setting (S).

We note that F_1 of the ATAS versions is consistently and considerably better than all baselines in all settings. E.g., line 6 shows system F_1 on $\mathcal{T}^{l}_{test}$ of ATAS-TC (.765 for S-SEL, .689 for U-SEL) and ATAS-CRF (.783 for S-SEL, .654 for U-SEL) compared to Z-CRF (.631), FRTC (.430), and the C-value baseline (.350) . The better results mainly come from higher recall (except for C-value, which is also beaten in precision). In general, precision of the baselines is higher, but recall much smaller than for ATAS. This shows that (i) statistical classifiers can be successfully trained for ATA using our method

[7]We use approximate randomization (Yeh, 2000) for all significance tests in this paper.

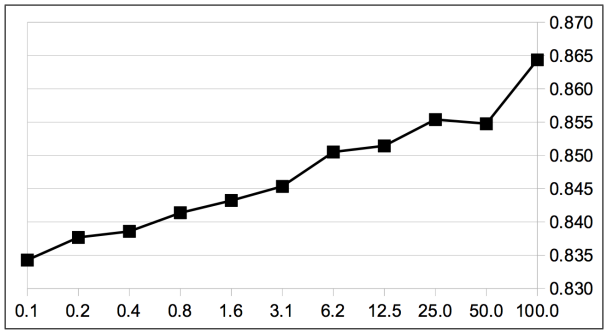

Figure 1: System F_1 as a function of training set size (in percent) in setting G.

for automatically generating training data and (ii) these classifiers beat a state-of-the-art system in both S-SEL and U-SEL settings.

Comparing S-SEL and U-SEL shows that precision and recall for U-SEL are lower than for S-SEL. For instance, F_1 of ATAS-TC on $\mathcal{T}^{\text{l}}_{\text{test}}$ is .765 for S-SEL and .689 for U-SEL; F_1 of ATAS-CRF is .783 for S-SEL and .654 for U-SEL (line 6). In general, we note a bigger drop in recall than in precision, indicating that U-SEL does not generalize as well as S-SEL. However, the U-SEL numbers are significantly better than the Z-CRF FRTC, and C-value baselines.

When comparing ATAS-TC with ATAS-CRF we note that ATAS-CRF consistently has higher precision and lower recall. In most cases, ATAS-TC has considerably higher recall, leading to higher F_1. This is not surprising given that feature selection was performed for ATAS-TC. Nevertheless, ATAS-CRF can compete with ATAS-TC in terms of F_1. Furthermore, ATAS-CRF produces more stable results because it shows less variance in F_1 across settings.

Comparing S and G scores shows that knowing exact boundaries has a great impact on results, especially on precision; looking at S-SEL numbers in line 4 in Table 3, precision for ATAS-TC (resp., ATAS-CRF) is .696 in S vs. .753 in G (resp., .774 in S vs. .832 in G). Similar differences also hold for U-SEL numbers. In general, ATAS-TC profits more from knowing exact boundaries than ATAS-CRF. This leads us to the conclusion that the linguistic filter would greatly benefit from a (statistical) measure of unithood. Note that this also holds for the baselines; deciding about the termness of gold boundary candidates seems to be easier, especially for C-value.

All observations hold for $\mathcal{T}^{\text{l}}_{\text{dev}}$ and $\mathcal{T}^{\text{l}}_{\text{test}}$. However, numbers are higher for $\mathcal{T}^{\text{l}}_{\text{dev}}$ because the ratio of FRTCs to candidates is higher than for $\mathcal{T}^{\text{l}}_{\text{test}}$ (38% vs. 27%) which improves classification performance on $\mathcal{T}^{\text{l}}_{\text{dev}}$ – this holds for ATAS as well as for the baselines.

To investigate the quality of the extracted training data, consider Figure 1. It shows F_1 in setting G as a function of training set size in percent of the total training set $\mathcal{T}^{\text{u}}_{\text{tdg}}$. For each evaluation point, we randomly add training examples from the full set. F_1 starts at .834 for 0.1% of training data (344 training examples) and rises to .864 for 100% (353,238 examples), with a small drop at 50%. Note that 1000 examples roughly correspond to one annotated patent. The main results of this experiment are that (i) a modest amount of automatically labeled training data gives good performance and (ii) the more automatically labeled data the better. The last point is not a trivial finding, given that training data was generated automatically. The logarithmic graph shows a nearly linear increase in F_1 for each doubling of the training data.

To further investigate the quality of the generated training data, we compared automatically and manually produced training examples. We compare results for 13238 manual and 13238 automatic labels (setting G, ATAS-TC). We get precision and recall of .811 and .805 for manual and .762 and .850 for automatic annotations, resulting in similar F1 scores: .808 vs. .804 for manual and automatic annotations, respectively. We believe that the differences in recall are an artifact of the randomization we performed before removing automatic training samples. Manual labels are entire patents; in contrast, automatic labels come from all patents in the training set, leaving us with a more diverse set than the manual version.

5.6 Error Analysis

We found two major types of false negatives. First, infrequent TERMS are problematic. It is hard to judge termness when having limited information about a candidate, especially if it appears only once or twice in a document. Second, POS errors prevent the system from finding some candidates; e.g., the noun "current" is frequently mistagged as adjective. Incorrect POS tags also lead to incorrect boundaries.

We found four major types of false positives. First, incorrect modifiers lead to partially incorrect TERMS. 27% of false positives are of this type. Second, incorrectly recognized figure references cause incorrect system decisions; e.g., our patterns incorrectly parse an expression like "value *PBA*" as a figure reference even though it is instead a named output of a component. Third, very frequent non-terms are commonly classified as TERMS. Almost all frequent candidates are TERMS, so that the TERM candidate classifier has difficulty correctly identifying the exceptions from this pattern.

Finally, if a candidate is a TERM in one context it may be a non-term in another. A good example for this are general single token TERMS like "apparatus". Before figure references they are TERMS, e.g., "one preferred form of apparatus 22". In such cases the figure reference serves as a disambiguator. However, in other positions they are non-terms, e.g., "They include braces, collars, splints and other similar apparatus".

6 Conclusion and Future Work

This paper introduces a method for ATA with two novel aspects: (i) new powerful features for ATA and (ii) a procedure for generating an ATA training set in an unsupervised fashion. The training set generation method produces high quality training data, even when compared to manual annotations. It is language-independent: It can be applied to patents in any language if the definition of TERM candidates is modified for the target language. It is also domain-independent: it can be applied to patents of any domain. The training data can be successfully used to train ATA models, both TERM candidate classification as well as CRF models. Even in a completely unsupervised setting the models outperform a state-of-the-art baseline. We found that using more automatically labeled training data and using better TERM boundaries results in better performance.

In future work, we plan to incorporate TERM variation patterns (Daille et al., 1996; Jacquemin, 2001) in the expansion process to decrease the number of FNs and increase recall. We would also like to improve the terminology identification module because we found that incorrect identified boundaries affect performance greatly.

Finally, we are planning to extend our approach to languages other than English. Our methods are language-independent to the extent that a body of patents exists for many common languages. Since we generate the training set automatically, all we need to do to cover another language is to adapt the linguistic filters for candidate identification.

Abstract

This paper presents an unsupervised approach for the task of clustering the results of a search engine when the query is a person name shared by different individuals. We propose an algorithm that calculates the number of clusters and establishes the groups of web pages according to the different individuals without the need to any training data or predefined thresholds, as the successful state of the art systems do. In addition, most of those systems do not deal with social media web pages and their performance could fail in a real scenario. In this paper we also propose a heuristic method for the treatment of social networking profiles. Our approach is compared with four gold standard collections for this task obtaining really competitive results, comparable to those obtained by some approaches with supervision.

1 Introduction

Resolving the ambiguity of person names in web search results is a challenging problem becoming an area of interest for Natural Language Processing (NLP) and Information Retrieval (IR) communities. This task can be defined informally as follows: given a query of a person name in addition to the results of a search engine for that query, the goal is to cluster the resultant web pages according to the different individuals they refer to. Thus, the challenge of this task is estimating the number of different individuals and grouping the pages of the same individual in the same cluster. The difficulty of this task resides in the fact that a single person name can be shared by many people: according to the U.S. Census Bureau, 90000 different names are shared by 100 million people (Artiles et al., 2007). This problem has had an impact in the Internet and that is why several vertical search engines specialized in web people search have appeared in the last years, e.g. `spokeo.com` or `123people.com`. This task should not be mixed up with *entity linking* (EL), which goal is to link name mentions of entities in a document collection to entities in a reference knowledge base (typically Wikipedia), or to detect new entities.

The main difficulties of clustering web pages referring to the same individual come from their possible heterogeneous nature. For example, some pages may be professional sites, while others may be blogs containing personal information. In addition, the popularity of social networking services makes the search engine usually returns several social profiles belonging to different individuals sharing the same name, as much from the same social networking service as from different services. These social pages often introduce noisy information and make the state of the art algorithms break down (Berendsen et al., 2012). Due to these problems, the users have to refine the queries with additional terms. This task gets harder when the person name is shared by a celebrity or a historical figure, because the results of the search engines are dominated by that individual, making the search of information about other individuals more difficult.

WePS[1] (Web People Search) evaluation campaigns proposed this task in a web searching scenario providing several corpora for evaluating the results of their participants, particularly WePS-1, WePS-2 and WePS-3 campaigns. This framework allows our approach to be compared with the state of the art

[1]http://nlp.uned.es/weps/

Proceedings of COLING 2014, the 25th International Conference on Computational Linguistics: Technical Papers, pages 301–310, Dublin, Ireland, August 23-29 2014.

systems. We also evaluate our system with ECIR2012 corpus[2], a data set that includes social networking profiles, providing a more real scenario for this task.

The most successful state of the art systems have addressed this problem with some kind of supervision. This work proposes a data-driven method for this task with the aim of eliminating the elements of human involvement in the process as much as possible. The main contribution of this work is a new unsupervised approach for resolving person name ambiguity of web search results based on the use of capitalized n-grams. In our approach the decision if two web pages have to be grouped only depends on the information of both pages. In addition, we also propose a heuristic method for the treatment of social media profile web pages in this context.

The paper is organized as follows: in Section 2 we discuss related work; Section 3 details the way we represent the web pages, the algorithm and the heuristic for social pages; in Section 4 we describe the collections used for evaluating our method and we show our results making a comparison with other systems; the paper ends with some conclusions and future work in Section 5.

2 Related Work

Several approaches have been proposed for clustering search results for a person name query. The main differences among all of them are the features they use to represent the web pages and the clustering algorithm. However, the most successful of them have in common that they use some kind of supervision: learning thresholds and/or fixing manually the value of some parameters according to training data.

Regarding the way of representing a web page, the most popular features used by the most successful state of the art approaches are Name Entities (NE) and Bag of Words (BoW) weighted by TF-IDF function. In addition to such features, the systems usually use other kind of information. Top systems from WePS-1 and WePS-2 campaigns, CU_COMSEM (Chen and Martin, 2007) and PolyUHK (Chen et al., 2009), distinguish several kind of tokens according to different schemes (URL tokens, title tokens, ...) and build a feature vector for each sort of tokens, using also information based on the noun phrases appearing in the documents. PolyUHK also adds pattern techniques, attribute extraction and detection when a web page is written in a formal way. A more recent system, HAC_Topic (Liu et al., 2011), also uses BoW of local and global terms weighted by TF-IDF. It adds a topic capturing method to create a Hit List of shared high weighted tokens for each cluster obtaining better results than WePS-1 participants. On the other hand, the WePS-3 best system, YHBJ (Chong and Shi, 2010), uses information extracted manually from Wikipedia adding to BoW and NE weighted by TF-IDF.

Regarding the clustering algorithms, looking at WePS campaigns results, the top ranked systems have in common the use of the Hierarchical Agglomerative Clustering algorithm (HAC) described in (Manning et al., 2008). Different versions of this algorithm were used by (Chen and Martin, 2007; Chen et al., 2009; Elmacioglu et al., 2007; Liu et al., 2011; Balog et al., 2009; Chong and Shi, 2010).

(Berendsen et al., 2012) presented another gold standard for this task, ECIR2012, composed by Dutch person names and social media profile web pages. The system of the authors, UvA, distinguishes the web pages between social ones and non social ones, clusters each group separately and then combines both clustering solutions. They represent each web page as a BoW vector weighted by TF-IDF, and use cosine similarity for comparing web pages. They use HAC algorithm for clustering non social web pages, while use a "one in one" policy for the social ones. Finally, they mix both groups by means of an algorithm which penalizes clusters with social webs or simply taking the union of both clustering solutions. They perform a partial parameter sweep on the WePS-2 data set to fix the clustering thresholds, while explore combinations of other system parameters.

The only system that does not use training data, DAEDALUS (Lana-Serrano et al., 2010), which uses k-Medoids, got poor results in WePS-3 campaign. In short, the successful state of the art systems need some kind of supervised learning using training data or fixing parameters manually. In this paper we explore and propose an approach to address this problem by means of data-driven techniques without the use of any kind of supervision.

3 Proposed Approach

We distinguish two main phases in this clustering task: web page representation (Sections 3.1 and 3.2) and web page grouping (Sections 3.3 and 3.4). In addition, we propose an heuristic to deal with social profiles web pages (Section 3.5).

3.1 Feature Selection

The aim of this phase is to extract relevant information that could identify an individual. We assume the main following hypotheses:

(i) Capitalized n-grams co-occurrence could be a reliable way for deciding when two web pages refer the same individual. Capitalized n-grams usually are Named Entities (organizations and company names, locations or other person names related with the individual) or information not detected by some NE recognizers as for example, the title of books, films, TV shows, and so on. In a previous study with WePS-1 training corpus using the Stanford NER[3] to annotate NE, we detected that only 55.78% of the capitalized tokens were annotated as NE or components of a NE by the NER tool. So the use of capitalized tokens allows increase the number of features compared to the use of only NE. We also compared the n-gram representation with capitalized tokens and with NE. We found that 30.97% of the 3-grams of capitalized tokens were also NE 3-grams, and 25.64% of the 4-grams of capitalized tokens were also NE 4-grams. So even in the case of n-grams the use of capitalized tokens increases the number of features compared to the use of only NE. Table 1 shows the differences in performance when using n-grams representation with NE or with capitalized tokens.

(ii) If two web pages share capitalized n-grams, the higher is the value of n, the more probable the two web pages refer to the same individual. In this case we define "long enough n-grams" as those compose by at least 3 capitalized tokens.

Thus, a web page W is initially represented as the sequence of tokens starting in uppercase, in the order as they appear in the web page. In each step of the algorithm, a web page W will be represented by its long enough n-grams, taking different values for n, as we describe in Section 3.4. Notice that some web pages could not be represented with this proposal because all their content was written in lowercase. In the case of the collections that we describe in Section 4.1, 0.63% of the web pages are not represented for this reason.

3.2 Weighting Functions

We test the well known TF and TF-IDF functions, and z-score (Andrade and Medina, 1998). The z-score of a n-gram a in a web page W_i is defined as follows: $z\text{-}score(a, W_i) = \frac{TF(a,W_i)-\mu}{\sigma}$, where $TF(a, W_i)$ is the frequency of the n-gram a in W_i; μ is the mean frequency of the background set; and σ is the standard deviation of the background set. In this context the background set is the set of web pages that share the person name. This score gives an idea of the distance of the frequency of an n-gram in a web page from the general distribution of this n-gram in the background set.

3.3 Similarity Functions

To determine the similarity between two web pages we try the cosine distance, a widely measure used in clustering, and the weighted Jaccard coefficient between two bags of n-grams defined as $W.Jaccard(W_i^n, W_j^n) = \frac{\sum_k min(m(t_{k_i}^n,i),m(t_{k_j}^n,j))}{\sum_k max(m(t_{k_i}^n,i),m(t_{k_j}^n,j))}$, where the meaning of $m(t_{k_i}^n, i)$ is explained in Section 3.4. Since weighted Jaccard coefficient needs non-negative entries and we want the cosine similarity of two documents to range from 0 to 1, we translate the values of the z-score so that they are always non-negative.

3.4 Algorithm

The algorithm $UPND$ (Unsupervised Person Name Disambiguator) can be seen in Algorithm 1. The description of this first algorithm does not take into account social profile web pages.

[3] http://nlp.stanford.edu/software/CRF-NER.shtml

$UPND$ algorithm receives as input a set of web documents with a mention to the same person name, let be $\mathcal{W} = \{W_1, W_2, \ldots, W_N\}$, and starts assigning a cluster C_i for each document W_i. $UPND$ also receives as input a pair of positive integer values r_1 and r_2, such that $r_2 \geq r_1$, specifying the range of values of n in the n-grams extracted from each web document. In each step of the algorithm we assign to each web page W_i a bag of n-grams $W_i^n = \{(t_1^n, m(t_1^n, i)), (t_2^n, m(t_2^n, i)), \ldots, (t_{k_i}^n, m(t_{k_i}^n, i))\}$, where each t_r^n is a n-gram extracted from W_i and $m(t_r^n, i)$ is the corresponding weight of the n-gram t_r^n in the web page W_i, being $r \in \{1, 2, \ldots, k_i\}$. In Algorithm 1 the function $setNGrams(n, \mathcal{W})$ in line 6 calculates for each web page in the set $\mathcal{W}$ its bag of n-grams representation. $Sim(W_i^n, W_j^n)$ in line 9 refers to the similarity between web pages W_i and W_j.

To decide when two web pages refer the same individual we propose a threshold γ. For each pair of web pages represented as bag of n-grams, let be W_i^n and W_j^n, we compute the threshold as follows: $\gamma(W_i^n, W_j^n) = \frac{min(m,k) - shared(W_i^n, W_j^n)}{max(m,k)}$, where m and k are the number of n-grams of W_i and W_j respectively, and $shared(W_i^n, W_j^n)$ is the number of n-grams shared by those web pages i.e. $shared(W_i^n, W_j^n) = |W_i^n \cap W_j^n|$. Notice that $shared(W_i^n, W_j^n)$ is superiorly limited by $min(m, k)$.

This threshold holds two desirable properties: (i) The more n-grams are shared by W_i and W_j, the lower $\gamma(W_i^n, W_j^n)$ is, so the clustering condition of the algorithm is less strict. (ii) It avoids the penalization due to big differences between the size of the web pages.

Thus, we decide that two web pages W_i and W_j refer to the same person if $Sim(W_i^n, W_j^n) \geq \gamma(W_i^n, W_j^n)$, so $C_i = C_i \cup C_j$ (lines 9, 10 and 11).

We assume that we can get accurate and reliable information for disambiguating with n-grams of at least size 3. Thus, we propose to iterate this process for 3-grams and 4-grams, i.e. $UPND(\mathcal{W}, 3, 4)$. We consider that selecting a value of n grater than 4 could lead to find few n-grams, so that many web pages could be under-represented. On the other hand, previous experiments using also bigrams showed that they are not suitable for this approach. This algorithm is polynomial and has a computational cost in $\mathcal{O}(N^2)$, where N is the number of web pages.

Algorithm 1 $UPND(\mathcal{W}, r_1, r_2)$

Require: Set of web pages that shared a person name $\mathcal{W} = \{W_1, W_2, ..., W_N\}$, $r_1, r_2 \geq 1$ such that $r_2 \geq r_1$

Ensure: Set of clusters $\mathcal{C} = \{C_1, C_2, ..., C_l\}$

1: **for** $n = 1$ **to** N **do**
2: $C_i = \{W_i\}$
3: **end for**
4: $\mathcal{C} = \{C_1, C_2, ..., C_N\}$.
5: **for** $n = r_1$ **to** r_2 **do**
6: $setNGrams(n, \mathcal{W})$.
7: **for** $i = 1$ **to** N **do**
8: **for** $j = i + 1$ **to** N **do**
9: **if** $Sim(W_i^n, W_j^n) \geq \gamma(W_i^n, W_j^n)$ **then**
10: $C_i = C_i \cup C_j$
11: $\mathcal{C} = \mathcal{C} \setminus \{C_j\}$
12: **end if**
13: **end for**
14: **end for**
15: **end for**
16: **return** $\mathcal{C}$

3.5 Social Media Treatment

Social networking services have increased their popularity and number of users in the last years. This fact affects this task mainly in two ways. On one hand, as a result of the success of this kind of platforms,

a lot of web pages contain terms related to them (e.g. the name of these platforms: Twitter, Facebook, LinkedIn, etc.). On the other hand, for a person name query in a search engine, it usually returns several profiles of such person name that are as much in the same as in different social networking services. These profiles usually are from different people sharing the same name, so they should be in different clusters. Most of the methods of the state of the art do not take into account this fact, usually taking as features tokens from the URL or the title of each web page, which includes the name of these platforms. This practice could lead to add noise to the representation of the web pages.

(Berendsen et al., 2012) proposed the "one in one" baseline to deal with social platform web pages, which creates a singleton cluster for each social web page. However, its main disadvantage is that it does not consider that a same individual could have accounts in several social platforms. A search engine could also return web pages from a social platform which are not profiles, as for example, a group page of Facebook where a person expounds an opinion, in addition to the profile of the same individual in that social platform. In these cases the "one in one" baseline also fails.

We propose a heuristic method that takes into account the limitations of the "one in one" heuristic, letting group social web pages from different platforms and also cluster social web pages from the same social platform. The algorithm that implements our heuristic is $SUPND$ (Social UPND). This algorithm applies $UPND$ with the following restriction: two web pages assigned to the same social networking service cannot be compared. This policy is taken because when a search engine returns several links from the same social platform, they usually refer to different individuals. However, this does not necessarily imply that two web pages belonging to the same social site cannot belong to the same cluster, because they would be compared to other webs pages separately, possibly ending up in the same cluster in a transitive way. For example, giving two web pages from Facebook, let be FB_1 and FB_2, and a non-social web page W, then FB_1 and FB_2 would not be compared, however each FB_i would be compared with W. If $SUPND$ decides to cluster each FB_i with W, then finally both web pages, from the same platform, would be in the same cluster. To identify the social web pages we obtain a list of social media platforms from Wikipedia[4], so when looking at the URL of a web page, we can detect if it corresponds to any of those social media platforms. If it is the case, we assign to that web page its social media site. The computational cost of $SUPND$ is the same of $UPND$.

4 Experiments

In this section we present the corpora of web pages used, the preprocessing of each web page, the experiments carried out and the obtained results.

4.1 Web People Search Collections

WePS is a competitive evaluation campaign that proposes several tasks including resolution of disambiguation on the Web data. In particular, WePS-1, WePS-2 and WePS-3 campaigns provide an evaluation framework consisting in several annotated data sets composed of English person names.

In these experiments we use WePS-1 (Artiles et al., 2007) test corpus composed by 30 English person names and the top 100 search results from Yahoo! search engine; WePS-2 (Artiles et al., 2009a) containing 30 person names and the top 150 search results from Yahoo! search engine; and WePS-3 (Artiles et al., 2010) containing 300 person names and the top 200 search results from Yahoo! All WePS corpora have few social profile web pages, so the impact of this kind of pages in the results of the algorithms is insignificant. We also use the ECIR2012 corpus, which is composed by 33 Dutch person names selected from query logs of a people search engine. For each person name the web pages set is built retrieving several profiles from social media platforms as Facebook, Twitter or LinkedIn, and results returned by Google, Bing and Yahoo! search engines. This data set gives a more real scenario for this task than the WePS ones, because it includes social network profiles of several person sharing the same name.

[4] en.wikipedia.org/wiki/Category:Social_networking_services

4.2 Corpus Preprocessing

Given a person name and a set of web pages, we first discard web pages that do not mention such name using several patterns that take into account the usual structure of person names.

For each not discarded web page, we delete the name and the surname because they appear in all the remaining documents and are the object of the ambiguity. We also delete stop words.

4.3 Results and Discussion

We present our results for all the corpora comparing them with the state of the art systems. The figures in the tables are macro-averaged, i.e., they are calculated for each person name and then averaged over all test cases. For WePS data sets we get the same results for $UPND$ and $SUPND$ algorithms, because these collections include few social networking profiles. The metrics used in this section are the BCubed metrics defined in (Bagga and Baldwin, 1998): BCubed precision (BP), BCubed recall (BR) and their harmonic mean $F_{0.5}(BP/BR)$. (Artiles, 2009) showed that these metrics are accurate for clustering tasks, particularly for person name disambiguation in the Web. We use the Wilcoxon test (Wilcoxon, 1945) to detect statistical significance in the differences of the results considering a confidence level of 95%. In order to compare our algorithm with the WePS better results using the Wilcoxon test, the samples consist in the pairs of values $F_{\alpha=0.5}(BP/BR)$ of each system for each person name.

First, Table 1 shows the results of $UPND$ using n-grams of capitalized tokens and n-grams of NE with WePS-1 training corpus. Experiments include the three weighting functions and the two similarity functions. The results of using n-grams of NE rank below those obtained with n-grams of capitalized tokens in all cases. The Wilcoxon test comparing the results of both representations shows that there are significant differences between them, except TF and TF-IDF with cosine. So we can conclude that in our approach using n-grams of capitalized tokens outperforms the use of n-grams of NE, what confirms our hypothesis.

	TF		z-score		TF-IDF	
Representation	W. Jaccard	Cosine	W. Jaccard	Cosine	W. Jaccard	Cosine
Capitalized n-gram	**0.82**	**0.69**	**0.83**	**0.78**	**0.81**	**0.63**
NE (Stanford NER)	0.77	0.6	0.77	0.72	0.76	0.6

Table 1: $F_{0.5}(BP/BR)$ results of $UPND$ algorithm comparing capitalized n-gram and NE n-gram representations with WePS-1 training corpus.

In Table 2 we show the results of $UPND$ for all WePS test data sets with the three weighting functions and the two similarity measures.

		WePS-1			WePS-2			WePS-3		
		BP	BR	$F_{0.5}$(BP/BR)	BP	BR	$F_{0.5}$(BP/BR)	BP	BR	$F_{0.5}(BP/BR)$
W. Jaccard	TF	0.73	0.77	0.74	0.82	0.82	**0.81**	0.46	0.70	0.50
	z-score	0.70	0.78	0.72	0.80	0.84	**0.81**	0.44	0.72	0.50
	TF-IDF	0.73	0.77	0.73	0.82	0.82	**0.81**	0.46	0.70	0.50
Cosine	TF	0.92	0.61	0.72	0.95	0.61	0.73	0.75	0.45	0.51
	z-score	0.85	0.69	**0.76**	0.91	0.73	**0.81**	0.62	0.56	**0.53**
	TF-IDF	0.94	0.57	0.7	0.96	0.52	0.65	0.79	0.40	0.49

Table 2: Results of $UPND$ algorithm for WePS test data sets.

The combination of z-score with cosine gets the best balance between the values of BP and BR, reaching the highest results of $F_{\alpha=0.5}$ for the three WePS corpora. The combination of TF-IDF with cosine gets the best BP results, but BR results are the lowest. On the other hand, the combination of z-score and Jaccard gets the best BR results, but the BP results are the lowest.

Regarding the significance of the differences between the best results, the improvement between z-score with cosine and z-score with Jaccard is significant in WePS-1 and WePS-3, but not in WePS-2. The improvement between z-score with cosine and Jaccard with TF is significant only in WePS-3.

Thus, we select the combination of z-score as weight function and cosine as similarity function as the most suitable combination for our algorithm. Therefore we use it in the following experiments.

Table 3 shows the results of $UPND$ with WePS-1 test, WePS-2 and WePS-3 corpora in addition to the top ranking systems of the campaigns, and also the results obtained by HAC_Topic system in the case of WePS-1. We include the results obtained by three unsupervised baselines called ALL_IN_ONE, ONE_IN_ONE and Fast AP. ALL_IN_ONE provides a clustering solution where all the documents are assigned to a single cluster, ONE_IN_ONE returns a clustering solution where every document is assigned to a different cluster, and Fast AP applies a fast version of Affinity Propagation described in (Fujiwara et al., 2011) using the function TF-IDF to weight the tokens of each web page, and the cosine distance to compute the similarity.

	System	BP	BR	$F_{0.5}(BP/BR)$

Table 3: Results of $UPND$ and the top state of the art systems with WePS corpora: (+) means system with supervision; (-) without supervision and (*) campaign participant. Significant differences between $UPND$ and other systems are denoted by (†); (•) means that in this case the statistical significance is not evaluated.

Our method $UPND$ outperforms WePS-1 participants and all the unsupervised baselines described before. HAC_Topic also outperforms the WePS-1 top participant systems and our algorithm. This system uses several parameters obtained by training with the WePS-2 data set: token weight according to the kind of token (terms from URL, title, snippets, ...) and thresholds used in the clustering process. Note that WePS-1 participants used the training corpus provided to the campaign, the WePS-1 training data, so in this case the best performance of HAC_Topic could be not only because of the different approach, but also because of the different training data set.

Our algorithm obtains significative better results than the WePS-1 top participant results, and HAC_Topic obtains significative better results than it according to the Wilcoxon test. $UPND$ obtains significative better results than IRST-BP system (the third in the WePS-1 ranking), also based on the co-ocurrence of n-grams.

Regarding WePS-2 we add in Table 3 two oracle systems provided by the organizers. These systems use BoW of tokens (ORACLE_1) or bigrams (ORACLE_2) weighted by TF-IDF, deleting previously stop words, and later apply HAC with single linkage with the best thresholds for each person name. We do not include the results of the HAC_Topic system since it uses this data set for training their algorithm.

The significance test shows that the top WePS-2 systems PolyUHK, UVA_1 and ITC-UT_1 obtain

similar results than $UPND$, however they use some kind of supervision. The results of all these systems are the closest to the oracle systems provided by the organizers, which know the best thresholds for each person name.

In the case of WePS-3, the organizers did not take into account the whole clustering solution provided by the systems like in previous editions, but only checks the accuracy of the clusters corresponding to two selected individuals per person name. In this case, the first two systems YHBJ_2 and $UPND$ do not have significant difference in their results. Notice that YHBJ_2 system makes use of concepts extracted manually from Wikipedia. Note that $UPND$ also obtains significative better results than DAEDALUS_3, the only one participant that does not use training data.

Regarding the experiments with the ECIR2012 corpus, which contains social profiles, Table 4 shows the results of the two versions of our algorithm and the results of the system of the University of Amsterdam (UvA). As far as we know, no other systems have been tested with this gold standard. $SUPND$ obtains significative better results than $UPND$ due to its special treatment for social web pages. The UvA system outperforms our algorithm $SUPND$ and this improvement is significative. Note that the heuristic for social pages in $SUPND$ outperforms $UPND$ using the "one in one" heuristic.

System	BP	BR	$F_{0.5}(BP/BR)$
(+) UvA (best perf.)	0.90	0.80	**0.83** †
(-) $SUPND$	0.95	0.68	0.78 •
(-) $UPND$ (one in one)	0.98	0.62	0.74 †
(-) $UPND$	0.74	0.74	0.72 †

Table 4: Results of $SUPND$ and $UPND$ algorithms for ECIR2012 corpus: (+) means system with supervision and (-) without supervision. Significant differences between $SUPND$ and other systems are denoted by (†); (•) means that in this case the statistical significance is not evaluated.

After all these experiments, we can conclude that our approach gets the best results of all the completely unsupervised approaches. Moreover, the precision scores for all collections are very high and confirm that our approach is accurate to get relevant information for characterizing an individual. We also obtain competitive recall results, what lead to a competitive system that carries out person name disambiguation in web search results with minimum human supervision.

5 Conclusions and Future Work

We present a new approach for person name disambiguation of web search results. Our method does not need training data to calculate thresholds to determine the number of different individuals sharing the same name, or whether two web pages refer to the same individual or not. Although supervised approaches have been successful in many NLP and IR tasks, they require enough and representative training data to guaranty the results will be consistent for different data collections, which requires a huge human effort.

The two algorithms proposed provide a clustering solution for this task by means of data-driven methods that do not need learning from data. Our approach is not very expensive in computational cost, obtaining very competitive results in several data sets compared with the best state of the art systems.

Our proposal is based on getting reliable information for disambiguating, particularly long n-grams composed by uppercase tokens. According to our results, this hypothesis has shown successful, getting high precision values and acceptable recall scores. Anyway, we would like to improve recall results without losing of precision, filter out noisy capitalized n-grams, and build an alternative representation for web pages containing all their tokens in lowercase.

We have observed that this task gets harder when we have to deal with social media profiles. A system thought for being used in a real scenario has to take into account this kind of web pages, since they are usually returned by search engines when a user introduces a person name as a query. Most state of the art systems do not deal with this problem. We have proposed in this paper a new heuristic method for processing social platforms profiles for this clustering task.

Person name disambiguation has been mainly addressed in a monolingual scenario, e.g. WePS corpora are English data sets and Dutch the ECIR2012 collection. We would like to address this task in a multilingual scenario. Although search engines return their results taking into account the country of the user, with some queries we can get results written in several languages. This scenario has not been considered by the state of the art systems so far.

Abstract

Results from psychology show a connection between a speaker's expertise in a task and the language he uses to talk about it. In this paper, we present an empirical study on using linguistic evidence to predict the expertise of a speaker in a task: playing chess. Instructional chess literature claims that the mindsets of amateur and expert players differ fundamentally (Silman, 1999); psychological science has empirically arrived at similar results (e.g., Pfau and Murphy (1988)). We conduct experiments on automatically predicting chess player skill based on their natural language game commentary. We make use of annotated chess games, in which players provide their own interpretation of game in prose. Based on a dataset collected from an online chess forum, we predict player strength through SVM classification and ranking. We show that using textual and chess-specific features achieves both high classification accuracy and significant correlation. Finally, we compare our findings to claims from the chess literature and results from psychology.

1 Introduction

It has been recognized that the language used when describing a certain topic or activity may differ strongly depending on the speaker's level of expertise. As shown in empirical experiments in psychology (e.g., Solomon (1990), Pfau and Murphy (1988)), a speaker's linguistic choices are influenced by the way he thinks about the topic. While writer expertise has been addressed previously, we know of no work that uses linguistic indicators to rank experts.

We present a study on predicting chess expertise from written commentary. Chess is a particularly interesting task for predicting expertise: First, using data from competitive online chess, we can compare and rank players within a well-defined ranking system. Second, we can collect textual data for experimental evaluation from web resources, eliminating the need for manual annotation. Third, there is a large amount of terminology associated with chess, which we can exploit for n-gram based classification.

Chess is difficult for humans because it requires long-term foresight (*strategy*) as well as the capacity for internally simulating complicated move sequences (*calculation* and *tactics*). For these reasons, the game for a long time remained challenging even for computers. Players have thus developed general principles of chess strategy on which many expert players agree. The dominant expert view is that the understanding of fundamental strategical notions, supplemented by the ability of calculation, is the most important skill of a chess player. A good player develops a long-term *plan* for the course of the game. This view is the foundation of many introductory works to chess (e.g., Capablanca (1921), one of the earliest works).

Silman (1999) presents games he played with chess students, analyzing their commentary about the progress of the game. He claims that players who fail to adhere to the aforementioned basic principles tend to perform worse and argues that the students' thought processes reflect their playing strength directly. Lack of strategical understanding marks the difference between amateur and expert players. Experts are mostly concerned with *positional* aspects, i.e., the optimal placement of pieces that offers a

Proceedings of COLING 2014, the 25th International Conference on Computational Linguistics: Technical Papers, pages 311–321, Dublin, Ireland, August 23-29 2014.

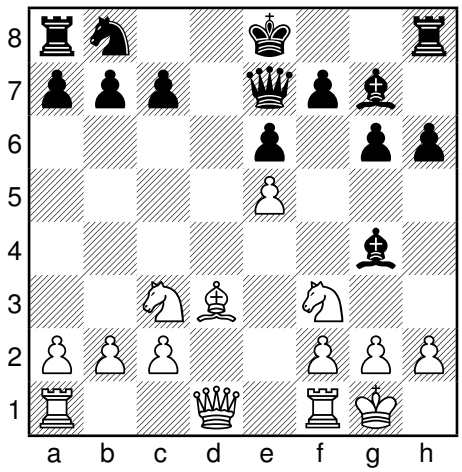

Figure 1: Example chess position, white to play

long-lasting advantage. Amateurs often have *tactical* aspects in mind, i.e., short-term attacking opportunities and exploits that potentially lead to loss of material for their opponents. A correlation between chess strength and verbalization skills has been shown empirically by Pfau and Murphy (1988), who used experts to assess the quality of the subjects' writing.

In this paper, we investigate the differences between the mindset of amateurs and experts expressed in written game commentary, also referred to as *annotated games*. When studying chess, it is best practice to review one's own games to further one's understanding of the game (Heisman, 1995). Students are encouraged to *annotate* the games, i.e., writing down their thought process at each move. We address the problem of predicting the player's strength from the text of these annotations. Specifically, we want to predict the rank of the player at the point when a given game was played. In competitive play, the rank is determined through a numerical rating system – such as the Elo rating system (Elo, 1978) used in this paper – that measures the players' relative strength using pairwise win expectations.

This paper makes the following contributions. First, we introduce a novel training dataset of games annotated by the players themselves – collected from online chess forum. We then formulate the task of playing strength prediction. For each annotated game, each game viewed as a document, we predict the rating class or overall rank of the player. We show that (i) an SVM model with n-gram features succeeds at partitioning the players into two rating classes (above and below the mean rating); and (ii) that ranking SVMs achieve significant correlation between the true and predicted ranking of the players. In addition, we introduce novel chess-specific features that significantly improve the results. Finally, we compare the predictions made by our model to claims from instructional chess literature and results from psychology research.

We next give an overview of basic chess concepts (Section 2). Then, we introduce the dataset (Section 3) and task (Section 4). We present our experimental results in Section 5. Section 6 contains an overview of related work.

2 Basic Chess Concepts

2.1 Chess Terminology

We assume that the reader has basic familiarity with chess, its rules, and the value of individual pieces. For clarity, we review some basic concepts of chess terminology, particularly elementary concepts related to tactics and strategy in an example position (Figure 1).[1]

From a *positional* point of view, white is ahead in *development*: all his *minor pieces* (bishops and knights) have moved from their starting point while black's knight remains on b8. White has also *castled* (a move where the rook and king move simultaneously to get the king to a safer spot on either side of the board) while black has not. White has a *space* advantage as he occupies the e5-square (which is in black's

[1]Modified from the game Dzindzichashvili – Yermolinsky (1993) which is the first position discussed in (Silman, 1999)

1.e4 e5 2.Nf3 Nc6 3.Bc4 Nh6 4.Nc3 Bd6 Trying to follow basic opening principals, control center, develop. etc **5.d3 Na5 6.Bb5** Moved bishop not wanting to trade, but realized after the move that my bishop would be harassed by the pawn on c7 **6...c6 7.Ba4** Moved bishop to safety, losing tempo **7...Qf6 8.Bg5 Qg6 9.O-O b5** Realized my bishop was done, might as well get 2 pawns **10.Nxb5 cxb5 11.Bxb5 Ng4 12.Nxe5** Flat out blunder, gave up a knight, at least I had a knight I could capture back **12...Bxe5 13.Qxg4 Bxb2 14.Rab1 Bd4 15.Rfe1** Moved rook to E file hoping to eventually attack the king. **15...h6 16.c3** Poor attempt to move the bishop, I realized it after I made the move **16...Bxc3 17.Rec1 Be5 18.d4** Another crappy attempt to move that bishop **18...Bxd4 19.Rd1 O-O 20.Rxd4 d6 21.Qd1** I don't remember why I made this move. **21...Qxg5 22.Rxd6 Bh3 23.Bf1** Protecting g2 **23...Nc4 24.Rd5 Qg6 25.Rc1 Qxe4 26.f3 Qe3+ 27.Kh1 Nb2 28.Qc2 Rac8 29.Qe2 Qxc1 30.gxh3 Nc4 31.Qe4 Qxf1#**

Figure 2: Example of an annotated game from the dataset (by user aevans410, rated 974)

half of the board) with a pawn. This pawn is potentially *weak* as it cannot easily be defended by another pawn. Black has both of his bishops (the *bishop pair*) which is considered advantageous as bishops are often superior to knights in open positions. Black's light-square bishop is *bad* as it is obstructed by black's own pawns (although it is outside the *pawn chain* and thus flexible). *Strategically*, black might want to improve the position of the light-square bishop, make use of his superior dark-square bishop, and try to exploit the weak e5 pawn. Conversely, white should try create posts for his knights in black's territory. *Tactically*, white has an opportunity to move his knight to b5 (written Nb5 in algebraic chess notation), from where it would attack the pawn on c7. If the knight could reach c7 (currently defended by black's queen), it would *fork* (*double attack*) black's king and rook, which could lead to the trade of the knight for the rook on the next move (which is referred to as winning the *exchange*). White's knight on f3 is *pinned*, i.e., the queen would be lost if the knight moved. Black can win a pawn by *removing the defender* of e5, the knight on f3, by capturing it with the bishop.

This brief analysis of the position shows the complex theory and terminology that has developed around chess. The paragraph also shows an example of game annotation (although not every move in the game will be covered as elaborately in practice in amateur analyses).

2.2 Elo Rating System

Our goal in this paper is to predict the ranking of chess players based on their game annotations. We will give a brief overview of the Elo system (Elo, 1978) that is commonly used to rank players. Each player is assigned a score that is changed after each game depending on the expected and actual outcome. On `chess.com`, a new player starts with an initial rating of 1200 (an arbitrary number chosen for historical reasons, which has since become a wide-spread convention in chess). Assuming the current ratings R_a and R_b of two players a and b, the expected outcome of the game is defined as

$$E_a = \frac{1}{1 + 10^{-\frac{R_a - R_b}{400}}}.$$

E_a is then used to conduct a (weighted) update of R_a and R_b given the actual outcome of the game. Thus, Elo ratings make pairwise adjustments to the scores. The differences between the ratings of two players predict the probability of one winning against the other. However, the absolute ratings do not carry any meaning by themselves.

3 Annotated Chess Game Data

For supervised training, we require a collection of chess games annotated by players of various strengths. An annotated chess game is a sequence of chess moves with natural language text commentary associated to specific moves. While many chess game collections are available, some of them containing millions of games, the majority are unannotated. The small fraction of annotated games mostly features commentary by masters rather than amateurs, which is not interesting for a contrastive study.

The game analysis forum on `chess.com` encourages players to post their annotated games for review through the community. While several games are posted each day, we can only use a small subset of them.

Parameter	Value
# games	182
# different players	130
mean # moves by game	42
mean # annotated moves by game	16
mean # words by game	114

Table 1: Dataset statistics

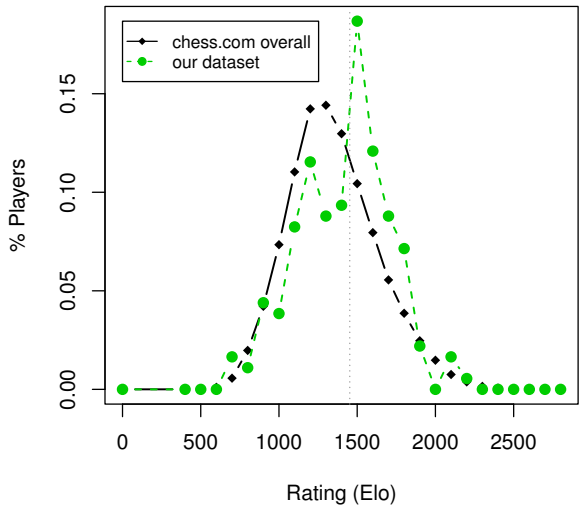

Figure 3: Rating distribution on `chess.com` and our dataset.[4] Each point shows the percentage of players in a bin of width 50 around the value. Dotted line: Median on our dataset used for binning.

Many games are posted without annotations, instead soliciting annotation from the community. Others are missing the rating of the player at the time the game was played – the user profile shows only the current rating for the player which may differ strongly from their historical one.

We first downloaded all available games from the forum archive. The games are stored in portable game notation (PGN, Edwards (1994)). Next, we manually removed games where the annotation had been conducted automatically by a chess program. We also removed games that had annotations at fewer than three moves. The final dataset consists of 182 games with annotations in English and known player rating.[2] We reproduce an example game from the data in Figure 2. This game is typical as the first couple of moves are not commented (as opening moves are typically well-known). Then, the annotator comments on select moves that he believes are key to the progress of the game. Table 1 shows some statistics about the dataset.

The distribution of the ratings in our dataset is shown in Figure 3 in comparison to the overall standard chess rating distribution on `chess.com`.[3] Elo ratings assume a normal distribution of players. We see that overall, the distributions are quite similar, although we have a higher peak and our sample mean is shifted towards higher ratings (1347 overall vs 1462 on our dataset). It is more common for mid-level players to request annotation advice than it is for low-rated players (who might not know about this practice) or high-rated players (who do not look for support by the lower-rated community).

The dataset is still somewhat noisy as players may obtain different ratings depending on the type of venue (over-the-board tournament vs online chess) or the amount of time the players had available (*time control*). Differences in these parameters lead to different rating distributions.[4] For this reason, the total ordering given through the ratings may be difficult to predict. Thus, we will conduct experiments both

on ranking and on classification where the rating range is binned into two rating classes.

4 Predicting Chess Strength from Annotations

4.1 Classification and Ranking

The task addressed in this paper is prediction on the game level, i.e., predicting the strength of the player of each game at the time when the game was played. We view a game as a document – the concatenation of the annotations at each move – and extract feature vectors as described in Section 4.2. We pursue two different machine learning approaches based on support vector machines (SVMs) to predicting chess strength: classification and ranking.

The simplest way to approach the problem is classification. For this purpose, we divide the range of observed rating into two evenly spaced rating classes at the median of the overall rating range (henceforth *amateur* and *expert*). The classification view has obvious disadvantages. At the boundaries of the bins, the distinction between them becomes difficult.

To predict a total ordering of all players, we use a ranking SVM (Herbrich et al., 1999). This model casts ranking as learning a binary classification function that decides whether $\mathit{rank}(\mathbf{x_1}) > \mathit{rank}(\mathbf{x_2})$ over all possible pairs of example feature vectors $\mathbf{x_1}$ and $\mathbf{x_2}$ with differing *rank*.

Note that since Elo ratings are continuous real numbers, it would be conceivable to fit a regression model. However, Elo is designed as a pairwise ranking measure. While a relative difference in Elo represents the probability of one player beating the other, the absolute Elo rating is not directly interpretable.[5]

4.2 Features

We extract unigrams (UG) and bigrams (BG) from the texts. In addition, we propose the following two chess-specific feature sets derived from the text:[6]

Notation (NOT). We introduce two indicators for whether the annotations contain certain types of formal chess notation. The feature SQUARE is added if the annotation contains a reference to a specific square on the chess board (e.g., *d4*). If the annotation contains a move in algebraic notation (e.g., *Nxb4+*, meaning that a knight moved to b4, captured a piece there and put the enemy king in check), the feature MOVE is added.

Similarity to master annotations (MS). This feature is intended to compensate for the lack of training data. We used a master-annotated database consisting of 500 games annotated by chess masters which is available online.[7] As we do not know the exact rating of the annotators, and to avoid strong class imbalances, we cannot make use of the games directly through supervision. Instead, we calculate the cosine similarity between the centroid[8] of the n-gram feature vectors of the master games and each game in the `chess.com` dataset. The cosine similarity between each game and the master centroid is added as a numerical feature.

Additionally, the master similarity scores can be used on their own to rank the games. This can be viewed distant supervision as strength is learned from an external database. We will evaluate this ranking in comparison with our trained models.

5 Experiments

This section, contains experimental results on classifying and ranking chess players. We first present quantitative evaluation of the classification and ranking models and discuss the effect of chess-specific

[5]Preliminary experiments with SVM regression showed little improvements over a baseline of assigning the mean rating to all games. This suggests that the distribution of rankings is difficult to model – possibly due to the low number of annotated games on which the model can be trained.

[6]We also tried using the length of the annotation as well as the number of annotated moves as a feature, which did not contribute any improvements.

[7]`http://www.angelfire.com/games3/smartbridge/famous_games.zip`

[8]We also tried a k-NN approach where we computed the mean similarity of a game from our dataset to its k nearest neighbors among the master games ($k \in 1, 2, 5, \infty$), but found that this approach performed worse.

	Model	Features	$F_1^{(\downarrow)}$	$F_1^{(\uparrow)}$	$F_1^{(\varnothing)}$

features. Second, we qualitatively compare the predictions of our models with findings and claims from the literature about the connection between a player's mindset and strength.

5.1 Experimental Setup

To generate feature vectors, we first concatenate all the annotations for a game, tokenize and lowercase the texts, and remove punctuation as well as a small number of stopwords. We exclude rare words to avoid overfitting: We remove all n-grams that occur fewer than 5 times, and add the chess-specific features proposed above. Finally, we L_2-normalize each vector.

We use linear SVMs from LIBLINEAR and SVMs with RBF kernel from LIBSVM (Chang and Lin, 2011). We run all experiments in a 10-fold cross-validation setup.

We measure macro-averaged F_1 for our classification results. We evaluate the ranking model using two measures: pairwise ranking accuracy (Acc_r), i.e., the accuracy over the binary ranking decision for each player pair; and Spearman's rank correlation coefficient ρ for the overall ranking. To test whether differences between results are statistical significant, we apply approximate randomization (Noreen, 1989) for F_1, and the test by Steiger (1980) for correlations, which is applicable to ρ.

5.2 Classification

We first investigate the classification case, i.e., whether we can distinguish players below and above the rating mean. Table 2 shows the results for this experiment. We show F_1 scores for the lower and higher half of the players ($F_1^{(\downarrow)}$ and $F_1^{(\uparrow)}$, respectively), and the macro average of these two scores ($F_1^{(\varnothing)}$). We first note that all SVM classifiers (lines 2–5) score significantly higher than the majority baseline (line 1). When adding bigrams (line 3) and chess-specific notation features (line 4), F_1 increases. However, these improvements are not statistically significant. The master similarity feature (line 5) leads to a drop in F_1 from the previous line. The relatively low rank correlation between the master similarity scores and the two classes ($\rho = 0.334$) leads to this effect. The low correlation itself may occur because the master games were annotated by a third party (instead of the players), leading to strong differences in style.

There are several reasons for misclassification. Many errors occur in the dense region around the class boundary. Also, shorter game annotations are more difficult to classify than longer ones. For detailed error analysis, we first examine the most positively and negatively weighted features of the trained models (Table 3). We will provide a more detailed look into the features in Section 5.4. We

find that there are noticeable differences in the writing styles of amateurs and experts. According to the model, one of the most prominent distinctions is that amateurs tend to refer to the opponent as *he*, whereas experts use *white* and *black* more frequently. However, it is of course not universally true, which leads to the misclassification of some experts as amateurs. Another difference in style is that amateur players tend to write about the game in the past tense. This is a manifestation of an important distinction: Amateurs often state the obvious developments of the game (e.g., *Flat out blunder, gave up a knight* in Figure 2) or speculate about options (e.g., *hoping to eventually attack*), while experts provide more thorough positional analysis at key points.

5.3 Ranking

We now turn to ranking experiments (Table 4). We first evaluate the ranking produced by ordering the games by their similarity to the master centroid (line 1). We find that the resulting rank correlation is low but significant.

The results for the linear SVM ranker are shown in lines 2–5. Total ranking is considerably more difficult than binary classification of rating classes. Using a linear SVM, we again achieve low but significant correlations. The linear classifiers (lines 2–5) do not significantly outperform the standalone master similarity (MS) baseline (line 1). Chess-specific features (lines 4 and 5) boost the results, outperforming the bigram models (line 3) significantly. The improvement from adding the MS centroid score feature is not significant.

We again perform error analysis by examining the feature weights (Table 5). We find an overall picture similar to the classification setup (cf. Table 3). The notation feature serves as a good indicator for the upper rating range (cf. Table 3) as experienced players find it easier to express themselves through notation. We observed that lower players tend to express moves in words (e.g., "move my knight to d5") rather than through notation (Nd5), which could serve as an explanation for why pieces (*bishop*, *knight*, *rook*) appear among the top features for amateur players.

However, some features change signs between the two experiments (e.g., *king*, *square*). This effect may indicate that the binary ranking problem is not linearly separable, which is plausible; mid-rated players may use terms that neither low-rated nor high-rated players use. Examining correlations at different ranking ranges confirms this suggestion. In top and bottom thirds of the rating scale, the true and predicted ranks are not correlated significantly. This means that the ranking SVM only succeeds at ranking players in middle third of the rating scale. To introduce non-linearity, we conduct further experiments with an SVM with a radial basis function (RBF) kernel.

The results of this experiment are shown in lines 6–9 of Table 4. All RBF models perform better than

the unigram and bigram linear models; all except for the unigram model (lines 7–9) also yield weakly significant improvements over the MS baseline. Adding the notation features (line 8 improves the results and leads to improvements with stronger significance. The RBF kernel makes feature weight analysis impossible, so we cannot perform further error analysis.

5.4 Comparing the Learned Models and Strength Indicators from the Chess Literature

There are many conjectures from instructional chess literature and results from psychological research about various aspects of player behavior. In this section, we compare these to the predictions made by our supervised expertise model. In Table 6, we list selected weights from the best classification model (line 3 in Table 2). We opt for analzying the classifier rather than the ranker as we find the former more directly interpretable.

Long-Term vs Short-Term Planning. The SVM model reflect the short-term nature of the amateurs' thoughts in several ways: (i) Amateurs focus on specific moves rather than long-term plans, and thus, terms like *capture* and *take* are deemed predictive for lower ratings. (ii) Amateurs often think piece-specific (Silman, 1999), particularly about moves with minor pieces (*bishop* or *knight*), and these terms receive high negative weights, pointing to lower ratings. Related to this, Reynolds (1982) observed that amateurs often focus on the current location of a piece, whereas experts mostly consider possible future locations. The SVM model learns this by weighting bigrams of the form * *on*, where * is a piece, as indicators for low ratings. (iii) Many terms related to elementary tactics (e.g., *pin*, *fork*) indicate lower-rated players, whereas terms relating to tactical foresight (e.g., *threat*, *danger*, *stop*) as well as positional terms (e.g., *weakness*, *light* and *dark* squares, *variation*) indicate higher-rated players.

Emotions. A popular and wide-spread claim is that weaker chess players often lose because they are too emotionally invested in the game and thus get carried away (e.g., Cleveland (1907), Silman (1999)). We experimented with a sentiment feature, counting polar terms in the annotations using a polarity lexicon (Wilson et al., 2005). However, this feature did not improve our results.

Manual examination of features expressing sentiment reveals that both amateurs and experts use subjective terms. We note that the vocabulary of subjective expressions is very constrained for stronger

players while it is open for weaker ones. Expert players tend to assess positions as *winning* or *losing* for a side, whereas weaker players tend to use terms such as *like* and *hate*. Both terms are identified as indicators of the respective strength class in our models. Other subjective assessments (e.g., *good* and *bad*) are divided among the classes. Emotional tendencies of amateurs can also be observed through objective indicators. As discussed above, stronger players talk about the game with a more distanced view, often referring to their opponent by their color (*white* or *black*) rather than using the pronoun *he*. Lower-rated players appear to use terms indicating competitions more frequently, such as *fight*.

Confidence. Silman (1999) argues that weaker players lack confidence, which leads to them losing track of their own plans and to eventually follow their opponent's will (often called *losing the initiative*). This process is indeed captured by our trained models. Terms of high confidence (such as *know*, *will*) are weighted towards the stronger class, whereas terms with higher uncertainty (such as *thinking*, *believe*, *maybe*, *hoping*) indicate the weaker class. This observation is in line with findings on self-assigned confidence judgments of chess players (Reynolds, 1992). The sets of terms expressing certainty and uncertainty, respectively, are small in our dataset, so weights for most terms can be learned directly on the n-grams.

Time Management. It has been suggested that deficiencies in time management are responsible for many losses at the amateur level, particularly in fast games (e.g., blitz chess, where each player has 5 minutes to complete the game), for example due to poor pattern recognition skills of beginners (Calderwood et al., 1988). In the trained models, we see that the term *time* itself is actually considered a good indicator for stronger players. *Time* is often used to signify number of moves. So, when used on its own, *time* is referring to efficient play, which is indicative of strong players. Conversely, the terms *clock* and *time pressure* are deemed good features to identify weaker players.

Chess Terminology. As shown in Section 2.1 and throughout this paper, there is a vast amount of chess terminology. We observe that frequent usage of such terms (e.g., *blunder* – a grave mistake, *tempo*, *checkmate* – experts use *mate*, *opening*, *castle*) actually indicate a weaker player. This seems counterintuitive at first, as we may expect lower-rated players to be less familiar with such terms. However, it appears that they are frequently overused by weaker players. This also holds for metaphorical terms, such as *fall* or *eat* instead of *capture*.

6 Related Work

The treatment of writer expertise in extralinguistic tasks in NLP has mostly focused on two problems: (i) retrieval of experts for specific areas – i.e., predicting the area of expertise of a writer (e.g., Tu et al. (2010; Kivimäki et al. (2013)); and (ii) using expert status in different downstream applications such as sentiment analysis (e.g., Liu et al. (2008)) or dialog systems (e.g., Komatani et al. (2003)). Conversely, our work is concerned with predicting a ranking by expertise within a single task.

Several publications have dealt with natural language processing related to games. Chen and Mooney (2008) investigate grounded language learning where commentary describing the specific course of a game is automatically generated. Commentator expertise is not taken into account in this study. Branavan et al. (2012) introduced a model for using game manuals to increase the strength of a computer playing the strategy video game *Civilization II*. Cadilhac et al. (2013) investigated the prediction of player actions in the strategy board game *The Settlers of Catan*. Our approach differs conceptually from theirs as their main focus lies on modeling concrete *actions* in the game (either predicting or learning them); our goal is to predict *player strength*, i.e., to learn to compare players among each other. Rather than explicitly modeling the game, commentary analysis aims to provide insight into specific thought processes.

Work in psychology research by Pfau and Murphy (1988) showed the quality of chess players' verbalization about positions is correlated significantly with their rating. While they use manual assessments by chess masters to determine the quality of a player's writing, our approach is to learn this distinction is automatically given the ratings.

7 Conclusion

In this paper, we presented experiments on predicting the expertise of speakers in a task using linguistic evidence. We introduced a classification and a ranking task for automatically ranking chess players by playing strength using their natural language commentary. SVM models succeed at predicting either a rating class or an overall ranking. In the ranking case, we could significantly boost the results by using chess-specific features extracted from the text. Finally, we compared the predictions of the SVM with popular claims from instructional chess literature as well as results from psychology research. We found that many of the traditional findings are reflected in the features learned by our models.

Abstract

In this paper, a large scale modern Tibetan text corpus is built, which includes about 190 thousands documents, 67.21 million words, 93.66 million syllables in total. Based on the corpus, statistics are made in several language units in different granularities. Statistical data show that : a syllable has 3.26 letters or 2.20 super characters in average, while a sentence has 75.40 letters or 63.14 super characters. The top 10 super characters, syllables, words take up 66.3156%, 16.5556%, 24.6415% of the corpus respectively. Curves for the n-gram frequency-rank list of super chars, syllables and words are plotted. It shows that when all the n-gram phrases for $n = 1, 2, \ldots, 5$ are put together and sorted by frequency in descending order, the frequency-rank curves in log-log axes can be fitted well by a straight line for the unit of syllable and word respectively. But for the unit of super character, we didn't find a curve that can be fitted well enough by a straight line even if we combine all the n-grams for $n = 1, 2, \ldots, 10$.

1 Introduction

The statistical property is the natural property of a language. In recent tens of years, people made statistical analysis on Tibetan characters or syllables. But it's difficult to make statistics on larger language units such as word and n-gram word phrases, especially on a large scale corpus. There are two reasons resulting in the difficulty. First, as Tibetan is a resource poor language, it's hard to build a large scale Tibetan text corpus. Second, Tibetan word segmentation technology is not well developed even until now.

In this paper, we report our word on the statistics on Tibetan based on the language units such as character, syllable, word and their n-gram pairs on a large scale corpus. The remainder of the paper is organized as follow. Tibetan language units are introduced in Section 2. We recall the related work in Section 3. In Section 4, the methods which is used to build the corpus and to segment Tibetan text into language units are described in detail. We make statistics on the corpus and list the most frequency Tibetan language units and test Zipf's law respectively in Section 5. Section 6 concludes this paper.

2 Language Units of Tibetan

Generally speaking, Tibetan is a alphabetic writing system. But there is a unit larger than letter but smaller than syllable, which is different from other language such as English and Chinese. Meanwhile, people have used different terms (in English) to express the same unit or the same term to express different units. So we must make a clarification in this Section.

2.1 Letter, Character and Super Character

There are 30 consonants and 4 vowel signs in modern Tibetan. Several other consonants and vowel signs are also used in Tibetan text to transliterate Sanskrit script. There are only 4 vowel signs (writing) for the vowels (reading) /e/, /i/, /o/ and /u/, but there isn't any signs for the vowel /a/, so every consonant has

Yesterday this rich man bought an expensive house.									

Figure 4: A Tibetan sentence.

an inherent vowel /a/. Other vowels can be indicated using a variety of diacritics which appear above or below the main letter. Each of these consonants and vowel signs is called a "letter".

In Tibetan encoding schema used in ISO/IEC 10646 and Unicode standard (Consortium, 2013), each Tibetan consonant has two or even more code points to denote its normal form or subjoined form, or other variant forms which are only used in very special context. Each variant form is called a "character" corresponding to a code point in ISO/IEC 10646. In Figure 1, seven characters form a Tibetan syllable. Note that three consonants and a vowel sign are clustered.

Different from the encoding schema with small unit used in ISO/IEC 10646, in Chinese notional standard GB/T 20542 and GB/T 22238 on Tibetan coded character set and some legacy Tibetan encodings, another encoding schema is used. In this schema, the cluster of consonants and vowel sign in Figure 1 is assigned only one code point. Figure 2 shows the schema. The encoding unit shown in Figure 2 is called "字丁 " (Zi Ding) in Chinese but the Chinese term doesn't have an exact English translation, and we call it "super character" or "super char" briefly in this paper.

2.2 Syllable, Word and Sentence

A syllable contains one or up to seven character(s). Syllables are separated by a marker known as "tsheg", which is simply a superscripted dot. People sometime use the Chinese term "字 " (Zi, exactly a character in Chinese script) to denote "syllable". The term "字 " is often translated to "word" in English. But "word" mainly used to express a larger language unit as an item in the vocabulary. So we use the term "syllable" in this paper, and take "word" as a larger language unit which is made up of one or more syllables and has meanings.

Note that in Tibetan "tsheg" is used as the delimiter between two syllables. But there is no another delimiter to mark the boundary between two words. Thus there is a lack of word boundaries in Tibetan. Figure 3 shows the structure of a Tibetan word which is made up of two syllables and means "show" or "exhibition".

In Tibetan text, some monosyllable words, including "འི", "ས", "ར", "འང", "འམ", "འོ" (We call them abbreviation markers (AM) in this paper), can glue to the previous word without a syllable delimiter "tsheg", which produce many abbreviated syllables. For example, when the genitive case word "འི" follows the word "རྒྱལ་པོ" (king), we don't put a "tsheg" between them and get the fused form "རྒྱལ་པོའི" (king[+genitive]). The existence of abbreviated syllables contributes to the difficulty to segment Tibetan sentence into words.

Tibetan sentence contains one or more phrase(s), which contain one or more words. Another marker known as "shed" indicates the sentence boundary, which looks like a vertical pipe. Figure 4 shows a Tibetan sentence and its translation in English.

3 Related Work

In the early 1930s, G. K. Zipf pointed out a statistical feature of large language corpora (both written texts and speech streams) which, remarkably, is observed in many languages, and for different authors and styles (Zipf, 1935). He noticed that the number of words $w(n)$ which occur exactly n times in a language corpus varies with n as $w(n) \sim 1/n^{\gamma}$, where the exponent is close to 2, which results in the well known Zipf's law. The general form of Zipf's law states that:

$$y = f(r) = \frac{C}{r^{\alpha}} \tag{1}$$

where α is a positive parameter close to 1.

Zipf showed that, by and large, his law held for words, syllables and morphemes. Consequently, it is natural to ask if the law also holds for pairs of words. Egghe devised a mathematical argument that it, in fact, does not, but that the exact relation can be approximated by a power law (Egghe, 1999). He extended his investigations to parts of words, namely to the study of N-grams (Egghe, 2000).

Zipfs law was the source of a lively debate related to the structure of DNA. It was claimed (Mantegna et al., 1994) that Zipf's law shows the difference between coding and non-coding DNA as non-coding (so-called junk) DNA fits Zipf's law much better than coding DNA. This would mean, according to the authors, that non-coding regions of DNA may carry new biological information. Yet, this does not mean that junk DNA is a kind of language. Other scientists (Chatzidimitriou-Dreismann et al., 1996), however, have shown that this distinction is not universal and lacks all biological basis.

Zipf's law has been tested on the Internet. It turned out that popularity of Internet pages is described according to Zipf's law. This fact can be used to design better cache tables (Masaki and Takahashi, 1998; Breslau et al., 1998; Adamic and Huberman, 2002). Zipf's studies on city sizes still lead to new developments in geographical and economical studies (Gabaix, 1999a; Gabaix, 1999b; Okuyama et al., 1999; Ioannides and Overman, 2003; Soo, 2005; Soo, 2007).

Back to text, Li (1992) found that the distribution of word frequencies for randomly generated texts is very similar to Zipf's law observed in natural languages such as English (Li, 1992). Ha et al. (2002) investigated the law for two languages English and Mandarin and for n-gram word phrases as well as for single words. The law for single words is shown to be valid only for high frequency words. However, when single word and n-gram phrases are combined together in one list and put in order of frequency the combined list follows Zipf's law accurately for all words and phrases, down to the lowest frequencies in both languages. The Zipf curves for the two languages are then almost identical (Ha et al., 2002).

In recent years, researchers also made statistics on Tibetan. Jiang and Dong (1994) made statistics on the length and different structural mode of Tibetan syllables, and counted up the number of initial clusters and finals of Tibetan syllables, as well as the number of Tibetan letters at different positions in syllables (Jiang and Dong, 1994; Jiang and Dong, 1995). In a further research Jiang (1998; Jiang and Kong (2006; Jiang and Long (2010) , they made statistics on Tibetan letters, and found that the 1th order and 2nd order entropy of Tibetan is 3.9913 bits and 1.2531 bits resplectively (Jiang, 1998), while on super character they are 4.82 and 3.12 (Jiang and Kong, 2006; Jiang and Long, 2010). Wang and Chen (2004) made similar research to calculate the frequency and information entropy of Tibetan character and syllable based on a corpus of $20,000,000$ characters, and discovered that the most frequent 703 Tibetan syllables cover 90% of the corpus (Wang and Chen, 2004). She also presented the research on the frequency-rank relation of Tibetan super character and syllable, and found that the distributions follow Zipf's law too (Wang, 2004). But no further research is reported on whether she tests Zipf's law on larger language units of Tibetan. Other researchers also made statistics on Tibetan syllable's structural mode based a static corpus such as syllable list or dictionary (Gao and Gong, 2005; Ai et al., 2009). Lu et al. (2003) presented the theories and approaches to calculate the frequencies of Tibetan characters, pieces, syllables and words based on a large scale Tibetan corpus including about $40,000,000$ syllables (Lu et al., 2003). However, a large part of the corpus they used are Buddhist literatures and the work can't be done well without a pragmatic Tibetan word segmentation tool (Chen et al., 2003a; Chen et al., 2003b; Jiang, 2006; Jiang and Kong, 2006; Sun et al., 2009; Sun et al., 2010; Lu and Shi, 2011; Liu et al., 2012a).

At present, people already find methods to build a large scale corpus from Tibetan web sites with low cost. Liu et al. (2012b) presented their method to extract the title, content, author and other useful information of articles from several news and broadcasting web sites (Liu et al., 2012b). It's not a difficult work to implement a pragmatic Tibetan word segmentation tool based on the former researches (Chen et al., 2003a; Chen et al., 2003b; Sun et al., 2009; Sun et al., 2010; Liu et al., 2012a) So it's time to make statistics on the frequency distribution of larger language units such as word and n-gram word phrase for Tibetan to see whether they follow Zipf's law.

4 Methods and Corpus

We present our methods to build the corpus and to segment Tibetan text into different units mentioned above.

4.1 Building a Large Scale Tibetan Text Corpus

Previously Liu et al. (2012b) proposed an approach to build a large scale text corpus for Tibetan natural language processing. We adopt the method to build our corpus. we crawled eight Tibetan websites which mainly focus on news and broadcastings. Topic pages but hub pages are selected with a rule based method by checking the url. We analysed the layout structure mode of each web site and built templates to extract topic title, publishing date, author, topic content and some other topic related informations.

Consequently, a large scale Tibetan text corpus is built, which includes about 190 thousands documents, 67.21 million words, 93.66 million syllables and 265 million super characters in total. The sources and scales in different units are shown in Table 1.

♯	source	♯document	♯sentence	♯word	♯syllable	♯super character

Table 1: the sources and scales of the corpus.

It's a heavy task to manually classify those document into domains. However, we still can get the domain information for a certain subsets of the corpus. For some web sites listed above, we can get the domain information from the URL of each web page. For instance, the URL "http://tb.chinatibetnews.com/xzmeishi/2011-12/05/content_831210.htm" shows it belongs to a column called "xzmeishi". so it must be a page about Tibetan foods, because "xz" is the abbreviated form of Chinese word "xizang" (西藏), which means the Tibetan Autonomous Region, while "meishi" means "delicious food". So we can classify the documents in the corpus into domains. Table 2 and 3 list the domains of subsets of the documents from two web sites named "China Tibet News" and "Tibetan's web of China" respectively. Obviously, a large part of the documents in the corpus are news as expected, because nearly all of the 8 web sites are hold by news agencies or radio stations.

4.2 Methods to Segment Tibetan Text

As described in section 2, there is a delimiter between two Tibetan syllables. So we can segment the text into syllables by adding segmentation mark after the delimiter. The encoding schema can be used to segment text into smaller language units.

The challenge lies in the word segmentation. With a similar method to those methods proposed by other researchers (Chen et al., 2003a; Chen et al., 2003b; Jiang and Kong, 2006; Sun et al., 2009; Sun et al., 2010; Liu et al., 2012a), we implemented a segmenter. As mentioned in Section 2.2, some monosyllable words can glue to the previous word without a syllable delimiter "tsheg", which produce many

Table 3: Domains of a subset of the documents from ”Tibetan’s web of China”.

abbreviated syllables. So Tibetan has a significant number of complex words where the sounds have been synthesized due to internal sandhi something like Sanskrit. As some of those abbreviated syllables can also be used as normal syllables, they lead to considerable problem in Tibetan word segmentation. So in the first step, we analyse the structure of each syllable in the sentence, and break them into normal syllables and abbreviated mark candidates and take them as the basic units (unbreakable units). Then, in the second step, some special case-auxiliary words (which are all monosyllable words) are used as separators to break the sentence into blocks. Consequently, both the forward maximum matching method and backward maximum matching method are used to segment each block into words. Mean while, it detects ambiguities by bidirectional segmentation, and makes disambiguation with word frequency. A previous research shows that the precision of this method reaches 96.98% (Liu et al., 2012a). The following example shows the main procedure of the method.

Input: དཚོས་སྤྱི་ཚོགས་རིང་ལུགས་ཀྱི་སྤྱི་ལ་དབང་བའི་ལམ་ལུགས་དང་ཇོག་བསྟུན་ཐོག་སྤྲོད་ཀྱི་ཐ་དོན་མཐའ་འཇྱོངས་བྱས་ཡོད།

Translation: We have always followed the principles of socialist public ownership and distribution according to work.

Step 1: ད་ (ཚོ་ས་) སྤྱི་ ཚོགས་ རིང་ ལུགས་ ཀྱི་ སྤྱི་ ལ་ དབང་ (བ་ཞི་) ལམ་ ལུགས་ དང་ ཇོག་ བསྟུན་ ཐོག་ སྤྲོད་ ཀྱི་ ཐ་ དོན་ མཐའ་ འཇྱོངས་ བྱས་ ཡོད །

Step 2: (ད་ ཚོ་ ས་ སྤྱི་ ཚོགས་ རིང་ ལུགས་) ཀྱི་ (སྤྱི་ ལ་ དབང་ བ་ ཞི་ ལམ་ ལུགས་ དང་ ཇོག་ བསྟུན་ ཐོག་ སྤྲོད་) ཀྱི་ (ཐ་ དོན་ མཐའ་ འཇྱོངས་ བྱས་ ཡོད་) །

Step 3: (ད་ ཚོ་) (ས་) (སྤྱི་ ཚོགས་ རིང་ ལུགས་) ཀྱི་ (སྤྱི་ ལ་ དབང་ བ་ ཞི་ ལམ་) (ལུགས་) (དང་) (ཇོག་) (བསྟུན་) (ཐོག་) (སྤྲོད་) ཀྱི་ (ཐ་ དོན་) (མཐའ་ འཇྱོངས་) (བྱས་ ཡོད་) ।

Output: དཚོ་ ས་ སྤྱི་ཚོགས་རིང་ལུགས་ ཀྱི་ སྤྱི་ལ་དབང་བའི་ལམ་ ལུགས་ དང་ ཇོག་ བསྟུན་ ཐོག་ སྤྲོད་ ཀྱི་ ཐ་དོན་ མཐའ་འཇྱོངས་ བྱས་ཡོད ।

Note that, in step 1, two abbreviated syllable candidates are found and given in parentheses. In step 2, the two occurrences of the case-auxiliary word ཀྱི་ break the sentence into several blocks, and each block is segmented into words consequently in step 3. In this paper, as we mainly focus on Tibetan text, so in the segmentation, all Latin words, Latin numbers, Chinese phrases, Tibetan alphabetic numbers such as " ༦༣༣༡༨༩༩ " (6331089) and so on are all replaced by place-holders.

4.3 Counting and Calculation

The SRI Language Modelling Toolkit (SRILM) (Stolcke and others, 2002) is used to count the frequencies in our work.

5 Statistical Data and Analysis

In this section, we show the statistical data and check whether the frequency-rank on the units of super character, syllable and word follows Zipf's law respectively. As there isn't many enough items in the frequency list, we won't check it on the units of letter and character. For the other units, the number of occurrences of each n-gram is listed in Table 4.

unit	super char	syllable	word
unigram	265,197,659	93,657,584	67,209,927
bigram	260,565,029	89,024,954	62,577,297
trigram	256,022,772	84,521,746	58,085,930
4-gram	251,638,774	80,194,075	54,051,877
5-gram	247,285,278	76,155,897	50,242,999
Total	1,280,709,512	423,554,256	292,168,030

Table 4: Number of occurrences of each Tibetan n-gram in different units in the corpus.

5.1 Letter Frequency

In total, Tibetan 83 letters are used in the corpus, of which 39 letters are consonants and 8 letters are vowel signs. Letter ཹ and ཿ didn't occur in the corpus, which means people might prefer to use two letters to spell each of them. The other are Tibetan punctuations and signs. There are also 200 non Tibetan characters used in the corpus. The 47 letters and the two delimiters are listed in Table 5. The character "P", "C" and "V" in the table denote "Punctuation", "Consonant" and "Vowel" respectively. The "theg" shares 23.45% of the corpus while the "thed" shares 1.33%, which shows that a syllable has 3.26 letters (not including the "theg" itself), while a sentence has 75.40 letters in average. 4 of the 8 vowels occur frequently while the other 4 vowels are rarely used. The 2 punctuations share 24.7762% of the corpus while 4 vowels in modern Tibetan share 16.0805%, and the 30 consonants in modern Tibetan share 58.3918%. All these 36 letters share 99.2485% of the corpus in total. The other 4 vowels and 9 consonants which is used to transliterate Sanskrit script are rarely used. They share only 0.0437%. Other Tibetan signs and non Tibetan characters share 0.7078%.

5.2 Character Frequency

There are 119 Tibetan characters used in the corpus in total, including Tibetan punctuations and signs, but Tibetan number is replaced with a place-holder. As there are 83 letters as described in the former subsection, the other 36 characters are the second or third forms of Tibetan consonants. As the frequency of Tibetan character is seldom a concerned issue, we don't make any further remarks on it.

5.3 Super Character Frequency

There are 1,466 super characters used in the corpus in total. The topmost frequently occurred super characters and n-gram super char phrases for $n = 2, 3$ are listed in Table 6. As expected, the "theg" is the most frequently occurred one when we take it as a super character, which shares 31.22%. It indicates that a syllable is formed by 2.20 super characters in average. The "theg" shares 1.5837%, which indicates that a sentence has 63.14 super characters in average.

Table 6: The topmost frequently occurred super characters and n-gram super char phrases.

The frequency-rank curves of the n-gram for $n = 1, 2, 3, 4, 5$ are plotted with log-log axes in Figure 5. A straight line with $slop = -1.0$ is also plotted in the figure. It's obvious that the curves don't follow Zipf's law so exactly. The high frequency parts of the curves follow Zipf's law at large, but as the rank increases the curves have more rapid decreases than a linear curve with slop $= -1.0$ when the rank > 100. However, we still found that the curve becomes more straight when the n increases.

Similar to Ha et al. (2002), we also combine the frequency list of the n-grams for all $n = 1, 2, \ldots, 5$ together in one list and put in order of frequency. The frequency-rank curve is plotted in Figure 6. A straight line with slope $= -1.0$ is also plotted in the figure, which shows that there are large gaps between

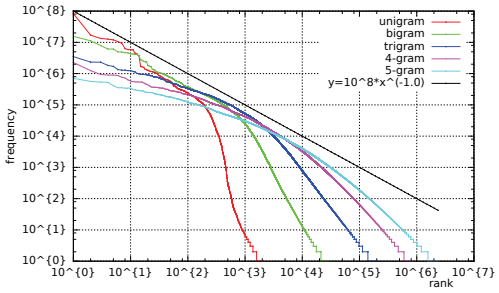

Figure 5: Frequency-rank of super chars and their n-grams.

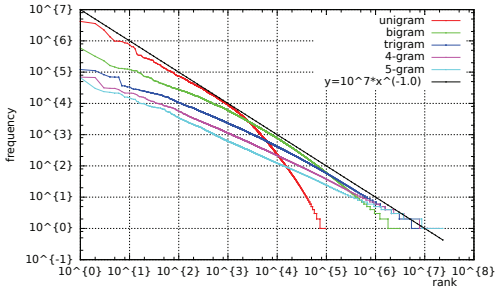

Figure 9: Frequency-rank of words and word n-grams.

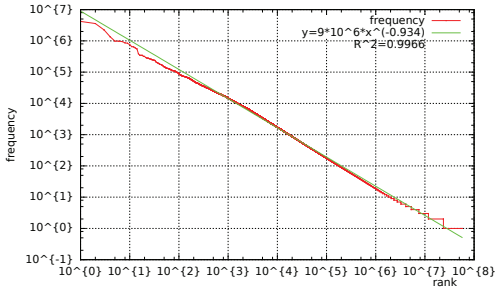

Figure 10: Frequency-rank of combined word n-gram list.

the curve and the line. Obviously it doesn't follow Zipf's law well.

5.4 Syllable Frequency

There are 27,546 syllables and 200 other characters occurred in the corpus in total. The topmost frequently occurred syllables and n-gram syllable phrases for $n = 2, 3$ are listed in Table 7. As expected, the "thed" is the most frequently used unigram when we take is as a syllable. It shares 4.4843% of the corpus. Most of the top 15 unigrams are case auxiliary words (monosyllable word), including གིས་ , ལ་ , ལས་ , ནས་ , གྱི་ and གི་ . The conjunction དང་ , the two nominalization markers པ་ and བ་ are also in the top 10 list. The top 10 syllables take up 16.5556% of the corpus.

The frequency-rank curves of the n-gram for $n = 1, 2, 3, 4, 5$ are plotted with log-log axes in Figure 7. A straight line with $slop = -1.0$ is also plotted in the figure , which shows that the curves don't follow Zipf's law very exactly. The high frequency parts of the curves when $n = 1, 2$ follow Zipf's law at large, but as the rank increases the curves have more rapid decreases than a linear curve with slop $= -1.0$ when the rank > 1000 and the rank > 10000 respectively. The curve becomes more straight when the n increases, and becomes almost straight lines when $n = 3, 4, 5$.

We also combine the frequency list of the n-grams for all $n = 1, 2, \ldots, 5$ together in one list and

Total		16,561,510	24.6415	Total	2,040,746	2.8406	Total	339,983	0.5058

Table 8: The topmost frequently occurred words and n-gram word phrases.

There are 96,296 words(including Tibetan punctuations, signs) used in the corpus in total. The topmost frequently occurred words and n-gram word phrases for $n = 2, 3$ are listed in Table 8. As expected, the "thed" is the most frequently used unigram when we take is as a word. It shares 6.2489% of the corpus. Almost all of the top 10 unigrams are auxiliary case words (monosyllable word), including ནི་ , ཀྱི་ , ལ་ , ར་ , ནས་ , གྱི་ , གི་ and ས་ . The top 10 words take up 24.6415% of the corpus.

The frequency-rank curves of the n-gram for $n = 1, 2, 3, 4, 5$ are plotted with log-log axes in Figure 9. A straight line with $slop = -1.0$ is also plotted in the figure , which shows that the curves don't follow Zipf's law very exactly. The high frequency part of the curve when $n = 1$ follows Zipf's law at large, but as the rank increases the curve has more rapid decreases than a linear curve with slop $= -1.0$ when the rank > 1000. The curve becomes more straight when the n increases, and becomes almost straight lines when $n = 3, 4, 5$.

We also combine the frequency list of the n-grams for all $n = 1, 2, \ldots, 5$ together in one list and put in order of frequency. The frequency-rank curve is plotted in Figure 10. A fitting straight line

$y = 2 \times 10^7 \times x^{-0.934}$ with $R^2 = 0.9966$ is also plotted in the figure, which shows that the curve can be well fitted by the line. Thus, it follows Zipf's law.

5.6 Further Discussion

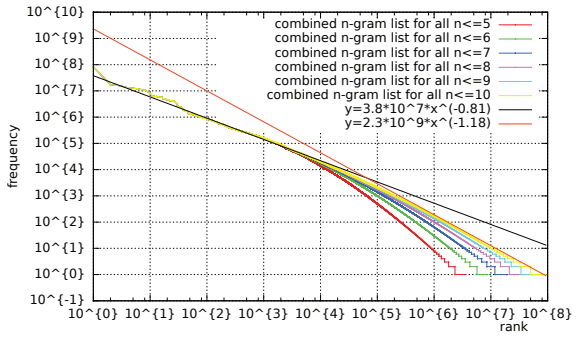

Figure 11: Frequency-rank of combined Tibetan word n-gram lists for $n <= 5, 6, 7, 8, 9, 10$.

Comparing the curves in Figure 5, 7 and 9, we find that the curves with the same n for all $n = 1, 2, 3, 4, 5$ become more straight when the granularity becomes larger. It's similar in the combined n-gram curves in Figure 6, 8 and 10. As it's shown that the two combined n-gram frequency lists for all $n <= 5$ on syllable and word follow Zipf's law well. So, the question is that whether we can find a larger M, which for the combined n-gram list for all all $n < m$, the frequency-rank curve in log-log axes is straight enough. To find the M, the frequency-rank curves for the combined n-gram super character lists for $m = 5, 6, 7, 8, 9, 10$ are plotted respectively in Figure 11. From the figure, we see that the head parts of the curves are overlapped, which correspond to the high frequency parts of the combined n-gram lists, while the tail parts of the curves are divergent. As the m increases, the tail part of the curve becomes closer to the straight line $y = 3.8 \times 10^7 \times x^{-0.81}$. This mainly results from that the frequency of the n-gram decreases when the n increase, and the low frequency part of the combined n-gram list includes more n-grams. However, the two straight lines of $y = 3.8 \times 10^7 \times x^{-0.81}$ and $y = 2.3 \times 10^9 \times x^{-1.18}$ in the figure show that any one of those curves can't be fitted well by a straight line. The reason leading to this somewhat unusual result is an issue to be made further research and analysis.

6 Conclusion

In the former section, we make statistics on different Tibetan language units : letter, super character, syllable and word, and their n-gram phrases. It shows that when we put all the n-gram phrases for $n = 1, 2, \ldots, 5$ together and sort all of them by frequency in descending order, then the frequency-rank curves in log-log axes can be fitted well for the unit of syllable and word respectively. But for the unit of super character, we didn't find a curve which can be fitted well enough by a straight line when we combine all the n-grams for $n <= m$ even if m is up to 10.

Simple or Complex? Assessing the readability of Basque Texts

Itziar Gonzalez-Dios, María Jesús Aranzabe, Arantza Díaz de Ilarraza, Haritz Salaberri

University of the Basque Country (UPV/EHU)
itziar.gonzalezd@ehu.es

Abstract

In this paper we present a readability assessment system for Basque, *ErreXail*, which is going to be the preprocessing module of a Text Simplification system. To that end we compile two corpora, one of simple texts and another one of complex texts. To analyse those texts, we implement global, lexical, morphological, morpho-syntactic, syntactic and pragmatic features based on other languages and specially considered for Basque. We combine these feature types and we train our classifiers. After testing the classifiers, we detect the features that perform best and the most predictive ones.

1 Introduction

Readability assessment is a research line that aims to grade the difficulty or the ease of the texts. It has been a remarkable question in the educational domain during the last century and is of great importance in Natural Language Processing (NLP) during the last decade. Classical readability formulae like Flesh formula (Flesch, 1948), Dale-Chall formula (Chall and Dale, 1995) and The Gunning FOG index (Gunning, 1968) take into account raw and lexical features and frequency counts. NLP techniques, on the other hand, make possible the consideration of more complex features.

Recent research in NLP (Si and Callan, 2001; Petersen and Ostendorf, 2009; Feng, 2009) has demonstrated that classical readability formulae are unreliable. Moreover, those metrics are language specific.

Readability assessment is also used as a preprocess or evaluation in Text Simplification (TS) systems e.g. for English (Feng et al., 2010), Portuguese (Aluísio et al., 2010), Italian (Dell'Orletta et al., 2011), German (Hancke et al., 2012) and Spanish (Štajner and Saggion, 2013). Given a text the aim of these systems is to decide whether a text is complex or not. So, in case of being difficult, the given text should be simplified.

As far as we know no specific metric has been used to calculate the complexity of Basque texts. The only exception we find is a system for the auto-evaluation of essays *Idazlanen Autoebaluaziorako Sistema* (IAS) (Aldabe et al., 2012) which includes metrics similar to those used in readability assessment. IAS analyses Basque texts after several criteria focused on educational correction such as the clause number in a sentence, types of sentences, word types and lemma number among others. It was foreseen to use this tool in the Basque TS system (Aranzabe et al., 2012). The present work means to add to IAS the capacity of evaluating the complexity of texts by means of new linguistic features and criteria.

In this paper we present *ErreXail*, a readability assessment system for Basque, a Pre-Indo-European agglutinative head-final pro-drop language, which displays a rich inflectional morphology and whose orthography is phonemic. *ErreXail* classifies the texts and decides if they should be simplified or not. This work has two objectives: to build a classifier which will be the preprocess of the TS system and to know which are the most predictive features that differ in complex and simple texts. The study of the most predictive features will help in the linguistic analysis of the complex structures of Basque as well.

This paper is organised as follows: In section 2 we offer an overview about this topic. We present the corpora we gathered and its processing in section 3. In section 4 we summarise the linguistic features we

Proceedings of COLING 2014, the 25th International Conference on Computational Linguistics: Technical Papers, pages 334–344, Dublin, Ireland, August 23-29 2014.

implemented and we present the experiments and their results in section 5. The present system, *ErreXail*, is described in section 6 and in section 7 we compare our work with other studies. Finally, we conclude and outline the future work (section 8).

2 Related work

In the last years new methods have been proposed to assess the readability in NLP. For English, Si and Callan (2001) use statistical models, exactly unigram language models, combined with traditional readability features like sentence length and number of syllables per word. Coh-Metrix (Graesser et al., 2004) is a tool that analyses multiple characteristics and levels of language-discourse such us narrativity, word concreteness or noun overlap. In the 3.0 version[1] 108 indices are available. Pitler and Nenkova (2008) use lexical, syntactic, and discourse features emphasising the importance of discourse features as well. Schwarm and Ostendorf (2005) combine features from statistical language models, parse features, and other traditional features using support vector machines.

It is very interesting to take a look at readability systems for other languages as well. Some readability metrics take them into account special characteristics linked to languages. For example, in Chinese the number of strokes is considered (Pang, 2006), in Japanese the different characters (Sato et al., 2008), in German the word formation (vor der Brück et al., 2008), in French the *passé simple* (François and Fairon, 2012) and the orthographic neighbourhood (Gala et al., 2013) and in Swedish vocabulary resources (Sjöholm, 2012; Falkenjack et al., 2013) among many other features. For Portuguese, Coh-metrix has been adapted (Scarton and Aluísio, 2010) and in Arabic language-specific formulae have been used (Al-Ajlan et al., 2008; Daud et al., 2013). Looking at free word order, head final and rich morphology languages, Sinha et al. (2012) propose two new measures for Hindi and for Bangla based on English formulae. Other systems use only machine learning techniques, e.g. for Chinese (Chen et al., 2011).

The systems whose motivation is Text Simplification analyse linguistic features of the text and then they use machine learning techniques to build the classifiers. These systems have been created for English (Feng et al., 2010), Portuguese (Aluísio et al., 2010), Italian (Dell'Orletta et al., 2011) and German (Hancke et al., 2012). We follow the similar methodology for Basque since we share the same aim.

Readability assessment can be focused on different domains such as legal, medical, education and so on. Interesting points about readability are presented in DuBay (2004) and an analysis of the methods and a review of the systems is presented in Benjamin (2012) and Zamanian and Heydari (2012).

3 Corpora

Being our aim to build a model to distinguish simple and complex texts and to know which are the most predictive features based on NLP techniques, we needed to collect the corpora. We gathered texts from the web and compiled two corpora. The first corpus, henceforth *T-comp*, is composed by 200 texts (100 articles and 100 analysis) from the *Elhuyar aldizkaria*[2], a monthly journal about science and technology in Basque. *T-comp* is meant to be the complex corpus. The second corpus, henceforth *T-simp*, is composed by 200 texts from *ZerNola*[3], a website to popularise science among children up to 12 years and the texts we collected are articles. To find texts specially written for children was really challenging. Main statistics about both corpora are presented in Table 1.

Corpus	Docs.	Sentences	Tokens	Verbs	Nouns
T-comp	200	8593	161161	52229	59510
T-simp	200	2363	39565	12203	13447

Table 1: Corpora statistics

Both corpora were analysed at various levels:

1. Morpho-syntactic analysis by *Morpheus* (Alegria et al., 2002)

[1] `http://cohmetrix.memphis.edu/cohmetrixpr/cohmetrix3.html` (accessed January, 2014)
[2] `http://aldizkaria.elhuyar.org/` (accessed January, 2014)
[3] `http://www.zernola.net/` (accessed January, 2014)

2. Lemmatisation and syntactic function identification by *Eustagger* (Aduriz et al., 2003)

3. Multi-words item identification (Alegria et al., 2004a)

4. Named entities recognition and classification by *Eihera* (Alegria et al., 2004b)

5. Shallow parsing by *Ixati* (Aduriz et al., 2004)

6. Sentence and clause boundaries determination by *MuGak* (Aranzabe et al., 2013)

7. Apposition identification (Gonzalez-Dios et al., 2013)

This preprocess is necessary to perform the analysis of the features presented in section 4.

4 Linguistic features

In this section we summarise the linguistic features implemented to analyse the complexity of the texts. We distinguish different groups of features: global, lexical, morphological, morpho-syntactic, syntactic and pragmatic features. There are in total 94 features. Most of the features we present have already been included in systems for other languages but others have been specially considered for Basque.

4.1 Global features

Global features take into account the document as whole and serve to give an overview of the texts. They are presented in Table 2.

Averages
Average of words per sentence
Average of clauses per sentence
Average of letters per word

Table 2: Global features

These features are based on classical readability formulae and in the criteria taken on the simplification study (Gonzalez-Dios, 2011), namely the sentence length and the clause number per sentence. They are also included in IAS (Aldabe et al., 2012).

4.2 Lexical features

Lexical features are based on lemmas. We calculate the ratios of all the POS tags and different kinds of abbreviations and symbols. We concentrate on particular types of substantives and verbs as well. Part of theses ratios are shown in Table 3. In total there are 39 ratios in this group.

Ratios
Unique lemmas / all the lemmas
Each POS / all the words
Proper Nouns / all the nouns
Named entities / all the nouns
Verbal nouns / all the verbs
Modal verbs / all the verbs
Causative verbs / all the verbs
Intransitive verbs with one arg. (*Nor* verbs) / all the verbs
Intransitive verbs with two arg. (*Nor-Nori* verbs) / all the verbs
Transitive verbs with two arg. (*Nor-Nork* verbs) / all the verbs
Transitive verbs with three arg. (*Nor-Nori-Nork*) verbs / all the verbs
Acronyms / all the words
Abbreviations / all the words
Symbols / all the words

Table 3: Lexical features

Among those features, we want to point out the causative verbs and the intransitive or transitive verbs with one, two or three arguments (arg.) as features related to Basque. Causative verbs are verbs with the

suffix *-arazi* and they are usually translated as "to make someone + *verb*", e.g. *edanarazi*, that stands for "to make someone drink". Other factitive verbs are translated without using that paraphrase like *jakinarazi* that means "to notify", lit. "to make know". The transitivity classification is due to the fact that Basque verb agrees with three grammatical cases (ergative *Nork*, absolutive *Nor* and dative *Nori*) and therefore verbs are grouped according to the arguments they take in Basque grammars.

4.3 Morphological features

Morphological features analyse the different ways lemmas can be realised. These features are summarised in Table 4 and there are 24 ratios in total.

Ratios
Each case ending / all the case endings
Each verb aspect / all the verbs
Each verb tense / all the verbs
Each verb mood / all the verbs
Words with ellipsis / all the words
Each type of words with ellipsis / all the words with ellipsis

Table 4: Morphological features

Basque has 18 case endings (absolutive, ergative, inessive, allative, genitive...), that is, 18 different endings can be attached to the end of the noun phrases. For example, if we attach the inessive *-n* to the noun phrase *etxea* "the house", we get *etxean* "at home". The verb features considered the forms obtained with the inflection.

Verb morphology is very rich in Basque as well. The aspect is attached to the part of the verb which contains the lexical information. There are 4 aspects: puntual (aoristic), perfective, imperfective and future aspect. Verb tenses are usually marked in the auxiliary verb and there are four tenses: present, past, irreal and archaic future[4]. The verbal moods are indicative, subjunctive, imperative and potential. The latter is used to express permissibility or possible circumstances.

Due to the typology of Basque, ellipsis[5] is a normal phenomenon and ellipsis can be even found within a word (verbs, nouns, adjective...); for instance, *dioguna* which means "what we say". This kind of ellipsis occurs e.g. in English, Spanish, French and German as well but in these languages it is realised as a sentence; but it is expressed only by a word in Basque.

4.4 Morpho-syntactic features

Morpho-syntactic features are based on the shallow parsing (chunks[6]) and in the apposition detection (appositions). These features are presented in Table 5.

Ratios
Noun phrases (chunks) / all the phrases
Noun phrases (chunks) / all the sentences
Verb phrases / all the phrases
Appositions / all the phrases
Appositions / all the noun phrases (chunks)

Table 5: Morpho-syntactic features

Contrary to the features so far presented, the morpho-syntactic features take into account mainly more than a word. About apposition, there are 2 types in Basque (Gonzalez-Dios et al., 2013) but we consider all the instances together in this work.

[4]The archaic future we also take into account is not used anymore, but it can be found in old texts. Nowadays, the aspect is used to express actions in the future.

[5]Basque is a pro-drop language and it is very normal to omit the subject, the object and the indirect object because they are marked in the verb. We do not treat this kind of ellipsis in the present work.

[6]Chunks are a continuum of elements with a head and syntactic sense that do not overlap (Abney, 1991).

4.5 Syntactic features

Syntactic features consider average of the subordinate clauses and types of subordinate clauses. They are outlined in Table 6 and there are 10 ratios in total. The types of adverbial clauses are temporal, causal, conditional, modal, concessive, consecutive and modal-temporal. The latter is a clause type which expresses manner and simultaneity of the action in reference to the main clause.

Ratios
Subordinate clauses / all the clauses
Relative clauses / subordinate clauses
Completive clauses / subordinate clauses
Adverbial clauses / subordinate clauses
Each type of adverbial clause / subordinate clauses

Table 6: Syntactic features

In this first approach we decided not to use dependency based features like dependency depth or distance from dependent to head because dependency parsing is time consuming and slows down the preprocessing. Moreover, the importance of syntax is under discussion: Petersen and Ostendorf (2009) find that syntax does not have too much influence while Sjöholm (2012) shows that dependencies are not necessary. Pitler and Nenkova (2008) pointed out the importance of syntax. but Dell'Orletta et al. (2011) demonstrate that for document classification reliable results can be found without syntax. Anyway, syntax is necessary for sentence classification.

4.6 Pragmatic features

In our cases, the pragmatic features we examine are the cohesive devices. These features are summed up in Table 7. There are 12 ratios in total.

Ratios
Each type of conjunction / all the conjunctions
Each type of sentence connector / all the sentence connectors

Table 7: Pragmatic features

Conjunction types are additive, adversative and disjuntive. Sentence connector types are additive, adversative, disjuntive, clarificative, causal, consecutive, concessive and modal.

5 Experiments

We performed two experiments, the first one to build a classifier and the second one to know which are the most predictive features. For both tasks we used the WEKA tool (Hall et al., 2009).

In the first experiment we ran 5 classifiers and evaluated their performance. Those classifiers were Random Forest (Breiman, 2001), the J48 decision tree (Quinlan, 1993), K-Nearest Neighbour, IBk (Aha et al., 1991), Naïve Bayes (John and Langley, 1995) and Support Vector Machine with SMO algorithm (Platt, 1998). We used 10 fold cross-validation, similar to what has been done in other studies.

Taking into account all the features presented in section 4, the best results were obtained using SMO. This way, 89.50 % of the instances were correctly classified. The F-measure for complex text was 0.899 %, for simple texts was 0.891 % and the MAE was 0.105 %. The results using all the features are shown in Table 8.

Random Forest	**J48**	**IBk**	**Naïve Bayes**	**SMO**
88.50	84.75	72.00	84.50	**89.50**

Table 8: Classification results using all the features

We classified each feature type on their own as well and the best results were obtained using only lexical features, 90.75 %. The classification results according to their feature group are presented in Table 9. We only present the classifiers with the best results and these are remarked in bold.

Classifier	Random Forest	J48	SMO
Global	74.25	73.50	**74.75**
Lex.	88.00	85.00	**90.75**
Morph.	**82.00**	71.75	75.00
Morpho-synt.	**78.25**	76.25	72.75
Synt.	71.25	**73.75**	67.75
Prag.	67.50	**70.50**	65.75

Table 9: Classification results of each feature type

We also made different combinations of feature types and the accuracy was improved. The best combination group was the one formed by lexical, morphological, morpho-syntactic and syntactic features and they obtain 93.50 % with SMO. Best results are show in Table 10.

Feature Group	Random Forest	SMO
Global+Lex	87.50	**89.50**
Global+Lex+Morph	87.75	**89.00**
Global+Lex+Morph+Morf-sint	89.25	**89.50**
Global+Lex+Morph+Morph-sint+Sintax	87.25	**90.25**
Morph+Morph-sint	**84.25**	82.25
Morph+Morph-sint+Sintax	**83.25**	80.75
Morph+Morof-sint+Sintax+Prag	**83.75**	82.00
Lex+Morph	88.75	**92.75**
Lex+Morph+Morph-sint	**89.25**	**89.25**
Lex+Morph+Morph-sint+Sintax	89.75	**93.50**
Lex+Morph+Morph-sint+Sintax+Prag	88.50	**90.25**
Sintax+Prag	**78.25**	73.50

Table 10: Classification results using different feature combinations

Combining the feature types, SMO is the best classifier in most of the cases but Random Forest outperforms the results when there are no lexical features.

In the second experiment, we analysed which were the most predictive linguistic features in each group. We used Weka's Information Gain (InfoGain AttributeEval) to create the ranking and we ran it for each feature group. In Table 11 we present the 10 most predictive features taking all the features groups into account.

The results of this experiment are interesting for the linguistic studies on Text Simplification. It shows us indeed which phenomena we should work on next. In these experiment we notice as well the relevance of the lexical features and that syntactic features are not so decisive in document classification.

The features with relevance 0 have been analysed as well. Some of them are e.g. the ratio of the inessive among all the case endings, the ratio of the indicative mood among all the verbal moods, the ratio of the adjectives among all the words and the ratio of the ratio of the present tense among all the verbal tenses.

We also performed a classification experiment with the top 10 features and J48 is the best classifier (its best performance as well). These results are presented in Table 12.

To sum up, our best results are obtained using a combination of features (Lex+Morph+Morph-sint+Sintax). We want to remark the importance of lexical features as well, since they alone outperform all the features and 5 of them are among the top ten features.

6 System overview

The readability system for Basque *ErreXail* has a three-stage architecture (Figure 1).

So, given a Basque written text, we follow next steps:

1. The linguistic analysis will be carried out, that is, morpho-syntactic tagging, lemmatisation, syntactic function identification, named entity recognition, shallow parsing, sentence and clause boundaries determination and apposition identification will be performed. We will use the tools presented in section 3.

Feature and group	Relevance
Proper nouns / common nouns ratio (Lex.)	0.2744
Appositions / noun phrases ratio (Morpho-synt.)	0.2529
Appositions / all phrases ratio (Morpho-synt.)	0.2529
Named entities / common nouns ratio (Lex.)	0.2436
Unique lemmas / all the lemmas ratio (Lex.)	0.2394
Acronyms / all the words ratio (Lex.)	0.2376
Causative verbs / all the verbs ratio (Lex.)	0.2099
Modal-temporal clauses / subordinate clauses ratio (Synt.)	0.2056
Destinative case endings / all the case endings ratio (Morph.)	0.1968
Connectors of clarification / all the connectors ratio (Prag.)	0.1957

Table 11: Most predictive features

Random Forest	J48	IBk	Naïve Bayes	SMO
87.75	**88.25**	72.00	83.25	87.00

Table 12: Classification results using the top 10 features

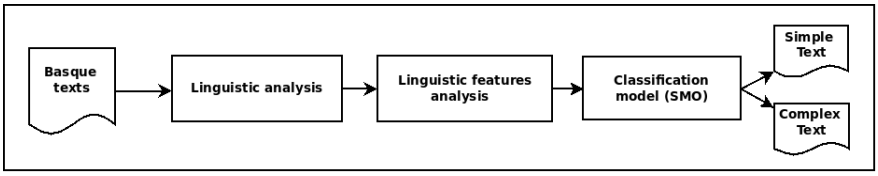

Figure 1: The architecture of system

2. Texts will be analysed according to the features and measures presented in section 4.

3. We will use the SMO Support Vector Machine as classification model, since that was the best classifier in the experiments exposed in section 5. To speed up the process for Text Simplification, we will analyse only the combination of lexical, morphological, morpho-syntactic and syntactic (Lex+Morph+Morph-sint+Sintax) features.

Although the first application of this system will be the preprocessing of texts for the Basque TS system, the system we present in this paper is independent and can be used for any other application. We want to remark that this study, as it is based on other languages, could be applied to any other language as well provided that the text could be analysed similar to us.

7 Discussion

The task of text classification has been carried out by several studies before. Due to our small corpus we were only able to discriminate between complex and simple texts like Dell'Orletta et al. (2011) and Hancke et al. (2012), other studies have classified more complexity levels (Schwarm and Ostendorf, 2005; Aluísio et al., 2010; François and Fairon, 2012). In this section we are going to compare our system with other systems that share our same goal, namely to know which texts should be simplified.

Comparing our experiment with studies that classify two grades and use SMO, Hancke et al. (2012) obtain an accuracy of 89.7 % with a 10 fold cross-validation. These results are very close to ours, although their data compiles 4603 documents and ours 400. According to the feature type, their best type is the morphological, obtaining 85.4 % of accuracy. Combining lexical, language model and morphological features they obtain 89.4 % of accuracy. To analyse their 10 most predictive features, they use Information Gain as well but we do not share any feature in common.

Dell'Orletta et al. (2011) perform three different experiments but only their first experiment is similar to our work. For that classification experiment they use 638 documents and follow a 5 fold cross-validation process of the Euclidian distance between vectors. Taking into account all the features the accuracy of their system is 97.02 %. However, their best performance is 98.12 % when they only use the combination of raw, lexical and morpho-syntactic features.

Aluísio et al. (2010) assess the readability of the texts according to three levels: rudimentary, basic and advanced. In total they compile 592 texts. Using SMO, 10 fold cross-validation and standard classification, they obtain 0.276 MAE taking into account all the features. The F-measure for original texts is 0.913, for natural simplification 0.483 and for strong simplification 0.732. They experiment with feature types as well but they obtain their best results using all the features. Among their highly correlated features they present the incidence of apposition in second place as we do here. We do not have any other feature in common.

Among other readability assessment whose motivation is TS, Feng et al. (2010) use LIBSVM (Chang and Lin, 2001) and Logistic Regression from WEKA and 10 fold cross-validation. They assess the readability of grade texts and obtain as best results 59.63 % with LIBSVM and 57.59 % with Logistic Regression. Since they assess different grades and use other classifiers it is impossible to compare with our results but we find that we share predictive features. They found out that named entity density and and nouns have predictive power as well.

8 Conclusion and perspectives

In this paper we have presented the first readability assessment system for the Basque language. We have implemented 94 ratios based on linguistic features similar to those used in other languages and specially defined for Basque and we have built a classifier which is able to discriminate between difficult and easy texts. We have also determined which are the most predictive features. From our experiments we conclude that using only lexical features or a combination of features types we obtain better results than using all the features. Moreover, we deduce that we do not need to use time consuming resources like dependency parsing or big corpora to obtain good results.

For the future, we could implement new features like word formation or word ordering both based in other languages and in neurolinguistic studies that are being carried out for Basque. Other machine learning techniques can be used, e.g. language models and in the case of getting a bigger corpora or a graded one, we could even try to differentiate more reading levels. We also envisage readability assessment at sentence level in near future.

Abstract

In this paper, we have studied the effect of two important factors influencing text readability in Bangla: the target reader and text properties. Accordingly, at first we have built a novel Bangla readability dataset of 135 documents annotated by 50 readers from two different backgrounds. We have identified 20 different features that can affect the readability of Bangla texts; the features were divided in two groups, namely, 'classic' and 'non-classic'. Preliminary correlation analysis reveals that text features have varying influence on the text hardness stated by the two groups. We have employed support vector machine (SVM) and support vector regression (SVR) techniques to model the reading difficulties of Bangla texts. In addition to developing different models targeted towards different type of readers, separate combinations of features were tested to evaluate their comparative contributions. Our study establishes that the perception of text difficulty varies largely with the background of the reader. To the best of our knowledge, no such work on text readability has been recorded earlier in Bangla.

1 Introduction

Readability of a text generally refers to how well a reader is able to comprehend the content of a text, through reading (Dale and Chall, 1948). Readability is a complex cognitive phenomenon where, the cognitive load of a text for a reader depends on both the characteristics of a text like, lexical choice, syntactic complexity, semantic complexity, discourse level complexity and on the background of the user. Several experiments have already established that readability of texts are quite language dependent and existing readability measures in English cannot directly be used to compute readability of other languages like, Bangla and Hindi (Sinha et al., 2012). Yet, compared to the numerous readability measures in English and other European languages(Benjamin, 2012), few initiatives have been taken to compute text readability in a Eastern Indo-Aryan language like Bangla or any other Indian languages which are structurally very different from many of their Indo-European cousins such as English, which is of West-Germanic descent (Sinha et al., 2012). One important factor that affects the readability of a text is the background of the respective reader. According to Dale (Dale, 1949), "The interpretation of the expressed thought is related more to the reader's informational background and motivations than to the internal evidences of the expressional facility of the author". Reader's background is a complex derivative of one's educational and socio-economic state. As per one of the pioneering works in readability by Dale and Chall (1949), the outcome of reading depends on many characteristics of the prospective readers including "reading abilities, interests, age, sex, intellectual

Proceedings of COLING 2014, the 25th International Conference on Computational Linguistics: Technical Papers, pages 345–354, Dublin, Ireland, August 23-29 2014.

maturity, background of information etc." However, we do not know of any such investigations for Bangla text readability that have investigate the way background of a reader affect the readability of text. Such language specific study is needed as Bangla as a language is very different from English and the inapplicability of English readability formulae for Bangla text has already been established.

Considering the above issues as our motivation, in this paper we have developed models to predict reading difficulty of a Bangla document perceived according to different target reader groups. To categorize among different reader groups, we have considered age, education and socio-economic data as indicators of comprehension ability. In addition, we have also explored the impact of different types of text features on text comprehensibility in Bangla. However, development and evaluation of such model requires availability of well-annotated resources. To the best of our knowledge, no automatically accessible data annotated according to the reading difficulty level is available for Bangla. Therefore, we have developed a digital resource pool of Bangla text documents in Unicode encoding that can be used for various NLP tasks such as feature extraction, document analysis etc. Such a dataset is essential to analyze readability of text documents based on the target reader. Next, we have visualized the text readability problem from a machine learning perspective as a classification problem using support vector machines (SVM) and an estimation problem using support vector regression (SVR). Our study is based on a wide range of textual features, from the syntactic and lexical features of a text like, its average sentence length, average word length in terms of visual units, to discourse level features like, number of jukta-akshars (consonant conjuncts) , number of different parts of speeches, named entity and lexical relations (refer to section 3). Although regression analysis has been previously used to model the text readability in Bangla, reader group specific analysis and machine learning techniques like support vectors have not been used so far. We have considered two target reader groups namely Group-1(or Adult group) with average age of 23 Yrs and Group-2 (or minor's group) with average age of 15 Yrs.

The organization of the paper is as follows: section 2 presents a brief literature survey on existing readability metrics for English and Bangla; section 3 defines the features of a text considered in this study, and empirical data collection, section 4 discusses the experiment observations, the prediction techniques and presents the results and validations for the two techniques. Finally, section 5 offers conclusion and perspective.

2 Related Works

The quantitative analysis of text readability started with L.A. Sherman in 1880 (Sherman, 1893). Till date, English and other languages have got over 200 readability metrics (DuBay, 2004; Rabin et al., 1988).The existing quantitative approaches towards predicting readability of a text can be broadly classified into three categories (Benjamin, 2012):

Classical methods: they analyze the syntactic features of a text like sentence length, paragraph length etc. The examples are Flesch Reading Ease Score (Flesch, 1948), FOG index (Gunning, 1968), Fry graph (Fry, 1968), SMOG (McLaughlin, 1969) etc. The formulae do not take into account the background of the reader and the semantic features of the text such as whether the actual contents are making sense or not. Despite their shortcomings, these simple metrics are easy to calculate and provide a rough estimation of reading difficulty of a text provided.

Cognitively motivated methods: texts are analyzed based on the cognitive features like, cohesion, organization and users' background. Proposition and inference model (Kintsch and Van Dijk, 1978), prototype theory (Rosch, 1978), latent semantic analysis (Landauer et al., 1998), Coh-metrix (Graesser et al., 2004) are some prominent members of this group. This group of models moves beyond the surface features of a text and try to measure objectively the different cognitive indicators associated with text and the reader. However, it has been observed that, many situations, some traditional indicators perform as well as the newer and more difficult versions (Crossley et al., 2007).

Statistical language modeling: This class of approaches incorporates the power machine learning methods to the field of readability. They are particularly useful in determining readability of web texts (Collins-Thompson and Callan, 2005; Collins-Thompson and Callan, 2004; Si and Callan, 2003) (Liu et al., 2004). SVM has been used to identify grammatical patterns within a text and classification based on it (Schwarm and Ostendorf, 2005; Heilman et al., 2008; Petersen and Ostendorf, 2009). Although, these methods sound promising, the problem is that they cannot act as standalone measure:

they need an amount of training data for classifiers appropriate to a particular user group and often these measures takes into account complex text features which for resource poor languages need manual effort to annotate.

In Bangla, only a couple of works have been executed on text readability. Das and Roychoudhury (Das and Roychoudhury, 2006) studied a miniature model with respect to one parametric and two parametric fits. They have used seven paragraphs from seven literary texts. They considered two structural features of a text: average sentence length and number of syllables per 100 words. They found the two-parametric fit as better performer. Sinha et al. (Sinha et al., 2012) has developed two readability formulae for Bangla texts using regression analysis. For their study sixteen texts of length, about 100 words were used. They have considered six structural or syntactic features of a text for the work. They have demonstrated that the English readability formulae such as Flesch Reading Ease Index, SMOG Index do not perform appropriately while being applied to Bangla documents. They have found the textual features like average word length, number of polysyllabic words and number of jukta-akshars in a text to be the most influential ones. Both the works mentioned have taken into account a small subset of potentially important text features; none them have considered feature such as the extent of text cohesion. Moreover, their study did not explore the influence of readers' background on text readability. In our study, we have addressed the issue of readers' background as well as the effect of features at different textual level.

3 Empirical Data Collection

As mentioned, there is no annotated data present in Bangla, which can provide a direct classification of text difficulty for Bangla readers. Therefore, we have undertaken an effort to annotate the experiment texts with the target readers of Bangla.

3.1 Participants

Our objective in this study is to investigate how readability varies with the background of the reader. Therefore, two different target reader groups have been considered to study the relationship of effect of text parameters on comprehension and user background. SEC[1] or socio-economic classification has been stated according to the standards of Market Research Society of India (MRSI). MRSI has defined 12 socio-economic strata: A1 to E3, in the decreasing order. These strata have been designed based on the education level of the chief wage earner of the family and the number of "consumer durables" (as per a predefined list including agricultural land) owned by the family. It has been seen that this way of grading reflect the social and economic position of a household in terms of fields such as education, awareness etc. As can be inferred from the chart, the participants range from classes C2 to E1 (C2, D1, D2, E1), which represents the medium to low social-economic classes.

Type	Background	Mean age (Standard deviation)
Group 1 (adult): 25 native speakers of Bangla	Education: pursuing graduation	22.8 (1.74)
	SEC: C2-E1	
Group 2 (minors): 25 native speakers of Bangla	Education: pursuing secondary or higher secondary	15 (1.24)
	SEC: C2-E2	

Table1: User Statistics

3.2 Readability corpus preparation

We have stated in the introduction about the scarcity of annotated digital resource pool in Bangla useful for automatic processing. Although there are a few works on text readability in Bangla, the data is not available in accessible formats. To address the problem, we have developed a corpus of Bangla documents. The current size of the resource is about 250 documents of length about 2000 words spanning over broad categories such as News, literature, blogs, articles etc. A number of different text

[1] http://imrbint.com/research/The-New-SEC-system-3rdMay2011.pdf

features were computed against each document. The descriptions of the features and the justification for them have been stated below.

3.3 Feature selection:

Inferring from the cognitive load theory (Paas et al., 2003), we have assumed that the cognitive load exerted by a text on a reader depends on syntactic and lexical properties of a text like, average sentence length, average word length, number of polysyllabic words and as well as discourse features like the counts of the different parts of speeches and the number of co-references one has to resolve in order to comprehend the text. The logic behind such assumptions is as follows: while processing a text a user has to parse the sentences in it and extract semantically relevant meaning from those sentences and the words. In order to process a sentence, one has to take into account the length of the sentence and types of words contained in it; in addition, to infer the meaning of a sentence, it is important to establish the connections or the nature of dependencies among the different words in a sentence. The role of a word is determined by its parts of speech and its way of use in that context; apart from it, the words can have varied complexity based on factors like their length, count of syllables. Similarly, at the discourse level, a reader not only has to comprehend each sentence or paragraph, but also has to infer the necessary co-references among them to understand the message conveyed by the text. The complexity of this task depends on the number of entities (noun, proper nouns) in the text, how one entity is connected with other, relationships like synonymy, polysemy, and hyponymy. To capture the effects of all these parameters in our readability models, we have considered text features over a broad range. The details of the features are presented in Table 2. The word features like average word length, average syllable per word, sentence features like average sentence length and discourse features like number of polysyllabic words, number of jukta-akshars (consonant conjuncts) have been calculated as stated by Sinha et al. (Sinha et al., 2012), as the features need customizations for Bangla. The calculations based on lexical chains have been followed from Galley and McKeown (Galley and McKeown, 2003).

Feature	Description
word features	
average word length	Bangla orthographic word consists of a combination of four types of graphemes[2], each of them is considered as a single visual unit. Average word length is total word length in terms of visual units divided by number of words.
average syllable per word	Total word length in terms of syllable divided by total number of words.
sentence features	
average sentence length	Total sentence length in terms of words divided by number of sentence.
$(noun phrase)	Average number of NP per sentence
$(verb phrase)	Average number of VP per sentence
$(adjective)	Average number of adjectives per sentence
$(postposition)	Average number of postpositions per sentence. Bangla grammar has postpositions, instead of prepositions present in English. Unlike English, postpositions in Bangla do not belong to separate part of speech. The postpositions require their object noun to take possessive, objective or locative case. Suffixes act as the case markers.
$(entity)	average number of named entity per sentence
$(unique entity)	Average number of unique entity per sentence
$(clauses)	Average number of clauses per sentence

[2] http://en.wikipedia.org/wiki/Bengali_alphabet#Characteristics_of_the_orthographic_word

discourse features	
Number of polysyllabic words and normalized measure for 30 sentences	Polysyllabic words are the words whose count of syllable exceeds 2.
number of jukta-akshars (consonant conjuncts)	Total number of jukta-akshars in a text of 2000 words. It is an important feature for Bangla because each of the clusters has separate orthographic and phonemic (in some cases) representation than the constituents consonants.
#(noun phrase)	Total number of NP in the document
#(verb phrase)	Total number of VP in the document
#(adjective)	Total number of adjective in the document.
#(postposition)	Total number of postpositions in the document.
#(entity)	Total number of named entity in the document
#(unique entity)	Total number of unique entity in the document
#(lexical chain)*	Total number of lexical chain in the document
average lexical chain length*	Computed over the document

Table2: Details of text features considered for the study

The features marked with * in the above table have been manually annotated against each text. The other features, though they are computed automatically, a round of manual checking was incorporated for the sake of correctness.

Expert annotations and user annotations:

Since there is no formal ranking of Bangla texts according to their reading levels, therefore, the documents were then annotated by language experts to approximate the suitable reading level for each document. However, to develop any practical readability application, feedbacks from actual users are necessary. From the resource pool mentioned in Introduction, 135 texts were chosen for the present study: two sets of distinct 45 texts were for each group: for the adult group those were the texts annotated by experts to have relatively high reading level and for the minor's group, the texts were annotated as having relatively low reading level; pairwise t-test were performed between the two type of text features to assure that their difference is significant ($p<0.05$).

The rest 45 texts are common to both the groups to account for the difference in comprehension for the same document and the assumption that may in some cases group 2 participants have comparable reading skill as of group 1: consequently, the texts annotated by experts as demanding high reading level were selected for this purpose. These were required to ensure that the experimental data spans over a broad range and is unbiased. The text details are presented in table 2 below.

Source of Texts	Number of texts		
	Gr.1	Gr.2	common
Literary corpora_classical	5	5	5
Literary corpora_contemporay	6	5	6
News corpora_general news	6	6	5

Article corpora_ scholar	6	7	7
Article corpora_general	6	6	6

Table3: Text details

Each participant was asked 2 questions: "How easy was it for you to understand/comprehend the text?" and "How interesting was the reading to you?". Against each question, they were to answer on a 5 point scale (1=easy, 5=very hard). Inter-rater reliability was measured through Krippendorff's alpha[3]

[3] http://en.wikipedia.org/wiki/Krippendorff's_alpha

and $\alpha = 0.81$ was found. Therefore, we concluded that annotators agree more often than would have occurred by chance. We have measured the correlation between the outcomes of two questions corresponding to each of the fifty annotators; and found that in each case the correlation was greater than 0.8 ($p < 0.05$). Therefore, the questions can be considered as equivalent, and subsequently we have considered the rating for the first question as user input for our readability models. Corresponding to each text, the average of the user ratings was considered for further processing.

4 Analysis and Model Development

4.1 Correlation coefficients

We have performed partial spearman correlation between each of the features and user rating. Table 4 presents some of the examples from each type of features due to the space limitation; results corresponding to other features are also described subsequently. The following features have selected as they have been used in the existing literature for Bangla (Sinha et al., 2012). The correlations are presented separately for the distinct texts and the common texts delivered to the two groups of users. This will allow us to investigate is there any significance difference of reading feedbacks between the different target populations.

Feature	Correlation coefficient r (Significance (if p<0.05) p value)			
	Different texts		Common texts	
	Gr. 1	Gr. 2	Gr.1	Gr. 2
Word features

Table 4: Correlation coefficients (user rating vs text features)

Some interesting observations can be made from the above table:

- Average sentence length or mean number of words per sentence have been long found to be a strong predictor of text difficulty [1]. In our case, while this holds true for the adult data, the correlation is less for the minors and it is not significant.
- Average syllable per word does not hold significant correlation for the adult data in both cases but it does for the minor's group
- Jukta-akshars or consonant conjuncts have major impact on text readability in Bangla (Sinha et al., 2012). For adult data, it can be seen that this feature has a strong and significant correlation, which not true for the user data of group 2 for separate texts. On the other hand, for the common texts this feature was found to have high significant correlation with both the reader groups. This is may be due to the nature of the common texts.
- Apart from the above two cases, the above table also presents evidence in support of the fact that the reader's perception of text difficulty in relation to text features changes with the target reader background.

The impact of the remaining features has been discussed here with respect to the two different types of text scenarios:

Distinct texts for two groups:

- In case of the readers from the first group, the user ratings have high correlation ($r > 0.65$) with $(clauses), #(verb phrases), #(unique entity), #(lexical chain) and average lexical chain length. The correlations are also significant. However, the correlations with $(noun phrase), $(verb phrase) $(postpositions), #(postpositions), #(adjective) were found to be insignificant. The correlation of user annotation with features such as $(entity), $(unique entity) were found to be low ($r < 0.45$) but significant.

- The group 2 readers were found to show high ($r > 0.65$) and significant correlation with $(verb phrases), $(unique entity), $(clauses), #(entity), #(lexical chain) and average lexical chain span. The correlations with $(postposition), #(postpositions) were not significant. Features like $(noun phrase), $(adjective) and #(adjective) were found to have low ($r < 0.45$) but significant correlations with user ratings.

Common texts for both groups:

- It has been observed that the group 2 user ratings have higher correlation with the sentence level features than the discourse level features. In particular, features such as number of $(noun phrase), $(adjective), $(unique entity) and $(clauses) have high correlation with the text difficulty ratings provided by the minor's group. Among the discourse level features #(entity) and #(unique entity)have a high correlation, but #(verb phrase), #(adjective) were found to have not significant influence.

- On the other hand, the adult data are more inclined towards discourse features such as #(noun phrase) and #(verb phrase), #(unique entity) in a document. This may be due to the ability of the older people to comprehend the text as a whole rather than inferring meaning from individual units at a time. From sentence level feature $(clause) was found to be significant and important in terms of correlation, but $(noun phrase), $(adjective) do not bear significant correlation.

- Properties like lexical chain, which require a reader to establish connections among different attributes of a concept have great significance for both group1 and group2 annotations.

- For both the user groups the influence of average $(postposition and #(postposition) were found to be little and insignificant.

From the above discussions, it is evident that the two different target reader groups show a large difference in their reading pattern and perception of text difficulty. The difference has been observed in both the cases: when they were presented with different type of texts and with same texts. Therefore, it has been established that the target reader background plays an important role in modelling text difficulty. Accordingly, in the following sections, we have developed different models of different reader groups, and in the process we have also shown that the models have different parameter values and configurations.

4.2 Computational modelling

Analyses of correlation coefficients give an estimation of trend in user ratings against text features. The next step is to develop suitable models for automatic readability prediction. To achieve the objective, we have used machine-learning methods such as support vector machine (SVM) and support vector regression (SVR) techniques. In addition, we have also presented a comparative study of performances of different text features in readability model building in this section. The features have been used in three combinations. First they were divided in two categories i) comprising of only the six features mentioned in table 4 as they represent the 'classical' features used extensively to model text readability, and ii) second category consists of the rest 14 features and the group is termed 'non-classical' , this yielded the first two combinations. The third combination consists of all the features. Therefore, we have evaluated six different types of SVM and SVR models for each group.

We have employed a binary SVM classifier here. Given a training set instance-class pairs $(\overline{x_i}, y_i)$, $i = 1 \ldots l$, where $\overline{x_i} \in R^n$ and $\overline{y} \in \{1, -1\}^l$, the general equation of a SVM is (Manning et al., 2008):

$$\frac{1}{2}\overline{w}^T\,\overline{w} + C\sum_{i}^{l}\xi_i \;\; is\; minimized,$$

$$\overline{w} = weight\; vector, C = regularization\; term \qquad \ldots (\text{equation: } 1)$$

$$y_i\left(\overline{w}^T\Phi(\overline{x_i}) + b\right) \geq 1 - \xi_i, \qquad \xi_i(slack\; variable) \geq 0 \qquad \ldots (\text{equation: } 2)$$

In this work, we have taken 90 texts against each group of users by combining the 45 reader group specific texts and 45 common texts (refer to section 3). Then for each category of reader, the texts were shuffled randomly. We have used 70 texts for training and 20 texts for evaluation of the model and performed 2-fold cross validation. The minimum, maximum and median of the rating distribution lie respectively at **(2.33)**, **(8.4)** and **(5.92)** for adult (group1) and at **(1.83)**, **(8.2)** and **(5.5)** for minor (group 2). To train and test the SVM models, we needed to spit the data in two classes (easy and hard), this has been done by assigning the ratings less than the median in to class easy (label '-1') and the rest to the class hard (label '1'), i.e., the user ratings were mapped to the label space $\overline{y}$. In case of SVR, the label space mapping was not required. The text features were mapped to the feature space $\overline{x_i}$. Although we have tested four types of kernel functions: linear, polynomial, radial basis and sigmoid on the data using LIBSVM (Chang and Lin, 2011) software, here only the results corresponding to linear and polynomial kernels have been presented as the other two kernels performed poorly. To evaluate the quality of the classifications for SVM, multiple correlation (R) and percentage of texts accurately classified (Acc) have been used. R denotes the extent to which the predictions are close to the actual classes and its square (R^2) indicates the percentage of dependent variable variation that can be explained by the model. Therefore, while percentage accuracy is an indicator to how well the model has performed to classify, R indicates the extent of explanatory power it posses. A better fit will have large R-value as well as Acc. For SVR, root mean square error (RMSE) has been reported instead of Acc; a good fit will have less RMSE. Below tables present, the SVM and SVR results for adult and minor's data for different kernels and different combination of features. The kernels were evaluated for a number of SVM parameter combinations and only the result corresponding to the most efficient one is presented.

Features	Classic features		Non-classic features		All features	
SVM parameters	C = 10; d = 2; r = 0; $\gamma = 1/6 = 0.1$; $\xi_i = 0.01$ (total support vector = 28)					
Kernel	R	Acc.	R	Acc.	R	Acc.
linear	0.75	76%	0.73	79%	0.80	87%
Polynomial	0.73	75%	0.72	75%	0.75	79.5%

Table 5: SVM for group1 readers

Features	Classic features		Non-classic features		All features	
SVM parameters	C = 1; d = 2; r = 0; $\gamma = 1/6 = 0.1$; $\xi_i = 0.001$ (total support vector = 22)					
Kernel	R	Acc.	R	Acc	R	Acc.
Linear	0.75	75%	0.72	77%	0.83	86%
Polynomial	0.71	70%	0.73	72%	0.78	76%

Table 6: SVM for group2 readers

Features	Classic		Non-classic features		All features	
Kernel	R	RMSE	R	RMSE	R	RMSE
linear	0.56	1.6	0.53	1.7	0.68	1.1
Polynomial	0.43	2.2	0.47	11.2	0.56	23.3

Table 7: SVR for group1 readers

Features	Classic		Non-classic features		All	
Kernel	R	RMSE	R	RMSE	R	RMSE
linear	0.50	1.5	0.54	1.4	0.65	1.2
Polynomial	0.47	3.1	0.45	15.5	0.51	29.7

Table 8: SVR for group2 readers

From table 5 and table 6, it can be seen that the SVM for the two target reader groups differ significantly in term of parameter attributes and their accuracy. It is also evident that incorporating only non-classic features versus classic features improves the accuracy of SVM very slightly and both types of features have similar explanatory power; combining both the classic and non -classic feature improves the accuracy and multiple correlations significantly. The SVR from table 7 and table 8 show the similar trend in terms of feature performances: classic and non-classis features have comparable RMSE and R, but there is significant gain when the two types are taken together. The regression equations for group1 and group2 readers differ in the coefficients of the feature variables; these imply that the two groups require different readability models. Moreover, the linear kernel was found to perform better than the polynomial kernel in all the cases.

5 Conclusion

In this paper, we have studied the effect of two important factors affecting text readability in Bangla: the target reader and text properties. We have found that the perception of text difficulty varies largely with the background of the reader. Accordingly, we have developed computational models to compute readability of Bangla text documents based on the target reader group. In order to achieve our goal we have first developed a novel Bangla dataset annotated in terms of text readability by users with varying age group. A preliminary analysis of the reading pattern of each target group was performed by analysing the correlation of text features with user annotations. Next, we have applied the SVM classifier to classify text documents into two different classes namely, *hard* and *easy*; the SVM for the two reader groups have different properties, implying the difference between two corresponding models. We have also compared the performance of the classifier based on the feature set they use. We observed that in contrast to applying only the classical features or the non-classic features, performance of the classifier improves if both types of features are used. This is true for both the adult as well as the minor's dataset. Overall, we have achieved an accuracy of around 86% for the minor's dataset and 87% for the adult dataset respectively. In addition to classification, support vector regression has been used to model text difficulty from an estimation perspective. The result of the SVR also establishes our previous findings. To the best of our knowledge, no such work on text readability has been recorded earlier in Indian languages, especially in Bangla. The next step of this study is to analyse the performance of the readability formula from one group (say adult) when applied to the other group (say minors) and vice versa. We will also repeat our study with more spread apart user groups spread over less diverse economic strata. In future, we are planning to develop for multi-class text readability models. The work will also be extended to model text comprehensibility for reading disabilities in Bangla.

Abstract

Word Sense Induction (WSI) aims to automatically induce meanings of a polysemous word from unlabeled corpora. In this paper, we first propose a novel Bayesian parametric model to WSI. Unlike previous work, our research introduces a layer of hidden concepts and view senses as mixtures of concepts. We believe that concepts generalize the contexts, allowing the model to measure the sense similarity at a more general level. The Zipf's law of meaning is used as a way of pre-setting the sense number for the parametric model. We further extend the parametric model to non-parametric model which not only simplifies the problem of model selection but also brings improved performance. We test our model on the benchmark datasets released by Semeval-2010 and Semeval-2007. The test results show that our model outperforms state-of-the-art systems.

1 Introduction

Word Sense Induction (WSI) aims to automatically induce meanings of a polysemous word from unlabeled corpora. It discriminates among meanings of a word by identifying clusters of similar contexts. Unlike the task of Word Sense Disambiguation (WSD), which classifies polysemous words according to a pre-existing and usually hand-crafted inventory of senses, WSI makes it attractive to researchers by eliminating dependence on a particular sense inventory and learning word meaning distinction directly based on the contexts as observed in corpora.

Almost all WSI work relies on the distributional hypothesis, which states that words occurring in similar contexts will have similar meanings. To effectively discriminate among contexts, proper representation of contexts would be a key issue. Basically, context can be represented as a vector of words co-occurring with the target word within a fixed context window. The similarity between two contexts of the target word can then be measured by the geometrical distance between the corresponding vectors. To ease the sparse problem and capture more semantic content, some kinds of generalizations or abstractions are needed. For example, a context of *bank* including *money* may not share similarity with that including *cash* measured at word level. However, given the conceptual relationship between *money* and *cash*, the two contexts actually share high similarity.

One straightforward way of introducing conceptualization is to assign semantic code to context words, where semantic codes could be derived from WordNet or other resources like thesauruses. However, two problems remain to be tackled. The first one concerns ambiguities of context words. Context words may have multiple semantic codes and thus word sense disambiguation to context words or other extra cost is needed. The second one concerns the nature of WSI task. WSI actually is target-word-specific, which means the conceptualization should be done specifically to different target words. A general purpose conceptualization defined by a thesaurus may not well meet this requirement and may not be equally successful in discriminating contexts of different target words.

To address these problems, we first propose a parametric Bayesian model which jointly finds conceptual representations of context words and the sense of the target word. We do this by introducing a layer of target-specific conceptual representation between the target sense layer and the context words layer

Proceedings of COLING 2014, the 25th International Conference on Computational Linguistics: Technical Papers, pages 355–364, Dublin, Ireland, August 23-29 2014.

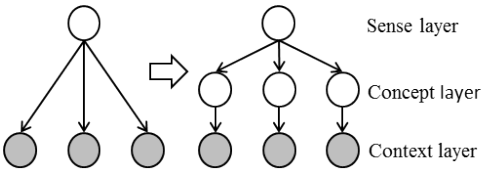

Figure 1: Architecture of our model

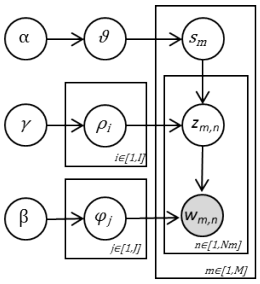

Figure 2: Graphical notation of the Basic Model

through a Bayesian framework as illustrated in Figure 1. From the generative perspective, the sense of the target word is first sampled. Then the sense generates different conceptual configurations which in turn generate different contexts. With a deeper architecture, our model makes it possible to induce word senses at a more abstract level, i.e. the concept level, which is not only less sparse but also more semantically oriented. Both the senses of the target word and the latent concepts are inferred automatically and unsupervisedly with inference procedure given enough contexts involving a target word. The latent concepts inferred with the model share similarities with those defined in thesauruses, as both of them cluster semantically related words. However, since the latent concepts are inferred with regard to individual target words, they are target-word-specific and thus fit the WSI task better than general purpose concepts defined in thesauruses. Context words may still correspond to multiple latent concepts. However, the disambiguation is implicitly done in the process of the word sense induction.

Setting the number of senses that the algorithm should arrive at is another problem frequently exercising the minds of WSI people. Instead of trying different sense numbers on a word-by-word basis, we propose to use Zipf's law of meaning (Zipf, 1945) to guide the selection of the sense numbers in this paper. With the law of meaning, sense numbers could be set on an all-word basis, rather than on a word-by-word basis. This is not only simple but also efficient, especially in the case where there are a large number of target words to be concerned.

We further extend the parametric model into a non-parametric model, as it allows adaptation of model complexity to data. By extending our model to non-parametric model, the need to preset the numbers of senses and latent concepts are totally removed and, moreover, the model performance is also improved.

We evaluate our model on the commonly used benchmark datasets released by both Semeval-2010 (Manandhar et al., 2010) and Semeval-2007 (Agirre and Soroa, 2007). The test results show that our models perform much better than the state-of-the-art systems.

2 The parametric model

2.1 Basic Model

The main point of our work is that different senses are signaled by contexts with different concept configurations, where different concepts are formally defined as different distributions over context words. Formally, we denote by $P(s)$ the global multinomial distribution over senses of an ambiguous word and by $P(w|z)$ the multinomial distributions over context words w given concept z. Context words are generated by a mixture of different concepts whose mixture proportion is defined by $P(z|s)$, such that:

$$P(w_i) = \sum_j P(s=j) \sum_k P(z_i = k|s=j) P(w_i|z_i = k)$$

Following the model, each context word w_i surrounding the target word is generated as follows: First, a sense s is sampled from $P(s)$ for the target word. Then for each context word position i, a concept z_i is sampled according to mixture proportion $P(z|s)$ and w_i is finally sampled from $P(w|z)$.

Figure 2 shows the model with the graphical notation, where M is the number of instances of contexts regarding to a concerned target word and N_m is the number of word tokens in context m. s_m is the sense label for target word in context m. $w_{m,n}$ is the n-th context word in context m. $z_{m,n}$ is the concept label associated with $w_{m,n}$. I is the total number of senses to be induced. J is the total number

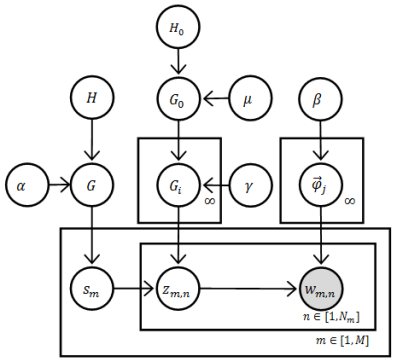

Figure 3: Graphical notation of the non-parametric WSI model

of concepts. $\vec{\theta}$ is the notational shorthand for the sense distribution $P(s)$, $\vec{\rho}_i$ is the shorthand for the i-th sense-concept distribution $P(z|s = i)$, and $\vec{\varphi}_j$ is the j-th concept-word distribution $P(w|z = j)$. Following conventional Bayesian practice, $\vec{\theta}$, $\vec{\rho}_i$ and $\vec{\varphi}_j$ are assumed to be drawn from Dirichlet priors with symmetric parameter α, γ, β respectively. The observed variable is represented with shaded node and hidden variable with unshaded node.

2.2 Zipf's law of meaning

Most of the WSI work requires that the number of senses to be induced be specified ahead of time. One straightforward way to deal with this problem is to repeatedly try different numbers of senses on a development set and select the best performed number. However, this should be done in principle on a word-by-word basis, and thus could be time-consuming and prohibitive when there are lots of target words to be concerned. A more systematic way of setting sense numbers in Bayesian models is extending the parametric model into a non-parametric model, which will be described in detail in section 3.

To work with our parametric model, we propose in this paper that an empirical law, Zipf's law of meaning (Zipf, 1945), could be used to guide the sense number selection. Zipf's law of meaning states that the number of sense of a word is proportional to its frequency as shown in the following equation:

$$I = K * f^b \tag{1}$$

where I is the number of word senses and f is the frequency of the word. K is the coefficient of proportionality which is unknown and b is about 0.404 according to an experimental study done by Edmonds (2006).

Certainly, Zipf's law of meaning is not as strict as a rigorous mathematical law. However, it sketches the distribution of the sense numbers with word frequencies of all words and allows us to estimate the sense numbers on an all-word basis by selecting appropriate coefficient K. This is not only simple but also efficient, especially in the case that there are a large number of target words to be concerned.

3 Non-parametric Model

A limitation of the parametric model is that the sense number I of the target word and the number J of latent concepts need to be fixed beforehand. Bayesian non-parametric (BNP) models offer elegant approach to the problem of model selection and adaption. Rather than comparing models that vary in complexity, the BNP approach is to fit a single model that can adapt its complexity to the data. Unlike the parametric approach, BNP approach assumes an infinite number of clusters, among which only a few are active given the training data. Our basic model can be naturally extended into a BNP model as shown in Figure 3. Instead of assuming a finite number of senses, we place a nonparametric, Dirichlet process (DP) prior on the sense distribution as follows:

$$\begin{aligned} G &\sim DP(\alpha, H) \\ s_m &\sim G, m = 1, 2, \ldots, M \end{aligned}$$

where α is the concentration parameter and H is the base measure of the Dirichlet process.

For each sense s_i of the target words, we place a Hierarchical Dirichlet process (HDP) prior on the mixture proportion to latent concepts shown as follows:

$$\begin{aligned} G_0 &\sim DP(\mu, H_0) \\ G_i &\sim DP(\gamma, G_0), i = 1, 2, \ldots \\ z_{m,n} &\sim G_i, n = 1, 2, \ldots, N_m \\ w_{m,n} &\sim \vec{\varphi}_{z_{m,n}} \end{aligned}$$

where μ and γ are concentration parameters to G_0 and G_i, H_0 is the base measure of G_0.

By using HDP priors, we make sure that the same set of concept-word distributions is shared across all senses and all contexts of a target word, since each random measure G_i inherits its set of concepts from the same G_0.

As in parametric model, $\vec{\varphi}_j$ is the j-th concept-word distribution $P(w|z = j)$, however, there are now an infinite number of such distributions. So is the number of senses. However, with a fixed number of contexts of the target word, only a finite number of senses and concepts are active and they could be inferred automatically by the inference procedure.

4 Model Inference

We use Gibbs sampling (Casella and George, 1992) for inference to both the parametric and nonparametric model. As a particular Markov Chain Monte Carlo (MCMC) method, Gibbs sampling is widely used for inference in various Bayesian models (Teh et al., 2006; Li and Li, 2013; Li and Cardie, 2014).

4.1 The Parametric Model

For the parametric model, we use collapsed Gibbs sampling, in which the sense distribution $\vec{\theta}$, sense-concept distribution $\vec{\rho}_i$ and concept-word distribution $\vec{\varphi}_j$ are integrated out. At each iteration, the sense label s_m of the target word in context m is sampled from conditional distribution $p(s_m|\vec{s}_{\neg m}, \vec{z}, \vec{w})$, and the concept label $z_{m,n}$ for the context word $w_{m,n}$ is sampled from conditional distribution $p(z_{m,n}|\vec{s}, \vec{z}_{\neg(m,n)}, \vec{w})$. Here $\vec{s}_{\neg m}$ refers to all current sense assignments other than s_m and $\vec{z}_{\neg(m,n)}$ refers to all current concept assignment other than $z_{m,n}$.

The conditional distribution $p(s_m|\vec{s}_{\neg m}, \vec{z}, \vec{w})$ and $p(z_{m,n}|\vec{s}, \vec{z}_{\neg(m,n)}, \vec{w})$ can be derived as shown in equation (2) and (3) respectively:

$$p(s_m = i|\vec{s}_{\neg m}, \vec{z}, \vec{w}; \alpha, \beta, \gamma) \propto (c_i^{\neg m} + \alpha) \cdot \frac{\prod_{j=1}^{J} \prod_{x=1}^{f_{m,j}} (c_{i,j}^{\neg m} + \gamma + x - 1)}{\prod_{x=1}^{f_{m,*}} (\sum_{j=1}^{J} c_{i,j}^{\neg m} + J * \gamma + x - 1)} \tag{2}$$

$$p(z_{m,n} = j|\vec{s}, \vec{z}_{\neg(m,n)}, \vec{w}; \alpha, \beta, \gamma) \propto (c_{s_m,j}^{\neg(m,n)} + \gamma) \cdot \frac{(c_{j,w_{m,n}}^{\neg(m,n)} + \beta)}{\sum_{t=1}^{V} c_{j,t}^{\neg(m,n)} + V * \beta} \tag{3}$$

Here, $c_i^{\neg m}$ is the number of instances with sense i. $c_{i,j}^{\neg m}$ is the number of concept j in instances with sense i. Both of them are counted without the m-th instance of the target word. $c_{s_m,j}^{\neg(m,n)}$ is defined in a similar way with $c_{i,j}^{\neg m}$ but without counting the word position (m, n). $c_{j,w_{m,n}}^{\neg(m,n)}$ is the number of times word $w_{m,n}$ is assigned to concept j without counting word position (m, n). $f_{m,j}$ is the number of concept j assigned to context words in instance m and $f_{m,*}$ is the total number of words in contexts of instance m. V stands for the size of the word dictionary, i.e. the number of different words in the data. x is an index which iterates from 1 to $f_{m,*}$.

$\vec{\theta}$, $\vec{\rho}_i$ and $\vec{\varphi}_j$ can be estimated in a similar way, we now only show as example the estimation of $\vec{\rho}_i$, parameters for sense-concept distributions. According to their definitions as multinomial distributions with Dirichlet prior, applying Bayes' rule yields:

$$p(\vec{\rho}_i|\vec{z}; \vec{\gamma}) = \frac{p(\vec{\rho}_i; \vec{\gamma}) * p(\vec{z}|\vec{\rho}_i; \vec{\gamma})}{Z_{\vec{\rho}_i}} = Dir(\vec{\rho}_i|\vec{c}_i + \vec{\gamma})$$

where $\vec{c_i}$ is the vector of concept counts for sense i. Using the expectation of the Dirichlet distribution, values of $\rho_{i,j}$ can be worked out as follows:

$$\rho_{i,j} = \frac{c_{i,j} + \gamma}{\sum_{k=1}^{J} c_{i,k} + J * \gamma}$$

Different read-outs of $\rho_{i,j}$ are then averaged to produce the final estimation.

4.2 The Non-parametric Model

Chinese restaurant process (CRP) and Chinese restaurant franchise (CRF) process (Teh et al., 2006) have been widely used as sampling scheme for DP and HDP respectively. As our non-parametric model involves both DP and HDP, we use both CRP and CRF based sampling for model inference.

In the CRP metaphor to DP, there is one Chinese restaurant with an infinite number of tables, each of which can seat an infinite number of customers. The first customer enters the restaurant and sits at the first table. The second customer enters and decides either to sit with the first customer or by herself at a new table. In general, the $n+1$st customer either joins an already occupied table k with probability proportional to the number n_k of customers already sitting there, or sits at a new table with probability proportional to α. As in our model, when we sample the sense s_m for each context, we assume that tables correspond to senses of target words and customers correspond to whole contexts in which the target word occurs.

In the CRF metaphor to HDP, there are multiple Chinese restaurants, and each one has infinitely many tables. On each table the restaurant serves one of infinitely many dishes that other restaurants may serve as well. At each table of each restaurant one dish is ordered from the menu by the first customer who sits there, and it is shared among all customers who sit at that table. The menu is shared by all the restaurants. To be specific to our model, when we sample the concept $z_{m,n}$ for each context word, we assume each sense s_m of the target word corresponds to a restaurant and each word $w_{m,n}$ corresponds to a customer while concept $z_{m,n}$ corresponds to the dishes served to the customer by the restaurant. Neither the number of restaurant nor the number of dishes is finite in our model.

For model inference, we first sample s_m using CRP-based sampling and then we sample $z_{m,n}$ for each s_m using CRF-based sampling. The sampling of s_m and $z_{m,n}$ are done alternately, but not independently. The sampling of s_m is conditional on the current value of $z_{m,n}$ and vice versa, conforming to the scheme of Gibbs Sampling.

The equation for sampling s_m is derived as in equation (4):

$$p(s_m = i|\vec{s}_{\neg m}, \vec{z}, \vec{w}) \propto \begin{cases} c_i^{\neg m} \cdot p(\vec{z}_m|\vec{z}_{\neg m}, s_m = i) & \textbf{if} \quad i = old \\ \alpha \cdot p(\vec{z}_m|\vec{z}_{\neg m}, s_m = i^{new}) & \textbf{else} \end{cases}$$

$$where$$

$$p(\vec{z}_m|\vec{z}_{\neg m}, s_m = i) = \frac{\prod_{j=1}^{J}\prod_{x=1}^{f_{m,j}}(c_{i,j}^{\neg m} + \gamma * \frac{c_{t,j}^{\neg m}}{c_{t,*}^{\neg m}+\mu} + x - 1)}{\prod_{x=1}^{f_{m,*}}(\sum_{j=1}^{J} c_{i,j}^{\neg m} + \gamma + x - 1)} \tag{4}$$

Here $p(\vec{z}_m|\vec{z}_{\neg m}, s_m = i)$ is estimated block-wise for context m according to the CRF metaphor. $c_i^{\neg m}$ and $c_{i,j}^{\neg m}$ are defined in the same way as that in equation (2). $c_{t,j}^{\neg m}$ is the number of tables with dish j in all restaurants but m and $c_{t,*}^{\neg m}$ means the number of tables in all restaurants but m. x is an index which iterates from 1 to $f_{m,*}$.

Sampling $z_{m,n}$ needs more steps than sampling s_m as we need to record the table assignment for each dish (concept). For each dish $z_{m,n}$ of a customer $w_{m,n}$, we first sample the table at which the customer sits according to the following equations:

$$p(t_{m,n} = t|\vec{t}_{\neg(m,n)}, \vec{z}_{\neg(m,n)}, w_{m,n}, s_m = i) \propto \begin{cases} c_{i,t}^{\neg(m,n)} \cdot p_j^{\neg(m,n)}(w_{m,n}) & \textbf{if} \quad t = old \\ \gamma \cdot p(w_{m,n}|\vec{t}_{\neg(m,n)}, t_{m,n} = t, \vec{z}_{\neg(m,n)}, w_{m,n}) & \textbf{else} \end{cases}$$

$$where$$

$$p_j^{\neg(m,n)}(w_{m,n}) = p(w_{m,n}|z_{m,n} = j, \vec{w}_{\neg(m,n)}) = \frac{c_{j,w_{m,n}}^{\neg(m,n)} + \beta}{\sum_{t=1}^{V} c_{j,t}^{\neg(m,n)} + V\beta}$$

	Basic Model	BNP
α	1.0	0.2
β	0.05	0.01
γ	0.05	0.2
μ	N/A	0.001
K	0.27	N/A
Concept number	20	N/A
Context window	$\pm$ 5 words	$\pm$ 9 words

Table 1: Hyperparamters of our models

Here $c_{i,t}^{\neg(m,n)}$ is the number of customers on table t in restaurant i and $c_{j,w_{m,n}}^{\neg(m,n)}$ has the same meaning as in equation (3). If the sampled table t is previously occupied, then $z_{m,n}$ is set to the dish j assigned to t according to the CRF metaphor. If the sampled table t is new, the probability $p(w_{m,n}|\vec{t}_{\neg(m,n)}, t_{m,n} = t, \vec{z}_{\neg(m,n)}, w_{m,n})$ is calculated using equation (5), which is the sum of the probability of all previously ordered dishes and the newly ordered dish.

$$p(w_{m,n}|\vec{t}_{\neg(m,n)}, t_{m,n} = t, \vec{z}_{\neg(m,n)}, w_{m,n}) = \sum_{j=1}^{J} \frac{c_{t,j}^{\neg(m,n)}}{c_{t,*}^{\neg(m,n)} + \mu} \cdot p_j^{\neg(m,n)}(w_{m,n}) + \frac{\mu}{c_{t,*}^{\neg(m,n)} + \mu} \cdot p_{j^{new}}^{\neg(m,n)} \tag{5}$$

Because a new table is added, we then sample a new dish for this table according to equation (6).

$$p(z_{m,n} = j|\vec{t}, \vec{z}_{\neg(m,n)}) \propto \begin{cases} c_{t,j}^{\neg(m,n)} \cdot p_j^{\neg(m,n)}(w_{m,n}) & \textbf{if} \quad j = old \\ \mu \cdot p_{j^{new}}^{\neg(m,n)}(w_{m,n}) & \textbf{if} \quad j = new \end{cases} \tag{6}$$

After the dish j is sampled, it is assigned to the new table and the number of table serving dish j is added.

Parameters $\vec{\theta}$, $\vec{\rho}_i$ and $\vec{\varphi}_j$ can be estimated in the same way as described in section 4.1.

5 Experiment

5.1 Experiment Setup

Data Our primary WSI evaluation is based on the standard dataset in Semeval-2010 Word sense induction & Disambiguation task (Manandhar et al., 2010). The target word dataset consists of 100 words, 50 nouns and 50 verbs. There are a total number of 879,807 sentences in training set and 8,915 sentences in testing set. The average number of word senses in the data is 3.79.

Model Selection The trail data of Semeval-2010 WSI task is used as development set for parameter tuning, which consists of training and test portions of 4 verbs. The 4 verbs are different words than the 100 target words in the training data. There are only about 138 instances on average for each target word in the training part of the trial data. To make a development set of more reasonable size, the trial data are supplemented with 6K instances of the 4 verbs extracted from the British National Corpus (BNC)[1] corpus. As we use the Zipf's law of meaning to guide the selection of number of senses, BNC was also used to count word frequencies.

The final hyper-parameters are set as in Table 1. In all the following experiments, Gibbs sampler is run for 2000 iterations with burn-in period of 500 iterations. Every 10th sample is read out for parameter estimating after the burn-in period to avoid autocorrelation. Due to the randomized property of Gibbs sampler, all results in the next sections are averaged over 5 runs. The average running time for each target word is about 7 minutes on a computer equipped with an Intel Core i5 processor working at 3.1GHz and 8GB RAM.

Pre-Processing For each instance of the target word in training data and testing data, all words are lemmatized and stop words like '*of*', '*the*', '*a*' which are irrelevant to word sense distinction are filtered. Words occurring less than twice are removed.

Evaluation method Semeval-2010 WSI task presents two evaluation schemes which are supervised evaluation and unsupervised evaluation. In supervised evaluation, the gold standard dataset is split into

[1] www.natcorp.ox.ac.uk/

Model	Supervised Evaluation		Unsupervised Evaluation		Averaged #s
	80-20 split	60-40 split	V-Measure	Paired-Fscore	
Basic Model	64.12	63.68	11.52	**44.42**	5
Basic Model + Zipf	66.4	65.25	15.2	35.12	7.66
BNP	**69.3**	**68.9**	**21.4**	23.1	15.62

Table 2: Test results with different configurations.

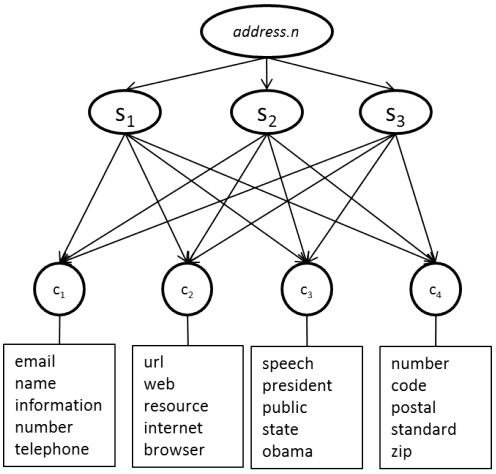

Figure 4: Examples of concepts induced with the BNP model specific to the target word *address.n* (with c_i denoting concept)

a mapping and an evaluation parts. The first part is used to map the automatically induced senses to gold standard senses. The mapping is then used to calculate the system's F-Score on the second part. According to the size of mapping data and evaluation data, the evaluation results are measured on two different splits which are 80-20 splits and 60-40 splits. 80-20 splits means that 80% of the test data are used for mapping and 20% are used for evaluation. In unsupervised evaluation, the system outputs are compared by using metrics V-Measure (Rosenberg and Hirschberg, 2007) and Paired F-Score (Artiles et al., 2009).

5.2 Experiment Results

Table 2 lists all experiment results. The Basic Model stands for the parametric model with fixed number of senses for all target words. The number of senses is set to 5 which gives the best performance on development set. Basic Model + Zipf is the model with the number of sense estimated by Zipf's law of meaning. BNP stands for our non-parametric model. As we can see, compared with the Basic Model with fixed sense number, the model using Zipf's law of meaning achieves improved performance. This means Zipf's law of meaning has positive effect in setting the sense number of the WSI task. BNP achieves the best performance on both supervised evaluation and V-measure evaluation. In terms of Paired F-score, however, the Basic Model gets the best results while BNP performs worst. This is consistent with what claimed by Manandhar et al. (2010), that Paired F-score tends to penalize the model with higher number of clusters.

As stated before, our models not only perform word sense induction but also group the context words into concepts. Figure 4 shows 4 of the concepts induced by BNP with regard to the target word *address.n*. Senses of *address.n* are defined as the mixture of concepts and concepts are defined as distributions over context words. We only list the top five words with the highest probabilities under each concept. As shown in Table 2, the non-parametric model induces much finer granularity of senses than the gold standard, it makes distinction among *email address*, *web address*, and even *ip address*. A possible solution is to further measure the closeness of senses based on the sense representations induced and merge similar senses to produce coarser granularity of senses.

Model	F-score(%)
BNP+position	**69.7**
BNP	69.3
Basic Model + Zipf	66.4
Basic Model	64.1
HDP	65.8
HDP+position (Lau et al., 2012)	68
distNB (Choe and Charniak, 2013)	65.4
UoY (Korkontzelos and Manandhar, 2010)	62.4

Model	F-score(%)
BNP+position	**88.0**
BNP	86.1
HDP (Yao and Van Durme, 2011)	85.7
HDP+position (Lau et al., 2012)	86.9
Feature-LDA (Brody and Lapata, 2009)	85.5
1-layer-LDA (Brody and Lapata, 2009)	84.6
HRG (Klapaftis and Manandhar, 2010)	87.6
I2R (Niu et al., 2007)	86.8

Table 3: Comparison with state-of-the-arts on Semeval-2010 data (left) and Semeval-2007 data (right)

5.3 Comparison with previous work

Much previous work (Brody and Lapata, 2009; Klapaftis and Manandhar, 2010; Yao and Van Durme, 2011) tested their models only on Semeval-2007 dataset (Agirre and Soroa, 2007) which consists of roughly 27K instances of 65 target verbs and 35 target nouns, coming from the Wall Street Journal corpus (WSJ) (Agirre and Soroa, 2007). For a complete comparison, we also test our model on the Semeval-2007 dataset. Since training data was not provided as part of the original Semeval-2007 dataset, we follow the approach of previous work (Brody and Lapata, 2009; Yao and Van Durme, 2011; Lau et al., 2012) to construct training data for each target word by extracting instances from the BNC corpus. Following paractices as much previous work (Brody and Lapata, 2009; Yao and Van Durme, 2011; Lau et al., 2012) did, we compare with previous work with supervised F-score on 80-20 data split in Semeval-2010 and noun data in Semeval-2007.

Table 3 (left) compares our models against the state-of-the-art systems tested on 80-20 data split in Semeval-2010. HDP+position (Lau et al., 2012) improved the HDP model (Yao and Van Durme, 2011) by including a position feature. distNB (Choe and Charniak, 2013) extends the naive Bayes model by reweighting the conditional probability of a context word given the sense by its distance to the target word. UoY (Korkontzelos and Manandhar, 2010) is the best performing system in Semeval-2010 competition which used a graph-based model. We re-implemented and tested the HDP model on the Semeval-2010 dataset since Yao and Van Durme (2011) and Lau et al. (2012) did not report their HDP results on this dataset.

Different with normal practice in WSI work, there is no feature engineering in our model. However, our BNP model outperformed all the systems on supervised evaluation. Even the Basic Model outperformed the best performing Semeval-2010 system. Especially, our BNP model performs much better than the HDP model. Both Lau et al. (2012) and Choe and Charniak (2013) show benefit of using positional information. Since our model does not exclude further feature engineering, we also introduce a position feature[2] into our non-parametric model (**BNP+position**) as in Lau et al. (2012). This contributes to a further 0.4% rise in performance.

Table 3 (right) compares our models with previous work on the nouns dataset in Semeval-2007. We divides systems being compared into two groups. The first group model the WSI task with Bayesian framework, while the second group uses models other than Bayesian model. Feature-LDA is the LDA-based model proposed by Brody and Lapata (2009) which incorporates a large number of features into the model. The 1-layer-LDA is their model with only bag-of-words features. HRG is a hierarchical random graph model. I2R is the best performing system in Semeval-2007. As shown in Table 3 (right), our BNP model with position feature (**BNP+position**) outperforms all systems. If we restrict our attention to the first group in which all models are Bayesian model, our BNP model without feature engineering outperforms the HDP model which is also non-parametric model without feature engineering.

6 Related Work

A large body of previous work is devoted to the task of Word Sense Induction. Almost all work relies on the distributional hypothesis, which states that words occurring in similar contexts will have similar meanings. Different work exploits distributional information in different forms, including context clustering models (Schütze, 1998; Niu et al., 2007; Pedersen, 2010; Elshamy et al., 2010; Kern et al., 2010), graph-based models (Korkontzelos and Manandhar, 2010; Klapaftis and Manandhar, 2010) and Bayesian

[2]Formally, the position feature is the context words with its relative position to the target word.

models. For Bayesian models, Brody and Lapata (2009) firstly introduced a Bayesian model to WSI task. They used the LDA-based model in which contexts of target word were viewed as documents as in the LDA model (Blei et al., 2003) and senses as topics. They trained a separate model for each target word and included a variety of features such as words, part-of-speech and dependency information. Yao and Van Durme (2011) extended LDA-based model into non-parametric HDP model but removed the feature engineering. Lau et al. (2012) showed improved supervised F-score by including position feature to the HDP model. Choe and Charniak (2013) proposed a reweighted naive Bayes model by incorporating the idea that words closer to the target word are more relevant in predicting the sense.

Our model differs from the context clustering models and graph-based models, as it is a Bayesian probabilistic model. Our work also differs from the LDA-based models. LDA topics were actually re-interpreted as senses of target word as Brody and Lapata (2009) applied the LDA to WSI tasks, so did Yao and Van Durme (2011) and Lau et al. (2012). They induced word senses by firstly tagging (sampling) senses (of target words) to context words and selecting the mostly tagged sense as sense of target words. Our model could be viewed as an extension of LDA, but fit the WSI task more naturally and much better. We distinguish senses of target words from concepts of context words and assume that they are separate. Therefore, our model has two hidden layers corresponding to the sense of the target word and the concepts of the context words respectively. Basically, one decide the sense of the target word based on the concept configuration of context words, instead of tagging senses of target word to context words. The separation of senses of target word and concepts of context words is actually not only required by linguistic intuition but also leads to improvement by our experiment. Our model is also different from the naive Bayes model since our model induces senses of the target word at concept level while naive Bayes model works at word level and does not involve conceptualization to context words at all.

7 Conclusion

In this paper, we first proposed a parametric Bayesian generative model to the task of Word Sense Induction. It is distinct from previous work in that it introduces a layer of latent concepts that generalize the context words and thus enable the model to measure the sense similarity at a more general level. We also show in this paper that Zipf's law of meaning can be used to guide the setting of sense numbers on an all-word basis, which is not only simple but also independent of the clustering methods being used. We further extend our parametric model to non-parametric model which not only simplifies the problem of model selection but also bring improved performance. The test results on the benchmark datasets show that our model outperforms the state-of-the-art systems.

Abstract

Automatically inferring new relations from already existing ones is a way to improve the quality and coverage of a lexical network and to perform error detection. In this paper, we devise such an approach for the crowdsourced JeuxDeMots lexical network and we focus especially on word refinements. We first present deduction (generic to specific) and induction (specific to generic) which are two inference schemes ontologically founded and then propose a transfer schema devoted to infer relations with and for word refinements.

1 Introduction

Efficiently building useful resources for Computational Linguistics (CL) is of a crucial interest. Most of existing lexical-semantic networks have been built by hand (like for instance WordNet (Miller et al., 1990)) and, despite that assisting tools are generally designed for consistency checking, the task remains time consuming and costly. Fully automated approaches are generally limited to term co-occurrences as extracting precise semantic relations between terms from corpora remains at best difficult. Crowdsourcing approaches are flowering in CL especially with the advent of Amazon Mechanical Turk or in a broader scope Wikipedia, to cite the most well known examples. WordNet is such a lexical network, constructed at great cost, based on synsets which can be roughly considered as concepts (Fellbaum, 1988). EuroWordnet (Vossen., 1998) a multilingual version of WordNet and WOLF (Sagot., 2008) a French version of WordNet, were built by automated crossing of the original Princeton WordNet and other lexical resources along with some more or less manual checking. Navigli (2010) constructed automatically BabelNet a large multilingual lexical network from term co-occurrences in Wikipedia. Although being very large and multilingually connected (which is tremendously usefull for machine translation, for instance) it contains few various lexical-semantic relations.

An *ideal* lexical-semantic network contains interconnected lemmas, word forms and multi-word expressions as entry points (nodes) along with word meanings and concepts. The idea itself of *word senses* as forwarded in the lexicographic tradition may be debatable in the context of resources for semantic analysis, and we generally prefer to consider the psycholinguistic idea of *word usages*. A given polysemous word, as identified by locutors, has several usages that might differ substantially from word senses as classically defined. A given usage can also in turn have several deeper refinements and the whole set of usages can take the form of a decision tree. For a very classical example, *bank* can be related to money or river : *bank* $\gtrdot$ *'bank>money'* and *bank* $\gtrdot$ *'bank>river'*. A *'bank>money'* can be distinguished as the financial institution or the actual building.

In the context of a collaborative construction, such a lexical resource should be considered as being constantly evolving and a general pragmatic rule of thumb is to have no definite certitude about the state of an entry. For a polysemous term, some refinements might be just missing at a given time

Proceedings of COLING 2014, the 25th International Conference on Computational Linguistics: Technical Papers, pages 365–375, Dublin, Ireland, August 23-29 2014.

notwithstanding the evolution of language which might be very fast, especially in technical domains. There is no way (unless by inspection) to know if a given entry refinements are fully completed, and even if this question is really relevant.

Creating collaboratively a lexical-semantic network (or, in all generality, any similar resource) can be devised according to two broad strategies. Firstly, it can be designed as a contributive system like Wikipedia where people willingly add and complete entries (like for Wiktionary). Secondly, contribution can be undertaken indirectly thanks to games (also known as GWAP (vonAhn, 2008)). In this case, players do not need to be aware that while playing they are helping building a lexical and semantic resource. In any case, the built network is not free of errors which are (or should be) corrected along their discovery. Thus, a large number of obvious relations may be missing in the lexical network but are indeed necessary for a high quality resources usable in various NLP applications, or even crucial notably for textual semantic analysis.

For example, contributors seldomly indicate that a particular bird type can fly, as it is considered as an obvious generality. Only notable facts which are not easily deductible are naturally contributed. Conversly, well known exceptions are also generally contributed and take the form of a negative weight and anotated as such (for example, *fly* $\xrightarrow{agent:-100}$ *ostrich* [exception: bird]). In order to consolidate the lexical network, we adopt a strategy based on a simple inference mechanism to propose new relations from those already existing. The approach is strictly endogenous (i.e. self-contained) as it doesn't rely on any other external resources. Inferred relations are submitted either to contributors for voting or to experts for direct validation/invalidation. A large percentage of the inferred relations has been found to be correct However, a non negligible part of them are found to be wrong and understanding why is both interesting and useful. The explanation process can be viewed as a *reconciliation* between the inference engine and contributors who are guided through a dialog to explain why they found the considered relation incorrect. The possible causes for a wrong inferred relation may come from three possible origins: false premises that were used by the inference engine, exception or confusion due to some polysemy.

In (Sajous et al., 2013) an endogenous enrichment of Wiktionary is done thanks to a crowdsourcing tool. A quite similar approach of using crowdsourcing has been considered by (Zeichner, 2012) for evaluating inference rules that are discovered from texts. In (Krachina, 2006), some specific inference methods are conducted on text with the help of an ontology. Similarly, (Besnard, 2008) capture explanation with ontology-based inference. OntoLearn (Velardi, 2006) is a system that automatically build ontologies of specific domains from texts and also makes use of inferences. There have been also researchs on taxonomy induction based on WordNet (see (Snow, 2006)). Although extensive work on inference from texts or handcrafted resources has been done, almost none endogenously on lexical network built by the crowds. In this article, we first present the principles behind the lexical network construction with crowdsourcing and *games with a purpose* (also known as human-based computation games) and illustrated them with the JeuxDeMots (JDM) project. Then, we present the outline of an *elicitation engine* based on an *inference engine* using deduction, induction and especially relation transfer schemes. The reconciliation engine which presents the second part of the elicitation engine is detailed on previous papers (Zarrouk, LREC2014) (Zarrouk, TALN2013). An experimentation with a discussion is then detailed.

2 Crowdsourced lexical networks

For validating our approach, we used the JDM lexical network, which has been made freely available by its authors, and constructed thanks to a set of associatory games (Lafourcade, 2007). There is an increasing trend of using online GWAPs (game with a purpose (Thaler et al., 2011)) method for feeding such resources. Beside manual or automated strategies, contributive approaches are flowering and becoming more and more popular as they are both cheap to set up and efficient in quality.

The network is composed of terms (as vertices) and typed relations (as links between vertices) with weights. It contains terms and possible refinements. There are more than 50 types for relations, that range from ontological (hypernym, hyponym), to lexical-semantic (synonym, antonym) and to se-

mantic role (agent, patient, instrument). The weight of a relation is interpreted as a strength, but not directly as a probability of being valid. The JDM network is not an ontology with some pristine, factorized and well-thought hierarchy of concepts or terms. A given term can have a substantial set of hypernyms that covers a large part of the ontological chain to upper concepts. For example, hypernym(cat) = {feline, mammal, living being, pet, vertebrate, ...}. Heavier weights associated to terms are those felt by users as being the most relevant. On the 1st of January 2014, there are more than 6 800 000 relations and roughly 310 000 lexical items in the JDM lexical network (according to the figures given by the game site: http://jeuxdemots.org). To our knowledge, there is no other, in French at least, existing freely available crowdsourced lexical-network, especially with weighted relations, thus enabling strongly heuristics or psycho-linguistically motivated methods.

3 Inferring Semantic Relations...

Adding new relations to the JDM lexical network may rely on two components: (a) an inference engine and (b) a reconciliator. The inference engine proposes relations as if it was a contributor, to be validated by other human contributors or experts. In case of invalidation of an inferred relation, the reconciliator is invoked to try to assess why the inferred relation was found wrong. Elicitation here should be understood as the process to transform some implicit knowledge of the user into explicit relations in the lexical network. The core ideas about inferences in our engine are the following:

- inferring is to derive new premises (taking the form of relations between terms) from previously known premises, which are existing relations;
- candidate inferences may be logically blocked on the basis of the presence or the absence of some other relations;
- candidate inferences can be filtered out on the basis of a strength evaluation. The strong assumption here is to consider strengh as a confidence level, which is in fact only partially exact. More precisely, high strengh values clearly correlate to confidence, but we cannot say much about low strength values.

Figure 1: On the left, triangular deductive inference scheme where logical blocking based on the polysemy of the central term B which has two distinct meanings B' and B'' is applied. Arrows labelled $\geqslant$ are word meaning/refinements. The relation R? is the conclusion that may be blocked. On the right, (A *is-a* B) and (A R C) are the premises, and (B R C) is the induction proposed for validation. Term A may be polysemous with refinements holding premises, thus inducing a probably wrong relation.

3.1 ... by Deduction and by Induction...

Inferring by deduction (Zarrouk, RANLP2013) is a top-down scheme based on the transitivity of the ontological relation *is-a* (hypernym). If a term A is a kind of B and B holds some relation R with C, then we can expect that A holds the same relation type with C. The scheme can be formally written as follows:

$$\exists\, A \xrightarrow{is\text{-}a} B \quad \wedge \quad \exists\, B \xrightarrow{R} C \quad \Rightarrow \quad A \xrightarrow{R} C$$

For example, *shark* $\xrightarrow{is\text{-}a}$ *fish* and *fish* $\xrightarrow{has\text{-}part}$ *fin*, thus we can expect that *shark* $\xrightarrow{has\text{-}part}$ *fin*. The inference engine is applied on terms having at least one hypernym (the scheme could not be applied otherwise). Of course, this scheme is far too naive, especially considering the resource we are dealing with and may produce wrong relations. Indeed, the central term B is possibly polysemous and ways to avoid probably wrong inferences can be done through a *logical blocking*: if there are two distinct meanings for B that hold respectively the first and the second relation, then most probably

the inferred relation is wrong (see figure 1) and hence should be blocked. Moreover, if one of the premises is tagged by contributors as *true but irrelevant*, then the inference is blocked.

It is possible to evaluate a confidence level (on an open scale) for each produced inference, in a way that dubious inferences can be eliminated out through *statistical filtering*. The weight w of an inferred relation is the geometric mean of the weights of the premises (relations (A *is-a* B) and (B R C) in figure 1). If the second premise has a negative value, the weight is not a number and the proposal is discarded. As the geometric mean is less tolerant to small values than the arithmetic mean, inferences which are not based on two rather strong relations (premises) are unlikely to pass.

$$w(A \xrightarrow{R} C) = (\, w(A \xrightarrow{is-a} B) \times w(B \xrightarrow{R} C)\,)^{1/2} \quad \Rightarrow \quad w3 = (w1 \times w2)^{1/2}$$

Although making a transitive closure over a knowledge base is not new, doing so considering word usages (refinements) over a crowdsourced lexical network is an original approach. As for the deductive inference, induction (Zarrouk, RANLP2013) exploits the transitivity of the relation *is-a*. If a term A is a kind of B and A holds a relation R with C, then we might expect that B could hold the same type of relation with C. More formally we can write: $\exists\, A \xrightarrow{is-a} B \;\wedge\; \exists\, A \xrightarrow{R} C \;\Rightarrow\; B \xrightarrow{R} C$
For example, *shark* $\xrightarrow{is-a}$ *fish* and *shark* $\xrightarrow{has-part}$ *jaw*, thus we might expect that *fish* $\xrightarrow{has-part}$ *jaw*. This scheme is a generalization inference. The principle is similar to the one applied to the deduction scheme and similarly some logical and statistical filtering may be undertaken. The central term here A, is possibly polysemous (as shown in figure 1). In that case, we have the same polysemy issues with the deduction, and the inference may be blocked. The estimated weight for the induced relation is:

$$w(B \xrightarrow{R} C) = (w(A \xrightarrow{R} C))^2 \,/\, w(A \xrightarrow{is-a} B) \quad \Rightarrow \quad w2 = (w_3)^2 / w_1$$

3.2 ... and Performing Reconciliation

Inferred relations are presented to the validator to decide of their status. In case of invalidation, a reconciliation procedure is launched in order to diagnose the reasons: error in one of the premises (previously existing relations are false), exception or confusion due to polysemy (the inference has been made on a polysemous central term). A dialog is initiated with the user. To know in which order to proceed, the reconciliator checks if the weights of the premises are rather strong or weak.

Errors in the premises. We suppose that the relation (A *is-a* B) (in figures 1) has a relatively low weight. The reconciliation process asks the validator if that relation is true. It sets a negative weight to this relation if it is false so that the inference engine blocks further inferences. Else, if the relation (A *is-a* B) is true, we ask about the second relation (B R C or A R C) and proceed as above if the answer is negative. Otherwise, we check the other cases (exception, polysemy).

Errors due to exceptions. For the *deduction*, in case we have two trusted relations, the reconciliation process asks the validators if the inferred relation is a kind of exception relatively to the term B. If it is the case, the relation is stored in the lexical network with a negative weight and annotated as *exception*. Relations that are exceptions do not participate further as premises for deducing. For the *induction*, in case we have two trusted relations, the reconciliator asks the validators if the relation ($A \xrightarrow{R} C$) (which served as premise) is an exception relatively to the term B. If it is the case, in addition to storing the false inferred relation ($B \xrightarrow{R} C$) in the lexical network with a negative weight, the relation ($A \xrightarrow{R} C$) is annotated as *exception*. In the induction case, the exception is a true premise which leads to a false induced relation. In both cases of induction and deduction, the *exception* tag concerns always the relation ($A \xrightarrow{R} C$). Once this relation is annotated as an exception, it will not participate as a premise in inferring generalized relations (bottom-up model) but can still be used in inducing specified relations (top-down model).

Errors due to Polysemy. If the central term (B for deduction and A for induction) presenting a polysemy is mentioned as polysemous in the network, the refinement terms $term_1$, $term_2$, ... $term_n$ are presented to the validator so he can choose the appropriate one. The validator can propose new terms as refinements if he is not satisfied with the listed ones (inducing the creation of new appropriate refinements). If there is no meta information indicating that the term is polysemous, we ask

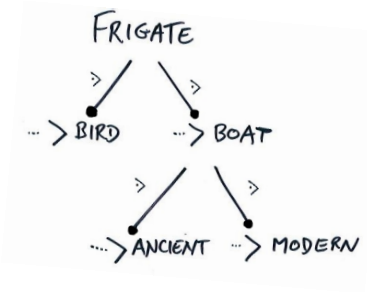

Figure 2: Refinement (noted $\gg$) tree of the term *frigate*. The first level discriminates between *frigate>bird* and *frigate>boat* which itself is refined between *(frigate>boat)>ancient* and *(frigate>boat)>modern*. This tree is a part of the lexical network which makes use of a specific refinement relation. Each refinement is connected to other terms of the network.

first the validator if it is indeed the case. After this procedure, new relations will be included in the network with positive values and the inference engine will use them later on as premises.

3.3 Transferring Relations with Refinements

A given polysemous word, as identified by locutors, has several usages that might differ substantially from word senses as classically defined. A given usage can also in turn have several deeper refinements and the whole set of usages can take the form of a decision tree. For example, *frigate* can be a bird or a ship. A *frigate>boat* can be distinguished as a modern ship with missiles and radar (*frigate>boat>modern*) or an ancient vessel with sails (*frigate>boat>ancient*). Having proper relations between refinements and other terms or refinements is crucial for word sense disambiguation.

The purpose of this scheme is to *enrich refinements and terms that are ontologically connected*. As its name indicates, this scheme requires the term A to have at least a refinement A' and at least one support relation that is ontological. The Relation Inference Scheme with Refinements (RIS_R) scheme, for each synonym, hypernym or hyponym (the support) B of the start term A, tries to share the outgoing relations between A' and B. The relations exchanged are the inferred relations to be validated or rejected latterly. To increase the relevance of the proposed relations, we make sure that some relation exists between the refinement term A' and the term B. For example, suppose we have A: $rose$ which has two refinements at least A': *rose>flower* and *rose>color* and a hypernym B: $plant$. In this example, the terms A': *rose>flower* and B: $plant$ are related (some relation exists between them) unlike the terms A': *rose>color* and B: $plant$. This strategy avoid proposing for example *rose>color* $\xrightarrow{has-part}$ *leaf* (an outgoing relation coming from B).

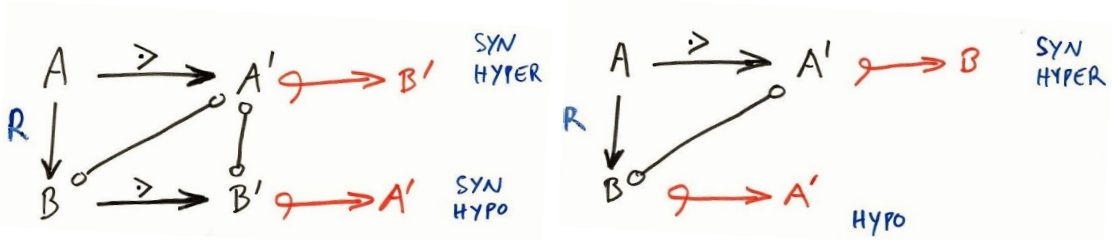

Figure 3: Relation Inference Scheme with Refinements (RIS_R). Above A (resp. B) has a refinement A' (resp. B'). Outgoing relations of A' are copied as outgoing relations of B' and vice-versa, according to the support relation (syn, hyper, hypo). On the right, we are in a *minimal* situation where B has no refinement.

Another strategy is not to propose outgoing relations from an hypernym to its hyponyms. The direction of the transfer is always from the hyponym to the hypernym because generally, outgoing relations of an hypernym are not all valid for its hyponyms. For example, for the term A: *animal* having a refinement A': *animal>zoology* which can have as parts *fin, scale, fang*... Those relations x $\xrightarrow{has-part}$ *(fin, scale, fang)* are not valid for the hyponym *cow*, for example.

This scheme has a behavior subtly different according to the nature of the term B (synonym, hypernym or hyponym) relatively to A. In figure 3, we use the following notations:

- $A \looparrowright B$: propose all the outgoing relations of A as outgoing relations for the term B (other notation as $\mathbb{C}$ to copy relations and $\mathbb{D}$ to displace them are available but not used here);
- $A \circ\!\!-\!\!-\!\!\circ B$: a relation between A and B in any direction exists.

4 Experimentations and Discussion

Our experiments consisted in applying and assessing the schemes presented above on the entire lexical network. This has been once during one run. At the time of writing of this article, the JeuxDeMots consists in more than 6 800 000 relations betweeen 310 000 terms. Specifically, it contains over 150 000 hypernym *is-a* relations, 170 000 syn relations and 27 000 hyponym relations.

Relation type	**Proposed %**
is-a (x is a type of y)	6.2
has-parts (x is composed of y)	25
holonyms (y specific of x)	7.2
typical place (of x)	7.2
charac (x as characteristic y)	13.7
agent-1 (x can do y)	13.3
instr-1 (x instrument of y)	1.7
patient-1 (x can be y)	1
place-1 (x located in the place y)	9.8
place > action (y can be done in place x)	3.4
object > mater (x is made of y)	0.3

Table 1: Percentages of relation proposed per relation type globally for deduction and induction.

4.1 Assessing Deduction and Induction

We applied the inference engine on around **32 000** randomly selected terms having at least one hypernym or one hyponym and thus produced by deduction more than **2 700 000** inferences and produced by induction over **430 000** relation candidates. The threshold for filtering was set to a weight of 25. This value is relevant as when a human contributor proposed relation is validated by experts, it is introduced with a default weight of 25 (the choice of this particular value is arbitrary and could have been different). The transitive *is-a* (Table1) is not very productive which might seem surprising at first glance. In fact, the *is-a* relation is already quite populated in the network, and as such, fewer new relations can be inferred. The figures are inverted for some other relations that are not so well populated in the lexical network but still are potentially valid. The *has-parts* relation and the agent semantic role (the *agent-1* relation) are by far the most productive types.

Deduction	**% valid**		**% error**		
Rel type	**rlvt**	**¬ rlvnt**	**prem**	**excep**	**pol**

Table 2: On the left, number of propositions produced by *deduction* and ratio of relations found as true or false. On the right, Number of propositions produced by *induction* and ratio of relations found as true or false.

Table 2 presents some evaluations of the status of the inferences proposed by the inference engine through deduction and induction respectively. Inferences are valid for an overall of 80-90% with around 10% valid but not relevant (like for instance *dog* $\xrightarrow{has-parts}$ *proton*). We observe that error number in premises is quite low, and errors can be easily corrected. Of course, not all possible errors are detected through this process. More interestingly, the reconciliation allows in 5% of the cases to

RIS_R	# existed	# proposed	productivity
syn	38 792	105 288	271.41%
hyper	139 490	101 908	73.05%
hypo	38 756	101 336	261.47%

Table 3: The number of relations existing before application of the scheme and those proposed by the scheme. The statistics were made on the terms on which the scheme has proposed inferences

identify polysemous terms and refinements. Globally false negatives (inferences voted false while being true) and false positives (inferences voted true while being false) are evaluated to less than 0,5%. For the induction process, the relation *is-a* is not obvious (a lexical network is not reductible to an ontology and multiple inheritance is possible). Result seems about 5% better than for the deduction process: inferences are valid for an overall of 80-95%. The error number is quite low. The main difference with the deduction process is on errors due to polysemy which is lower with the induction process. To try to assess a baseline for those results, we compute the full closure of the lexical network, i.e. we produce iteratively all possible candidate relations until no more could be found, each candidate being considered as correct and participating to the process. We got more than 6 million relations out of which 45% were wrong (evaluated on around 1 000 candidates randomly chosen).

4.2 Assessing Relation Transfer

We applied the scheme of refinements relation transfer with three different support relations:
• RIS_R (synonym): the scheme applied with syn as support (in case of existence of B' the terms A' and B' share relations.)
• RIS_R (hyponym): the scheme applied with hypo (relations are shared from B or B' to A')
• RIS_R (hypernym): the scheme applied with R=hyper (relations are shared from A' to B or B').
RIS_R stands for *Relation Inference Schema with Refinements*.

Relation type	**syn**	**hypo**	**hyper**
associated	50 946	39 325	51 960
has-part	13 362	13 120	8 049
is-a	3 711	5 114	5 707
hyponym	6 463	10 186	6 326
holonym	1 927	1 407	3 757
charac	10 378	10 063	7 614
location	5 921	9 251	5 529
agent-1	6 887	9 366	3024
other	5 693	4 076	9 370

Relation type	**syn**	**hypo**	**hyper**
associated	92.4%	65%	60.8%
has-part	93.2%	46.9%	80.8%
is-a	86.2%	56.4%	46%
hyponym	69.7%	60%	65%
holonym	74.4%	60.7%	64.2%
charac	91.5%	73.9%	90.5%
location	91.1%	81%	79.5%
agent-1	92.1%	78.9%	90.9%

Table 4: On the left, relations proposed by type of the support relation and relation type of the conclusion. On the right, percentage of valid relations by type of the support relation and relation type of the conclusion.

Relation Transfer Productivity - Since the schema has a condition to be applied, the propositions (inferred relations) are made for only **6 349** terms fullfilling the constraints. The whole process produced **308 532** inferences presenting totally new relations not existing before in the network which make about **49** new relations per entry. The RIS_R(syn) produced **2.7** times the existing relations which make it the most productive version, followed by the RIS_R(hypo) producing **2.6** times and the RIS_R(hyper) with a productivity of **0.73** (table 3). The inferred relations are detailed by relation type in the left table 4. The different relation types are variously productive, and this is mainly due to the number of existing relations and the distribution of their type. The "associated" type is the most proposed from both three schemes and this is explained by the large semantic spectre of this relation type since it refers to every term associated to the target term. In the network, the most possessed relations of a term are typed with the associated relations. The amount of the relations proposed is related to the one existing in the network. If a relation type is quite populated in the network, fewer new relations can be inferred. The figures are inverted for some other relations that are not so well populated in the lexical network but still are potentially valid.

Relation Transfer Accuracy - The validation process was applied manually on a sample of around 1 000 propositions randomly choosen for each scheme. The synonym version has the highest accuracy with **90.76 %** valid relations, hypernym version with **72.69 %** and **66.24 %** for the hyponym version (table 4). The synonym version of the scheme has systematically the best accuracy for all the relation types. Some accuracy percentages are lower than others for some reasons. In certain cases, some outgoing relations of an hyponym do not suit for the hypernym. For example:
• A: animal • A': animal>animalia • $B(hypo)$: cat
⇒ The inference scheme will propose the outgoing relation of cat (*cat* $\xrightarrow{is-a}$ *pet*) to $animal$>$animalia$ (*animal>animalia* $\xrightarrow{is-a}$ *pet*) which is wrong and this explain the weak percentage of accuracy for example of the relation *is-a* (56.4% by the RIS_R(hypo) and 46% by the RIS_R(hyper)) and $has-part$ (46.9% by the RIS_R(hypo)).
Another reason is that in the network, some terms are not refined (or not completely refined) which can lead to some wrong relations, as for example: • A: cheese • A': cheese>dairy product • $B(hypo)$: goat [1]
⇒ The inference scheme will propose the relation (*cheese>dairy product* $\xrightarrow{has-part}$ *teats*) which is wrong and thus because the term $goat$ is not yet refined into *goat>dairy product* and *goat>animal*.

From the figures, we can make the following observations. First, global results show that produced inferences are strongly valid with synonyms. The results are poorer with hypernyms and hyponyms (table 4) which is obvious regarding that with synonym, the terms exchanging relations are roughly at the same level of the taxonomic hierarchy which is not the case when they are related with an hyponym or hypernym relation.

5 Conclusion

We have presented some issues in inferring new relations from existing ones to consolidate a lexical-semantic network built with games and user contributions. To be able to enhance the network quality and coverage, we proposed an elicitation engine based on inferences (induction, deduction and relation transfer with refinements) and reconciliation. If an inferred relation is proven wrong, a reconciliation process is conducted in order to identify the underlying cause and solve the problem.

We focused our work on the transfer of relations related to word usage (refinements) with help of a support relation being either synonym, hypernym or hyponym. Unlike deduction and induction, the transfer scheme does not rely directly on the relation (*is-a*), but merely on terms that may be ontologicaly connected to the target. Experiments showed that relation transfer for refinements is quite productive (compared to deduction and induction), and is satisfying in correctness especially with synonym as support relation. The most obvisous reason is that in general a (quasi-)synonym is almost at the same level with the target term, and at least much more often than a hypernym or hyponym. User evaluation showed that wrong inferred relations (between around 20-15% of all inferred relations) are still logically sound and could not have been dismissed *a priori*. Relation transfer with refinements can conclusively be considered as a usefull and efficient tool for relation inference, and it may be really crucial as support for building information to be used in word sense disambiguation. In particular, it can help proposing hypernyms for the target term when they are missing, making possible further deductions or inductions. Hence, a virtuous circle may be initiated.

Still, the main difficulty of such approach relies in setting the various parameters in order to achieve an appropriate and fragil tradeoff between an over-restrictive filter (many false negatives, resulting in information losses) and a too lenient engine (many false postive, resulting in more human effort). The elicitation engine we presented through schemes based on deduction, induction and more precisely on relation transfer is an efficient error detector and a polysemy identifier. The actions taken during the reconciliation forbid an inference proven wrong or exceptional to be inferred again. Each inference scheme may be supported by the two others in particular for refinements, and if a given inference has been produced by more than one of these three schemes, it is almost surely correct.

[1] In french, some dairy products are called sometimes by the name of the producer animal, like $chevre$(*goat*) for the cheese made from the goat's milk

An additional inference scheme, *abduction*, reinforced our inference engine and guided it through producing accurate new relations with an interesting accuracy. This scheme can be viewed as an example based strategy. Hence abduction relies on similarity between terms, which may be formalized in our context as sharing some outgoing relations between terms. The abductive inferring layout supposes that relations held by a term can be proposed to similar terms. Abduction first selects a set of similar terms to the target term A which are considered as proper examples. The outgoing relations from the examples which are not common with those of A are proposed as potential relations for A and then presented for validation/invalidation to users. Unlike induction and deduction, abduction can be applied on terms with missing or irrelevant ontological relations, and can generate ontological relations to be used afterward by the inference loop. This scheme was detailed in our paper (M. Zarrouk, EACL2014).

Researches are undertaken on (semi)automating the inference schemes or inference rules (scheme with just one or two unknown terms) discovery by our elicitation system. Enhancements are also considered on our previous schemes as for exemple defining the inference's scope especially in deduction and induction (example: what to do to avoid transferring invalid inferences from the term *animal* as *has-part wings* to its hyponyms like *cat* or *fish*).

We are also modelling a declarative query language that allows users to manipulate the lexical-semantic network and to apply our elicitation engine according to their needs while remaining focused on their request and without drifting in database access or linguistic domain.

A Supervised Learning Approach Towards Profiling the Preservation of Authorial Style in Literary Translations

Gerard Lynch

University College Dublin
Ireland
firstname.lastname@ucd.ie

Abstract

Recently there has been growing interest in the application of approaches from the text classification literature to fine-grained problems of textual stylometry. This paper seeks to answer a question which has concerned the translation studies community: how does a literary translator's style vary across their translations of different authors? This study focuses on the works of Constance Garnett, one of the most prolific English-language translators of Russian literature, and uses supervised learning approaches to analyse her translations of three well-known Russian authors, Ivan Turgenev, Fyodor Dosteyevsky and Anton Chekhov. This analysis seeks to identify common linguistic patterns which hold for all of the translations from the same author. Based on the experimental results, it is ascertained that both document-level metrics and n-gram features prove useful for distinguishing between authorial contributions in our translation corpus and their individual efficacy increases further when these two feature types are combined, resulting in classification accuracy of greater than 90 % on the task of predicting the original author of a textual segment using a Support Vector Machine classifier. The ratio of nouns and pronouns to total tokens are identified as distinguishing features in the document metrics space, along with occurrences of common adverbs and reporting verbs from the collection of n-gram features.

1 Introduction

The application of *supervised learning* technologies to textual data from the humanities in order to shed light on stylometric questions has become more popular of late. In particular, these approaches have been applied to questions from the field of translation studies, which concern the notion of *translationese*[1] detection in Italian and other languages, (Baroni and Bernardini, 2006; Ilisei et al., 2010; Ilisei and Inkpen, 2011; Popescu, 2011; Koppel and Ordan, 2011; Lembersky et al., 2011). Work has also been carried out on source language detection from translation corpora, (van Halteren, 2008; Lynch and Vogel, 2012) and translation direction detection in parallel MT training corpora, (Kurokawa et al., 2009), which can have applications in the domain of machine translation where the direction of bilingual translation corpora has been shown to impact on the accuracy of automated translations using such corpora[2].

This work seeks to apply these methods to the task of identifying authorial style within a corpus of translations by the same translator. Venuti (1995) mentions the concept of the *translator's invisibility*, that the measure of the best translator is that their style is not distinguishable in the translation, that their main concern and focus is to deliver the original text in a faithful manner. Of course, this task is often subject to their own vocabulary choices and as was often the case, cultural or personal bias of the translator or the regime or government in which they were operating. Identifying the former case will

[1] The subset or dialect of language which consists solely of translations from another language.

[2] Translating FR-EN, a smaller bilingual corpus of French translated to English provides similar qualitative results (BLEU score) to a larger corpus consisting of English translated to French.

Proceedings of COLING 2014, the 25th International Conference on Computational Linguistics: Technical Papers, pages 376–386, Dublin, Ireland, August 23-29 2014.

be the focus of this work, as choices of vocabulary or sentence construction can be isolated through the application of machine learning methods, although the latter is also a highly interesting question, albeit a more complex one to tackle using the methods at hand.[3]

2 Previous work

Baroni and Bernardini (2006) were among the first to apply advanced machine learning techniques to questions of textual stylometry, although use of linguistic features and metrics was already established in studies such as Borin and Pruetz (2001) who worked on POS distributions in translated Swedish and work by Mikhailov and Villikka (2001) who examined translated Finnish using statistical methods and metrics from authorship attribution. Baroni and Bernardini (2006) investigated a corpus of translated and original text from an Italian current affairs journal using a Support Vector Machine classifier, managing ca. 87% accuracy in distinguishing the two textual classes. Their study also investigated the performance of humans on such a task and found that the machine learning algorithm was more consistent although it was outperformed by one of the expert human analysts. Ilisei et al. (2010) used textual features such as type-token ratio and readability scores in their work on detecting translated text in Spanish and obtained comparable accuracy to Baroni and Bernardini (2006) who mostly used mixed POS and word n-grams. Popescu (2011) employed a different approach using a feature set consisting of n-grams of characters, and maintained reasonable accuracy in classifying translated literary works from originals.

Koppel and Ordan (2011) concerned themselves with the concept of *dialects* of translationese and whether translations from the same source language were more similar to one another than translations from different source languages and to what extent genre affected translationese. In their experiments on the Europarl corpus and a three source-language corpus from the International Herald Tribune, they found that training on one corpus and testing on another reported low accuracy, indicating genre effects, coupled with the fact that training on a corpus of translations from one source language and testing on a corpus translation from another source language obtained poorer results than using a corpus of translations from several source languages.

van Halteren (2008) investigated the predictability of source language from a corpus of Europarl translations and predicted source language with an accuracy of over 90%, using multiple translations of a source text in different languages. Distinguishing features from the Europarl corpus included phrases such as *a certain number* in texts of French origin, *framework conditions* in texts of a German origin and various features that were particular to the nature of the corpus as a collection of parliamentary speeches.[4] More recently, Lynch and Vogel (2012) revisited the source language detection task with a focus on literary translations, and obtained classification accuracy of ca. 80% on a corpus of translations into English from Russian, German and French using a feature set containing a combination of ratios of parts of speech and POS n-grams. Texts translated from French had a higher ratio of nouns to total words than the other two categories, and the frequency of contractions such as *it's* and *that's* varied between the subcorpora.

Focusing on the stylistic variation of individual translators from the point of view of researchers in translation studies, Baker (2000) defined frameworks for performing stylistic analyses of translator's using quantitative methods. Her own examples examined translators of Portuguese and Arabic and focused on the translation of common verbs, such as *say* and *tell*. She found that the frequency of these verbs was a distinguishing metric between translators but was careful to mention that these features might vary depending on the corpora in question. Winters (2007) profiled translator style in two translations of F. Scott Fitzgeralds *The Beautiful and the Damned*, focusing on modal particles and speech act reporting verbs as a distinguishing aspect of translatorial style. Vajn (2009) applied textual metrics such as type-token ratio and relative vocabulary richness to two translations of Plato's *Republic* to investigate the variation between two translations by Benjamin Jowett and Robin Waterfield and developed a theory of co-authorship to explain the complementary stylistic effect of authorial and translatorial style.

[3] See Li et al. (2011) and Wang and Li (2012) for examples of studies of translation from Chinese and English which take the cultural background of translators into account when discussing distinguishable features.

[4] German native speakers addressed the congregation in a different manner to English native speakers, for example.

Ongoing work in translation studies and digital humanities have examined the question of translatorial vs. authorial style using computational analyses. Burrows (2002) investigated the stylistic properties of several English translations of Roman poet Juvenal using his own Delta metric developed for authorship attribution and the frequencies of common words, Lucic and Blake (2011) investigated two translations of German author Rainer Maria Rilke in English using the Stanford Lexical Parser and found differing patterns of syntactic structure such as negation modifiers and adverbial modifiers.[5]

Recently, Forsyth and Lam (2013) analysed two parallel English translations of the French-language correspondence of Theo and Vincent Van Gogh using k-nearest neighbour classifiers and a feature set consisting of the sixty-nine most frequent words and found that a distinct authorial style for each of the brothers was preserved in both translations, with translatorial style also proving distinguishable, albeit to a lesser extent than its authorial counterpart. Lynch (2013) investigated two English translators of Henrik Ibsen's dramas using machine learning methods and found that document metrics and n-gram features similar to those used in this current study proved accurate in distinguishing authorship of parallel translations of the same source, and also that document metrics such as average sentence length distributions learned from translations of different works by the same author could be used to classify the author of a parallel translation, indicating that the translators' styles were learnable across a diverse corpus of works by the same author.

Rybicki (2006) used Burrow's Delta to investigate the stylistic nature of character idiolects in dramatic translation, focusing on Polish drama, and found that the translated idiolects tended to cluster in similar patterns[6] to the idiolects in the original text. Lynch and Vogel (2009) worked on a similar topic, the clustering of character idiolects in English and German translations of Henrik Ibsen's plays using the χ^2 metric. Rybicki and Heydel (2013) used Burrow's Delta, and dendrogram clustering to investigate the case of a Polish translation of Virginia Woolf's *Night and Day* and found that the method identified the point in the novel where one translator had taken over from another[7] Rybicki (2012) had previously used these techniques to distinguish translatorial style in a large corpus of Polish translations and concluded that such style was not to be captured using the methods at hand, which consisted of using Burrow's Delta metric with five thousand of the most frequent words. Although the metric performed well at clustering translations by author, it failed to cluster translations by translator, leading the author to conclude that as Venuti (1995) had claimed, the best translators are in fact invisible.

Although these studies are generally of an exploratory nature and often seek to draw conclusions about particular literary works and figures, the methodologies used are general to textual stylometry and have been successfully applied to emerging tasks in computational linguistics such as MT quality estimation, (Felice and Specia, 2012), personality detection (Mairesse and Walker, 2008), sentiment analysis (Gamon, 2004), fraud detection (Goel and Gangolly, 2012) and many other studies where textual analyses are pertinent.

3 Motivation and background to study

In this study, the translations of a literary translator of a number of different authors are examined in order to measure the extent to which authorial style is preserved by the translator in question. This analysis encompasses features represented by n-grams of words or POS tags and also stylometric metrics based on whole texts, such as type-token ratio, lexical richness and readability scores. Previous work (Rybicki and Heydel, 2013; Burrows, 2002; Rybicki, 2012; Koppel and Ordan, 2011) focused on lists of highly frequent words in their analysis of translations. By using supervised learning techniques, it is possible to investigate exactly which words are discriminating between author's idiolects in translation, regardless of frequency, together with abstract representations of word types and textual metrics, which present an alternative overview of the data in question.

This study examines the translations of British translator Constance Garnett (1861-1946) from the Russian originals written by Fyodor Dosteyevsky, Ivan Turgenev and Anton Chekhov. Moser (1988) and

[5] *not* and *nearly*.

[6] Villians with villians, heroes with heroes and female and male characters formed separate clusters

[7] The original translator passed away before she could finish the translation, hence the completion by another party.

Remnick (2005) write about Garnett's[8] life, describing her early days as a student of Latin and Greek in Cambridge, marriage to publisher and literary figure Edward Garnett and her chance introduction to Russian literature by the chance meeting with a young revolutionary in London. Along with the three aforementioned characters, she also translated works by Leo Tolstoy and Nikolai Gogol, Alexander Ostrovsky and Alexander Herzen, seventy works in all.

According to Moser (1988), her reputation was firmly established with her translations of Turgenev and thereafter Garnett was more or less responsible for igniting the English language-world's love affair with Dosteyevsky. Her translations were not without criticism however, Moser (1988) mentioning that Edmund Wilson believed she caused Russian authors to sound *more or less the same*, a claim echoed later by Joseph Brodsky who remarked that the average Western English-language reader cannot distinguish Tolstoy's voice from Dosteyevsky's, as they are in fact reading Constance Garnett's own voice.

Indeed, Remnick (2005) describes Garnett's translation style and mentions how she translated at breakneck speed, often skipping over sections which she did not understand. He also mentions Vladimir Nabokov's disdain for Garnett's translations, who was known to scribble vitriolic notes in the margins of Garnett translations during his tenure as a professor at Cornell and Wellesley in the United States. Remnick notes that children's book author Kornei Churnosky praised her translations of Turgenev and Chekhov but was less than pleased with her rendering of Dosteyevsky, complaining that she had smoothed over the erratic and challenging original text of that particular author. Thus, this work focuses on these claims of distinguishability in particular, for it is exactly these characteristics that can, in principle, be investigated using *supervised learning* techniques: Is it the case that one can automatically distinguish Garnett's renderings of Dosteyevsky from her translations of Turgenev, and if so, based on which textual characteristics, word distributions or individual word frequencies?

4 Corpus and methodology

The corpus was limited in these experiments to works by Dosteyevsky, Turgenev and Chekhov as these were the three authors translated by Garnett for which the most public domain text was available. Texts were downloaded from Project Gutenberg.[9]The final corpus consisted of eight works by Turgenev, seven works by Dosteyevsky and eleven collections of short stories by Chekhov. A selection of random text was made from each work matching the size of the smallest possible size of a work by each author and this selection was then divided into chunks of ten kilobytes each. The resulting corpus contains 942 segments from the three authors, 330 from Chekhov, 192 from Turgenev and 420 from Dosteyevsky. TagHelperTools was used to create the n-gram tokens, (Rosé et al., 2008) and calculate nineteen document statistics using TreeTagger, (Schmid, 1994) to tag texts for parts-of-speech. Weka, (Frank et al., 2005) was used for the *supervised learning* experiments, the SMO implemenation of a Support Vector Machine classifier along with the Naive Bayes and Simple Logistic Regression algorithms were used in the experiments.

The eighteen document level metrics used in the experiments are listed in Table 2. These were influenced by features used by Ilisei et al. (2010) in work which examined the problem of *translationese* detection in Spanish text. The two readability metrics employed are the Coleman-Liau Index, (Coleman and Liau, 1975) and the Automated Readability Index, (Smith and Senter, 1967). The n-gram features are calculated using TagHelper tools and the frequency of these features were reduced to a binary variable detailing the occurrence or non-occurrence of each feature in each segment.

5 Experiments

5.1 Document-level metrics

Experiments were carried out using different feature sets on the corpus described in Section 4. The experiments seek to classify the original author of a translated textual segment. The SVM classifier managed to achieve 87% accuracy when averaged using ten-fold cross validation on the whole corpus

numratio	numerals : total words	typetoken	word types : total words

Table 2: Document-level metrics used

using document-level features only. This result suggests that the authorial style of the three authors in question has indeed been preserved in translation.

Examining the features ranked by information gain in Table 3, it is clear that the ratio of nouns to total words and the ratio of pronouns to total words are highly distinguishing between the original authors. Ratio of prepositions to total words and the type-token ratio also feature in more elevated positions on the list than readability scores and sentence length measures.

5.2 N-gram features

The next set of experiments concerned the use of n-gram features, namely word unigram and POS bi-grams. For the word features, all noun features were removed as these, while providing clues to the identity of the author of a translation, are arguably not universal features of authorial style[10]. Verb features were not removed in such a fashion, however it may be argued that these also contain topical information and should be treated with caution. The remaining features were ranked by efficacy using the information gain metric and ten-fold cross validation and a subset of one hundred features were used for the classification experiments.

The SVM classifier in Weka with a linear kernel obtained 89.5% accuracy using a dataset of 100 words. The Simple Logistic regression classifier obtained 91.5% accuracy using the same feature set. This feature set was obtained by ranking the total list of word unigrams using information gain over ten-fold cross validation and removing the noun features as mentioned above. These high accuracy scores

[10]There is interest in lexical variation in translation, (Kenny, 2001) but this work focuses on stylistic features such as verbs and closed-class words as they are less prone to bias from the themes or topics in a text

obtained further reinforce the results obtained by using the document-level metrics, that a distinct textual style is learnable from the translations by Garnett of Dosteyevsky, Tolstoy and Turgenev. A number of these features and their relative frequencies are displayed in Table 6.

Feature	Rank.	Feature	Rank.
nounratio	1	avgwordlength	2

18 doc metrics	Naive Bayes	87.89%
100 words	SVM	89.5%
100 words	SimpLog	91.5%
1021 POS bigrams	SVM	83 %
1021 POS bigrams	SimpLog	78.98%
1021 POS bigrams	Naive Bayes	80%
1153 mix	SVM	95%
1153 mix	SVM	94.6 %
1153 mix	SimpLog	95%

Table 4: Accuracy overview

Using the 1021 unique POS bigrams which are present in the corpus as features, 83% classification accuracy was obtained using the SVM classifier, with Naive Bayes and Simple Logistic Regression managing 80% and 78.98% respectively.

5.3 Combined feature sets

Combining the feature sets from each of the experiments above, accuracy is improved. SVM obtains 95% accuracy, Naive Bayes and Simple Logistic Regression manage 94.6% and 95% respectively. This combined set contains 1153 features, 1021 POS bigrams, one hundred words and eighteen document level features. Ranking these features using ten-fold cross validation and Information Gain, the ranking displayed in Table 5 is obtained. Word unigrams and document-level features dominate the top fifty ranked features, with a number of POS-bigrams also occurring in the list.

6 Discussion

Tables 6 and 7 reflect the individual characteristics of each of the three authorial subcorpora examined here. The translations of Turgenev are distinguished by the higher average frequencies of the verbs *observed*, *repeated* and *replied*. Taking the value of the document-level metrics into account, Turgenev is to some extent unremarkable by these measures, although his works report higher average values for the two readability metrics, CLI and ARI, than the other two authors. The translations of Dosteyevsky distinguish themselves by the higher frequencies of adverbial forms such as *almost* and *perhaps*, which

Feature	Rank.	Feature	Rank.	Feature	Rank	Feature	Rank

Table 6: Relative frequencies for distinguishing words by author: Max values in bold

reflect uncertainty, but also adverbial forms such as *certain*, *certainly* and *simply*. They report a high average word length, and both a lower ratio of nouns to total words and lexical richness measure than the other two texts. They are not particular distinguished by their frequencies of verbal usage. The Chekhov translations are distinguishable by higher frequencies of *near* and *smell*, coupled with a lower average sentence length[11] and lower ratios of pronouns and prepositions to total words respectively. The three sentence type metrics are also distinctive. Perhaps the genre of the corpus has an effect here, as all of the included works by Chekhov are short stories while contributions from the other authors are primarily novels and novellas. Temporal variation or development of translatorial style may also play a role in any distinction, Garnett first began translating Turgenev in the late 19th century, followed by Dosteyevsky and Chekhov in the early 20th century, and it is probable that her knowledge of Russian and own writing style in English may have evolved over these years.

Reporting verbs[12] have been examined by Winters (2007), Mikhailov and Villikka (2001) and Baker (2000) in their work on finding distinguishing features of parallel translations of the same text. Here they

[11] Just over fifteen words, compared with over eighteen words for the other two authors.

[12] *Observed*, *repeated*, *replied* can be considered part of this category.

Table 7: Mean and standard deviation per author: document metrics

occur as distinguishing features of authorial idiolects within works by the same translator. Of course, the efficacy of these features may be increased in these experiments as a result of eliminating noun features, although this was done in an attempt to mitigate the effect of topic based classification of the works of a particular author, and focus on features which represent deeper stylistic patterns. Further analyses of these phenomena must consult the nature of the source text, investigating to what degree of accuracy can the original works of each author be distinguished from one another.

7 Conclusions and Future Directions

This study has demonstrated the efficacy of supervised learning techniques as applied to the task of distinguishing authorial style in a literary corpus translated from Russian to English by a single translator. Both document metrics and n-gram features perform very well for this task, obtaining accuracies of over 80% using feature sets from each category. Combined feature sets improved performance, resulting in 95% classification accuracy between the three authors in question. Highly ranked features included the ratio of nouns to total words, the ratio of pronouns to total words and the ratios of prepositions to total words, also adverbs and reporting verbs such as *almost*, *observed*, *replied* and *repeated* and *near*. These results imply that in this case there is indeed a clear preservation of the individual authorial style by the translator in question, which to some extent refutes the claims of stylistic similarity or sameness across this particular translator's canon.[13], and supports the theory of a *translator's invisibility* as claimed by Venuti (1995). One aspect of the problem not focused on in this study is the relationship between the source and target text, and it is of interest in future work to investigate to what degree the stylistic shifts in translator's style reflect the original source text, or does the translator in fact create their own defined idiolect for a particular author? Further work may investigate how Garnett's style is distinct from another translator, there is evidence of stylistic differences existing between authors, and also between translators, with different features proving discriminating in both cases, as found in studies by Forsyth and Lam (2013) and Lynch (2013).

Future work on this topic will encompass a wider range of translators and languages in order to inves-

[13]Comments by Vladimir Nabokov and others as refered to by Remnick (2005).

tigate more general patterns in translated literature. Results using relatively shallow linguistic features such as POS n-grams and word class distributions have proven themselves useful in distinguishing authorial variation in a translator's style, however it is also of interest to apply deeper linguistic processing to these texts in order to investigate more fine-grained elements of authorial and translatorial style within text. Examples of technologies which could be applied include semantic role labeling, (Swier and Stevenson, 2004) deep syntactic parsing, (Lucic and Blake, 2011), and LDA for detecting levels of metaphor (Heintz et al., 2013), in order to obtain a clearer picture of the stylistic structure of such documents.

Author Verification Using Common N-Gram Profiles of Text Documents

Abstract

Authorship verification is the problem of answering the question whether or not a sample text document was written by a specific person, given a few other documents known to be authored by them. We propose a proximity based method for one-class classification that applies the Common N-Gram (CNG) dissimilarity measure. The CNG dissimilarity (Kešelj et al., 2003) is based on the differences in the frequencies of n-grams of tokens (characters, words) that are most common in the considered documents. Our method utilizes the pairs of most dissimilar documents among documents of known authorship. We evaluate various variants of the method in the setting of a single classifier or an ensemble of classifiers, on a multilingual authorship verification corpus of the PAN 2013 Author Identification evaluation framework. Our method yields competitive results when compared to the results achieved by the participants of the PAN 2013 competition on the entire set, as well as separately on two subsets — English and Spanish ones — out of the three language subsets of the corpus.

1 Introduction

The task of computational detection of who wrote a given text is a widely studied linguistic and machine learning problem with applications in domains such as forensics, security, criminal and civil law, or literary research. The authorship verification problem is a type of such a computational authorship analysis task, in which, given a set of documents written by one author, and a sample document, we are asked whether or not this sample document was written by this given author. This is different from the more traditional problem of deciding who among a finite number of candidate authors for which we are given sample writings, wrote a document in question, and, albeit more difficult, is often considered to better reflect the real-life problems related to authorship detection (Koppel et al., 2012).

We describe our one-class proximity based classification method and evaluate it on the multilingual dataset of the Authorship Identification competition task of PAN 2013 (evaluation lab on uncovering plagiarism, authorship, and social software misuse) (Juola and Stamatatos, 2013).

During the competition, to which a variant of our method has been submitted (Jankowska et al., 2013), it yielded ranking 5th (joint) out of 18 with respect to the accuracy, and 1st rank out of 10 in the secondary ranking based on the area under the ROC curve (AUC), which evaluates the ordering of instances by the confidence score. In this paper we show some further experiments on how a different way of tuning the classifier parameters, using solely the training dataset of the competition, as well as an ensemble of classifiers based on our method, without any parameter tuning, leads to competitive accuracy results while still achieving high AUC values.

2 Related Work

The author analysis has been studied extensively in the context of the authorship attribution problem, in which there is a small set of candidate authors out of which the author of a questioned document is to

Proceedings of COLING 2014, the 25th International Conference on Computational Linguistics: Technical Papers, pages 387–397, Dublin, Ireland, August 23-29 2014.

be selected. There are several papers (Stamatatos, 2009; Juola, 2008; Koppel et al., 2009) presenting excellent surveys of this area.

The two main categories (Stamatatos, 2009) of solutions for the problem are similarity based approaches, in which a classification is performed in a Neigherst Neighbour scheme, attributing a sample text to the author whose writing is most similar according to some measure, and machine-learning based approaches, in which each document by an author is treated as a data sample within a class, and a supervised classifier is trained on these data.

A more limited research has been performed on an open-set variant on this problem, in which it is possible that none of the candidate authors wrote a document in question, with authorship verification being the extreme case of an open-set problem with only one candidate. The "unmasking method" for authorship verification (Koppel and Schler, 2004) is successful for novel-length texts. This approach, similarly as our method, falls into a category of *intrinsic* methods (Juola and Stamatatos, 2013); it uses only the documents in question, without constructing classes of other authors. The ensemble of one-class classifiers (Halvani et al., 2013), which achieved high accuracy at the PAN 2013 Author Identification competition, is also an example of such an intrinsic method. It varies from our approach by using a different scheme of creating the dissimilarity between an unknown document and the known authorship set of texts, based on the Nearest Neighbour technique (Tax, 2001), as well as by a different distance measure and features used.

Another way of approaching the author verification problem is to cast it into a binary or multi-class classification, by creating a class or classes of other authors. The "imposters" method (Koppel and Winter, 2014) generates a very large set of texts by authors that did not write the questioned document, to transform the problem into a open-set author attribution problem with many candidates, handled by an ensemble-based similarity method (Koppel et al., 2011). A modified version of the imposters method (Seidman, 2013) achieved first ranking in the PAN 2013 Authorship Identification competition. The method (Veenman and Li, 2013), which achieved the highest accuracy on the English set in this competition, is also of such an *extrinsic* type; its first step is a careful selection of online documents similar to the ones in the problems. The method (Ghaeini, 2013), which produces competitive ordering of verification instances, uses weighted k-NN approach using classes of other authors created from other verification instances.

3 Methodology

The formulation of the authorship verification task for the Author Identification Task at PAN 2013 is the following: "Given a set of documents (no more than 10, possibly only one) by the same author, is an additional (out-of-set) document also by that author?" (Juola and Stamatatos, 2013).

We approach this task with an algorithm based on the idea of proximity based methods for one-class classification. In one-class classification framework, an object is classified as belonging or not belonging to a target class, while only sample examples of objects from the target class are available during the training phase. Our method resembles the idea of the k-centers algorithm for one-class classification (Ypma et al., 1998; Tax, 2001), with k being equal to the number of all training documents in the target set (i.e., written by the given author). The k-centers algorithm is suitable for cases when there are many data points from the target class; it uses equal radius sphere boundaries around the target data points and compares the sample document to the closest such centre. We propose a different classification condition, described below, utilizing the pairs of most dissimilar documents within the set of known documents.

Let $A = \{d_1, ..., d_k\}$, $k \geq 2$, be the input set of documents written by a given author, which we will call *known documents*. If only one known document is provided, we split it in half and treat these two chunks as two known documents. Let u be the input sample document, of which the authorship we are to verify, that is return the answer "Yes" or "No" to the posed question whether it was written by the given author.

Our algorithm calculates for each known document $d_i, i = 1, 2, ..., k$, the maximum dissimilarity between this document and all other known documents: $D^{max}(d_i, A)$, as well as the dissimilar-

ity between this document and the sample document u: $D(d_i, u)$, and finally the dissimilarity ratio $r(d_i, u, A) = \frac{D(d_i,u)}{D^{max}(d_i,A)}$ (and thus $r(d_i, u, A) < 1$ means that there exists a known document more dissimilar to d_i than u, while $r(d_i, u, A) > 1$ means that all the known documents are more similar to d_i than u). The average $M(u, A)$ of the dissimilarity ratio over all known documents $d_1, d_2, ..., d_k$ from A, is the subject of the thresholding: the sample u is classified as written by the same person as the known documents if and only if $M(u, A)$ is at most equal to a selected threshold θ. Notice that in this framework the dissimilarity between the documents does not need to be a metric distance, i.e., it does not need to fulfil the triangle inequality (as is the case for the dissimilarity measure we choose).

For the dissimilarity measure between documents we use the Common N-Gram (CNG) dissimilarity; proposed by Kešelj et al. (2003); this dissimilarity (or its variants) used in the Nearest Neighbour classification scheme (Common N-gram classifier) was successfully applied to authorship classification tasks (Kešelj et al., 2003; Juola, 2008; Stamatatos, 2007). The CNG dissimilarity is based on the differences in the usage frequencies of the most common n-grams of tokens (usually characters, but possibly other tokens) of the documents. Each document is represented by a *profile*: a sequence of the most common character n-grams (strings of characters of the given length n from the document) coupled with their frequencies (normalized by the length of the document). The dissimilarity between two documents of the profiles P_1 and P_2 is defined as follows:

$$D(P_1, P_2) = \sum_{x \in (P_1 \cup P_2)} \left(\frac{f_{P_1}(x) - f_{P_2}(x)}{\frac{f_{P_1}(x) + f_{P_2}(x)}{2}} \right)^2 \quad (1)$$

where x is a character n-gram from the union of two profiles, and $f_{P_i}(x)$ is the normalized frequency of the n-gram x in the the profile P_i, $i = 1, 2$ ($f_{P_i}(x) = 0$ whenever x does not appear in the profile P_i). The parameters of the dissimilarity are the length of the n-grams n and the length of the profile L. As our method is based on the ratios of dissimilarities between documents, we take care that the documents in a given problem are always represented by profiles of the same length. We experiment with two ways of selecting the length of the profiles. In the dynamic-length variant, the length of profiles is selected separately for each problem, based on the number of n-grams in the documents in the given instance (parametrized as a fraction f of all n-grams of the document that contains the least number of them). In the fixed-length variant, we use a selected fixed length L of profiles. For a one-class classifier we need to select two parameters defining the features used for dissimilarity (length of the n-grams n, and either the fixed length L of a profile, or the fraction f defining the profile length), and the parameter θ (for classifying by thresholding the average dissimilarity ratio M).

We linearly scale the measure M to represent it as a confidence score in the range from 0 (the highest confidence in the answer "No") to 1 (the highest confidence in the answer "Yes"), with the answer "Yes" given if and only if the confidence score is at least 0.5. The value of M equal to θ is transformed to the score 0.5, values greater than θ to the scores between 0 and 0.5, and values less than θ to the scores between 0.5 and 1 (a cutoff of 0.1 is applied, , i.e. all values of $M(u, A) < \theta - \textit{cutoff}$ are mapped to the score 1, and all values of $M(u, A) > \theta + \textit{cutoff}$ are mapped to the score 0).

4 Training and test datasets

We leverage the evaluation framework of the PAN 2013 competition task of Author Identification (Juola and Stamatatos, 2013), the datasets of which were carefully created for authorship verification, with effort made to match within each problem instance the texts by the same genre, register, theme and time of writing. The dataset consists of English, Greek and Spanish subsets. In each instance, the number of documents of known authorship is not greater than 10 (possibly only one). The dataset is divided into the training set `pan13-ai-train` and the test set `pan13-ai-test`. The training set was made available for the participants before the competition; the test set was used to evaluate the submissions and subsequently published (PAN, 2013).

To enrich the training dataset for our competition submission, we also compiled ourselves two additional datasets using existing sets for other authorship identification tasks. `mod-pan12-aa-EN` is

an English author verification set compiled from the fiction corpus for the Traditional Authorship Attribution sub task of the PAN 2012 competition (PAN, 2012; Juola, 2012). `mod-Bpc-GR` is a Greek author verification set compiled from the Greek dataset of journal articles (Stamatatos et al., 2000). It is important to note that these sets are different from the competition dataset in that we did not attempt to match the theme or time of writing of the texts.

Table 1 presents characteristics of the datasets.

	`pan13-ai-train`

Table 1: Characteristics of datasets used in our authorship verification experiments.

5 Evaluation measures

In our experiments we use two measures of evaluation, based on the measures proposed for the PAN 2013 competition. The accuracy is the fraction of all problems that have been answered correctly. The AUC measure is the area under the ROC curve based on the confidence scores. It is the nature of applications of authorship verification, such as forensics, that makes the confidence score and not only the binary answer, an important aspect of a solution (Gollub et al., 2013).

For our method accuracy is equivalent to the measure that was used in the competition for the main evaluation. This measure is F_1, defined based on the fact that in the competition it was allowed to withdraw an answer (i.e., use an "I do not know" option). Precision and recall were defined as follows: $recall = \frac{\#correct\_answers}{\#problems}$, $precision = \frac{\#correct\_answers}{\#answers}$, and F_1 is the harmonic mean of precision and recall. For any method that, as our method, provides the answer "Yes" or "No" for all problem instances, the accuracy and F_1 are equivalent.

6 Types of classifiers

A single classifier of our method requires two parameters defining the features to be used to represent a document (the length of an n-gram and the length of a profile), as well as a selection of the threshold for the dissimilarity for the classification decision. We tune and evaluate four version of such single classifiers. Combining many such one-class classifiers, each using different combination of features defining parameters, into one ensemble, allows to remove or mitigate the parameter tuning. We describe the creation and the evaluation of four types of ensembles.

Table 2 reports the considered space for feature defining parameters. On a training set, for a given combination of feature defining parameters (n,L) or (n,f), we use the accuracy at the optimal threshold (a threshold θ that maximizes the accuracy), as a measure of performance for these parameters.

Parameters	
n	length of n-grams
L	# of n-grams: profile length (fixed-length)
f	fraction of n-grams for profile length (dynamic-length)
θ	threshold for classification
θ_{2+}	threshold for classification if at least 2 known documents are given
θ_1	threshold for classification if only one known document is given

Space of considered parameters	
n for character n-grams	$\{3, 4, ..., 9, 10\}$
n for word n-grams	$\{1, 2, 3\}$
L	$\{200, 500, 1000, 1500, 2000, 2500, 3000\}$

Table 2: Parameters for four variants of single one-class classifiers and four ensembles of one-class classifiers based on our method.

6.1 Single classifiers

For single character n-gram classifiers, we tuned the parameters for each language separately on training data, by selecting feature defining parameters based on their performance, and selecting the thresholds

to correspond to the optimal thresholds. Table 2 reports the parameters of four variants of single classifiers. We include our two submissions to the PAN 2013 Authorship Identification competition: the final submission `vF1` and the preliminary submission `vD1`. The other two classifiers were tuned and tested after the competition.

Our preliminary submission `vD1` (Table 2) is tuned on `pan13-ai-train`, with f chosen ad-hoc. This is the only classifier among the reported variants that does not use a preprocessing of truncation of all documents in a given problem instance to the length of the shortest document, which tend to increase the accuracy for cases of a significant difference in the length of documents.

For tuning of parameters of the final submission `vF1` (Table 2) we use not only `pan13-ai-train`, but also additional training sets `mod-pan12-aa-EN` and `mod-Bpc-GR`. We also introduce two threshold values: one for cases when there are at least two known documents, and another one for the cases when there is only one known document (which has to be divided in two). The intuition behind this double threshold approach is that when there is only one known document, the two halves of it can be more similar to each other than in other cases. After the parameters are selected based on subsets of training sets with only these problems that contain at least two known documents, the additional threshold is selected based on the optimal threshold on a modified "1-only" training set, from the problem of which all known documents except of a random single one is removed. For Spanish, with only three training instances with more than one known document, we use the same parameters as for English.

For tuning of `vF2` and `vD2` (Table 2) we use only competition training data, without the additional corpora used for `vF1`. Feature parameters are selected based on the performance on the subsets containing at least two known documents, and on the "1-only" modified sets (which allows us to use the Spanish training set for tuning the Spanish classifiers).

6.2 Ensembles of classifiers

We test ensembles of single one-class classifiers based on our method, with the ensemble combining answers of the classifiers, and each classifier using different set of features. An important advantage of an ensemble is the alleviation of the problem of tuning the parameters. Each classifier uses a different combination of parameters n and L defining the features. And as many classifiers are used, instead of tuning the threshold of a single classifier based on some training data, the threshold of each classifier is set to some fixed value, with 1 being a natural choice, as it corresponds to checking whether or not the unknown document is (on average) less similar to each given known document than the author's document that is most dissimilar to this given known document.

We test majority voting and voting weighted by the confidence scores of single classifiers. For each ensemble we combine answers of the classifiers in order to obtain the confidence score of the ensemble. For majority voting the confidence score of the ensemble is the ratio of the number of classifiers that output "Yes" to the total number of classifiers, the confidence score of the weighted voting is the average of the confidence scores of the single classifiers.

We experiment with n-grams being characters (utf8-encoded) and words (converted to uppercase). Table 2 summarize the ensembles. The ensemble `eC` is of all character n-gram classifiers in our space of considered parameters n and L; `eW` is of all word n-gram classifiers; `eCW` is of all classifiers of `eC` and `eW`. These ensembles do not use any training data. We also create a classifier `eCW_sel` (Table 2), which is a subset of the classifiers of `eCW`, selected based on the performance of the single classifiers on the training data of the competition. For each language separately, we remove classifiers that on the training data achieved lowest accuracies at their respective optimal thresholds, while keeping at least half of the character based classifiers and at least half of the word based classifiers. (For Spanish, `eCW_sel` and `eCW` differ just by one classifier: the only one that on the small Spanish training set has the optimal accuracy less than 1.)

7 Results

The accuracy and the area under the ROC curve (AUC) values achieved by the variants of our method on the PAN 2013 Author Identification test dataset are presented in Table 3. The table states also the

best PAN 2013 competition results of other participants[1] (that is the results of these participants that achieved the highest accuracy or AUC on any (sub)set). There were 17 other participants for which there are accuracy (or F_1) results, 9 of which submitted also confidence scores evaluated by AUC.

Table 3: Area under the ROC curve (AUC) and F_1 (which is equal to accuracy for all algorithms except for (Ghaeini, 2013)) on the test dataset of PAN 2013 Author Identification competition task. Results of variants of our method compared with competition results of those among other competition participants that achieved the highest value of any evaluation measure on any (sub)set. The highest result in any category is bold; the highest result by other competition participants in any category is boxed.

All variants of our method perform better on the English and Spanish subset than on the Greek one, both in terms of the accuracy and in terms of AUC. On the Greek subset they are all outperformed by other competition participant(s). This is most likely due to the fact that the Greek subset was created in a way that makes it especially difficult for algorithms that are based on CNG character-based dissimilarity (Juola and Stamatatos, 2013), by using a variant of CNG dissimilarity for the character 3-grams in order to select difficult cases. This particularity of the set may also be the reason why the ensemble eC of character n-gram classifiers performed worse than other methods on this set.

The variants of our method are competitive in terms of the ordering of the verification instances according to the confidence score as measured by AUC. During the competition, our final submission vF1 achieved the first ranking according to the AUC on the entire set, the highest AUC on the English subset, and the second-highest AUC values on the Spanish and Greek subset, out of 10 participants that submit-

[1]The results of our methods are on the published competition dataset. The results by other participants are the published competition results. The actual competition evaluation set for Spanish may have some text in a different encoding then the published set; our final submission method vF1 yielded on it a different result than on the published dataset.

ted confidence scores. All variants of our method perform better than any other competition participant on the entire set. On the English subset the single classifiers and the ensembles with weighted voting have AUC above 0.8, and out of those only eC has AUC lower than the best result by other participants. On the Spanish subset all variants of our method achieved AUC above 0.8, with vD2 achieving AUC higher than the best competition result on this subset.

In terms of overall accuracy on the entire set, the ensembles combining character and word based classifiers: eCW with majority voting and eCW_sel with both types of voting, achieve accuracy higher then the best overall accuracy in the competition. They also match or surpass the best competition accuracy on the English subset, and match the best competition accuracy on the Spanish subset. The highest accuracy on the English subset was achieved by eC with weighted voting, eCW with majority voting, and eCW_sel with majority voting (higher than the best competition result). vF2 yields on the Spanish subset accuracy higher than the best competition result.

For the ensembles of classifiers, on the English and Spanish subsets, the AUC for voting weighted by the confidence scores are higher than the AUC for the majority voting, but not so on the Greek subset. This is consistent with the fact that on the Greek subset the confidence scores for single classifier variants yield worse ordering (AUC) than on other sets. Creation of eCW_sel by removing from the ensemble eCW the classifiers that perform worst on the training data improves the Greek results, and slightly the English results.

We tested the statistical significance of accuracy differences between all pairs of accuracies reported in Table 3 by the exact binomial McNemar's test (Dietterich, 1998). Only few of these differences are statistically significant. On the entire set these are: the difference between the accuracy of eCW with majority voting and of eC with majority voting, vD1 and vF1, as well as the difference between the accuracies of eCW_sel with weighted voting and of vF1. On the Greek subset, this is the difference between the accuracies of the submission (Seidman, 2013) and the lower accuracy of eC with weighted voting.

		English mod-pan12-aa-EN		Greek mod-Bpc-GR	
		accuracy	AUC	accuracy	AUC
vD1		0.545	0.649	0.605	0.661
vD2		0.727	0.826	0.566	0.698
vF2		**0.773**	**0.843**	0.618	0.709
eC	majority	0.636	**0.843**	0.658	0.694
	weighted	0.682	0.806	0.671	0.703

	weighted	0.682	0.826	0.737	0.737

Table 4: Accuracy and area under ROC curve (AUC) of our method on other English and Greek datasets. The sets were compiled by ourselves for the purpose of enriching training domain for other variant of our classifier. The highest result in any category is bold.

The datasets mod-pan12-aa-EN and mod-Bpc-GR were compiled by ourselves from other authorship attribution sets for the purpose of enriching the training corpora for our final submission vF1. The comparison between results on the English and Greek subsets of vF1 with the results of vF2 (for which these additional sets were not used), shows that vF2 achieved better results on English data. while vF1 has higher AUC on Greek data.

Though these additional sets were not created specifically for authorship verification evaluation, we

examine the results of our methods on these sets (with the exception of vF1, which is tuned on them). We present the results in Table 4. vD1 performs poorly on mod-pan12-aa-EN. This is in part due to the fact that in this set the documents in a given problem instance can differ significantly with respect to the length, and the variant vD1 does not use the preprocessing of truncation all files withing a problem to the same length. The variants vD2 and vF2 (which apply this truncation) yielded accuracy and AUC similar in value to the ones achieved on the PAN 2013 English subset. The ensembles containing character n-gram classifiers yielded similar AUC on mod-pan12-aa-EN as on the PAN2013 English subset, close in value to 0.8. But their accuracies are distinctly lower than the results on the English competition subset, with values below 0.7 (for each such an ensemble, vast majority of the misclassified instances are false negatives: cases classified as not written by the same person when in fact they are). For mod-Bpc-GR the single classifiers (with parameters tuned on the competition Greek subset) perform rather poorly, with results similar but lower in values than the results yielded on the competition Greek test set. The ensembles containing word n-gram based classifiers perform better than the ensembles containing only the character n-gram classifiers, yielding both AUC and accuracy in the range of 0.71 – 0.75.

8 Future Work

It will be of interest to investigate the relation between the performance of our method and the number and the length of the considered texts. An interesting direction indicated by results of our experiments is also the analysis of the role of word n-grams and character n-grams for authorship verification depending on the genre of the texts, and on the topical similarity between the documents.

9 Conclusions

We present our proximity based one-class classification method for authorship verification. The method uses for each document of known authorship the most dissimilar document of the same author, and examines how much more or less similar is the questioned document. We use Common N-Gram dissimilarity based on differences in frequencies of character and word n-grams.

We evaluate our method on the set of PAN 2013 Authorship Identification competition. One variant of our method was submitted to the competition. The ordering by scores indicating the confidence that the documents were written by the same person, yielded by our method, and evaluated by area under ROC curve (AUC), is competitive with respect to other participants of the competition, overall, and on the English and Spanish subsets. On the entire set, AUC by each variant of our method is higher than the best result by other participants. In terms of accuracy, the method also performs better on the English and Spanish subsets of the dataset, and worse on the Greek one. An ensemble combining character based classifiers and word based classifiers yields the best accuracy, surpassing the best competition result on the entire set and on the English subset, while matching the best competition result on the Spanish subset.

As all proximity based one-class classification algorithms, our method relies on a selected threshold on the proximity between the questioned text and the set of documents of known authorship. Additionally, a single classifier requires two parameters defining the features representing documents. Ensembles of classifiers allow to alleviate the parameter tuning, by using many classifiers for many combinations of feature defining parameters, with a threshold fixed to 1 (a natural, albeit arbitrary, value).

Abstract

Our previous work focuses on combining translation memory (TM) and statistical machine translation (SMT) when the TM database and the SMT training set are the same. However, the TM database will deviate from the SMT training set in the real task when time goes by. In this work, we concentrate on the task when the TM database and the SMT training set are different and even from different domains. Firstly, we dynamically merge the matched TM phrase-pairs into the SMT phrase table to meet the real application. Secondly, we propose an improved integrated model to distinguish the original and the newly-added phrase-pairs. Thirdly, a simple but effective TM adaptation method is adopted to favor the consistent translations in cross-domain test. Our experiments have shown that merging the TM phrase-pairs achieves significant improvements. Furthermore, the proposed approaches are significantly better than the TM, the SMT and previous integration works for both in-domain and cross-domain tests.

1 Introduction

Since the translation memory (TM) system and the statistical machine translation (SMT) system complement each other in those matched sub-segments and unmatched sub-segments (Wang et al., 2013), combining them can improve the output quality significantly, especially when high-similarity fuzzy matches are available. Therefore, combining TM and SMT is drawing more and more attention in recent years (He et al., 2010a; 2010b; 2011; Koehn and Senellart, 2010; Zhechev and van Genabith, 2010; Ma et al., 2011; Dara et al., 2013; Wang et al., 2013).

Those previous works on combining TM and SMT can be classified into four categories: (1) selecting the better translation sentence from TM and SMT (He et al., 2010a; 2010b; Dara et al., 2013); (2) incorporating TM matched sub-segments into SMT in a pipelined manner (Koehn and Senellart, 2010; He et al., 2011; Ma et al., 2011); (3) only enhancing the SMT phrase table with new TM phrase-pairs (Bi çici and Dymetman, 2008; Simard and Isabelle, 2009); and (4) incorporating the associated TM information with each source phrase to guide the SMT decoding (Wang et al., 2013).

However, all previous works mentioned above only focus on the case in which the TM database and the SMT training set share the same data-set. Nonetheless, in real applications, the TM database will deviate from the SMT training set when time goes by, because the TM database will be dynamically enlarged when more translations are generated by the human translator. Therefore, this paper will concentrate on a more realistic case, in which the TM database and the SMT training set are different and even from different domains.

When the TM database and the SMT training set share the same data-set, the integrated model (Wang et al., 2013) can avoid the drawbacks of the pipeline approaches and outperforms the other approaches significantly. However, this integrated model only refers to the TM information but not adopts the matched TM phrase-pairs as candidates during decoding. Therefore, many TM phrase-pairs cannot be covered by the SMT phrase table when the TM database and the SMT training set are dif-

Proceedings of COLING 2014, the 25th International Conference on Computational Linguistics: Technical Papers, pages 398–408, Dublin, Ireland, August 23-29 2014.

ferent. It is thus impossible to generate those unseen TM target phrases. This problem would even get worse when the TM database and the SMT training set are from different domains.

To make the integrated model meet the real application, we dynamically merge the matched TM phrase-pairs into the SMT phrase table. In addition, an improved integrated model is proposed to distinguish the original SMT phrase-pairs and the newly-added ones extracted from TM. Furthermore, a simple but effective TM adaptation method is adopted to favor the consistent translation in cross-domain test. To our best knowledge, this is the first unified framework for integrating TM into SMT during decoding when the TM database and the SMT training set are different (even from different domains).

On the TM database which consists of Chinese–English computer technical documents, our experiments have shown that merging the matched TM phrase-pairs achieves significant improvement when the fuzzy match score is above 0.5. Besides, the proposed approaches are significantly better than either the SMT or the TM systems for both the in-domain and the cross-domain tests when the fuzzy match score is above 0.4. Furthermore, the proposed approaches also outperform previous integration works significantly in all test conditions.

2 Integrated Model

Wang et al. (2013) incorporated the TM information into the phrase-based SMT, and re-defined the translation problem as:

$$\hat{t} = \arg\max_t P(t|s, tm\_s, tm\_t, tm\_f, s\_a, tm\_a)$$

Where s denotes the given source sentence, t is a corresponding target translation, and $\hat{t}$ is the final result; $[tm\_s, tm\_t, tm\_f, s\_a, tm\_a]$ is the associated information of the best TM sentence-pairs; tm_s and tm_t are the corresponding TM source and target sentences, respectively; tm_f denotes its corresponding fuzzy match score (from 0 to 1); s_a is the monolingual alignment information between s and tm_s; and tm_a denotes the bilingual word alignment information between tm_s and tm_t.

With the TM information, this problem can be simplified to:

$$\hat{t} \triangleq \text{argmax}\left\{P\left(\bar{t}_1^{\text{K}}\middle|\bar{s}_{a(1)}^{a(\text{K})}\right) \times \prod_{k=1}^{K} \max_{tm\_\bar{t}_{a(k)}} P(M_k|L_k, z)\right\} \quad (1)$$

Where $\bar{s}_{a(k)}$ and $\bar{t}_k$ denote the k-th associated source and target phrases, respectively; $tm\_\bar{s}_{a(k)}$ and $tm\_\bar{t}_{a(k)}$ are the corresponding TM source and target phrases associated with the given source phrase $\bar{s}_{a(k)}$ (total K phrases without insertion). M_k is the corresponding TM target phrase matching status for the current target candidate $\bar{t}_k$, which reflects the quality of the given candidate; L_k is the linking status vector of $\bar{s}_{a(k)}$ (the aligned source phrase, within $\bar{s}_{a(1)}^{a(\text{K})}$, of $\bar{t}_k$), which indicates the matching and linking status in the source side (and is closely related to the matching status of the target side). tm_f is uniformly divided into ten fuzzy match intervals and the index z specifies the corresponding interval.

In Equation (1), the first factor is just the typical phrase-based SMT model, and the second factor $P(M_k|L_k, z)$ is the information derived from the TM sentence pair. Afterwards, the factor $P(M_k|L_k, z)$ was further derived with TM matching status as follows:

$$P(M_k|L_k, z) \approx \begin{Bmatrix} \text{P}(TCM_k|SCM_k, NLN_k, LTC_k, SPL_k, SEP_k, z) \\ \times \text{P}(LTC_k|CSS_k, SCM_k, NLN_k, SEP_k, z) \\ \times \text{P}(CPM_k|TCM_k, SCM_k, NLN_k, z) \end{Bmatrix} \quad (2)$$

Where the first factor reflects the TM content matching status, the second factor is the relationship between various TM target phrases, and the third factor is the reordering information implied by TM. Equation (2) is adopted to guide the SMT decoding, and is denoted as the integrated Model-III in (Wang et al., 2013) (also called **Model-III** in this paper thereafter).

For space limitation, only those features which are also adopted in our additional introduced probability factor (to be specified later) will be briefly introduced here:

Target Phrase Content Matching Status (TCM): It indicates the content matching status between $\bar{t}_k$ and $tm\_\bar{t}_{a(k)}$, and reflects the quality of $\bar{t}_k$. It is a member of {*Same*, *High*, *Low*, *NA* (*Not-Applicable*)}.

Source Phrase Content Matching Status (SCM): It indicates the content matching status between $\bar{s}_{a(k)}$ and $tm\_\bar{s}_{a(k)}$, and affects the matching status of $\bar{t}_k$ and $tm\_\bar{t}_{a(k)}$ greatly. It is a member of {*Same*, *High*, *Low*, *NA*}.

Number of Linking Neighbors (NLN): Usually, the context of a source phrase would affect its target translation. The more similar the context is, the more likely that the translation is the same. NLN is adopted to measure the context similarity.

3 Proposed Approaches

3.1 Merging the TM Phrase-Pairs

Since all TM phrase-pairs are only referred while re-scoring the SMT candidates in Model-III, they are not regarded as candidates during decoding. When the TM database and the SMT training set are the same, this restriction is reasonable because the SMT phrase table can cover all the continuous TM phrase pairs within the phrase length limit. However, this would not be true when the TM database and the SMT training set are different. Therefore, the SMT phrase table should be further enhanced with those matched new TM phrase pairs in this case.

According to their relations with the SMT phrase table, TM phrase pairs can be classified into three different categories: (1) the whole TM phrase-pair can be found in the original SMT phrase table; (2) only TM source phrase exists in the original SMT phrase table, but its corresponding target phrase does not; (3) even TM source phrase cannot be found in the original SMT phrase table. Since the first category has been covered by the original SMT phrase table, only the phrase-pairs from the second and the third categories should be added into the SMT phrase table dynamically for each input sentence. To distinguish those newly added phrase-pairs from the original SMT phrase-pairs, we use eight additional feature weights λ_m for the translation probability (lexical and phrase transfer in both directions) and two more feature weights for the phrase penalty (details will be specified later in Section 4).

The above approach is inspired by the work of (Bi ɕci and Dymetman, 2008). However, there are three differences between our approach and theirs. Firstly, we add all those matched TM phrase-pairs (include all associated sub-phrase pairs), while Bi ɕci and Dymetman (2008) only added the longest matched one; Secondly, we add all the possible TM target phrase-pairs for a given TM source phrase while they extracted only one TM target phrase regardless of the existence of multiple TM target candidates; Lastly, we use different feature weights to distinguish those newly added TM phrase-pairs from the original SMT phrase-pairs, while they treated them equally.

3.2 Distinguishing the TM Phrase-Pairs

As mentioned in Section 3.1, we need to merge those TM matched phrase pairs into the SMT phrase table when the TM database and the SMT training set are different. However, the original integrated Model-III does not distinguish the newly added TM phrase-pairs from those original SMT phrase-pairs in $P(M_k|L_k,z)$. Therefore, we introduce two new features ***Source Phrase Origin*** (**SPO**) and ***Target Phrase Origin*** (**TPO**), which are a member of {*Original*, *Newly-Added*}, to the original Model-III in (Wang et al., 2013) to favor the newly added TM phrase-pairs, and re-derive $P(M_k|L_k,z)$ as follows (assume that TPO is only dependent on SPO, NLN and z):

$$\begin{aligned} & P(M_k|L_k,z) \\ & \triangleq P([TCM,LTC,CPM,TPO]_k|[SCM,NLN,CSS,SPL,SEP,SPO]_k,z) \\ & \approx \left\{ \begin{array}{l} \mathrm{P}(TCM_k|SCM_k,NLN_k,LTC_k,SPL_k,SEP_k,z) \\ \quad \times \mathrm{P}(LTC_k|CSS_k,SCM_k,NLN_k,SEP_k,z) \\ \quad \times \mathrm{P}(CPM_k|TCM_k,SCM_k,NLN_k,z) \\ \quad \times \mathrm{P}(TPO_k|SPO_k,NLN_k,z) \end{array} \right\} \end{aligned} \quad (2)$$

The additional factor $\mathrm{P}(TPO_k|SPO_k,NLN_k,z)$ in the above equation is added to handle those newly added TM phrase-pairs. This would be the proposed ***Distinguishing Model***. For the phrases from the original SMT phrase table, both the SPO and TPO features would be "*Original*"; for the phrases from the second category mentioned in Section 3.1, the SPO would be "*Original*" but the TPO would be "*Newly-Added*"; for the phrases from the third category, both the SPO and TPO features would be "*Newly-Added*".

3.3 TM Adaptation

In real applications, the TM database is usually not big enough to train an SMT system when it is applied to a special technical domain other than the news domain. Besides, many professional translators do not want to expose the whole TM database to the SMT system providers (Cancedda, 2012). In this situation, we will be forced to first train an SMT model on an **out** domain (usually the news domain) which possesses a lot of training data, and then fix the obtained phrase-based SMT model. Afterwards, we incorporate it on line with an additional TM database which is from another **in** domain.

To simulate the above scenario, we will thus train our integrated model on the out domain. However, we have a domain-mismatch problem for this cross-domain test. Generally, in the technical domain, which is suitable for TM application, the translations (especially for technical terms) are much more consistent than that in the news domain. That is, the same source phrase in various places tends to have exactly the same translation in technical domains. Therefore, when we use Distinguishing Model to perform forced decoding, the obtained results would possess different statistics among the in-domain development set and the out-domain training set. For example, at interval [0.9, 1.0), when SCM is "Same", 94.6% of TCM are "Same" in the development set (**in**), while this ratio is only 65.1% in the training set (**out**). Therefore, the factor $P(TCM_k|SCM_k, NLN_k, LTC_k, SPL_k, SEP_k, z)$ from the test set will possess a different probability distribution in comparison with that from the training set. However, the development set is not big enough (only a few hundreds sentence-pairs at each interval) to re-train all TM factors of the proposed model. Therefore, we simply add the following h_1 feature to reflect the tendency of having high translation consistency in the development set:

$$h_1(\bar{t}, \bar{s}, z) = \begin{cases} 1.0, if\ SCM_k = Same \text{ and } TCM_k = Same \\ 0.0, otherwise \end{cases}$$

Where $\bar{s}$ and $\bar{t}$ denote the source phrase, the target candidate, respectively.

Furthermore, various source synonyms might generate the same translation (Zhu et al., 2013). Therefore, even SCM≠Same, we still favor the SMT phrase-pair candidate which exactly matches TM target phrase. For example, if source words are synonyms such as "需要" (want) and "要" (want), "如果" (if) and "若" (if), "立即" (at once) and "马上" (at once), the target translations would be the same. Therefore, the issue of having high translation consistency in the technical domain is also applied. We thus further add the following h_2 feature to reflect the tendency of having high translation consistency in this case ("High" and "Low" are grouped into "Other" for the SCM):

$$h_2(\bar{t}, \bar{s}, z) = \begin{cases} 1.0, if\ SCM_k = Other \text{ and } TCM_k = Same \\ 0.0, otherwise \end{cases}$$

Afterwards, the associated feature weights are tuned on the development set.

4 Experiments

4.1 Experimental Setup

We use the same TM data-set adopted by Wang et al. (2013), which is a Chinese–English TM database consisting of computer technical documents. It includes about 267k sentence pairs. All the experiments are conducted around this TM data-set. To compare the performances under different conditions, the same development set and the test set will be shared by both in-domain and cross-domain tests. Since the associated SMT training-set and TM database will vary under different experimental configurations, they will be specified later in each sub-section.

In this work, the translation memory system (denoted as **TM**) and the phrase-based machine translation system (denoted as **SMT**) are adopted as our two baseline systems. Following (Wang et al., 2013), for TM, the word-based fuzzy match score is adopted as the similarity measure; also, for the phrase-based SMT system, the same Moses toolkit (Koehn et al., 2007) and the same set of following features are adopted: the phrase translation model, the language model, the distance-based reordering model, the lexicalized reordering model and the word penalty. The system configurations are as follows: GIZA++ (Och and Ney, 2003) is used to obtain the bidirectional word alignments. Afterwards, "intersection" refinement (Koehn et al., 2003) is adopted to extract phrase-pairs. We use SRI Language Model

toolkit (Stolcke, 2002) to train a 5-gram model with modified Kneser-Ney smoothing (Kneser and Ney, 1995; Chen and Goodman, 1998) on the target-side (English) training corpus. All the feature weights and the weight for each probability factor are tuned on the development set with minimum-error-rate training (MERT) (Och, 2003). The maximum phrase length is set to 7 in our experiments.

To compare our proposed models with those state-of-the-art methods, we re-implement two XML-Markup approaches (Koehn and Senellart, 2010; and the upper bound version of (Ma et al, 2011)) and the Model-III (Wang et al., 2013) as three baseline systems, and denote them as **Koehn-10**, **Ma-11-U** and **Model-III**, respectively. Similar to (Wang et al., 2013), we only re-implement the XML-Markup method used in (Ma et al, 2011), but not their discriminative learning method.

Following (Wang et al., 2013), we also train the TCM, LTC and CPM factors in the SMT training set with cross-fold translation. Since the TPO factor (conditioning on NLN and Distinguishing Model) is based on Model-III, we first use Model-III to generate the desired results on the development set via forced decoding, and then generate the training samples of TPO factor for Distinguishing Model.

In this work, the translation performance is measured with case-insensitive BLEU-4 score (Papineni et al., 2002) and TER score (Snover et al., 2006). Statistical significance tests are conducted with re-sampling (1,000 times) approach (Koehn, 2004) in 95% confidence level.

4.2 In-Domain Translation Results

In the in-domain test, the original TM dataset is first randomly divided into two parts. The first part is then adopted as the new TM database, while the second part is adopted as the SMT training set. The detailed corpus statistics is shown in Table 1. Since the TM database is different from that adopted in (Wang et al., 2013), the statistics shown in Table 2 at each interval is also different from theirs.

All matched TM phrase-pairs are extracted according to the word alignment generated from the phrase-based SMT system. Since there are not enough samples to estimate the translation probabilities for those newly added TM phrase-pairs, we use the following method to assign the translation probabilities. For those TM phrase-pairs that only their source phrases exist in the original SMT phrase table (the second category mentioned in Section 3.1), as their source phrases have already existed in the SMT phrase table, there is at least one associated target phrase in the original SMT phrase table. For each new TM phrase-pair, we thus directly assign the maximum probability among its associated original target phrases to it. For those TM phrase-pairs that even their source phrase cannot be found in the original SMT phrase table (the third category), as there is no corresponding phrase-pair in the original SMT phrase table, we will simply assign probability "1.0" (this value is not important as its associated weight will be tuned later) as their four translation probabilities. To distinguish those newly added phrase-pairs from the original SMT phrase-pairs, we use eight additional feature weights for the translation probability and two more feature weights for the phrase penalty.

To evaluate the effectiveness of adding TM phrase-pairs, we compare the cases of whether merging TM phrase-pairs or not for both SMT and Model-III. Table 3 and Table 4 give the translation results in BLEU and TER, respectively. "SMT" and "Model-III" denote that we do not merge the TM phrase-pairs into the SMT phrase table during decoding. That is, they only use the original SMT phrase table.

(0.0, 1.0)	58.58	40.88	38.55 +	37.26 *#	36.47 +*#	**36.28** +*#	45.63	38.73

Table 4: In-Domain Translation Results (TER). The marks are the same as that in Table 3.

"SMT$^+$" and "Model-III$^+$" mean that we merge the TM phrase-pairs into the SMT phrase table dynamically. In these tables, "+" indicates that those newly added TM phrase-pairs significantly improve the translation results ("SMT" vs. "SMT$^+$", "Model-III" vs. "Model-III$^+$", and "Model-III" vs. "Distinguishing").

It can be seen that adding TM phrase-pairs significantly improve the translation results when the fuzzy match score is above 0.5 (comparing SMT with SMT$^+$, and Model-III with Model-III$^+$). For example, at interval [0.9, 1.0), those added TM phrase-pairs significantly improve the SMT system from 63.65 to 73.55, and Model-III from 80.69 to 86.40. However, if Model-III$^+$ is compared with Model-III, the improvements from merging the TM phrase-pairs get less when the fuzzy match score decreases, because the matched TM parts are fewer at low fuzzy match intervals.

Also, with the same original SMT phrase table, Model-III exceeds the SMT system at each interval. For example, at interval [0.9, 1.0), the TM information significantly improve the translation result from 63.65 to 80.69. It thus shows that the TM information is very useful. However, it is still worse than the TM in TER (13.32 vs. 10.42). On the other hand, although Model-III has greatly exceeded the SMT at each interval, Model-III$^+$ still significantly outperforms Model-III at most intervals. Therefore, the benefit of utilizing TM information and the benefit of adding TM phrase-pairs are not covered by each other and can be jointly enjoyed. Take the interval [0.9, 1.0) as an example, the TM information first improve the translation results from 63.65 (SMT) to 80.69 (Model-III), and then the added TM phrase-pairs further boosts it to 86.40 (Model-III$^+$).

Besides, Table 3 and Table 4 also present the translation results of our other two baselines (Koehn-10 and Ma-11-U), and the proposed Distinguishing Model. Scores marked with "*" indicate that they are significantly better ($p < 0.05$) than both the TM and the SMT+ baselines, and those marked with "#" are significantly better ($p < 0.05$) than Koehn-10. Scores marked with "$" are significantly better than Model-III$^+$. The bold entries are the best result at each interval.

In comparison with the TM and the SMT$^+$ systems, Model-III$^+$ is significantly better than both of them in either BLEU or TER scores when the fuzzy match score is above 0.5; also, Distinguishing Model outperforms both the TM and the SMT$^+$ systems in either BLEU or TER scores when the fuzzy match score is above 0.4. Furthermore, the improvements from both Model-III$^+$ and Distinguishing Model get less when the fuzzy match score decreases, as the TM information is less reliable at low fuzzy match intervals.

Across all intervals (the last row in the table), Distinguishing Model not only achieves the best BLEU score (52.56), but also gets the best TER score (36.28). At those intervals when the fuzzy match score is above 0.4, Model-III$^+$ and Distinguishing Model are the best two in either BLEU or TER scores. Besides, Distinguishing Model slightly exceeds Model-III$^+$ at most intervals. However, both Model-III$^+$ and Distinguishing Model achieve significant improvements over the TM and the SMT$^+$.

Compared with previous works, it can be seen that both Model-III$^+$ and Distinguishing Model significantly outperform Koehn-10 in either BLEU or TER scores at all intervals, and are significantly better than Model-III when the fuzzy match score is above 0.6. Furthermore, the proposed approaches (both Model-III$^+$ and Distinguishing Model) achieve a much better TER score than the TM system does at the interval [0.9, 1.0); while Model-III and Koehn-10 are worse than the TM system at this interval. Also, both Model-III$^+$ and Distinguishing Model exceed Ma-11-U at most intervals. Therefore, it can be concluded that the proposed models outperform previous approaches significantly in this scenario.

To further verify the proposed approaches in this case, we swap the TM database and the SMT training set and re-run the experiments. Similar and significant improvements are still observed: both Model-III$^+$ and the Distinguishing Model achieve significant improvements over the TM and the SMT$^+$. All those results have shown that the proposed approaches are robust.

In real environments, the SMT training set and the TM database could be the same before translation projects starts. However, the TM database will gradually deviate from the SMT training set while the translation task progresses. Nonetheless, our experiments have shown that the proposed Distinguishing Model is effective even when the TM database and the SMT training set are totally different (which would be the extreme case for real applications). Therefore, it can be concluded that this proposed approach is robust.

4.3 Cross-Domain Translation Results

To evaluate the cross domain performance, we adopt the news corpora about computer and science from CWMT09 (Liu and Zhao, 2009) as the SMT training set, and adopt the whole TM dataset as the TM database. The SMT training set includes about 404k bilingual sentence-pairs (which includes about 9M Chinese words and 8.7M English words). Corpus statistics is shown in Table 5. Since the TM database and the test set (also the development set) are the same as that in (Wang et al., 2013), the statistics at each interval is the same as theirs but different from Table 2.

The training procedure is the same as that mentioned in the last sub-section. Table 6 and Table 7 present the translation results of TM, SMT, SMT$^+$, two baselines (Koehn-10 and Model-III), and three proposed approaches (Model-III$^+$, Distinguishing and Adaptation). The Adaptation approach means that we add two consistent related features based on Distinguishing Model (Section 3.3). All the formats are the same as that adopted in Table 3 and Table 4. Besides, scores marked by "&" are significantly better than Distinguishing Model.

Comparing the TM with the SMT, the performance of in-domain TM significantly exceeds that of out-domain SMT. Since the fuzzy match intervals are divided according to the TM database, the translation result of the SMT system at interval [0.8, 0.9) even slightly outperforms that at interval [0.9, 1.0). Besides, adding TM phrase-pairs significantly improves the translation results when the fuzzy match score is above 0.5 (SMT vs. SMT$^+$, and Model-III vs. Model-III$^+$). Furthermore, the benefit of utilizing TM information and the benefit of adding TM phrase-pairs are not covered by each other, and can be jointly enjoyed. Furthermore, compared with TM, SMT, SMT$^+$ and Model-III, both Model-III$^+$ and Distinguishing Model achieve better translation results when the fuzzy match score is above 0.4. All observed trends are similar to that in the last sub-section.

Table 7: Cross-Domain Translation Results (TER). The marks are the same as that in Table 6.

However, both Model-III$^+$ and Distinguishing Model are worse than Koehn-10 at some high fuzzy match intervals. The reason is that the TM factors are trained on the news domain but the test set is from computer technical domain. Therefore, it is not strange that the Adaptation approach achieves the best translation results at all intervals in either BLEU or TER when the fuzzy match score is above 0.4. At most intervals, the Adaptation approach significantly outperforms Koehn-10 in either BLEU or TER, especially for the high fuzzy match intervals such as [0.9, 1.0) and [0.8, 0.9). Furthermore, the Adaptation approach achieves better TER than the TM system and Koehn-10 at intervals [0.9, 1.0) and [0.8, 0.9). All obtained results have shown that the Adaptation approach is effective and robust for cross-domain test. Moreover, it can be seen that the h1 feature (mentioned in Section 3.3) is more effective than the h2 feature.

5 Related Work

According to the way of combination, those previous works can be classified into four categories (as specified in Section 1). The first category uses a classifier (or a re-ranker) to judge whether TM or SMT gives a better translation sentence, and then delivers the better one to the post-editor (He et al., 2010a; He et al., 2010b; Dara et al., 2013). Since the outputs of SMT and TM are not merged but only re-ranked, the possible improvement resulted from those approaches is quite limited.

The second category incorporates TM matched parts into the SMT input sentence in a pipelined manner (Koehn and Senellart, 2010; Zhechev and van Genabith, 2010; He et al., 2011; Ma et al., 2011). These approaches usually translate the sentence in two stages: (1) first determine whether the

extracted TM sentence pair should be adopted or not, and then merge the relevant translations of matched parts into the input sentence; (2) then force the SMT system to only translate those unmatched parts at decoding. There are three drawbacks for this kind of pipeline approaches (Wang et al., 2013). Firstly, whether those matched parts should be adopted or not is determined at the sentence level. Secondly, they select only one TM target phrase before decoding. Thirdly, they do not utilize the SMT probabilistic information for the matched parts.

The third category mainly adds the longest matched TM phrase pairs into the SMT phrase table (Bi ̧ici and Dymetman, 2008; Simard and Isabelle, 2009), and associates them with a fixed large probability value to favor the TM target phrase. However, they only add one aligned target phrase for each matched source phrase and did not distinguish the original and the newly-added phrase-pairs.

The last category incorporates the associated TM information of each source phrase into the SMT during decoding (Wang et al., 2013). This category can avoid the drawbacks of the pipeline approaches, and thus achieves superior results when the TM database and the SMT training set are the same. However, they only refer to the TM information and do not regard the TM phrase-pairs as candidates during decoding. Therefore, the superiority of this approach disappears when the TM database and the SMT training set are different, because many TM phrase-pairs cannot be found in the original SMT phrase table in this case.

Our approach combines the strength of both the third and the last categories. During decoding, the associated TM information is referred to re-score the SMT candidates. At the same time, all matched TM phrase-pairs are dynamically merged into the phrase table. Moreover, this is the first unified framework for integrating TM into SMT at decoding when the TM database and the SMT training set are different. Although some previous works of the second and third categories can be also applied when the TM database and the SMT training set are different, they did not explicitly focus on and test this case.

Last, since the example-based machine translation (EBMT, [Nagao, 1984]) is similar to that of using TM, some approaches (Watanabe and Sumita, 2003; Smith and Clark, 2009; Dandapat et al., 2011; 2012; Phillips, 2011) also combined EBMT with SMT. It would be interesting to compare our approaches with theirs in the future.

6 Conclusion

Combining TM and SMT can greatly improve the translation performance and reduce human post-editing effort. In comparison with those previous approaches, our work makes the following contributions:

(1) Dynamically merge the matched TM phrase-pairs into the SMT phrase table to meet the real application;
(2) Propose an improved integrated model to distinguish the original SMT phrase-pairs from the newly-added ones extracted from TM;
(3) Adopt a simple but effective TM adaptation method to favor the consistent translation in cross-domain test.

This is the first work adopting a unified framework to integrate the TM information into the SMT model during decoding when the TM database and the SMT training set are different. On the TM database which consists of Chinese–English computer technical documents, our experiments have shown that merging the TM phrase-pairs achieves significant improvements when the fuzzy match score is above 0.5. Furthermore, the proposed approaches are significantly better than either the SMT or the TM systems for both the in-domain and the cross-domain tests. Last, the proposed approaches outperform previous works significantly in all test conditions.

Abstract

Machine Translation (MT) Quality Estimation (QE) aims to automatically measure the quality of MT system output without reference translations. In spite of the progress achieved in recent years, current MT QE systems are not capable of dealing with data coming from different train/test distributions or domains, and scenarios in which training data is scarce. We investigate different multitask learning methods that can cope with such limitations and show that they overcome current state-of-the-art methods in real-world conditions where training and test data come from different domains.

1 Introduction

Machine Translation (MT) Quality Estimation (QE) aims to automatically predict the quality of MT output without using reference translations (Blatz et al., 2003; Specia et al., 2009). QE systems usually employ supervised machine learning models that use different information extracted from (source, target) sentence pairs as features along with quality scores as labels. The notion of quality that these models measure can be indicated by different scores. Some examples are the average number of edits required to post-edit the MT output, i.e., human translation edit rate[1] (HTER (Snover et al., 2006)), and the time (in seconds) required to post-edit a translation produced by an MT system (Specia, 2011).

Research on QE has received a strong boost in recent years due to the increase in the usage of MT systems in real-world applications. Automatic and reference-free MT quality prediction demonstrated to be useful for different applications, such as: deciding whether the translation output can be published without post-editing (Soricut and Echihabi, 2010), filtering out low-quality translation suggestions that should be rewritten from scratch (Specia et al., 2009), selecting the best translation output from a pool of MT systems (Specia et al., 2010), and informing readers of the translation whether it is reliable or not (Turchi et al., 2012). Another example is the computer-assisted translation (CAT) scenario, in which it might be necessary to predict the quality of translation suggestions generated by different MT systems to support the activity of post editors working with different genres of text.

The dominant QE framework presents some characteristics that can limit models' applicability in such real-world scenarios. First, the scores used as training labels (HTER, time) are costly to obtain because they are derived from manual post-editions of MT output. Such requirement makes it difficult to develop models for domains in which there is a limited amount of labeled data. Second, the learning methods currently used (for instance in the framework of QE shared evaluation campaigns)[2] assume that training and test data are sampled from the same distribution. Though reasonable as a first evaluation setting to promote research in the field, this controlled scenario is not realistic as different data in real-world applications might be post-edited by different translators, the translations might be generated by different MT systems and the documents being translated might belong to different domains or genres. To

[1] Edit distance is calculated as the number of edits (word insertions, deletions, substitutions, and shifts) divided by the number of words in the reference. Lower HTER values indicate better translations.

[2] In the last two editions of the yearly Workshop on Machine Translation, several QE shared tasks have been proposed (Callison-Burch et al., 2012; Bojar et al., 2013).

Proceedings of COLING 2014, the 25th International Conference on Computational Linguistics: Technical Papers, pages 409–420, Dublin, Ireland, August 23-29 2014.

overcome these limitations a plausible research objective is to exploit techniques that: (i) allow domains and distributions of features to be different between training and test data, and (ii) that cope with the scarce amount of training labels by sharing information across domains, a common scenario for transfer learning.

In this paper we investigate the use of techniques that can exploit the training instances from different domains to learn a QE model for a specific target domain for which there is a small amount of labeled data. In particular, we are interested in approaches that allow not only learning from one single source domain but also from multiple source domains simultaneously, by leveraging the labels from all available data to improve results in a target domain.

Given these requirements, we experiment with different *multitask learning* techniques that perform transfer learning via a common task structure (domain relatedness). Furthermore, we employ an approach based on *feature augmentation* that has been successfully used in other natural language processing tasks. We present a series of experiments over three domains with increasing amounts of training data, showing that our adaptive approaches outperform competitive baselines.

The contributions of our work are: (i) a first exploration of techniques that overcome the limitation of current QE learning methods when dealing with data with different training and test distributions and domains, and (ii) an empirical verification of the amount of training data required by such techniques to outperform competitive baselines on different target domains. To the best of our knowledge, this is the first work addressing the challenges posed by domain adaptation in MT QE.

2 Related Work

Quality estimation has recently gained increasing attention, also boosted by two evaluation campaigns organized within the Workshop on Machine Translation (WMT) (Callison-Burch et al., 2012; Bojar et al., 2013). The bulk of work done so far has focused on the controlled WMT evaluation framework and, in particular, on two major aspects of the problem: feature engineering and machine learning methods.

Feature engineering accounts for linguistically-based predictors that aim to model different perspectives of the quality estimation problem. The research ranges from identifying indicators that approximate the complexity of translating the source sentence and designing features that model the fluency of the automatically generated translation, to linguistically motivated measures that estimate how adequate the translation is in comparison to the source sentence in terms of meaning (Blatz et al., 2003; Mehdad et al., 2012; Hardmeier et al., 2012; Rubino et al., 2012; Specia et al., 2012; de Souza et al., 2013a).

State-of-the-art QE explores different supervised linear or non-linear learning methods for regression or classification such as Support Vector Machines (SVM), different types of Decision Trees, Neural Networks, Elastic-Net, Gaussian Processes, Naive Bayes, among others (Specia et al., 2009; Buck, 2012; Beck et al., 2013; Souza et al., 2014). Another aspect related to the learning methods that has received attention is the optimal selection of features in order to overcome issues related with the high-dimensionality of the feature space (Soricut et al., 2012; de Souza et al., 2013a; Beck et al., 2013; de Souza et al., 2013b).

Despite constant improvements, such learning methods have limitations. The main one is that they assume that both training and test data are independently and identically distributed. As a consequence, when they are applied to data from a different distribution or domain they show poor performance. This limitation harms the performance of QE systems for several real-world applications, such as CAT environments. Advanced CAT systems currently integrate suggestions obtained from MT engines with those derived from translation memories (TMs). In such framework, the compelling need to speed up the translation process and reduce its costs by presenting human translators with good-quality suggestions raises interesting research challenges for the QE community. In such environments, translation jobs come from different domains that might be translated by different MT systems and are routed to professional translators with different idiolect, background and quality standards (Turchi et al., 2013). Such variability calls for flexible and adaptive QE solutions by investigating two directions: (i) modeling translator behaviour (Turchi et al., 2014) and (ii) maximize the learning capabilities from all the available data. The second research objective motivates our investigation on methods that allow the training and test domains and

the distributions to be different.

Recent work in QE focused on aspects that are problematic even in the controlled WMT scenario, and are closely related to the flexibility/adaptability issue. Focusing on the first of the two aforementioned directions (i.e. modeling translators' behaviour), Cohn and Specia (2013) propose a Multitask Gaussian Process method that jointly learns a series of annotator-specific models and that outperforms models trained for each annotator. Our work differs from theirs in that we are interested in the latter research direction (i.e. coping with domain and distribution diversity) and we use in and out-of-domain data to learn robust in-domain models. Our scenario represents a more challenging setting than the one tackled in (Cohn and Specia, 2013), which does not consider different domains.

In *transfer learning* there are many techniques suitable to fulfill our requirements. The aim of transfer learning is to extract the knowledge from one or more source tasks and apply it to a target task (Pan and Yang, 2010). One type of transfer learning is *multitask learning* (MTL), which uses domain-specific training signals of related tasks to improve model generalization (Caruana, 1997). Although it was not originally thought for transferring knowledge to a new task, MTL can be used to achieve this objective due to its capability to capture task relatedness, which is important knowledge that can be applied to a new task (Jiang, 2009).

Domain adaptation is a kind of transfer learning in which source and target domains (i.e. training and test) are different but the tasks are the same (Pan and Yang, 2010). The domain adaptation techniques that inspire our work have been successfully applied to a variety of NLP tasks (Blitzer et al., 2006; Jiang and Zhai, 2007). For instance, an effective solution for supervised domain adaptation, EasyAdapt (SVR FEDA henceforth), was proposed in (Daumé III, 2007) and applied to named entity recognition, part-of-speech tagging and shallow parsing. The approach transforms the domain adaptation problem into a standard learning problem by augmenting the source and target feature set. The feature space is transformed to be a cross-product of the features of the source and target domains augmented with the original target domain features. In *supervised* domain adaptation one has access to out-of-domain labels and wants to leverage a small amount of available in-domain labeled data to train a model (Daumé III, 2007), the case of this study. This is different from the *semi-supervised* case in which in-domain labels are not available.

3 Adaptation for QE

An important assumption in MTL is that different tasks (domains in our case) are correlated via a certain structure. Examples of such structures are the hidden layers in a neural network (Caruana, 1997) and shared feature representation (Argyriou et al., 2007) among others. This common structure allows for knowledge transfer among tasks and has been demonstrated to improve model generalization over single task learning (STL) for different problems in different areas. Under this scenario, several assumptions can be made about the relatedness among the tasks, leading to different transfer structures. We explore three approaches to MTL that deal with task relatedness in different ways. These are the "Dirty" approach to MTL (Jalali et al., 2010), Sparse Trace MTL (Chen et al., 2012) and Robust MTL (Chen et al., 2011). The three approaches use different regularization techniques that capture task relatedness using norms over the weights of the features.

Before describing the three approaches, we introduce some basic notation similar to (Chen et al., 2011). In MTL there are T tasks and each task $t \in T$ has m training samples $\{(x_1^{(t)}, y_1^{(t)}), \ldots, (x_m^{(t)}, y_m^{(t)})\}$, with $x_i^{(t)} \in \mathbb{R}^d$ where d is the number of features and $y_i^{(t)} \in \mathbb{R}$ is the output (the response variable or label). The input features and labels are stacked together to form two different matrices $X^{(t)} = [x_1^{(t)}, \ldots, x_m^{(t)}]$ and $Y^{(t)} = [x_1^{(t)}, \ldots, x_m^{(t)}]$, respectively. The weights of the features for each task are represented by W, where each column corresponds to a task and each row corresponds to a feature.

The **"Dirty"** approach to MTL follows the idea that different tasks may share the same discriminative features (Argyriou et al., 2007). However, it also considers that different tasks might have different discriminative features that are inherent to each task. Therefore, the method encourages shared-sparsity among tasks and among features in each task. It decomposes W into two components, one is a row-

sparsed matrix that corresponds to the features shared among the tasks and the other is an element-wise sparse matrix that corresponds to the non-shared features that are important for each task independently. More formally, the "Dirty" approach is explained by Equation 1.

$$\min_{W} \sum_{t=1}^{T} ||(W^{(t)}X^{(t)} - Y^{(t)})||_2^2 + \lambda_s||S||_1 + \lambda_b||B||_{1,\infty} \text{ subject to: } W = S + B \quad (1)$$

where $||(W^{(t)}X^{(t)} - Y^{(t)})||_2^2$ is the least squares loss function, S is the regularization term that encourages element-wise sparsity and B is the block-structured row-sparsity regularizer. The $||.||_2$ is the l_2-norm (Euclidean distance), $||.||_1$ is the l_1-norm (given by $\sum_{i=1} |x_i|$) and $||.||_{1,\infty}$ is the row grouped l_1-norm. The λ_s and λ_b are non-negative trade-off parameters that control the amount of regularization applied to S and B, respectively.

Sparse Trace MTL considers the problem of learning incoherent sparse and low-rank patterns from multiple related tasks. This approach captures task relationship via a shared low-rank structure of the weight matrix W. As computing the low-rank structure of a matrix leads to a NP-hard optimization problem, Chen et al. (2012) proposed to compute the trace norm as a surrogate, making the optimization problem tractable. In addition to learning the low-rank patterns, this method also considers the fact that different tasks may have different inherent discriminative features. It decomposes W into two components: S, which models element-wise sparsity, and Q, which captures task relationship via the trace norm. The convex problem minimized by Sparse Trace is given in Equation 2.

$$\min_{W} \sum_{t=1}^{T} ||(W^{(t)}X^{(t)} - Y^{(t)})||_2^2 + \lambda_s||S||_1 \text{ subject to: } W = S + Q, ||Q||_* < \lambda_p \quad (2)$$

where $||.||_*$ is the trace norm, given by the sum of the singular values σ_i of W, i.e., $||W||_* = \sum_{i=1} \sigma_i(W)$. Here, λ_p controls the rank of Q and λ_s controls the sparsity of S.

The key assumption in MTL is that tasks are related in some way. However, this assumption might not hold for a series of real-world problems. In situations in which tasks are not related a negative transfer of information among tasks might occur, harming the generalization of the model. One way to deal with this problem is to: (i) group related tasks in one structure and share knowledge among them, and (ii) identify irrelevant tasks maintaining them in a different group that does not share information with the first group. This is the idea of **Robust** MTL (RMTL henceforth). The algorithm approximates task relatedness via a low-rank structure like Sparse Trace and identifies outlier tasks using a group-sparse structure (column-sparse, at task level). Robust MTL is described by Equation 3. It employs a non-negative linear combination of the trace norm (the task relatedness component L) and a column-sparse structure induced by the $l_{1,2}$-norm (the outlier task detection component S). If a task is an outlier it will have non-zero entries in S.

$$\min_{W} \sum_{t=1}^{T} ||(W^{(t)}X^{(t)} - Y^{(t)})||_2^2 + \lambda_l||L||_* + \lambda_s||S||_{1,2} \text{ subject to: } W = L + S \quad (3)$$

where $||S||_{1,2}$ is the group regularizer that induces sparsity on the tasks.

4 Experimental Setting

In this section we describe the data used for our experiments, the features extracted, the set up of the learning methods, the baselines used for comparison and the evaluation of the models. The goal of our experiments is to show that the methods presented in Section 3 outperform competitive baselines and standard QE learning methods that are not capable of adapting to different domains. We experiment with three different domains of comparable size and evaluate the performance of the adaptive methods and the standard techniques with different amounts of training data. The MTL models described in section 3 are trained with the Malsar toolkit implementation (Zhou et al., 2012). The hyper-parameters are optimized

using 5-fold cross-validation in a grid search procedure. The parameter values are searched in an interval ranging from 10^{-3} to 10^{3}.

4.1 Data

Our experiments focus on the English-French language pair and encompass three very different domains: newswire text (henceforth News), transcriptions of Technology Entertainment Design talks (TED) and Information Technology manuals (IT). Such domains are a challenging combination for adaptive systems since they come from very different sources spanning speech and written discourse (TED and News/IT, respectively) as well as a very well defined and controlled vocabulary in the case of IT.

Each domain is composed of 363 tuples formed by the source sentence in English, the French translation produced by an MT system and a human post-edition of the translated sentence. For each pair (translation, post-edition) we use as labels the HTER score computed with TERCpp[3]. For the three domains we use half of the data for training (181 instances) and half of the data for testing (182 instances). The limited amount of instances for training contrasts with the 800 or more instances of the WMT evaluation campaigns and is closer to real-world applications where the availability of large and representative training sets is far from being guaranteed (e.g. the CAT scenario).

The sentence tuples for the first two domains are randomly sampled from the Trace corpus[4]. The translations were generated by two different MT systems, a state-of-the-art phrase-based statistical MT system and a commercial rule-based system. Furthermore, the translations were post-edited by up to four different translators, as described in (Wisniewski et al., 2013).

Domain	No. of tokens	Vocab. size	Avg. sent. length
TED source	6858	1659	19
TED target	7016	1828	19
IT source	3310	1004	9
IT target	3134	1049	8
News source	7605	2273	21
News target	8230	2346	23

Table 1: Datasets statistics for each domain.

The TED talks domain is formed by subtitles of several talks in a range of topics presented in the TED conferences. The complete dataset has been used for MT and automatic speech recognition systems evaluation within the International Workshop on Spoken Language Translation (IWSLT). The News domain is formed by newswire text used in WMT translation campaigns and covers different topics. The IT texts come from a software user manual translated by a statistical MT system based on the state-of-the-art phrase-based Moses toolkit (Koehn et al., 2007) trained on about 2M parallel sentences. The post-editions were collected from one professional translator operating on the Matecat[5] CAT tool in real working conditions. Table 1 provides macro-indicators (number of tokens, vocabulary size, average sentence length) that evidence the large difference between the domains addressed by our experiments and give an idea of the difficulty of the task.

A peculiarity of the TED domain is that it is formed by manual transcriptions of speech translated by different MT systems, configuring a different type of discourse than News and IT. In TED, the vocabulary size in the source and target sentences is lower than that of the News domain but higher than IT. News presents the most varied vocabulary, which is an evidence of the more varied lexical choice represented by the several topics that compose the domain. Moreover, News has the highest average sentence length, a characteristic of non-technical written discourse, which tends to have longer sentences than spoken discourse and domains dominated by technical jargon. Such a characteristic is exactly what differentiates IT from the other two domains. IT sentences are technical and present a reduced average number of

[3] http://sourceforge.net/projects/tercpp/

[4] http://anrtrace.limsi.fr/trace_postedit.tar.bz2

[5] www.matecat.com

words, as evidenced by the vocabulary size (the smallest among the three domains). These numbers suggest a divergence between IT and the other two domains, possibly making adaptation more difficult.

4.2 Features

For all the experiments we use the same feature set composed of seventeen features proposed in (Specia et al., 2009). The set is formed by features that model the complexity of translating the source sentence (e.g. the average source token length or the number of tokens in the source sentence), and the fluency of the translated sentence produced by the MT system (e.g. the language model probability of the translation). The decision to use this feature set is motivated by the fact that it demonstrated to be robust across language pairs, MT systems and text domains (Specia et al., 2009). The 17 features are:

- number of tokens in the source sentence and in the generated translation;
- average source token length;
- average number of occurences of the target word within the generated translation;
- language model probability of the source sentence and generated translation;
- average number of translations per source word in the sentence: as given by IBM 1 model thresholded so that $P(t|s) > 0.2$ weighted by the inverse frequency of each word in the source side of the SMT training corpus ◯;
- average number of translations per source word in the sentence: as given by IBM 1 model thresholded so that $P(t|s) > 0.01$ weighted by the inverse frequency of each word in the source side of the SMT training corpus;
- percentage of unigrams◯, bigrams and trigrams◯ in the first quartile of frequency (lower frequency words) in a corpus of the source language;
- percentage of unigrams◯, bigrams and trigrams in the fourth quartile of frequency (higher frequency words) in a corpus of the source language;
- percentage of unigrams in the source sentence seen in the source side of the SMT training corpus;
- number of punctuation marks in the source sentence and in the hypothesis translation;

4.3 Baselines

As a term of comparison, we consider these baselines in our experiments. A simple to implement but difficult to beat baseline when dealing with regression on tasks with different distributions is to compute the mean of the training labels and use it as the prediction for each testing point (Rubino et al., 2013). Hereafter we refer to this baseline as μ. Since supervised domain adaptation techniques should outperform models that are trained only on the available in-domain data, we also use as baseline the regressor built only on the available in-domain data (SVR in-domain). Furthermore, as a third baseline, we train a regressor by pooling together training data of all domains, combining source and target data without any kind of task relationship mechanism (SVR Pooling).

The baselines are trained on the feature set described earlier in Section 4.2 with an SVM regression (SVR) method using the implementation of Scikit-learn (Pedregosa et al., 2011). The radial basis function (RBF) kernel is used for all baselines. The hyper-parameters of the model are optimized using randomized search optimization process with 50 iterations as described in (Bergstra and Bengio, 2012) and used previously for QE in (de Souza et al., 2013a). The best parameters are found using 5-fold cross-validation on the training data and ϵ, γ and C are sampled from exponential distributions scaled at 0.1 for the first two parameters and scaled at 100 for the last one. It is important to notice that the SVR with RBF kernel methods learn non-linear models that have been shown to perform better than linear models on the set of features used for predicting HTER. On the contrary, the MTL methods presented in Section 3 are methods that do not explore kernels or any other kind of non-linear learning method.

Source / Target	IT_{tgt}	$News_{tgt}$	TED_{tgt}
IT_{src}	0.2081	0.2341	0.2232
$News_{src}$	0.2368	0.1690	0.2130
TED_{src}	0.2183	0.2263	0.1928

Table 2: Results of the SVR in-domain baseline trained and evaluated in each domain (average of 50 different shuffles). Rows represent the domain data used to train the model and columns represent the domain data used to evaluate the model. Scores are MAE.

4.4 Evaluation

The accuracy of the models is evaluated with the mean absolute error (MAE), which was also used in previous work and in the WMT QE shared tasks (Bojar et al., 2013). MAE is the average of the absolute difference between the prediction $\hat{y}_i$ of a model and the gold standard response y_i (Equation 4). As it is an error measure, lower values mean better performance.

$$MAE = \frac{1}{m}\sum_{i=1}^{m}|\hat{y}_i - y_i| \tag{4}$$

To test the statistical significance of our results we need to perform comparisons of multiple models. In addition, we would like to test the significance over different training amounts. Given these requirements we need to perform multiple hypothesis tests instead of paired tests. It has been shown that for comparisons of multiple machine learning models, the recommended approach is to use a non-parametric multiple hypothesis test followed by a post-hoc analysis that compares each pair of hypothesis (Demšar, 2006). In our experiments we use the Friedman test (Friedman, 1937; Friedman, 1940) followed by a post-hoc analysis of the pairs of regressors using Holm's procedure (Holm, 1979) to perform the pairwise comparisons when the null hypothesis is rejected. All tests for both Friedman and post-hoc analysis are run with $\alpha = 0.05$. For more details about these methods, we refer the reader to (Demšar, 2006; Garcia and Herrera, 2008) which provide a complete review about the application of multiple hypothesis testing to machine learning methods.

5 Results and Discussion

Our experiments are organized as follows. First, we evaluate the performance of single task learning methods on different cross-domain experiments. Then, we report the evaluation for the multitask learning methods and discuss the results.

5.1 Single Task Learning

With the objective of having an insight about the difference between the domains, we train the SVR in-domain baseline with all available training data for each domain and evaluate its performance on the same domain and in the two remaining domains.

Results are reported in Table 2, where the diagonal shows the figures for the in-domain evaluation. These numbers suggest that the IT domain configures a more difficult challenge for the learning algorithm. The IT in-domain model (IT_{src}-IT_{tgt}) presents a performance 21% inferior to News and 8% inferior to TED. For all models trained on a source domain different than the target domain there is a drop in performance, as it is expected from a system that assumes that training and test data are sampled from the same distribution. In addition, when predicting IT using the model trained on News, we have a perfomance drop of 13% whereas using the model trained on TED the performance drops up to 4%.

5.2 Multitask learning

We run the baselines described in Section 4.3 and the methods described in Section 3 on different amounts of training data, ranging from 18 to 181 instances (10% and 100%, respectively). The motivation is to verify how much training data is required by the MTL methods to outperform the baselines for a target domain. Table 3 presents the results for the three domains with models trained on 30, 50 and

100% of the training data (54, 90 and 181 instances, respectively). Each method was run on 50 different train/test splits of the data in order to account for the variability of points in each split.

Method	TED	News	IT
30 % of training data (54 instances)			
mean	0.1951	0.1711	0.2174
SVR In-Domain	0.2013	0.1753	0.2235
SVR Pooling	0.1962	0.1899	0.2201
SVR FEDA	0.1952	0.1839	0.2193
MTL Dirty	0.1954	0.1708	0.2193
MTL SparseTrace	0.1976	0.1743	0.2222
MTL RMTL	**0.1946**	**0.1685**	**0.2162**
50% of training data (90 instances)			
mean	0.1943	0.1707	0.2170
SVR In-Domain	0.1976	0.1711	0.2183
SVR Pooling	0.1951	0.1865	0.2191
SVR FEDA	0.1937	0.1806	0.2161
MTL Dirty	0.1927	0.1678	0.2148
MTL SparseTrace	0.1922	0.1672	0.2157
MTL RMTL	**0.1878**	**0.1653**	**0.2119**
100% of training data (181 instances)			
mean	0.1936	0.1690	0.2162
SVR In-Domain	0.1928	0.1690	0.2081
SVR Pooling	0.1927	0.1849	0.2203
SVR FEDA	0.1908	0.1757	0.2107
MTL Dirty	0.1878	0.1666	0.2083
MTL SparseTrace	0.1881	0.1661	0.2094
MTL RMTL	**0.1846**	**0.1653**	**0.2075**

Table 3: Average performance of fifty runs of the models on different train and test splits with 30, 50 and 100 percent of training data. The average scores reported are the MAE.

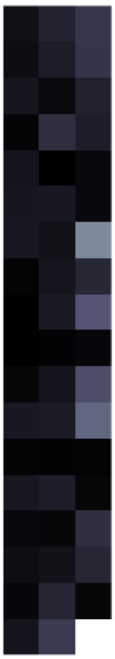

Figure 1: Visualization of the RMTL task outlier model when trained on all the 181 instances of training data. Cells with darker shades are closer to zero. Cells with lighter shades are closer to one. Columns with only black entries are considered inlier tasks (domains). From left to right, columns correspond to News, TED and IT domains. The first 17 rows correspond to the features used to train the model and the last row in corresponds to the bias term.

For all three domains, a general trend is that MTL RMTL is the method that reaches the lowest MAE when compared to all the other models. Given the difference among the domains, it is very likely that MTL Dirty and MTL SparseTrace suffer from the negative transfer problem (the assumption that all tasks are similar does not hold). MTL RMTL is the only method among the methods presented here that copes with negative transfer among tasks. The significance tests indicate that MTL RMTL improvements are statistically significant with respect to all baselines depending on the range of training data used to compute the test.

- For **TED**, the Friedman test rejects the null hypothesis with $p = 4.62^{-5}$. Post-hoc analysis indicates that there are differences statistically significant between MTL RMTL and all the three baselines with $p \leq 0.002$.

- For **News**, the Friedman test measures significant differences with $p = 1.14^{-9}$ and the post-hoc analysis indicates that MTL RMTL is statistically significant with respect to SVR in-domain and SVR Pooling with $p = 0.002$ for varying amounts of training data from 10 to 100%. As can be seen in Figure 2, MTL RMTL starts with a very high MAE using 10% of the data (approximately 0.21 MAE) but improves dramatically with 20% of the data. Calculating the significance test with 20 to 100% of training data, MTL RMTL is significantly better than all baselines with $p \leq 2.89^{-10}$.

- For **IT**, in a similar situation to the News domain, RMTL is significantly better than all baselines

trained on 30% to 100% of the training data (Friedman test's $p = 2.86^{-4}$ and post-hoc analysis' $p \leq 3.73^{-7}$).

Another observed trend is that the MTL models benefit from increasing amounts of training data. MTL RMTL has an improvement in performance of 5.13% for TED, 4% for News and 1.85% for IT when trained on 100% of the training data in comparison with the model trained on 30% of training data.

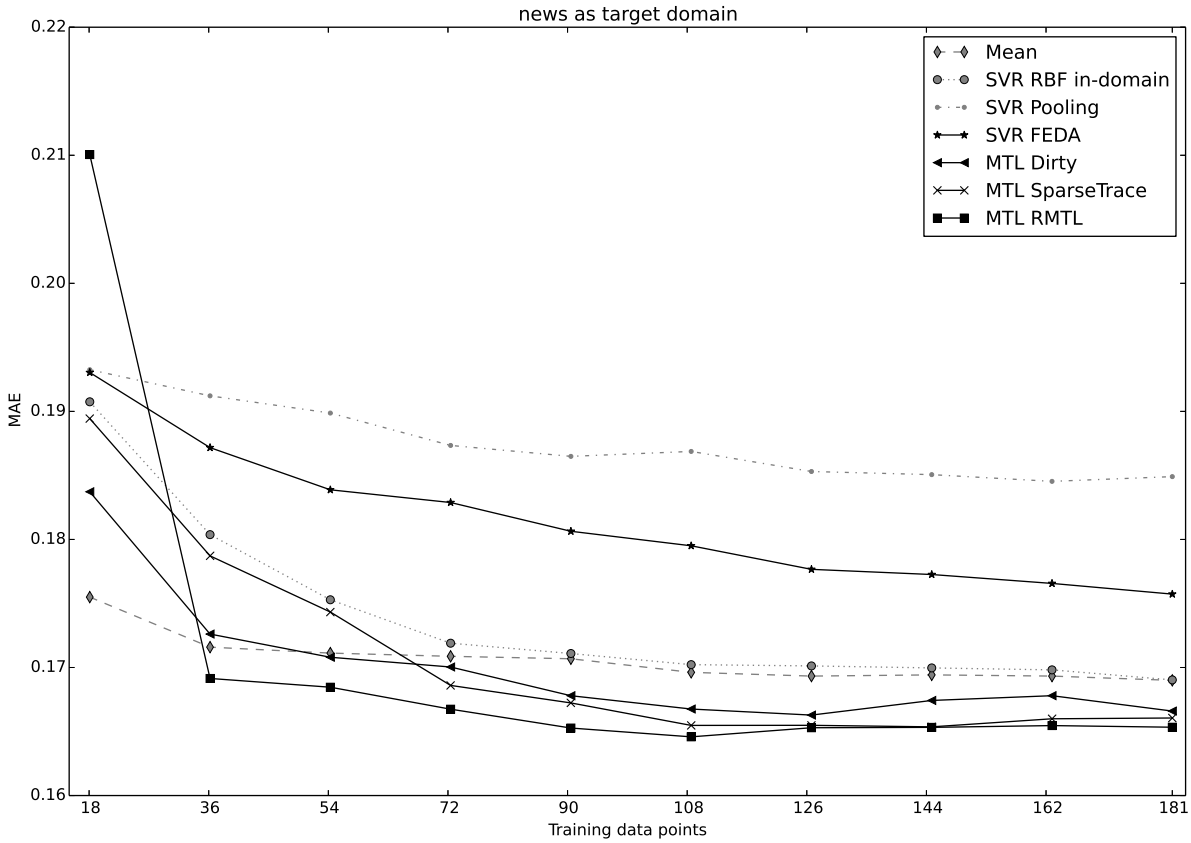

Figure 2: Learning curves for the News domain.

The results for the IT domain are in line with the in-domain experiments in which we observed that IT is a more challenging domain in comparison to TED and News. The MAE of IT is always higher than for the other domains on in-domain and MTL experiments. Another evidence of this is the model learned by the RMTL method when using all training data and run on one of the 50 training/test splits. A graphic representation of the RMTL outlier task detection component (described in Section 3) is shown in Figure 1.

From left to right, each column represents News, TED, and IT domains, respectively, while each row is the instantiation of a feature in the corresponding task. Columns with non-black entries represent outlier tasks. The highest number of entries with lighter shades is in the third column, IT. Several features in this task are considered outliers with respect to the same features in the other tasks. Consequently, the learning method takes the weights into consideration to a greater extent when learned with the outlier model for the IT domain. Entries with the lightest shades in the IT domain correspond to the features marked with ◯ in Section 4.2. These outlier features are directly affected by the length of the sentences on which they are computed (source or target) given that the number of tokens influences the final value of the feature. This outcome goes in the same direction of our analysis of the three domains (Section 4.1) that indicates a very different vocabulary size and average sentence length for IT when compared to the other two domains.

To a lesser extent than IT, News and TED domains also present a few lighter-shaded entries in the outlier component (1st and 2nd column). This suggests that MTL RMTL was capable of transfering information among the domains in a more efficient way than the other MTL methods analyzed.

Overall the experiments presented show encouraging results in the direction of coping with QE data coming from different domains/genres, translated by different MT systems and post-edited by different translators. Results show that even in such difficult conditions, the methods investigated are capable of outperforming competitive baselines based on non-linear models on different domains. As a rationale, models that consider not only similarity between the domains but also deal with some sort of dissimilarity should be considered. This is the case of the best performing method, MTL RMTL, which identifies outlier tasks in order to avoid negative transfer among tasks.

6 Conclusion

In this work we presented an investigation of methods that overcome limitations presented by current MT QE state-of-the-art systems when applied to real world conditions. In such scenarios (e.g. CAT environment) the requirements are two-fold: (i) learning in the presence of different train/test feature and label distributions and across different domains/genres, and (ii) the capability of learning with scarce training data. In our experiments, we explored transfer learning methods, in particular multitask learning, and we showed that such methods can cope with the needs of real-world scenarios.

We showed that multitask learning methods are capable to learn robust models for three different domains that perform better than three strong baselines trained on the same amount of data. The methods explored here benefit from increasing amounts of training data but also perform well when operating with very limited amounts of data. We believe that the results obtained in this first exploration of model adaptation for the problem can encourage the MT QE community to shift the focus from controlled scenarios to more applicable, real-world contexts that require more robust methods.

Abstract

We investigate the use of generalized representations (POS, morphological analysis and word clusters) in phrase-based models and the N-gram-based *Operation Sequence Model (OSM)*. Our integration enables these models to learn richer lexical and reordering patterns, consider wider contextual information and generalize better in sparse data conditions. When interpolating generalized OSM models on the standard IWSLT and WMT tasks we observed improvements of up to +1.35 on the English-to-German task and +0.63 for the German-to-English task. Using automatically generated word classes in standard phrase-based models and the OSM models yields an average improvement of +0.80 across 8 language pairs on the IWSLT shared task.

1 Introduction

The increasing availability of digital text has galvanized the use of empirical methods in many fields including Machine Translation. Given bilingual text, it is now possible to automatically learn translation rules that required years of effort previously. Bilingual data, however, is abundantly available for only a handful of language pairs. The problem of reliably estimating statistical models for translation becomes more of a challenge under sparse data conditions especially when translating into morphologically rich or syntactically divergent languages. The former becomes challenging due to lexical sparsity and the latter suffers from sparsity in learning underlying reordering patterns. The last decade of research in Statistical Machine Translation has witnessed many attempts to integrate linguistic analysis into SMT models, to address the challenges of (i) translating into morphologically rich language languages, (ii) modeling syntactic divergence across languages for better generalization in sparse data conditions.

The integration of the *Operation Sequence Model* into phrase-based paradigm (Durrani et al., 2013a; Durrani et al., 2013b) improved the reordering capability and addressed the problem of the phrasal independence assumption in the phrase-based models. The OSM model integrates translation and reordering into a single generative story. By jointly considering translation and reordering context across phrasal boundaries, the OSM model considers much richer conditioning than phrasal translation and lexicalized reordering models. However, due to data sparsity the model often falls back to very small context sizes. We address this problem by learning operation sequences over generalized representations such as POS and Morph tags. This enables us to learn richer translation and reordering patterns that can generalize better in sparse data conditions. The model benefits from wider contextual information as we show empirically in our results.

We investigate two methods to combine generalized OSM models with the lexically driven OSM model and experimented on German-English translation tasks. Our best system that uses a linear combination of different OSM models gives significant improvements over a competitive baseline system. An improvement of up to +1.35 was observed on the English-to-German and up to +0.63 BLEU points on the German-to-English task over a factored augmented baseline system (Koehn and Hoang, 2007).

POS taggers and morphological analyzers, however, are not available for many resource poor languages. In the second half of the paper we investigate whether annotating the data with automatic word

Proceedings of COLING 2014, the 25th International Conference on Computational Linguistics: Technical Papers, pages 421–432, Dublin, Ireland, August 23-29 2014.

clusters helps improve the performance. Word clustering is similar to POS-tagging/Morphological annotation except that it also captures interesting syntactic and lexical semantics, for example countries and languages are grouped in separate clusters, animate objects are differentiated from inanimate objects, colors are grouped in a separate cluster etc. Word clusters, however, deterministically map each word type to a unique[1] cluster, unlike POS/Morph tagging, and therefore might be less useful for disambiguation. We use the `mkcls` utility in GIZA (Och and Ney, 2003) to cluster source and target vocabularies into classes and will therefore refer to automatic classes as Och clusters/classes in this paper.

We first use Och classes as an additional factor in phrase-based translation model, along with a target LM model over cluster-ids to improve the baseline system. We then additionally use the OSM model over cluster-ids. Our experiments include translation from English to Dutch, French, Italian, Polish, Portuguese, Russian, Spanish, Slovenian and Turkish on IWSLT shared task data. Our results show an average improvement of +0.80, ranging from +0.41 to +2.02. Compared to the improved baseline system obtained by using Och classes as a factor in phrase-based translation models, adding an OSM model over cluster-ids improved performance in four (French, Spanish, Dutch and Slovenian) out of eight cases. In other cases performance stayed constant or dropped slightly. We also used POS annotations for three tasks, namely translating from English into French, Spanish and Dutch to compare the performance of the two different kinds of generalizations. Surprisingly, using Och classes always performed better than using POS annotations. The rest of the paper is organized as follows. Section 2 gives an account on related work. Section 3 discusses the factor-based OSM model. Section 4 presents the experimental setup and the results. Section 5 concludes the paper.

2 Related Work

Previous work on integrating linguistic knowledge into SMT models can be broken into two groups. The first group focuses on using linguistic knowledge to improve reordering between syntactically different languages. A second group focuses on translating into morphologically rich languages.

Initial efforts to use linguistic annotation focused on rearranging source sentences to be in the target order. Xia and McCord (2004) proposed a method to automatically learn rewrite rules to preorder source sentences. Collins et al. (2005) and Popović and Ney (2006) proposed methods for reordering the source using a small set of handcrafted rules. Crego and Mariño (2007) use syntactic trees to derive rewrite rules. Hoang and Koehn (2009) used POS tags to create templates for surface word translation to create longer phrase translation. A whole new paradigm of using syntactic annotation to address long range reorderings has emerged following Galley et al. (2006), Zollmann and Venugopal (2006), Chiang (2007) etc. Crego and Yvon (2010) and Niehues et al. (2011) used a Tuple Sequence Model (TSM) over POS tags in an N-gram-based search to improve mid-range reorderings. Our work is similar to them except that OSM model is substantially different from the TSM model as it integrates both the translation and reordering mechanisms into a combined model. Therefore both translation and reordering decisions can benefit from richer generalized representations.

A second group of work addresses the problem of translating into morphologically richer languages. The idea of translating to stems and then inflecting the stems in a separate step has been studied by Toutanova et al. (2008), de Gispert and Mariño (2008), Fraser et al. (2012), Chahuneau et al. (2013) and others. Koehn and Hoang (2007) proposed to integrate different levels of linguistic information as factors into the phrase-based translation model. Yeniterzi and Oflazer (2010) used source syntactic structures as additional complex tag factors for English-to-Turkish phrase-based machine translation. Green and DeNero (2012) proposed a target-side, class-based agreement model to handle morpho-syntactic agreement errors when translating from English-to-Arabic. El Kholy and Habash (2012) tested three models to find out which features are best handled by modeling them as a part of translation, and which ones are better predicted through generation, also in the English-to-Arabic task. Several researchers attempted to use word lattices to handle generalized representation (Dyer et al., 2008; Hardmeier et al., 2010; Wuebker and Ney, 2012). Automatically clustering the training data into word classes in order to obtain smoother

[1]We are referring to hard clustering here. Soft clustering is intractable as it requires a marginalization over all possible classes when calculating the n-gram probabilities.

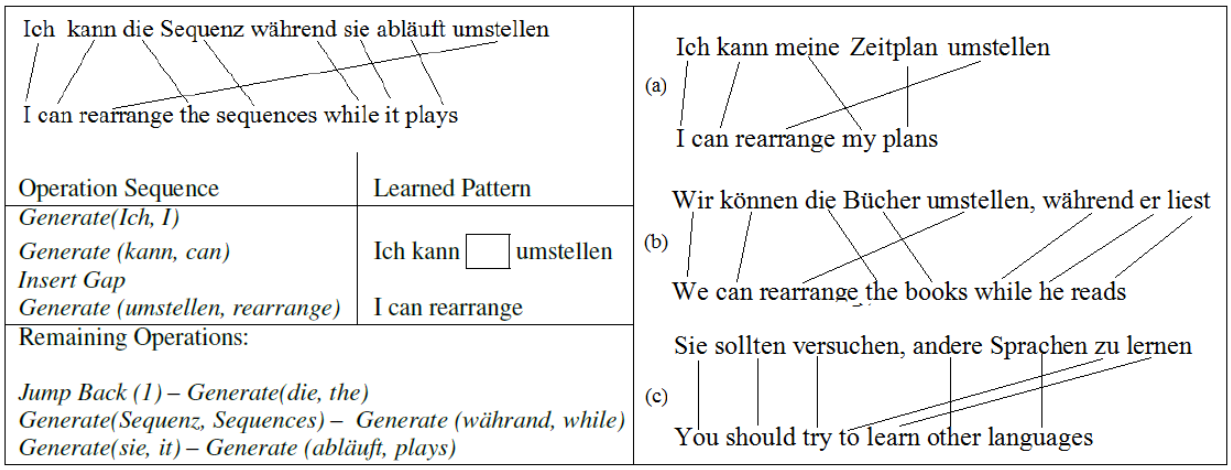

Figure 1: Operation Sequence Model – Training Sentence with Generation and Test Sentences

distributions and better generalizations has been a widely known and applied technique in natural language processing. Training based on word classes has been previously explored by various researchers. Cherry (2013) addressed data sparsity in lexicalized reordering models by using sparse features based on word classes. Other parallel attempts on using word-class models include Wuebker et al. (2013), Chahuneau et al. (2013) and Bisazza and Monz (2014).

More recent research has started to set apart from the conventional maximum likelihood estimates toward neural network-based models that use continuous space representation (Schwenk, 2012; Le et al., 2012; Hu et al., 2014; Gao et al., 2014). Although these methods have achieved impressive improvements, traditional models continue to dominate the field due to their simplicity and low computational complexity. How much of the improvement will be retained when scaling these models to all available data instead of a limited amount will be interesting.

3 Operation Sequence Model

The Operation Sequence Model (Durrani et al., 2011) is an instance of the N-gram based SMT framework (Casacuberta and Vidal, 2004; Mariño et al., 2006). It represents the translation process through a sequence of operations. An operation can be to simultaneously generate source or target words or to perform reordering. Reordering is carried out through jump and gap operations. The model is different from its ancestors in that it strongly integrates translation and reordering into a single generative story in which translation decisions can influence and get impacted by the reordering decisions and vice versa. Given a bilingual sentence pair $< F, E >$ and its alignment A, a sequence of operations $o_1, o_2 \ldots, o_J$ is generated deterministically through a conversion algorithm. The model is learned by learning Markov chains over these sequences and is formally defined as:

$$p_{osm}(F, E, A) = \prod_{j=1}^{J} p(o_j | o_{j-n+1}, ..., o_{j-1})$$

Figure 1 shows an example of an aligned bilingual sentence pair and the corresponding operation sequence used to generate it. There is a 1-1 correspondence between a sentence pair and its operation sequence. We thus get a unique sequence for every bilingual sentence pair given the alignment.

3.1 Motivation

Due to data sparsity it is impossible to observe all possible reordering patterns with all possible lexical choices in translation operations. The lexically driven OSM model therefore often backs off to very small context sizes. Coming back to the training example in Figure 1. The useful reordering pattern

learned through this example is:

Ich kann □ umstellen → I can rearrange

which is memorized through the operation sequence:

Generate(Ich, I) – Generate(kann, can) – Insert Gap – Generate(umstellen, rearrange)

It can generalize to the test sentence shown in Figure 1(a). However, it fails to generalize to the sentences in Figure 1(b) and (c) although the underlying reordering pattern is the same. The second part of the German verb complex usually appears at the end of a clause or a sentence and needs to be moved in order to produce the correct English word order. However, due to data sparsity such a combination of lexical decisions and reordering decisions may not be observed during training. The model would therefore fail to generalize in such circumstances. This problem can be addressed by learning a generalized form of the same reordering rule. By annotating the corpus with word classes such as POS tags, we obtain the reordering pattern:

PPER VMFIN □ VVINF → PP MD VB

memorized through the operation sequence:

Generate (PPER,PP) – Generate (VMFIN,MD) – Insert Gap – Generate (VVINF,VB)

This rule generalizes to all the test sentences in Figure 1. Since the OSM model strongly couples translation and reordering, the probability of each translation or reordering operation depends on the n previous translation/reordering decisions. The generalization of the model by replacing words with POS tags allows the model to consider a wider syntactic context, thus improving lexical decisions and the reordering capability of the model. Using different kinds of word classes, we can also control the type of abstraction. Using lemmas for example, we can map different forms of the verb "können – can" (kann, kannst, konnte) to a single class. Och clusters can provide different levels of granularity.

3.2 Models

Given that we can learn OSM models over different word representations, the question then is how to combine the lexically driven OSM model with an OSM model based on a generalized word representation. The simplest approach is to treat each OSM model as a separate feature in the log-linear framework, thus summing up the weighted log probabilities. The effect of this is similar to an *And* operation. A translation is considered good if both, the word-based OSM and the POS-based OSM models indicate that it is a good translation. However, an *Or* operation might be more desirable in some scenarios. The operation *Generate (trotz, in spite of)* should be ranked high although the POS-based operation *Generate(APPR, IN IN IN)* is improbable. Similarly, the generalized operation sequence:

Insert Gap – Generate (ADJ, JJ) – Jump Back – Generate (NOM, NN)

that captures the swapping of noun and adjective in French-English, should be ranked higher even though *noir* (black) never appeared after *cheval* (horse) during training and the sequence:

Insert Gap – Generate (noir, black) – Jump Back – Generate (cheval , horse)

is never observed. Instead of using both the models, a single model that could switch between different generalized OSMs during translation and choose the one which gives the best prediction in each situation, can be used. In order to achieve this effect, we formulated a second model that interpolates the lexically driven OSM model with its generalized variants. However, we can only

interpolate two models that predict the same representation. The lexically driven OSM predicts the surface forms whereas the POS-based OSM predicts POS translations. To make the two comparable, we multiply the POS-based OSM probability with the probability of the lexical operation given the POS operation. More specifically the probability of the generalized model gm can be defined as:

$$p_{gm}(o_j|o_{j-n+1}^{j-1}) = p_{osm_{pos}}(o'_j|o'^{j-1}_{j-n+1})\ p(o_j|o'_j) \tag{1}$$

where $p_{osm_{pos}}$ is the operation sequence model learned over POS tags and $p(o_j|o'_j)$ is the probability of the lexical operation given the POS-based operation. It is 1 for all reordering operations. We assume here that for each lexical operation o_j a corresponding POS-based operation o'_j is uniquely determined. With $p_{osm_{sur}} = p_{osm_{sur}}(o_j|o_{j-n+1}^{j-1})$ (lexically driven OSM model) and $p_{gm} = p_{gm}(o_j|o_{j-n+1}^{j-1})$ (generalized OSM model as described above), the overall probability of the new model p_{osm} is defined as:

$$p_{osm} = \alpha p_{osm_{sur}} + (1-\alpha)p_{gm} \tag{2}$$

Such an interpolation is expensive in the discriminative training. It would require a sub-tuning routine inside of tuning, a main loop to train all the features including the OSM model and an inner loop to distribute the weight assigned to OSM model among lexically driven and POS-based OSM models. We therefore just take the larger one of the two model values and add a POS-based translation penalty ϕ. The value of this penalty is the number of times that the POS-based operation was chosen when translating a sentence. This penalty acts similarly as the prior α above. Using this formulation, the model could therefore be redefined as:

$$p_{osm} = \begin{cases} p_{osm_{sur}} & \text{if } p_{osm_{sur}} \geq e^{\lambda} p_{gm} \\ e^{\lambda} p_{gm} & \text{otherwise} \end{cases} \tag{3}$$

where λ is the weight for the POS driven translation penalty ϕ. This allows the optimizer to control whether it prefers the lexically driven or the POS-driven OSM model. By setting a very low weight λ the optimizer can force the translator to always choose lexically driven OSM. This formulation can be extended to multiple generalized OSM models based on e.g. POS tags, morphological tags, or word clusters. Equation 2 can be rewritten as follows:

$$p_{osm} = \alpha_1 p_{osm_{sur}} + \sum_{i=2}^{n} \alpha_i p_{gm_i} \tag{4}$$

with $\sum_{i=1}^{n} \alpha_i = 1$ and p_{gm_i} defined analogous to Equation 1.

Setting $p_{gm_1} = p_{osm_{sur}}$ and $\lambda_1 = 0$, we can again simplify Equation 4 by taking the maximum to:

$$p_{osm} = \max_{i=1}^{n} e^{\lambda_i} p_{gm_i} \tag{5}$$

We use a translation penalty ϕ_i for each generalized model and tune its weight λ_i along with the weights of other features. We will refer to this model as $\mathbf{Model_{or}}$ in this paper and the commonly used log-linear interpolation of the features as $\mathbf{Model_{and}}$. The intuition behind $\mathbf{Model_{or}}$ is that we back-off to generalized representations only when the lexically driven model doesn't provide enough contextual evidence. The downside of this approach, however, is that unlike $\mathbf{Model_{and}}$, it cannot distribute weights over multiple features and solely relies on a single model.

4 Evaluation

Data: We ran experiments with data made available for the translation task of the IWSLT-13 (Cettolo et al., 2013): International Workshop on Spoken Language Translation[2] and WMT-13 (Bojar et al., 2013): Eighth Workshop on Statistical Machine Translation.[3] The sizes of bitext used for the estimation of translation and monolingual language models are reported in Table 1.

We used LoPar (Schmid, 2000) to obtain morphological analysis and POS annotation of German and MXPOST (Ratnaparkhi, 1998), a maximum entropy model for English POS tags. For other language pairs we used TreeTagger (Schmid, 1994).

Table 2: Evaluating Generalized OSM Models for German-English pairs – Bold: Statistically Significant (Koehn, 2004) w.r.t Baseline

Baseline System: We trained a Moses system (Koehn et al., 2007), replicating the settings described in (Birch et al., 2013) developed for the 2013 Workshop on Spoken Language Translation. The features included: a maximum sentence length of 80, grow-diag-final-and symmetrization of GIZA++ alignments, an interpolated Kneser-Ney smoothed 5-gram language model with KenLM (Heafield, 2011) used at runtime, a lexically-driven 5-gram operation sequence model (Durrani et al., 2013b) with 4 additional supportive features: 2 gap-based penalties, 1 distance-based feature and 1 deletion penalty, lexicalized reordering, sparse lexical and domain features (Hasler et al., 2012), a distortion limit of 6, 100-best translation options, Minimum Bayes Risk decoding (Kumar and Byrne, 2004), Cube Pruning (Huang and Chiang, 2007), with a stack-size of 1000 during tuning and 5000 during test and the no-reordering-over-punctuation heuristic. We used the compact phrase table representation by Junczys-Dowmunt (2012). For our German-to-English experiments, we used compound splitting (Koehn and Knight, 2003). German-to-English and English-to-German baseline systems also used POS and morphological target sequence models built on the in-domain subset of the parallel corpus using Kneser-Ney smoothed 7-gram models and as additional factors in phrase translation models (Koehn and Hoang, 2007). We used an unsupervised transliteration model (Durrani et al., 2014) to transliterate OOV words when translating into Russian.

Tuning and Test: The systems were tuned on the dev2010 dataset and evaluated on the test2010-2013 datasets made available for the IWSLT-13 workshop. We performed a secondary set of experiments for German-English pairs using tuning and test sets made available for the WMT-13 workshop. We concatenated the news-test sets 2008 and 2009 to obtain a large dev-set of 4576 sentences. Evaluation was performed on the news-test set 2013 which contains 3000 sentences. Tuning was performed using the k-best batch MIRA algorithm (Cherry and Foster, 2012) with at most 25 iterations. We use BLEU (Papineni et al., 2002) as a metric to evaluate our results.

Results I – Using Linguistic Annotation: We trained 5-gram OSM models over different representations and added these to the baseline system. First we evaluated $\mathbf{Model_{and}}$ ($\mathbf{M_{and}}$) which uses a MIRA tuned linear combination of different OSM models versus $\mathbf{Model_{or}}$ ($\mathbf{M_{or}}$) which computes only one OSM model but allows the generator to switch between different OSM models built on various generalized forms. Table 2 shows results from running experiments on German-English pairs. We found that the simpler model $\mathbf{Model_{and}}$ outperforms $\mathbf{Model_{or}}$ in all the experiments. $\mathbf{Model_{or}}$ does not give significant improvements over the baseline system and shows an occasional drop. This result is contrary to the expectation formulated in Section 3.2. We speculate that the optimizer faces problems to train this kind of model, because it cannot take into account that the selected OSM model can change when the weight parameter is modified. It assumes that the feature stays constant. In our formulation the same

derivation can occur with different feature scores in different decoding runs and the optimizer is unable to handle this. Our speculation is based on the observation of λ_ϕ, the weight of feature ϕ which allows the translator to switch between different OSM models. The value of λ_ϕ was not stable across different iterations and different experiments.

$\mathbf{Model_{and}}$ consistently improves the baseline. Adding an OSM model over [pos, morph] (source:pos, target:morph) combination gave the best results, giving a statistically significant gain of +1.06 on the $\mathbf{iwslt_{10}}$ test-set and +0.50 on the $\mathbf{wmt_{13}}$ test-set. Using an OSM model over a [pos,pos] combination also showed improvements, however, not as much as using morphological tags. Morphological tags provide richer information for disambiguation when translating into German. Note that the baseline system also used a target sequence model over morphological tags. Nevertheless using an OSM [pos,morph] model still gives significant improvements which shows that learning a joint model over source and target units is more fruitful than only considering target-side information. Using both the models together gave best results for English-to-German giving a further improvement of +0.29 on the $\mathbf{iwslt_{10}}$ task but no real gain on the $\mathbf{wmt_{13}}$ task. Using morphological tags also produced the best results for the German-to-English pair, giving a statistically significant gain of +0.63 on $\mathbf{iwslt_{10}}$ and +0.35 on $\mathbf{wmt_{13}}$. Using both the models together did not give any further significant improvements. The results changed by +0.10 and -0.09 on the $\mathbf{wmt_{13}}$ and $\mathbf{iwslt_{10}}$ test-sets respectively.

Results-II – Using Och Classes: In our secondary experiments we tested the effect of using Och clusters. The overall goal was to study whether using unsupervised word classes can serve the same purpose as POS tags and to compare the two methods of annotating the data. We obtained Och clusters using the `mkcls` utility (Och, 1999) in GIZA++ (Och and Ney, 2003). This is generally run during the alignment process where data is divided into 50 classes to estimate IBM Model-4. Chahuneau et al. (2013) found mapping data to 600 Och clusters useful, so we used this as well. We additionally experimented with using 200 and 1000 classes. We integrated Och clusters as additional factors[4] when training the phrase-translation models and used a monolingual n-gram model over cluster-ids built on the target-side of the in-domain corpus. Then we added a 5-gram OSM model over cluster-ids. We replace surface forms with their cluster-ids in source and target corpus and convert it to operation sequences, that jointly generate source and target cluster-ids. We only used $\mathbf{Model_{and}}$ for these experiments when adding an OSM model over cluster-ids.

Table 3: Evaluating Phrase-based and N-gram-based Translation Models over Och Clusters

Table 3 shows results from using models based on cluster-ids. The left side of the table evaluate the use of adding a target sequence model over cluster-ids using a factored-based translation model. Results improved consistently in all resource poor languages (pt, pl, tr) giving significant improvements in most of the cases. Mixed results were obtained for the pairs with a reasonable amount of parallel data (fr, es, nl), showing an occasional drop in performance. However, improvements can be found for all the language pairs.

[4]Note that adding cluster-ids in factored models alone has no impact in this scenario, as we are using hard clustering (each word deterministically maps onto a unique cluster-id). In a joint source-target factored model which is what we are using, it will result in an identical distribution as the baseline system.

In the right half of the table we tested whether additionally using an OSM model built over cluster-ids, on top of a phrase-based system that uses cluster-ids as factor and target language model, improves the performance any further. Consistent improvements were seen in Spanish and French. Better systems were produced in the case of French, Spanish, Dutch and Slovenian. No improvements were observed for Turkish and Portuguese whereas the performance got worse in Polish and Russian.

Using 50 classes consistently improved the baseline. Different numbers of clusters provide different levels of abstraction and granularity. We also tried using OSM models over different numbers of clusters simultaneously for English-to-Spanish, English-to-French and English-to-Dutch pairs in an effort to explore whether using different numbers of clusters to classify data provides different information. A slight gain was observed for EN-ES as the best system improved from 34.73 to 34.95. No further gains were observed for the other two pairs.

We also used POS annotation as a factor instead of Och clusters in French, Spanish and Dutch. See the POS columns of Table 3. Using POS as an additional factor, did not improve over the baseline performance. A significant drop was seen in the case of English-to-Spanish. Using a POS-based OSM on top of the POS-based phrase-model did not help either except for Spanish where results got improved by +0.44 over its phrase-based variant that used a POS factor. However, using Och clusters produced better results in all three cases. We speculate that the reason for this result is that Och clusters are more evenly distributed as compared to POS tags where the distribution is biased toward noun class and secondly Och clusters are optimized for language modeling. Also each word is deterministically mapped to a single class but can have multiple POS tags. The latter thus causes a sparser translation model. Finally Table 4 shows the comparison of results on $\mathbf{iwslt_{11-13}}$ by running baseline $\mathbf{B_0}$ and best systems $\mathbf{B_x}$ in Tables 3.

Analysis: In a post-evaluation analysis we confirmed whether using generalized OSM models actually consider a wider contextual window than its lexically driven variant. The graph shown in Figure 2 shows average context size considered (on top of each set of bars) and percentages of 1-5 gram matches by different OSM models. The results show that the probability of an operation is conditioned on less than a trigram in the OSM model over surface forms. In comparison OSM models over POS, morph or cluster-ids consider a window of roughly 4 previous operations thus considering more contextual information. The percentage of 5-gram matches increases from 15.5% to 59.2% using POS-based OSM model and up to 45.6% in morph-based OSM model, the number of unigram matches are decreased from 8.30% to less than 1% in both the models. Similar observation is made for the OSM models over clusters where 5-gram matches improve from 12% to 30% on average, showing the ability of the generalized models to use richer conditioning thus improving the translation quality.

We also analyzed what kind of words are clustered together using Och classes and found that clusters capture both syntax and lexical semantics. Figure 2 (b) shows several useful clusters to exhibit this. We also saw negative examples where words from different classes are clustered together. “Boy”, “Girl” and “Man” for example were clustered into a single class but “Woman” in another. Similarly “Grey” and “Orange” were grouped together with animated objects.

5 Conclusion

In this paper we investigated the usefulness of integrating word classes in phrase-based models and Operation Sequence N-gram models. We explored two models of interpolating generalized OSM models and tested variations on the standard IWSLT and WMT tasks. Our results showed that the simpler more commonly used method of integrating the models in the log-linear framework worked best. We showed that by learning OSM models over generalized POS and morphological representations, we were able to build richer models that outperformed state-of-the-art baseline systems. Statistically significant gains of up to +1.35 and +0.63 were observed in English-to-German and German-to-English tasks. We also made use of Och classes as additional factors in phrase translation and language models. These were tested translating from English to 8 different languages which includes a mixture of morphologically rich (French, Spanish and Russian, Dutch, and Turkish) and sparse data (Portuguese, Polish, Slovenian and Turkish) languages. Our results show that using clusters was helpful in all of the cases. Using the OSM model over word-clusters additionally improved the performance further. Our results show an average improvement of +0.80, ranging from +0.41 to +2.02. Our EN-FR systems were ranked third (on tst2013) and second (on tst2011-tst2012) in IWSLT-13 translation task following EU-Bridge (Freitag et al., 2013) which used our output for system combination. The code to train class-based models has been made available to the research community via the Moses toolkit. See Advanced Features[5] in the Moses Decoder for details.

ysuklee@us.ibm.com

Abstract

Arabic words are often ambiguous between name and non-name interpretations, frequently leading to incorrect name translations. We present a technique to disambiguate and transliterate names even if name interpretations do not exist or have relatively low probability distributions in the parallel training corpus. The key idea comprises named entity classing at the preprocessing step, decoding of a simple confusion network created from the name class label and the input word at the statistical machine translation step, and transliteration of names at the post-processing step. Human evaluations indicate that the proposed technique leads to a statistically significant translation quality improvement of highly ambiguous evaluation data sets without degrading the translation quality of a data set with very few names.

1 Introduction

Arabic person and location names are often ambiguous between name and non-name interpretations, as noted in (Hermjakob et al., 2008; Zayed et al., 2013). (1) and (2) illustrate such ambiguities for Iraqi Arabic, where the ambiguous names and their translations are in bold-face and the Buckwalter transliteration of Arabic is provided in parentheses:[1]

(1) a. انـي ساكـن بـشقـة يـم الـمـدرسة ب**خضراء**
(Any sAkn b$qp ym Almdrsp b**xDrA'**)
I live in an apartment near the school in **Khadraa**

b. مـصبـوغة **خضراء**
(mSbwgp **xDrA'**)
It is painted **green**

(2) a. شيـقـدر يـقـول إلـك **صبـاح**
($yqdr yqwl Alk **SbAH**)
What can **Sabah** tell you?

b. **صبـاح** الـخيـر إنـت أكـيـد نـقـيـب حسام
(**SbAH** Alxyr Ant Akyd nqyb HsAm)
Good **morning** you must be captain Hosam

In this paper, we propose a technique for disambiguating and transliterating Arabic names in an end-to-end statistical machine translation system. The key idea lies in name classing at the preprocessing step, decoding of a simple confusion network created from the class label *$name*, and the input word at the machine translation step, and transliteration of names by a character-based phrase transliteration model at the post-processing step.

While Bertoldi et al. (2007) propose confusion network decoding to handle multiple speech recognition outputs for phrase translation and Dyer et al. (2008) generalize lattice decoding algorithm to

[1]Arabic should be read from right to left, and the Buckwalter transliteration should be read from left to right.

Proceedings of COLING 2014, the 25th International Conference on Computational Linguistics: Technical Papers, pages 433–443, Dublin, Ireland, August 23-29 2014.

tackle word segmentation ambiguities for hierarchical phrase-based translation, the current proposal is the first to deploy a confusion network for name disambiguation and translation. The character-based phrase transliteration model captures the asymmetry between Arabic and English vowel systems by treating English vowels as spontaneous words attachable to the neighboring target phrases for phrase (a sequence of characters) acquisition.

Confusion network decoding enables the system to choose between name and other translations of the source word on the basis of the decoding cost computed from all of the decoder feature functions which incorporate name tag scores into translation model scores. Probabilistic choice between name versus non-name interpretations makes the technique robust to name classing errors, without stipulating the frequency threshold of the names to be transliterated in order to avoid translation quality degradation (Hermjakob et al., 2008; Li et al., 2013). A tight integration of named entity detection and classing into the machine translation system, coupled with a generative approach to name transliteration, enables the system to produce reliable name translations even when name interpretations do not exist or have relatively low distributions in the parallel corpus, distinguishing the current proposal from Hermjakob et al. (2008).

In Section 2, we give an overview of the translation system. In Section 3, we discuss the model training and confusion network decoding. In Section 4, we detail name transliteration model. We present the experimental results in Section 5. We discuss related work in Section 6 and conclude the paper in Section 7.

2 End-to-end Translation System Overview

Arabic name disambiguation and transliteration techniques are incorporated into an end-to-end phrase translation system (Och and Ney, 2002; Koehn et al., 2003; Koehn et al., 2007). Our phrase translation system builds on Tillmann (2003) for translation model training and an in-house implementation of Ney and Tillmann (2003) for beam search phrase decoding.

Iraqi Arabic to English end-to-end phrase translation systems are trained on DARPA TransTac data (Hewavitharana et al., 2013), comprising 766,410 sentence pairs (~6.8 million morpheme tokens in Arabic, ~7.3 million word tokens in English; ~55k unique vocabulary in Arabic and ~35k unique vocabulary in English). The data consist of sub-corpora of several domains including military combined operations, medical, humanitarian aid, disaster relief, etc., and have been created primarily for speech-to-speech translations. The process flow of Arabic to English translation incorporating the proposed technique is shown in Figure 1. The components relevant to name disambiguation and transliteration are in bold face.

Given the input sentence (3), the spelling normalizer normalizes آني to اني.

(3) آني ساكن بشقة يم المدرسة بخضراء
(|ny sAkn b$qp ym Almdrsp bxDrA')

The morpheme segmenter segments a word into morphemes (Lee et al., 2003; Lee, 2004; Habash and Sadat, 2006) as in (4), where # indicates that the morpheme is a prefix.

(4) اني ساكن ب# شقة يم ال# مدرسة ب# خضراء
(Any sAkn b# $qp ym Al# mdrsp b# xDrA')

Part-of-speech tagging is applied to the morphemes, identifying a name with the tag NOUN_PROP. The input word tagged as NOUN_PROP is classified as name, denoted by the label *$name* in (5).

(5) اني ساكن ب# شقة يم ال# مدرسة ب# $name_(خضراء)
(Any sAkn b# $qp ym Al# mdrsp b# $name_(xDrA'))

The token $name_(خضراء) is decomposed into the class label *$name* and the source word بخضراء, creating a simple confusion network for decoding. The beam search phrase decoder computes the translation costs for all possible input phrases including the phrase pair "*$name* | *$name*",[2] using all of

[2] The source phrase *$name* translates to the target phrase *$name*.

the decoder feature functions. Assuming that the translation cost for *$name* being translated into *$name* is the lowest, the decoder produces the translation (6), where the name classed source word خضراء retains its Arabic spelling .

(6) I live in an apartment near the school in خضراء

The Arabic word خضراء in (6) is transliterated into *khadraa* by the NAME/OOV transliteration module. And the system produces the final translation output (7).

(7) I live in an apartment near the school in khadraa

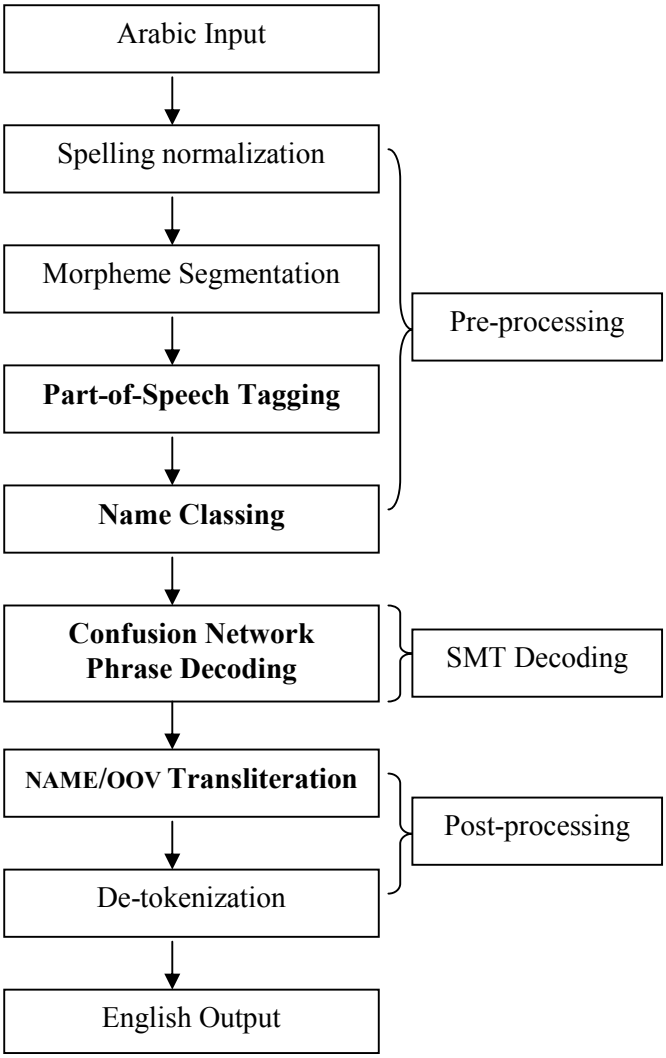

Figure 1. Process Flow of Arabic to English Phrase Translation Decoding

We use an in-house implementation of the maximum entropy part-of-speech tagger described in Adwait (1996) for name classing. The part-of-speech tagger is trained on the combination of LDC-released Arabic Treebank data containing about 3 million morpheme tokens from MSA (modern standard Arabic) and in-house annotated TransTac Iraqi Arabic data containing about 63k morpheme tokens.

F-score of the tagger on proper noun tags, NOUN_PROP, is about 93% on 2,044 MSA name tokens derived from Arabic Treebank: Part 3 v 3.2 (LDC2010T08), and about 81.4% on 2,631 Iraqi Arabic name tokens derived from the DARPA TransTac corpus.

3 Model Training and Confusion Network Decoding

We train translation and language models with name classing to obtain proper translation and language model probabilities of the class label *$name*. We extend the baseline phrase beam search decoder to handle a relatively simple confusion network (CN hereafter) and incorporate the name part-of-speech tagging scores into the decoder feature functions.

3.1 Translation Model

For any name classed input word, *$name_(orig)* in (5), we would like to have the name translation, *$name* → *$name*, always available in addition to other translations of the input word obtainable from the parallel training corpus.

In order to estimate *$name* distributions without obfuscating the distributions of other training vocabulary, we apply name classing only to words that occur less than 3 times in the training corpus and part-of-speech tagged with NOUN_PROP. The reasons are three-fold: 1) we need to keep all non-name translations of the training vocabulary, 2) typical low frequency words include names and typos, 3) even with *$name* classing on low frequency words only, the overall *$name* count is high enough for a robust probability estimation.

After name classing of words occurring less than 3 times, *$name* occurs 6,944 times (122th most frequent token) in Arabic and 9,707 times (108th most frequent token) in English. We train both phrase translation and distortion models on the name classed parallel corpus. Note that the frequency restriction applies only to model training. During decoding, any word labeled with *$name* may be name transliterated regardless of its frequency in the training corpus, differentiating the current technique from (Li et al., 2013).

3.2 Language Models

To properly capture the name and non-name ambiguities, we interpolate two types language models: 1) 5-gram language model trained on the English side of the parallel corpus without name classing (LM1), 2) 5-gram language model trained on the English side of the parallel corpus and additional monolingual corpora with name classing (LM2).

Each language model is smoothed with modified Kneser-Ney (Chen and Goodman, 1998). The two sets of language models are interpolated, as in (8), where α is set to 0.1. We find the optimal interpolation weight on the basis of BLEU scores of the development test data set containing about 30k word tokens in Arabic and about 43k word tokens in English.

(8) $\alpha \cdot LM1 + (1-\alpha) \cdot LM2$

3.3 Confusion Network Decoding

The confusion network containing the class label *$name* and the source word is handled by an extension of the baseline phrase decoder. The baseline decoder utilizes 11 feature functions including those in (9)[3] through (14), where $\bar{f}$ denotes the source phrase and $\bar{e}$, the target phrase, and ***s***, the source sentence, ***t***, the target sentence and *a*, a word alignment. We use the in-house implementation of the simplex algorithm in Zhao et al. (2009) for decoder parameter optimization.

(9) Direct phrase translation model for $pr(\bar{e} \mid \bar{f})$
(10) Distortion models(Al-Onaizan and Papineni, 2006)
(11) Mixture language models

[3] We do not use $pr(\bar{f} \mid \bar{e})$

(12) Lexical weights $p_w(\bar{f}|\bar{e},a)$ & $p_w(\bar{e}|\bar{f},a)$, cf. (Koehn et al., 2003)
(13) Lexical weights p_w (**t**|**s**,a) & p_w (**s**|**t**,a)
(14) Word and phrase penalties (Zens and Ney, 2004)

Lexical weight $p_w(\bar{e}|\bar{f},a)$ in (12) is computed according to (15), where $j = 1, \ldots, n$ source word positions and $i = 1,\ldots, m$ target word positions within a phrase, N = source phrase length, $w(e|f)$ = the lexical probability distribution:[4]

(15) $$p_w(\bar{e}|\bar{f},a) = (\prod_{j=1}^{n} w_{\max(j,i)\in a}(e_i|f_j)) / N$$

Lexical weight $p_w(\mathbf{t}|\mathbf{s},a)$ in (13) is computed according to (16), where K = number of phrases in the input sentence, $k = k^{th}$ phrase, and $pr_{w\_k}(\bar{e}|\bar{f},a) = p_{w\_k}(\bar{e}|\bar{f},a)$ without normalization by the source phrase length N.

(16) $$p_w(\mathbf{t}|\mathbf{s},a) = \prod_{k=1}^{K} pr_{w\_k}(\bar{e}|\bar{f},a)$$

We augment the baseline decoder in two ways: First, we incorporate the maximum entropy part-of-speech tagging scores of names into the translation scores in (9), (12) and (13). We simply add the name part-of-speech tag cost, i.e. –log probability, to the translation model costs. Second, the decoder can activate more than one edge from one source word position to another, as shown in Figure 2.[5] The name classed input is split into two tokens *$name* and *xDrA'*, leading to two separate decoding paths. The choice between the two paths depends on the overall decoding cost of each path, computed from all of the decoder feature functions.

Since the decoding path to *$name* is always available when the input word is classed as *$name* at the pre-processing step, the technique can discover the name interpretation of an input word even if the name interpretation is absent in the parallel training corpus. Even when the input word occurs as a name in the training corpus but has a lower name translation probability than non-name translations in the baseline phrase table, it can be correctly translated into a name as long as the word is labeled as *$name* and the decoder feature functions support the *$name* path in the given context. When a non-name token is mistakenly labeled as *$name*, the confusion network decoder can recover from the mistake if the non-name path receives a lower decoding cost than the *$name* path.[6] If the input token is name classed and the correct name translation also exists in the baseline phrase table with a high probability, either path will lead to the correct translation, and the decoder chooses the path with the lower translation cost.

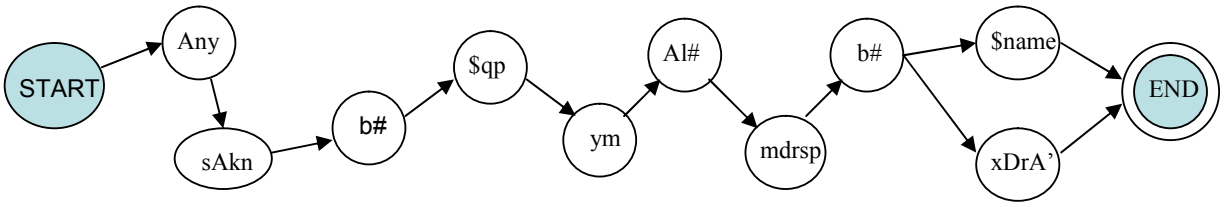

Figure 2. Confusion Network Decoding Paths for Name Classed Input

[4] Estimated in the manner described in Koehn et al. (2003).
[5] Arabic is represented by Buckwalter transliteration scheme.
[6] The decoding scores are computed as cost on the basis of –log likelihood of various component models. And therefore, a smaller decoding cost indicates a higher translation quality.

4 Character-Based Phrase Transliteration Models

All instances of un-translated input words, which include names and OOVs, are transliterated in the post-processing step. Character-based phrase transliteration models are trained on 9,737 unique name pairs. 965 name pairs are obtained from a name lexicon and the remaining 8,772 name pairs are automatically derived from the parallel training corpus as follows: 1) Take each side of the parallel corpus, i.e. Iraqi Arabic or English. 2) Mark names manually or automatically. 3) Apply word alignment to the name-marked parallel corpus in both directions. 4) Extract name pairs aligned in both directions. For name marking, we used the manual mark-up that was provided in the original data.

5-gram character language models are trained on about 120k entries of names in English. In addition to about 9.7k names from the English side of the parallel names, about 110k entries are collected from wiki pages, English Gigaword 5th Edition (LDC2011T07), and various name lexicons.

4.1 Phrase Extraction with English Vowels as Spontaneous Words

Short vowels are optional in written Arabic, whereas all vowels have to be obligatorily specified in English for a word to be valid (Stalls and Knight, 1998; Al-Onaizan and Knight, 2002b). We model the asymmetrical nature of vowels between the two languages by treating all instances of unaligned English vowels – *a, e, i, o, u* – as spontaneous words which can be attached to the left or to the right of an aligned English character for phrase extractions. An example GIZA++ (Och and Ney, 2003) character alignment is shown in Figure 3. Arabic name is written left to right to illustrate the monotonicity of the alignments.

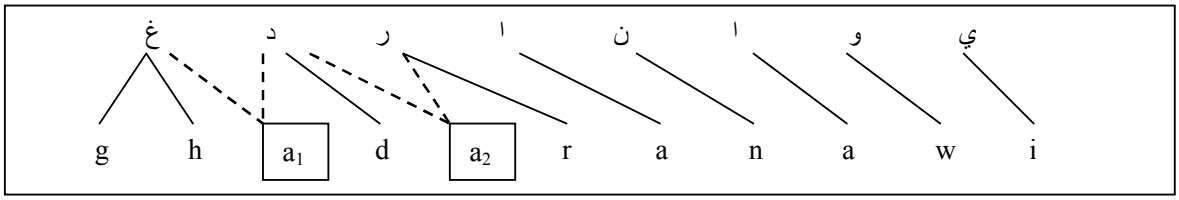

Figure 3. Automatic Character Alignment between Arabic and English names

In Figure 3, solid lines indicate the automatic machine alignments. English vowels in rectangular boxes indicate null alignments by the aligner. The dotted lines indicate the potential attachment sites of the unaligned vowels for phrase extractions. The first instance of unaligned *a* (denoted by a_1) may be a part of the phrases containing the preceding consonant sequence *g h*, or the following consonant *d*. The second instance of unaligned *a* (denoted by a_2) may be a part of the phrases containing the preceding consonant *d* or the following consonant *r*.[7]

4.2 Experiments

We use exact match accuracy[8] to evaluate transliteration qualities. Systems are tested on 500 unique name pairs including 52 names unseen in the training corpus. Experimental results are shown in Table 1.[9] Note that using English vowels as spontaneous words dramatically improves the accuracy from 21.6% to 89.2%.

Decoding is carried out by the baseline phrase decoder discussed in Section 3.3, using the same decoder feature functions except for the distortion models. Using only phrase translation and language model probabilities for decoding results in 74.4% accuracy on SYSTEM4, much lower than 90% accuracy with all decoder feature functions. The same language model is used for all experiments. For the end-to-

[7] Attachment of unaligned English vowels takes place after phrase extractions and should be distinguished from a heuristic alignment of unaligned English vowels to Arabic characters before phrase extractions.
[8] A transliteration is correct if and only if it exactly matches the truth, i.e. gold standard.
[9] GIZA++ word aligner is trained with 5 iterations of IBM MODEL 1, 5 iterations of HMM, 5 iterations of IBM MODEL 3 and 5 iterations of IBM MODEL 4. HMM word aligner (Vogel et al., 1996) is trained with 15 iterations of IBM MODEL 1 and 6 iterations of HMM.

end translation quality evaluations in Section 5, we use SYSTEM4. Exact match accuracy of SYSTEM4 on the 52 unseen name pairs is 46%.

Systems	Character Alignments	Symmetrization[10]	Target spontaneous words	Accuracy
SYSTEM1	GIZA++	Union	None	21.6%
SYSTEM2	HMM	Refined	None	86.8%
SYSTEM3	GIZA++	Union	All English vowels: *a, e, i, o, u*	89.2%
SYSTEM4	GIZA++ & HMM	Union	All English vowels: *a, e, i, o, u*	90.0%

Table 1. Name transliteration accuracy on 500 names according to various phrase extraction techniques

5 End-to-end Translation System Experimental Results

End-to-end translation quality experiments are carried out on 3 evaluation data sets shown in Table 2. TransTac.eval has a low out-of-vocabulary (OOV) and a low name ratios, and has been used as the test data for system development among DARPA BOLT–C[11] program partners. TransTac.oov has a high OOV and a high name ratios, and has been created in-house for OOV detection system developement. TransTac.name has a low OOV and a high name ratios, and was used for the TransTac 2008 name translation evaluations.

Evaluation Data Sets	TransTac.eval	TransTac.oov	TransTac.name
sentence count	3,138	344	79
token count	36,895	3,053	514
OOV ratio	0.4%	4.7%	0.6%
name ratio	~0.5%	~11.3%	~15.4%

Table 2. Translation Quality Evaluation Data Statistics

5.1 Systems, Metrics and Results

End-to-end translation system evaluation results are shown in Table 3. Bold-faced and italicized scores indicate that the system's translation quality is statistically significantly better than all other systems with over 95% confidence, i.e. two-tailed P value < 0.05 in paired t-tests.

Metrics	EvalSets / Systems	TransTac.eval	TransTac.oov	TransTac.name	TransTac.name_spnorm
Uncased BLEU (4-gram & 1 ref)	baseline	33.35	30.72	35.03	37.39
	OOVTranslit	33.35	31.93	35.03	37.54
	name_t	32.94	31.81	32.97	40.15
	CN	33.35	32.60	32.19	40.97
HUMAN (6-point scale)	baseline	3.16	1.45	3.19	3.19
	OOVTranslit	3.22	2.88	3.36	3.36
	name_t	2.16	2.79	3.58	3.58
	CN	3.20	***3.09***	***3.86***	***3.86***

Table 3. Translation Quality Evaluation Result

The system *baseline* is trained without name classing and decoded by the baseline decoder without name classing. The system OOVTranslit is trained and decoded the same way as the baseline except that all instances of un-translated OOVs are transliterated at the post-processing step. The system *name_t* is

[10] Bi-directional word alignment symmetrization methods, as defined in Och and Ney (2003), include union, intersection and refined.

[11] BOLT stands for Broad Operational Language Translation and BOLT-C focuses on speech-to-speech translation with dialog management.

trained without name classing and decoded by the baseline decoder with name classing.[12] The system *CN* is trained with name classing and decoded by the CN decoder with name classing.[13]

We evaluate the systems, using automatic BLEU (Papineni et al., 2002), and 6-point scale human evaluations. Lowercased BLEU scores are computed with 1 reference translation up to 4-grams. Scoring criteria for human evaluations are as follows. **0**: exceptionally poor; **1**: poor; **2**: not good enough; **3**: good enough; **4**: very good; **5**: excellent. Human evaluations are conducted on a subset of the automatic evaluation data containing names.[14] We exclude the input sentences for which all systems produce the same translation output. This leaves 201 sentences from TransTac.eval, 197 sentences from TransTac.oov, 64 sentences from TransTac.name.

5.2 Result Analysis

We observe that human evaluation scores are relatively consistent with BLEU scores on two data sets, TransTac.eval and TransTac.oov. TransTac.eval contains very few names. Therefore, incorrect name classing at the pre-processing step hurts the translation quality for the system *name_t*. The CN decoder can improve the translation quality by recovering from a name classing error by choosing the non-name path. Transliteration of OOVs (OOVTranslit) can improve the translation quality if any of the OOVs are names. Human evaluations capture the behaviors of the CN decoder and OOVTranslit by giving a slightly higher (statistically insignificant) score to OOVTranslit, 3.22, and the CN decoder, 3.20, than to the baseline, 3.16. All three systems, baseline, OOVTranslit and CN, however, received the same BLEU scores, 33.35. This seems to reflect the fact humans can easily capture the spelling variation of names whereas the automatic evaluation with 1 reference cannot.

Transtac.oov has a high OOV and a high name ratios and all OOVs are names. Therefore, name classing improves the translation quality as long as the correctly classed names out-number the incorrectly classed ones, explaining the higher translation quality of *name_t* than the baseline. OOVTranslit improves the translation quality over the baseline because all OOVs are names. The CN decoder out-performs all three other systems by correctly disambiguating non-OOV names and transliterating name OOVs. BLEU scores and human evaluation scores show the same pattern.

For TransTac.name with a high name and a low OOV ratios, however, human evaluation and BLEU scores show the opposite pattern, although none of the BLEU scores are statistically significantly better than others (note the small evaluation data size of 79 segments and 514 tokens). Since most names in this data set are known to the translation vocabulary and is highly ambiguous, we expect the CN decoder to out-perform all other systems. This expectation is borne out in the human evaluations, but not in BLEU scores. Our analysis indicates that the apparent inconsistency between BLEU and human evaluation scores is primarily due to spelling variations of a name, which are not captured by BLEU with just one reference, cf. (Li et al., 2013). Out of the human evaluated 64 names in TransTac.name, the baseline system produced the same spelling as the reference 34 times (53.13%), which contrasts with 28 times (43.75%) by the CN decoder. Overall, the CN decoder produced 62 correct name translations, about 20% more than 49 correct translations by the baseline system. Table 4 shows the names for which the reference spelling agrees with the baseline system, but disagrees with the CN decoding followed by transliteration.

Reference	CN output	Reference	CN output	Reference	CN output
tikrit	*tikreet*	*mariam*	*maryam*	*mousa*	*moussa*
ajlan	*al-`ajlan*	*jaafar*	*gaafar*	*basra*	*al-basra*

Table 4. Name Spelling Variations

[12] We ensure that any name classed input word *$name* is translated into *$name* by adding *$name* to the translation vocabulary, and the input word for *$name* is transliterated in the post-processing stage.

[13] We also evaluated another system, called name_st, which is trained with name classing and decoded with name classing using the baseline decoder. BLEU scores on TransTac.eval and TransTac.oov indicated that model training and decoding with name classing (name_st) is only slightly better than model training without name classing and decoding with name classing (name_t).

[14] For TransTac.eval data, we selected the sentences containing words tagged as name, i.e. NOUN_PROP, by the automatic part-of-speech tagger. The name ratio around 0.5% in Table 2 is computed on the basis of human annotations on the reference translation.

To verify that the inconsistency between BLEU and human evaluation scores is due to name spelling variations which humans capture but automatic metrics does not, we recomputed BLEU scores after normalizing spellings of the system outputs to be consistent with the reference translation spelling. The recomputed BLEU scores are denoted by TransTac.name_spnorm in Table 3, which shows that the recomputed BLEU scores are indeed consistent with the human evaluation scores.[15] Also note that the translation quality improvement by transliterating OOV names is well captured in human evaluation scores, 3.19 in the baseline vs. 3.36 in the system OOVTranslit, but not in BLEU scores, 35.03 in both baseline and OOV-Translit.

We point out that the same name is often spelled differently in various parts of our training corpus and even in the same reference translation, e.g. *al-aswad* vs. *aswad*, *jassim* vs. *jasim*, *risha* vs. *rasha*, *mahadi* vs. *mehdi* vs. *mahdi*, etc., as had been noted in Al-Onaizan and Knight (2002b), Huang et al. (2008).

6 Related Work

Al-Onaizan and Knight (2002a) propose an Arabic named entity translation algorithm that performs at near human translation accuracy when evaluated as an independent name translation module. Hassan et al. (2007) propose to improve named entity translation by exploiting comparable and parallel corpora. Hermjakob et al. (2008) present a method to learn when to transliterate Arabic names. They search for name translation candidates in large lists of English words/phrases. Therefore, they cannot accurately translate a name if the correct English name is missing in the word lists. Their restriction of named entity transliteration to rare words cannot capture name interpretations of frequent words, e.g. صباح (Sabah/morning), if the name interpretations are absent in the parallel corpus. Li et al. (2013) propose a Name-aware machine translation approach which tightly integrates high accuracy name processing into a Chinese-English MT model. Similar to Hermjakob et al. (2008), they restrict the use of name translation to names occurring less than 5 times in the training data. They train the translation model by merging the name-replaced parallel data with the original parallel data to prevent the quality degradation of high frequency names.

Onish et al. (2010) present a lattice decoding for paraphrase translations, which can handle OOV phrases as long as their paraphrases are found in the training corpus. They build the paraphrase lattices of the input sentence, which are given to the Moses lattice decoder. They deploy the source-side language model of paraphrases as a decoding feature.

Stalls and Knight (1998) propose a back-transliteration technique to recover original spelling in Roman script given a foreign name or a loanword in Arabic text, which consist of three models: a model to convert an Arabic string to English phone sequences, a model to convert English phone sequences to English phrases, a language model to rescore the English phrases. They use weighted finite state transducers for decoding. Al-Onaizan and Knight (2002b) propose a spelling-based source-channel model for transliteration (Brown et al., 1993), which directly maps English letter sequences into Arabic letter sequences, and therefore overcomes Stalls and Knight's major drawback that needs a manual lexicon of English pronunciations. Sherif and Kondrak (2007) propose a substring-based transliteration technique inspired by phrase based translation models and show that substring (i.e. phrase) models out-perform letter (i.e. word) models of Al-Onaizan and Knight (2002b). Their approach is most similar to the current approach in that we both adopt phrase-based translation models for transliteration. The current approach and Sherif and Kondrak (2007), however, diverge in most technical details including word alignments, phrase extraction heuristics and decoding, although it is not clear how they estimate transliteration probabilities. Crucially, we use the same set of decoder feature functions (excluding distortion models) as the end-to-end phrase translation system including lexical weights for phrases and a sentence in both directions and word/phrase penalties, whereas Sherif and Kondrak (2007) use only transliteration and language models for substring

[15] The spellings of the CN decoder output are normalized as follows: 38 instances of names, 2 instances of *'s* to *is*, 2 instances of *the city of arar* to *arar city* and 1 instance of *talk with* to *speak to*. Only name spelling normalizations were necessary for other system outputs.

transducer. We noted in Section 4 that inclusion of all decoder feature functions improves the accuracy by 15.6% absolute, compared with using just translation and language models for decoding.

7 Conclusion

We proposed a confusion network decoding to disambiguate Arabic names between name and non-name interpretations of an input word and character-based phrase transliteration models for NAME/OOV transliteration.

Name classing at the pre-processing step, coupled with name transliteration at the post-processing step, enables the system to accurately translate OOV names. Robust TM/LM probability estimations of names on the class label *$name* enable the system to correctly translate names even when the name interpretation of an in-vocabulary word is absent from the training data. Confusion network decoding can recover from name classing errors by choosing an alternative decoding path supported by decoder feature functions, obviating the need for stipulating a count threshold of an input token for name translation. The character-based phrase transliteration system achieves 90% exact match accuracy on 500 unique name pairs, utilizing all of the phrase decoder feature functions except for distortion models. We capture the asymmetries of English and Arabic vowel systems by treating any instance of an unaligned English vowel as a spontaneous word that can be attached to the preceding or following target phrases for phrase acquisition.

Although we proposed the confusion network decoding and character-based phrase transliteration models in the contexts of Arabic name disambiguation and transliteration tasks, the techniques are language independent and may be applied to any languages.

Abstract

In this study we compare two machine translation devices on twelve machine translation medical-domain specific tasks, and two transliteration tasks, altogether involving twelve language pairs, including English-Chinese and English-Russian, which do not share the same scripts. We implemented an analogical device and compared its performance to the state-of-the-art phrase-based machine translation engine Moses. On most translation tasks, the analogical device outperforms the phrase-based one, and several combinations of both systems significantly outperform each system individually. For the sake of reproducibility, we share the datasets used in this study.

1 Introduction

A *proportional analogy* is a relation between 4 objets, x, y, z and t, noted $[x : y :: z : t]$, which reads x is to y as z is to t. A *formal proportional analogy*, hereafter analogy, is a proportional analogy which involves a relationship at the graphemic level, such as [*atomkraftwerken* : *atomkriegen* :: *kraftwerks* : *kriegs*] in German. *Analogical learning* is a holistic learning paradigm (sketched in Section 2) which relies on proportional analogies for generalizing a training set.

Lepage and Denoual (2005b) pioneered the application of analogical learning to Machine Translation (MT). Different variants of their system have been tested within the IWSLT evaluation campaigns (Lepage and Denoual, 2005a; Lepage and Lardilleux, 2008; Lepage et al., 2008; Lepage et al., 2009). Since then, a number of studies have been investigating analogical learning for performing more specific machine translation tasks. Langlais et al. (2009) applied it to translating medical terms, and Langlais and Patry (2007) investigated the more specific task of translating unknown words, a problem simultaneously investigated in (Denoual, 2007). Recently, Langlais (2013) applied formal analogies to transliterate English proper names into Chinese.

Those works suggest, at least on the tasks investigated, that analogical translation typically shows better precision than phrase-based Statistical MT (SMT), but at a much lower recall. Still, the analogical devices tested in these works vary from task to task, making it difficult to draw a clear picture of the strengths and weaknesses of analogy-based translation. In this study, we perform a systematic comparison of an analogical and a phrase-based MT engine for the translation of fourteen different testbeds. We also improve the state-of-the-art of analogical learning by revisiting the aggregation step of the process. In particular, we observe that ranking analogical candidates according to random forests improves the performance of the analogical device, over training a classifier, as proposed for instance in (Langlais, 2013). On each task we tackle, we report improvements to the state-of-the-art in analogical learning.

In the remainder of this paper, we describe the principle of analogical learning and sketch our analogical device in Section 2. We describe our experimental protocol in Section 3. We analyze the performance of several variants of our analogical device in Section 4 and compare it to a state-of-the-art phrase-base SMT engine. We conclude this work and discuss future avenues in Section 5.

Proceedings of COLING 2014, the 25th International Conference on Computational Linguistics: Technical Papers, pages 444–454, Dublin, Ireland, August 23-29 2014.

2 ANALOGICAL LEARNING

2.1 Principle

We note $[x : y :: z : ?]$ an *analogical equation*. It can have 0 or several solutions, depending on the definition of analogy being considered. We are given a training set (or memory) of pairs of *input* and *output* forms that are in (translation) relation: $L = \{\langle x_1, y_1\rangle, \ldots, \langle x_l, y_l\rangle\}$, and we note $\tau(x)$ the set of output forms to which the input form x corresponds in the training set: $\tau(x) = \{y : \langle x, y\rangle \in L\}$.

Given an input form u unseen at training time, analogical learning generates its associated output form (in our case its translation), by accomplishing 3 steps. First, analogies in the input space $[x : y :: z : u]$ are searched for. Second, output equations $[x' : y' :: z' : ?]$ are solved for all x', y', and z' in $\tau(x)$, $\tau(y)$, and $\tau(z)$ respectively. By applying those two steps (that we call the *generator*), a number of candidate solutions are typically produced. They need to be aggregated. This is the purpose of the third step, or *selector*. Note that for the mapping to happen between input and output strings, there is no attempt to align subsequences of forms in both spaces, as it is typically done in statistical MT. There is actually no alignment whatsoever: analogies are treated in each space separately, and the mapping is the result of the inductive bias which promotes that an analogy in the input space corresponds to an analogy in the output space.

Figure 1 depicts the overall process for the translation of the English term *proton pump inhibitors* into Spanish, given a memory of pairs such as $\langle$*blood coagulation factors*, *factores de coagulación sanguínea*$\rangle$ and $\langle$*proton pumps*, *bombas de protones*$\rangle$. 6 input analogies are being identified (2 are reported), therefore 6 (output) equations are being solved, yielding a total of 5268 different forms that are sorted in decreasing order of frequency with which they have been generated. This is the output of the generator. The reference translation (in bold) ranks 11$^{\text{th}}$ according to frequency. The aggregator finally selects two candidates from this list. The best ranked one according to the aggregator is the correct translation.

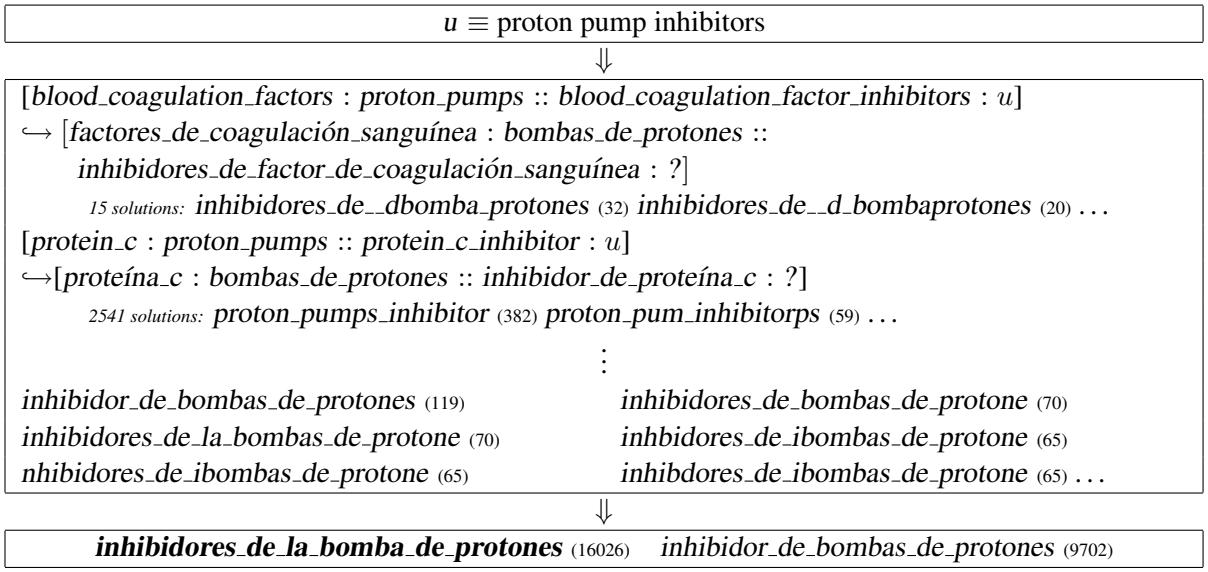

Figure 1: Excerpt of the translation session of the English term *proton pump inhibitors* into Spanish. The reference translation is in bold. Spaces are underlined for readability.

2.2 Implementation

Implementing such a learning procedure requires the definition of a formal analogy, the implementation of an analogical solver, as well as a way to handle computational issues: the identification of input analogies is an operation a priori cubic in the size of the input space. We describe each component of our implementation below. In practice, and for the tasks we consider in this work, our implementation allows the translation of an input form within a few seconds on average.

We would like to point out that analogical learning often suffers from a silence issue, that is, there are (input) forms for which no solution is provided. This may happen because no input analogy is identified, or because none yields an output equation with solutions. In contrast, there are many forms for which several candidate translations will be provided, thus the need for a good aggregator (see next section). This happens because an equation typically allows many solutions, and because many input analogies might be identified for solving a given input form.

Formal Analogy We used the definition of formal analogy proposed by Yvon et al. (2004), where an analogy is defined in terms of *d-factorizations*. A d-factorization of a string x over an alphabet Σ, noted f_X, is a sequence of d *factors* $f_X \equiv (f_X^1, \ldots, f_X^d)$, where $f_X^i \in \Sigma^*$ for all i, and such that $f_X^1 \odot f_X^2 \odot f_X^d \equiv x$; where $\odot$ denotes the concatenation operator.

Definition 1. *$\forall\, x, y, z$ and $t \in \Sigma^\star$, [x : y :: z : t] **iff** there exists a 4-uple of d-factorizations (f_X, f_Y, f_Z, f_t) of x, y, z and t respectively, such that $\forall i \in [1, d]$, $(f_Y^i, f_Z^i) \in \left\{(f_X^i, f_t^i), (f_t^i, f_X^i)\right\}$. The smallest d for which this holds is called the degree of the analogy.*

For instance, [*protein_c* : *proton_pumps* :: *protein_c_inhibitor* : *proton_pump_inhibitors*] because of the 4-uple of 3-factorizations shown in Fig. 2, whose factors are aligned column-wise for clarity, and where spaces (underlined) are treated as regular characters. There is no 4-uple of d-factorizations, with d smaller than 3. Therefore, the degree of this analogy is 3. Note that there are many 4-uple of d-factorizations for d greater than 3.

Figure 2: A 4-uple of 3-factorizations demonstrating that [*protein_c* : *proton_pumps* :: *protein_c_inhibitor* : *proton_pump_inhibitors*].

f_X	$\equiv$	(	*protein_c*	ϵ	ϵ)
f_Y	$\equiv$	(	*proton_pump*	ϵ	*s*)
f_Z	$\equiv$	(	*protein_c*	*_inhibitor*	ϵ)
f_t	$\equiv$	(	*proton pump*	*_inhibitor*	*s*)

Analogical Solver With the aforementioned definition, it has been showed by Yvon et al. (2004) that the set of solutions to an analogical equation is a rational language, therefore we can build a finite-state machine for encoding those solutions. In practice however, the automaton is non-deterministic, and in the worst case, enumerating the solutions can be exponential in the length of the forms involved in the equation. We adopted the solution proposed in (Langlais et al., 2009) which consists in sampling this automaton without building it. The more we sample this automaton, the more solutions we produce. It is sufficient to note that typically, a solver produces several solutions to an equation, many being simply spurious, which means that, while they obey the definition of formal analogy, they are not valid forms.

Figure 3: Three most frequent solutions to the equation [*protein_c* : *proton_pumps* :: *protein_c_inhibitor* : *?*] along with their frequency, as a function of the number of samples considered 10^n. nb stands for the total number of solutions produced.

n	nb	solutions		
1	43	*p_inhibitorroton_pumps* (2)	*proton_p_inhiubitomrps* (2)	*prot_ion_pnhibitumorps* (2)
2	320	*proton_pumps_inhibitor* (8)	*proton_pum_inhibitposr* (4)	*prot_inhibion_pumtorps* (4)
3	2 597	*proton_pumps_inhibitor* (121)	*roton_pumpps_inhibitor* (19)	*proton_pump_inhsibitor* (19)
4	16 006	*proton_pumps_inhibitor* (764)	*proton_pump_inhibsitor* (103)	*proton_pump_isnhibitor* (95)
5	72 610	*proton_pumps_inhibitor* (3706)	*proton_pump_sinhibitor* (501)	*proton_pump_inhibitosr* (481)

To illustrate this, Figure 3 reports the solutions produced to the equation [*protein_c* : *proton_pumps* :: *protein_c_inhibitor* : *?*] by our implementation of the solver, as a function of the number of samplings done in the automaton. Clearly, many solutions are not valid forms in English, although they define

proper solutions according to the aforementioned definition. Note that with enough sampling, the solution *proton_pumps_inhibitor* (involving a degree-2 analogy) is the most frequently generated one, while the solution *proton_pump_inhibitors* involved in the analogy illustrated in Figure 2 is generated less often (typically at the 10^{th} position).

Searching input analogies Identifying input analogies for an input term u is an operation a priori cubic in the size of the input space. Langlais and Yvon (2008) developed an algorithm for speeding up the search procedure that we adopted in this work. The main idea is to exploit a property of formal analogies (Lepage and Shin-ichi, 1996):

$$[x : y :: z : u] \Rightarrow |x|_c + |u|_c = |y|_c + |z|_c \quad \forall c \in \mathcal{A} \tag{1}$$

where $\mathcal{A}$ is the (input) alphabet, and $|x|_c$ stands for the number of occurrences of symbol c in x.

The strategy consists in first selecting a form x in the input space. This enforces a set of necessary constraints on the counts of symbols that any two forms y and z must satisfy for $[x : y :: z : u]$ to hold. By considering all forms x in turn, we collect a set of candidate triplets for u. We then have to find out which of these triplets form an analogy with u. Formally, we search for:

$$\begin{aligned}\{\langle x, y, z\rangle : \quad & x \in \mathcal{I}, \\ & \langle x, y\rangle : y \in \mathcal{I} \text{ and } |x|_c + |u|_c = |y|_c + |z|_c \quad \forall c \in \mathcal{A}, \\ & [x : y :: z : u]\}\end{aligned} \tag{2}$$

where $\mathcal{I} \equiv \{x_1, \ldots, x_l\}$. This strategy relies on the fact that one can efficiently identify the pairs $\langle y, z\rangle$ that satisfy a set of constraints on symbol counts. See (Langlais et al., 2009) for the *tree-count* solution we implemented in this work.

3 Experimental Protocol

3.1 Tasks

We use two families of tasks in this study. The first one concerns the translation of medical terms, the second one is about transliterating proper names. The main characteristics of the datasets we consider are reported in Table 1. If both tasks are of importance in practice, we admit that they are rather specific. The reason for this is that analogical learning is quite computationally intensive. Therefore, tackling broader tasks, such as those typically considered in MT evaluation campaigns is currently too challenging.

Medical term translation We use the datasets described in (Langlais et al., 2009). Part of the data comes from the Medical Subject Headings (MESH) thesaurus. This thesaurus is used by the US National Library of Medicine to index the biomedical scientific literature in the MEDLINE database. The MESH material concerns five language pairs with three relatively close European languages (English-French, English-Spanish and English-Swedish), a more distant one (English-Finnish) and one pair involving different scripts (English-Russian). The material was split in three randomly selected parts (TRAIN, DEV and TEST), so that the development and test material contain exactly 1000 terms each. Roughly a third of the examples are pairs of single-word terms.

For the Spanish-English language pair, a set of medical terms from the Medical Drug Regulatory Activities thesaurus (MEDDRA) is also available. This dataset contains roughly three times more terms than the Spanish-English material from the MESH dataset. Forms in the dataset are typically longer and the percentage of examples that are pairs of single-word terms is only 5.6%. This set is used for studying how the silence rate of analogical learning evolves with the size of the training set.

We are pleased to share those datasets. They can be downloaded at `http://rali.iro.umontreal.ca/rali/?q=en/12-medical-translation-tasks`.

Proper name transliteration This task is part of the NEWS evaluation campaign conducted in 2009 (Li et al., 2009). The organizers of this evaluation campaign kindly provided us with the Chinese-English dataset. This task has been investigated recently by Langlais (2013). This allows a direct comparison of our analogical system. We also consider the reverse transliteration direction, *i.e.*, the transliteration of

Chinese proper names into English. This was done by simply switching the source and target languages in the NEWS dataset.

	TRAIN		TEST	DEV	
	nb	$avg.$	nb	oov%	oov%	examples:

Table 1: Main characteristics of our datasets. nb indicates the number of pairs of terms in a bitext, $avg.$ indicates the average length (in symbols) of the foreign forms; oov% indicates the percentage of out-of-vocabulary types (space-separated types of TEST or DEV unseen in TRAIN).

3.2 Evaluation Metrics

All the tasks we consider are characterized by a rather high out-of-vocabulary rate (see Table 1). Thus, word-based translation is not an adequate solution. Therefore, we devised engines which translate sequences of symbols (characters), without taking into account the notion of word.[1] In particular, spaces in forms were considered as any ordinary symbol. Measuring how close a candidate translation is to a reference is of little interest here, since typically, a medical term only has one reference translation that we seek to discover. Therefore, rewarding partially correct translations (like a metric such as BLEU (Papineni et al., 2002) does) is not especially useful. Therefore we report the *accuracy* of the first candidate proposed by a translation device for each source term. Accuracy is measured as the percentage of test forms for which the first candidate is the sanctioned one. So in the example of Figure 1, the aggregator illustrated in the bottom frame would get one point since the first translation produced is the sanctioned one, while an aggregator that would pick the most frequently generated candidate would receive no point. Accuracy is the main metric of the NEWS evaluation campaign, and we used the NEWS 2009 official evaluation script[2] in order to compute it. Also of interest for the analogical devices, is the *silence rate*, computed as the percentage of input forms for which no output is generated. As we will see, on some tasks, this ratio can be rather high, a clear limitation of the analogical approach we discuss in Section 5.

3.3 Systems

3.3.1 Reference System

We compare a number of analogical devices to the state-of-the-art statistical translation engine Moses (Koehn et al., 2007). In a nutshell, SMT seeks to find the optimal translation $\hat{e}$ of a sentence f using to a log-linear combination of models (h_i), including a language model $p(e)$ which scores how likely a hypothesis is in the target language, and a translation model $p(f|e)$ which predicts the likelihood that two sentences are translations:

$$\hat{e} = \underset{e}{\operatorname{argmax}}\, p(f|e)p(e) \approx \underset{e}{\operatorname{argmax}} \exp\left(\sum_i \lambda_i h_i(e, f)\right) \quad (3)$$

[1] We tried it, but the results are very low.

[2] http://translit.i2r.a-star.edu.sg/news2009/

We trained such a system at the character level,[3] very similarly to the approach described in (Finch and Sumita, 2010). Such a system has been massively used as a key component by the participants of the NEWS 2009 evaluation campaign. We used the default configuration of Moses for training and testing the SMT engine. We trained a 5-gram character-based language model on the target part of the TRAIN material.[4] We used the DEV corpus for tuning the coefficients (λ_i) given to each model. The resulting system have high BLEU scores (*e.g.*, 55.7 for the CN–EN NEWS task). A random extract of the phrase-table learnt by Moses for the English-Swedish system is shown in Figure 4.

3.3.2 Analogical Systems

We ran our analogical generator for translating the DEV set, using the TRAIN set as a memory. The candidate translations generated were used for training our aggregators in a supervised way. Then, we generated the translation of the TEST terms with our analogical device, making use of the TRAIN and the DEV set as a memory. Adding the DEV corpus to the memory used by the generator is acceptable since it does not involve training. We only consider the (at most) 100 most frequently generated forms for each input term. This certainly decreases the recall of the analogical device, but simplifies the overall process. These candidates are passed on to the aggregator, and one candidate is finally selected.

Aggregators A number of aggregators have been proposed in the literature. Lepage and Denoual (2005b; Stroppa and Yvon (2005) keep the candidate that has been generated the most frequently. We call this aggregator FREQ henceforth. Langlais et al. (2009) trained a binary classifier to recognize good examples from bad ones. A training instance in their case was constituted by an input analogy, and the corresponding output equation along with one solution produced. Therefore, for the translation of the input form u, any pair ($[x : y :: z : u]$, $[x' : y' :: z' : c]$), with x', y', and z' in $\tau(x')$, $\tau(y')$, and $\tau(z')$ respectively, and c a candidate translation would be considered for classification. The authors had to face a particularly unbalanced classification task. Indeed, when translating a test form, a large number of input analogies can be considered (hundreds) and therefore a large number of output equations, each generating potentially numerous solutions (recall the translation session in Figure 1). They reported for instance that on the English-to-Finnish translation direction, they had over 2.7 million instances to classify among which slightly less than 4200 were positive ones. Not only is this task very unbalanced, it is also challenging to train a classifier on that many instances.

In this work, we reframe the classification task as one of identifying the correct candidate among the 100 most frequently generated ones. An instance in this setting is simply a candidate form, and not a pair of analogies as in (Langlais et al., 2009). This is still an unbalanced task, since typically at most one candidate will be correct, but the ratio 1:100 is more manageable, and the classification task is easier to deploy. A total of 81 features are computed for each candidate form:

ANA is a set of 59 features (mostly analogical ones, therefore the name). Some features are characterizing the candidate solution thanks to a character-based language model (the same 5-gram language model used by Moses). Others are characterizing the process with which a given candidate is generated, such as the number of input analogies involved, the number of target equations that generated the candidate, the average degree of the analogies involved, etc. The remaining features are cohort-based ones, such as the rank of the candidate according to frequency, to the language model, etc.

[3] This was done by separating each character in the training material by a space; true spaces being previously substituted by a special character not belonging to the alphabet.

[4] A Markov model of order 4. We tried higher order models, without gains.

IBM is a set of 18 features that are capitalizing on statistical word alignment. The alignment models being used are word-based generative models that are exploited by Moses in order to build the phrase table, namely IBM models, therefore the name of the feature set. Different likelihood-based features were computed, as well as rank features (the rank of the likelihood of the candidate in the cohort of candidates, the ratio of its likelihood over the highest likelihood in the cohort, etc.). To our knowledge, this is the first attempt to capitalize on such features in the analogical sphere.

MOS is a set of 4 features that are exploiting the n-best solutions we asked Moses to produce. The idea being that if Moses ranks a given analogical candidate well (in rank or in score), this is a good indicator of the salience of this candidate. The two main features are the rank of the candidate in the n-best list and its score as given by Moses (or 0 if Moses does not produce the candidate).

We point out that an analogical device with an aggregator that uses the features ANA and IBM is basically making use of the same models (language and IBM) as those used by Moses. It is therefore interesting to compare this configuration to Moses. Also, the aggregators that are making use of the MOS features are performing a kind of combination that has not been explored so far. Note also that we did not engineer task-specific features. For instance, for the medical term translation task, terms and their translation often share the same latin root, which could be exploited to boost performance.

We investigated two families of classifiers: voted-perceptrons (Freund and Schapire, 1999) and support vector machines (Cortes and Vapnik, 1995). We investigated all the metaparameters that `LibSVM` (Chang and Lin, 2011) offers (penalization, kernels, etc.), but did not manage to outperform the performance of the former classifier (an in-house implementation) that we trained with 500 epochs. Therefore we only report the results of the voted-perceptron classifier (VP). Classifying each candidate solution separately is not optimal. This is why we also investigated reranking algorithms in this study. To our knowledge, this is the first time reranking is applied in analogical learning. We tested the algorithms implemented in `RankLib`[5] and `SVMRank`[6] toolkits, and found random forests (Breiman, 2001) to be the most beneficial. We note it RF in the sequel. We only considered bipartite ranking in this work (Argarwal, 2005).

4 Results

4.1 MESH

The accuracy of the translation devices we trained are summarized in Table 2 for the 10 translation directions we tested. This table calls for several comments. First, it is noticeable that our implementation of analogical learning with the FREQ aggregator (line LYZ) outperforms the equivalent configuration in (Langlais et al., 2009) by roughly 10 absolute points in accuracy. We also observe a slight reduction of the silence rate, which still remains high, since on average 54.6% of the test forms do not receive any candidate solution. Second, we observe that Moses slightly outperforms the FREQ variant at a silence rate of 0 (a decision is always returned by Moses). This suggests that FREQ is actually more precise than Moses and calls for a simple combination where the analogical device is trusted whenever it produces a candidate solution, and Moses otherwise. This is illustrated in line CASC(FREQ,MOSES). We observe a clear improvement over each system: almost 10 absolute accuracy points on average are gained by this combination (38.6%). Third, we observe that the aggregators that are relying on a classifier or a reranker offer better performance than picking the most frequently generated form (as done by FREQ). The gains are not especially high, but are consistent over all translation directions. Overall, it seems that the random forest reranker we investigated (the best reranker we tried) offers the best performance on average. This represents 92% of the reachable accuracy according to line ORACLE which involves a perfect classifier. This validates the usefulness of the features we designed. As far as features are concerned, it seems that using all of them leads to better performance overall, and that the configurations that are making use of the ANA and IBM feature sets are comparable or higher than Moses. Cascading the best analogical device with Moses (last line) finally gives a slight boost in accuracy. In the end, the best system we tested correctly translated 41.9% of the test terms in the first position on average across translation directions.

Table 2: Accuracy on the MESH tasks. Figures in parenthesis are silence rates. LYZ stands for the system described in (Langlais et al., 2009), reproduced according to Table 4, p. 492. *avg.* indicates the average over the 10 translation directions.

4.2 MEDDRA

The results presented so far show that the analogical device is more accurate than the statistical one, but that it suffers from a high silence rate. We tested whether increasing the size of the training set would lower the silence rate. We used the datasets of MEDDRA for this. The results are reported in the left column of Table 3. We observe that the silence rate decreases drastically, since less than a fourth of the test forms do not receive a candidate translation. We also observe that the analogical devices, even the simplest FREQ, are far more accurate than Moses (over 30 absolute points on average). The poor performance of the SMT engine might be explained by the fact that the forms in the MEDDRA datasets are longer in terms of characters, therefore reducing the chance of getting the full translation right. Again, combining both approaches does improve accuracy, but the improvement is small since Moses is much less accurate on this task. Also, we observe that using a classifier is preferable to picking the most frequently generated form, and again, the random forest reranker delivers the best performance on average. It is noticeable however, that the performance is far less than the oracle's, therefore, there is still room for improvement.

4.3 NEWS

The right column of Table 3 summarizes the performance of the transliteration devices we trained on the NEWS tasks. The silence rate is rather low (less than 4%). Here again, we observe that aggregating by classifying or reranking is preferable to picking the most frequent solution. There is no clear difference between random forest and voted perceptron here. On the English-to-Chinese transliteration tasks, Moses outperforms the analogical devices, but the opposite is observed for the reverse transliteration direction. Our best configuration slightly outperforms the best analogical device reported in (Langlais, 2013), but the gain is likely not significant.

4.4 Examples of translations

We conducted a random inspection of the outputs produced by Moses and by the analogical device which uses a voted perceptron classifier trained on the ANA and the IBM features.[7] We report in Figure 5 a few examples that we found representative of the problems each translation device faces. The FI–EN example shows a case where Moses fails to produce a valid sequence of words. The EN–ES example illustrates the weakness of Moses at reordering words. The CN–EN example shows the incorrect transliterations made by both systems, and the EN–CN one illustrates a failure of the analogical engine were *ph* and *us* are transliterated separately.

5 Discussion

We have applied analogical learning on a number of key tasks involving various language pairs. Overall, we confirm the findings of Langlais et al. (2009) and Langlais (2013) that analogical devices are typically more accurate than statistical phrase-based SMT, but that they are too often silent. We also verified that cascading the analogical device with Moses increases accuracy. We compared a number of classification algorithms and rerankers, and observed that overall, reranking by random forest

[7] This variant fares well compared to Moses in terms of information used (same language and IBM models).

delivers the best performance. Our implementation outperforms previously reported ones. Our generator is more efficient than the one described in (Langlais et al., 2009). Reranking candidate solutions is preferable to their classification, as proposed in (Langlais, 2013). In order to foster reproducibility, the datasets related to the medical-translation tasks we investigated can be downloaded at `http://rali.iro.umontreal.ca/rali/?q=en/12-medical-translation-tasks`.

We believe this systematic comparison shows the high potential of analogical learning as a translation engine. Still, this work raises a number of issues that we must address. First, we need to find ways to remedy analogical learning's high silence rate. Lepage and Denoual (2005b) describe a recursive process where the input form is split into two parts whenever no solution is returned in the first place. This process is at the very least costly and deserves further investigations. Lepage and Lardilleux (2008) augments the training set with sub-sentential alignment (bootstrapping). Second, the solver we use is producing many solutions that are currently ranked according to frequency. We are addressing the issue of producing less, but more accurate solutions, by integrating structured learning in the solver. Last, we investigated here the translation of sequences of characters on modestly sized tasks. We want to tackle broader translation tasks, *e.g.*, translating plain sentences, as done in (Lepage and Denoual, 2005b), to see whether our analogical device is still beneficial.

Acknowledgements

We thank the reviewers for their valuable comments and apologize for having failed to taking all of them into account in this version. This work has been partially funded by the Natural Science and Engineering Research Council of Canada. We are grateful to Fabrizio Gotti for his advice.

Abstract

Linguistic accommodation is a recognised indicator of social power and social distance. However, different individuals will vary their language to different degrees, and only a portion of this variance will be due to accommodation. This paper presents the *Zelig Quotient*, a method of normalising linguistic variation towards a particular individual, using an author's other communications as a baseline, thence to derive a method for identifying accommodation-induced variation with statistical significance. This work provides a platform for future efforts towards examining the importance of such phenomena in large communications datasets.

1 Introduction

"Zelig...protects himself by becoming like whoever he is around."
- The Narrator, Zelig (Allen, 1983)

When people converse, they often become more alike in their language in many different dimensions (Garrod and Pickering, 2004). This can include similarity in pronunciation (Giles, 1973), speech rates (Street, 1984), pause and utterance duration (Cappella, 1979), and volume (Natale, 1975). Similarly, in written communications people often converge in terms of features such as linguistic style (Danescu-Niculescu-Mizil and Lee, 2011), vocabulary, and syntax (Scissors et al., 2008). Communication Accommodation Theory (Giles and Ogay, 2007) proposes that interactants can adjust their communication style, such as accent, vocabulary, and use of jargon to sound more (convergence) or less (divergence) like the other person. Individuals typically converge to signal affinity with their interlocutor, and diverge to show interpersonal or social distance.

One area which has been largely overlooked, to date, is the role played by an individual's inherent tendency to accommodate (or not). We propose that some people are more apt than others to change their typical linguistic style to converge to that of their conversational partner. This paper introduces the Zelig Quotient, which is a new method for capturing the degree to which the variation in an individual's language use can be explained by their accommodation towards the style of their interlocutor. Using this score, it is then possible to measure the significance of an individual's accommodation within a specific communication pair: does each individual accommodate more or less than their personal norm?

In this paper, we firstly consider existing computational measures of linguistic accommodation. Although useful in measuring accommodation of specific linguistic features within dialog, current measures

Proceedings of COLING 2014, the 25th International Conference on Computational Linguistics: Technical Papers, pages 455–465, Dublin, Ireland, August 23-29 2014.

do not permit examination of the role of an individual's inherent (or latent) predisposition to accommodate their linguistic style. Further, another area that has yet to be explored is the influence of social status and relationships between interlocutors on the likelihood of accommodation. We therefore demonstrate the applicability of the Zelig Quotient by applying the technique to large datasets of communications from three online community forums, in which social status and relationships between interlocutors are clearly defined. We close with a discussion of potential future directions in which the Zelig Quotient could be applied.

1.1 Computational Measures of Linguistic Accommodation

Several computational measures of linguistic accommodation already exist. These measures typically capture the extent to which language use increases in similarity or becomes 'adapted' either within a piece of text or between individuals in dialog. Church (2000) developed a method for determining lexical adaptation in text, by examining the probability of one word appearing in the later half of a document when it appears in the earlier half. This method has been used and extended by other researchers in the examination of lexical adaptation over time (Reitter et al., 2006), adaptation of syntactic constructions (Dubey et al., 2005) and to measure the prevalence and strength of linguistic feature adaptation in dialogs (Stenchikova and Stent, 2007). Along similar lines, linguistic style matching (LSM) techniques with LIWC measures (quantitative analysis of standard language categories) (Pennebaker et al., 2001) reveal the extent to which language use is coordinated between group members, either on a whole conversation or turn-by-turn level (Niederhoffer and Pennebaker, 2002). Ireland et al. (Ireland et al., 2011) used LSM techniques to study the predictive value of stylistic similarity in a social setting. They found that similarity of a few stylistic categories (such as the distribution of pronouns and determiners) was a good indicator of whether two individuals would vote to see one another again in a speed dating scenario.

The work of Huffaker et al. (2006) is particularly relevant to our examination of accommodation within online community forums. Huffaker et al compared three different measures of lexical convergence to assess message similarly in an online community over time. These included: Spearman's Rank Correlation, which has been used to determine message similarity between corpora (Kilgarriff, 2001), 'Zipping', referring to data compression algorithms, which has been used to measure the complexity of documents (Benedetto et al., 2002), and Latent Semantic Analysis, which has been used to measure semantic similarity across corpora (Coccaro and Jurafsky, 1998). All three measures showed divergence in message similarity both between individuals, and in the community as a whole, across time.

However, the common theme with all these techniques is that although they can effectively measure adaptation of linguistic feature use within and between dialogs, they fail to capture the precise direction of convergence or divergence between individuals (i.e., do both interactants within a conversational pair accommodate their language use to the same extent?) Thus, existing computational measures of linguistic accommodation fail to provide a fine-grained view of the dynamics of convergence within dyads or large groups. The measures discussed above only capture the extent to which members of the group match one another, and overlook precise details of an individual's movement from their existing language use towards that of the group.

1.2 Individual's Propensity to Accommodate

Further, whilst accommodation within dyads and groups has been measured extensively, one area which has been largely overlooked, to date, is the role played by an individual's inherent tendency to accommodate (or not). Some individuals may have a relatively stable linguistic style, whereas other individuals may be more likely to accommodate their linguistic style towards that of their conversational partner. We have been unable to find any methods for reliably measuring an individuals propensity to accommodate towards their interlocutors. We hypothesize that individuals are not equal with respect to their accommodation and propose the Zelig measure, detailed within this paper, as a means for quantifying this characteristic.

One factor which could conceivably influence an individual's tendency to accommodate is *social power*. Giles and Coupland (1991) state that "the power variable is one that emerges a number of times in the accommodation literatures and in ways that support the model's central predictions" (p.

Category	Examples	Category	Examples
Personal pronouns	I, his, their	Auxillary verbs	shall, be, was
Impersonal pronouns	it, that, anything	High-frequency adverbs	very, rather, just
Articles	a, an, the	Negations	no, not, never
Conjunctions	and, but, because	Quantifiers	much, few, lots
Prepositions	in, under, about		

Table 1: Word Categories Used for Calculating Linguistic Style

19). Demonstrations of the role of social power in accommodation include interviewees converging their speech style towards that of their interviewers during employment interviews (Willemyns et al., 1997), students accommodating their verbal and non-verbal behaviours to academic faculty members (Jones et al., 1999) and witnesses in courtrooms accommodating to the linguistic style of the questioning legal professional (Gnisci, 2005). Thus, individuals with low social power are more likely to accommodate their linguistic style. The Zelig Quotient allows explicit examination of research questions of this nature concerning accommodation and divergence associated with demographic variables such as social power.

2 The Zelig Quotient

"Wanting only to be liked, he distorted himself beyond measure."
- The Narrator, Zelig (Allen, 1983)

We propose the Zelig Quotient, a measure for normalizing linguistic variation. The Zelig Quotient is named for Leonard Zelig, the central character of the Woody Allen film Zelig, who is described as "the human chameleon" due to his propensity for taking on the characteristics of other people. This is the logical extreme of accommodating to one's audience. An author who always adopts the language style of the intended reader is totally Zelig-like, whereas an author who does not adapt at all has zero likeness. Opposite behaviour to Zelig (moving away from the audience) is also possible. Over-accommodation occurs when the author adopts elements of linguistic style of their intended reader, but emphasises to the point of overuse. In extreme cases this would be detected as parody. We need, therefore, to distinguish not only the distance between author and reader, but also the orientation. The Zelig Quotient thus shows the extent to which an individual changes their linguistic style from their 'typical' or baseline style, to move either towards or away from each of their conversational partners. The average Zelig score across all conversational partners can then be used to demonstrate the individual's general tendency to accommodate their language use to that of others.

2.1 Feature Selection

We have selected to study a set of features which are stylistic rather than semantic in nature; although consideration of whether two people are talking about the same topic is a valid research question, we currently wish to focus on their linguistic style. The best features for our purposes are those able to be varied with comparative freedom, without affecting the meaning of a message. We use a set of nine such features, taken from the linguistic style matching study conducted by Ireland et al. (2011) (see Table 1).

We used LIWC dictionaries for each category. LIWC processes a text file word by word, comparing each word to the dictionary and providing a count of the words in the file which match each category in the dictionary. Sums of words in each category are presented as percentage of total words in the file to correct for differences in text length between text files (Pennebaker et al., 2001). The use of LIWC is the basis of much recent work on linguistic style accommodation (Niederhoffer and Pennebaker, 2002; Danescu-Niculescu-Mizil et al., 2011; Danescu-Niculescu-Mizil and Lee, 2011) to which we want to relate.

2.2 Calculating the Zelig Quotient

We assume an author has a baseline linguistic style resulting in a baseline value for each of our stylistic features. However, we expect variation in the observed values due to sampling, an author's natural variation, constraints of message content and format, etc. as well as any movement due to accommodation.

We can estimate a baseline value for a specific feature, μ_f, by averaging over all the messages we have for an author a. Previous research has used a similar technique for establishing the baseline level of a lexical item in a dialog in order to study accommodation (Church, 2000; Stenchikova and Stent, 2007).

$$\mu_f(a) = \sum_{m=1}^{n_a} f_m(a)/n_a \tag{1}$$

where m is a message, n_a is the number of messages for a and $f_m(a)$ is the feature value in m.

We can further estimate the proportion of variance due to 'noise' and that due to accommodation by also calculating the average feature values on an author-reader (a, r) pairwise basis.

$$f(a, r) = \sum_{m=1}^{n_{ar}} f_m(a, r)/n_{ar} \tag{2}$$

where n_{ar} is the number of messages written by a to reader r.

Measuring the variance within a pair and then averaging over all pairs that author is party to gives an estimate of the natural variation in feature value for an author.

$$\sigma_f^2(a) = \frac{1}{R_a} \sum_r \sum_{m=1}^{n_{ar}} (f_m(a) - \mu_f(a))^2/n_{ar} \tag{3}$$

where R_a is the number of recipients of messages from author a.

The movement in a feature due to accommodation is simply taken to be the difference between the value seen within a communicative pair, and the author's baseline value.

Having calculated scores for several features, some of which may change more readily than others, we can consider authors as having corresponding points in an F-dimensional feature space described by the vector of feature values. The generalised phenomenon of accommodation can then be measured in terms of movement in this feature space, rather than movement in individual features. Note that to avoid bias towards particular features when considering overall movement, feature scales must be comparable. Movement in an author's language may be large, but it may not necessarily be towards the reader.

We represent movement and distances between the author's baseline position, accommodated position, and the reader's position as vectors in the feature space:

$$\mu = \{\mu_1(a), \mu_2(a), ..., \mu_F(a)\}$$
$$a = \{f_1(ar), f_2(a, r), ..., f_F(a, r)\}$$
$$r = \{f_1(r), f_2(r), ..., f_F(r)\}$$

We use the law of cosines to yield the cosine of the angle between the vector connecting the reader to the author's baseline position, and that connecting the reader to the author's accommodated position. The angle will be greater than 90° if the author has over-accommodated, and will therefore have a negative cosine value. However, the dot product of these two vectors gives the cosine of the inner angle. Therefore, normalising by this gives a value of +/- 1 according to whether accommodation movement is less or more than the amount required to meet the reader.

Multiplying the accommodated distance by this +/-1 factor gives us a definition of an accommodation metric that expresses the accommodation as the change in directed distance from the reader, proportional to the amount required from the author's unaccommodated position. This may be greater than 1 (over-accommodation) or less than zero (divergence). In vector notation we define accommodation as:

$$Acc(a, r) = 1 - \left(\frac{|\vec{ar}|}{|\vec{\mu r}|}\right)\left(\frac{|\vec{\mu r}|^2 + |\vec{ar}|^2 - |\vec{\mu a}|^2}{2(\vec{\mu r} \cdot \vec{ar})}\right) \tag{4}$$

The dot product of $\vec{\mu r}$ and $\vec{ar}$ is zero if the two vectors are orthogonal. However this is matched by a zero value in the numerator and we take the final parentheses value in equation (4) to be 1 in this case. In the other pathological case where $|\vec{\mu r}|$ is zero, the implication is that author and reader have the same preferred position, i.e. there is nothing meaningful to say about accommodation between the two.

Having estimated author to reader accommodation, we are now in a position to estimate how readily the author adapts to others, by averaging over the set of readers. This gives us our Zelig factor, Z.

$$Zelig(a) = \frac{1}{R_a}\sum_{r=1}^{R_a} 1 - \left(\frac{|\vec{ar}|}{|\vec{\mu r}|}\right)\left(\frac{|\vec{\mu r}|^2 + |\vec{ar}|^2 - |\vec{\mu a}|^2}{2(\vec{\mu r}\cdot\vec{ar})}\right) \tag{5}$$

A positive (+) Zelig Quotient signifies the author readily accommodates, with a Zelig Quotient of 1 indicating the author always adapts their linguistic style to that of their audience. A negative (-) Zelig Quotient suggests divergence in the authors linguistic style (moving away from the audience).

Significance of values can be estimated from the variance. Here we take movement beyond one standard deviation of the authors total message distribution. The significance of an author's Zelig Quotient then follows from averaging the variance seen over the pairs the author is party to.

$$Zelig_{min}(a) = \sqrt{\frac{1}{R_a}\sum_{r=1}^{R_a}\frac{\sum_{f=1}^{F}(\sigma_f(a) - \mu_f(a))^2}{\sum_{f=1}^{F}(f(r) - \mu_f(a))^2}} \tag{6}$$

This model assumes that there are latent baseline distributions for feature values but does not suggest a generative function. Further work will determine appropriate distribution models for features, to be parameterised from the estimation methods presented here.

3 Zelig in Online Communications

To demonstrate the utility of the Zelig Quotient, our study uses scraped forum data from three large online communities (note, the names of the forums have been anonymised to protect the identity of the community members).

The first (ForumA) contains circa 2800 threads, 21000 posts, 250 currently active members and three years of historical data. The second (ForumB) contains approximately 160,000 threads, 2.25 million posts, 1500 currently active members and historical data is available for a period of approximately 10 years. The third (ForumC) contains approximately 50,000 threads, 550,000 posts, and currently 824 active members. Historical data is available for a period of approximately seven years.

All three of the online community forums are powered by vBulletin, a system which allows users to earn reputation points for their activity. Users can 'up-vote' or 'down-vote' each others' posts, which either adds or subtracts reputation points from that user. The number of reputation points received or deducted depends on who is casting their up/down-vote. Having more reputation enables a voter to have a greater influence on the reputation of others. Reputation can also be earned as the number of posts made by a user, or the age of their account, increases. This system essentially enables a power structure within the community, and is useful for differentiating between veteran communities members who contribute a lot to the community and, based on their up-votes, have a considerable amount of expertise or valuable information/opinions to share (i.e. Leaders), from relatively new and inexperienced community members whose contributions are less significant (i.e. Non-Leaders).

From each community we sample the top 10% of all members from the complete historical data (ForumA n = 70, ForumB n = 98, ForumC n = 169) based on reputation score and assign them to our 'Leader' category. For our 'Non-Leader' category we select an equally sized sample group (same n), which are evenly distributed across the remaining 90%, based on reputation score. One-time posters were removed prior to sampling.

3.1 Hypotheses

We hypothesise that, in accordance with Communication Accommodation Theory (Giles and Ogay, 2007), the Zelig Quotients for high power individuals (which we will refer to as Leaders) and low power

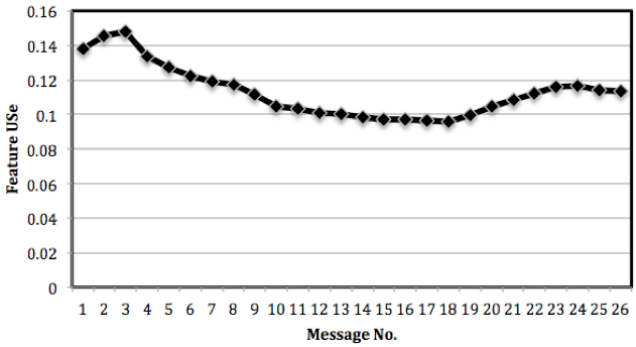

Figure 1: Moving average for an individual's linguistic feature use

individuals (referred to as Non-Leaders) will differ significantly. The power variable has been shown to have a strong influence on communication accommodation. Since people with lower status have greater cause to try to gain social approval by converging towards others, we hypothesise that:

H1: Non-Leaders (i.e. people with low power) will exhibit greater linguistic style accommodation/more Zelig-like behaviour than Leaders (people with high power)

Furthermore, it has been shown that those with low power often show greater convergence when communicating with somebody in a superior position. For example, foremen converge more to managers than to workers, and managers converge more to higher managers than to foremen (Taylor et al., 1978). Similarly, salespeople converge more to customers than vice versa, as the customers in these settings hold greater economic power (Van den Berg, 1986).

H2: People accommodate more with interlocutors who have higher power (Leaders) than those who have lower power (Non-Leaders)

3.2 Method

One challenge when working with scraped data from online community discussion threads, is accurately reconstructing who is talking to whom. Unlike in e-mail communication, vBulletin forums lack a mechanism for explicitly stating who a post is a reply to. Posters therefore append their post to the end of an ever-growing thread, regardless of whether they are addressing the first post, last post or any post in between. Of course, their communication may not even be aimed at any single person, and instead might be intended for a whole community audience.

Since the Zelig measure we have presented requires dyadic comparisons of linguistic style features, it is necessary to reconstruct a dyadic conversation structure for all of the forum threads. Previous work has examined features for accurate reply reconstruction of threaded conversations (Aumayr et al., 2011); re-building the correct structure from a collapsed conversation thread without explicit reply mechanisms. Many features are useful for reply graph reconstruction, for example: reply distance (how closely a post appears to that which it is responding), time difference (how soon after a post a response is written), quotation links (how explicit citations of previous posts are used) and cosine similarity (how closely the contents of two posts match). Aumayr et al. (2011) demonstrated that accuracy (as indicated by measurements of precision and recall) can be achieved by simply combining the use of reply distance and quotation links. That is to say, posts are typically responses to those which they appear closest to within a thread, or those which they explicitly cite. Therefore, for our analysis we treat each post as a response to the author of the closest post (the one directly preceding it within the thread) or the author that is cited within the post.

In order to calculate variations in each individuals' linguistic style, we calculate their baseline style as the moving average of their previous communications (either globally or within each particular dyad). Figure 1 illustrates this moving average for a particular LIWC feature changing with each message sent by an individual. Our moving average approach has the advantage that accommodation is calculated according to the movement towards a persons' linguistic style at a given point in time, rather than simply an average of their linguistic style in their entire communications (including those that occur later).

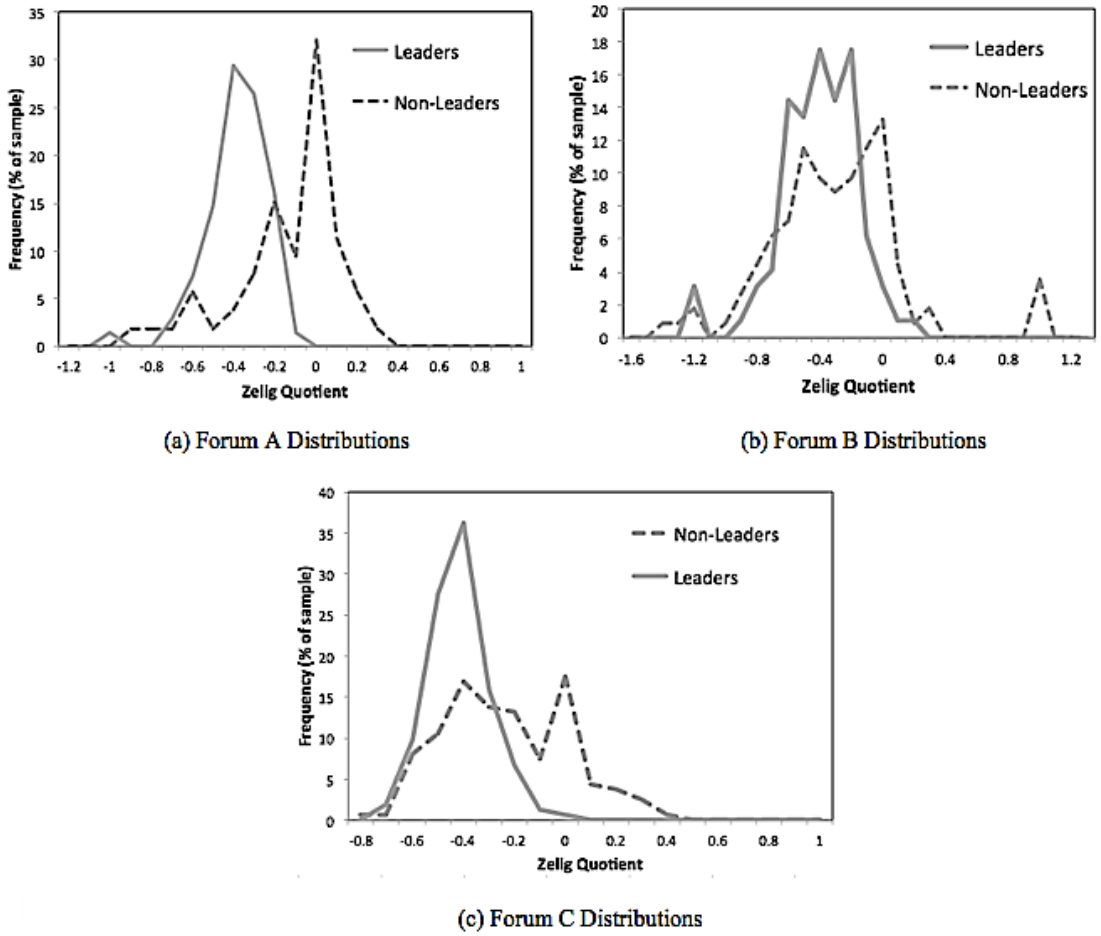

Figure 2: Zelig Quotient Distributions for members of Forum A, Forum B and Forum C

4 Results

Figure 2 shows the frequency distributions of Zelig Quotients for individuals within each of the three communities.

Our results show that the Zelig Quotients of community members follow a relatively normal distribution, centered around a Zelig Quotient of approximately -0.4 in all three communities, though there are obvious differences between the Zelig Quotient distributions for our two sample groups of Leaders vs. Non-Leaders.

Our analysis reveals that divergent communication is a common behaviour for a large proportion of each online community. That is, many community members receive a negative Zelig Quotient. Our results, therefore, go against the prevailing findings in linguistics and psychology, which suggest that individuals often constitute themselves as a community, speaking in a collective voice, and converging in terms of linguistic style.

4.1 Divergence is common

Within communication accommodation theory, convergence is generally regarded as positive and divergence as negative. Divergent communicators are often evaluated as insulting, impolite, and hostile (Bradac and Giles, 2005). Convergent speakers are evaluated as more competent, attractive, likeable and cooperative (Giles et al., 1991). Divergence is the typically the result of communicators wanting to differentiate themselves from each other and emphasize distinct identities. This can be the case particularly where there are power or status differences between interlocutors, as individuals attempt to communicate their social differences by engaging in dissimilar communication behaviours (Street, 1991). If their

points of view start deviating, so too do their communication styles (McPherson et al., 2001). Observing the Zelig distribution of a community is therefore likely to provide a valuable insight into the overall 'unity' of its members. Our results are consistent with Huffaker et al. (2006), who found increasing dissimilarity with the words used by community forum users over a six-week period. Thus, our results suggest that a large proportion of individuals within online communities have a tendency to differentiate themselves from others.

However, divergent communication is not always inherently negative. Attributions of the speaker's motives by the recipient can influence the extent to which convergent and divergent communications are perceived to be positive or negative. For instance, convergence can be evaluated as positive when attributed to speaker's internal positive motives; however convergence can also be viewed negatively when attributed to external factors. The same is true for divergent communications. When divergence is perceived by the recipient as being unintentional or positively motivated, recipients evaluate the speaker and their communications more favourably than if it is evaluated as being intentional or negatively motivated (Gasiorek and Giles, 2012). Thus, divergent communication does not neccessarily have negative connotations for the relationship between speakers and recipients.

Whilst linguistic style convergence does occur within the communities we have examined, a relatively small proportion of members (typically less than 10%) demonstrate a tendency to accommodate to others in a near Zelig-like way. A larger proportion of each community (between 15 - 35%) tend to maintain their typical linguistic style, with their Zelig Quotient of 0 indicating that fluctuations in style are due to noise rather than convergence or divergence.

The following results describe in more detail the differences in Zelig Quotients for our two sample groups, Leaders and Non-Leaders.

4.2 Non-Leaders are more Zelig-like than Leaders

We conducted independent samples t-tests in order to compare the Zelig Quotient means for Leaders and Non-Leaders in each of the online communities. There were common significant differences across all three communities: Non-Leaders in ForumA had significantly greater Zelig Quotients (M= -0.181, SD= 0.270) than Leaders (M= -0.432, SD= 0.148); $t(119)= 6.492$, $p < 0.001$. Similarly, ForumB Non-Leaders (M= -0.345, SD= 0.425) were more Zelig-like than Leaders (M= -0.461, SD= 0.254); $t(206)= 2.346$, $p < 0.05$, and ForumC Non-Leaders (M= -0.306, SD= 0.276), were also more Zelig-like than Leaders (M= -0.468, SD= 0.121); $t(327)= 6.885$, $p < 0.001$.

These results lead us to accept H1; Non-Leaders' linguistic style variation can be attributed to their accommodation towards the style of their interlocutor, to a greater degree than for Leaders. Furthermore, our results illustrate that analysis using the Zelig Quotient uncovers important accommodation trends within textual conversation data, which are in accordance with Communication Accommodation Theory.

As well as a comparison between high and low reputation groups (Leaders and Non-Leaders, respectively), a Spearman's Rank Order correlation was run to determine the relationship between reputation rank and Zelig rank within the community. We found weak but statistically significant negative correlations between reputation and Zelig Quotient within ForumB ($rs(316) = -0.1406$, $p = 0.011889$) and ForumC ($rs(179) = -0.1729$, $p = 0.019863$), further suggesting that Zelig-like behaviour is most common within the lowest reputation ranks.

4.3 Interactions between Leaders and Non-Leaders

In order to test H2 and examine how interactions between Leaders and Non-Leaders influenced accommodation, each individual within a dyad was classified as either communicating 'Up' or 'Down' the reputation hierarchy (either from Non-leader to Leader, or Leader to Non-Leader, respectively). Independent samples t-tests were conducted in order to compare the mean Zelig Quotients for dyads from each category. The tests revealed a statistically significant difference within two of the three communities, with Zelig Quotients significantly lower in 'downward' communications for ForumA - Upwards (n = 72, M= -0.283 , SD= 0.456), Downwards (n = 72, M= -0.588, SD= 0.711); $t(142)= 3.066$, $p < 0.01$, and ForumC - Upwards (n=1280, M= -0.388, SD= 0.570), Downwards (n=1280, M= -0.530, SD= 0.723); $t(2558)= 5.528$, $p < 0.001$. Within ForumB, those communicating up the hierarchy were also more

Zelig-like, however the difference was considered not to be statistically significant - Upwards (n=295, M= -0.383, SD= 0.634), Downwards (n=295, M= -0.444, SD= 0.601); t(588)= 1.208, p = 0.228.

These results lead us to accept H2; community members are more Zelig-like when communicating with people above them in terms of reputation/status.

4.4 Finding the Zeligs: Who are they?

To conclude our analysis, we address the question: 'Who are the Zelig characters within our corpora?'. By focusing our attention on the individuals that have positive $Zelig$ values ($Z > 0$), our results point to a clear and consistent answer across all three datasets - *almost all Zelig-like individuals are Non-Leaders*, however, Non-Leaders are *not* all Zeligs. Within our sample populations for each community Non-Leaders account for the vast majority of those with Zelig values greater than 0 (100% in ForumA, 91.6% in ForumB, and 100% in ForumC). These results are consistent with the idea that individuals with lower power are sensitive to the language used by a higher power interlocutor (Niederhoffer and Pennebaker, 2002); the Zelig Quotient has captured the greater tendency of Non-Leaders to alter their baseline linguistic style in order to converge with the linguistic style of Leaders, instead of the other way around.

The Zelig-like behaviour of non-leaders could potentially be attributable to their acclimatisation to community expectations; shifting their behaviour more frequently at the earliest stages of their community life and converging more towards the linguistic styles of others, until they gradually stabilise and become more attuned to the community norms, perhaps even progressing to leadership roles themselves. A useful future investigation would be to track the progress of the Zelig-like Non-Leaders over time, to see if their propensity to adapt and change their linguistic style affects their ability to progress within the community, e.g. does linguistic style convergence enable them to earn reputation more quickly, or provide an indicator of longevity within the community?

5 Conclusions and Future Work

> *"...and it shows exactly what you can do if you're a total psychotic."*
> - Leonard Zelig, Zelig (Allen, 1983)

We have presented a metric for measuring linguistic accommodation in a systematic manner, considering not only the context of an individual pair's communications, but the background models for both individuals. Thus, the Zelig Quotient provides an objective, quantifiable measure of convergence and divergence in language use between individuals, as defined by the movement in an individual's typical linguistic style towards or away from the typical linguistic style of their conversational partner. The Zelig Quotient is meaningful for differentiating between those who typically accommodate their language use towards many people (Zelig-like individuals) from those who don't. In addition, the metric includes calculation of pair-wise author to reader accommodation scores. Thus, a full picture of how an individual is behaving in terms of convergence and divergence can be gained by examining these pair-wise scores. In combination, these two scores together provide a comprehensive and illuminating picture of an individual's accommodation behaviour. This provides a framework for investigating the circumstances surrounding such variation in language use, over large datasets, in a manner which has not previously been undertaken.

We acknowledge that community forums such as these may not be the ideal dataset for evaluating dyadic accommodation, as authors may be addressing multiple people. However, it is worth noting the use of the Zelig metric seems to be effective even in this community forum dataset. Work on testing the metric on a wide range of existing datasets, including courtroom interactions and dyadic therapeutic interactions, is ongoing.

There are a number of additional possibilities for future work. Firstly, although in the current study we focussed on linguistic features that are stylistic in nature, it would be simple to alter the Zelig metric to use greater, fewer or entirely different linguistic features, for instance to explore semantic or content aspects of language. We have so far considered only a small set of linguistic style features, and it may be worth expanding this to a greater variety; in particular, concentrating on features which have been

shown to be the subject of accommodation in sociolinguistic studies (such as Bunz & Campbell, 2004). We also intend to test the metric with languages other than English in future research. Secondly, the separation between our two sample groups in terms of Zelig distributions suggests that this Quotient may be useful as a predictor of group membership/reputation score. A considerable body of work has attempted to accurately classify community members based on their communication behaviours and our results suggest that Zelig may be useful in this domain. We also intend to investigate in more detail what kinds of relationships are characterized by higher levels of accommodation, to see whether this accords with underpinning theories of politeness and social identity. Group dynamics, including linguistic accommodation to group norms in multiparty communication, and the individual's contribution to constructing a group identity, is also a large area ripe for further study.

Abstract

This article aims to analyze how agreement regarding the central unit (macrostructure) influences agreement when establishing rhetorical relations (microstructure). To do so, the authors conducted an empirical study of abstracts from research articles in three domains (medicine, terminology, and science) in the framework of Rhetorical Structure Theory (RST). The results help to establish a new criteria to be used in RST-based annotation methodology of rhetorical relations. Furthermore, a set of verbs which can be utilized to detect the central unit of abstracts was identified and analyzed with the aim of designing a preliminary study of an automatic system for identifying the central unit in rhetorical structures.

2 Introduction

One of the biggest challenges in annotating the rhetorical structure of discourse has to do with the reliability of annotation. When two or more individuals annotate a text, discrepancies generally arise as a result of the way each human annotator interprets the text (Taboada and Mann, 2006). Besides, markers specifying the rhetorical relations between discourse units do not always exist (Taboada, 2006). Even if they appear in the text, these markers do not always establish rhetorical relations unequivocally (van Dijk, 1998; Mann and Thompson, 1987). Despite this ambiguity, discourse markers are considered to be a form of linguistic evidence which are used to signal coherence relations and which are useful in detecting certain rhetorical relations (Georg et al., 2009; Iruskieta et al., 2009; Pardo and Nunes, 2004).

In searching for linguistic evidence to determine the rhetorical structure of texts, scholars have analyzed not only discourse markers but also verbs. For example, Pardo and Nunes (2004) first rhetorically annotated their Corpus TCC (a Portuguese corpus containing scientific texts in the computational domain) and then analyzed verbs related to certain rhetorical relations, finding that verbs such as *buscar* 'search, look for', *objetivar* 'objectify, intend', *pretender* 'intend, mean', *procurar* 'search, look for', *servir* 'serve, meet the requirements of', and *visar* 'aim, drive' are related to the PURPOSE relation.

Proceedings of COLING 2014, the 25th International Conference on Computational Linguistics: Technical Papers, pages 466–475, Dublin, Ireland, August 23-29 2014.

They also found that other rhetorical relations such as CAUSE, EVIDENCE and RESULT are indicated by other types of verbs.

This paper aims to answer the following research questions:

(i) Does agreement about the central unit affect inter-annotator reliability when annotating rhetorical relations?

(ii) Are there some types of verbs that can be used as "indicators" (Paice, 1980) to identify the central unit of a rhetorical structure?

Besides we focus on how to identify the unit associated with the main node in the rhetorical structure tree or, in other words, the "central unit" (CU) (Stede, 2008), the "central proposition" (Pardo et al., 2003), the "central subconstituent" (Egg and Redeker, 2010) or the "salient unit of the root node" (Marcu, 1999). To our knowledge, no other research has attempted to identify this unit, the central unit of a rhetorical structure tree, by semantically studying the verb within the framework of RST. This topic, however, could have both theoretical and methodological implications.

The structure of the paper is as follows: Section 3 describes the theoretical framework, corpus and methodology utilized in this study. Section 4 lays out the results obtained. Section 5 presents a preliminary study on the semantic classes of the verbs beloging to central unit. The final section presents conclusions and suggests directions for future research.

3 Theory, corpus and methodology

3.1 Theory

Various theories describe the relational structure of a text (Asher and Lascarides, 2003; Grosz and Sidner, 1986; Mann and Thompson, 1987). This study is based on Mann and Thompson's (1987) Rhetorical Structure Theory (RST), an applied, language-independent theory that describes coherence between text fragments. It combines the idea of nuclearity –that is, the importance of an individual fragment from within the discourse– with the presence of rhetorical relations (RR) (hypotactic and paratactic relations) between these fragments. Mann and Thompson (1987) argue that nuclear units play a more important role for text coherence than satellites.

This has significant implications for automatic text summarization. Ono et al. (1994) and Rino and Scott (1996) suggest that the summary of a text can be obtained by deleting optional satellites, an argument based on the property of nuclearity in hypotactic relations. Da Cunha (2008) describes rules based on nuclearity which can be used to summarize medical texts. For a more in-depth, critical explanation of nuclearity, see Stede (2008) and for additional information on RST, see Taboada and Mann (2006) and Mann and Taboada (2010).

According to RST, hypotactic and paratactic relations connect elementary discourse units (EDUs) or groups of discourse units (span). Elementary units cannot be divided into simpler units. In this paper, a "central unit" is defined as the clause which best expresses the topic or main idea of the text. The central unit of a rhetorical structure tree is the elementary unit or group of elementary units which comprise the nucleus of its main node. Hypotactic units have a single nucleus in the central unit, while paratactic units contain multiple nuclei.

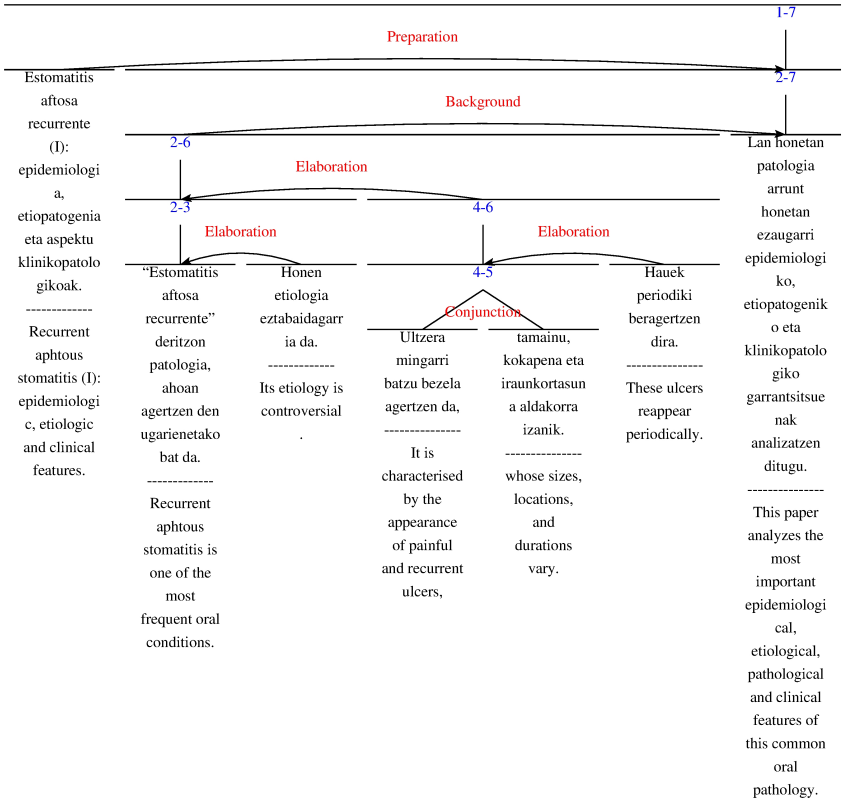
For example,[1] in the rhetorical structure tree presented in Figure 1, unit 7 is the central unit of the elementary units that are numbered from 1 to 7, since it is the nuclear unit of the root node which and has the relation PREPARATION associated to it. The root node covers the entire structure of the text, and since it is not linked to any other unit, no other associated nuclei have the same degree of central importance (Marcu, 1999). The central unit indicates the most important unit in the structure, which is indicated in Figure 1 by the verb *analizatzen* 'analyze'.

Determining nuclearity (that is, deciding which of the two associated spans has a more central role based on the intentions of the writer) is key in assigning rhetorical relations. In fact, Stede (2008) has questioned the way in which rhetorical structure is represented in RST based on several reasons:

i) It is not clear what grounds are used to make the decision: is it because of nuclearity or because of the effect of a rhetorical relation?

[1] Examples are extracted from the Basque corpus used in this study (Iruskieta, 2014).

Figure 1: A rhetorical structure tree for text GMB0301 (Annotator 1)



ii) Nuclearity poses challenges for annotation. This led Carlson et al. (2001) to present multi-nuclear versions of some nuclear relations from the classic extended classification.

We also identified the same problems. Examples (1) and (2) demonstrate how different choices of nuclearity affect agreement in rhetorical relations.

(1) [*Emaitza:*]$_1$ [*Erabiltzaileen perfil orokorra ondokoa dela esan daiteke: gizonezkoa (% 51,4), heldua (43,2 urteko media) eta patologia traumatologikoagatik kontsultatzen duena (% 50,5).*]$_2$
GMB0401
[Results:]$_1$ [The average user is as follows: male (51.4%), middle-aged (43.2 years old), and treated for trauma (50.5%).]$_2$

Annotator 1 (A1) decides that the second unit in Example (1) is more important than the first unit. The second annotator (A2), however, makes the exact opposite decision. Both annotators arrive reach their conclusions based on structural reasons. Disagreements about the importance of each text fragment influence the rhetorical relation: A1 annotates the relation as PREPARATION while A2 chooses to label the relation as ELABORATION.

Example (2) demonstrates how different interpretations of nuclearity affect agreement with regard to the rhetorical relation.

(2) [*Erabiltzaileen % 80ak bere kabuz erabakitzen dute larrialdi zerbitzu batetara jotzea*]$_1$ [*eta kontsulta hauen % 70a larritasun gutxikotzat jotzen dituzte zerbitzu hauetako medikuek.*]$_2$
GMB0401
[It is calculated that about 80% of users come to emergency services on their own initiative]$_1$ [and that 70% of visits are considered minor by health care personnel.]$_2$

A1 believes that the second unit in Example (2) provides more detailed characteristics about the users (e.g. the second unit is a satellite of the first unit) and therefore annotates the relation as hypotactic

(ELABORATION). A2, on the other hand, annotates the same discourse segment as a paratactic relation (CONJUNCTION), considering the marker *eta* 'and' to be the most significant element, indicating that she or he believes that two different elements of emergency services are being discussed.

According to Bateman and Rondhuis (1997), when determining nuclearity at the higher levels of a tree structure, RST clearly establishes a global view of a text, since an analysis is by definition incomplete until all units in the text have a function which is depicted by a single structure. It is logical that if nuclearity plays a role in determining rhetorical relations at the lower levels of a rhetorical structure, it will also affect the structure's higher levels. If two annotators have a different global point of view (e.g. they annotate different central units), they will also annotate different rhetorical relations. Therefore, our hypothesis is that trees which have the same global interpretation of text structure will have greater agreement in the annotation process; i.e., in the labeling of rhetorical relations, while those with differing global structures will have lower agreement. This hypothesis underpins the methodology used to answer the first research question of this study.

The next subsection describes the corpus used for this study.

3.2 Corpus

This study sought to analyze short but well structured texts written in Basque in order to determine linguistic evidence which could be used to indicate the central unit of rhetorical structure. The corpus utilized in this study consists of three corpora from the same genre (abstracts) from three different specialized domains: medicine, terminology and science. The communicative goal of these texts is to present specialized knowledge, since both the writer and readers are experts. Medical texts include the abstracts of all medical articles written in Basque in the *Gaceta Médica de Bilbao* (GMB) 'Medical Journal of Bilbao' between 2000 and 2008. Terminology texts are abstracts from the proceedings of the *Congreso Internacional de Terminología* (TERM) 'International Conference on Terminology' organized by UZEI –the Basque Centre for Terminology– in 1997, while scientific articles are abstracts of papers from the University of the Basque Country's *Jornadas de Investigacin de la Facultad de Ciencia y Tecnología* (ZTF) 'Research Conference of the Faculty of Science and Technology', which took place in 2008.

After the annotation process (central unit and rhetorical relations among others), the annotated corpus was evaluated (Iruskieta et al., Forthcoming) and harmonized by a judge (Iruskieta, 2014). The harmonized corpus can be consulted in the RST Basque TreeBank[2] (Iruskieta et al., 2013a).

3.3 Methodology

Before presenting the process followed to get our goals, let us explain that, when we began this research, the GMB corpus had previously been annotated manually (Iruskieta et al., 2013b) by two linguists using the extended classification of RST (Mann and Taboada, 2010) while the other two corpora (TERM and ZTF) were not tagged. The results of the comparison done about the relationship of agreement between the annotation of the central unit and the annotation of the rhetorical structure in GMB led us to redefine the annotation strategy for TERM and ZTF in the sense that we asked annotators to identify the central unit (one or more) before tagging the rhetorical structure.

The steps carried out for the annotation of the corpora were the following:

A. Elementary Discourse Units segmentation. The corpus was segmented at intra-sentential level using a minimal set of criteria (Iruskieta et al., 2011a) by each annotator using the RSTTool program (O'Donnell, 1997)

B. Central unit identification (TERM and ZTF). Both annotators determined the central unit[3] and the verbs present in the central unit of a scientific abstract in TERM and ZTF domains.[4]

[2]The RST Basque TreeBank is available at `http://ixa2.si.ehu.es/diskurtsoa/en/fitxategiak.php`.

[3]We calculate a baseline to illustrate the complexity of the central unit selection reporting the average number of EDUs: average number of 22.58 EDUs per central unit candidates per text. The average was calculated based on the number of EDUs, over the number of texts.

[4]The central units (CU) can be consulted also in RST Basque TreeBank.

C. Rhetorical tree structure annotation. Rhetorical relations were annotated by each annotator using the RSTTool program with the extended classification (Mann and Taboada, 2010) of RST.

D. Evaluation. Agreement in rhetorical tree structures were manually evaluated following the qualitative methodology proposed in Iruskieta et al. (Forthcoming), but taking into account the structures with the same central unit and distinguishing between the rhetorical relations linked or not to central unit.

E. Interpretation. We compared the results of central unit agreement and disagreemens to check for possible correlations using a t-test formula at 99.5% confidence.

4 Results

Our main hypothesis is that an agreement on central unit leads us to a higher agreement on rhetorical relations; in other words, identifying the main idea of the text helps the human annotator in the identification of the structure of the text and, therefore, the agreement between annotators is higher.[5]

4.1 Correlation between agreement on rhetorical relations and agreement on central unit

The observation made about the GMB, where we argued that annotators agree more on rhetorical relations when they annotated the same central unit, remained after considering results of a more extended corpus with two new corpora (TERM and ZTF) and two additional annotators.

Results confirm this fact even when the difference has been substantially reduced from 0.1497 to 0.0426 when more data (all the corpus) were considered. Table 1 presents the global results of the comparison between the agreement on central unit ('= CU')[6] and mean agreement on rhetorical relations for the corpus as a whole.

	GMB			**Corpus**		
	= CU	**≠ CU**	**Diff.**	**= CU**	**≠ CU**	**Diff.**
Mean	0.7456	0.5959	**0.1497**	0.5915	0.5489	**0.0426**
SD	0.1833	0.1749		0.1429	0.1125	

Table 1: Mean agreement (and standard deviation) of the central unit and rhetorical relations

We perform a significant test for the differences. We confirmed that the populations being compared have a normal distribution following the Kolmogorov-Smirnov test (p-value of K-S test was 0.913) and have the same variance (p-value of F-test was 0.063). Therefore, two tail independent samples t-test was used with a 0.013 p-value, denying the null hypothesis.

Other hypothesis and combinations were analyzed with positive results: a significant agreement was observed when we compared agreement in rhetorical relation linked to central unit when annotators tagged the same central unit and when they tagged different central units. It is very difficult to establish which rhetorical relation are linked to central unit when annotators do not tag the same central unit.

4.2 Correlation between agreement on rhetorical relations linked or not to central unit

After our main hypothesis was confirmed, we went ahead in the tree structure and we checked whether there is higher agreement in rhetorical relations linked to the central unit (considering the structures where there was agreement in central unit), than in the other relations of the tree structure. For example, in the rhetorical structure tree presented in Figure 1, we consider two relations linked to central unit PREPARATION (1>2-7) and BACKGROUND (2-6>7), while the other four relations are not linked to central unit (ELABORATION (2<3), ELABORATION (2-3<4-6), ELABORATION (4-5<6) and CONJUNCTION (4=5). Table 2 presents the results of relations linked to central unit with relation not linked to central unit:

In structures with the same central unit we compare between the agreement in rhetorical relations linked to the central unit and all the other relations. Percent agreement is substantially higher when we

[5]The results of all corpora considered indicate that the change in methodology improved central unit agreement between annotators slightly in TERM and ZTF. This highlights the benefits of a first step followed in TERM and ZTF which entails detecting the central unit.

[6]And '≠ CU' for disagreement on central unit.

Table 2: Comparison between rhetorical relations linked and no-linked to central unit in structures with the same central unit

observe the relations linked to the central unit: 17.3% higher than the agreement on the relations that are not linked to the central unit. Populations being compared follow a normal distribution (p-value of K-S test was 0.93) but they do not have the same variance (p-value of F-test is 0.09). The result of the null hypothesis was rejected (p-value of t-test was smaller than 0.001), so we can establish a correlation. The average rhetorical relation agreement on a text according to the central unit, is no different to the average percentage of agreement in the rhetorical relations linked to the UC to those not linked.

4.3 Discussion of results

To illustrate the results on agreement (or not) on central unit and average agreement on rhetorical relations linked (or not) from Tables 1 and 2, we present comparisons of the populations in Figure 2:

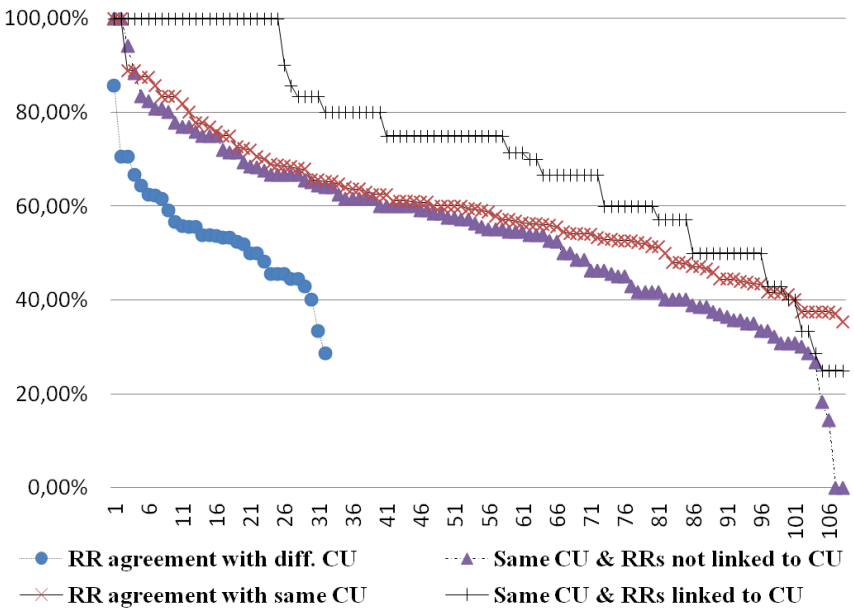
a. When the central unit was the same, the average agreement on relations is represented with red crosses.

b. When the central unit was different, the average agreement on relations is represented with blue circles.

c. When the central unit was the same and the relations are linked to central unit with black crosses.

d. When the central unit was the same and the relations are not linked to central unit with violet triangles.

Figure 2: Representation of mean agreement between RR (vertical) and the number of relations considered in a structure (horizontal) according to the central unit.



These results help to answer the first research question of this study and seem to indicate that there is a correlation between these two kinds of agreement: i) greater agreement on detecting the central unit correlates with greater agreement on the annotation of rhetorical relations (results from Table 1 are ilustrated in Figure 2 comparing the distance of the red croses [a] with blue circles [b]), ii) also on those which are linked to the central unit (results from Table 2 are ilustrated in Figure 2 comparing the distance

of the black croses $[c]$ with the violet triangles $[d]$).

This analysis leads to two conclusions:

i) When considering the methodology for labeling rhetorical structure, annotating the central unit is an important first step before labeling rhetorical relations at least in short texts such as abstracts.

ii) In Computational Linguistics, a process which helps to automatically identify the central unit is important for determining some restrictions in rhetorical structure mainly determined by the genre/domain structure.

In order to discuss these results, first of all we have to consider that the central unit is a nuclear unit and that relations are linked at various levels (intra-sentential level and inter-sentential level); there are more relations linked at inter-sentential level. For example, in Figure 1 two relations linked to central unit are only at inter-sentential level. This seems to show that these results (rhetorical relations linked to central unit) are not so trivial, since the degree of agreement expected at higher level tree structures is lower. In other words, the agreement at lower levels is higher than in the high level. For example, Marcu and Echihabi (2002) argue that automatic annotation of certain rhetorical relations should be addressed first at intra-sentential level because they are less ambiguous. Soricut and Marcu (2003) mention that some of the rhetorical relations are derived from syntactic structures. These results (11.50% higher agreement at intra-sentential level, than at inter-sentential level in the GMB corpus) were confirmed in Basque by Iruskieta et al. (2011b).

5 Identifying the semantic class of verbs in the central unit

Our final goal is the automatic detection of central unit. To this end, we wanted to find lexical-semantic markers in the central unit[7] in each domain in greater detail. The meanings of the main verbs were analyzed and their semantic class determined as per the SUMO ontology (Niles, 2003). The relation between meaning and semantic class was obtained by means of the MCR semantic database, which includes various lexical-semantic and ontological databases. Data from the GMB, TERM, and ZTF corpora are grouped in Table 3 by semantic classes at the most general level, e.g. "Intentional Psychological Process" (IPP), "Social Interaction" (SI), "Internal Change" (IC) and "Predicate".

SUMO	SUMO	MCR synset	GMB	TERM	ZTF
IP-IPP	Reasoning	analyze$_1$, show$_2$, base$_1$	**0.4615**	0.2273	0.0870
	Comparing	value$_2$, compare$_1$	**0.2692**		
	Classifying	classify$_1$			0.0870
	Learning	review$_1$	0.0385		
	Guiding	take$_3$		0.0455	
	Process	gain$_4$			0.1739
IP-IPP		recognize$_2$, determine$_8$, hold$_6$, focus$_1$	0.0385	0.0909	0.0435
IP-SI	Communication	present$_2$, addres$_9$, recount$_1$, propose$_1$	0.0385	**0.4545**	0.0435
IP		perform$_1$, target$_1$, set-up$_{15}$, work$_1$, make$_3$, use$_1$	0.1154	0.0909	0.0870
IP	Searching-Investigating	investigate$_1$			0.0435
IP	Organizational Process	serve$_2$			0.0435
IC		palliate$_2$		0.0455	
Predicate		be$_1$, develop$_5$, constitute$_1$, hold$_4$	0.0385	0.0455	0.3913

Table 3: Summary comparison of verbs by domain

The results of this empirical study indicate that each domain tends to use verbs from the same semantic class. For example, in the GMB corpus, the central unit was usually marked with verbs from the IPP category. On the other hand, in the TERM corpus, verbs from the IPP and SI category. Verbs in the central unit of the ZTF corpus are marked with IPP and Predicate class.

Therefore, the results demonstrate that:

[7]Results show that there are multiple EDUs functioning as the central unit of the text in the three corpora: 9 multiple EDU functioning as central unit in GMB, 2 multiple EDUs in TERM and 3 multiple EDUs in ZTF.

i) A study is needed to identify the SUMO class of the verbs used in a specific domain. For example in our corpus the central units is indicated with verbs that belong to the IPP class for all three domains. However, other classes also have to be considered, SI for TERM and Predicate for ZTF.

ii) In the case of weak verbs, other indicators[8] help to identify the central unit. The TERM and ZTF corpora are more marked by noun class indicators than the GMB corpus (Iruskieta, 2014). Another reason is that the direct observation of the central unit makes the central unit selection more consistent. An evidence of that is that all the verbs in central unit are from the same SUMO class in TERM and ZTF corpora by both annotators. Futhermore, it could also be argued that the use of different verbs has to do not only with the field but also with the medium: the GMB corpus derives from texts published in a periodical while the TERM and ZTF corpora include texts published in Conference proceedings. In other words, it could be argued that the medium influences the writing style, and consequently, impacts the verb classes used in the texts. This is in line with the main argument of this study, since different verbs are used to indicate the central unit in the TERM and ZTF corpora, which share the same medium but belong to different fields.

So far, this paper has provided a partial answer to the second research question. However, to automatically detect the central unit by means of verbs (with the help of other types of signals) it is necessary to consider these three issues:

i) The verb form which is used in the central unit might also be used in non-central units in the rhetorical structure tree.

ii) Tools which disambiguate the sense of analyzed verbs are necessary in order to know what SUMO class they belong to.[9]

iii) The central unit is not always indicated with a verb and, therefore, other types of signals (or combinations) can help in the automatic identification of the central unit.

The next phase of this research considered whether verb forms which appear in the central unit unequivocally indicate this unit or whether they can also appear in other types of units. This entailed calculating the frequency with which each studied verb appeared and counting the percentage of appearances which correspond to the central unit.

From the results obtained so far we can't establish any clear tendency but rather some preliminary conclusions that must be ratified with the analysis of more data.

Phenomena related to the central unit appeared in this study of ambiguity:

i) In GMB corpus verbs that indicate the central unit with a high enough frequency are from IPP category *baloratu* 'value2'; there exist other verbs that can be considered but they are not so frequent, e.g. *alderatu* 'compare$_1$', *gainbegiratu* 'review$_1$', *aztertu* and *analizatu* 'analyze$_1$', and *ezagutu* 'recognize$_2$'.

ii) In TERM corpus, the second sense of the verb present in MCR, 'present$_2$' (its equivalents in Basque are the verbs *plazaratu*, *aurkeztu*, *aipatu*, *berri eman* and *jardun*), has a high frequency but a high degree of ambiguity. We can't identify the central unit on the basis of its occurrence.

iii) In the ZTF corpus, the central unit was not always indicated with a verb.

6 Conclusions and future research

After considering the relationship between identifying the central unit in a text and annotating its rhetorical structure, it has been demonstrated that a correlation exists between these two tasks, since a greater degree of agreement with regard to the central unit leads to a greater degree of agreement in rhetorical. Besides there is more agreement in rhetorical relations linked to the central units than in relations that are not linked.

This study has investigated verbs which mark the central unit of a rhetorical structure and the correlation of the agreement in central unit with the agreement in rhetorical relations. Its goal has been

[8] According to Paice (1980) indicators can be nouns ('paper', 'method', 'result'), determiners ('this', 'the', 'a') and pronouns ('we', 'I'), among others.

[9] In attempting to automatically detect coherence relations which are not indicated or vaguely indicated using WordNet (Miller et al., 1990) Sporleder and Lascarides (2007) obtained better results using morphological strategies than using semantic generalization strategies. This is due to the fact that, as far as we know, NLP has yet to focus on disambiguating words.

to consider aspects which are relevant for establishing a methodology to help set general criteria for identifying the central unit of texts.

This study also considered which verbs appear in the central units, their semantic classes (according to SUMO categories), and how they identify the central unit. Verbs used to indicate the central units vary in different domains: in the GMB corpus, the central unit was more frequently and the least ambiguously indicated with verbs from the IPP category (SUMO), while in the TERM, SI verbs were most frequent and the least ambiguous.

Testing these results in a larger corpus (and different domains and text structures) could lead to applications for automatic text summarization tasks (classifying clauses), since the central unit is the most important unit in the text.

Furthermore, this study has explained the steps to automatically detect the central unit based on the ambiguity of the verb which marks the central unit. More studies about other indicators (and their combinations) are necessary to automatically detect the central unit.

Measuring Lexical Cohesion: Beyond Word Repetition

Abstract

This paper considers the problem of finding topical shifts in documents and in particular at what information can be leveraged to identify them. Recent research on topical segmentation usually assumes that topical shifts in discourse are signalled by changes in vocabulary. This information, however, is not always a sufficient indicator of a topical shift, especially for certain genres. This paper explores an additional source of information. Our hypothesis is that the type of a referring expression is an indicator of how accessible its antecedent is. The shorter and less informative the expression (*e.g.,* a personal pronoun *versus* a lengthy post-modified noun phrase), the more accessible the antecedent is likely to be and the more likely it is that the topic under discussion has remained constant between the two mentions. We explore how this information can be used to augment a lexically-based topical segmenter. We test our hypothesis on two types of data, literary narratives and lecture notes. The results suggest that our similarity metric is useful: depending on the settings it either slightly improves the performance or leaves it unchanged. They also suggest that certain types of referring expressions are more useful than others.

1 Introduction

In the past 10 years, research on topical segmentation has mostly centred on using surface vocabulary to identify topical shifts. The intuition is that if the vocabulary changes perceptibly, so does *the topic* under discussion. One popular way to model this assumption is by probabilistic graphical models. A document may be modelled as a sequence of strings (*e.g.,* sentences) generated by a latent topic variable, where the topic variables correspond to distributions over a finite vocabulary. Similarity-based methods are an alternative methodology. The segmenter explicitly measures the amount of lexical similarity between sentences. Places where similarity is low are likely to indicate shifts of topic. The common thread among these approaches is that they rely almost exclusively on the explicitly mentioned words.

The idea that vocabulary shifts indicate topical shifts dates back to Youmans (1991). Indeed, by and large, introducing new concepts almost necessarily requires that the concepts be named and described. How densely the concepts are explicitly mentioned and how often the mentions are repeated depends to a large degree on the genre and on the cognitive complexity of the document. In scientific papers or legal documents clarity is paramount, so the author will endeavour to state things explicitly and avoid ambiguity. The less complicated the document, however, the less it is necessary to explicitly repeat terminology. In literature, for example, word repetition is not only uncommon, but it is usually a sign of bad writing. In casual conversations, the topic can easily be never mentioned explicitly. How can we identify topical shifts in a document whose author does not "hold the reader's hand"?

It turns out that lexical cohesion (or, put simply, word repetition) is only one of several devices of cohesion (Halliday and Hasan, 1976, p. 29) Other possibilities are reference, substitution, ellipsis and conjunction. In this paper we mainly explore referential cohesion.

Proceedings of COLING 2014, the 25th International Conference on Computational Linguistics: Technical Papers, pages 476–485, Dublin, Ireland, August 23-29 2014.

Figure 1: An example dialogue from the *Moonstone* corpus

"What's wrong now?" I said once more.

"Rosanna's late again for dinner," says Nancy. "And I'm sent to fetch her in. All the hard work falls on my shoulders in this house. Let me alone, Mr. Betteredge!"

The person here mentioned as Rosanna was our second housemaid. "Where is she?" I inquired. [. . .]

"At the sands, of course!" says Nancy, with a toss of her head. "She had another of her fainting fits this morning, and she asked to go out and get a breath of fresh air. I have no patience with her!"

"Go back to your dinner, my girl," I said. "I have patience with her, and I'll fetch her in."

Figure 1 shows a snippet of a dialogue from the publicly available *Moonstone* corpus (Kazantseva and Szpakowicz, 2012). The two speakers discuss a specific person, *Rosanna*, yet her name is mentioned explicitly only twice. In the remainder of the dialogue the author uses pronouns to refer to this person, whose identity is evident from the context. Running an automatic segmenter on such a document would likely be challenging since focal concepts – characters – are often referred to by pronouns or definite noun phrases (NPs) instead of explicit repetition.

The focal entity *Rosanna* is introduced once and then it is referred to by nominal and pronominal anaphora, not by explicit repetition. Simplifying things somewhat, we can say that merely by the virtue of encountering a referring expression (*e.g., she* or *the person*), we know that it refers to something that must be clear from the context. The type of the referring expression also contains information about the availability of the antecedent. A *she* implies that the 'she' in question is rather obvious, that is to say, the antecedent is nearby and, more important for our purposes, the topical thread continues. A more verbose referring expression (*e.g., the woman in red*) is more likely in situations where the antecedent is less obvious and the reader needs additional information to disambiguate the expression.

The idea that the type of referring expression tells a lot about the accessibility of its antecedent dates back to Givón (1981). He postulated that the more informative the referring expression is, the less accessible the antecedent will be. Figure 2 shows the list of expressions from the least to the most informative. Projecting this information onto our task, we can say that the more informative the expression is, the less continuity there will be in the topic.

The main contribution of this work is to show how such information can be used to improve the quality of text segmentation. We extract NPs and classify them by informativeness. This is achieved with the help of a syntactic parser, but a lighter form of processing might do, perhaps even if it captured personal pronouns. Using this information, we augment and correct a matrix of lexical similarities between sentences, a structure frequently used as an input to a topical segmenter.

The results of using coreferential similarity are evaluated on a dataset of manually segmented chapters from a novel (Kazantseva and Szpakowicz, 2012) and on transcripts of lectures in Artificial Intelligence (Malioutov and Barzilay, 2006). We try the new similarity matrix on two publicly available similarity-based segmenters APS (Kazantseva and Szpakowicz, 2011) and MinCutSeg (Malioutov and Barzilay, 2006). The results suggest that the new matrix never hurts, and in several case improves, the performance of the segmenter, especially for the novel. We also check whether this metric would still be useful if instead of the traditionally used lexical similarity we used a similarity metric which took synonymy into account. In this case, the margin of improvement is lower, but still the coreferential similarity metric never hurts the performance and often improves it.

Section 2 of the paper gives an overview of related work. Section 3 describes our similarity metric and how we compute it. Section 4 shows the details of the experiments, while Section 5 discusses the results. We conclude in Section 6 with a discussion of how our metric can be improved and simplified.

2 Background and related work

Much of research on topical segmentation of text is based on the idea that changes of topic are usually accompanied by vocabulary changes. Introduced by Youmans (1991), it has since formed the backbone

of research on topical segmentation. We now briefly review recent work on text segmentation. Since the focus of this research is on what information is useful for text segmentation, this review emphasizes representations rather than algorithms.

Perhaps the simplest way of estimating topical similarity between sentences is to measure cosine similarity between corresponding feature vectors. It has been used extensively in text segmentation. Hearst (1994; 1997) describes TextTiling, an algorithm which identifies topical shifts by sliding a window through the document and measures cosine similarity between adjacent windows. The drops in similarity signal shifts of topic. More recently, Malioutov and Barzilay (2006) as well as Kazantseva and Szpakowicz (2011) use graph cuts and factor graph clustering for text segmentation. Both systems rely on cosine similarity between bag-of-word vectors as an underlying representation.

While cosine similarity between vectors is easy to compute, it is hardly a reliable metric of topical similarity. Several researchers have used *lexical chains* – first introduced by Halliday and Hasan (1976) – to improve the performance of topical segmenters.[1] The intuition behind using lexical chains for text segmentation is that the beginning and end of a chain tend to correspond to the beginning and end of a topically cohesive segment. One version of TextTiling (Hearst, 1997) uses lexical chains manually constructed using Roget's Thesaurus. Okumura and Honda (1994) apply automatically created lexical chains to segment a small set of documents in Japanese. More recently, Marathe (2010) tried to build lexical chains using distributional semantics and apply the method to text segmentation.

Other proposals to move beyond word repetition in topical segmentation include the use of bigram overlap in (Reynar, 1999), information about collocations in (Jobbins and Evett, 1998), LSA (Landauer and Dumais, 1997) in (Choi et al., 2001; Olney and Cai, 2005) and WordNet in (Scaiano et al., 2010).

It should be noted that much of the recent work on topical segmentation revolves around generative models. For example Blei and Moreno (2001) use HMM,while Eisenstein and Barzilay (2008), Misra et al. (2011) and Du et al. (2013) use higher-order models. We do not review this work in detail here because it centers on algorithms for text segmentation and not on the information supplied to those algorithms, which is the focus of this research. Fundamentally, the text is modelled as a sequence of tokens generated by latent topic variables. Although probabilistic segmenters can be extended to use additional information (*e.g.,* Eisenstein and Barzilay (2008) augment their segmenter with information about discourse markers), it is not trivial to change these models to include information such as synonymy, co-reference and so on. That is why we do not review them in detail here.

As this brief review shows, a number of approaches have been proposed to measure cohesion between sentences, that is to say, to describe to what extent a pair of sentences is "about the same thing". Most of them have a common denominator: they use explicit lexical information, sometimes augmented by semantic relations from thesauri or ontologies.

Lexical resources, such as ontologies and knowledge-bases, may help improve the quality of segmentations, but such resources are not always available. They also may cause problems with precision. More important, however, they do not solve a more fundamental problem: a text may be highly cohesive and coherent without being tightly bound by either lexical cohesion or synonymy.

The main ideas developed in this work originate in (Givón, 1981). The author looks at the functional domain of topical accessibility. A number of coding devices affect this property. They are listed in Figure 2, ordered from the devices used to mark the most continuous topics to those which mark the least continuous topics. The order in Figure 2 is governed by a simple principle: the more accessible the topic is, the less information is used to code it. The author argues that the continuum is applicable in many languages. He also mentions that while the exact values of the phenomenon in question are difficult to predict or even estimate, their relative order can be predicted with certainty, even if some devices are unavailable in some languages.

In a similar spirit, Ariel (2014) groups non-initial NPs into expressions with *low accessibility* (definite NPs and proper names), those with *intermediate accessibility* (personal and demonstrative pronouns) and those with *high accessibility* (pronouns).

In this work, we propose to leverage the presence and type of co-referential relations to improve

[1] Very simply put, a lexical chain is a sequence of related words in a text.

the results of two recent similarity-based segmenters. Instead of resolving anaphoric references, we assume that their mere presence often indicates topic continuity. With this augmented model, we segment fiction and spoken lecture transcripts, the two types of data where low rates of lexical cohesion preclude achieving segmentation of good quality using only surface information about token types.

3 Estimating coreferential similarity

In order to see whether knowledge about types of referential expressions is useful for measuring topical similarity, we incorporate this information into two publicly available similarity-based topical segmenters, *MCSeg* (Malioutov and Barzilay, 2006) and *APS* (Kazantseva and Szpakowicz, 2011). Normally, both *MCSeg* and *APS* measure similarity between sentences by computing cosine similarity between the vectors corresponding to bag-of-words representation for each sentence:

$$sim(s_1, s_2) = \frac{s_1 \bullet s_2}{||s_1|| \times ||s_2||} \quad (1)$$

Each atomic unit of text is represented as a vector of features corresponding the occurrences of each token type. The vectors are weighted using $tf.idf$ values for each token type. Next, a segmenter measures cosine similarity between vectors according to Equation 1. That is the fundamental representation in both *MCSeg* and *APS*. *MCSeg* identifies segment boundaries by creating a weighted cyclic graph and cutting it so as to maximize the sum of edges within segments and to minimize the sum of severed edges. *APS* segments the sequence by finding segment centres – points which best capture the content of a segment – and assigning data points to best segment centres so as to maximize net similarity.

The proposed similarity metric relies on the following idea: in order to measure how many concepts two sentences share, we do not need to resolve anaphoric expressions in full, but only to map them onto sentences which contain their most recent antecedent (without actually naming the antecedents). We do that by parsing the documents with the Connexor parser (Tapanainen and Järvinen, 1997) and extracting all NPs with their constituents. Next, we attempt to classify the NPs into categories which would roughly correspond to those listed in Figure 2 and to those in (Ariel, 2014).

A manual study by Brown (1983) suggests that the average referential distance for animate and inanimate entities differs widely within the same document.[2] That is why it makes sense to distinguish between these two types. In the end, then, we classify each identified NP into one of the categories listed in Figure 3. The list is not exhaustive and in some cases an NP may belong to more than one type. In practice, however, an NP is always assigned a single type dictated by the implementation.

[2]Brown (1983, pp. 323-324) compares referring expressions which denote human and non-human entities. She uses three measurements: average distance to the nearest antecedent, average ambiguity and persistence. On all three counts, human and non-human entities appear to have different distributions.

Figure 2: Linguistic coding devices which signal topic accessibility (Givón, 1981)

Most continuous (least surprising)

1. zero anaphora
2. unstressed pronouns (*e.g., He* was speaking loudly.)
3. right-dislocated definite noun phrases (NPs) (*e.g.,* It is no good, *that book*.)
4. neutral-ordered definite NPs (*e.g., That book* is no good.)
5. left-dislocated definite NPs (*e.g., That book*, it is no good.)
6. Y-moved NP's (*e.g., The book* they read in turns.)
7. cleft/focus constructions (*e.g.,* It was *that book*, that was on her mind for weeks.)
8. referential indefinite NPs (*e.g.,* He picked up *a book* and left.)

Least continuous (most surprising)

Figure 3: Categories of noun phrases taken into account when computing coreferential similarity

1. animate personal pronouns (*he, she, they*)
2. inanimate pronouns (*it*)
3. demonstrative pronouns (*that, those*)
4. animate proper names (*John Hernecastle*)
5. inanimate proper names (*London*)
6. animate definite noun phrases (*the man*)
7. inanimate definite noun phrases (*the jewel*)
8. animate indefinite noun phrases (*a man*)
9. inanimate indefinite noun phrases (*a jewel*)

Finally, coreferential similarity between sentences S_i and S_j is measured as follows:

$$coref\_sim(S_i, S_j) = \left(\frac{\sum_{t=0}^{|T|} count_t^{S_j} \times weight_t}{|S_1| \times |S_2|}\right)^{(j-i-1)\times decayFactor} \quad (2)$$

T is the set of of all types of referring expressions which we consider – those given in Figure 3. $count_t^{S_j}$ is the number of times when an expression of type t appears in the most recent sentence, S_j. Note that we only consider the referring expressions in the most recent sentence, because a referring expression, by its nature, must refer to something previously mentioned. The "tightness" of the link is controlled by setting $weight_t$ for each expression type t. $weight_t$ effectively specifies how likely it is that the antecedent for an expression of a type t appears in sentence s_i. The values of the weights are set experimentally on the holdout data. They can almost certainly be further fine-tuned. Intuitively, the settings of the weights reflect the logic behind Givón's theory. Consider an example vector of weights for expressions, where a higher weight corresponds to a more accessible antecedent (for animate and inanimate entities respectively).

<personal_pronouns_anim: 4, demonstr_pronouns_anim: 2, proper_names_anim: 1,
def_np_anim: 0.5, indef_np_anim: 0, pronouns_inanim: 2, demonstr_pronouns_inanim: 2,
proper_names_inanim: 0, def_np_inanim: 0, indef_np_inanim: 0>

The denominator of Equation 2 normalizes the value by the product of the lengths of sentences S_1 and S_2. The exponent $(j - i - 1) \times decayFactor$ is responsible for decreasing similarity as the distance between sentence S_i and S_j increases. The decay factor, $0 < decayFactor < 1$, is set experimentally, and $j - i$ is the distance between sentences S_i and S_j, $i < j$.

Figure 4 contains a walk-through example of computing referential similarity between two sentences.

The coreferential similarity as defined by Equation 2 is rather limited. The first limitation is the range: it can only measure similarity between nearby sentences or paragraphs, because it only makes sense between the closest occurrences of an antecedent and a subsequent referring expression. For example, it does not make sense to measure coreferential similarity between sentences that are several paragraphs apart. Even if they indeed talk about the same entities, the topic has most likely been re-introduced several times in between. That is why we only compute coreferential similarity for sentences no more than $decayWindow$ sentences apart. The value of $decayWindow$ is usually between 2 and 6 and it is set experimentally on the holdout set for each corpus.

The values of $coref_sim$ are usually quite small and the information used is rather one-sided. We use it, therefore, in addition to, not instead of, lexical similarity. In our experiments, we first compute lexical similarity between sentences (or paragraphs) and then modify the lexical matrix by adding to it the matrix of coreferential similarity.

Figure 4: An example of computing coreferential similarity

$$coref\_sim(S_i, S_j) = \left(\frac{\sum_{t=0}^{|T|} count_t^{S_j} \times weight_t}{|S_1| \times |S_2|}\right)^{(j-i-1)\times decayFactor}$$

S1: "At the sands, of course!" says Nancy, with a toss of her head.
S2: "She had another of her fainting fits this morning, and she asked to go out and get a breath of fresh air."

Expression counts:	Weights:
personal_pronouns_anim: 2 (she, she)	4
demonstr_pronouns_anim: 0	2
proper_names_anim: 1	1
def_np_anim: 0	0.5
indef_np_anim: 0	0
pronouns_inanim: 0	2
demonstr_pronouns_inanim: 1	2
proper_names_inanim: 0	0
def_np_inanim: 2 (this morning, fainting fits)	0
indef_np_inanim: 1 (a breath)	0

$$coref\_sim(S_2, S_1) = \frac{2 \times 4 + 1 \times 1 + 1 \times 2}{21 \times 22}^{(2-1-1)\times 0.5} = 0.0234$$

4 Experimental results

The effectiveness of coreferential similarity metric has been tested in practice. A set of experiments compared how much the metric improves the quality of topical segmentations. To this end, we ran *APS* and *MCSeg* with and without adding coreferential similarity to lexical similarity, and compared the results. We chose these segmenters for comparison because $coreferential\_similarity$ can only be naturally incorporated into a similarity-based segmenter.

Data. In our experiments we used two publicly available datasets. The first one is a set of lectures on Artificial Intelligence (Malioutov and Barzilay, 2006). The dataset contains 22 documents which were manually annotated for the presence of topical shifts. The second dataset is the *Moonstone* dataset described in (Kazantseva and Szpakowicz, 2012). It contains 20 chapters from Wilkie Collins's novel, each annotated by 4-6 people. To reconcile these multiple reference annotations, we create a majority gold standard. It only contains segment breaks which were marked by at least 30% of the annotators. Both segmenters are compared against this gold standard. There is a fair amount of disagreement between the annotators of this dataset. The average inter-annotator *windowDiff* is 0.38 (Kazantseva and Szpakowicz, 2012, pp. 215-216), but if one takes into account near-hits, then at least 50% of the boundaries are marked by more than two annotators.

Both datasets are quite challenging. The lecture dataset contain a lot of rather informal speech and there is not as much lexical repetition as would be in a more formal text. The *Moonstone* dataset is an example of literary language, full of small digressions, dialogue and so on.

The first dataset is annotated at the level of individual sentences. The second dataset is annotated at the level of paragraphs. We segment both datasets at the level of the gold-standard annotations (sentences for lectures, paragraphs for the novel).

When working with paragraphs, $coref\_sim$ is computed slightly differently:

$$coref\_sim(p_i, p_j) = \left(\frac{\sum_{t=0}^{|T|} count_t^{p_j} \times weight_t}{|p_1| \times |p_2|}\right)^{(j-i-1)\times decayFactor} \quad (3)$$

In this case, $count_t^{p_j}$ refers to the number of occurrences of expression of type t in the first $paragraphCutOff$ sentences of the paragraph p_j, instead of the whole paragraph. The rationale behind this heuristic is that the referring expressions in the opening sentences of the paragraph are likely to refer

to entities from the previous paragraph, while expressions in the middle or the end of the paragraph are likely to refer to entities introduced inside the paragraph.

Segmenters and baselines. We use two publicly available topical segmenters in our experiments: *MCSeg* and *APS*. The default version of each segmenter computes a similarity matrix between sentence in the input document. The values in the matrix correspond to cosine similarity (Equation 1) computed after the removal of stop words and weighting the bag-of-word vectors by $tf.idf$. The results obtained using these default matrices are our first baseline.

In our experiments, we modify this matrix by adding to it the matrix of coreferential similarities. The values of coreferential similarities are rather small and most modifications are localized. That is because the value of $decayWindow$ is set between 2 and 6 (see Section 3).

In addition to the matrices based on cosine similarity, we wanted to see if using a more intelligent measure of topical similarity improves the results. We built one more flavour of similarity matrices using the *DKPro Similarity* framework (Bär et al., 2013). The framework contains a model of textual similarity which has been used by the winning system at the SemEval Textual Similarity 2012 shared evaluation. We use this model (further *STS-2012*) as a more competitive baseline for computing topical similarity.

The *STS-2012* baseline consists of a log-linear regression model trained on the SemEval 2012 training data. It combines an assortment of measures of textual similarity to come up with its judgments. The metrics include n-gram overlap, semantic similarity measures (based on both corpora and lexical resources) and several measures of stylistic similarity. We chose to use this relatively complicated metric because of its competitive performance at SemEval 2012. The system, however, was not designed to measure topical similarity *per se*, especially between many sentences coming from the same source document. By default, the *STS-2012* baseline outputs values between 1 and 5. These were normalized to be between 0 and 1.

Similarly to the experimental design with cosine similarity matrices, we try running the segmenters using *STS-2012* with and without adding coreferential similarity matrix to it.

On both datasets we set the weights for various types of referential expressions using hold-out sets of two files. When setting the weights, we were guided by the principle captured in Figure 2: personal pronouns suggest the tightest link, followed by demonstrative pronouns, proper names, and so on.

It should be noted that because we had to modify the native representation of both segmenters by supplying a matrix computed using non-native code, we could not use the proper training scripts which come with the segmenters. In effect, the results are likely to be lower than they could have been. Even so, this is acceptable for our purposes because we are interested in the improvement gained by using coreferential similarity, not in obtaining the best possible segmentation via the setting of the best parameters.

Processing. We computed the underlying lexical similarity matrices using the same procedure as described in (Malioutov and Barzilay, 2006; Kazantseva and Szpakowicz, 2011), but using our own code. In other words, we built a matrix of cosine similarities after removing stop words and weighting the underlying vectors by $tf.idf$ values.

In order to compute coreferential similarity, all documents were parsed using the Connexor parser (Tapanainen and Järvinen, 1997). The parser was chosen because it produces high-quality partial parses of long sentences often encountered in the *Moonstone* dataset. We also tagged named entities and labelled NPs as animate or inanimate using the Stanford Core NLP suite.[3]

Metrics. We compare topical segmentations using the *windowDiff* metric:

$$winDiff = \frac{1}{N-k} \sum_{i=1}^{N-k} (|ref - hyp| \neq 0) \tag{4}$$

windowDiff slides a window of size k through the input sequence of length N. At every position of the window, the metric compares the number of boundaries in the reference sequence and in the hypothetical sequence. The number of erroneous windows is normalized by the total number of windows to obtain the final value. *windowDiff* is a penalty metric: lower values correspond to better segmentations.

Table 1: Results of comparing *APS* and *MCSeg* using four different matrix types (*windowDiff* values and standard deviation)

5 Evaluation

Table 1 presents the results of running *APS* and *MCSeg* using four different input matrices each. The first column shows the combination of the name of the segmenter and the specific input matrix. *APS* and *MCSeg* refer to the cases where both segmenters were run using simple cosine similarity matrices. STS refers to matrices computed using *STS-2012* from the *DKPro Similarity* framework. $coref\_sim$ refers to cosine similarity matrices modified by adding a matrix with coreferential similarities. $STS-coref\_sim$ are matrices computed using *STS-2012* which had coreferential similarity added to them.

In all experiments, we set the weights for different types of referring expressions on two hold-out files. The remainder of the data is divided into five folds. Standard deviation reported in the tables is computed across folds.

Coreferential similarity improves the results of the cosine matrix for both segmenters, but the improvement on the AI dataset is rather small (1% for *APS* and 2% for *MCSeg*).

It is interesting to see that in most cases using STS matrices slightly hurts the performance of the segmenters compared to using simple cosine similarity matrices. The only exception is running *MCSeg* on the *Moonstone* dataset which improves the performance by 3%.

Adding a matrix of coreferential similarities to STS matrices slightly improves the performance on the *Moonstone* dataset and leaves it practically unchanged on the dataset of AI lectures.

It is somewhat surprising that using *STS-2012* for similarity computation does not improve, and occasionally worsens, the results compared to using simple cosine similarity. Coreferential similarity, on the other hand, produces a small but consistent improvement.

We have examined the vectors of weights used in these experiments (set using hold-out data). On the *Moonstone* dataset, the results are the best when personal animate pronouns get the highest weight, followed by demonstrative animate pronouns, as well as inanimate pronouns, both regular and demonstrative. Other expression types are assigned either a very small weight or the value 0, effectively making them inconsequential. We hypothesize that this is due to the fact that the novel discusses people, their relations and interactions, making animate entities central for estimating topical links.

The vectors used on the AI lecture dataset are similar, except that here the highest weights are given to demonstrative and regular inanimate pronouns. These are followed by demonstrative and then regular animate pronouns. This distribution is likely due to the fact that the lecture dataset discusses abstract concepts, while people are likely to be noted more tangentially. We are not sure how to explain the fact that in this dataset demonstrative pronouns have a slightly higher weight than the regular ones.

Identifying and categorizing noun phrases requires either high-quality NP-tagging or parsing. On the other hand, most pronouns can be captured very easily, perhaps even using a list of words. It is interesting to note that the most gain is due to these "cheap" types of referring expressions. In the future, we plan to implement a lighter version of the coreferential similarity metric which only considers pronouns.

6 Conclusions and future work

This paper has presented a method for improving the quality of topical segmentations by using information about referential expressions in nearby sentences. The method slightly improves the quality of segmentations and, what is even more important, seems never to worsen the results.

The necessity to perform complete parsing of the input document is a drawback of the current approach. We note in Section 5, however, that the only types of referential expressions which improve performance are personal and demonstrative pronouns. Those can be easily captured without parsing. In the near future we plan to investigate such a light-weight version of $coref\_sim$ metric.

Another way to improve our current implementation would be a more objective method of setting the weights for different types of referring expressions. At present, the expressions are set by hand on a small hold-out set of documents. This is far from ideal. We plan to investigate if using logistic regression or expectation maximization would make the system more robust.

Abstract

The most widely used similarity measure in the field of natural language processing may be cosine similarity. However, in the context of Twitter, the large scale of massive tweet data inevitably makes it expensive to perform cosine similarity computations among tremendous data samples. In this paper, we exploit binary coding to tackle the scalability issue, which compresses each data sample into a compact binary code and hence enables highly efficient similarity computations via Hamming distances between the generated codes. In order to yield semantics sensitive binary codes for tweet data, we design a binarized matrix factorization model and further improve it in two aspects. First, we force the projection directions employed by the model nearly orthogonal to reduce the redundant information in their resulting binary bits. Second, we leverage the tweets' neighborhood information to encourage similar tweets to have adjacent binary codes. Evaluated on a tweet dataset using hashtags to create gold labels in an information retrieval scenario, our proposed model shows significant performance gains over competing methods.

1 Introduction

Twitter is rapidly gaining worldwide popularity, with 500 million active users generating more than 340 million tweets daily[1]. Massive-scale tweet data which is freely available on the Web contains rich linguistic phenomena and valuable information, therefore making it one of most favorite data sources used by a variety of Natural Language Processing (NLP) applications. Successful examples include first story detection (Petrovic et al., 2010), local event detection (Agarwal et al., 2012), Twitter event discovery (Benson et al., 2011) and summarization (Chakrabarti and Punera, 2011), etc.

In these NLP applications, one of core technical components is tweet similarity computing to search for the desired tweets with respect to some sample tweets. For example, in first story detection (Petrovic et al., 2010), the purpose is to find an incoming tweet that is expected to report a novel event not revealed by the previous tweets. This is done by measuring *cosine* similarity between the incoming tweet and each previous tweet.

One obvious issue is that cosine similarity computations among tweet data will become very slow once the scale of tweet data grows drastically. In this paper, we investigate the problem of searching for most similar tweets given a query tweet. Specifically, we propose a binary coding approach to render computationally efficient tweet comparisons that should benefit practical NLP applications, especially in the face of massive data scenarios. Using the proposed approach, each tweet is compressed into short-length binary bits (*i.e.*, a *compact binary code*), so that tweet comparisons can be performed substantially faster through measuring Hamming distances between the generated compact codes. Crucially, Hamming distance computation only involves very cheap NOR and popcount operations instead of floating-point operations needed by cosine similarity computation.

Compared to other genres of data, similarity search in tweet data is very challenging due to the short nature of Twitter messages, that is, a tweet contains too little information for traditional models to extract

Proceedings of COLING 2014, the 25th International Conference on Computational Linguistics: Technical Papers, pages 486–496, Dublin, Ireland, August 23-29 2014.

Symbol	Definition
n	Number of tweets in the corpus.
d	Dimension of a tweet vector, *i.e.*, the vocabulary size.
$\boldsymbol{x}_i$	The sparse *tf-idf* vector corresponding to the i-th tweet in the corpus.
$\bar{\boldsymbol{x}}_i$	The vector subtracted by the mean $\boldsymbol{\mu}$ of the tweet corpus: $\bar{\boldsymbol{x}}_i = \boldsymbol{x}_i - \boldsymbol{\mu}$.
$X, \bar{X}$	The tweet corpus in a matrix format, and the zero-centered tweet data.
r	The number of binary coding functions, *i.e.*, the number of latent topics.
f_k	The k-th binary coding function.

Table 1: Symbols used in binary coding.

latent topical semantics. For instance, in our collected dataset, there exist only 11 words per tweet on average. We address the sparsity issue pertaining to tweet data by converting our previously proposed topic model*Weighted Textual Matrix Factorization* (WTMF) (Guo and Diab, 2012) to a binarized version. WTMF maps a tweet to a low-dimensional semantic vector which can easily be transformed to a binary code by virtue of a sign function. We consider WTMF a good baseline for the task of tweet retrieval, as it has achieved state-of-the-art performance among unsupervised systems on two benchmark short-text datasets released by Li et al. (2006) and Agirre et al. (2012).

In this paper, we improve WTMF in two aspects. The first drawback of the WTMF model is that it focuses on exhaustively encoding the local context, and hence introduces some overlapping information that is reflected in its associated projections. In order to remove the redundant information and meanwhile discover more distinct topics, we employ a gradient descent method to make the projection directions nearly orthogonal.

The second aspect is to enrich each tweet by its neighbors. Because of the short context, most tweets do not contain sufficient information of an event, as noticed by previous work (Agarwal et al., 2012; Guo et al., 2013). Ideally, we would like to learn a model such that the tweets related to the same event are mapped to adjacent binary codes. We fulfill this purpose by augmenting each tweet in a given training dataset with its neighboring tweets within a temporal window, and assuming that these neighboring (or similar) tweets are triggered by the same event. We name the improved model *Orthogonal Matrix Factorization with Neighbors* (OrMFN).

In our experiments, we use Twitter hashtags to create the gold (*i.e.*, groundtruth) labels, where tweets with the same hashtag are considered semantically related, hence relevant. We collect a tweet dataset which consists of 1.35 million tweets over 3 months where each tweet has exactly one hashtag. The experimental results show that our proposed model OrMFN significantly outperforms competing binary coding methods.

2 Background and Related Work

2.1 Preliminaries

We first introduce some notations used in this paper to formulate our problem. Suppose that we are given a dataset of n tweets and the size of the vocabulary is d. A tweet is represented by all the words it contains. We use notation $\boldsymbol{x} \in \mathbb{R}^d$ to denote a sparse d-dimensional *tf-idf* vector corresponding to a tweet, where each word stands for a dimension. For ease of notation, we represent all n tweets in a matrix $X = [\boldsymbol{x}_1, \boldsymbol{x}_2, \cdots, \boldsymbol{x}_n] \in \mathbb{R}^{d \times n}$. For binary coding, we seek r binarization functions $\left\{ f_k : \mathbb{R}^d \rightarrow \{1, -1\} \right\}_{k=1}^{r}$ so that a tweet $\boldsymbol{x}_i$ is encoded into an r-bit binary code (*i.e.*, a string of r binary bits). Table 1 illustrates the symbols used in this paper for notation.

Hamming Ranking: In the paper we evaluate the quality of binary codes in terms of Hamming ranking. Given a query tweet, all data items are ranked in an ascending order according to the Hamming distances between their binary codes and the query's binary code, where a Hamming distance is the number of bit positions in which bits of two codes differ. Compared with cosine similarity, computing Hamming distance can be substantially efficient. This is because fixed-length binary bits enable very cheap logic operations for Hamming distance computation, whereas real-valued vectors require floating-point op-

erations for cosine similarity computation. Since logic operations are much faster than floating-point operations, Hamming distance computation is typically much faster than cosine similarity computation[2]

2.2 Binary Coding

Early explorations of binary coding focused on using random permutations or random projections to obtain binary coding functions (aka, hash functions), such as Min-wise Hashing (MinHash) (Broder et al., 1998) and Locality-Sensitive Hashing (LSH) (Indyk and Motwani, 1998). MinHash and LSH are generally considered *data-independent* approaches, as their coding functions are generated in a randomized fashion. In the context of Twitter, the simple LSH scheme proposed in (Charikar, 2002) is of particular interest. Charikar proved that the probability of two data points colliding is proportional to the angle between them, and then employed a random projection $\boldsymbol{w} \in \mathbb{R}^d$ to construct a binary coding function:

$$f(\boldsymbol{x}) = \text{sgn}\big(\boldsymbol{w}^\top \boldsymbol{x}\big) = \begin{cases} 1, & \text{if } \boldsymbol{w}^\top \boldsymbol{x} > 0, \\ -1, & \text{otherwise.} \end{cases} \quad (1)$$

The current held view is that *data-dependent* binary coding can lead to better performance. A data-dependent coding scheme typically includes two steps: 1) learning a series of binary coding functions with a small amount of training data; 2) applying the learned functions to larger scale data to produce binary codes.

In the context of tweet data, Latent Semantic Analysis (LSA) (Landauer and Dumais, 1997) can directly be used for data-dependent binary coding. LSA reduces the dimensionality of the data in X by performing singular value decomposition (SVD) over X: $X = U\Sigma V^\top$. Let $\bar{X}$ be the zero-centered data matrix, where each tweet vector $\boldsymbol{x}_i$ is subtracted by the mean vector $\boldsymbol{\mu}$, resulting in $\bar{\boldsymbol{x}}_i = \boldsymbol{x}_i - \boldsymbol{\mu}$. The r coding functions are then constructed by using the r eigenvectors $\boldsymbol{u}_1, \boldsymbol{u}_2, \cdots, \boldsymbol{u}_r$ associated with the r largest eigenvalues, that is, $f_k(\boldsymbol{x}) = \text{sgn}\big(\boldsymbol{u}_k^\top \bar{\boldsymbol{x}}\big) = \text{sgn}\big(\boldsymbol{u}_k^\top (\boldsymbol{x} - \boldsymbol{\mu})\big)$ $(k = 1, \cdots, r)$. The goal of using zero-centered data $\bar{X}$ is to balance 1 bits and -1 bits.

Iterative Quantization (ITQ) (Gong and Lazebnik, 2011) is another popular unsupervised binary coding approach. ITQ attempts to find an orthogonal rotation matrix $R \in \mathbb{R}^{r \times r}$ to minimize the squared quantization error: $\|B - RV\|_{\text{F}}^2$, where $B \in \{1, -1\}^{r \times n}$ contains the binary codes of all data, $V \in \mathbb{R}^{r \times n}$ contains the LSA-projected and zero-centered vectors, and $\|\cdot\|_{\text{F}}$ denotes Frobenius norm. After R is optimized, the binary codes are simply obtained by $B = \text{sgn}(RV)$.

Much recent work learns nonlinear binary coding functions, including Spectral Hashing (Weiss et al., 2008), Anchor Graph Hashing (Liu et al., 2011), Bilinear Hashing (Liu et al., 2012b), Kernelized LSH (Kulis and Grauman, 2012), etc. Concurrently, supervised information defined among training data samples was incorporated into coding function learning such as Minimal Loss Hashing (Norouzi and Fleet, 2011) and Kernel-Based Supervised Hashing (Liu et al., 2012a). Our proposed method falls into the category of *unsupervised, linear, data-dependent* binary coding.

2.3 Applications in NLP

The NLP community has successfully applied LSH in several tasks such as first story detection (Petrovic et al., 2010), and paraphrase retrieval for relation extraction (Bhagat and Ravichandran, 2008), etc. This paper shows that our proposed data-dependent binary coding approach is superior to data-independent LSH in terms of the quality of generated binary codes.

Subercaze et al. (2013) proposed a binary coding approach to encode user profiles for recommendations. Compared to (Subercaze et al., 2013) in which a data unit is a whole user profile consisting of all his/her Twitter posts, we tackle a more challenging problem, since our data units are extremely short – namely, a single tweet.

[2]We recognize that different hardware exploiting techniques such as GPU or parallelization accelerate cosine similarity. However, they don't change the inherent nature of the data representation. They can be equally applied to Hamming distance and we anticipate significant speed gains. We relegate this exploration of different implementations of Hamming distance to future work.

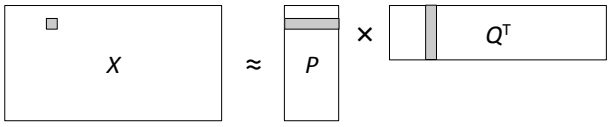

Figure 1: Weighted Textual Matrix Factorization. The $d \times n$ matrix X is approximated by the product of a $d \times r$ matrix P and an $n \times r$ matrix Q. Note in the figure we used the transpose of the Q matrix.

3 Weighted Textual Matrix Factorization

The WTMF model proposed by Guo and Diab (2012) is designed to extract latent semantic vectors for short textual data. The low-dimensional semantic vectors can be used to represent the tweets in the original high-dimensional space. WTMF achieved state-of-the-art unsupervised performance on two short text similarity datasets, which can be attributed to the fact that WTMF carefully handles missing words (the missing words of a text are the words with 0 values in a data vector $\boldsymbol{x}$).

Assume that there are r latent dimensions/topics in the data, the matrix X is approximated by the product of a $d \times r$ matrix P and an $n \times r$ matrix Q, as in Figure 1. Accordingly, a tweet $\boldsymbol{x}_j$ is represented by an r-dimensional vector $Q_{j,\cdot}$; similarly, a word w_i is generalized by the r-dimensional vector $P_{i,\cdot}$ (the ith row in matrix P). The matrix factorization scheme has an intuitive explanation: the inner-product of a word profile vector $P_{i,\cdot}$ and a tweet profile vector $Q_{j,\cdot}$ is to approximate the TF-IDF value X_{ij}: ${P_{i,\cdot}}^\top Q_{j,\cdot} \approx X_{ij}$ (as illustrated by the shaded parts in Figure 1).

Intuitively, $X_{ij} = 0$ suggests that the latent topics of the text $\boldsymbol{x}_j$ are not relevant to the word w_i. Note that 99% of the cells in X are 0 because of the short contexts, which significantly diminishes the contribution of the observed words to the searching of optimal P and Q. To reduce the impact of missing words, a small weight w_m is assigned to each 0 cell of X in the objective function:

$$\sum_i \sum_j W_{ij} \left({P_{i,\cdot}}^\top Q_{j,\cdot} - X_{ij} \right)^2 + \lambda ||P||_2^2 + \lambda ||Q||_2^2,$$
$$W_{i,j} = \begin{cases} 1, & \text{if } X_{ij} \neq 0, \\ w_m, & \text{if } X_{ij} = 0. \end{cases} \tag{2}$$

where λ is the regularization parameter. Alternating Least Squares (Srebro and Jaakkola, 2003) is used to iteratively compute the latent semantic vectors in P and Q:

$$P_{i,\cdot} = \left(Q^\top \tilde{W}^{(i)} Q + \lambda I \right)^{-1} Q^\top \tilde{W}^{(i)} X_{i,\cdot}^\top,$$
$$Q_{j,\cdot} = \left(P^\top \tilde{W}^{(j)} P + \lambda I \right)^{-1} P^\top \tilde{W}^{(j)} X_{\cdot,j} \tag{3}$$

where $\tilde{W}^{(i)} = \text{diag}(W_{i,\cdot})$ is a $n \times n$ diagonal matrix containing the i-th row of the weight matrix W. Similarly, $\tilde{W}^{(j)} = \text{diag}(W_{\cdot,j})$ is a $d \times d$ diagonal matrix containing the j-th column of W.

As in Algorithm 1 line 6-9, P and Q are computed iteratively, i.e., in a iteration each $P_{i,\cdot}(i = 1, \cdots, d)$ is calculated based on Q, then each $Q_{j,\cdot}(j = 1, \cdots, n)$ is calculated based on P. This can be computed efficiently since: (1) all $P_{i,\cdot}$ share the same $Q^\top Q$; similarly all $Q_{j,\cdot}$ share the same $P^\top P$; (2) X is very sparse. More details can be found in (Steck, 2010).

Adapting WTMF to binary coding is straightforward. Following LSA, we use the matrix P to linearly project tweets into low-dimensional vectors, and then apply the sign function. The k-th binarization function uses the k-th column of the P matrix ($P_{\cdot,k}$) as follows

$$f_k(\boldsymbol{x}) = \text{sgn}\left(P_{\cdot,k} \bar{\boldsymbol{x}}\right) = \begin{cases} 1, & \text{if } P_{\cdot,k} \bar{\boldsymbol{x}} > 0, \\ -1, & \text{otherwise.} \end{cases} \tag{4}$$

4 Removing Redundant Information

It is worth noting that there are two explanations of the $d \times r$ matrix P. The rows of P, denoted by $P_{i,\cdot}$, may be viewed as the collection of r-dimensional latent profiles of words, which we observe frequently

Algorithm 1: OrMF

Procedure P = `OrMF` $(X, W, \lambda, n\_itr, \alpha)$
$n\_words, n\_docs \leftarrow$ size(X);
randomly initialize P, Q;
$itr \leftarrow 1$;
while $itr < n\_itr$ **do**
  for $j \leftarrow 1$ **to** n_docs **do**
    $Q_{j,\cdot} = \left(P^\top \tilde{W}^{(j)} P + \lambda I\right)^{-1} P^\top \tilde{W}^{(j)} X_{\cdot,j}$
  for $i \leftarrow 1$ **to** n_words **do**
    $P_{i,\cdot} = \left(Q^\top \tilde{W}^{(i)} Q + \lambda I\right)^{-1} Q^\top \tilde{W}^{(i)} X_{i,\cdot}^\top$
  $c =$ mean(diag$(P^\top P)$);
  $P \leftarrow P - \alpha P(P^\top P - cI)$;
  $itr \leftarrow itr + 1$;

in the WTMF model. Meanwhile, columns of P are projection vectors, denoted by $P_{\cdot,k}$, which are similar to eigenvectors U obtained by LSA. The projection vector $P_{\cdot,k}$ is employed to multiply to a zero centered data vector $\bar{\boldsymbol{x}}$ to generate a binary string: sgn$({P_{\cdot,k}}^\top \bar{\boldsymbol{x}})$. In this section, we focus on the property of the P matrix columns.

As in equation 3, each row in matrices P and Q is iteratively optimized to approximate the data: ${P_{i,\cdot}}^\top Q_{j,\cdot} \approx X_{ij}$. While it does a good job at preserving the existence/relevance of each word in a short text, it might encode repetitive information by means of the dimensionality reduction or the projection vectors $P_{\cdot,k}$ (the columns of P). For example, the first dimension $P_{\cdot,1}$ may be 90% about the $politics$ topic and 10% about the $economics$ topic, and the second dimension $P_{\cdot,2}$ is 95% on $economics$ and 5% on $technology$ topics, respectively.

Ideally we would like the dimensions to be uncorrelated, so that more distinct topics of data could be captured. One way to ensure the uncorrelatedness is to force P to be orthogonal, i.e., $P^\top P = I$. It implies ${P_{\cdot,j}}^\top P_{\cdot,k} = 0$ if $k \neq j$.

4.1 Implementation of Orthogonal Projections

To produce nearly orthogonal projections in the current framework, we could add a regularizer $\beta(P^\top P - I)^2$ with the weight β in the objective function of the WTMF model (equation 6). However, in practice this method does not lead to the convergence of P. This is mainly caused by the phenomenon that any word profile $P_{i,\cdot}$ becomes dependent of all other word profiles after an iteration.

Therefore, we adopt a simpler method, gradient descent, in which P is updated by taking a small step in the direction of the negative gradient of $(P^\top P - I)^2$. It is also worth noting that $(P^\top P - I)^2$ requires each projection $P_{\cdot,k}$ to be a unit vector because of ${P_{\cdot,k}}^\top P_{\cdot,k} = 1$, which is infeasible when the nonzero values in X are large. Therefore, we multiply the matrix I by a coefficient c, which is calculated from the mean of the diagonal of $P^\top P$ in the current iteration. The following two lines are added at the end of an iteration:

$$\begin{aligned} c &\leftarrow \text{mean}(\text{diag}(P^\top P)), \\ P &\leftarrow P - \alpha P(P^\top P - cI). \end{aligned} \tag{5}$$

This procedure is presented in Algorithm 1. Accordingly, the magnitude of P is not affected. The step size α is fixed to 0.0001. We refer to this model as Orthogonal Matrix Factorization (OrMF).

5 Exploiting Nearest Neighbors for Tweets

We observe that tweets triggered by the same event do not have very high cosine similarity scores among them. This is caused by the inherent short length of tweets such that usually a tweet only describes one

aspect of an event (Agarwal et al., 2012; Guo et al., 2013). Our objective is to find the relevant tweets given a tweet, and then learn a model that assigns similar binary bits to these relevant tweets.

5.1 Modeling Neighboring Tweets

Given a tweet, we treat its nearest neighbors in a temporal window as its most relevant tweets. We assume that the other aspects of an event can be found in its nearest neighbors. Accordingly, we extract t neighbors for a tweet from 10,000 most chronologically close tweets. In this current implementation, we set $t = 5$.

Under the weighted matrix factorization framework, we extend each tweet by its t nearest neighbors. Specifically, for each tweet, we incorporate additional words from its neighboring tweets. The values of the new words are averaged. Moreover, these new words are treated differently by assigning a new weight w_n to them, since we believe that the new words are not as informative as the original words in the tweet.

We present an illustrative example of how to use neighbors to extend the tweets. Let $\boldsymbol{x}_1$ be a tweet with the following words (the numbers after the colon are TF-IDF values):

$\boldsymbol{x}_1$ = {obama:5.5, medicare:8.3, website:3.8}

which has two nearest neighbors:

$\boldsymbol{x}_{27}$ = {obama:5.5, medicare:8.3, website:3.8, down:5.4}

$\boldsymbol{x}_{356}$ = {obama:5.5, medicare:8.3, website:3.8, problem:7.0}

Then there are two additional words added in $\boldsymbol{x}_1$ whose values are averaged. The new data vector $\boldsymbol{x}'_1$ is:

$\boldsymbol{x}'_1$ = {obama:5.5, medicare:8.3, website:3.8, down:2.7, problem:3.5}

Therefore, the algorithm is run on the new neighbor-augmented data matrix, denoted by X', and the weight matrix W becomes

$$W_{i,j} = \begin{cases} 1, & \text{if } X'_{ij} \neq 0 \ \&j \text{ is an original word,} \\ w_n, & \text{if } X'_{ij} \neq 0, \ \&j \text{ is from neighbor tweets,} \\ w_m, & \text{if } X'_{ij} = 0. \end{cases} \tag{6}$$

This model is referred to as Orthogonal Matrix Factorization with Neighbors (OrMFN).

5.2 Binary coding without Neighbors

It is important to point out that the data used by OrMFN, X', could be a very small subset of the whole dataset. Therefore we only need to find neighbors for a small portion of the data. After the P matrix is learned, the neighborhood information is implicitly encoded in the matrix P, and we still apply the same binarization function $\text{sgn}({P_{\cdot,k}}^\top \bar{\boldsymbol{x}})$ on the whole dataset (in large scale) **without** neighborhood information. We randomly sample 200,000 tweets for OrMFN to learn P; neighbors are extracted only for these 200,000 tweets (note that the neighbors are from the 200,000 tweets as well), and then we use the learned P to generate binary codes for the whole dataset 1.35 million tweets **without** searching for their nearest neighbors.[3]

Our scheme has a clear advantage: the binary coding remains very efficient. During binarization for any data, there is no need to compare 10,000 most recent tweets to find nearest neighbors, which could be time-consuming. An opposite example is the method presented in (Guo et al., 2013), where t most nearest neighbor tweets were extracted, and a tweet profile $Q_{j,\cdot}$ was explicitly forced to be similar to its neighbors' profiles. However, for each new data, the approach proposed in (Guo et al., 2013) requires computing its nearest neighbors.

6 Experiments

6.1 Tweet Data

We crawled English tweets spanning three months from October 5th 2013 to January 5th 2014 using the Twitter API.[4] We cleaned the data such that each hashtag appears at least 100 times in the corpus, and

[3] When generating the binary codes for the 200,000 tweets, these tweets are not augmented with neighbor words.

[4] https://dev.twitter.com

each word appears at least 10 times. This data collection consists of 1,350,159 tweets, 15 million word tokens, 30,608 unique words, and 3,214 unique hashtags.

One of main reasons to use hashtags is to enhance accessing topically similar tweets (Efron, 2010). In a large-scale data setting, it is impossible to manually identify relevant tweets. Therefore, we use Twitter hashtags to create groundtruth labels, which means that tweets marked by the same hashtag as the query tweet are considered relevant. Accordingly, in our experiments all hashtags are removed from the original data corpus. We chose a subset of hashtags from the most frequent hashtags to create groundtruth labels: we manually removed some tags from the subset that are not topic-related (e.g., *#truth*, *#lol*) or are ambiguous; we also removed all the tags that are referring to TV series (the relevant tweets can be trivially obtained by named entity matching). The resulting subset contains 18 hashtags.[5]

100 tweets are randomly selected as queries (test data) for each of the 18 hashtags. The median number of relevant tweets per query is 5,621. The small size of gold standard makes the task relatively challenging. We need to identify 5,621 (0.42% of the whole dataset) tweets out of 1.35 million tweets.

200,000 tweets are randomly selected (not including the 1,800 queries) as training data for the data dependent models to learn binarization functions.[6] The functions are subsequently applied on all the 1.35 million tweets, including the 1,800 query tweets.

6.2 Evaluation

We evaluate a model by the search quality: given a tweet as query, we would like to rank the relevant tweets as high as possible. Following previous work (Weiss et al., 2008; Liu et al., 2011), we use mean precision among top 1000 returned list (MP@1000) to measure the ranking quality. Let pre@k be the precision among top k return data, then MP@1000 is the average value of pre@1, pre@2...pre@1000. Obviously MP gives more reward on the systems that can rank relevant data in the top places, e.g., if the highest ranked tweet is a relevant tweet, then all the precision values (pre@2, pre@3, pre@4...) are increased. We also calculate the precision and recall curve at varying values of top k returned list.

6.3 Methods

We evaluate the proposed unsupervised binary coding models OrMF and OrMFN, whose performance is compared against 5 other unsupervised methods, LSH, SH, LSA, ITQ, and WTMF. All the binary coding functions except LSH are learned on the 200,000 tweet set. All the methods have the same form of binary coding functions: $\text{sgn}({P_{\cdot,k}}^\top \bar{\boldsymbol{x}})$, where they differ only in the projection vector $P_{\cdot,k}$. The retrieved tweets are ranked according to their Hamming distance to the query, where Hamming distance is the number of different bit positions between the binary codes of a tweet and the query.

For ITQ and SH, we use the code provided by the authors. Note that the dense matrix $\bar{X}\bar{X}^\top$ is impossible to compute due the large vocabulary, therefore we replace it by sparse matrix $XX^\top$. For the three matrix factorization based methods (WTMF, OrMF, OrMFN) we run 10 iterations. The regularizer λ in equation 6 is fixed at 20 as in (Guo and Diab, 2012). A small set of 500 tweets is selected from the training set as tuning set to choose the missing word weight w_m in the baseline WTMF, and then its value is fixed for OrMF and OrMFN. The same 500 tweets tuning set is used to choose the neighbor word weight w_n. In fact these models are very stable, consistently outperforming the baselines regardless of different values of w_m and w_n, as later shown in Figure 4 and 5.

We also present the results of cosine similarity on the original word space (COSINE) as an upper bound of the binary coding methods. We implemented an efficient algorithm for COSINE, which is the algorithm 1 in (Petrovic et al., 2010). It firstly normalizes each data to a unit vector, then cosine similarity is calculated by traversing only once the tweets via inverted word index.

6.4 Results

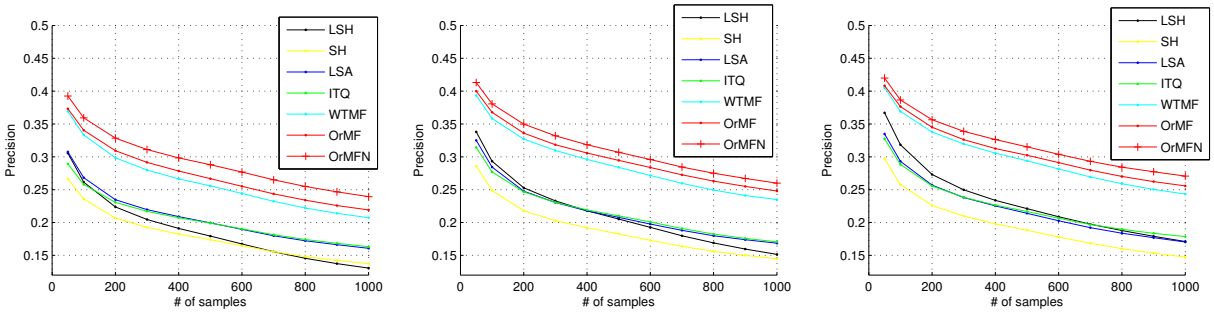
Table 2 summarizes the ranking performance measured by MP@1000 (the mean precision at top 1000 returned list). Figures 2 and 3 illustrate the corresponding precision and recall curve for the Hamming

[5]The tweet dataset and their associated list of hashtags will be available upon request.

[6]Although we use the word "training", the hashtags are never seen by the models. The training data is used for the models to learn the word co-occurrence, and construct binary coding functions.

Models	Parameters	r=64	r=96	r=128
LSH	–	19.21%	21.84%	23.75%
SH	–	18.29%	19.32%	19.95%
LSA	–	21.04%	22.07%	22.67%
ITQ	–	20.8%	22.06%	22.86%
WTMF	$w_m = 0.1$	26.64%	29.39%	30.38%
OrMF	$w_m = 0.1$	27.7%	30.48%	31.26%
OrMFN	$w_m = 0.1, w_n = 0.5$	**29.73%**	**31.73%**	**32.55%**
COSINE	–	33.68%		

Table 2: Mean precision among top 1000 returned list



(a) $r = 64$ (b) $r = 96$ (c) $r = 128$

Figure 2: Hamming ranking: precision curve under top 1000 returned list

distance ranking. The number of r binary coding functions corresponds to the number of dimensions in the 6 data-dependent models LSA, SH, ITQ, WTMF, OrMF and OrMFN. The missing words weight w_m is fixed as 0.1 based on the tuning set in the three weighted matrix factorization based models WTMF, OrMF and OrMFN. The neighbor word weight w_n is chosen as 0.5 for OrMFN. Later in Section 6.4.1 we show that the performance is robust using varying values of w_m and w_n.

As the number of bits increases, all binary coding models yield better results. This is understandable since the binary bits really record very tiny bits of information from each tweet, and more bits, the more they are able to capture more semantic information.

SH has the worst MP@1000 performance. The reason might be it is designed for vision data where the data vector is relatively dense. ITQ yields comparable results to LSA in terms of MP@1000, yet the recall curve in Figure 3b,c clearly shows the superiority of ITQ over LSA.

WTMF outperforms LSA by a large margin (around 5% to 7%) through properly modeling missing words, which is also observed in (Guo and Diab, 2012). Although WTMF already reaches a very high MP@1000 performance level, OrMF can still achieve around 1% improvement over WTMF, which can be attributed to orthogonal projections that captures more distinct topics. At last, leveraging neighborhood information, OrMFN is the best performing model (around 1% improvement over OrMF). The trend holds consistently across all conditions. The precision and recall curves in Figures 2 and 3 confirm the trend observed in Table 2 as well.

All the binary coding models yield worse performance than COSINE baseline. This is expected, as the binary bits are employed to gain efficiency at the cost of accuracy: the 128 bits significantly compress the data losing a lot of nuanced information, whereas in the high dimensional word space 128 bits can be only used to record two words (32 bits for two word indices and 32 bits for two TF-IDF values). We manually examined the ranking list. We found in the binary coding models, there exist a lot of ties (128 bits only result in 128 possible Hamming distance values), whereas the COSINE baseline can correctly rank them by detecting the subtle difference signaled by the real-valued TF-IDF values.

Figure 4: Weighted matrix factorization based models: MP@1000 vs. missing word weight w_m

6.4.1 Analysis

We are interested in whether other values of w_m and w_n can generate good results – in other words, whether the performance is robust to the two parameter values. Accordingly, we present their impact on MP@1000 in Figure 4 and 5. In Figure 4, the missing word weight w_m is chosen from $\{0.05, 0.08, 0.1, 0.15, 0.2\}$, where in OrMFN the neighbor weight w_n is fixed as 0.5. The figure indicates we can achieve even better MP@1000 around 33.2% when selecting the optimal $w_m = 0.05$. In general, the curves for all the code length are very smooth; the chosen value of w_m does not have a negative impact, e.g., the gain from OrMF over WTMF is always positive.

Figure 5 demonstrates the impact of varying the values of neighbor word weight w_n from $\{0, 0.25, 0.5, 0.75, 1\}$ on OrMFN tested in different r conditions. Note that when $w_n = 0$ indicating that no neighbor information is exploited, the OrMFN model is simply reduced to the OrMF model. Based on the Figure illustration we can conclude that integrating neighboring word information always yields a positive effect, since any value of $w_n > 0$ yields a performance gain over $w_n = 0$ which is OrMF.

6.5 Computation Cost

The data-dependent models involve 2 steps: 1) learning coding functions from a small dataset, and 2) binary coding for the large scale whole dataset.[7] In real-time scenarios, the time is only spent on the 2nd step that involves no matrix factorization. The computation cost of binary coding for all models (LSH, ITQ, LSA, WTMF, OrMF and OrMFN) are roughly the same: $\text{sgn}({P_{\cdot,k}}^\top \bar{\boldsymbol{x}})$. Note that ${P_{\cdot,k}}^\top \bar{\boldsymbol{x}} = {P_{\cdot,k}}^\top \boldsymbol{x} - {P_{\cdot,k}}^\top \mu$ where $\boldsymbol{x}$ is a very sparse vector (with 11 non-zeros values on average) and ${P_{\cdot,k}}^\top \mu$ can be precomputed. On the other hand, calculating Hamming distance on binary codes is also very fast using the logic operations.

[7] Learning the binarization functions can be always done on a small dataset, for example in this paper all the data dependent models are run on the 200,000 tweets, hence it performs very fast. In addition, in the OrMFN model, there is no need to find nearest neighbors for the whole dataset in the 2nd step (the binary coding step).

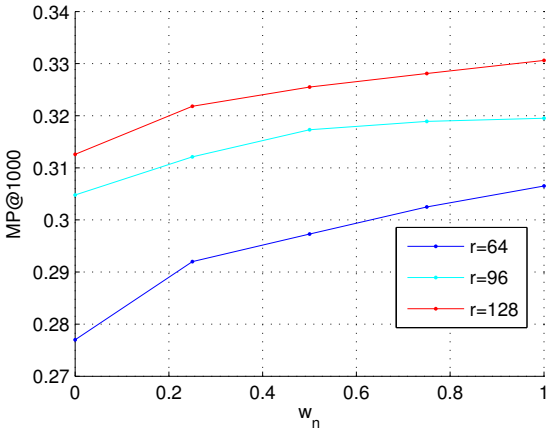

Figure 5: OrMFN model: MP@1000 vs. neighbor word weight w_n

7 Conclusion

In this paper, we proposed a novel unsupervised binary coding model which provides efficient similarity search in massive tweet data. The proposed model, OrMFN, improves an existing matrix factorization model through learning nearly orthogonal projection directions and leveraging the neighborhood information hidden in tweet data. We collected a dataset whose groundtruth labels are created from Twitter hashtags. Our experiments conducted on this dataset showed significant performance gains of OrMFN over the competing methods.

Abstract

Recent work has shown success in learning word embeddings with neural network language models (NNLM). However, the majority of previous NNLMs represent each word with a single embedding, which fails to capture polysemy. In this paper, we address this problem by representing words with multiple and sense-specific embeddings, which are learned from bilingual parallel data. We evaluate our embeddings using the word similarity measurement and show that our approach is significantly better in capturing the sense-level word similarities. We further feed our embeddings as features in Chinese named entity recognition and obtain noticeable improvements against single embeddings.

1 Introduction

Word embeddings are conventionally defined as compact, real-valued, and low-dimensional vector representations for words. Each dimension of word embedding represents a latent feature of the word, hopefully capturing useful syntactic and semantic characteristics. Word embeddings can be used straightforwardly for computing word similarities, which benefits many practical applications (Socher et al., 2011; Mikolov et al., 2013a). They are also shown to be effective as input to NLP systems (Collobert et al., 2011) or as features in various NLP tasks (Turian et al., 2010; Yu et al., 2013).

In recent years, neural network language models (NNLMs) have become popular architectures for learning word embeddings (Bengio et al., 2003; Mnih and Hinton, 2008; Mikolov et al., 2013b). Most of the previous NNLMs represent each word with a single embedding, which ignores polysemy. In an attempt to better capture the multiple senses or usages of a word, several multi-prototype models have been proposed (Reisinger and Mooney, 2010; Huang et al., 2012). These multi-prototype models simply induce K prototypes (embeddings) for every word in the vocabulary, where K is predefined as a fixed value. These models still may not capture the real senses of words, because different words may have different number of senses.

We present a novel and simple method of learning sense-specific word embeddings by using bilingual parallel data. In this method, word sense induction (WSI) is performed prior to the training of NNLMs. We exploit bilingual parallel data for WSI, which is motivated by the intuition that the same word in the source language with different senses is supposed to have different translations in the foreign language.[1] For instance, 制服 can be translated as *investment* / *overpower* / *subdue* / *subjugate* / *uniform*, etc. Among all of these translations, *subdue* / *overpower* / *subjugate* express the same sense of 制服, whereas *uniform* / *investment* express a different sense. Therefore, we could effectively obtain the senses of one word by clustering its translation words, exhibiting different senses in different clusters.

The created clusters are then projected back into the words in the source language texts, forming a sense-labeled training data. The sense-labeled data are then trained with recurrent neural network langugae model (RNNLM) (Mikolov, 2012), a kind of NNLM, to obtain sense-specific word embeddings. As a concrete example, Figure 1 illustrates the process of learning sense-specific embeddings.

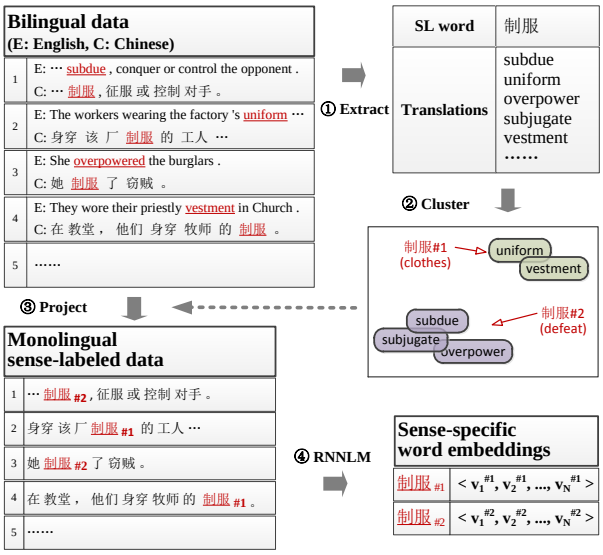

Figure 1: An illustration of the proposed method. SL stands for *source language*.

To evaluate the sense-specific word embeddings we have learned, we manually construct a Chinese polysemous word similarity dataset that contains 401 pairs of words with human-judged similarities. The performance of our method on this dataset shows that sense-specific embeddings are significantly better in capturing the sense-level similarities for polysemous words.

We also evaluate our embeddings by feeding them as features to the task of Chinese named entity recognition (NER), which is a simple semi-supervised learning mechanism (Turian et al., 2010). In order to use sense-specific embeddings as features, we should discriminate the word senses for the NER data first. Therefore, we further develop a novel monolingual word sense disambiguation (WSD) algorithm based on the RNNLM we have already trained previously. NER results show that sense-specific embeddings provide noticeable improvements over traditional single embeddings.

Our contribution in this paper is twofold:

- We propose a novel approach of learning sense-specific word embeddings by utilizing bilingual parallel data (Section 3). Evaluation on a manually constructed polysemous word similarity dataset shows that our approach better captures word similarities (Section 5.2).
- To use the sense-specific embeddings in practical applications, we develop a novel WSD algorithm for monolingual data based on RNNLM (Section 4). Using the algorithm, we feed the sense-specific embeddings as additional features to NER and achieve significant improvement (Section 5.3).

2 Background: Word Embedding and RNNLM

There has been a line of research on learning word embeddings via NNLMs (Bengio et al., 2003; Mnih and Hinton, 2008; Mikolov et al., 2013b). NNLMs are language models that exploit neural networks to make probabilistic predictions of the next word given preceding words. By training NNLMs, we obtain both high performance language models and word embeddings.

Following Mikolov et al. (2013b), we use the recurrent neural network as the basic framework for training NNLMs. RNNLM has achieved the state-of-the-art performance in language modeling (Mikolov, 2012) and learned effective word embeddings for several tasks (Mikolov et al., 2013b). The architecture of RNNLM is shown in Figure 2.

The input layer of RNNLM consists of two components: $\mathbf{w}(t)$ and $\mathbf{h}(t-1)$. $\mathbf{w}(t)$ is the *one-hot* representation of the word at time step t,[2] $\mathbf{h}(t-1)$ is the output of hidden layer at the last time step. Therefore, the input encodes all previous history when predicting the next word at time step t. Compared

[2] A feature vector of the same size of the vocabulary, and only one dimension is on.

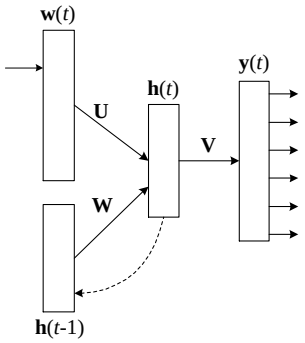

Figure 2: The basic architecture of RNNLM.

with other feed-forward NNLMs, the RNNLM can theoretically represent longer context patterns. The output $\mathbf{y}(t)$ represents the probability distribution of the next word $p(\mathbf{w}(t+1)|\mathbf{w}(t), \mathbf{h}(t-1))$. The output values are computed as follows:

$$\mathbf{h}(t) = f(\mathbf{U}\mathbf{w}(t) + \mathbf{W}\mathbf{h}(t-1)) \quad (1)$$

$$\mathbf{y}(t) = g(\mathbf{V}\mathbf{h}(t)) \quad (2)$$

where f is a sigmoid function and g is a softmax function.

The RNNLM is trained by maximizing the log-likelihood of the training data using stochastic gradient descent (SGD), in which back propagation through time (BPTT) is used to efficiently compute the gradients. In the RNNLM, $\mathbf{U}$ is the embedding matrix, where each column vector represents a word.

As discussed in Section 1, the RNNLM and even most NNLMs ignore the polysemy phenomenon in natural languages and induce a single embedding for each word. We address this issue and introduce an effective approach for capturing polysemy in the next section.

3 Sense-specific Word Embedding Learning

In our approach, WSI is performed prior to the training of word embeddings. Inspired by Gale et al. (1992) and Chan and Ng (2005), who used bilingual data for automatically generating training examples of WSD, we present a bilingual approach for unsupervised WSI, as shown in Figure 1. First, we extract the translations of the source language words from bilingual data (①). Since there may be multiple translations for the same sense of a source language word, it is straightforward to cluster the translation words, exhibiting different senses in different clusters (②).

Once word senses are effectively induced for each word, we are able to form the sense-labeled training data of RNNLMs by tagging each word occurrence in the source language text with its associated sense cluster (③). Finally, the sense-tagged corpus is used to train the sense-specific word embeddings in a standard manner (④).

3.1 Translation Words Extraction

Given bilingual data after word alignment, we present a way of extracting translation words for source language words by exploiting the translation probability produced by word alignment models (Brown et al., 1993; Och and Ney, 2003; Liang et al., 2006).

More formally, we notate the Chinese sentence as $c = (c_1, ..., c_I)$ and English sentence as $e = (e_1, ..., e_J)$. The alignment models can be generally factored as:

$$p(c|e) = \sum_a p(a, c|e) \quad (3)$$

$$p(a, c|e) = \prod_{j=1}^{J} p_d(a_j|a_{j-}, j) p_t(c_j|e_{a_j}) \quad (4)$$

where a is the alignment specifying the position of an English word aligned to each Chinese word, $p_d(a_j|a_{j-}, j)$ is the distortion probability, and $p_t(c_j|e_{a_j})$ is the translation probability which we use.

Table 1: Results of our approach on a sample of polysemous words. The second column lists the extracted translation words of the source language word (Section 3.1). The third column lists the clustering results using affinity propagation (Section 3.2). The last column lists the nearest neighbour words computed using the learned sense-specific word embeddings (Section 5.2.2).

In this paper, we use the alignment model proposed by Liang et al. (2006). We utilize the bidirectional translation probabilities for the extraction of translations, where a foreign language word w_e is determined as a translation of source language word w_c only if both translation probabilities $p_t(w_c|w_e)$ and $p_t(w_e|w_c)$ exceed some threshold $0 < \delta < 1$.

The second column of Table 1 presents the extraction results on a sample of source language words with the corresponding translation words.

3.2 Clustering of Translation Words

For each source language word, its translation words are then clustered so as to separate different senses. At the clustering time, we first represent each translation word with a feature vector (point), so that we can measure the similarities between points. Then we perform clustering on these feature vectors, representing different senses in different clusters.

Different from Apidianaki (2008) who represents all occurrences of the translation words with their contexts in the foreign language for clustering, we adopt the embeddings of the translation words as the representations and directly perform clustering on the translation words,[3] rather than the contexts of occurrences. The embedding representation is chosen for two reasons: (1) Word embeddings encode rich lexical semantics. They can be directly used to measure word similarities. (2) Embedding representation of the translation words leads to extremely high-efficiency clustering, because the number of translation words is orders of magnitude less than their occurrences.

Moreover, since the number of senses of different source language words is varied, the commonly-used k-means algorithm becomes inappropriate for this situation. Instead, we employ affinity propagation (AP) algorithm (Frey and Dueck, 2007) for clustering. In AP, each cluster is represented by one of the samples of it, which we call an *exemplar*. AP finds the *exemplars* iteratively based on the concept of "message passing". AP has the major advantage that the number of the resulting clusters is dynamic, which mainly depends on the distribution of the data. Compared with other possible clustering approaches, such as hierarchical agglomerative clustering (Kartsaklis et al., 2013), AP determines the number of resulting clusters automatically without using any partition criterions.

The third column of Table 1 lists the resulting clusters of the translation words for the sampled polysemous words. We can see that the resulting clusters are meaningful: senses are well represented by clusters of translation words.

3.3 Cross-lingual Word Sense Projection

The produced clusters are then projected back into the source language to identify word senses.

[3]The publicly available word embeddings proposed by Collobert et al. (2011) are used.

For each occurrence w^o of the word w in the source language corpora, we first select the aligned word with the highest marginal edge posterior (Liang et al., 2006) as its translation. We then identify the sense of w^o by computing the similarities of its translation word with each *exemplar* of the clusters, and select the one with the maximum similarity. When w^o is aligned with *NULL*, we heuristically identify its sense as the most frequent sense of w that appears in the bilingual dataset.

After projecting the word senses into the source language, we obtain a sense-labeled corpus, which is used to train the sense-specific word embeddings with RNNLM. The training process is exactly the same as single embeddings, except that the words in our training corpus has been labeled with senses.

4 Application of Sense-specific Word Embeddings

One of the attractive characteristic of word embeddings is that they can be directly used as word features in various NLP applications, including NER, chunking, etc. Despite of the usefulness of word embeddings on these applications, previous work seldom concerns that words may have multiple senses, which cannot be effectively represented with single embeddings. In this section, we address this problem by utilizing sense-specific word embeddings.

We take the task of Chinese NER as a case study. Intuitively, word senses are important in NER. For instance, 美 is likely to be an NE of Location when it refers to *America*. However, when it expresses the sense of *beautiful*, it should not be an NE.

Using sense-specific word embedding features for NER is not as straightforward as using single embeddings. For each word in the NER data, we first need to determine the correct word sense of it, which is a typical WSD problem. Then we use the embedding which corresponds to that sense as features. Here we treat WSD as a sequence labeling problem, and solve it with a very natural algorithm based on RNNLM we have already trained (Section 3).

4.1 RNNLM-based Word Sense Disambiguation

Given the automatically induced word sense inventories and the RNNLM which has already been trained on the sense-labeled data of source language, we first develop a greedy decoding algorithm for the sequential WSD, which works deterministically. Then we improve it using beam search.

Greedy. For word $\mathbf{w}$, we denote the sense-labeled $\mathbf{w}$ as $\mathbf{w}_{s^k}$, where s^k represents the k^{th} sense of $\mathbf{w}$. In each step, a single decision is made and the sense of next word ($\mathbf{w}(t+1)$) which has the maximum RNNLM output is chosen, given the current (sense-labeled) word $\mathbf{w}(t)_{s^*}$ and the hidden layer $\mathbf{h}(t-1)$ at the last time step as input. We simply need to compute a shortlist of $\mathbf{y}(t)$ associated with $\mathbf{w}(t+1)$, that is, $\mathbf{y}(t)|_{\mathbf{w}(t+1)}$ at each step. This process is illustrated in Figure 3.

Beam search. The greedy procedure described above can be improved using a left-to-right beam search decoding for obtaining a better sequence. The beam-search decoding algorithm keeps B different sequences of decisions in the agenda, and the sequence with the best overall score is chosen as the final sense sequence.

Note that the dynamic programming decoding (e.g. viterbi) is not applicable here, because of the recurrent characteristic of RNNLM. At each step, decisions made by RNNLM depends on all previous decisions instead of the previous state only, hence markov assumption is not satisfied.

5 Experiments

5.1 Experimental Settings

The Chinese-English parallel datasets we use include *LDC03E24*, *LDC04E12* (1998), the *IWSLT* 2008 evaluation campaign dataset and the *PKU 863* parallel dataset. All corpora are sentence-aligned. After cleaning and filtering the corpus,[4] we obtain 918,681 pairs of sentences (21.7M words).

In this paper, we use *BerkeleyAligner* to produce word alignments over the parallel dataset.[5] *BerkeleyAligner* also gives translation probabilities and marginal edge posterior probabilities. We adopt the

[4]Sentences that are too long (more than 40 words) or too short (less than 10 words) are discarded.

[5]code.google.com/p/berkeleyaligner/

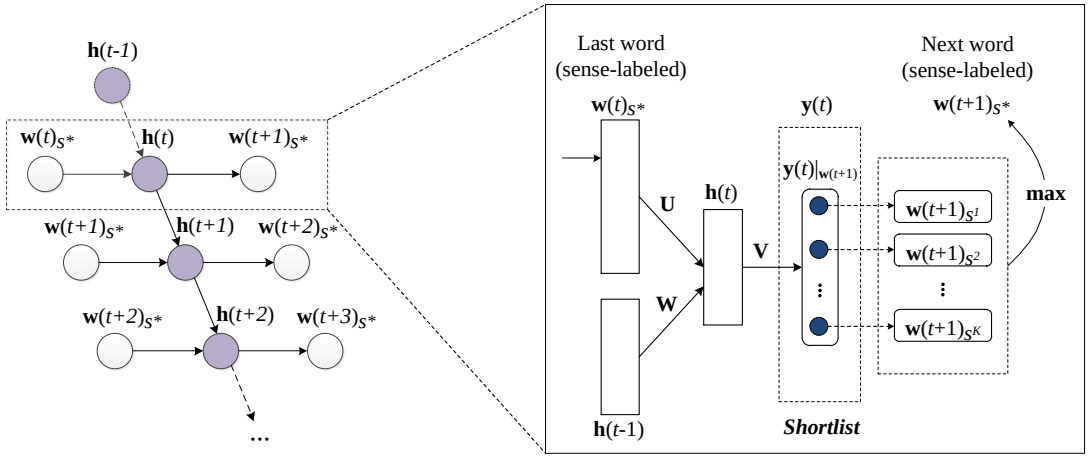

Figure 3: Using RNNLM for WSD by sequential labeling (left). Decision at each step of the RNNLM-based WSD algorithm (right).

scikit-learn tool (Pedregosa et al., 2011) to implement the AP clustering algorithm.[6] The AP algorithm is not fully automatic in deciding the cluster number. There is a tunable parameter calls *preference*. A *preference* with a larger value encourages more clusters to be produced. We set the *preference* at the median value of the input similarity matrix to obtain a moderate number of clusters. The *rnnlm* toolkit developed by Mikolov et al. (2011) is used to train RNNLM and obtain word embeddings.[7] We induce both single and sense-specific embeddings with 50 dimensions. Finally, We obtain embeddings of a vocabulary of $217K$ words, with a proportion of 8.4% having multiple sense clusters.

5.2 Evaluation on Word Similarity

Word embeddings can be directly used for computing similarities between words, which benefits many practical applications. Therefore, we first evaluate our embeddings using a similarity measurement.

Word similarities are calculated using the *MaxSim* and *AvgSim* metric (Reisinger and Mooney, 2010):

$$MaxSim(u, v) = \max_{1 \le i \le k_u, 1 \le j \le k_v} s(u^i, v^j) \quad (5)$$

$$AvgSim(u, v) = \frac{1}{k_u \times k_v} \sum_{i=1}^{k_u} \sum_{j=1}^{k_v} s(u^i, v^j) \quad (6)$$

where k_u and k_v are the number of the induced senses for words u and v, respectively. $s(\cdot, \cdot)$ can be any standard similarity measure. In this study, we use the *cosine* similarity.

Previous works used the WordSim-353 dataset (Finkelstein et al., 2002) or the Chinese version (Jin and Wu, 2012) for the evaluation of general word similarity. These datasets rarely contain polysemous words, and thus is unsuitable for our evaluation. To the best of our knowledge, no datasets for polysemous word similarity evaluation have been published yet, either in English or Chinese. In order to fill this gap in the research community, we manually construct a Chinese polysemous word similarity dataset.

5.2.1 Chinese Polysemous Word Similarity Dataset Construction

We adopt the HowNet database (Dong and Dong, 2006) in constructing the dataset. HowNet is a Chinese knowledge database that maintains comprehensive semantic definitions for each word in Chinese. The process of the dataset construction includes three steps: (1) Commonly used polysemous words are extracted according to their sense definitions in HowNet. (2) For each polysemous word, we select several other words to form word pairs with it. (3) Each word pair is manually annotated with similarity.

In step (1), we mainly took advantage of HowNet for the selection of polysemous words. However, the synsets defined in HowNet are often too fine-grained and many of them are difficult to distinguish,

[6] scikit-learn.org

[7] www.fit.vutbr.cz/~imikolov/rnnlm/

particularly for non-experts. Therefore, we manually discard those words with senses that are hard to distinguish.

In step (2), for each polysemous word w selected in step 1, we sample several other words to form word pairs with w. The sampled words can be roughly divided into two categories: *related* and *unrelated*. The *related* words are sampled manually. They can be the *hypernym*, *hyponym*, *sibling*, *(near-)synonym*, *antonym*, or *topically related* to one sense of w. The *unrelated* words are sampled randomly.

In step (3), we ask six graduate students who majored in computational linguistics to assign each word pair a similarity score. Following the setting of WordSim-353, we restrict the similarity score in the range (0.0, 10.0). To address the inconsistency of the annotations, we discard those word pairs with a standard deviation greater than 1.0. We end up with 401 word pairs annotated with acceptable consistency. Unlike the WordSim-353, in which most of the words are nouns, the words in our dataset are more diverse in terms of part-of-speech tags.

Table 2 lists a sample of word pairs with annotated similarities from the dataset. The whole evaluation dataset will be publicly available for the research community.[8]

Word	Paired word	Category	Mean.Sim	Std.Dev
制服	征服$_{conquer}$	synonym	8.60	0.29
	重点$_{key\ point}$	unrelated	0.12	0.19
出	进$_{enter}$	autonym	7.90	0.97
	发表$_{publish}$	near-synonym	7.86	0.76
花	茎$_{plant\ stem}$	sibling	7.80	0.12
	费用$_{cost}$	topic-related	5.86	0.90
面	食物$_{food}$	hypernym	6.50	0.71

Table 2: Sample word pairs of our dataset. The unrelated words are randomly sampled. $Mean.Sim$ represents the mean similarity of the annotations, $Std.Dev$ represents the standard deviation.

5.2.2 Evaluation Results

Following Zou et al. (2013), we use Spearman's ρ correlation and Kendall's τ correlation for evaluation. The results are shown in Table 3. By utilizing sense-specific embeddings, our approach significantly outperforms the single-version using either *MaxSim* or *AvgSim* measurement.

For comparison with multi-prototype methods, we borrow the context-clustering idea from Huang et al. (2012), which was first presented by Schütze (1998). The occurrences of a word are represented by the average embeddings of its context words. Following Huang et al.'s settings, we use a context window of size 10 and all occurrences of a word are clustered using the spherical k-means algorithm, where k is tuned with a development set and finally set to 2.

System	**MaxSim**		**AvgSim**	
	$\rho \times 100$	$\tau \times 100$	$\rho \times 100$	$\tau \times 100$
Ours	**55.4**	**40.9**	49.3	35.2
SingleEmb	42.8	30.6	42.8	30.6
Multi-prototype	40.7	29.1	38.3	27.4

Table 3: Spearman's ρ correlation and Kendall's τ correlation evaluated on the polysemous dataset.

Surprisingly, the *multi-prototype* method performs even slightly worse than the single-version, which suggests that learning a fixed number of embeddings for every word may even harm the embedding. Additionally, the clustering process of the multi-prototype approach suffers from high memory and time cost, especially for the high-frequency words.

[8] ir.hit.edu.cn/~jguo

To obtain intuitive insight into the superior performance of sense-specific embeddings, we list in the last column of Table 1 the nearest neighborhoods of the sampled words in the evaluation dataset. The list shows that we are able to find the different meanings of a word by using sense-specific embeddings.

5.3 Application on Chinese NER

We further apply the sense-specific embeddings as features to Chinese NER. We first perform WSD on the NER data using the algorithm introduced in Section 4. For beam search decoding, the beam size B is tuned on a development set and is finally set to 16.

We conduct our experiments on data from *People's Daily* (Jan. and Jun. 1998).[9] The original corpus contains seven NE types.[10] In this study, we select the three most common NE types: Person, Location, Organization. The data from January are chosen as the training set (37,426 sentences). The first 2,000 sentences from June are chosen as the development set and the next 8,000 sentences as the test set.

CRF models are used in our NER system and are optimized by L2-regularized SGD. We use the CRFSuite (Okazaki, 2007) because it accepts feature vectors with numerical values. The state-of-the-art features (Che et al., 2013) are used in our baseline system. For both single and sense-specific embedding features, we use a window size of 4 (two words before and two words after).

5.3.1 Results

Table 4 demonstrates the performance of NER on the test set. As desired, the single embedding features improve the performance of our baseline, which were also shown in (Turian et al., 2010). Furthermore, the sense-specific embeddings outperform the single word embeddings by nearly 1% F-score (88.56 vs. 87.58), which is statistically significant (p-value < 0.01 using one-tail t-test).

System	P	R	F
Baseline	93.27	81.46	86.97
+SingleEmb	93.55	82.32	87.58
+SenseEmb (greedy)	93.38	83.56	88.20
+SenseEmb (beam search)	**93.59**	**84.05**	**88.56**

Table 4: Performance of NER on test data.

According to our hypothesis, the sense-specific embeddings should bring considerable improvements to the NER of polysemous words. To verify this, we evaluate the per-token accuracy of the polysemous words in the NER test data. We again adopt HowNet to determine the polysemy. Words that are defined with multiple senses are selected as test set. Figure 4 shows that the sense-specific embeddings indeed improve the NE recognition of the polysemous words, whereas the single embeddings even decrease the accuracy slightly. We also obtain improvements on the NE recognition of the monosemous words, which provide evidences that more accurate prediction of polysemous words is beneficial for the prediction of the monosemous words through contextual influence.

6 Related Work

Previous studies have explored the NNLMs, which predict the next word given some history or future words as context within a neural network architecture. Schwenk and Gauvain (2002), Bengio et al. (2003), Mnih and Hinton (2007), and Collobert et al. (2011) proposed language models based on feed-forward neural networks. Mikolov et al. (2010) studied language models based on RNN, which managed to represent longer history information for word-predicting and demonstrated outstanding performance.

Besides, researchers have also explored the word embeddings learned by NNLMs. Collobert et al. (2011) used word embeddings as the input of various NLP tasks, including part-of-speech tagging, chunking, NER, and semantic role labeling. Turian et al. (2010) made a comprehensive comparison of various types of word embeddings as features for NER and chunking. In addition, word embeddings

[9] www.icl.pku.edu.cn/icl_groups/corpus/dwldform1.asp

[10] Person, Location, Organization, Date, Time, Number and Miscellany

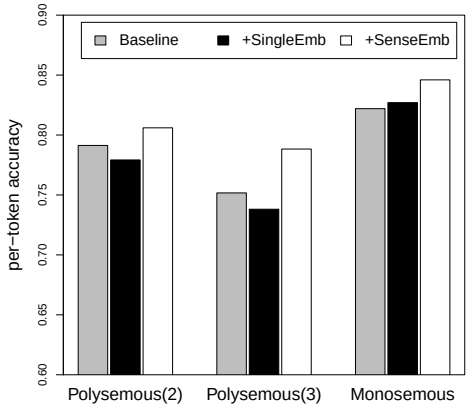

Figure 4: Per-token accuracy on the polysemous and monosemous words in the NER test data. Polysemous(k) represents the set of words that have more than or equal to k senses defined in HowNet.

are shown to capture many relational similarities, which can be recovered by vector arithmetic in the embedding space (Mikolov et al., 2013b; Fu et al., 2014). Klementiev et al. (2012) and Zou et al. (2013) learned cross-lingual word embeddings by utilizing MT word alignments in bilingual parallel data to constrain translational equivalence.

Most previous NNLMs induce single embedding for each word, ignoring the polysemous property of languages. In an attempt to capture the different senses or usage of a word, Reisinger and Mooney (2010) and Huang et al. (2012) proposed multi-prototype models for inducing multiple embeddings for each word. They did this by clustering the contexts of words. These multi-prototype models simply induced a fixed number of embeddings for every word, regardless of the real sense capacity of the specific word.

There has been a lot of work on using bilingual resources for word sense disambiguation (Gale et al., 1992; Chan and Ng, 2005). By using aligned bilingual data along with word sense inventories such as WordNet, training examples for WSD can be automatically gathered. We employ this idea for word sense induction in our study, which is free of any pre-defined word sense thesaurus.

The most similar work to our sense induction method is Apidianaki (2008). They presented a method of sense induction by clustering all occurrences of each word's translation words. In their approach, occurrences are represented with their contexts. We suggest that clustering contexts suffer from high memory and time cost, as well as data sparsity. In our method, by clustering the embeddings of translation words, we induce word senses much more efficiently.

To evaluate word similarity models, researchers often apply a dataset with human-judged similarities on word pairs, such as WordSim-353 (Finkelstein et al., 2002), MC (Miller and Charles, 1991), RG (Rubenstein and Goodenough, 1965) and Jin and Wu (2012). For context-based multi-prototype models, (Huang et al., 2012) constructs a dataset with context-dependent word similarity. To the best of our knowledge, there is no publicly available datasets for context-unaware polysemous word similarity evaluation yet. This paper fills this gap.

7 Conclusion

This paper presents a novel and effective approach of producing sense-specific word embeddings by exploiting bilingual parallel data. The proposed embeddings are expected to capture the multiple senses of polysemous words. Evaluation on a manually annotated Chinese polysemous word similarity dataset shows that the sense-specific embeddings significantly outperforms the single embeddings and the multi-prototype approach.

Another contribution of this study is the development of a beam-search decoding algorithm based on RNNLM for monolingual WSD. This algorithm bridges the proposed sense-specific embeddings and practical applications, where no bilingual information is provided. Experiments on Chinese NER show that the sense-specific embeddings indeed improve the performance, especially for the recognition of the polysemous words.

Abstract

The work presented here addresses the use of unmarked contexts in pattern-based nominal lexical semantic classification. We define unmarked contexts to be the counterposition of the class-indicatory, or marked, contexts. Its aim is to evaluate how unmarked contexts can be used to improve the accuracy and reliability of lexical semantic classifiers. Results demonstrate that the combined use of both types of distributional information (marked and unmarked) is crucial to improve classification. This result was replicated using two different corpora, demonstrating the robustness of the method proposed.

1 Introduction

Lexical resources annotated with lexical semantic classes have been successfully incorporated into a wide range of NLP applications, such as grammar induction (Agirre *et al.*, 2011) and the building and extending of semantic ontologies (Abbès *et al.*, 2011). However, lexical semantic tagging in large lexica is mostly done by hand, implying high costs with regard to maintenance and domain tuning. As the use of an inadequate lexicon is one of the causes of poor performance of NLP applications, current research to improve the automatic production of rich language resources, and of class-annotated lexica, in particular, is critical.

One way to approach this task is through supervised cue-based lexical semantic classification. Based on the distributional hypothesis (Harris, 1954), according to which words occurring in the same contexts can be said to belong to the same class, cue-based lexical semantic classification uses particular linguistic contexts where nouns occur as cues that represent distinctive distributional traits of a lexical class. Yet, training a classifier with information about word occurrences in a corpus within a selected number of contexts can present a challenge, mainly because specific words might be observed in a number of class-indicative contexts but not always are.

This type of marked, or class-indicative, context (e.g. co-occurrence with specific prepositions, predicate selectional restrictions, and grammatical information, such as indirect objects) are sparse in any corpus as, being so specific, they do not occur often with each target noun. Using only exclusive class-indicative contexts as features in nominal lexical semantic classification has been shown to not always provide sufficient information to make a decision regarding class membership of a noun (Bel *et al.*, 2012), especially when the data does not contain relevant co-occurrences or when those co-occurrences are too disperse to be correlated.

Recent work on the use of distributional models for nominal classification tasks (Romeo *et al.*, 2014) discusses potential bottlenecks of models using data extracted with lexico-syntactic patterns as features, identifying data sparsity as one of the major issues affecting the performance of these systems. In fact, the selection of class-indicative information, in an attempt to provide relevant information to classifiers and thus reduce noise, naturally limits the amount of data available to the system, often resulting in sparse vectors.

Resulting from the necessity of selecting the information provided to classifiers, in an attempt to improve the accuracy of classification decisions, the sparse data problem in nominal lexical semantic classification is one of the crucial issues to be addressed to improve the performance of these systems. We propose to approach this issue by utilizing a larger fraction of the distributional information available in a corpus, by incorporating information typically considered non-indicatory of semantic class membership, which we will designate as *unmarked contexts* (see Section 3 for a definition).

Proceedings of COLING 2014, the 25th International Conference on Computational Linguistics: Technical Papers, pages 508–519, Dublin, Ireland, August 23-29 2014.

Our hypothesis is that the distributional behavior of nouns of a particular class in this type of generally occurring contexts can show certain characteristics in common that may be explored in the context of lexical semantic classification. Our goal in the work presented here is to evaluate to which extent this information, in combination with the widely explored class-indicative lexico-syntactic contexts, can be used to improve results in classification tasks, by providing more information to classifiers. To do this, we experiment with English nouns of the following lexical semantic classes: INFORMATION (INF), ORGANIZATION (ORG), LOCATION (LOC), EVENT (EVT) and HUMAN (HUM).

The work presented in this paper is structured as follows: Section 2 describes theoretical claims used in approaches to nominal lexical semantic classification, as well as related work; Section 3 elaborates upon the concept of unmarked contexts; Section 4 describes the methodology followed; Section 5 presents the results obtained; Section 6 discusses their implications; and Section 7 concludes with final remarks and future work.

2 Motivation and Related Work

In semantic classification approaches grounded in usage-based theories of grammar (Goldberg, 2006), a lexical class is seen as a generalization of the systematic co-distribution of a number of words and contexts. Construction-based grammar hypotheses allow us to predict there are sets of word occurrences that, together, constitute a class mark, indicating a particular semantic class, in line with the structuralist notion of markedness (Jakobson, 1971).

The identification of relevant cues for machine learning classification is problematic as low frequency evidence is typically disregarded by automatic systems. To overcome this problem, Bel (2010) applied smoothing methods, demonstrating increases in accuracy, though low frequency words remained problematic for classifiers when evidence was scarce, and thus not considered as a positive cue for the class, although it was indicative.

In Bel *et al*. (2012) we built on this hypothesis, assuming only frequently occurring contexts would be efficient for classification tasks, and considering only frequent predicates, prepositions, affixes, etc., as well as negative cases (i.e. marked cues for other classes), as indicators for a class membership decision. Thus, we ignored all information that, although frequent, co-occurred with nouns from all classes and was deemed not distinctive of a particular class, as well as all information that, though distinctive, was not frequent enough to be used by the classifier.

Table 1 provides examples of contexts considered in that work, which did not rely on unique, exclusive hints, but a number of them that, when correlated, could identify members of a given class. However, our results were inconclusive, a fact which we attributed to the high impact of sparse data.

Class	Examples of lexico-syntactic patterns
ORG	x-NN (found|establish|organize)-VBD
LOC	(inside|outside)-IN (the|a|an)-(DT|Z) x-NN
INF	(submit|publish|report)-V* (the|a|an)-(DT|Z) x-NN
EVT	during-IN (the|a|an)-(DT|Z) x-NN
HUM	x-(-er|–or| –man)-NN

Table 1: Examples of lexico-syntactic patterns indicative of 5 different lexico-semantic classes, which we refer to as *marked contexts*.

According to Bybee (2010), general contexts, not exclusive to a particular class (i.e. unmarked contexts, as defined in Section 3), are more frequent than contexts marked toward a particular class, as they occur with nouns of all classes. In view of this, it becomes apparent that a large part of available distributional data is not taken into consideration when these very general co-occurrences observed with nouns of all classes (e.g. co-occurrence with an article) are treated as stop words or contexts in lexical semantic classification tasks.

The basic claim leading most authors to neglect this kind of context is that, due to its assumed undifferentiated distribution, this information presents a challenge for classifiers to accurately use it in class membership decisions, which is bound to negatively affect results (see Cooke and Gillam (2008), Turney and Pantel (2010), Bullinaria and Levy (2012), among many others). In contrast with this mainstream position, Rumshisky *et al*. (2007) argued there is an asymmetry in the way certain word

senses are used in language, preferably or rarely occurring in certain very general contexts (e.g. subject position, occurrence with an adjectival modifier, etc.).

This type of asymmetry is essentially referring to a difference in how general, semantically neutral distributional contexts are more or less frequent in data, depending on the sense in which a word is used. We hypothesize that these tendencies can also be observed when considering different lexical semantic classes.

In this paper, we propose a way to include this type of asymmetry in the information provided to classifiers to verify its impact on their overall performance. Considering such distributional evidence will increase the amount of information made available to classifiers. Our main claim is that devising a strategy to informatively include this type of distributional information in classification tasks can allow us to take advantage of a bigger portion of the data available in corpora and improve the accuracy of classifiers in this way.

3 Unmarked contexts

In contrast with mainstream approaches to cue-based lexical-semantic classification, we argue for the inclusion of a type of distributional information typically not considered to be indicatory of class membership, and thus not informative to automatic classification systems. These are very general contexts of occurrence typically disregarded as semantically-empty and thought to be too general to contribute any relevant information. At the same time, they correspond to a large amount of corpus data that is a priori not considered due to the assumption that it does not provide any information.

Examples of such distributional information regard whether nouns occur preceeded by an article, in singular or plural form, whether they are a head or a complement in NPs containing the preposition *of*, if they occur as the subject of the verb to *be*, etc. We will henceforth designate these contexts as ***unmarked contexts***, the counterposition of the class-indicatory contexts, i.e. ***marked contexts***, used as class marks in cue-based lexical-semantic classification systems.

Following the conclusions of Rumshisky *et al.* (2007) regarding asymmetries in the distribution of word senses in general contexts, our hypothesis is that the distribution of members of a class with respect to their occurrence in particular unmarked contexts is consistent and thus can be captured and used to inform classifiers and improve results, when considered along with other indicatory, or marked, contexts.

We also hypothesize that unmarked contexts will alleviate problems caused by data sparsity in classification tasks by providing additional information to classifiers. To assess to which extent this information can be used in classification tasks, we had to identify such contexts and verify whether our hypothesis was confirmed, i.e. if they showed significant variations in terms of distribution that might be explored to augment the amount of information made available to classifiers[1]. Additionally, and given the specific properties of this type of distributional information, we also had to define a strategy to informatively provide it to classifiers (see Section 3.2 for details).

3.1 Identifying unmarked contexts

Considering the characteristics of the contexts discussed above, we identified 32 unmarked contexts under a frequency criterion (see Table 2 for a description of the different contexts identified), hypothesizing that more frequent contexts combine with more nouns in the corpus and thus should not be marked for any restricted set. However, although they are not considered to be class marks, we expect these contexts to be asymmetrically distributed between lexical semantic classes, in an analogous way to what was observed by Rumshisky *et al*. (2007) with regard to the distributional behavior of different word senses in language use.

We studied the distribution of these contexts in a web-crawled corpus (see Section 4), comparing the distribution of each context over all the nouns in the corpus and over nouns defined as part of a specific lexical semantic class, according to a gold standard (see Section 4.2). To do this, we calculated the mean of occurrence of nouns pertaining to a particular class in a specific unmarked context,

[1] The approach detailed in this paper contrasts with a 'bag of words' approach to classification as, even in the case of what we call unmarked contexts, we rely on cue information to populate our vectors. Thus, the information provided to classifiers takes into consideration linguistic information, such as syntactic order or dependencies. Moreover, our use of linguistically-motivated features, from the inherently distinctive to the more generic, reduces the amount of data needed to obtain a desired level of performance.

as well as the mean of occurrence of all the nouns in the corpus in that same context; we then determined if there was a statistically significant difference[2] between the behavior of nouns from specific classes and the behavior of nouns in general with regard to the contexts identified as unmarked.

Feature Type	Description	Examples
article	target noun preceded by a(n) (in)definite article	*(a|an)-(DT|Z) x-NN* or *(the)-(DT|Z) x-NN*
number	target noun in plural/singular form	*x-NNS* or *x-NN*
copula	target noun as subject/object of verb *to be*	*x-NN* be-*VBZ* or be-*VBZ x-NN*
modifiers	adjective or nominal modifier preceding target noun	*x-JJ x-NN* or *x-NN x-NN*
preposition *of*	target noun preceding/following the preposition *of*	*x-NN of-IN* or *of-IN x-NN*
subject of V	target noun as subject of each of the 20 most frequent verbs in the corpus	*x-NN (have|get|make|see|do|take|go|use|find|help|read|know|provide|give|keep|come|say|create|visit) -VB(Z|D)*

Table 2: Description of unmarked contexts identified and used in our experiments.

The results showed there were statistically significant differences ($p<0.05$) in the behavior of nouns in particular classes with regard to certain unmarked contexts. For instance, the occurrence of INF, ORG, LOC, and HUM nouns with a definite article (*the-DT*) showed to be significantly different from its average occurrence with all the nouns in the corpus. The occurrence with an indefinite article (*a|an-DT*), on the other hand, showed to be significantly different for LOC nouns, while the co-occurrence with an adjective (*x-JJ*) was significantly different for INF nouns.

3.2 A strategy to encode unmarked context information in feature vectors

The preliminary study mentioned in Section 3.1 provided evidence confirming that there are, in fact, differences in the behavior of particular lexical semantic classes with regard to their occurrence in unmarked contexts. Thus, the next step consisted in determining the best way to make this information available to classifiers.

Aiming to check the validity of our hypothesis in general, the results obtained in the aforementioned study were not used directly to narrow down the information to include in the vectors used by the classifiers to avoid the risk of over-fitting. Moreover, what was at stake, considering our theoretical hypothesis, was to devise a strategy to account for specific differences between the behavior of each noun considered for classification and the average behavior of all nouns in the corpus with regard to each context considered. Thus, information regarding all 32 unmarked contexts was provided to the classifiers for all lexical classes considered.

To mirror the specificity of the distribution of each noun with regard to each context considered, we subtracted the mean of occurrence of nouns in each context from the actual occurrences of the target noun represented by the vector in that same context to obtain each feature *f*, as defined in Equation 1, where c_i represents a given context, *t* a target noun, *n* any noun belonging to *N*, the set of all nouns in the corpus, and *freq* frequency of occurrence (e.g. $freq(t \mid c_i)$ = frequency of occurrence of the target noun *t* in context c_i).

Equation 1: $$f = \frac{freq(t \mid ci)}{freq(t)} - \frac{1}{|N|} \sum_{n \in N} \left[\frac{freq(n \mid ci)}{freq(n)} \right]$$

Using the difference between the number of occurrences of a given noun and the average occurrence of all nouns in a specific context, we encode the deviation of the behavior of that noun with re-

[2] In this work, statistical significance was calculated using Student's t-test (cf. Krenn and Samuelsson, 1997).

gard to the general behavior of all nouns in the corpus, under the hypothesis that nouns of the same class display similar tendencies in terms of deviant behavior in the contexts considered, providing relevant information to the classifier. We apply our method to two different corpora making apparent its robustness.

4 Experimental design and setup

In order to evaluate the impact of using distributional information on unmarked contexts for lexical-semantic classification tasks, first, we had to extract distributional information regarding the unmarked contexts identified (see Section 3.1), as well as distributional information regarding class-indicative marked contexts. In our experiments, we used the marked contexts identified and described in Bel *et al*. (2012) (see Table 1 for examples).

Once the distributional information was extracted, we incorporated it in feature vectors, using the different aforementioned strategies for encoding distributional information regarding marked and unmarked contexts, respectively, as detailed further below in this section. Once all of the information was compiled, the vectors were provided to classifiers.

As previously mentioned, our experiments covered English nouns of the classes: INF, ORG, HUM, EVT and LOC (see Section 4.2). For the purpose of the work presented here, we experimented with two corpora to determine the transferability and robustness of our method, independently of specific corpus data.

We first used a general web-crawled corpus (Pecina *et al.*, 2011) consisting of 30 million PoS-tagged English tokens (henceforth Corpus A) to identify unmarked contexts (see Section 3.1) as well as to train our classifiers.

We also employed an excerpt of the web-crawled UkWaC corpus (Baroni *et al.*, 2009), consisting of 60 million PoS-tagged English tokens (henceforth Corpus B) to test our approach on unknown data, in this way ensuring that our approach and classifiers are not over-fitted to any specific corpus, instead confirming that the method we propose can be generalized, and the results obtained are replicable given any dataset.

Regular expressions over both corpora were used to identify occurrences of nouns in marked and unmarked contexts. For marked contexts, the relative frequency of each pattern seen with a particular noun was stored in an *n*-dimensional vector.[3] The occurrences of a noun in unmarked contexts were encoded in the same vectors following the strategy outlined in Section 3.2 (see Equation 1).

4.1 Classification

For classification, we used the Logistic Model Trees (LMT) (Landwehr *et al.*, 2005) Decision Tree (DT) classifier in the WEKA (Witten and Frank, 2005) implementation in a 10-fold cross-validation setting. We conducted binary classifications, one for each semantic class considered. We measure the success of our approach in regards to the joint performance of individual classifiers in accurately distinguishing members of each individual class from any other noun. This method was used in the classification experiments over both corpora described above.

4.2 Gold Standard Description

In regards to the gold standard lists used for training and evaluation, we automatically extracted from WordNet (Miller *et al.*, 1990) all of the nouns encoded in this repository of lexical information that contained a sense corresponding to a class considered in our experiments (e.g. *people* in the case of HUM).

The gold standards were not contrasted with the actual occurrences of the nouns in the corpora. They were, however, balanced with respect to class members and elements not belonging to the class, resulting in the dataset described in Table 3. Each noun appears *x* times in any corpus considered. The elements not belonging to a class were randomly selected from the set of nouns that do not contain a sense in WordNet that corresponded to the target class being classified.

For a fair comparison, the baseline classification model was obtained using the context patterns described in Bel *et al*. (2012) with the LMT classifier, using the previously described gold standard lists over Corpus A. This baseline allows us to assess the impact of unmarked contexts in nominal lexical

[3] In this work, *n* is equal to the amount of marked contexts plus unmarked contexts considered for each class.

semantic classification, since the classifiers proposed here that are provided with information on the distributional behavior of nouns in unmarked contexts also use Bel *et al.* (2012)'s context patterns to extract class-indicative, or marked, distributional information regarding the nouns to classify.

Class	**ORG**	**LOC**	**EVT**	**INF**	**HUM**
Class members	138	157	260	262	246
Elements not belonging to the class	135	156	260	259	246

Table 3: Number of nouns included in gold standards per class.

5 Results

Tables 4 and 5 show results obtained in our experiments in terms of Precision (P), Recall (R) and F-Measure (F). The overall accuracy of all classifiers for each experiment is also provided. The baseline classifiers achieve an average accuracy of 70.84%. By including unmarked contexts in the vectors provided to the classifiers, the average accuracy of the classifiers rises to 75.16%, representing an error reduction of 4.32 points. We tested the statistical significance ($p<0.1$) of this increase in the accuracy of classification and, for all classes except for HUM, the increase in accuracy between the baseline results and those obtained when including unmarked contexts is significant. These results are discussed in detail in Section 6.

Knowing a potential downside of using unmarked contexts in classification tasks is an increase in noise (see Section 6.1 for a detailed discussion regarding this concept), we conducted an error analysis of the results obtained, which made apparent that most of the noise was due to imprecise information extracted with our regular expressions, leading us to revise them. As these revisions resulted from the observation that a portion of the errors in the baseline results was due to imprecise regular expressions, they did not consist in the definition of new marked contexts, rather in a revision of how to extract marked contexts already considered in this work from corpora data. Thus, these revisions resulted in more accurate and better defined regular expressions.

As indicated by the results, these revisions in combination with the unmarked contexts further raised the average accuracy of the classifiers to 76.35% (see Table 4), representing an error reduction of 5.51 points with regard to the baseline. Having obtained these promising results over the data in the corpus used to develop our approach (Corpus A), it was crucial to verify the replicability of our method using a different and completely independent corpus, as described in Section 4. Moreover, replicating the original experiments over a different corpus was also crucial to assure that the revisions made to the regular expressions did not result in any over-fitting between the extraction of distributional information and the corpus being used. The results obtained for the experiments conducted over Corpus B are presented in Table 5.

Table 4: Precision (P), Recall (R), and F-Measure (F) of classifiers over Corpus A.

The classifiers that include unmarked contexts yielded an average accuracy of 76.03% over Corpus B, representing an error reduction of 3.34 points with regard to the classifier including only marked contexts (using the revised version of Bel *et al.* (2012)'s cues), which is a statistically significant improvement ($p<0.05$). Moreover, these results represent an improvement of accuracy by 5.19 points with regard to the baseline. This demonstrates, on the one hand, that the definition of relevant contexts based on Corpus A data did not result in an over-fitted approach; and, on the other hand, that the

method presented here is robust, as we used our classifiers over a completely different corpus (cf. Section 3) and still yielded comparable results. Due to space limitations, below we detail only the results obtained on Corpus B data, as these are independent of all the preliminary studies conducted and thus demonstrate the potential applicability of our approach to any corpus.

Table 6: Precision (P) and Recall (R) of classification of members and non-members of different lexical classes over Corpus B

Table 6 presents the precision and the recall of each individual classifier over Corpus B both with regard to the members of a given class, and those nouns that are not members of that class. This table allows us to identify more precisely how the unmarked contexts contribute to the error reduction in classification.

According to the results, unmarked contexts allow us to gain an average of 10.2 points in recall for class members, demonstrating that they provide useful information to classifiers, which allows them to cover cases which they were not able to before, most likely due to phenomena such as data sparsity. However, the impact on precision varies between classes, as the inclusion of very frequent information in the vectors representing target nouns may provide additional noise to the classifier (see Section 6.1).

The precision of classification of class members decreases slightly with the inclusion of unmarked contexts, although the differences are not statistically significant ($p<0.1$). However, the precision of the classification of nouns not belonging to the classes considered significantly increases ($p<0.1$) with the inclusion of unmarked contexts in all cases except for HUM. This shows that although unmarked contexts do not contribute to a better definition of the characteristics of individual classes (see Table 6), they allow for a cleaner discrimination of members and non-members of a class, contributing to a better partition of the classification space.

Class	marked contexts		marked + unmarked contexts	
	FN (%)	FP (%)	FN (%)	FP (%)
ORG	23.32	6.71	13.43	9.98
LOC	22.30	5.75	14.74	9.71
EVT	21.91	10.42	13.82	12.97
INF	18.94	12.00	17.26	12.63
HUM	7.79	6.01	8.90	6.45

Table 7: Percentage of False Negatives (FN) and False Positives (FP) in classifiers over Corpus B with and without unmarked contexts.

Table 7 presents the percentage of False Positives (FP), i.e. nouns incorrectly marked as members of the class, and False Negatives (FN), i.e. nouns incorrectly marked as not belonging to a class, in the results of each classifier both with and without the inclusion of unmarked contexts. Again, for each of the classes, except HUM, the inclusion of unmarked contexts decreases the percentage of FN, mirroring a reduction in silence. Yet, there was an increase of FP across all classes, signifying an increase of the noise provided to the classifier. These results are discussed in detail in Section 6.

6 Discussion

In Section 5, we presented the results obtained in our experiments using distributional information regarding both marked and unmarked contexts for the classification of English nouns. Overall, our results show that unmarked contexts either improve accuracy or do not affect classification results. Specifically, the improvements in accuracy are particularly significant for those classes for which there were difficulties to find enough occurrences in marked contexts in previous experiments, i.e. those classes with a higher level of FN when classified without using unmarked contexts. This way, the results confirm our general hypothesis that the distribution of words in unmarked contexts, when considered along with contexts marked towards a lexical semantic class, provides information to improve classifiers, particularly when not enough class-specific information is available. In this section we analyze the results obtained, making apparent the main advantages of our proposal.

6.1 A trade-off between silence and noise

An important result of our experiments is the overall reduction in the negative effect of silence in our classifiers, which decreased by an average of 5.21% (see the difference in terms of FN in Table 7), resulting in an increase in accuracy (see Table 5): as more information is supplied to the classifier, the additional information permits more accurate membership decisions. To illustrate this, we consider examples from the INF, ORG and EVT classes, for which there was not enough information for classification when unmarked contexts were not considered. The inclusion of unmarked contexts provided information resulting in correct classifications.

The INF noun *theorem* illustrates this case: *theorem* occurs 118 times in the corpus, though only 8 times in marked contexts, which was not enough to accurately classify it as a member of the INF class. As this noun occurs in class-marked contexts, but not enough times for the classifier to make an accurate prediction regarding its class membership, we can consider that the lack of enough information provided to the classifier is responsible for its misclassification. However, after the inclusion of information regarding the behavior of this noun in unmarked contexts, the classifier was able to accurately decide for its inclusion as a member of the INF class. This was also observed in the case of the ORG noun *secretariat* and the EVT noun *impulse*, which occur 190 and 154 times, respectively, in the corpus, yet only 8 and 12 times in marked contexts, which was not enough for an accurate classification. Again, the inclusion of information regarding the distribution of these nouns in unmarked contexts provided the classifier with sufficient information to allow for correct classification.

One of the main concerns regarding the use of unmarked distributional information was the introduction of extra noise as a side effect and the way this affects classification results. For the purpose of the work presented in this paper, we define noise as contradictory distributional information, particularly the occurrence of nouns that are not members of a particular class in prototypical contexts of that particular class, which provides misleading information to classifiers. The impact of this misleading information is made apparent by the amount of FP observed in classification results. In contrast, silence has to do with the well known problem of data sparsity, which can be caused by the particular distribution of lexical, and thus strict, though informative, contexts used in cue-based classification tasks, which are often rare in any corpus of any size due to their specificity.

In our experiment, we did identify some cases of nouns correctly ruled out as members of a class when using only marked cues, which were incorrectly classified as class members after the inclusion of unmarked contexts. The slight increase of FP in our results (see Table 7) shows our method does introduce some extra noise into the classifier, although, in the overall results, this is compensated by the larger amount of nouns that were correctly classified after the inclusion of unmarked distributional information (see Tables 4 and 5).

Analyzing the additional FP observed, we identify two different cases: (i) nouns correctly classified using only marked contexts as not belonging to a class based on a borderline probability, which were

incorrectly classified as members of that class when unmarked contexts were also considered, again based on a borderline probability; and (ii) nouns correctly classified as not belonging to a class as they hardly or never occurred in class-marked contexts, but whose behavior in unmarked contexts was similar to that of members of the class being classified, thus providing contradictory information to the classifier and resulting in incorrect classification.

The first case is illustrated by a noun like *biography*, which was predicted not to be a member of the LOC class with a borderline probability score (0.47). The inclusion of unmarked contexts provided information to the classifier, which slightly changed this probability (0.56), and resulted in an incorrect classification. The noun *megalopolis* illustrates the other case. Occurring only 3 times in class-marked contexts of the INF class, this LOC noun had been correctly classified as not belonging to the INF class. Yet, its behavior in unmarked contexts showed more similarities with members of the INF class than with non-members, resulting in its incorrect classification. Illustrating two paradigmatic cases of noise in the results of the classifiers, these examples make apparent how unmarked contexts are sometimes responsible for incorrect class membership decisions, and how further improving their use in classification tasks, particularly in the case of "borderline" classification decisions, remains a promising line of research to explore in the future (see Section 7).

6.2 More robust classification decisions

Besides the reduction of the impact of silence in the results of the classifiers, with the consequent improvements in accuracy, as discussed in the previous section, we also noticed that the introduction of unmarked contexts provided additional information regarding the distribution of nouns that were classified by chance (i.e. correctly classified nouns, with a borderline probability score), resulting in more robust classification decisions. We saw this with the EVT noun *consolidation* and the LOC noun *coalfield*. Each of these nouns was correctly classified using only marked contexts, yet with borderline probability scores: 0.52 and 0.53, respectively. Upon providing information on unmarked contexts to the classifier, these nouns continued to be correctly classified but with much higher probability scores, and thus more reliable: 0.75 and 0.76, respectively.

These examples are considerably different from those discussed in Section 6.1, as these are far from being cases of silence. In fact, the EVT noun *consolidation* occurs 312 times in the corpus and 317 times in marked contexts while the LOC noun *coalfield* occurs 52 times in the corpus and 53 times in marked contexts[4]. In both cases, almost all of the occurrences in marked contexts were found to be in only one cue, which was therefore not strongly valued by the classifier, as few correlations between the evidence available could be made, hence the low probability scores observed. The inclusion of unmarked distributional information provides "bridging information", allowing for more reliable classifications, which is crucial to consider especially when the ultimate goal of improving and tuning classification systems is to employ classification results for the automatic production of language resources (see Section 1).

6.3 Classification results unevenly affected by unmarked contexts

As made apparent by the results, the contribution of unmarked contexts to the classification of different semantic classes is not always the same. For example, we observed that classes whose members demonstrated a more heterogeneous linguistic behavior, such as the ORG, LOC or EVT classes, improve more with the inclusion of unmarked distributional information than classes with a more homogeneous distributional behavior. To make our statement clearer, we claim that some nominal classes are composed of nouns that tend to occur in a wider range of contexts, thus displaying a more heterogeneous and disperse distributional behavior. This heterogeneity is made apparent by an analysis of the overall distribution of the marked cues between the members of each lexical semantic class. In contrast with heterogeneous noun classes, other classes are composed of members that display a more homogeneous collective behavior that is more easily captured by distributional approaches[5].

[4] Note that a single occurrence in corpus data can activate more than one cue considered in our experiments (for instance, in the case of a target noun that has a marked suffix and simultaneously occurs in a marked syntactic construction), hence the higher amount of occurrences in cues than overall occurrences in the corpus discussed in the examples introduced in this paragraph.

[5] Our analysis of the data showed that the dispersion of distributional behavior is independent of frequency.

Analyzing the distribution of cues between class members in Corpus B, we identified, in each class, a set of cues that occurred with the majority of nouns of the class, and which we will consider to represent the core linguistic behavior of each specific class. We also observed the amount of cues included in this set differed considerably from class to class (see Figure 1). Thus, the larger the amount of marked contexts shared by the majority of the members of a class, the more homogeneous we can claim their behavior to be.

In the specific case of the classes considered in this paper, 30.7% of the cues for the HUM class are shared by the majority of HUM nouns, while 26.6%, 13.3%, 9.5% and 9.1% of the cues for the INF, ORG, EVT and LOC classes, respectively, are shared by the majority of the nouns of these classes, as represented in Figure 1. An effect of a class collectively having a more heterogeneous linguistic behavior is that the evidence regarding each of its marks will typically be more disperse and, as a result, often not strong enough to be considered by classifiers, which explains the improvement introduced by unmarked contexts. In contrast, classes like HUM are composed of nouns that generally occur in a common set of prototypical contexts of that class. Thus, on the one hand, identifying contexts that mirror the prototypical behavior of that class is more straightforward and, on the other, class members almost always show enough occurrences in such contexts to be accurately classified.

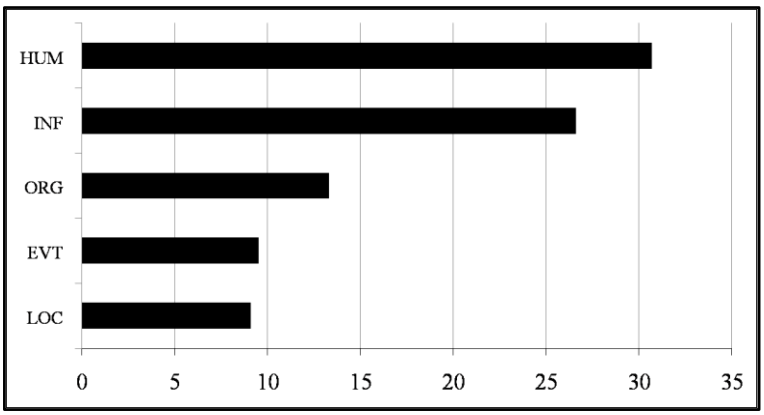

Figure 1: Percentage of cues shared by the majority of class members, per class

Additionally, there are also strong marks based on suffixes and degree of grammaticalization for the HUM class (as demonstrated in Bel *et al.* (2012)), which can be more readily captured by these more available marked contexts. For instance, on the one hand, suffixes, such as: *"-er"* and *"-or"* are indicative of many HUM type nouns (e.g. "doctor", "painter", "officer", etc.) while the preposition *"during"*, when preceding a nominal phrase, is very indicative of occurrences of EVT nouns. These examples are both instances of features that can be easily identified for inclusion in a feature vector, readily providing a large amount of class-indicative information. On the other hand, there are other types of features that although indicative, result in a much sparser vector because of their reliance of occurrence within corpus data. For instance the occurrence as the subject of an agentive verb, which is considered an indicative feature for the ORG class, does not necessarily occur readily with all members of the class, thus making marked contexts that provide a homogeneous representation of the class more difficult to capture.

In this way, the inclusion of extra contexts (e.g. unmarked contexts) are rendered ineffective when class membership decisions are already accurately made to a great extent (in our case 86.19% of the times) based on the information provided by marked contexts. This is consistent with the stability of the results reported for the HUM class in the different experiments performed, which did not demonstrate any significant changes with the inclusion of unmarked contexts.

7 Conclusions and Final Remarks

Our main goal in this paper was to evaluate how unmarked contexts can be used to improve the accuracy of nominal lexical semantic classification tasks. Departing from the hypothesis that these contexts can provide additional information to classifiers when there is not enough distinctive co-occurrence information available, the results reported demonstrate the use of unmarked contexts, which are typically discarded as non-discriminatory, can significantly improve the results of lexical semantic classification when considered along with marked contexts. Our results also show that using both types of

distributional information (marked and unmarked) is crucial to reduce the sparse data problem, thus improving classification (see increase in classification accuracy in Tables 4 and 5). Moreover, in our experiments, we apply this method to two independent corpora obtaining comparable results and thus demonstrating the robustness and transferability of our approach to any dataset.

The higher accuracy and error reduction achieved with the inclusion of unmarked contexts constitute a significant improvement with respect to the state of the art (Bel, 2010; Bel *et al.*, 2012; Romeo *et al.*, 2014), contributing particularly to the increase of accuracy and reliability of classifiers for classes that exhibit more disperse linguistic behavior. Moreover, the approach depicted here leaves room for further improvements and future work, particularly with regard to designing strategies to minimize the introduction of borderline false positives in classification.

One promising line of research to explore is the optimization of the inclusion of unmarked contexts in classification decisions. As detailed in the discussion, for the experiments depicted in this paper, we did not expect particular marked or unmarked features to be more useful than others, as we relied on the correlation of all the distributional information considered for each specific class to be indicative of class membership.

Another aspect to be further explored consists of determining the most effective amount of unmarked contexts to be provided to automatic systems. Building on the demonstration of the positive contribution of unmarked contexts in classification tasks, as indicated by the results obtained in the work depicted in this paper (see Section 5), we will start by determining the specific contribution to classification of each unmarked feature used. In this way, we would check whether there is a context, within our set, that is not contributing to the classification, in order to establish a threshold to systematically identify the information that is not relevant or whether we need to widen/relax our frequency criterion to include more unmarked contexts with the goal of elaborating a set of information to be as robust as possible, thus resulting in more accurate and more reliable classification decisions.

Finally, we believe the results obtained make a clear contribution towards the automatic production of high-quality language resources, which will benefit any NLP system that requires information on lexical semantic classes as an input.

Abstract

Personal skill information on social media is at the core of many interesting applications. In this paper, we propose a factor graph based approach to automatically infer skills from personal profile incorporated with both personal and skill connections. We first extract personal connections with similar academic and business background (e.g. co-major, co-university, and co-corporation). We then extract skill connections between skills from the same person. To well integrate various kinds of connections, we propose a joint prediction factor graph (JPFG) model to collectively infer personal skills with help of personal connection factor, skill connection factor, besides the normal textual attributes. Evaluation on a large-scale dataset from LinkedIn.com validates the effectiveness of our approach.

1 Introduction

With the large amount of user-generated content (UGC) published online every day in the context of social networks (Tan et al., 2011; Luo et al., 2013), such online social networks (e.g., Twitter, Facebook, and LinkedIn) have significantly enlarged our social circles and much affected our everyday life. One popular and important type of UGC is the personal profile, where people post their detailed information, such as education, experience and other personal information, on online portals. Social websites like Facebook.com and LinkedIn.com have created a viable business as profile portals, with the popularity and success largely attributed to their comprehensive personal profiles.
