Preface by the General Chair

Thank you so much for joining us in Copenhagen! Welcome to a cosmopolitan city of fantastic restaurants, lovely seascapes, rich history, and lots and lots of cyclists!

We have an exciting program lined up for you, with three Invited talks, fifteen workshops, seven tutorials, nine TACL presentations, 322 reviewed papers presented as both oral talks and posters, and twenty-one demos. I am especially grateful to our Program Chairs, Rebecca Hwa and Sebastian Riedel, who did a fantastic job managing a backbreaking 1,500 paper submissions (1466 reviewed papers). This involved 51 Area chairs and 980 reviewers. We tried some new things this year (never conducive to a smooth process) including a more careful handling of the COIs that result from Area Chair submissions, and the addition of a meta-review step to encourage more thoughtful reviewing. We are soliciting feedback on the meta-review process, from both reviewers and authors. Despite the additional time involvement, many of the Area Chairs embraced this new approach, and would like to repeat it. However, there are clearly a few dissenters, since Rebecca and Sebastian ended up writing around 200 meta-reviews themselves at the last minute! We are also trying to raise the visibility and status of the poster sessions by integrating them as parallel sessions alongside oral talks, with poster session chairs. This is in response to the survey results from EMNLP 2015 that indicated a decided preference for smaller, more frequent poster sessions during the day rather than evening mega-sessions. Finally, Rebecca and Sebastian are bringing you three outstanding invited speakers, Dan Jurafsky, Sharon Goldwater, and Nando de Freitas. No program chairs ever worked harder to bring you a superb set of presentations in an attendee friendly setting.

I am also very grateful to Victoria Fossum and Karl Moritz Hermann, our Workshop Chairs, who put together a terrific slate of fifteen workshops, and paid meticulous attention to ensuring that each workshop could hold exactly the poster sessions, invited talks and special events that it required. Our tutorial chairs, Alexandra Birch and Nathan Schneider, also outdid themselves, providing especially tempting tutorial offerings. Matt Post deserves to be singled out, for being an Advisor to our conscientious and successful Handbook Chair, Joachim Bingel, as well as becoming a welcome last minute addition to our excellent team of Demo Chairs, Lucia Specia and Michael Paul. Thanks are due to our Website Chair, Anders Johannsen, who responded promptly and deftly to all of our requests, and to our Student Volunteer and Student Sponsorship Chairs, Zeljko Agic and Yonatan Bisk, who brought you the helpful and energetic volunteers who keep things running smoothly.

Last but not least, many thanks to your hosts, our Local Arrangements Chairs, Dirk Hovy and Anders Søgaard and their team. Their concern has been increasing the enjoyment of your experience, and to that end they proposed a stunning venue, put together an amazing reception and Social Event, chose your conference bags, issued all the invitation letters for visas, helped create all the signs, etc., etc., etc. Dan Hardt, our Sponsorship chair, working with Anders and Dirk, raised an unusual amount of local sponsorships, all to defray the cost of the Social Event.

As always, we are extremely indebted to our generous sponsors. Our platinum sponsors are Google, Amazon, Baidu, Apple, Facebook, Bloomberg and Siteimprove. Gold sponsors include IBM Research, Microsoft, eBay, SAP, Textkernel, Maluuba, Zalando, Recruit Institute of Technology and Deloitte. Silver sponsors are Nuance, Oracle, Sogou, Huawei, Duolingo, CVTE, Unsilo and Wizkids. Snap Inc., Grammarly and Yandex are our Bronze sponsors.

Finally, many, many thanks to our Area Chairs, our reviewers, and our authors, whose outstanding research is being showcased here for your delectation. *Nyd det mens det varer!*

Best Regards,
Martha Palmer
EMNLP 2017 General Chair

Preface by the Program Committee Co-Chairs

Welcome to the 2017 Conference on Empirical Methods in Natural Language Processing! This is an exciting year; we have received a new record-high in the number of submissions: 1,509 papers. After discounting early withdraws, duplicates, and other invalid submissions, we sent out 1,418 submissions (836 long papers, 582 short papers) to be reviewed by the program committee. Ultimately, 216 long papers (25.8% acceptance rate) and 107 short papers (18.4% acceptance rate) have been accepted for presentation, making a total of 323 papers and an overall acceptance rate of 22.8%.

This year's technical program consists of three invited talks and 113 oral presentations and 219 poster presentations for the 323 long and short accepted papers as well as nine papers accepted to the Transactions of the Association for Computational Linguistics. To accommodate all the presentations in a compressed timeframe, we opted to have plenary sessions for the invited talks and the winners of the Best Paper Awards, while allotting three parallel oral sessions and thematically related poster sessions for all other presentations. We chose to have concurrent poster and oral sessions for several reasons. First, this is the preferred model of the majority (51.6%) of participants who filled out the EMNLP 2015 post-conference survey. Second, this allows us to spread out the poster presentations across three days in smaller thematically related clusters. Finally, this maximises the number of acceptances for the high quality submissions we received; by having more poster sessions, we are able to maintain the acceptance rates at the previous year's level despite an increase in submissions by 40%.

It would not have been possible to properly handle such a large number of submissions without the generous voluntary help from all the members of the program committee, which consists of 980 reviewers overseen by 51 area chairs. We continued last year's experiment of defining twelve relatively broad topic areas and assigning multiple area chairs to facilitate consistent ranking of larger sets of papers. Most technical program decisions, from the selection of papers to the modes of presentation to the choice of outstanding papers, are primarily made in a bottom-up fashion: reviewers assessed and scored papers, made recommendations for oral vs poster decisions, and marked papers suitable for best paper awards; area chairs ensured the quality of assessments, encouraged discussions and assembled opinions into their own recommendations; finally, we construct the technical program, considering the recommendations from the area chairs while taking into account venue constraints and balance across areas. A new experimental feature of this year's EMNLP reviewing process is the “meta review,” in which the area chairs briefly summarize the major discussions between the reviewers to give authors a more transparent view of the process.

Per EMNLP tradition, awards are given to outstanding papers in three categories: Best Long Paper, Best Short Paper, and Best Resource Paper. The selection process is bottom-up: based on the reviewers and area chairs' recommendations, we nominated four papers for each category; we invited expert members to form a Best Papers committee for each category; each committee reviews the candidates and select the winners. The awarded papers will be presented at a special plenary session on the last day of the conference.

We are extremely grateful that three amazing speakers have agreed to give invited talks at EMNLP. Nando de Freitas (Google Deepmind) will discuss simulated physical environments, and whether language would benefit from the development of such environments, and could contribute toward improving such environments and agents within them. Sharon Goldwater (University of Edinburgh) will describe work on developing unsupervised speech technology for those of the world's 7,000 or so languages not spoken in large rich countries. Dan Jurafsky (Stanford University) will talk about processing the language of policing to automatically measure linguistic aspects of the interaction from discourse factors like conversational structure to social factors like respect.

The conference would not have been possible without the support of various people inside and outside of the committee. In particular, we would like to thank:

- Martha Palmer, whose encouragement and advice as the general chair has been invaluable every step of the way;

- Chris Callison-Burch, who has given us excellent advice and support in his capacity as the SIGDAT Secretary;
- Priscilla Rasmussen, who always has the right answers;
- Xavier Carreras and Kevin Duh, who generously shared their experiences as the chairs of EMNLP 2016;
- Anders Johannsen, who is lightning fast with website updates;
- Our 51 area chairs: David Bamman, Mohit Bansal, Roberto Basili, Chris Biemann, Jordan Boyd-Graber, Marine Carpuat, Joyce Chai, David Chiang, Jinho Choi, Jennifer Chu-Carroll, Trevor Cohn, Cristian Danescu-Niculescu-Mizil, Dipanjan Das, Hal Daume, Mona Diab, Mark Dredze, Jacob Eisenstein, Sanja Fidler, Alona Fyshe, Dan Gildea, Ed Grefenstette, Hannaneh Hajishirzi, Julia Hockenmaier, Kentaro Inui, Jing Jiang, Philipp Koehn, Mamoru Komachi, Anna Korhonen, Tom Kwiatkowski, Gina Levow, Bing Liu, Nitin Madnani, Mausam, Rada Mihalcea, Marie-Francine Moens, Saif M. Mohammad, Mari Ostendorf, Sameer Pradhan, Alexander Rush, Anoop Sarkar, William Schuler, Hinrich Schütze, Sameer Singh, Thamar Solorio, Vivek Srikumar, Amanda Stent, Tomek Strzalkowski, Mihai Surdeanu, Andreas Vlachos, Scott Wen-tau Yih, Zhang Yue;
- The best papers award committee members: Chris Brew, Mike Collins, Kevin Duh, Adam Lopez, Ani Nenkova, Bonnie Webber, Luke Zettlemoyer;
- Preethi Raghavan and Siddharth Patwardhan, the publications co-chairs and Joachim Bingel, the conference handbook chair;
- Dirk Hovy and Anders Søgaard, the local arrangements co-chairs;
- Rich Gerber and Paolo Gai at SoftConf.

Finally, we'd like to thank SIGDAT for the opportunity to serve as Program Co-Chairs of EMNLP 2017. It is an honor and a rewarding learning experience. We hope you will be as inspired by the technical program as we are.

EMNLP 2017 Program Co-Chairs
Rebecca Hwa, University of Pittsburg
Sebastian Riedel, University College London

Organizing Committee

General Chair
Martha Palmer, University of Colorado

Local Arrangements Chair
Priscilla Rasmussen, ACL Business Manager

Program Committee Co-chairs
Rebecca Hwa, University of Pittsburgh
Sebastian Riedel, University College London

Invited Speaker: Dan Jurafsky, Stanford University
"Does This Vehicle Belong to You”? Processing the Language of Policing for Improving Police-Community Relations"

Abstract: Police body-cameras have the potential to play an important role in understanding and improving police-community relations. In this talk I describe a series of studies conducted by our large interdisciplinary team at Stanford that use speech and natural language processing on body-camera recordings to model the interactions between police officers and community members in traffic stops. We use text and speech features to automatically measure linguistic aspects of the interaction, from discourse factors like conversational structure to social factors like respect. I describe the differences we find in the language directed toward black versus white community members, and offer suggestions for how these findings can be used to help improve the fraught relations between police officers and the communities they serve.

Bio: Dan Jurafsky is Professor and Chair of Linguistics and Professor of Computer Science, at Stanford University. His research has focused on the extraction of meaning, intention, and affect from text and speech, on the processing of Chinese, and on applying natural language processing to the cognitive and social sciences. Dan’s deep interest in NLP education led him to co-write with Jim Martin the widely-used textbook "Speech and Language Processing” (whose 3rd edition is in (slow) progress) and co-teach with Chris Manning the first massive open online class on natural language processing. Dan was the recipient of the 2002 MacArthur Fellowship and is a 2015 James Beard Award Nominee for his book, "The Language of Food: A Linguist Reads the Menu".

Invited Speaker: Sharon Goldwater, University of Edinburgh
Towards more universal language technology: unsupervised learning from speech

Abstract: Speech and language processing has advanced enormously in the last decade, with successful applications in machine translation, voice-activated search, and even language-enabled personal assistants. Yet these systems typically still rely on learning from very large quantities of human-annotated data. These resource-intensive methods mean that effective technology is available for only a tiny fraction of the world’s 7000 or so languages, mainly those spoken in large rich countries.

This talk describes our recent work on developing unsupervised speech technology, where transcripts and pronunciation dictionaries are not used. The work is inspired by considering both how young infants may begin to acquire the sounds and words of their language, and how we might develop systems to help linguists analyze and document endangered languages. I will first present work on learning from speech audio alone, where the system must learn to segment the speech stream into word tokens and cluster repeated instances of the same word together to learn a lexicon of vocabulary items. The approach combines Bayesian and neural network methods to address learning at the word and sub-word levels.

Bio: Sharon Goldwater is a Reader at the University of Edinburgh’s School of Informatics, where she is a member of the Institute for Language, Cognition and Computation. She received her PhD in 2007 from Brown University and spent two years as a postdoctoral researcher at Stanford University before moving to Edinburgh. Her research interests include unsupervised learning for speech and language processing, computer modelling of language acquisition in children, and computational studies of language use. Dr. Goldwater co-chaired the 2014 Conference of the European Chapter of the Association for Computational Linguistics and is Chair-Elect of EACL. She has served on the editorial boards of the Transactions of the Association for Computational Linguistics, the Computational Linguistics journal, and OPEN MIND: Advances in Cognitive Science (a new open-access journal). In 2016, she received the Roger Needham Award from the British Computer Society, awarded for "distinguished research contribution in computer science by a UK-based researcher who has completed up to 10 years of post-doctoral research."

Invited Speaker: Nando de Freitas, Google Deepmind
Physical simulation, learning and language

Abstract: Simulated physical environments, with common physical laws, objects and agents with bodies, provide us with consistency to facilitate transfer and continual learning. In such environments, research topics such as learning to experiment, learning to learn and emergent communication can be easily explored. Given the relevance of these topics to language, it is natural to ask ourselves whether research in language would benefit from the development of such environments, and whether language can contribute toward improving such environments and agents within them. This talk will provide an overview of some of these environments, discuss learning to learn and its potential relevance to language, and present some deep reinforcement learning agents that capitalize on formal language instructions to develop disentangled interpretable representations that allow them to generalize to a wide variety of zero-shot semantic tasks. The talk will pose more questions than answers in the hope of stimulating discussion.

Bio: I was born in Zimbabwe, with malaria. I was a refugee from the war in Mocambique and thanks to my parents getting in debt to buy me a passport from a corrupt official, I grew up in Portugal without water and electricity, before the EU got there, and without my parents who were busy making money to pay their debt. At 8, I joined my parents in Venezuela and began school in the hood; see City of God. I moved to South Africa after high-school and sold beer illegally in black-townships for a living until 1991. Apartheid was the worst thing I ever experienced. I did my BSc in electrical engineering and MSc in control at the University of the Witwatersrand, where I strived to be the best student to prove to racists that anyone can do it. I did my PhD on Bayesian methods for neural networks at Trinity College, Cambridge University. I did a postdoc in Artificial Intelligence at UC Berkeley. I became a Full Professor at the University of British Columbia, before joining the University of Oxford in 2013. I quit Oxford in 2017 to join DeepMind full-time, where I lead the Machine Learning team. I aim to solve intelligence so that future generations have a better life. I have been a Senior Fellow of the Canadian Institute for Advanced Research for a long time. Some of my recent awards, mostly thanks to my collaborators, include: Best Paper Award at the International Conference on Machine Learning (2016), Best Paper Award at the International Conference on Learning Representations (2016), Winner of round 5 of the Yelp Dataset Challenge (2015), Distinguished Paper Award at the International Joint Conference on Artificial Intelligence (2013), Charles A. McDowell Award for Excellence in Research (2012), and Mathematics of Information Technology and Complex Systems Young Researcher Award (2010).

Table of Contents

Conference Program

Friday, September 8, 2017

19:00–22:00 Welcome Reception

Saturday, September 9, 2017

07:30–17:30 Registration Day 1

08:00–08:30 ***Morning Coffee***

08:30–09:00 Plenary Session. Opening Remarks

08:30–09:00 *Opening Remarks*
General Chair, PC Co-Chairs

09:00–10:00 Plenary Session. Invited Talk by Nando de Freitas

09:00–10:00 *Physical simulation, learning and language*
Nando de Freitas

10:00–10:30 ***Coffee Break***

Saturday, September 9, 2017 (continued)

10:30–12:10 Session 1A: Syntax 1

10:30–10:55 *Monolingual Phrase Alignment on Parse Forests*
Yuki Arase and Jun'ichi Tsujii

10:55–11:20 *Fast(er) Exact Decoding and Global Training for Transition-Based Dependency Parsing via a Minimal Feature Set*
Tianze Shi, Liang Huang and Lillian Lee

11:20–11:45 *Parsing with Traces: An O(nˆ4) Algorithm and a Structural Representation*
Jonathan K. Kummerfeld and Dan Klein

11:45–12:10 *Quasi-Second-Order Parsing for 1-Endpoint-Crossing, Pagenumber-2 Graphs*
Junjie Cao, Sheng Huang, Weiwei Sun and Xiaojun Wan

10:30–12:10 Session 1B: Information Extraction 1

10:30–10:55 *Position-aware Attention and Supervised Data Improve Slot Filling*
Yuhao Zhang, Victor Zhong, Danqi Chen, Gabor Angeli and Christopher D. Manning

10:55–11:20 *Heterogeneous Supervision for Relation Extraction: A Representation Learning Approach*
Liyuan Liu, Xiang Ren, Qi Zhu, Shi Zhi, Huan Gui, Heng Ji and Jiawei Han

11:20–11:45 *Integrating Order Information and Event Relation for Script Event Prediction*
Zhongqing Wang, Yue Zhang and Ching-Yun Chang

11:45–12:10 *Entity Linking for Queries by Searching Wikipedia Sentences*
Chuanqi Tan, Furu Wei, Pengjie Ren, Weifeng Lv and Ming Zhou

Saturday, September 9, 2017 (continued)

10:30–12:10 Session 1C: Multilingual NLP

10:30–10:55 *Train-O-Matic: Large-Scale Supervised Word Sense Disambiguation in Multiple Languages without Manual Training Data*
Tommaso Pasini and Roberto Navigli

10:55–11:20 *Universal Semantic Parsing*
Siva Reddy, Oscar Täckström, Slav Petrov, Mark Steedman and Mirella Lapata

11:20–11:45 *Mimicking Word Embeddings using Subword RNNs*
Yuval Pinter, Robert Guthrie and Jacob Eisenstein

11:45–12:10 *Past, Present, Future: A Computational Investigation of the Typology of Tense in 1000 Languages*
Ehsaneddin Asgari and Hinrich Schütze

10:30–12:10 Session 1D: Poster Session: Demo

12:10–13:40 *Lunch*

13:40–15:20 Session 2A: Machine Translation 1

13:40–14:05 *Neural Machine Translation with Source-Side Latent Graph Parsing*
Kazuma Hashimoto and Yoshimasa Tsuruoka

14:05–14:30 *Neural Machine Translation with Word Predictions*
Rongxiang Weng, Shujian Huang, Zaixiang Zheng, XIN-YU DAI and Jiajun CHEN

14:30–14:55 *Towards Decoding as Continuous Optimisation in Neural Machine Translation*
Cong Duy Vu Hoang, Gholamreza Haffari and Trevor Cohn

14:55–15:20 *Google's Multilingual Neural Machine Translation System: Enabling Zero-Shot Translation*
Melvin Johnson, Mike Schuster, Quoc V. Le, Maxim Krikun, Yonghui Wu, Zhifeng Chen, Nikhil Thorat, Fernanda Viégas, Martin Wattenberg, Greg Corrado, Macduff Hughes and Jeffrey Dean

Saturday, September 9, 2017 (continued)

13:40–15:20 Session 2B: Language Grounding

13:40–14:05 *Where is Misty? Interpreting Spatial Descriptors by Modeling Regions in Space*
Nikita Kitaev and Dan Klein

14:05–14:30 *Continuous Representation of Location for Geolocation and Lexical Dialectology using Mixture Density Networks*
Afshin Rahimi, Timothy Baldwin and Trevor Cohn

14:30–14:55 *Colors in Context: A Pragmatic Neural Model for Grounded Language Understanding*
Will Monroe, Robert X. D. Hawkins, Noah D. Goodman and Christopher Potts

14:55–15:20 *Obj2Text: Generating Visually Descriptive Language from Object Layouts*
Xuwang Yin and Vicente Ordonez

13:40–15:20 Session 2C: Discourse and Summarization

13:40–14:05 *End-to-end Neural Coreference Resolution*
Kenton Lee, Luheng He, Mike Lewis and Luke Zettlemoyer

14:05–14:30 *Neural Net Models of Open-domain Discourse Coherence*
Jiwei Li and Dan Jurafsky

14:30–14:55 *Affinity-Preserving Random Walk for Multi-Document Summarization*
Kexiang Wang, Tianyu Liu, Zhifang Sui and Baobao Chang

14:55–15:20 *A Mention-Ranking Model for Abstract Anaphora Resolution*
Ana Marasovic, Leo Born, Juri Opitz and Anette Frank

Saturday, September 9, 2017 (continued)

13:40–15:20 Session 2D: Poster Session. Embeddings

Hierarchical Embeddings for Hypernymy Detection and Directionality
Kim Anh Nguyen, Maximilian Köper, Sabine Schulte im Walde and Ngoc Thang Vu

Ngram2vec: Learning Improved Word Representations from Ngram Co-occurrence Statistics
Zhe Zhao, Tao Liu, Shen Li, Bofang Li and Xiaoyong Du

Dict2vec : Learning Word Embeddings using Lexical Dictionaries
Julien Tissier, Christopher Gravier and Amaury Habrard

Learning Chinese Word Representations From Glyphs Of Characters
Tzu-ray Su and Hung-yi Lee

Learning Paraphrastic Sentence Embeddings from Back-Translated Bitext
John Wieting, Jonathan Mallinson and Kevin Gimpel

Joint Embeddings of Chinese Words, Characters, and Fine-grained Subcharacter Components
Jinxing Yu, Xun Jian, Hao Xin and Yangqiu Song

Exploiting Morphological Regularities in Distributional Word Representations
Arihant Gupta, Syed Sarfaraz Akhtar, Avijit Vajpayee, Arjit Srivastava, Madan Gopal Jhanwar and Manish Shrivastava

Exploiting Word Internal Structures for Generic Chinese Sentence Representation
Shaonan Wang, Jiajun Zhang and Chengqing Zong

High-risk learning: acquiring new word vectors from tiny data
Aurélie Herbelot and Marco Baroni

Word Embeddings based on Fixed-Size Ordinally Forgetting Encoding
Joseph Sanu, Mingbin Xu, Hui Jiang and Quan Liu

VecShare: A Framework for Sharing Word Representation Vectors
Jared Fernandez, Zhaocheng Yu and Doug Downey

Word Re-Embedding via Manifold Dimensionality Retention
Souleiman Hasan and Edward Curry

MUSE: Modularizing Unsupervised Sense Embeddings
Guang-He Lee and Yun-Nung Chen

13:40–15:20 Session 2E: Poster Session. Machine Learning 1

Reporting Score Distributions Makes a Difference: Performance Study of LSTM-networks for Sequence Tagging
Nils Reimers and Iryna Gurevych

Learning What's Easy: Fully Differentiable Neural Easy-First Taggers
André F. T. Martins and Julia Kreutzer

Incremental Skip-gram Model with Negative Sampling
Nobuhiro Kaji and Hayato Kobayashi

Learning to select data for transfer learning with Bayesian Optimization
Sebastian Ruder and Barbara Plank

Unsupervised Pretraining for Sequence to Sequence Learning
Prajit Ramachandran, Peter Liu and Quoc Le

Efficient Attention using a Fixed-Size Memory Representation
Denny Britz, Melody Guan and Minh-Thang Luong

Rotated Word Vector Representations and their Interpretability
Sungjoon Park, JinYeong Bak and Alice Oh

A causal framework for explaining the predictions of black-box sequence-to-sequence models
David Alvarez-Melis and Tommi Jaakkola

Piecewise Latent Variables for Neural Variational Text Processing
Iulian Vlad Serban, Alexander G. Ororbia, Joelle Pineau and Aaron Courville

Saturday, September 9, 2017 (continued)

Learning the Structure of Variable-Order CRFs: a finite-state perspective
Thomas Lavergne and François Yvon

Sparse Communication for Distributed Gradient Descent
Alham Fikri Aji and Kenneth Heafield

Why ADAGRAD Fails for Online Topic Modeling
You Lu, Jeffrey Lund and Jordan Boyd-Graber

13:40–15:20 Session 2F: Poster Session. Sentiment Analysis 1

Recurrent Attention Network on Memory for Aspect Sentiment Analysis
Peng Chen, Zhongqian Sun, Lidong Bing and Wei Yang

A Cognition Based Attention Model for Sentiment Analysis
Yunfei Long, Lu Qin, Rong Xiang, Minglei Li and Chu-Ren Huang

Author-aware Aspect Topic Sentiment Model to Retrieve Supporting Opinions from Reviews
Lahari Poddar, Wynne Hsu and Mong Li Lee

Magnets for Sarcasm: Making Sarcasm Detection Timely, Contextual and Very Personal
Aniruddha Ghosh and Tony Veale

Identifying Humor in Reviews using Background Text Sources
Alex Morales and Chengxiang Zhai

Sentiment Lexicon Construction with Representation Learning Based on Hierarchical Sentiment Supervision
Leyi Wang and Rui Xia

Towards a Universal Sentiment Classifier in Multiple languages
Kui Xu and Xiaojun Wan

Capturing User and Product Information for Document Level Sentiment Analysis with Deep Memory Network
Zi-Yi Dou

Saturday, September 9, 2017 (continued)

Identifying and Tracking Sentiments and Topics from Social Media Texts during Natural Disasters
Min Yang, Jincheng Mei, Heng Ji, zhao wei, Zhou Zhao and Xiaojun Chen

Refining Word Embeddings for Sentiment Analysis
Liang-Chih Yu, Jin Wang, K. Robert Lai and Xuejie Zhang

A Multilayer Perceptron based Ensemble Technique for Fine-grained Financial Sentiment Analysis
Md Shad Akhtar, Abhishek Kumar, Deepanway Ghosal, Asif Ekbal and Pushpak Bhattacharyya

Sentiment Intensity Ranking among Adjectives Using Sentiment Bearing Word Embeddings
Raksha Sharma, Arpan Somani, Lakshya Kumar and Pushpak Bhattacharyya

Sentiment Lexicon Expansion Based on Neural PU Learning, Double Dictionary Lookup, and Polarity Association
Yasheng Wang, Yang Zhang and Bing Liu

15:20–15:50 ***Coffee Break***

15:50–17:30 **Session 3A: Machine Learning 2**

15:50–16:15 *DeepPath: A Reinforcement Learning Method for Knowledge Graph Reasoning*
Wenhan Xiong, Thien Hoang and William Yang Wang

16:15–16:40 *Task-Oriented Query Reformulation with Reinforcement Learning*
Rodrigo Nogueira and Kyunghyun Cho

16:40–17:05 *Sentence Simplification with Deep Reinforcement Learning*
Xingxing Zhang and Mirella Lapata

17:05–17:30 *Learning how to Active Learn: A Deep Reinforcement Learning Approach*
Meng Fang, Yuan Li and Trevor Cohn

15:50–17:30	**Session 3B: Generation**
15:50–16:15	*Split and Rephrase* Shashi Narayan, Claire Gardent, Shay B. Cohen and Anastasia Shimorina
16:15–16:40	*Neural Response Generation via GAN with an Approximate Embedding Layer* Zhen Xu, Bingquan Liu, Baoxun Wang, Chengjie SUN, Xiaolong Wang, Zhuoran Wang and Chao Qi
16:40–17:05	*A Hybrid Convolutional Variational Autoencoder for Text Generation* Stanislau Semeniuta, Aliaksei Severyn and Erhardt Barth
17:05–17:30	*Filling the Blanks (hint: plural noun) for Mad Libs Humor* Nabil Hossain, John Krumm, Lucy Vanderwende, Eric Horvitz and Henry Kautz
15:50–17:30	**Session 3C: Semantics 1**
15:50–16:15	*Measuring Thematic Fit with Distributional Feature Overlap* Enrico Santus, Emmanuele Chersoni, Alessandro Lenci and Philippe Blache
16:15–16:40	*SCDV : Sparse Composite Document Vectors using soft clustering over distributional representations* Dheeraj Mekala, Vivek Gupta, Bhargavi Paranjape and Harish Karnick
16:40–17:05	*Supervised Learning of Universal Sentence Representations from Natural Language Inference Data* Alexis Conneau, Douwe Kiela, Holger Schwenk, Loïc Barrault and Antoine Bordes
17:05–17:30	*Determining Semantic Textual Similarity using Natural Deduction Proofs* Hitomi Yanaka, Koji Mineshima, Pascual Martínez-Gómez and Daisuke Bekki

15:50–17:30 Session 3D: Poster Session. Syntax 2

Multi-Grained Chinese Word Segmentation
Chen Gong, Zhenghua Li, Min Zhang and Xinzhou Jiang

Don't Throw Those Morphological Analyzers Away Just Yet: Neural Morphological Disambiguation for Arabic
Nasser Zalmout and Nizar Habash

Paradigm Completion for Derivational Morphology
Ryan Cotterell, Ekaterina Vylomova, Huda Khayrallah, Christo Kirov and David Yarowsky

A Sub-Character Architecture for Korean Language Processing
Karl Stratos

Do LSTMs really work so well for PoS tagging? – A replication study
Tobias Horsmann and Torsten Zesch

The Labeled Segmentation of Printed Books
Lara McConnaughey, Jennifer Dai and David Bamman

Cross-lingual Character-Level Neural Morphological Tagging
Ryan Cotterell and Georg Heigold

Word-Context Character Embeddings for Chinese Word Segmentation
Hao Zhou, Zhenting Yu, Yue Zhang, Shujian Huang, XIN-YU DAI and Jiajun Chen

Segmentation-Free Word Embedding for Unsegmented Languages
Takamasa Oshikiri

Saturday, September 9, 2017 (continued)

15:50–17:30 Session 3E: Poster Session. Question Answering and Machine Comprehension

From Textbooks to Knowledge: A Case Study in Harvesting Axiomatic Knowledge from Textbooks to Solve Geometry Problems
Mrinmaya Sachan, Kumar Dubey and Eric Xing

RACE: Large-scale ReAding Comprehension Dataset From Examinations
Guokun Lai, Qizhe Xie, Hanxiao Liu, Yiming Yang and Eduard Hovy

Beyond Sentential Semantic Parsing: Tackling the Math SAT with a Cascade of Tree Transducers
Mark Hopkins, Cristian Petrescu-Prahova, Roie Levin, Ronan Le Bras, Alvaro Herrasti and Vidur Joshi

Learning Fine-Grained Expressions to Solve Math Word Problems
Danqing Huang, Shuming Shi, Chin-Yew Lin and Jian Yin

Structural Embedding of Syntactic Trees for Machine Comprehension
Rui Liu, Junjie Hu, Wei Wei, Zi Yang and Eric Nyberg

World Knowledge for Reading Comprehension: Rare Entity Prediction with Hierarchical LSTMs Using External Descriptions
Teng Long, Emmanuel Bengio, Ryan Lowe, Jackie Chi Kit Cheung and Doina Precup

Two-Stage Synthesis Networks for Transfer Learning in Machine Comprehension
David Golub, Po-Sen Huang, Xiaodong He and Li Deng

Deep Neural Solver for Math Word Problems
Yan Wang, Xiaojiang Liu and Shuming Shi

Latent Space Embedding for Retrieval in Question-Answer Archives
Deepak P, Dinesh Garg and Shirish Shevade

Question Generation for Question Answering
Nan Duan, Duyu Tang, Peng Chen and Ming Zhou

Learning to Paraphrase for Question Answering
Li Dong, Jonathan Mallinson, Siva Reddy and Mirella Lapata

Temporal Information Extraction for Question Answering Using Syntactic Dependencies in an LSTM-based Architecture
Yuanliang Meng, Anna Rumshisky and Alexey Romanov

Ranking Kernels for Structures and Embeddings: A Hybrid Preference and Classification Model
Kateryna Tymoshenko, Daniele Bonadiman and Alessandro Moschitti

Recovering Question Answering Errors via Query Revision
Semih Yavuz, Izzeddin Gur, Yu Su and Xifeng Yan

15:50–17:30 Session 3F: Poster Session. Multimodal NLP 1

An empirical study on the effectiveness of images in Multimodal Neural Machine Translation
Jean-Benoit Delbrouck and Stéphane Dupont

Sound-Word2Vec: Learning Word Representations Grounded in Sounds
Ashwin Vijayakumar, Ramakrishna Vedantam and Devi Parikh

The Promise of Premise: Harnessing Question Premises in Visual Question Answering
Aroma Mahendru, Viraj Prabhu, Akrit Mohapatra, Dhruv Batra and Stefan Lee

Guided Open Vocabulary Image Captioning with Constrained Beam Search
Peter Anderson, Basura Fernando, Mark Johnson and Stephen Gould

Zero-Shot Activity Recognition with Verb Attribute Induction
Rowan Zellers and Yejin Choi

Deriving continous grounded meaning representations from referentially structured multimodal contexts
Sina Zarrieß and David Schlangen

Hierarchically-Attentive RNN for Album Summarization and Storytelling
Licheng Yu, Mohit Bansal and Tamara Berg

Video Highlight Prediction Using Audience Chat Reactions
Cheng-Yang Fu, Joon Lee, Mohit Bansal and Alexander Berg

Saturday, September 9, 2017 (continued)

Reinforced Video Captioning with Entailment Rewards
Ramakanth Pasunuru and Mohit Bansal

Evaluating Hierarchies of Verb Argument Structure with Hierarchical Clustering
Jesse Mu, Joshua K. Hartshorne and Timothy O'Donnell

Incorporating Global Visual Features into Attention-based Neural Machine Translation.
Iacer Calixto and Qun Liu

Mapping Instructions and Visual Observations to Actions with Reinforcement Learning
Dipendra Misra, John Langford and Yoav Artzi

An analysis of eye-movements during reading for the detection of mild cognitive impairment
Kathleen C. Fraser, Kristina Lundholm Fors, Dimitrios Kokkinakis and Arto Nordlund

Evaluating Low-Level Speech Features Against Human Perceptual Data
Caitlin Richter, Naomi H Feldman, Harini Salgado and Aren Jansen

Sunday, September 10, 2017

07:30–17:30 **Registration Day 2**

08:00–09:00 ***Morning Coffee***

09:00–10:00 Plenary Session. Invited Talk by Sharon Goldwater

09:00–10:00 *Towards more universal language technology: unsupervised learning from speech*
Sharon Goldwater

10:00–10:30 *Coffee Break*

10:30–12:10 Session 4A: Reading and Retrieving

10:30–10:55 *A Structured Learning Approach to Temporal Relation Extraction*
Qiang Ning, Zhili Feng and Dan Roth

10:55–11:20 *Importance sampling for unbiased on-demand evaluation of knowledge base population*
Arun Chaganty, Ashwin Paranjape, Percy Liang and Christopher D. Manning

11:20–11:45 *PACRR: A Position-Aware Neural IR Model for Relevance Matching*
Kai Hui, Andrew Yates, Klaus Berberich and Gerard de Melo

11:45–12:10 *Globally Normalized Reader*
Jonathan Raiman and John Miller

10:30–12:10 Session 4B: Multimodal NLP 2

10:30–10:55 *Speech segmentation with a neural encoder model of working memory*
Micha Elsner and Cory Shain

10:55–11:20 *Speaking, Seeing, Understanding: Correlating semantic models with conceptual representation in the brain*
Luana Bulat, Stephen Clark and Ekaterina Shutova

11:20–11:45 *Multi-modal Summarization for Asynchronous Collection of Text, Image, Audio and Video*
Haoran Li, Junnan Zhu, Cong Ma, Jiajun Zhang and Chengqing Zong

11:45–12:10 *Tensor Fusion Network for Multimodal Sentiment Analysis*
Amir Zadeh, Minghai Chen, Soujanya Poria, Erik Cambria and Louis-Philippe Morency

10:30–12:10 Session 4C: Human Centered NLP and Linguistic Theory

10:30–10:55 *ConStance: Modeling Annotation Contexts to Improve Stance Classification*
Kenneth Joseph, Lisa Friedland, William Hobbs, David Lazer and Oren Tsur

10:55–11:20 *Deeper Attention to Abusive User Content Moderation*
John Pavlopoulos, Prodromos Malakasiotis and Ion Androutsopoulos

11:20–11:45 *Outta Control: Laws of Semantic Change and Inherent Biases in Word Representation Models*
Haim Dubossarsky, Daphna Weinshall and Eitan Grossman

11:45–12:10 *Human Centered NLP with User-Factor Adaptation*
Veronica Lynn, Youngseo Son, Vivek Kulkarni, Niranjan Balasubramanian and H. Andrew Schwartz

10:30–12:10 Session 4D: Poster Session. Semantics 2

Neural Sequence Learning Models for Word Sense Disambiguation
Alessandro Raganato, Claudio Delli Bovi and Roberto Navigli

Learning Word Relatedness over Time
Guy D. Rosin, Eytan Adar and Kira Radinsky

Inter-Weighted Alignment Network for Sentence Pair Modeling
Gehui Shen, Yunlun Yang and Zhi-Hong Deng

A Short Survey on Taxonomy Learning from Text Corpora: Issues, Resources and Recent Advances
Chengyu Wang, Xiaofeng He and Aoying Zhou

Idiom-Aware Compositional Distributed Semantics
Pengfei Liu, Kaiyu Qian, Xipeng Qiu and Xuanjing Huang

Macro Grammars and Holistic Triggering for Efficient Semantic Parsing
Yuchen Zhang, Panupong Pasupat and Percy Liang

A Continuously Growing Dataset of Sentential Paraphrases
Wuwei Lan, Siyu Qiu, Hua He and Wei Xu

Cross-domain Semantic Parsing via Paraphrasing
Yu Su and Xifeng Yan

A Joint Sequential and Relational Model for Frame-Semantic Parsing
Bishan Yang and Tom Mitchell

Getting the Most out of AMR Parsing
Chuan Wang and Nianwen Xue

AMR Parsing using Stack-LSTMs
Miguel Ballesteros and Yaser Al-Onaizan

An End-to-End Deep Framework for Answer Triggering with a Novel Group-Level Objective
Jie Zhao, Yu Su, Ziyu Guan and Huan Sun

Predicting Word Association Strengths
Andrew Cattle and Xiaojuan Ma

10:30–12:10 Session 4E: Poster Session. Discourse

Learning Contextually Informed Representations for Linear-Time Discourse Parsing
Yang Liu and Mirella Lapata

Multi-task Attention-based Neural Networks for Implicit Discourse Relationship Representation and Identification
Man Lan, Jianxiang Wang, Yuanbin Wu, Zheng-Yu Niu and Haifeng Wang

Chinese Zero Pronoun Resolution with Deep Memory Network
Qingyu Yin, Yu Zhang, Weinan Zhang and Ting Liu

How much progress have we made on RST discourse parsing? A replication study of recent results on the RST-DT
Mathieu Morey, Philippe Muller and Nicholas Asher

Sunday, September 10, 2017 (continued)

What is it? Disambiguating the different readings of the pronoun 'it'
Sharid Loáiciga, Liane Guillou and Christian Hardmeier

Revisiting Selectional Preferences for Coreference Resolution
Benjamin Heinzerling, Nafise Sadat Moosavi and Michael Strube

Learning to Rank Semantic Coherence for Topic Segmentation
Liang Wang, Sujian Li, Yajuan Lv and Houfeng WANG

GRASP: Rich Patterns for Argumentation Mining
Eyal Shnarch, Ran Levy, Vikas Raykar and Noam Slonim

Patterns of Argumentation Strategies across Topics
Khalid Al Khatib, Henning Wachsmuth, Matthias Hagen and Benno Stein

Using Argument-based Features to Predict and Analyse Review Helpfulness
Haijing Liu, Yang Gao, Pin Lv, Mengxue Li, Shiqiang Geng, Minglan Li and Hao Wang

Here's My Point: Joint Pointer Architecture for Argument Mining
Peter Potash, Alexey Romanov and Anna Rumshisky

Identifying attack and support argumentative relations using deep learning
Oana Cocarascu and Francesca Toni

10:30–12:10 Session 4F: Poster Session. Machine Translation and Multilingual NLP 1

Neural Lattice-to-Sequence Models for Uncertain Inputs
Matthias Sperber, Graham Neubig, Jan Niehues and Alex Waibel

Memory-augmented Neural Machine Translation
Yang Feng, Shiyue Zhang, Andi Zhang, Dong Wang and Andrew Abel

Dynamic Data Selection for Neural Machine Translation
Marlies van der Wees, Arianna Bisazza and Christof Monz

Neural Machine Translation Leveraging Phrase-based Models in a Hybrid Search
Leonard Dahlmann, Evgeny Matusov, Pavel Petrushkov and Shahram Khadivi

Translating Phrases in Neural Machine Translation
Xing Wang, Zhaopeng Tu, Deyi Xiong and Min Zhang

Towards Bidirectional Hierarchical Representations for Attention-based Neural Machine Translation
Baosong Yang, Derek F. Wong, Tong Xiao, Lidia S. Chao and Jingbo Zhu

Massive Exploration of Neural Machine Translation Architectures
Denny Britz, Anna Goldie, Minh-Thang Luong and Quoc Le

Learning Translations via Matrix Completion
Derry Tanti Wijaya, Brendan Callahan, John Hewitt, Jie Gao, Xiao Ling, Marianna Apidianaki and Chris Callison-Burch

Reinforcement Learning for Bandit Neural Machine Translation with Simulated Human Feedback
Khanh Nguyen, Hal Daumé III and Jordan Boyd-Graber

Towards Compact and Fast Neural Machine Translation Using a Combined Method
Xiaowei Zhang, Wei Chen, Feng Wang, Shuang Xu and Bo Xu

Instance Weighting for Neural Machine Translation Domain Adaptation
Rui Wang, Masao Utiyama, Lemao Liu, Kehai Chen and Eiichiro Sumita

Regularization techniques for fine-tuning in neural machine translation
Antonio Valerio Miceli Barone, Barry Haddow, Ulrich Germann and Rico Sennrich

Source-Side Left-to-Right or Target-Side Left-to-Right? An Empirical Comparison of Two Phrase-Based Decoding Algorithms
Yin-Wen Chang and Michael Collins

Using Target-side Monolingual Data for Neural Machine Translation through Multi-task Learning
Tobias Domhan and Felix Hieber

12:10–13:40 ***Lunch***

12:40–13:40 SIGDAT Business Meeting

13:40–15:20 Session 5A: Semantics 3

13:40–14:05 *Encoding Sentences with Graph Convolutional Networks for Semantic Role Labeling*
Diego Marcheggiani and Ivan Titov

14:05–14:30 *Neural Semantic Parsing with Type Constraints for Semi-Structured Tables*
Jayant Krishnamurthy, Pradeep Dasigi and Matt Gardner

14:30–14:55 *Joint Concept Learning and Semantic Parsing from Natural Language Explanations*
Shashank Srivastava, Igor Labutov and Tom Mitchell

14:55–15:20 *Grasping the Finer Point: A Supervised Similarity Network for Metaphor Detection*
Marek Rei, Luana Bulat, Douwe Kiela and Ekaterina Shutova

13:40–15:20 Session 5B: Computational Social Science 1

13:40–14:05 *Identifying civilians killed by police with distantly supervised entity-event extraction*
Katherine Keith, Abram Handler, Michael Pinkham, Cara Magliozzi, Joshua McDuffie and Brendan O'Connor

14:05–14:30 *Asking too much? The rhetorical role of questions in political discourse*

Monolingual Phrase Alignment on Parse Forests

Yuki Arase[1⋆] and **Junichi Tsujii**[⋆2]

Abstract

We propose an efficient method to conduct phrase alignment on parse forests for paraphrase detection. Unlike previous studies, our method identifies syntactic paraphrases under linguistically motivated grammar. In addition, it allows phrases to non-compositionally align to handle paraphrases with non-homographic phrase correspondences. A dataset that provides gold parse trees and their phrase alignments is created. The experimental results confirm that the proposed method conducts highly accurate phrase alignment compared to human performance.

1 Introduction

Paraphrase detection is crucial in various applications, which has been actively studied for years. Due to difficulties caused by the non-homographic nature of phrase correspondences, the units of correspondence in previous studies are defined as sequences of words like in (Yao et al., 2013) and not syntactic phrases. On the other hand, syntactic structures are important in modeling sentences, *e.g.*, their sentiments and semantic similarities (Socher et al., 2013; Tai et al., 2015).

In this paper, we present an algorithm to align syntactic phrases in a paraphrased pair of sentences. We show that (1) the problem of identifying a legitimate set of syntactic paraphrases under linguistically motivated grammar is formalized, (2) dynamic programing a la CKY (Cocke, 1969; Kasami, 1965; Younger, 1967) makes phrase alignment computationally feasible, (3) alignment quality of phrases can be improved using n-best parse forests instead of 1-best trees, and (4) non-compositional alignment allows non-homographic correspondences of phrases. Motivated by recent findings that syntax is important for phrase embedding (Socher et al., 2013) in which phrasal paraphrases allow semantic similarity to be replicated (Wieting et al., 2016, 2015), we focus on the syntactic paraphrase alignment.

Figure 1: Example of phrase alignments

Fig. 1 shows a real example of phrase alignments produced by our method. Alignment proceeds in a bottom-up manner using the compositional nature of phrase alignments. First, word alignments are given. Then, phrase alignments are recursively identified by supporting relations between phrase pairs. Non-compositional alignment is triggered when the compositionality is violated, which is common in paraphrasing.

For systematic research on syntactic phrase alignment in paraphrases, we constructed a gold standard dataset of paraphrase sentences with phrase alignment ($20,678$ phrases in 201 paraphrasal sentences). This dataset will be made public for future research on paraphrase alignment. The experiment results show that our method achieves 83.64% and 78.91% in recall and precision in terms of alignment pairs, which are 92% and 89% of human performance, respectively.

Proceedings of the 2017 Conference on Empirical Methods in Natural Language Processing, pages 1–11
Copenhagen, Denmark, September 7–11, 2017.

2 Related Work

Due to the large amount of sentence-level paraphrases collected (Dolan et al., 2004; Cohn et al., 2008; Heilman and Smith, 2010; Yin and Schütze, 2015; Biran et al., 2016), researchers can identify phrasal correspondences for natural language inferences (MacCartney et al., 2008; Thadani et al., 2012; Yao et al., 2013). Current methods extend word alignments to phrases in accordance with the methods in statistical machine translation. However, phrases are defined as a simple sequence of words, which do not conform to syntactic phrases. PPDB (Ganitkevitch et al., 2013) provides syntactic paraphrases similar to synchronous context free grammar (SCFG). As discussed below, SCFG captures only a fraction of paraphrasing phenomenon.

In terms of our approach, parallel parsing is a relevant area. Smith and Smith (2004) related monolingual parses in different languages using word alignments, while Burkett and Klein (2008) employed phrase alignments. Moreover, Das and Smith (2009) proposed a model that generates a paraphrase of a given sentence using quasi-synchronous dependency grammar (Smith and Eisner, 2006). Since they used phrase alignments simply as features, there is no guarantee that the output alignments are legitimate.

Synchronous rewriting in parallel parsing (Kaeshammer, 2013; Maillette de Buy Wenniger and Sima'an, 2013) derives parse trees that conform to discontinuous word alignments. In contrast, our method respects parse trees derived by linguistically motivated grammar while handling non-monotonic phrase alignment.

The synchronous assumption in parallel parsing has been argued to be too rigid to handle parallel sentence pairs or even paraphrasal sentence pairs. Burkett et al. (2010) proposed weakly synchronized parallel parsing to tackle this problem. Although this model increases the flexibility, the obtainable alignments are restricted to conform to inversion transduction grammar (ITG) (Wu, 1997). Similarly, Choe and McClosky (2015) used dependency forests of paraphrasal sentence pairs and allowed disagreements to some extent. However, alignment quality was beyond their scope. Weese et al. (2014) extracted SCFG from paraphrase corpora. They showed that parsing was only successful in 9.1% of paraphrases, confirming that a significant amount of transformations in paraphrases do not conform to compositionality or ITG.

	Explanation
s, t	Source and target sentences
τ	Phrase in the parse tree
$\tau_R, \tau_\emptyset$	τ_R is a phrase of a root node; $\tau_\emptyset$ is a special phrase with the null span that exists in every parse tree
ϕ	Phrase aligned to $\tau_\emptyset$
$\langle \cdot, \cdot \rangle$	Pair of entities; a pair itself can be regarded as an entity
$\{\cdot\}$	Set of entities
$m(\cdot)$	Derive the mother node of a phrase
$l(\cdot)$, $r(\cdot)$	Derive the left and right child nodes, respectively
$ds(\cdot)$	Derive descendants of a node including self; $\tau \in ds(\tau)$
$lca(\cdot, \cdot)$	Derive the lowest common ancestor (LCA) of two phrases

Table 1: Notation summary

3 Formulation of Phrase Alignment

In this study, we formalize the problem of legitimate phrase alignment. For simplicity, we discuss tree alignment instead of forests using Fig. 2 as a running example.

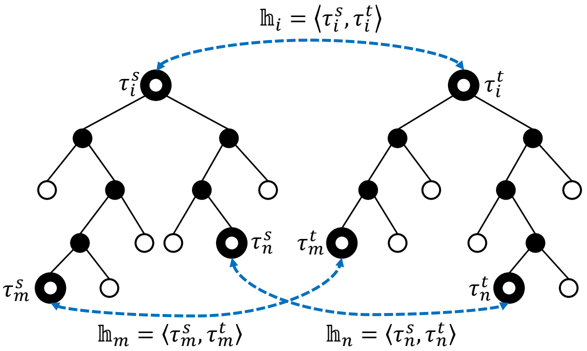
3.1 Notation

Table 1 describes the notation used in this paper. We call a paraphrased pair *source* sentence s and the other as *target* t. Superscripts of s and t represent the source and the target, respectively. Specifically, $\langle \tau^s, \tau^t \rangle$ is a pair of source and target phrases. We represent $f_1/f_2/\cdots/f_i(\cdot)$ to abbreviate $f_i(\cdots f_2(f_1(\cdot))\cdots)$ as an intuitive illustration. It should be noted that the order of the function symbols is reversed, *e.g.*, $l/r(\tau)$ $(= r(l(\tau)))$ derives the right-child of the left-child node of τ, and $l/ds(\tau)$ derives the left descendants of τ.

3.2 Definition of a Legitimate Alignment

A possible parse tree alignment of s and t is represented as a set of aligned pairs of phrases $\{\langle \tau_i^s, \tau_i^t \rangle\}$. τ_i^s and τ_i^t are the source and the target phrases that constitute the i-th alignment, respectively. Either τ_i^s or τ_i^t can be $\tau_\emptyset$ when a phrase does not correspond to another sentence, which is called a *null-alignment*. Each phrase alignment can have *support* relations as:

Definition 3.1. *A pair* $\mathbb{h}_i = \langle \tau_i^s, \tau_i^t \rangle$ *is supported by alignments of their descendant phrases when*



$\mathbb{h}_i = \langle \tau_i^s, \tau_i^t \rangle$
τ_i^s
τ_i^t
τ_n^s
τ_m^t
τ_m^s
τ_n^t
$\mathbb{h}_m = \langle \tau_m^s, \tau_m^t \rangle$
$\mathbb{h}_n = \langle \tau_n^s, \tau_n^t \rangle$

Figure 2: Alignment pair and its supports

$\langle\langle l/ds(\tau_i^s), l/ds(\tau_i^t)\rangle, \langle r/ds(\tau_i^s), r/ds(\tau_i^t)\rangle\rangle$ *or* $\langle\langle l/ds(\tau_i^s), r/ds(\tau_i^t)\rangle, \langle r/ds(\tau_i^s), l/ds(\tau_i^t)\rangle\rangle$ *exists. Pre-terminal phrases are supported by the corresponding word alignments.*

Support relations are denoted using $\Rightarrow$ or $\overset{R}{\Rightarrow}$ that represent the order of support phrases. Specifically, $\langle\langle l(\tau_i^s), l(\tau_i^t)\rangle, \langle r(\tau_i^s), r(\tau_i^t)\rangle\rangle \Rightarrow \mathbb{h}_i$ is straight while $\langle\langle l(\tau_i^s), r(\tau_i^t)\rangle, \langle r(\tau_i^s), l(\tau_i^t)\rangle\rangle \overset{R}{\Rightarrow} \mathbb{h}_i$ is inverted. In Fig. 2, $\langle\langle \tau_m^s, \tau_m^t\rangle, \langle \tau_n^s, \tau_n^t\rangle\rangle \Rightarrow \mathbb{h}_i$, where $\tau_m^s = l/ds(\tau_i^s)$ and $\tau_n^s = r/ds(\tau_i^s)$.

The number of all possible alignments in s and t, which is denoted as $\mathbb{H}$, is exponential to the length. However, only its fraction constitutes legitimate parse tree alignments. For example, a subset in which the same phrase in s is aligned with multiple phrases in t, called *competing* alignments, is not legitimate as a parse tree alignment. The relationships among phrases in parse trees impose constraints on a subset to provide legitimacy.

Given word alignments $\mathbb{W}$ that provide the basis for the phrase alignment, its legitimate set $\mathbb{W}_L \subset \mathbb{W}$ should be 1-to-1 alignments. Starting with $\mathbb{W}_L$, a legitimate set of phrase alignments $\mathbb{H}_L(\subset \mathbb{H})$ with an accompanying set of support relations, $\Delta_L(\subset \Delta)$ is constructed. A legitimate set of alignments $\langle \mathbb{H}_L, \Delta_L\rangle$ can be enlarged only by adding $\mathbb{h}_i$ to $\mathbb{H}_L$ with either the support relation $\Rightarrow$ or $\overset{R}{\Rightarrow}$ added to Δ_L. These assume competing alignments among the child phrases, thus cannot co-exist in the same legitimate set.

$\mathbb{h}_i$ can be supported by more than one pair of descendant alignments in Δ_L, *i.e.*, $\{\langle \mathbb{h}_m, \cdot\rangle\} \Rightarrow \mathbb{h}_i$ or $\{\langle \mathbb{h}_m, \cdot\rangle\} \overset{R}{\Rightarrow} \mathbb{h}_i$ exists. For $\mathbb{H}_m = \{\mathbb{h}_m\}$, we define the relationship $\leq$ for alignments, *i.e.*, $\mathbb{h}_p \leq \mathbb{h}_q$ meaning that $\tau_p^s \in ds(\tau_q^s) \wedge \tau_p^t \in ds(\tau_q^t)$. For example, in Fig. 2, $\mathbb{h}_m \leq \mathbb{h}_i$ and $\mathbb{h}_n \leq \mathbb{h}_i$.

Theorem 3.1. *There always exist the maximum pair* $\mathbb{h}_M \in \mathbb{H}_m$ *where* $\forall \mathbb{h}_m \in \mathbb{H}_m, \mathbb{h}_m \leq \mathbb{h}_M$.

$\langle \mathbb{H}_L, \Delta_L\rangle$ should satisfy the conditions in Definition 3.2 to be legitimate as a whole. We denote $\mathbb{h}_i \overset{*}{\mapsto} \mathbb{h}_j$ when a chain exists in Δ_L, which connects $\mathbb{h}_i$ to $\mathbb{h}_j$ regardless of straight or inverted directions of intermediate supports, e.g., $(\langle \mathbb{h}_i, \cdot\rangle \Rightarrow \mathbb{h}_{i+1}), (\langle \mathbb{h}_{i+1}, \cdot\rangle \overset{R}{\Rightarrow} \mathbb{h}_{i+2}), \ldots, (\langle \mathbb{h}_{j-1}, \cdot\rangle \Rightarrow \mathbb{h}_j)$. Note $\mathbb{h}_i \overset{*}{\mapsto} \mathbb{h}_i$ is always true.

Definition 3.2. $\langle \mathbb{H}_L, \Delta_L\rangle$ *should satisfy:*

1. *Root-Pair Containment:* $\langle \tau_R^s, \tau_R^t\rangle \in \mathbb{H}_L$
2. *Same-Tree:* $\{\tau_i^s \mid \langle \tau_i^s, \tau_i^t\rangle \in \mathbb{H}_L\}$ *are subsets of phrases in the same complete parse tree of* s *(same for* t*).*
3. *Relevance:* $\forall \mathbb{h}_i \in \mathbb{H}_L, \mathbb{h}_i \overset{*}{\mapsto} \langle \tau_R^s, \tau_R^t\rangle \in \Delta_L$
4. *Consistency: In* $\mathbb{H}_L$*, a phrase (*$\neq \tau_\emptyset$*) in the source tree is aligned with at most one phrase (*$\neq \tau_\emptyset$*) in the target tree, and vice versa.*
5. *Monotonous: For* $\langle \tau_i^s, \tau_i^t\rangle, \langle \tau_j^s, \tau_j^t\rangle \in \mathbb{H}_L$, $\tau_i^s \in ds(\tau_j^s)$ *iff* $\tau_i^t \in ds(\tau_j^t)$.
6. *Maximum Set:* $\mathbb{H}_L$ *is the maximum legitimate set, in the sense that* $\forall \langle \tau^s, \tau^t\rangle \in (\mathbb{H} \setminus \mathbb{H}_L), \{\langle \tau^s, \tau^t\rangle\} \cup \mathbb{H}_L$ *cannot be a legitimate set with any* Δ.

The *Same-Tree* condition is required to conduct an alignment on forests that consist of multiple trees in a packed representation. The *Consistency* condition excludes competing alignments. The *Monotonous* condition is a consequence of compositionality. The *Maximum Set* means if $\mathbb{h}_m, \mathbb{h}_n \in \mathbb{H}_L$ are in positions of a parse tree that can support $\mathbb{h}_i$, $\mathbb{h}_i$ and the support relation should be added to $\langle \mathbb{H}_L, \Delta_L\rangle$. Such a strict locality of compositionality is often violated in practice as discussed in Sec. 2. To tackle this issue, we add another operation to align phrases in a non-compositional way in Sec. 4.3.

3.3 Lowest Common Ancestor

The same aligned pair can have more than one support of descendant alignments because there are numerous descendant node combinations. However, the *Monotonous* and the *Maximum Set* conditions allow Δ_L to be further restricted so that each of aligned pairs in $\mathbb{H}_L$ has only one support.

Let us assume that alignment $\mathbb{h}_i$ is supported by more than one pair of descendant alignments

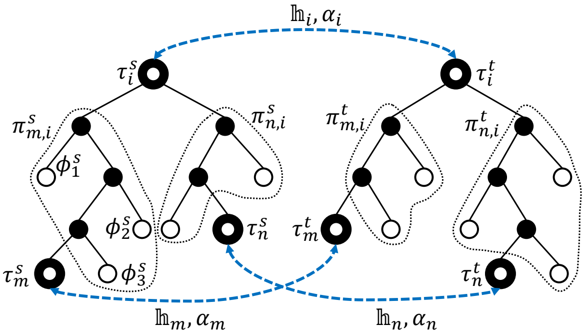


Figure 3: Inside probability depends on support alignments and paths to reach an LCA.

in Δ_L, *i.e.*, $\Delta_L \supseteq (\{\langle \mathbb{h}_m, \mathbb{h}_n \rangle\} \Rightarrow \mathbb{h}_i)$[1]. We denote $\mathbb{H}_m = \{\mathbb{h}_m\}$ and $\mathbb{H}_n = \{\mathbb{h}_n\}$. For each $\mathbb{h}_m \in \mathbb{H}_m$ and $\mathbb{h}_n \in \mathbb{H}_n$, we remove all support relations from Δ_L except for the maximum pairs or the pre-terminal alignments. The resultant set Δ'_L satisfies:

Theorem 3.2. *For all* $(\langle \mathbb{h}_m, \mathbb{h}_n \rangle \Rightarrow \mathbb{h}_i) \in \Delta'_L$, $\tau_i^s = lca(\tau_m^s, \tau_n^s)$ *and* $\tau_i^t = lca(\tau_m^t, \tau_n^t)$ *are true.*

In Fig. 2, τ_i^s is the lowest common ancestor (LCA) of τ_m^s and τ_n^s, and τ_i^t is the LCA of τ_m^t and τ_n^t. Theorem 3.2 constitutes the basis for the dynamic programming (DP) in our phrase alignment algorithm (Sec. 4.2).

4 Modeling of Phrase Alignment

We formally model the phrase alignment process as illustrated in Fig. 3, where $\mathbb{h}_i$ is aligned from descendant alignments, *i.e.*, $\mathbb{h}_m$ and $\mathbb{h}_n$.

4.1 Probabilistic Model

Similar to the probabilistic context free grammar (PCFG), the inside probability α_i of $\mathbb{h}_i$ is determined by the inside probabilities, α_m and α_n, of the support pairs, together with the probability of the rule, *i.e.*, the way by which $\mathbb{h}_m$ and $\mathbb{h}_n$ are combined to support $\mathbb{h}_i$ as shown in Fig. 3. It is characterized by four paths, $\pi_{m,i}^s$ (the path from τ_m^s to τ_i^s), $\pi_{n,i}^s$ (τ_n^s to τ_i^s), $\pi_{m,i}^t$ (τ_m^t to τ_i^t), and $\pi_{n,i}^t$ (τ_n^t to τ_i^t).

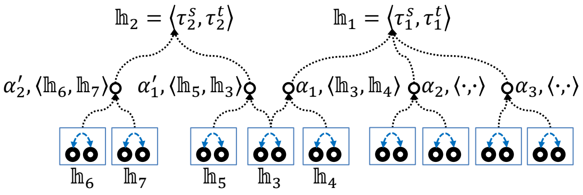
Each path consists of a set of null-aligned phrases $\phi \in \langle \phi, \tau_\emptyset \rangle$ and their mothers, *e.g.*, the path $\pi_{m,i}^s$ in Fig. 3 is a set of $\langle \phi_1^s, m(\phi_1^s) \rangle$, $\langle \phi_2^s, m(\phi_2^s) \rangle$, and $\langle \phi_3^s, m(\phi_3^s) \rangle$. We assume that each occurrence of a null-alignment is independent. Thus, its probability $\beta_{m,i}^s$ is computed as:

$$\beta_{m,i}^s = \Pi_{\phi_k^s \in \pi_{m,i}^s} P_r(\phi_k^s, \tau_\emptyset).$$

$\beta_{n,i}^s$, $\beta_{m,i}^t$, and $\beta_{n,i}^t$ are computed in the same manner. We abbreviate $\gamma_{m,n,i}^s = \beta_{m,i}^s \beta_{n,i}^s$, likewise $\gamma_{m,n,i}^t = \beta_{m,i}^t \beta_{n,i}^t$. Finally, α_i can be represented as a simple relation:

$$\alpha_i = \alpha_m \alpha_n P_r(\tau_i^s, \tau_i^t) \gamma_{m,n,i}^s \gamma_{m,n,i}^t. \qquad (1)$$

$P_r(\cdot,\cdot)$ is the alignment probability parameterized in Sec. 5. Since we assume that the structures of parse trees of s and t are determined by a parser, the values of $\gamma_{m,n,i}^s$ and $\gamma_{m,n,i}^t$ are fixed. Therefore, by traversing the parse tree in a bottom-up manner, we can identify an LCA (*i.e.*, τ_i) for phrases τ_m and τ_n while simultaneously computing $\gamma_{m,n,i}$.



$\mathbb{h}_2 = \langle \tau_2^s, \tau_2^t \rangle$
$\mathbb{h}_1 = \langle \tau_1^s, \tau_1^t \rangle$
$\alpha'_2, \langle \mathbb{h}_6, \mathbb{h}_7 \rangle$
$\alpha'_1, \langle \mathbb{h}_5, \mathbb{h}_3 \rangle$
$\alpha_1, \langle \mathbb{h}_3, \mathbb{h}_4 \rangle$
$\alpha_2, \langle \cdot,\cdot \rangle$
$\alpha_3, \langle \cdot,\cdot \rangle$
$\mathbb{h}_6$
$\mathbb{h}_7$
$\mathbb{h}_5$
$\mathbb{h}_3$
$\mathbb{h}_4$

Figure 4: Alignment pairs and packed supports

4.2 Alignment Algorithm

Algorithm 4.1 depicts our algorithm. Given word alignments $\mathbb{W} = \{\langle w_i^s, w_i^t \rangle\}$, it constructs legitimate sets of aligned pairs in a bottom-up manner. Like the CKY algorithm, Algorithm 4.1 uses DP to efficiently compute all possible legitimate sets and their probabilities in parallel. In addition, null-alignments are allowed when aligning an LCA supported by aligned descendant nodes.

$A[\cdot]$ is indexed by phrases in the parse tree of s and maintains a list of all possible aligned pairs. Furthermore, to deal with non-monotonic alignment (Sec. 4.3), it keeps all competing hypotheses of support relations using packed representations. Specifically, $\mathbb{h}_i$ is accompanied by its packed support list as illustrated in Fig. 4; $\mathbb{h}_1 = \langle \tau_1^s, \tau_1^t \rangle$ is aligned with supports of $\{\langle \alpha_j, \langle \mathbb{h}_m, \mathbb{h}_n \rangle \rangle\}$ like $\langle \alpha_1, \langle \mathbb{h}_3, \mathbb{h}_4 \rangle \rangle$. Depending on the support alignments, $\mathbb{h}_i$ has different inside probabilities, *i.e.*, α_1, α_2, and α_3. Since the succeeding process of alignment only deals with the LCA's of τ_1^s and τ_1^t that are independent of the support alignment, all

[1] $\Rightarrow$ and $\overset{R}{\Rightarrow}$ are not distinguished here.

function PACK($\langle \tau^s, \tau^t \rangle, \langle \alpha, \langle \mathbb{h}_m, \mathbb{h}_n \rangle \rangle, A$)
    if $\langle \tau^s, \tau^t \rangle \in A[\tau^s]$ then
        $A[\tau^s] \leftarrow A[\tau^s] \cup \langle \alpha, \langle \mathbb{h}_m, \mathbb{h}_n \rangle \rangle$   ▷ Merge supports and their inside probability
    else
        $A[\tau^s] \leftarrow (\langle \tau^s, \tau^t \rangle, \langle \alpha, \langle \mathbb{h}_m, \mathbb{h}_n \rangle \rangle)$
```

support relations are packed as a support list[2] by the PACK function.

4.3 Non-Compositional Alignment

A monotonic alignment requires $\tau^t_m \in \mathbb{h}_m$ and $\tau^t_n \in \mathbb{h}_n$ to have an LCA, which adheres to the compositionality in language. However, previous studies declared that the compositionality is violated in a monolingual phrase alignment (Burkett et al., 2010; Weese et al., 2014). Heilman and Smith (2010) discuss complex phrase reordering is prevalent in paraphrases and entailed text.

A non-monotonic alignment occurs when corresponding phrases have largely different orders, *i.e.*, one of them (*e.g.*, τ^t_m) is an ancestor of another (*e.g.*, τ^t_n) or the same phrase. Such a case could be exceptionally compatible, when τ^t_m has null-alignments and all the aligned phrases of τ^t_n fit in these null-alignments. A new alignment $\langle \tau^s_i, \tau^t_i (= \tau^t_m) \rangle$ would be non-monotonically formed. Fig. 5 shows a real example of non-compositional alignment produced by our method. The target phrase τ^t_n ("through the spirit of teamwork") is null-alignment when aligning τ^s_m and τ^t_m, but then the alignment to τ^s_n ("Relying on team spirit") is allowed by non-compositional alignment of τ^s_i.

Algorithm 4.2 Non-Compositional Alignment

```
1:  function TRACE($\tau_n, \tau_m$)   ▷ $\tau_n \in ds(\tau_m)$
2:      $V \leftarrow \emptyset$
3:      for all $[\tau_m]^i$ do
4:          if $\tau_n \in ds(\phi)$ for $\exists \phi \in \Phi^{[\tau_m]^i}$ then
5:              $V \leftarrow V \cup \langle \Psi^{[\tau_m]^i} \cup \tau_n, (\Phi^{[\tau_m]^i} \setminus \phi) \cup$ GAP($\tau_n, \phi$) $\rangle$
6:          else if $\tau_n \in ds(\psi)$ for $\exists \psi \in \Psi^{[\tau_m]^i}$ then
7:              $V \leftarrow V \cup$ TRACE($\tau_n, \psi$)
8:          else
9:              for all $[\tau_n]^j$ do
10:                 $V \leftarrow V \cup$ DOWN($[\tau_n]^j, [\tau_m]^i$)
11:     return $V$;
```

Unlike monotonous alignment, we have to verify whether the internal structures of τ^t_m and τ^t_n are compatible. Since the internal structures of τ^t_m and τ^t_n depend on their supporting alignments, their packed representations in A have to be unpacked, and each pair of supporting alignments for $\mathbb{h}_m$ and $\mathbb{h}_n$ must be checked to confirm compatibility. Furthermore, since the aligned phrases inside τ^t_m and τ^t_n have their own null-alignments, we need to unpack deeper supporting alignments as well.

Algorithm 4.2 checks if target phrases τ_m and $\tau_n \in ds(\tau_m)$ are compatible. We use the following notations: $[\tau_m]^i$ and $[\tau_n]^j$ represent the phrases of τ_m and τ_n with the i-th and j-th sets of supporting alignments, respectively. For τ^t_2 in Fig. 4, there are $[\tau^t_2]^1$ supported by $\langle \mathbb{h}_5, \mathbb{h}_3 \rangle$ and $[\tau^t_2]^2$ supported by $\langle \mathbb{h}_6, \mathbb{h}_7 \rangle$. $[\tau_m]^i$ consists of sets of aligned target phrases $\Psi^{[\tau_m]^i} = \{\psi_k^{[\tau_m]^i}\}$ and null-alignments $\Phi^{[\tau_m]^i} = \{\phi_l^{[\tau_m]^i}\}$ ($[\tau_n]^j$ is similar).

For each $[\tau_m]^i$, if τ_n fits in its null-alignment like in Fig. 5, the alignment information is updated at line 5, where GAP function takes two phrases and returns a set of null-alignments on a path between them. If τ_n is a descendant of a support of τ_m, the compatibility is recursively checked (line 7). Otherwise, the compatibility of the supports of τ_n and τ_m are recursively checked in DOWN function in a similar manner (line 10).

When TRACE function returns a set of $\{\langle \Psi^k, \Phi^k \rangle\}$, all $\psi \in \Psi^k$ are aligned with phrases in the source and their inside probabilities are stored in A. Thus we can compute the inside probability for each $\langle \Psi^k, \Phi^k \rangle$, which is stored in A to-

[2] This is true except for a non-compositional alignment where the packed representation must be unpacked.

gether with a new alignment pair $\langle \tau_i^s, \tau_i^t \rangle$ where $\tau_i^s = lca(\tau_m^s, \tau_n^s)$ and $\tau_i^t = \tau_m^t$.

4.4 Forest Alignment

Although we have discussed using trees for clarity, the alignment is conducted on forests. The alignment process is basically the same. The only difference is that the same pair has multiple LCAs. Hence, we need to verify if the sub-trees can be on the same tree when identifying their LCAs since multiple nodes may cover the same span with different derivations. This is critical for non-compositional alignment because whether the internal structures are on the same tree must be confirmed while unpacking them.

Our alignment process corresponds to reranking of forests and may derive a different tree from the 1-best, which may resolve ambiguity in parsing. We use a parser trained beforehand because joint parsing and alignment is computationally too expensive.

5 Parameterization

Next, we parameterize the alignment probability.

5.1 Feature-enhanced EM Algorithm

We apply the feature-enhanced EM (Berg-Kirkpatrick et al., 2010) due to its ability to use dependent features without an irrational independence assumption. This is preferable because the attributes of phrases largely depend on each other.

Our method is computationally heavy since it handles forests and involves unpacking in the non-compositional alignment process. Thus, we use Viterbi training (Brown et al., 1993) together with a beam search of size $\mu_b \in \mathbb{N}$ on the feature-enhanced EM. Also, mini-batch training (Liang and Klein, 2009) is applied. Such an approximation for efficiency is common in parallel parsing (Burkett and Klein, 2008; Burkett et al., 2010).

In addition, an alignment supported by distant descendants tends to fail to reach a root-pair alignment. Thus, we restrict the generation gap between a support alignment and its LCA to be less than or equal to $\mu_g \in \mathbb{N}$.

5.2 Features

In feature-enhanced EM, the alignment probability in Eq. (1) is parameterized using features:

$$P_r(\tau_i^s, \tau_i^t) \doteq \frac{\exp(\mathbf{w} \cdot \mathbb{F}(\boldsymbol{a}_i^s, \boldsymbol{a}_i^t))}{\sum_{\langle \tau_j^s, \tau_j^t \rangle, \tau_i^s = \tau_j^s} \exp(\mathbf{w} \cdot \mathbb{F}(\boldsymbol{a}_j^s, \boldsymbol{a}_j^t))},$$

where $\boldsymbol{a} \doteq (a_0, \cdots, a_n)$ consists of n attributes of τ. $\mathbb{F}(\cdot, \cdot)$ and $\mathbf{w}$ are vectors of feature functions and their weights, respectively.

In a parse tree, the head of a phrase determines its property. Hence, a lemmatized lexical head $a_{\text{lex}} \in \boldsymbol{a}$ combined with its syntactic category $a_{\text{cat}} \in \boldsymbol{a}$ is encoded as a feature[3] as shown below. We use semantic (instead of syntactic) heads to encode semantic relationships in paraphrases.

1: $\mathbb{1}(a_{\text{lex}}^s = \cdot, a_{\text{cat}}^s = \cdot, a_{\text{lex}}^t = \cdot, a_{\text{cat}}^t = \cdot)$
2: $\mathbb{1}(\text{SurfaceSim}(a_{\text{lex}}^s = \cdot, a_{\text{lex}}^t = \cdot))$
3: $\mathbb{1}(\text{WordnetSim}(a_{\text{lex}}^s = \cdot, a_{\text{lex}}^t = \cdot))$
4: $\mathbb{1}(\text{EmbeddingSim}(a_{\text{lex}}^s = \cdot, a_{\text{lex}}^t = \cdot))$
5: $\mathbb{1}(\text{IsPrepositionPair}(a_{\text{lex}}^s = \cdot, a_{\text{lex}}^t = \cdot))$
6: $\mathbb{1}(a_{\text{cat}}^s = \cdot, a_{\text{cat}}^t = \cdot)$
7: $\mathbb{1}(\text{IsSameCategory}(a_{\text{cat}}^s = \cdot, a_{\text{cat}}^t = \cdot))$

The first feature is an indicator invoked only at specific values. On the other hand, the rest of the

[3] We also tried features based on the configurations of the source and target sub-trees similar to (Das and Smith, 2009) as well as features based on the spans of null-alignments. However, none of them contributed to alignment quality.

features are invoked across multiple values, allowing general patterns to be learned. The second feature is invoked if two heads are identical or a head is a substring of another. The third feature is invoked if two heads are synonyms or derivations that are extracted from the WordNet[4]. The fourth feature is invoked if the cosine similarity between word embeddings of two heads is larger than a threshold. The fifth feature is invoked when the heads are both prepositions to capture their different natures from the content words. The last two features are for categories; the sixth one is invoked at each category pair, while the seventh feature is invoked if the input categories are the same.

To avoid generating a huge number of features, we reduce the number of syntactic categories; for contents (N, V, ADJ, and ADV), prepositions, coordinations, null (*i.e.*, for $\tau_\emptyset$), and others.

5.3 Penalty Function

Since our method allows null-alignments, it has a degenerate maximum likelihood solution (Liang and Klein, 2009) that makes every phrase null-alignment. Similarly, a degenerate solution overly conducts non-compositional alignment.

To avoid these issues, a penalty is incorporated:

$$P_e(\tau_i^s, \tau_i^t) = \begin{cases} \exp\{-(|\tau_i^s|_\phi + |\tau_i^t|_\phi + \mu_c + 1)^{\mu_n}\} \\ \qquad \text{(non-compositional alignment)} \\ \exp\{-(|\tau_i^s|_\phi + |\tau_i^t|_\phi + 1)^{\mu_n}\} \\ \qquad \text{(otherwise)} \end{cases}$$

where $|\cdot|_\phi$ computes the span of internal null-alignments, and $\mu_n \geq 1.0$ and $\mu_c \in \mathbb{R}_+$ control the strength of the penalties of the null-alignment and the non-compositional alignment, respectively. The penalty function is multiplied by Eq. (1) as a *soft-constraint* for re-ranking alignment pairs in Algorithm 4.1.

5.4 Combination with Parse Probability

Following the spirit of parallel parsing that simultaneously parses and aligns sentences, we linearly interpolate the alignment probability with the parsing probability once the parameters are tuned by EM. When aligning a node pair $\langle \tau_i^s, \tau_i^t \rangle$, the overall probability is computed as:

$$(1 - \mu_p)\alpha_i + \mu_p \varrho(\tau_i^s)\varrho(\tau_i^t),$$

where $\varrho(\cdot)$ gives the marginal probability in parsing and $\mu_p \in [0, 1]$ balances these probabilities.

6 Evaluation

As discussed in Sec. 2, previous studies have not conducted syntactic phrase alignment on parse trees. A direct metric does not exist to compare paraphrases that cover different spans, *i.e.*, our syntactic paraphrases and paraphrases of n-grams. Thus, we compared the alignment quality to that of humans as a realistic way to evaluate the performance of our method.

We also evaluated the parsing quality. Similar to the alignment quality, differences in phrase structures disturb the comparisons (Sagae et al., 2008). Our method applies an HPSG parser Enju (Miyao and Tsujii, 2008) to derive parse forests due to its state-of-the-art performance and ability to provide rich properties of phrases. Hence, we compared our parsing quality to the 1-best parses of Enju.

6.1 Language Resources

We used reference translations to evaluate machine translations[5] as sentential paraphrases (Weese et al., 2014). The reference translations of 10 to 30 words were extracted and paired, giving $41K$ pairs as a training corpus.

We use different kinds of dictionaries to obtain word alignments $\mathbb{W}$ as well as to compute feature functions. First, we extract synonyms and words with derivational relationship using WordNet. Then we handcraft derivation rules (*e.g.*, *create*, *creation*, *creator*) and extract potentially derivational words from the training corpus. Finally, we use prepositions defined in (Srikumar and Roth, 2013) as a preposition dictionary to compute the feature function.

In addition, we extend $\mathbb{W}$ using word embeddings; we use the MVLSA word embeddings (Rastogi et al., 2015) given the superior performance in word similarity tasks. Specifically, we compute the cosine similarity of embeddings; words with a higher similarity value than a threshold are determined as similar words. The threshold is empirically set as the 100th highest similarity value between words in the training corpus.

6.2 Gold-Standard Data

Since no annotated corpus provides phrase alignments on parse trees, we created one through two-phase manual annotation. First, a linguistic expert with rich experience on annotating HPSG trees

[4] http://wordnet.princeton.edu

[5] NIST OpenMT corpora: LDC2010T14, LDC2010T17, LDC2010T21, LDC2010T23, LDC2013T03

annotated gold-trees to paraphrasal sentence pairs sampled from the training corpus. To diversify the data, only one reference pair per sentence of a source language was annotated. Consequently, 201 paraphrased pairs with gold-trees (containing $20,678$ phrases) were obtained.

Next, three professional English translators identified paraphrased pairs including null-alignments given sets of phrases extracted from the gold-trees. These annotators independently annotated the same set, yielding $14,356$ phrase alignments where at least one annotator regarded as a paraphrase. All the annotators agreed that 77% of the phrases were paraphrases.

We used 50 sentence pairs for development and another 151 for testing. These pairs were excluded from the training corpus.

6.3 Evaluation Metric

Alignment Quality Alignment quality was evaluated by measuring the extent that the automatic alignment results agree with those of humans. Specifically, we evaluated how gold-alignments can be replicated by automatic alignment (called recall) and how automatic alignments overlap with alignments that at least an annotator aligned (called precision) as:

$$\text{Recall} = \frac{|\{\mathbb{h}|\mathbb{h} \in \mathbb{H}_a \wedge \mathbb{h} \in \mathbb{G} \cap \mathbb{G}'\}|}{|\mathbb{G} \cap \mathbb{G}'|},$$

$$\text{Precision} = \frac{|\{\mathbb{h}|\mathbb{h} \in \mathbb{H}a \wedge \mathbb{h} \in \mathbb{G} \cup \mathbb{G}'\}|}{|\mathbb{H}a|},$$

where $\mathbb{H}a$ is a set of alignments, while $\mathbb{G}$ and $\mathbb{G}'$ are the ones that two of annotators produce, respectively. The function of $|\cdot|$ counts the elements in a set. There are three combinations for $\mathbb{G}$ and $\mathbb{G}'$ because we had three annotators. The final precision and recall values are their averages.

Parsing Quality The parsing quality was evaluated using the CONLL-X (Buchholz and Marsi, 2006) standard. Dependencies were extracted from the output HPSG trees, and evaluated using the official script[6]. Due to this conversion, the accuracy on the relation labels is less important. Thus, we reported only the unlabeled attachment score (UAS)[7]. The development and test sets provide $2,371$ and $6,957$ dependencies, respectively.

	Roles of hyper-parameters
μ_n	Control penalty for null-alignment
μ_c	Control penalty for non-compositional alignment
μ_p	Balance alignment and parsing prob.
μ_b	Beam size at alignment
μ_g	Generation gap to reach an LCA

Table 2: Summary of the hyper-parameters

Method	Recall	Prec.	UAS	%
Human	90.65	88.21	–	–
Proposed	**83.64**	**78.91**	93.49	98
Monotonic	82.86*	77.97*	93.49	98
w/o EM	81.33*	75.09*	92.91*	86
1-best tree	80.11*	73.26*	93.56	100

Table 3: Evaluation results on the test set, where * represents p-value < 0.05 against our method.

Since all metrics were computed in a set, the approximate randomization (Noreen, 1989; Riezler and Maxwell, 2005) ($B = 10K$) was used for significance testing. It has been shown to be more conservative than using bootstrap resampling (Riezler and Maxwell, 2005).

6.4 Results and Discussion

Overall Results Table 2 summarizes the hyper-parameters, which were tuned to maximize UAS in the development set using the Bayesian optimization. For efficiency, we used $2K$ samples from the training corpus and set the mini-batch size in feature-enhanced EM to 200 similar to “rapid training” in (Burkett and Klein, 2008). We also set $\mu_b = 50$ during EM training to manage the training time.

Table 3 shows the performance on the test set for variations of our method and that of the human annotators. The last column shows the percentage of pairs where a root pair is reached to be aligned, called reachability. Our method is denoted as *Proposed*, while its variations include a method with only monotonic alignment (*monotonic*), without EM (*w/o EM*), and a method aligning only 1-best trees (1-*best tree*).

The performance of the human annotators was assessed by considering one annotator as the test and the other two as the gold-standard, and then taking the averages, which is the same setting as our method. We regard this as the pseudo inter-

[6] http://ilk.uvt.nl/conll/software.html

[7] Although omitted, the labeled attachment score showed the same tendency as UAS.

annotator agreement, since the conventional inter-annotator agreement is not directly applicable due to variations in aligned phrases.

Our method significantly outperforms the others as it achieved the highest recall and precision for alignment quality. Our recall and precision reach 92% and 89% of those of humans, respectively. Non-compositional alignment is shown to contribute to alignment quality, while the feature-enhanced EM is effective for both the alignment and parsing quality. Comparing our method and the one aligning only 1-best trees demonstrates that the alignment of parse *forests* largely contributes to the alignment quality. Although we confirmed that aligning larger forests slightly improved recall and precision, the improvements were statistically insignificant. The parsing quality was not much affected by phrase alignment, which is further investigated in the following.

Finally, our method achieved 98% reachability, where 2% of unreachable cases were due to the beam search. While understanding that the reachability depends on experimental data, ours is notably higher than that of SCFG, reported as 9.1% in (Weese et al., 2014). These results show the ability of our method to accurately align paraphrases with divergent phrase correspondences.

Effect of Mini-Batch Size We investigated the effect of the mini-batch size in EM training using the entire training corpus ($41K$ pairs). When increasing the mini-batch size from 200 to $2K$, recall, precision, and UAS values are fairly stable. In addition, they are insensitive against the amount of training corpus, showing the comparable values against the model trained on $2K$ samples. These results demonstrate that our method can be trained with a moderate amount of data.

Observations Previous studies show that parallel parsing improves parsing quality, while such an effect is insignificant here. We examine causes through manual observations.

The evaluation script indicated that our method corrected 34 errors while introducing 41 new errors[8]. We further analyzed these 75 cases; 12 cases are ambiguous as both the gold-standard and the output are correct. In addition, 8 cases are due to erroneous original sentences that should be disregarded, *e.g.*, " For two weeks ago,..." and "According to the source, will also meet...". Consequently, our method corrected 32 errors while introducing 23 errors in reality for 446 errors in 1-best trees, which achieves a 2.5% error reduction.

These are promising results for our method to improve parsing quality, especially on the PP-attachment (159 errors in 1-best), which contained 14 of the 32 corrected errors. Fig. 1 shows a real example; the phrase of "for a smoke" in the source was mistakenly attached to "ground floor" in the 1-best tree. This error was corrected as depicted.

Duan et al. (2016) showed that paraphrases artificially generated using n-best parses improved the parsing quality. One reason for limited improvement in our experiments may be because structural changes in our natural paraphrases are more dynamic than the level useful to resolve ambiguities. We will further investigate this in future.

7 Conclusion

We propose an efficient method for phrase alignment on parse forests of paraphrased sentences. To increase the amount of collected paraphrases, we plan to extend our method to align comparable paraphrases that are partially paraphrasal sentences. In addition, we will apply our method to parallel parsing and other grammar, *e.g.*, projective dependency trees. Furthermore, we will apply such syntactic paraphrases to phrase embedding.

Acknowledgments

We thank Professor Issei Sato for permission to use their package for Bayesian optimization. Special thanks also to Dr. Yuka Tateishi for her contribution to HPSG tree annotation. Advice and comments given by Professor Takuya Matsuzaki and Professor Yusuke Miyao have been a great help in applying Enju parser for this project. We appreciate the anonymous reviewers for their insightful comments and suggestions to improve the paper. This project is funded by Microsoft Research Asia and the Kayamori Foundation of Informational Science Advancement.

Supplemental Material

The supplemental material is available at our web site[9] that provides proofs of the theorems, pseudo-codes of the algorithms, and more experiment results with examples.

[8] Alignments were obtained by the model trained using the entire corpus with the $1K$ mini-batch size.

Abstract

We first present a minimal feature set for transition-based dependency parsing, continuing a recent trend started by Kiperwasser and Goldberg (2016a) and Cross and Huang (2016a) of using bi-directional LSTM features. We plug our minimal feature set into the dynamic-programming framework of Huang and Sagae (2010) and Kuhlmann et al. (2011) to produce the first implementation of worst-case $O(n^3)$ exact decoders for arc-hybrid and arc-eager transition systems. With our minimal features, we also present $O(n^3)$ global training methods. Finally, using ensembles including our new parsers, we achieve the best unlabeled attachment score reported (to our knowledge) on the Chinese Treebank and the "second-best-in-class" result on the English Penn Treebank.

1 Introduction

It used to be the case that the most accurate dependency parsers made global decisions and employed exact decoding. But transition-based dependency parsers (TBDPs) have recently achieved state-of-the-art performance, despite the fact that for efficiency reasons, they are usually trained to make local, rather than global, decisions and the decoding process is done approximately, rather than exactly (Weiss et al., 2015; Dyer et al., 2015; Andor et al., 2016). The key efficiency issue for decoding is as follows. In order to make accurate (local) attachment decisions, historically, TBDPs have required a large set of features in order to access rich information about particular *positions* in the stack and buffer of the current parser configuration. But consulting many positions means that although polynomial-time exact-decoding algorithms do exist, having been introduced by Huang and Sagae (2010) and Kuhlmann et al. (2011), unfortunately, they are prohibitively costly in practice, since the number of positions considered can factor into the exponent of the running time. For instance, Huang and Sagae employ a fairly reduced set of nine positions, but the worst-case running time for the exact-decoding version of their algorithm is $O(n^6)$ (originally reported as $O(n^7)$) for a length-n sentence. As an extreme case, Dyer et al. (2015) use an LSTM to summarize *arbitrary* information on the stack, which completely rules out dynamic programming.

Recently, Kiperwasser and Goldberg (2016a) and Cross and Huang (2016a) applied bi-directional long short-term memory networks (Graves and Schmidhuber, 2005, bi-LSTMs) to derive feature representations for parsing, because these networks capture wide-window contextual information well. Collectively, these two sets of authors demonstrated that with bi-LSTMs, *four* positional features suffice for the arc-hybrid parsing system (K&G), and *three* suffice for arc-standard (C&H).[1]

Inspired by their work, we arrive at a *minimal* feature set for arc-hybrid and arc-eager: it contains *only two* positional bi-LSTM vectors, suffers almost no loss in performance in comparison to larger sets, and out-performs a single position. (Details regarding the situation with arc-standard can be found in §2.)

Our minimal feature set plugs into Huang and Sagae's and Kuhlmann et al.'s dynamic program-

[1] We note that K&G were not focused on minimizing positions, although they explicitly noted the implications of doing so: "While not explored in this work, [fewer positions] results in very compact state signatures, [which is] very appealing for use in transition-based parsers that employ dynamic-programming search" (pg. 319). C&H also noted in their follow-up (Cross and Huang, 2016b) the possibility of future work using dynamic programming thanks to simple features.

Proceedings of the 2017 Conference on Empirical Methods in Natural Language Processing, pages 12–23
Copenhagen, Denmark, September 7–11, 2017. ©2017 Association for Computational Linguistics

ming framework to produce the first implementation of $O(n^3)$ *exact* decoders for arc-hybrid and arc-eager parsers. We also enable and implement $O(n^3)$ *global* training methods. Empirically, *ensembles* containing our minimal-feature, globally-trained and exactly-decoded models produce the best unlabeled attachment score (UAS) reported (to our knowledge) on the Chinese Treebank and the "second-best-in-class" result on the English Penn Treebank.[2]

Additionally, we provide a slight update to the theoretical connections previously drawn by Gómez-Rodríguez, Carroll, and Weir (2008, 2011) between TBDPs and the *graph-based* dependency parsing algorithms of Eisner (1996) and Eisner and Satta (1999), including results regarding the arc-eager parsing system.

2 A Minimal Feature Set

TBDPs incrementally process a sentence by making transitions through search states representing parser configurations. Three of the main transition systems in use today (formal introduction in §3.1) all maintain the following two data structures in their configurations: (1) a stack of partially parsed subtrees and (2) a buffer (mostly) of unprocessed sentence tokens.

To featurize configurations for use in a scoring function, it is common to have features that extract information about the first several elements on the stack and the buffer, such as their word forms and part-of-speech (POS) tags. We refer to these as *positional features*, as each feature relates to a particular position in the stack or buffer. Typically, millions of sparse indicator features (often developed via manual engineering) are used.

In contrast, Chen and Manning (2014) introduce a feature set consisting of *dense* word-, POS-, and dependency-label embeddings. While dense, these features are for the same 18 positions that have been typically used in prior work. Recently, Kiperwasser and Goldberg (2016a) and Cross and Huang (2016a) adopt bi-directional LSTMs, which have nice expressiveness and context-sensitivity properties, to reduce the number of positions considered down to four and three, for different transition systems, respectively.

Features	Arc-standard	Arc-hybrid	Arc-eager
$\{\overset{\rightarrow\leftarrow}{s}_2, \overset{\rightarrow\leftarrow}{s}_1, \overset{\rightarrow\leftarrow}{s}_0, \overset{\rightarrow\leftarrow}{b}_0\}$	$93.95_{\pm 0.12}$	$94.08_{\pm 0.13}$	$93.92_{\pm 0.04}$
$\{\overset{\rightarrow\leftarrow}{s}_1, \overset{\rightarrow\leftarrow}{s}_0, \overset{\rightarrow\leftarrow}{b}_0\}$	$94.13_{\pm 0.06}$	$94.08_{\pm 0.05}$	$93.91_{\pm 0.07}$
$\{\overset{\rightarrow\leftarrow}{s}_0, \overset{\rightarrow\leftarrow}{b}_0\}$	$54.47_{\pm 0.36}$	$94.03_{\pm 0.12}$	$93.92_{\pm 0.07}$
$\{\overset{\rightarrow\leftarrow}{b}_0\}$	$47.11_{\pm 0.44}$	$52.39_{\pm 0.23}$	$79.15_{\pm 0.06}$

Min positions	Arc-standard	Arc-hybrid	Arc-eager
K&G 2016a	-	4	-
C&H 2016a	3	-	-
our work	3	**2**	**2**

Table 1: *Top:* English PTB dev-set UAS% for progressively smaller sets of positional features, for greedy parsers with different transition systems. The "double-arrow" notation indicates vectors produced by a *bi*-directional LSTM. Internal lines highlight large performance drop-offs when a feature is deleted. *Bottom:* sizes of the minimal feature sets in Kiperwasser and Goldberg (2016a), Cross and Huang (2016a), and our work.

This naturally begs the question, what is the lower limit on the number of positional features necessary for a parser to perform well? Kiperwasser and Goldberg (2016a) reason that for the arc-hybrid system, the first and second items on the stack and the first buffer item — denoted by s_0, s_1, and b_0, respectively — are required; they additionally include the third stack item, s_2, because it may not be adjacent to the others in the original sentence. For arc-standard, Cross and Huang (2016a) argue for the necessity of s_0, s_1, and b_0.

We address the lower-limit question empirically, and find that, surprisingly, *two positions suffice* for the greedy arc-eager and arc-hybrid parsers. We also provide empirical support for Cross and Huang's argument for the necessity of three features for arc-standard. In the rest of this section, we explain our experiments, run only on an English development set, that support this conclusion; the results are depicted in Table 1. We later explore the *implementation implications* in §3-4 and then *test-set* parsing-accuracy in §6.

We employ the same model architecture as Kiperwasser and Goldberg (2016a). Specifically, we first use a bi-LSTM to encode an n-token sentence, treated as a sequence of per-token concatenations of word- and POS-tag embeddings, into a sequence of vectors $[\overset{\rightarrow\leftarrow}{w}_1, \ldots, \overset{\rightarrow\leftarrow}{w}_n]$, where each $\overset{\rightarrow\leftarrow}{w}_i$

[2] Our ideas were subsequently adapted to the *labeled* setting by Shi, Wu, Chen, and Cheng (2017) in their submission to the CoNLL 2017 shared task on Universal Dependencies parsing. Their team achieved the second-highest *labeled* attachment score in general and had the top average performance on the surprise languages.

is the output of the bi-LSTM at time step i. (The double-arrow notation for these vectors emphasizes the bi-directionality of their origin). Then, for a given parser configuration, stack positions are represented by $\overleftrightarrow{s}_j$, defined as $\overleftrightarrow{w}_{i(s_j)}$ where $i(s_j)$ gives the position in the sentence of the token that is the head of the tree in s_j. Similarly, buffer positions are represented by $\overleftrightarrow{b}_j$, defined as $\overleftrightarrow{w}_{i(b_j)}$ for the token at buffer position j. Finally, as in Chen and Manning (2014), we use a multilayer perceptron to score possible transitions from the given configuration, where the input is the concatenation of some selection of the $\overleftrightarrow{s}_j$s and $\overleftrightarrow{b}_k$s. We use greedy decoders, and train the models with dynamic oracles (Goldberg and Nivre, 2013).

Table 1 reports the parsing accuracy that results for feature sets of size four, three, two, and one for three commonly-used transition systems. The data is the development section of the English Penn Treebank (PTB), and experimental settings are as described in our other experimental section, §6. We see that we can go down to three or, in the arc-hybrid and arc-eager transition systems, even two positions with very little loss in performance, but not further. We therefore call $\{\overleftrightarrow{s}_0, \overleftrightarrow{b}_0\}$ our *minimal* feature set with respect to arc-hybrid and arc-eager, and empirically confirm that Cross and Huang's $\{\overleftrightarrow{s}_0, \overleftrightarrow{s}_1, \overleftrightarrow{b}_0\}$ is minimal for arc-standard; see Table 1 for a summary.[3]

3 Dynamic Programming for TBDPs

As stated in the introduction, our minimal feature set from §2 plugs into Huang and Sagae and Kuhlmann et al.'s dynamic programming (DP) framework. To help explain the connection, this section provides an overview of the DP framework. We draw heavily from the presentation of Kuhlmann et al. (2011).

3.1 Three Transition Systems

Transition-based parsing (Nivre, 2008; Kübler et al., 2009) is an incremental parsing framework based on transitions between parser configurations. For a sentence to be parsed, the system starts from a corresponding initial configuration, and attempts to sequentially apply transitions until a configuration corresponding to a full parse is produced. Formally, a transition system is defined as $\mathcal{S} = (C, T, c^s, C_\tau)$, where C is a nonempty set of configurations, each $t \in T : C \rightharpoonup C$ is a transition function between configurations, c^s is an initialization function that maps an input sentence to an initial configuration, and $C_\tau \subseteq C$ is a set of terminal configurations.

All systems we consider share a common tripartite representation for configurations: when we write $c = (\sigma, \beta, A)$ for some $c \in C$, we are referring to a stack σ of partially parsed subtrees; a buffer β of unprocessed tokens and, optionally, at its beginning, a subtree with only left descendants; and a set A of elements (h, m), each of which is an attachment (dependency arc) with head h and modifier m.[4] We write $m \curvearrowleft h$ to indicate that m left-modifies h, and $h \curvearrowright m$ to indicate that m right-modifies h. For a sentence $w = w_1, ..., w_n$, the initial configuration is (σ_0, β_0, A_0), where σ_0 and A_0 are empty and $\beta_0 = [\mathtt{ROOT}|w_1, ..., w_n]$; ROOT is a special node denoting the root of the parse tree[5] (vertical bars are a notational convenience for indicating different parts of the buffer or stack; our convention is to depict the buffer first element leftmost, and to depict the stack first element rightmost). All terminal configurations have an empty buffer and a stack containing only ROOT.

Arc-Standard The arc-standard system (Nivre, 2004) is motivated by bottom-up parsing: each dependent has to be complete before being attached. The three transitions, shift (sh, move a token from the buffer to the stack), right-reduce (re$_\curvearrowright$, reduce and attach a right modifier), and left-reduce (re$_\curvearrowleft$, reduce and attach a left modifier), are defined as:

$$\begin{aligned}
\mathsf{sh}[(\sigma, b_0|\beta, A)] &= (\sigma|b_0, \beta, A)\\
\mathsf{re}_\curvearrowright[(\sigma|s_1|s_0, \beta, A)] &= (\sigma|s_1, \beta, A \cup \{(s_1, s_0)\})\\
\mathsf{re}_\curvearrowleft[(\sigma|s_1|s_0, \beta, A)] &= (\sigma|s_0, \beta, A \cup \{(s_0, s_1)\})
\end{aligned}$$

Arc-Hybrid The arc-hybrid system (Yamada and Matsumoto, 2003; Gómez-Rodríguez et al., 2008; Kuhlmann et al., 2011) has the same definitions of sh and re$_\curvearrowright$ as arc-standard, but forces

[3] We tentatively conjecture that the following might explain the observed phenomena, but stress that we don't currently see a concrete way to test the following hypothesis. With $\{\overleftrightarrow{s}_0, \overleftrightarrow{b}_0\}$, in the arc-standard case, situations can arise where there are multiple possible transitions with missing information. In contrast, in the arc-hybrid case, there is only one possible transition with missing information (namely, re$_\curvearrowright$, introduced in §3.1); perhaps $\overleftrightarrow{s}_1$ is therefore not so crucial for arc-hybrid in practice?

[4] For simplicity, we only present unlabeled parsing here. See Shi et al. (2017) for labeled-parsing results.

[5] Other presentations place ROOT at the end of the buffer or omit it entirely (Ballesteros and Nivre, 2013).

the collection of left modifiers before right modifiers via its b_0-modifier $\mathsf{re}_{\curvearrowleft}$ transition. This contrasts with arc-standard, where the attachment of left and right modifiers can be interleaved on the stack.

$$\mathsf{sh}[(\sigma, b_0|\beta, A)] = (\sigma|b_0, \beta, A)$$
$$\mathsf{re}_{\curvearrowright}[(\sigma|s_1|s_0, \beta, A)] = (\sigma|s_1, \beta, A \cup \{(s_1, s_0)\})$$
$$\mathsf{re}_{\curvearrowleft}[(\sigma|s_0, b_0|\beta, A)] = (\sigma, b_0|\beta, A \cup \{(b_0, s_0)\})$$

Arc-Eager In contrast to the former two systems, the arc-eager system (Nivre, 2003) makes attachments as early as possible — even if a modifier has not yet received all of its own modifiers. This behavior is accomplished by decomposing the right-reduce transition into two independent transitions, one making the attachment (ra) and one reducing the right-attached child (re).

$$\mathsf{sh}[(\sigma, b_0|\beta, A)] = (\sigma|b_0, \beta, A)$$
$$\mathsf{re}_{\curvearrowleft}[(\sigma|s_0, b_0|\beta, A)] = (\sigma, b_0|\beta, A \cup \{(b_0, s_0)\})$$

(precondition: s_0 not attached to any word)

$$\mathsf{ra}[(\sigma|s_0, b_0|\beta, A)] = (\sigma|s_0|b_0, \beta, A \cup \{(s_0, b_0)\})$$
$$\mathsf{re}[(\sigma|s_0, \beta, A)] = (\sigma, \beta, A)$$

(precondition: s_0 has been attached to its head)

3.2 Deduction and Dynamic Programming

Kuhlmann et al. (2011) reformulate the three transition systems just discussed as deduction systems (Pereira and Warren, 1983; Shieber et al., 1995), wherein transitions serve as inference rules; these are given as the lefthand sides of the first three subfigures in Figure 1. For a given $w = w_1, ..., w_n$, assertions take the form $[i, j, k]$ (or, when applicable, a two-index shorthand to be discussed soon), meaning that there exists a sequence of transitions that, starting from a configuration wherein $head(s_0) = w_i$, results in an ending configuration wherein $head(s_0) = w_j$ and $head(b_0) = w_k$. If we define w_0 as ROOT and w_{n+1} as an end-of-sentence marker, then the goal theorem can be stated as $[0, 0, n + 1]$.

For arc-standard, we depict an assertion $[i, h, k]$ as a subtree whose root (head) is the token at h. Assertions of the form $[i, i, k]$ play an important role for arc-hybrid and arc-eager, and we employ the special shorthand $[i, k]$ for them in Figure 1. In that figure, we also graphically depict such situations as two consecutive half-trees with roots w_i and w_k, where all tokens between i and k are already attached. The superscript b in an arc-eager assertion $[i^b, j]$ is an indicator variable for whether w_i has been attached to its head ($b = 1$) or not ($b = 0$) after the transition sequence is applied.

Kuhlmann et al. (2011) show that all three deduction systems can be directly "tabularized" and dynamic programming (DP) can be applied, such that, *ignoring for the moment the issue of incorporating complex features* (we return to this later), time and space needs are low-order polynomial. Specifically, as the two-index shorthand $[i, j]$ suggests, arc-eager and arc-hybrid systems can be implemented to take $O(n^2)$ space and $O(n^3)$ time; the arc-standard system requires $O(n^3)$ space and $O(n^4)$ time (if one applies the so-called hook trick (Eisner and Satta, 1999)).

Since an $O(n^4)$ running time is not sufficiently practical even in the simple-feature case, *in the remainder of this paper we consider only the arc-hybrid and arc-eager systems, not arc-standard.*

4 Practical Optimal Algorithms Enabled By Our Minimal Feature Set

Until now, no one had suggested a set of positional features that was both information-rich enough for accurate parsing *and* small enough to obtain the $O(n^3)$ running-time promised above. Fortunately, our bi-LSTM-based $\{\overleftrightarrow{s}_0, \overleftrightarrow{b}_0\}$ feature set qualifies, and enables the fast optimal procedures described in this section.

4.1 Exact Decoding

Given an input sentence, a TBDP must choose among a potentially exponential number of corresponding transition sequences. We assume access to functions f_t that score individual configurations, where these functions are indexed by the transition functions $t \in T$. For a fixed transition sequence $\mathbf{t} = t_1, t_2, \ldots$, we use c_i to denote the configuration that results after applying t_i.

Typically, for efficiency reasons, greedy left-to-right decoding is employed: the next transition t_i^* out of c_{i-1} is $\arg\max_t f_t(c_{i-1})$, so that past and future decisions are not taken into account. The score $F(\mathbf{t})$ for the transition sequence is induced by summing the relevant $f_{t_i}(c_{i-1})$ values.

However, our use of minimal feature sets enables direct computation of an argmax over the entire space of transition sequences, $\arg\max_{\mathbf{t}} F(\mathbf{t})$, via dynamic programming, because our positions don't rely on any information "outside" the deduction rule indices, thus eliminating the need for ad-

(a) Arc-standard

(b) Arc-hybrid

(c) Arc-eager

(d) Edge-factored graph-based parsing.

Figure 1: 1a-1c: Kuhlmann et al.'s inference rules for three transition systems, together with CKY-style visualizations of the local structures involved and, to their right, conditions for the rule to apply. 1d: the edge-factored graph-based parsing algorithm (Eisner and Satta, 1999) discussed in §5.

ditional state-keeping.

We show how to integrate the scoring functions for the arc-eager system; the arc-hybrid system is handled similarly. The score-annotated rules are as follows:

$$\frac{[i^b, j] : v}{[j^0, j+1] : 0}(\mathsf{sh}) \quad \frac{[k^b, i] : v_1 \quad [i^0, j] : v_2}{[k^b, j] : v_1 + v_2 + \Delta}(\mathsf{re}_{\curvearrowleft})$$

where $\Delta = f_{\mathsf{sh}}(\overset{\to\leftarrow}{w}_k, \overset{\to\leftarrow}{w}_i) + f_{\mathsf{re}_{\curvearrowleft}}(\overset{\to\leftarrow}{w}_i, \overset{\to\leftarrow}{w}_j)$ — abusing notation by referring to configurations by their features. The left-reduce rule says that we can first take the sequence of transitions asserted by $[k^b, i]$, which has a score of v_1, and then a shift transition moving w_i from b_0 to s_0. This means that the initial condition for $[i^0, j]$ is met, so we can take the sequence of transitions asserted by $[i^0, j]$ — say it has score v_2 — and finally a left-reduce transition to finish composing the larger transition sequence. Notice that the scores for sh and ra are 0, as the scoring of these transitions is accounted for by reduce rules elsewhere in the sequence.

4.2 Global Training

We employ large-margin training that considers each transition sequence globally. Formally, for a training sentence $w = w_1, \ldots, w_n$ with gold transition sequence $\mathbf{t}^{\text{gold}}$, our loss function is

$$\max_{\mathbf{t}} \left(F(\mathbf{t}) + \mathit{cost}(\mathbf{t}^{\text{gold}}, \mathbf{t}) - F(\mathbf{t}^{\text{gold}}) \right)$$

where $\mathit{cost}(\mathbf{t}^{\text{gold}}, \mathbf{t})$ is a custom margin for taking $\mathbf{t}$ instead of $\mathbf{t}^{\text{gold}}$ — specifically, the number of mis-attached nodes. Computing this max can again be done efficiently with a slight modification to the scoring of reduce transitions:

$$\frac{[k^b, i] : v_1 \quad [i^0, j] : v_2}{[k^b, j] : v_1 + v_2 + \Delta'}(\mathsf{re}_{\curvearrowleft})$$

where $\Delta' = \Delta + \mathbf{1}\left(\mathit{head}(w_i) \neq w_j\right)$. This loss-augmented inference or cost-augmented decoding (Taskar et al., 2005; Smith, 2011) technique has previously been applied to graph-based parsing by Kiperwasser and Goldberg (2016a).

Efficiency Note The computation decomposes into two parts: scoring all feature combinations, and using DP to find a proof for the goal theorem in the deduction system. Time-complexity analysis is usually given in terms of the latter, but the former might have a large constant factor, such as 10^4 or worse for neural-network-based scoring functions. As a result, in practice, with a small n, scoring with the feature set $\{\overset{\to\leftarrow}{s}_0, \overset{\to\leftarrow}{b}_0\}$ ($O(n^2)$) can be as time-consuming as the decoding steps ($O(n^3)$) for the arc-hybrid and arc-eager systems.

5 Theoretical Connections

Our minimal feature set brings implementation of practical optimal algorithms to TBDPs, whereas previously only *graph-based* dependency parsers (GBDPs) — a radically different, non-incremental paradigm — enjoyed the ability to deploy them. Interestingly, for both the transition- and graph-based paradigms, the optimal algorithms build dependency trees bottom-up from local structures. It is thus natural to wonder if there are deeper, more formal connections between the two.

In previous work, Kuhlmann et al. (2011) related the arc-standard system to the classic CKY algorithm (Cocke, 1969; Kasami, 1965; Younger, 1967) in a manner clearly suggested by Figure 1a; CKY can be viewed as a very simple graph-based approach. Gómez-Rodríguez et al. (2008, 2011) formally prove that sequences of steps in the *edge-factored* GBDP (Eisner, 1996) can be used to emulate any individual step in the arc-hybrid system (Yamada and Matsumoto, 2003) and the Eisner and Satta (1999, Figure 1d) version. However, they did not draw an explicitly direct connection between Eisner and Satta (1999) and TBDPs.

Here, we provide an update to these previous findings, stated in terms of the expressiveness of scoring functions, considered as parameterization.

For the edge-factored GBDP, we write the score for an edge as $f_G(\overset{\to\leftarrow}{h}, \overset{\to\leftarrow}{m})$, where h is the head and m the modifier. A tree's score is the sum of its edge scores. We say that a parameterized dependency parsing model A *contains* model B if for every instance of parameterization in model B, there exists an instance of model A such that the two models assign the same score to every parse tree. We claim:

Lemma 1. *The arc-eager model presented in §4.1 contains the edge-factored model.*

Proof Sketch. Consider a given edge-factored GBDP parameterized by f_G. For any parse tree, every edge $i \curvearrowleft j$ involves two deduction rules, and their contribution to the score of the final proof is $f_{\mathsf{sh}}(\overset{\to\leftarrow}{w}_k, \overset{\to\leftarrow}{w}_i) + f_{\mathsf{re}_{\curvearrowleft}}(\overset{\to\leftarrow}{w}_i, \overset{\to\leftarrow}{w}_j)$. We set $f_{\mathsf{sh}}(\overset{\to\leftarrow}{w}_k, \overset{\to\leftarrow}{w}_i) = 0$ and $f_{\mathsf{re}_{\curvearrowleft}}(\overset{\to\leftarrow}{w}_i, \overset{\to\leftarrow}{w}_j) = f_G(\overset{\to\leftarrow}{w}_j, \overset{\to\leftarrow}{w}_i)$. Similarly, for edges $k \curvearrowright i$ in the other direction, we set

Model	Training	Features	PTB		CTB	
			UAS (%)	UEM (%)	UAS (%)	UEM (%)
Arc-standard	Local	$\{\overset{\rightarrow\leftarrow}{s}_2, \overset{\rightarrow\leftarrow}{s}_1, \overset{\rightarrow\leftarrow}{s}_0, \overset{\rightarrow\leftarrow}{b}_0\}$	$93.95_{\pm 0.12}$	$52.29_{\pm 0.66}$	$88.01_{\pm 0.26}$	$36.87_{\pm 0.53}$

	Local	$\{\overset{\rightarrow\leftarrow}{s}_0, \overset{\rightarrow\leftarrow}{b}_0\}$	$93.80_{\pm 0.12}$	$49.66_{\pm 0.43}$	$87.78_{\pm 0.09}$	$35.09_{\pm 0.40}$
	Global	$\{\overset{\rightarrow\leftarrow}{s}_0, \overset{\rightarrow\leftarrow}{b}_0\}$	$94.43_{\pm 0.08}$	$53.03_{\pm 0.71}$	$88.38_{\pm 0.11}$	$36.59_{\pm 0.27}$
Arc-eager	Local	$\{\overset{\rightarrow\leftarrow}{s}_2, \overset{\rightarrow\leftarrow}{s}_1, \overset{\rightarrow\leftarrow}{s}_0, \overset{\rightarrow\leftarrow}{b}_0\}$	$93.80_{\pm 0.12}$	$49.66_{\pm 0.43}$	$87.49_{\pm 0.20}$	$33.15_{\pm 0.72}$
	Local	$\{\overset{\rightarrow\leftarrow}{s}_0, \overset{\rightarrow\leftarrow}{b}_0\}$	$93.77_{\pm 0.08}$	$49.71_{\pm 0.24}$	$87.33_{\pm 0.11}$	$34.17_{\pm 0.41}$
	Global	$\{\overset{\rightarrow\leftarrow}{s}_0, \overset{\rightarrow\leftarrow}{b}_0\}$	$\mathbf{94.53}_{\pm 0.05}$	$53.77_{\pm 0.46}$	$\mathbf{88.62}_{\pm 0.09}$	$\mathbf{37.75}_{\pm 0.87}$
Edge-factored	Global	$\{\overset{\rightarrow\leftarrow}{h}, \overset{\rightarrow\leftarrow}{m}\}$	$94.50_{\pm 0.13}$	$\mathbf{53.86}_{\pm 0.78}$	$88.25_{\pm 0.12}$	$36.42_{\pm 0.52}$

Table 2: Test set performance for different training regimes and feature sets. The models use the same decoders for testing and training. For each setting, the average and standard deviation across 5 runs with different random initializations are reported. Boldface: best (averaged) result per dataset/measure.

$f_{\mathsf{ra}}(\overset{\rightarrow\leftarrow}{w}_k, \overset{\rightarrow\leftarrow}{w}_i) = f_G(\overset{\rightarrow\leftarrow}{w}_k, \overset{\rightarrow\leftarrow}{w}_i)$ and $f_{\mathsf{re}}(\overset{\rightarrow\leftarrow}{w}_i, \overset{\rightarrow\leftarrow}{w}_j) = 0$. The parameterization we arrive at emulates exactly the scoring model of f_G. □

We further claim that the arc-eager model is more expressive than not only the edge-factored GBDP, but also the arc-hybrid model in our paper.

Lemma 2. *The arc-eager model contains the arc-hybrid model.*

Proof Sketch. We leverage the fact that the arc-eager model divides the sh transition in the arc-hybrid model into two separate transitions, sh and ra. When we constrain the parameters $f_{\mathsf{sh}} = f_{\mathsf{ra}}$ in the arc-eager model, the model hypothesis space becomes exactly the same as arc-hybrid's. □

The extra expressiveness of the arc-eager model comes from the scoring functions f_{sh} and f_{re} that capture structural contexts other than head-modifier relations. Unlike traditional higher-order graph-based parsing that directly models relations such as siblinghood (McDonald and Pereira, 2006) or grandparenthood (Carreras, 2007), however, the arguments in those two functions do not have any fixed type of structural interactions.

6 Experiments

Data and Evaluation We experimented with English and Chinese. For English, we used the Stanford Dependencies (de Marneffe and Manning, 2008) conversion (via the Stanford parser 3.3.0) of the Penn Treebank (Marcus et al., 1993, PTB). As is standard, we used §2-21 of the Wall Street Journal for training, §22 for development, and §23 for testing; POS tags were predicted using 10-way jackknifing with the Stanford max entropy tagger (Toutanova et al., 2003). For Chinese, we used the Penn Chinese Treebank 5.1 (Xue et al., 2002, CTB), with the same splits and head-finding rules for conversion to dependencies as Zhang and Clark (2008). We adopted the CTB's gold-standard tokenization and POS tags. We report unlabeled attachment score (UAS) and sentence-level unlabeled exact match (UEM). Following prior work, all punctuation is excluded from evaluation. For each model, we initialized the network parameters with 5 different random seeds and report performance average and standard deviation.

Implementation Details Our model structures reproduce those of Kiperwasser and Goldberg (2016a). We use 2-layer bi-directional LSTMs with 256 hidden cell units. Inputs are concatenations of 28-dimensional randomly-initialized part-of-speech embeddings and 100-dimensional word vectors initialized from GloVe vectors (Pennington et al., 2014) (English) and pre-trained skip-gram-model vectors (Mikolov et al., 2013) (Chinese). The concatenation of the bi-LSTM feature vectors is passed through a multi-layer perceptron (MLP) with 1 hidden layer which has 256 hidden units and activation function tanh. We set the dropout rate for the bi-LSTM (Gal and Ghahramani, 2016) and MLP (Srivastava et al., 2014) for each model according to development-set performance.[6] All parameters except the word embed-

[6] For bi-LSTM input and recurrent connections, we consider dropout rates in $\{0., 0.2\}$, and for MLP, $\{0., 0.4\}$.

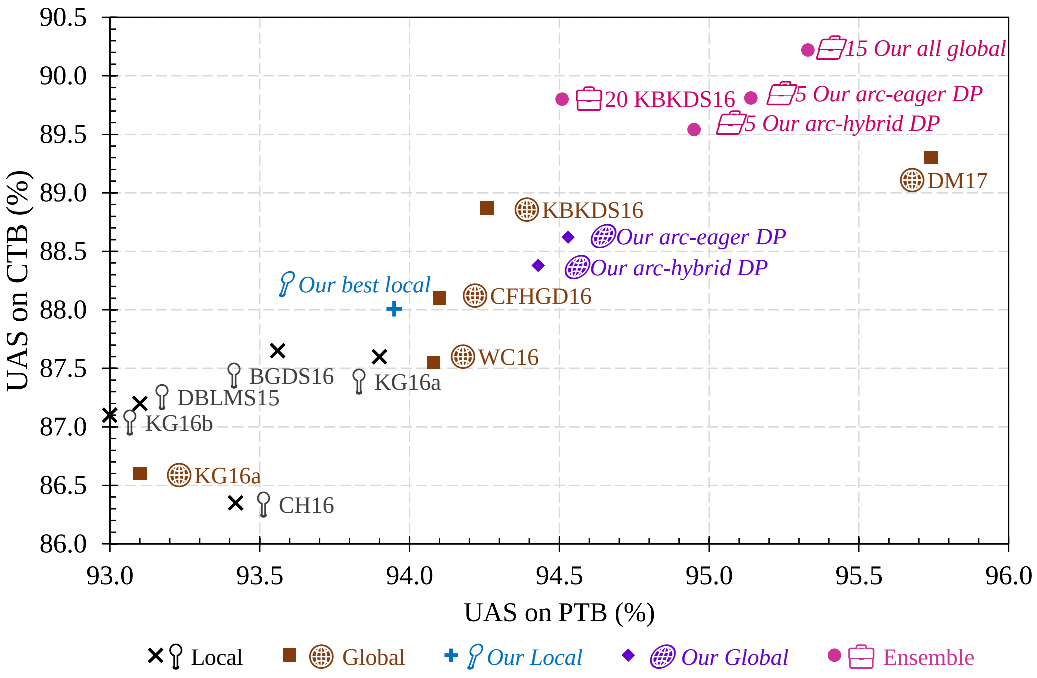

Figure 2: Comparing our UAS results with results from the literature. x-axis: PTB; y-axis: CTB. Most datapoint labels give author initials and publication year; citations are in the bibliography. Ensemble datapoints are annotated with ensemble size. Weiss et al. (2015) and Andor et al. (2016) achieve UAS of 94.26 and 94.61 on PTB with beam search, but did not report CTB results, and are therefore omitted.

dings are initialized uniformly (Glorot and Bengio, 2010). Approximately 1,000 tokens form a mini-batch for sub-gradient computation. We train each model for 20 epochs and perform model selection based on development UAS. The proposed structured loss function is optimized via Adam (Kingma and Ba, 2015). The neural network computation is based on the python interface to DyNet (Neubig et al., 2017), and the exact decoding algorithms are implemented in Cython.[7]

Main Results We implement exact decoders for the arc-hybrid and arc-eager systems, and present the test performance of different model configurations in Table 2, comparing global models with local models. All models use the same decoder for testing as during the training process. Though no global decoder for the arc-standard system has been explored in this paper, its local models are listed for comparison. We also include an edge-factored graph-based model, which is conventionally trained globally. The edge-factored model scores bi-LSTM features for each head-modifier pair; a maximum spanning tree algorithm is used to find the tree with the highest sum of edge scores. For this model, we use Dozat and Manning's (2017) biaffine scoring model, although in our case the model size is smaller.[8]

Analogously to the dev-set results given in §2, on the test data, the minimal feature sets perform as well as larger ones in locally-trained models. And there exists a clear trend of global models outperforming local models for the two different transition systems on both datasets. This illustrates the effectiveness of exact decoding and global training. Of the three types of global models, the arc-eager arguably has the edge, an empirical finding resonating with our theoretical comparison of their model expressiveness.

Comparison with State-of-the-Art Models Figure 2 compares our algorithms' results with those of the state-of-the-art.[9] Our models are competitive and an ensemble of 15 globally-trained models (5 models each for arc-eager DP, arc-hybrid DP and edge-factored) achieves 95.33 and 90.22 on PTB and CTB, respectively, reach-

[7] See https://github.com/tzshi/dp-parser-emnlp17.

[8] The same architecture and model size as other transition-based global models is used for fair comparison.

[9] We exclude Choe and Charniak (2016), Kuncoro et al. (2017) and Liu and Zhang (2017), which convert constituent-based parses to dependency parses. They produce higher PTB UAS, but access more training information and do not directly apply to datasets without constituency annotation.

ing the highest reported UAS on the CTB dataset, and the second highest reported on the PTB dataset among dependency-based approaches.

7 Related Work Not Yet Mentioned

Approximate Optimal Decoding/Training Besides dynamic programming (Huang and Sagae, 2010; Kuhlmann et al., 2011), various other approaches have been proposed for approaching global training and exact decoding. Best-first and A* search (Klein and Manning, 2003; Sagae and Lavie, 2006; Sagae and Tsujii, 2007; Zhao et al., 2013; Thang et al., 2015; Lee et al., 2016) give optimality certificates when solutions are found, but have the same worst-case time complexity as the original search framework. Other common approaches to search a larger space at training or test time include beam search (Zhang and Clark, 2011), dynamic oracles (Goldberg and Nivre, 2012, 2013; Cross and Huang, 2016b) and error states (Vaswani and Sagae, 2016). Beam search records the k best-scoring transition prefixes to delay local hard decisions, while the latter two leverage configurations deviating from the gold transition path during training to better simulate the test-time environment.

Neural Parsing Neural-network-based models are widely used in state-of-the-art dependency parsers (Henderson, 2003, 2004; Chen and Manning, 2014; Weiss et al., 2015; Andor et al., 2016; Dozat and Manning, 2017) because of their expressive representation power. Recently, Stern et al. (2017) have proposed minimal span-based features for constituency parsing.

Recurrent and recursive neural networks can be used to build representations that encode complete configuration information or the entire parse tree (Le and Zuidema, 2014; Dyer et al., 2015; Kiperwasser and Goldberg, 2016b), but these models cannot be readily combined with DP approaches, because their state spaces cannot be merged into smaller sets and thus remain exponentially large.

8 Concluding Remarks

In this paper, we have shown the following.

- The bi-LSTM-powered feature set $\{\overleftrightarrow{s}_0, \overleftrightarrow{b}_0\}$ is minimal yet highly effective for arc-hybrid and arc-eager transition-based parsing.

- Since DP algorithms for exact decoding (Huang and Sagae, 2010; Kuhlmann et al., 2011) have a run-time dependence on the number of positional features, using our mere two effective positional features results in a running time of $O(n^3)$, feasible for practice.

- Combining exact decoding with global training — which is also enabled by our minimal feature set — with an ensemble of parsers achieves 90.22 UAS on the Chinese Treebank and 95.33 UAS on the Penn Treebank: these are, to our knowledge, the best and second-best results to date on these data sets among "purely" dependency-based approaches.

There are many directions for further exploration. Two possibilities are to create even better training methods, and to find some way to extend our run-time improvements to other transition systems. It would also be interesting to further investigate relationships between graph-based and dependency-based parsing. In §5 we have mentioned important earlier work in this regard, and provided an update to those formal findings.

In our work, we have brought exact decoding, which was formerly the province solely of graph-based parsing, to the transition-based paradigm. We hope that the future will bring more inspiration from an integration of the two perspectives.

Acknowledgments: an author-reviewer success story We sincerely thank all the reviewers for their extraordinarily careful and helpful comments. Indeed, this paper originated as a short paper submission by TS&LL to ACL 2017, where an anonymous reviewer explained in the review comments how, among other things, the DP run-time could be improved from $O(n^4)$ to $O(n^3)$. In their author response, TS&LL invited the reviewer to co-author, suggesting that they ask the conference organizers to make the connection between anonymous reviewer and anonymous authors. All three of us are truly grateful to PC co-chair Regina Barzilay for implementing this idea, bringing us together!

We also thank Kai Sun for help with Chinese word vectors, and Xilun Chen, Yao Cheng, Dezhong Deng, Juneki Hong, Jon Kleinberg, Ryan McDonald, Ashudeep Singh, and Kai Zhao for discussions and suggestions. TS and LL were supported in part by a Google focused research grant to Cornell University. LH was supported in part by NSF IIS-1656051, DARPA N66001-17-2-4030, and a Google Faculty Research Award.

{junjie.cao,huangsheng,ws,wanxiaojun}@pku.edu.cn

Abstract

We propose a new Maximum Subgraph algorithm for first-order parsing to 1-endpoint-crossing, pagenumber-2 graphs. Our algorithm has two characteristics: (1) it separates the construction for noncrossing edges and crossing edges; (2) in a single construction step, whether to create a new arc is deterministic. These two characteristics make our algorithm relatively easy to be extended to incorporiate crossing-sensitive second-order features. We then introduce a new algorithm for quasi-second-order parsing. Experiments demonstrate that second-order features are helpful for Maximum Subgraph parsing.

1 Introduction

Previous work showed that treating semantic dependency parsing as the search for Maximum Subgraphs is not only elegant in theory but also effective in practice (Kuhlmann and Jonsson, 2015; Cao et al., 2017). In particular, our previous work showed that 1-endpoint-crossing, pagenumber-2 (1EC/P2) graphs are an appropriate graph class for modelling semantic dependency structures (Cao et al., 2017). On the one hand, it is highly expressive to cover a majority of semantic analysis. On the other hand, the corresponding Maximum Subgraph problem with an arc-factored disambiguation model can be solved in low-degree polynomial time.

Defining disambiguation models on wider contexts than individual bi-lexical dependencies improves various syntactic parsers in different architectures. This paper studies exact algorithms for second-order parsing for 1EC/P2 graphs. The existing algorithm, viz. our previous algorithm (GCHSW, hereafter), has two properties that make it hard to incorporate higher-order features in a principled way. First, GCHSW does not explicitly consider the construction of noncrossing arcs. We will show that incorporiating higher-order factors containing crossing arcs without increasing time and space complexity is extremely hard. An effective strategy is to only include higher-order factors containing only noncrossing arcs (Pitler, 2014). But this *crossing-sensitive* strategy is incompatible with GCHSW. Second, all existing higher-order parsing algorithms for projective trees, including (McDonald and Pereira, 2006; Carreras, 2007; Koo and Collins, 2010), require that which arcs are created in a construction step be deterministic. This design is also incompatible with GCHSW. In summary, it is not convenient to extend GCHSW to incorporate higher-order features while keeping the same time complexity.

In this paper, we introduce an alternative Maximum Subgraph algorithm for first-order parsing to 1EC/P2 graphs. while keeping the same time and space complexity to GCHSW, our new algorithm has two characteristics that make it relatively easy to be extended to incorporate crossing-sensitive, second-order features: (1) it separates the construction for noncrossing edges and possible crossing edges; (2) whether an edge is created is deterministic in each construction rule. We then introduce a new algorithm to perform second-order parsing. When all second-order scores are greater than or equal to 0, it exactly solves the corresponding optimization problem.

We implement a practical parser with a statistical disambiguation model and evaluate it on four data sets: those used in SemEval 2014 Task 8 (Oepen et al., 2014), and the dependency graphs extracted from CCGbank (Hockenmaier and Steedman, 2007). On all data sets, we find that our second-order parsing models are more ac-

Proceedings of the 2017 Conference on Empirical Methods in Natural Language Processing, pages 24–34
Copenhagen, Denmark, September 7–11, 2017.

curate than the first-order baseline. If we do not use features derived from syntactic trees, we get an absolute unlabeled F-score improvement of 1.3 on average. When syntactic analysis is used, we get an improvement of 0.4 on average.

2 Preliminaries

2.1 Maximum Subgraph Parsing

Semantic dependency parsing can be formulated as the search for Maximum Subgraph for graph class $\mathcal{G}$: Given a graph $G = (V, A)$, find a subset $A' \subseteq A$ with maximum total score such that the induced subgraph $G' = (V, A')$ belongs to $\mathcal{G}$. Formally, we have the following optimization problem:

$$\arg \max_{G^* \in \mathcal{G}(s,G)} \sum_{p \text{ in } G^*} s_{\text{part}}(s, p)$$

$\mathcal{G}(s, G)$ denotes the set of all graphs that belong to $\mathcal{G}$ and are compatible with s and G. G is usually a complete digraph. $s_{\text{part}}(s, p)$ evaluates the event that part p (from a candidate graph G^*) is good. We define the *order* of p according to the number of arcs it contains, in analogy with tree parsing in terminology. Previous work only discussed the first-order case:

$$\arg \max_{G^* \in \mathcal{G}(G)} \sum_{d \in \textsc{Arc}(G^*)} s_{\text{arc}}(d)$$

If $\mathcal{G}$ is the set of noncrossing or 1EC/P2 graphs, the above optimization problem can be solved in cubic-time (Kuhlmann and Jonsson, 2015) and quintic-time (Cao et al., 2017) respectively. Furthermore, ignoring one linguistically-rare structure in 1EC/P2 graphs descreases the complexity to $O(n^4)$. This paper is concerned with second-order parsing, with a special focus on the following factorizations:

And the objective function turns to be:

$$\sum_{d \in \textsc{Arc}(G^*)} s_{\text{arc}}(d) + \sum_{s \in \textsc{Sib}(G^*)} s_{\text{sib}}(s)$$

Sun et al. (2017) introduced a dynamic programming algorithm for second-order planar parsing. Their empirical evaluation showed that second-order features are effective to improve parsing accuracy. It is still unknown how to incorporate such features for 1EC/P2 parsing.

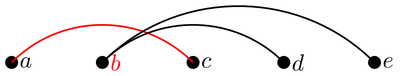

Figure 1: $e_{(a,c)}$'s crossing edges $e_{(b,d)}$ and $e_{(b,e)}$ share an endpoint b.

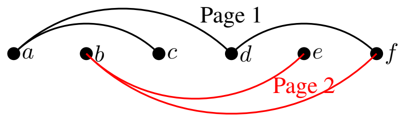

Figure 2: A pagenumber-2 graph. The upper and the lower figures represent two half-planes respectively.

2.2 1-Endpoint-Crossing, Pagenumber-2 Graphs

The formal description of the 1-endpoint-crossing property is adopted from (Pitler et al., 2013).

Definition 1. *Edges e_1 and e_2 cross if e_1 and e_2 have distinct endpoints and exactly one of the endpoints of e_1 lies between the endpoints of e_2.*

Definition 2. *A dependency graph is 1-Endpoint-Crossing if for any edge e, all edges that cross e share an endpoint p named pencil point.*

Given a sentence $s = w_0 w_1 \cdots w_{n-1}$ of length n, the vertices, i.e. words, are indexed with integers, an arc from w_i to w_j as $a_{(i,j)}$, and the common endpoint, namely pencil point, of all edges crossed with $a_{(i,j)}$ or $a_{(j,i)}$ as $pt(i, j)$. We denote an edge as $e_{(i,j)}$, if we do not consider its direction. Figure 1 is an example.

Definition 3. *A pagenumber-k graph means it consists at most k half-planes, and arcs on each half-plane are noncrossing.*

These half-planes may be thought of as the pages of a book, with the vertex line corresponding to the books spine, and the embedding of a graph into such a structure is known as a book embedding. Figure 2 is an example.

(Pitler et al., 2013) proved that 1-endpoint-crossing trees are a subclass of graphs whose pagenumber is at most 2. In Cao et al. (2017), we studied graphs that are constrained to be both 1-endpoint-crossing and pagenumber-2. In this paper, we ignored a complex and linguistic-rare

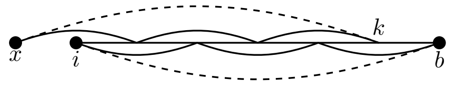

Figure 3: C structure has two crossing chains.

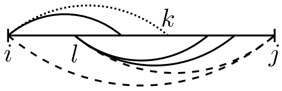

Figure 4: A prototype backbone of 1EC/P2 graphs. To decompose this structure, GCHSW focuses on $e_{(i,j)}$ and $e_{(l,j)}$, because these two edges can be optionally created without violation of both 1EC and P2 restrictions. Our algorithm focuses on the existence of $e_{(i,k)}$, and makes it the only edge that is constructed by applying a corresponding rule.

structure and studied a subset of 1EC/P2 graphs. The complex structure is named as C structures in our previous paper, and Figure 3 is the prototype of C structures. In this paper, we present new algorithms for finding optimal 1EC/P2, C-free graphs.

2.3 The GCHSWAlgorithm

Cao et al. (2017) designed a polynomial time Maximum Subgraph algorithm, viz. GCHSW, for 1EC/P2 graphs by exploring the following property: Every subgraph of a 1EC/P2 graph is also a 1EC/P2 graph. GCHSW defines a number of prototype backbones for decomposing a 1EC/P2 graph in a principled way. In each decomposition step, GCHSW focuses on the edges that can be created without violating either the 1EC nor P2 restriction. Sometimes, multiple edges can be created simultaneously in one single step. Figure 4 is an example.

There is an important difference between GCHSW and Eisner-style Maximum Spanning Tree algorithms (MST; Eisner, 1996; McDonald and Pereira, 2006; Koo and Collins, 2010). In each construction step, GCHSW allows multiple arcs to be constructed, but whether or not such arcs are added to the target graph depends on their arc-weights. If all arcs are assigned scores that are greater than 0, the output of our algorithm includes the most complicated 1EC/P2 graphs. For the higher-order MST algorithms, in a single construction step, it is clear whether adding a new arc, and which one. There is no local search. This deterministic strategy is also followed by Kuhlmann and Jonsson's Maximum Subgraph algorithm for noncrossing graphs. Higher-order MST models associate higher-order score functions with the construction of individual dependencies. Therefore the deterministic strategy is a prerequisite to incorporate higher-order features. The design of GCHSW is incompatible with this strategy.

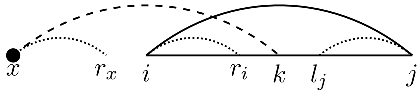

Figure 5: A typical structure of crossing arcs.

2.4 Challenge of Second-Order Decoding

It is very difficult to enumerate all high-order features for crossing arcs. Figure 5 illustrates the idea. There is a pair of corssing arcs, viz. $e_{(x,k)}$ and $e_{(i,j)}$. The key strategy to develop a dynamic programming algorithm to generate such crossing structure is to treat parts of this structures as intervals/spans together with an external vertex (Pitler et al., 2013; Cao et al., 2017). Without loss of generality, we assume $[i, j]$ makes up such an interval and x is the corresponding external vertex. When we consider $e_{(i,j)}$, its neighboring edges can be $e_{(i,r_i)}$ and $e_{(l_j,j)}$, and therefore we need to consider searching the best positions of both r_i and l_j. Because we have already taken into account three vertices, viz. x, i and j, the two new positions increase the time complexity to be at least quintic.

Now consider $e_{(x,k)}$. When we decompose the whole graph into inverval $[i, j]$ plus x and remaining part, we will factor out $e_{(x,k)}$ in a successive decomposition for resolving $[i, j]$ plus x. We cannot capture the second features associated to $e_{(x,k)}$ and $e_{(x,r_x)}$, because they are in different intervals, and when these intervals are combined, we have already hidden the position information of k. Explicitly encoding k increases the time complexity to be at least quintic too.

Pitler (2014) showed that it is still possible to build accurate tree parsers by considering only higher-order features of noncrossing arcs. This is in part because only a tiny fraction of neighboring arcs involve crossing arcs. However, this strategy is not easy to by applied to GCHSW, because GCHSW does not explicitly analyze sub-graphs of noncrossing arcs.

3 A New Maximum Subgraph Algorithm

Based on the discussion of Section 2.3 and 2.4, we can see that it is not easy to extend the existing algorithm, viz. GCHSW, to handle second-order features. In this paper, we propose an alternative first-order dynamic programming algorithm. Because ignoring one linguistically-rare structure associated with the **C** problem in GCHSW descreases the complexity, we exclude this structure in our algorithm. Formally, we introduce a new algorithm

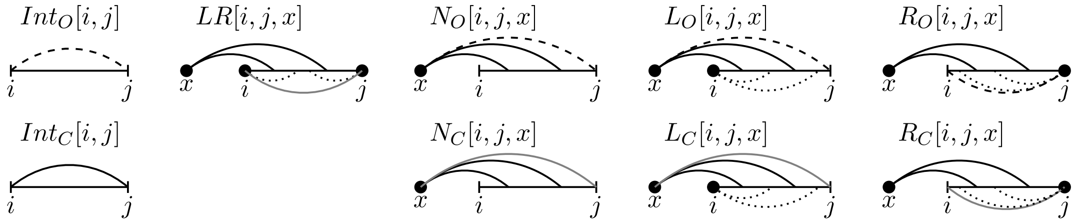

Figure 6: Graphical representations of sub-problems. Gray curves mean the corresponding edge in this sub-problem, but should be included in the final generated graph.

$$Int_O(i,j) \leftarrow \max \begin{cases} Int_O(i+1,j) \\ Int_C(i,j) \\ Int_C(i,k) + Int_O(k,j) \\ R_C(i,k,x) + Int_O(k,x) + L_O(x,j,k) + \mathrm{s}_{\mathrm{arc}}(i,k) \\ LR(i,k,x) + Int_O(k,x) + Int_O(x,j,k) + \mathrm{s}_{\mathrm{arc}}(i,k) \\ Int_O[i,x] + L_C[x,k,i] + N_O[k,j,x] + \mathrm{s}_{\mathrm{arc}}(i,k) \\ R_O[i,x,k] + Int_O[x,k] + L_O[k,j,x] + \mathrm{s}_{\mathrm{arc}}(i,k) \end{cases}$$

$$Int_C(i,j) \leftarrow \mathrm{s}_{\mathrm{arc}}(i,j) + \max \begin{cases} Int_O(i+1,j) \\ Int_C(i,k) + Int_O(k,j) \\ R_C(i,k,x) + Int_O(k,x) + L_O(x,j,k) + \mathrm{s}_{\mathrm{arc}}(i,k) \\ LR(i,k,x) + Int_O(k,x) + Int_O(x,j,k) + \mathrm{s}_{\mathrm{arc}}(i,k) \\ Int_O[i,x] + L_C[x,k,i] + N_O[k,j,x] + \mathrm{s}_{\mathrm{arc}}(i,k) \\ R_O[i,x,k] + Int_O[x,k] + L_O[k,j,x] + \mathrm{s}_{\mathrm{arc}}(i,k) \end{cases}$$

$$N_O(i,j,x) \leftarrow \max \begin{cases} Int_O(i,j) \\ N_C(i,j,x) + \mathrm{s}_{\mathrm{arc}}(x,j) \\ N_C(i,k,x) + Int_O(k,j) + \mathrm{s}_{\mathrm{arc}}(x,k) \end{cases}$$

$$N_C(i,j,x) \leftarrow \max \begin{cases} Int_O(i,j) \\ N_C(i,k,x) + Int_O(k,j) + \mathrm{s}_{\mathrm{arc}}(x,k) \end{cases}$$

$$LR(i,j,x) \leftarrow \max \left\{ L_O(i,k,x) + R_O(k,j,x) \right.$$

$$L_O(i,j,x) \leftarrow \max \begin{cases} Int_O(i,j) \\ L_C(i,j,x) + \mathrm{s}_{\mathrm{arc}}(x,j) \\ L_C(i,k,x) + N_O(k,j) + \mathrm{s}_{\mathrm{arc}}(x,k) \\ Int_O(i,k,x) + L_O(k,j) + \mathrm{s}_{\mathrm{arc}}(x,k) \end{cases}$$

$$R_O(i,j,x) \leftarrow \max \begin{cases} Int_O(i,j) \\ R_C(i,j,x) + \mathrm{s}_{\mathrm{arc}}(x,j) \\ N_C(i,k,j) + R_O(k,j,x) + \mathrm{s}_{\mathrm{arc}}(x,k) \\ R_O(i,k,x) + Int_O(k,j) + \mathrm{s}_{\mathrm{arc}}(x,k) \end{cases}$$

$$R_C(i,j,x) \leftarrow \max \begin{cases} N_C(i,k,j) + R_O(k,j,x) + \mathrm{s}_{\mathrm{arc}}(x,k) \\ R_O(i,k,x) + Int_O(k,j) + \mathrm{s}_{\mathrm{arc}}(x,k) \end{cases}$$

Figure 7: A dynamic program to find optimal 1EC/P2, **C**-free graphs with arc-factored weights.

to solve the following optimization problem:

$$\arg \max_{G^* \in \mathcal{G}(G)} \sum_{d \in \textsc{Arc}(G^*)} \mathrm{s}_{\mathrm{arc}}(d)$$

where $\mathcal{G}$ means 1EC/P2, **C**-free graphs. Our algorithm has the same time and space complexity to the degenerated version of GCHSW. We represent our algorithm using undirected graphs.

3.1 Sub-problems

Following GCHSW, we consider five sub-problems when we construct a maximum dependency graph on a given interval $[i,k]$. Though the sub-problems introduced by GCHSW and us handle similar structures, their definitions are quite different. The sub-problems are explained as follows:

Int $Int[i,j]$ represents an interval from i to j inclusively. And there is no edge $e_{(i',j')}$ such that $i' \in [i,j]$ and $j' \notin [i,j]$. We distinguish two sub-types for **Int**. $Int_O[i,j]$ may or may not contain $e_{(i,j)}$, while $Int_C[i,j]$ contains $e_{(i,j)}$.

LR $LR[i,j,x]$ represents an interval from i to j inclusively and an external vertex x. $\forall p \in [i,j], pt(x,p) = i$ or j. $LR[i,j,x]$ implies the existence of $e_{(i,j)}$, but does not contain $e_{(i,j)}$. When $LR[i,j,x]$ is combined with other DP sub-structures, $e_{(i,j)}$ is immediately created. $LR[i,j,x]$ disallows neither $e_{(x,i)}$ nor $e_{(x,j)}$.

N $N[i,j,x]$ represents an interval from i to j inclusively and an external vertex x. $\forall p \in [i,j], pt(x,p) \notin [i,j]$. $N[i,j,x]$ could contain $e_{(i,j)}$ but disallows $e_{(x,i)}$. We distinguish two sub-types. $N_O[i,j,x]$ may or may not contain $e_{(x,j)}$. $N_C[i,j,x]$ implies the existence of but does not contain $e_{(x,j)}$. When $N[i,j,x]$ is combined with others, $e_{(x,j)}$ is immediately created.

L $L[i,j,x]$ represents an interval from i to j inclusively as well as an external vertex x. $\forall p \in [i,j], pt(x,p) = i$. $L[i,j,x]$ could contain $e_{(i,j)}$ but disallows $e_{(x,i)}$. We distinguish sub-two types for **L**. $L_O[i,j,x]$ may or may not contain $e_{(x,j)}$. $L_C[i,j,x]$ implies the existence of but does not contain $e_{(x,j)}$. When it is combined with others, $e_{(x,j)}$ is immediately created.

R $R[i,j,x]$ represents an interval from i to j inclusively as well as an external vertex x. $\forall p \in [i,j], pt(x,p) = j$. $R[i,j,x]$ disallows $e_{(x,j)}$ and $e_{(x,i)}$. We distinguish two sub-types for **R**. $R_O[i,j,x]$ may or may not contain $e_{(i,j)}$. $R_C[i,j,x]$ implies the existence of but does not contain $e_{(i,j)}$. When it is combined with others, $e_{(i,j)}$ is immediately created.

3.2 Decomposing Sub-problems

Figure 7 gives a sketch of our dynamic programming algorithm. We give a detailed illustration for **Int**, a rough idea for **L** and **LR**, and omit other sub-problems. More details about the whole algorithm can be found in the supplementary note.

3.2.1 Decomposing an Int Sub-problem

Consider $Int_O[i,j]$ and $Int_C[i,j]$ sub-problem. Because the decomposition for $Int_C[i,j]$ is very similar to $Int_O[i,j]$ and needs to be modified by our second-order parsing algorithm, we only show the decomposition of $Int_C[i,j]$. Assume that $k (k \in (i,j))$ is the **farthest** vertex that is adjacent to i, and $x = pt(i,k)$. If there is no such k (i.e. there no arc from i to some other node in this interval), then we denote k as $\emptyset$. So it is to x. We illustrate different cases as following and give a graphical representation in Figure 8.

Case a: $k = \emptyset$**.** We can directly consider interval $[i+1,j]$. Because there is no edge from i to any node in $[i+1,j]$, $[i+1,j]$ is an $\mathbf{Int_O}$.

Case b: $x = \emptyset$**.** $x = \emptyset$ means that $e_{(i,k)}$ does not cross other arcs. So $[i,k]$ and $[k,j]$ are **Int**.

Case c: $x \in (k,j]$**.** $e_{(i,k)}$ is taken as a possible crossing edge. k and x divide the interval $[i,j]$ into three parts: $[i,k]$, $[k,x]$, $[x,j]$. Because x may be j, interval $[x,j]$ may only contain j and become an empty interval. We define x' as the pencil point of all edges from (i,k) to x, and distinguish two sub-problems as follows.

c.1 Assume that there exists an edge from k to some node r in $(x,j]$, so x' can only be k and pencil point of edges from k to $(x,j]$ is x. Thus interval $[i,k,x]$ is an **R**. Due to the existence of $e_{(i,k)}$, its sub-type is $\mathbf{R_C}$. The $e_{(i,k)}$ is created in this construction and thus not contained by $R_C[i,k,x]$. An edge from within $[k,x]$ to outside violates the 1EC restriction, so $[k,x]$ is an **Int**. Since x is endpoint of edge from k to $[x,r]$, interval $[k,j]$ is an $\boldsymbol{L_O}$ with external vertex k.

c.2 We assume no edge from k to any node in $[x,j]$, x' thus can be i or k. As a result, $[x,j]$ is an **Int** and $[i,k,x]$ is an **LR**.

Case d: $x \in (i,k)$**.**

d.1 Assume that there exist edges from i to (x,k), so the pencil point of edges from x to $(k,j]$ is i. Therefore $[k,j]$ is an **N**. Because x is pencil point of edges from i to $(x,k]$, $[x,k]$ is an **L**. Furthmore, it is an $\mathbf{L_C}$ because we generate $e_{(i,k)}$ in this step. It is obvious that $[i,x]$ is an **Int**.

d.2 Assume that there exists edges from k to (i,x), and the pencil point of edges from x to $(k,j]$ is thus k. Similar to the above analysis, we reach $R_O[i,x,k] + Int_O[x,k] + L_O[k,j,x] + e_{(i,k)} + e_{(i,j)}$.

For $Int_O[i,j]$, because there may be $e_{(i,j)}$, we add one more rule: $Int_O[i,j] = Int_C[i,j]$. And we do not need to create $e_{(i,j)}$ in all cases.

3.2.2 Decomposing an L Sub-problem

Without loss of generality, we show the decomposition of $L_O[i,j,x]$ as follows. For $L_C[i,j,x]$, we ignore Case b but follow the others.

Case a. If there is no more edge from x to $(i,j]$, then it will degenerate to $Int_O[i,j]$.

Case b. If there exists $e_{(x,j)}$, then it will degenerate to $L_C[i,j,x] + e_{(x,j)}$.

Case c. Assume that there are edges from x to (i,j) and $e_{(x,k)}$ is the farthest one. It divides $[i,j]$ into $[i,k]$ and $[k,j]$.

c.1 If there is an edge from x to (i,k), $[i,k]$ and $[k,j]$ are $L_C[i,k,x]$ and $N_O[k,j,i]$.

c.2 If there is no edge from x to (i,k), $[i,k]$ and $[k,j]$ are $Int_O[i,k]$ and $L_O[k,j,i]$.

Figure 8 is a graphical representation.

3.2.3 Decomposing an LR Sub-problem

$LR[i,j,x]$ means i or j is the pencil point of edges from x to (i,j). We show the decomposition of $LR[i,j,x]$ as follows:

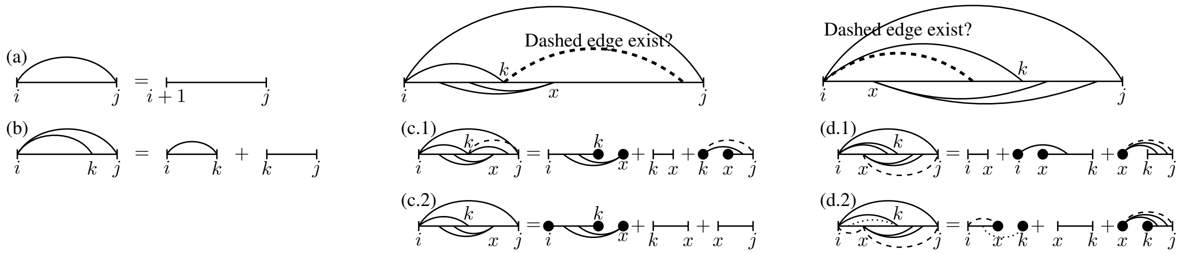

Figure 8: Decomposition for $Int_C[i,j]$ in the first-order parsing algorithm. $pt(i,k) = x$.

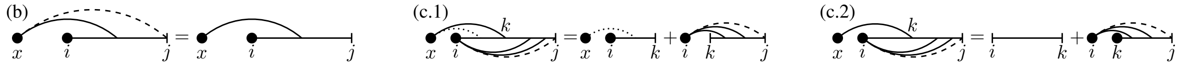

Figure 9: Decomposition for $L_O[i,j,x]$.

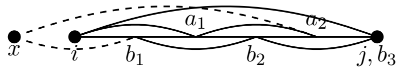

Figure 10: $b_3 = j$, Not both $e_{(x,b_1)}$ and $e_{(x,a_2)}$ exist.

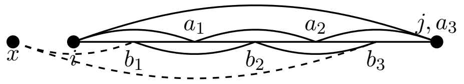

Figure 11: $a_3 = j$. Both $e_{(x,b_1)}$ and $e_{(x,b_3)}$ exist.

Case a. If there is a vertex k within (i,j), which divides $[i,j]$ into $[i,k]$ and $[k,j]$. And it guarantees no edge from $[i,k)$ to $(k,j]$. i is the pencil point of edges from x to $(i,k]$ because no edge from j to (i,k) can cross these edges. Similarly j has to be the pencil point of edges from x to (k,j). Obviously, $[i,k]$ is an L_O and $[k,j]$ is an R_O with external x. Thus the problem is decomposed as $L_O[i,k,x] + R_O[k,j,x]$.

Case b. If there is no such vertex k, there must be edges from $[i,k')$ to $(k',j]$ for every k' in (i,j) without considering $e_{(i,j)}$. For $i+1$, we assume $e_{(i,a_1)}$ is the farthest edge that goes from i. For a_1, we assume $e_{(b_1,b_2)}$ is the farthest edge from b_1 where b_1 is in (i,a_1) and b_2 is in (a_1,j). For b_2, we assume $e_{(a_1,a_3)}$ is the farthest edge from a_1 where a_3 is in (b_2,j) and a_1 is the pencil point. We then get the series $\{a_1, a_2, a_3 ... a_n\}$ and $\{b_1, b_2 ... b_m\}$ which guarantees $b_i < a_i$, $a_i < b_{i+1}$ and $max(a_n, b_m) = j$.

If $b_m = j$, we will get a graph like Figure 10. If $e_{(x,b_1)}$ exists, this LR subproblem degenerates to an L subproblem. If $e_{(x,a_n)}$ exists, this subproblem degenerates to an R subproblem.

If $a_m = j$, we will get a graph like Figure 11. If there exists only $e_{(x,b_1)}$ or $e_{(x,b_m)}$, we can solve it like $b_m = j$. If both exist, this is a typical C-structure like Figure 3 and we cannot get it through other decompostion.

The above discussion gives the rough idea of the correctness of the following conclusion.

Theorem 1. *Our new algorithm is sound and complete with respect to* 1EC/P2*, C-free graphs.*

3.3 Spurious Ambiguity

An **LR**, **L**, **R** or **N** sub-problem allows to build crossing arcs, but does not necessarily create crossing arcs. For example, $L_C[i,j,x]$ allows $e_{(i,j)}$ to cross with $e_{(x,y)}$ $(y \in (i,j))$. Because every subgraph of a 1EC/P2 graph is also a 1EC/P2 graph, we allow an $L_C[i,j,x]$ to be directly degenerated to $I_O[i,j]$. In this way, we can make sure that all subgraphs can be constructed by our algorithm. Figure 12 shows the rough idea. To generate the same graph, we have different derivations. The spurious ambiguity in our algorithm does not affect the correctness of first-order parsing, because scores are assigned to individual dependencies, rather than derivation processes. There is no need to distinguish one special derivation here.

4 Quasi-Second-Order Extension

We propose a second-order extension of our new algorithm. We focus on factorizations introduced in Section 2.1. Especially, the two arcs in a factor should not cross other arcs. Formally, we introduce a new algorithm to solve the optimization problem with the following objective:

$$\sum_{d \in \textsc{Arc}(G^*)} s_{\text{arc}}(d) + \sum_{s \in \textsc{Sib}(G^*)} \max(s_{\text{sib}}(s), 0)$$

In the first-order algorithm, all noncrossing edges can be constructed as the frontier edge of an $\mathbf{Int_C}$.

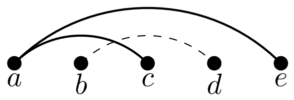

Figure 12: Illustration of spurious ambiguity. The two solid curves represent two arcs in the target graph, but not the dashed one. Excluding crossing edges leads to the first derivation: $Int_C[a,e] \Rightarrow e_{(a,e)} + Int_C[a,c] + Int_O[c,e] + e_{(a,c)}$. Assuming that a pair of crossing arcs may exist yields another derivation: $Int_C[a,e] \Rightarrow e_{(a,e)} + LR[a,c,d] + Int_O[k,d] + L_O[d,e,c] + e_{(a,c)}$; Then $LR[a,c,d] \Rightarrow L_O[a,b,d] + R_O[b,c,d] \Rightarrow Int_O[a,b] + Int_O[b,c]$.

So we can develop an exact decoding algorithm by modifying the composition for $\mathbf{Int_C}$ while keeping intact the decomposition for **LR**, **N**, **L**, **R**.

4.1 New Decomposition for Int_C

In order to capture the second-order features from noncrossing neighbors, we need to find the rightmost node adjacent to i, denoted as r_i, and the leftmost node adjacent to j, denoted as l_j,while $i < r_i \leq l_j < j$. To do this, we split $Int_C[i,j]$ into at most three parts to capture the sibling factors. Denote the score of adjacent edges $e_{(i,j_1)}$ and $e_{(i,j_2)}$ as $\mathrm{s}_2(i,j_1,j_2)$. When j is the inner most node adjacent to i, we denote the score as $\mathrm{s}_2(i,\emptyset,j)$. We give a sketch of the decomposition in Figure 14 and a graphical representation in Figure 13. The following is a rough illustration.

Case a: $r_i = \emptyset$**.** We further distinguish three sub-problems:

a.1 If $l_j = \emptyset$ too, both sides are the inner most second-order factor.

a.2 There is a crossing arc from j. This case is handled in the same way as the first-order algorithm.

a.3 $l_j \neq \emptyset$. We introduce a new decomposition rule.

Case b: There is a crossing arc from i**.**

b.1 $l_j = \emptyset$. Similar case to (a.2).

b.2 There is a crossing arc from j. Similar case to (a.2).

b.3 There is a noncrossing arc from j. We introduce a new rule to calculate $\textsc{Sib}(j,l_j,i)$.

Case c: There is a noncrossing arc from i**.**

c.1 $l_j = \emptyset$. Similar to (a.3).

c.2 There is a crossing arc from j. Similar to (b.3).

c.3 There is a noncrossing arc from j too. We introduce a new rule to calculate $\textsc{Sib}(i,r_i,j)$ and $\textsc{Sib}(j,l_j,i)$.

4.2 Complexity

The complexity of both first- and second-order algorithms can be analyzed in the same way. The sub-problem **Int** is of size $O(n^2)$, with a calculating time of order $O(n^2)$ at most. For sub-problems **L**, **R**, **LR**, and **N**, each has $O(n^3)$ elements, with a unit calculating time $O(n)$. Therefore both algorithms run in time of $O(n^4)$ with a space requirement of $O(n^3)$.

4.3 Discussion

A traditional second-order model takes as the objective function $\sum_{s \in \textsc{Sib}(G^*)} \mathrm{s_{sib}}(s)$. Our model instead tries to optimize $\sum_{s \in \textsc{Sib}(G^*)} \max(\mathrm{s_{sib}}(s), 0)$. This model is somehow inadequate given that the second-order score function cannot penalize a *bad* factor. When a negative score is assigned to a second-order factor, it will be taken as 0 by our algorithm.

This inadequacy is due to the spurious ambiguity problem that is illustrated in Section 3.3. Take the two derivations in Figure 12 for example. The derivation that starts from $Int_C[a,e] \Rightarrow Int_C[a,c] + Int_O[c,e]$ incorporates the second-order score $\mathrm{s_{sib}}(a,c,e)$. This is different when we consider the derivation that starts from $Int_C[a,e] \Rightarrow LR[a,c,d] + Int_O[k,d] + L_O[d,e,c]$. Because we assume temporarily that $e_{(a,c)}$ crosses others, we do not consider $\mathrm{s_{sib}}(a,c,e)$. We can see from this example that second-order scores not only depend on the derived graphs but also sensitive to the derivation processes.

If a second-order score is greater than 0, our algorithm selects the derivation that takes it into account since it increases the total score. If a second-order score is negative, our algorithm avoids including it by selecting other paths. In other words, our algorithm treats this score as 0.

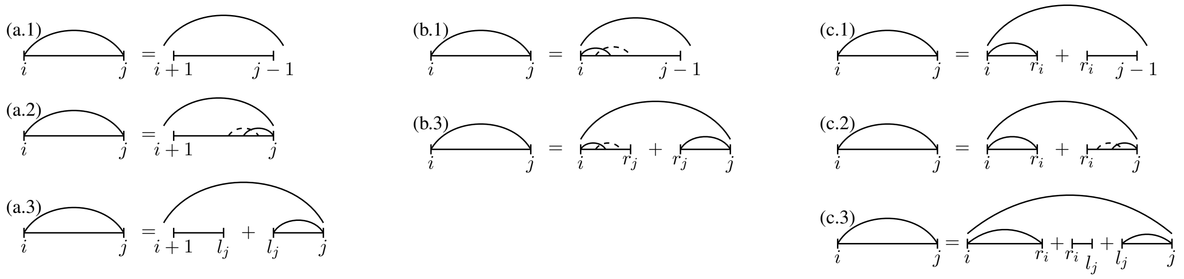

Figure 13: Decomposition for $Int_C[i,j]$ in the second-order parsing algorithm.

$$Int_C(i,j) \leftarrow \mathrm{s}_{\mathrm{arc}}(i,j) + \max \begin{cases} Int_O(i+1,j-1) + \mathrm{s}_{\mathrm{sib}}(i,\emptyset,j) + \mathrm{s}_{\mathrm{sib}}(j,\emptyset,i) \\ Int_O(i+1,j) + \mathrm{s}_{\mathrm{sib}}(i,\emptyset,j) \\ Int_O(i+1,l_j) + Int_C(l_j,j) + \mathrm{s}_{\mathrm{sib}}(i,\emptyset,j) + \\ \qquad \mathrm{s}_{\mathrm{sib}}(j,l_j,i) \\ Int_O(i,j-1) + \mathrm{s}_{\mathrm{sib}}(j,\emptyset,i) \\ Int_O(i,l_j) + Int_C(l_j,j) + \mathrm{s}_{\mathrm{sib}}(j,l_j,i) \\ Int_C(i,r_i) + Int_O[r_i,j-1] + \mathrm{s}_{\mathrm{sib}}(i,r_i,j) + \\ \qquad \mathrm{s}_{\mathrm{sib}}(j,\emptyset,i) \\ Int_C(i,r_i) + Int_O[r_i,j] + \mathrm{s}_{\mathrm{sib}}(i,r_i,j) \\ Int_C(i,r_i) + Int_O[r_i,l_j] + Int_C(l_j,j) + \\ \qquad \mathrm{s}_{\mathrm{sib}}(i,r_i,j) + \mathrm{s}_{\mathrm{sib}}(j,l_j,i) \\ R_C(i,k,x) + Int_O(k,x) + L_O(x,j,k) + e_{(i,k)} \\ LR(i,k,x) + Int_O(k,x) + Int_O(x,j,k) + e_{(i,k)} \\ Int_O[i,x] + L_C[x,k,i] + N_O[k,j,x] + e_{(i,k)} \\ R_O[i,x,k] + Int_O[x,k] + L_O[k,j,x] + e_{(i,k)} \end{cases}$$

Figure 14: Decomposition for $Int_C[i,j,x]$.

5 Practical Parsing

5.1 Derivation-Sensitive Training

We extend our quartic-time parsing algorithm into a practical parser. In the context of data-driven parsing, this requires an extra disambiguation model. As with many other parsers, we employ a global linear model. Following Zhang et al. (2016)'s experience, we define rich features extracted from word, POS-tags and pseudo trees. To estimate parameters, we utilize the averaged perceptron algorithm (Collins, 2002).

Our training proceudre is sensitive to derivation rather then derived graphs. For each sentence, we first apply our algorithm to find the optimal prediction derivation. The we collect all first- and second-order factors from this derivation to update parameters. To train a first-order model, because our algorithm includes all factors, viz. dependencies, there is no difference between our derivation-based method and a traditional derived structure-based method. For the second-order model, our method increases the second-order scores somehow.

5.2 Data and Preprocessing

We evaluate first- and second-order models on four representative data sets: CCGBank (Hockenmaier and Steedman, 2007), DeepBank (Flickinger et al., 2012), Enju HPSGBank (Miyao et al., 2005) and Prague Dependency TreeBank (Hajic et al., 2012). We use "standard" training, validation, and test splits to facilitate comparisons.

- Following previous experimental setup for English CCG parsing, we use section 02-21 as training data, section 00 as the development data, and section 23 for testing.

- The DeepBank, Enju HPSGBank and Prague Dependency TreeBank are from SemEval 2014 Task 8 (Oepen et al., 2014), and the data splitting policy follows the shared task.

Experiments for CCG-grounded analysis were performed using automatically assigned POS-tags that are generated by a symbol-refined HMM tagger (Huang et al., 2010). Experiments for the other three data sets used POS-tags provided by the shared task. We also use features extracted from pseudo trees. We utilize the Mate parser (Bohnet, 2010) to generate pseudo trees. All experimental results consider directed dependencies in a standard way. We report Unlabeled Precision (UP), Recall (UR) and F-score (UF), which are calculated using the official evaluation tool provided by SDP2014 shared task.

5.3 Accuracy

Table 1 lists the accuracy of our system. The output of our parser was evaluated against each dependency in the corpus. We can see that the first-order parser obtains a considerably good accuracy, with rich syntactic features. Furthermore, we can see that the introduction of higher-order features improves parsing substantially for all data sets, as expected. When syntactic trees are utilized, the

Table 2: Parsing accuracy evaluated on the test sets. "SJW" denotes the book embedding parser introduced in (Sun et al., 2017).

improvement is smaller but still significant on the three SemEval data sets.

Table 2 lists the parsing results on the test data together with the result obtained by Sun et al. (SJW; 2017)'s system. The building architectures of both systems are comparable.

1. Both systems have explicit control of the output structures. While Sun et al.'s system constrain the output graph to be P2 only, our system adds an additional 1EC restriction.
2. Their system's second-order features also includes both-side neighboring features.
3. Their system uses beam search and dual decomposition and therefore approximate, while ours perform exact decoding.

We can see that while our purely Maximum Subgraph parser obtains better results on DeepBank and CCGBank; while the book embedding parser is better on the other two data sets.

5.4 Analysis

Our algorithm is sensitive to the derivation process and may exclude a couple of negative second-order scores by selecting misleading derivations. Neverthess, our algorithm works in an exact way to include all positive second-order scores. Table 3 shows the coverage of all second-order factors. On average, 99.67% second-order factors are calculated by our algorithm. This relatively satisfactory coverage suggests that our algorithm is very effective to include second-order features. Only a very small portion is dropped.

6 Conclusion

This paper proposed two exact, graph-based algorithms for 1EC/P2 parsing with first-order and quasi-second-order scores. The resulting parser has the same asymptotic run time as Cao et al. (2017)'s algorithm. An exploration of other factorizations that facilitate semantic dependency parsing may be an interesting avenue for future work. Recent work has investigated faster decoding for higher-order graph-based projective parsing e.g. vine pruning (Rush and Petrov, 2012) and cube pruning (Zhang and McDonald, 2012). It would be interesting to extend these lines of work to decrease the complexity of our quartic algorithm.

Abstract

Organized relational knowledge in the form of "knowledge graphs" is important for many applications. However, the ability to populate knowledge bases with facts automatically extracted from documents has improved frustratingly slowly. This paper simultaneously addresses two issues that have held back prior work. We first propose an effective new model, which combines an LSTM sequence model with a form of entity position-aware attention that is better suited to relation extraction. Then we build TACRED, a large (119,474 examples) supervised relation extraction dataset, obtained via crowdsourcing and targeted towards TAC KBP relations. The combination of better supervised data and a more appropriate high-capacity model enables much better relation extraction performance. When the model trained on this new dataset replaces the previous relation extraction component of the best TAC KBP 2015 slot filling system, its F_1 score increases markedly from 22.2% to 26.7%.

1 Introduction

A basic but highly important challenge in natural language understanding is being able to populate a knowledge base with relational facts contained in a piece of text. For the text shown in Figure 1, the system should extract triples, or equivalently, knowledge graph edges, such as ⟨*Penner*, *per:spouse*, *Lisa Dillman*⟩. Combining such extractions, a system can produce a knowledge graph of relational facts between persons, organizations, and locations in the text. This task involves entity recognition, mention coreference and/or entity linking, and relation extraction; we focus on the most challenging "slot filling" task of filling in the relations between entities in the text.

Figure 1: An example of relation extraction from the TAC KBP corpus.

Organized relational knowledge in the form of "knowledge graphs" has become an important knowledge resource. These graphs are now extensively used by search engine companies, both to provide information to end-users and internally to the system, as a way to understand relationships. However, up until now, automatic knowledge extraction has proven sufficiently difficult that most of the facts in these knowledge graphs have been built up by hand. It is therefore a key challenge to show that NLP technology can effectively contribute to this important problem.

Existing work on relation extraction (e.g., Zelenko et al., 2003; Mintz et al., 2009; Adel et al., 2016) has been unable to achieve sufficient recall or precision for the results to be usable versus hand-constructed knowledge bases. Supervised training data has been scarce and, while techniques like distant supervision appear to be a promising way to extend knowledge bases at low cost, in practice the training data has often been too noisy for reliable training of relation extraction systems (Angeli et al., 2015). As a result most systems fail to make correct extractions even in apparently straightforward cases like Figure 1,

where the best system at the NIST TAC Knowledge Base Population (TAC KBP) 2015 evaluation failed to recognize the relation between *Penner* and *Dillman*.[1] Consequently most automatic systems continue to make heavy use of hand-written rules or patterns because it has been hard for machine learning systems to achieve adequate precision or to generalize as well across text types. We believe machine learning approaches have suffered from two key problems: (1) the models used have been insufficiently tailored to relation extraction, and (2) there has been insufficient annotated data available to satisfy the training of data-hungry models, such as deep learning models.

This work addresses both of these problems. We propose a new, effective neural network sequence model for relation classification. Its architecture is better customized for the slot filling task: the word representations are augmented by extra distributed representations of word position relative to the subject and object of the putative relation. This means that the neural attention model can effectively exploit the combination of semantic similarity-based attention and position-based attention. Secondly, we markedly improve the availability of supervised training data by using Mechanical Turk crowd annotation to produce a large supervised training dataset (Table 1), suitable for the common relations between people, organizations and locations which are used in the TAC KBP evaluations. We name this dataset the **TAC R**elation **E**xtraction **D**ataset (TACRED), and will make it available through the Linguistic Data Consortium (LDC) in order to respect copyrights on the underlying text.

Combining these two gives a system with markedly better slot filling performance. This is shown not only for a relation classification task on the crowd-annotated data but also for the incorporation of the resulting classifiers into a complete cold start knowledge base population system. On TACRED, our system achieves a relation classification F_1 score that is 7.9% higher than that of a strong feature-based classifier, and 3.5% higher than that of the best previous neural architecture that we re-implemented. When this model is used in concert with a pattern-based system on the TAC KBP 2015 Cold Start Slot Filling evaluation data, the system achieves an F_1 score of 26.7%, which exceeds the previous state-of-the-art by 4.5% absolute. While this performance certainly does not solve the knowledge base population problem – achieving sufficient recall remains a formidable challenge – this is nevertheless notable progress.

2 A Position-aware Neural Sequence Model Suitable for Relation Extraction

Existing work on neural relation extraction (e.g., Zeng et al., 2014; Nguyen and Grishman, 2015; Zhou et al., 2016) has focused on convolutional neural networks (CNNs), recurrent neural networks (RNNs), or their combination. While these models generally work well on the datasets they are tested on, as we will show, they often fail to generalize to the longer sentences that are common in real-world text (such as in TAC KBP).

We believe that existing model architectures suffer from two problems: (1) Although modern sequence models such as Long Short-Term Memory (LSTM) networks have gating mechanisms to control the relative influence of each individual word to the final sentence representation (Hochreiter and Schmidhuber, 1997), these controls are not explicitly conditioned on the entire sentence being classified; (2) Most existing work either

[1] Note: former spouses count as spouses in the ontology.

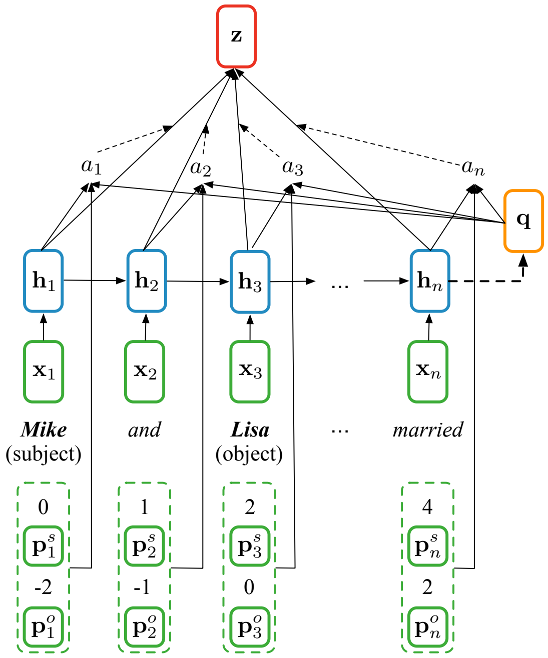

Figure 2: Our proposed position-aware neural sequence model. The model is shown with an example sentence *Mike and Lisa got married.*

does not explicitly model the positions of entities (i.e., subject and object) in the sequence, or models the positions only within a local region.

Here, we propose a new neural sequence model with a **position-aware attention mechanism** over an LSTM network to tackle these challenges. This model can (1) evaluate the relative contribution of each word after seeing the entire sequence, and (2) base this evaluation not only on the semantic information of the sequence, but also on the global positions of the entities within the sequence.

We formalize the relation extraction task as follows: Let $\mathcal{X} = [x_1, ..., x_n]$ denote a sentence, where x_i is the i-th token. A subject entity s and an object entity o are identified in the sentence, corresponding to two non-overlapping consecutive spans: $\mathcal{X}_s = [x_{s_1}, x_{s_1+1}, \dots, x_{s_2}]$ and $\mathcal{X}_o = [x_{o_1}, x_{o_1+1}, \dots, x_{o_2}]$. Given the sentence $\mathcal{X}$ and the positions of s and o, the goal is to predict a relation $r \in \mathcal{R}$ ($\mathcal{R}$ is the set of relations) that holds between s and o or no relation otherwise.

Inspired by the position encoding vectors used in Collobert et al. (2011) and Zeng et al. (2014), we define a position sequence relative to the subject entity $[p^s_1, ..., p^s_n]$, where

$$p^s_i = \begin{cases} i - s_1, & i < s_1 \\ 0, & s_1 \le i \le s_2 \\ i - s_2, & i > s_2 \end{cases} \tag{1}$$

Here s_1, s_2 are the starting and ending indices of the subject entity respectively, and $p^s_i \in \mathbb{Z}$ can be viewed as the relative distance of token x_i to the subject entity. Similarly, we obtain a position sequence $[p^o_1, ..., p^o_n]$ relative to the object entities.

Let $\mathbf{x} = [\mathbf{x}_1, ..., \mathbf{x}_n]$ be word embeddings of the sentence, obtained using an embedding matrix $\mathbf{E}$. Similarly, we obtain position embedding vectors $\mathbf{p}^s = [\mathbf{p}^s_1, ..., \mathbf{p}^s_n]$ and $\mathbf{p}^o = [\mathbf{p}^o_1, ..., \mathbf{p}^o_n]$ using a shared position embedding matrix $\mathbf{P}$ respectively. Next, as shown in Figure 2, we obtain hidden state representations of the sentence by feeding $\mathbf{x}$ into an LSTM:

$$\{\mathbf{h}_1, ..., \mathbf{h}_n\} = \text{LSTM}(\{\mathbf{x}_1, ..., \mathbf{x}_n\}) \tag{2}$$

We define a *summary* vector $\mathbf{q} = \mathbf{h}_n$ (i.e., the output state of the LSTM). This summary vector encodes information about the entire sentence. Then for each hidden state $\mathbf{h}_i$, we calculate an attention weight a_i as:

$$\begin{aligned} u_i = \mathbf{v}^\top \tanh(&\mathbf{W}_h\mathbf{h}_i + \mathbf{W}_q\mathbf{q} + \\ &\mathbf{W}_s\mathbf{p}^s_i + \mathbf{W}_o\mathbf{p}^o_i) \end{aligned} \tag{3}$$

$$a_i = \frac{\exp(u_i)}{\sum_{j=1}^n \exp(u_j)} \tag{4}$$

Here $\mathbf{W}_h, \mathbf{W}_q \in \mathbb{R}^{d_a \times d}$, $\mathbf{W}_s, \mathbf{W}_o \in \mathbb{R}^{d_a \times d_p}$ and $\mathbf{v} \in \mathbb{R}^{d_a}$ are learnable parameters of the network, where d is the dimension of hidden states, d_p is the dimension of position embeddings, and d_a is the size of attention layer. Additional parameters of the network include embedding matrices $\mathbf{E} \in \mathbb{R}^{|\mathcal{V}| \times d}$ and $\mathbf{P} \in \mathbb{R}^{(2L-1) \times d_p}$, where $\mathcal{V}$ is the vocabulary and L is the maximum sentence length.

We regard attention weight a_i as the relative contribution of the specific word to the sentence representation. The final sentence representation $\mathbf{z}$ is computed as:

$$\mathbf{z} = \sum\nolimits_{i=1}^n a_i\mathbf{h}_i \tag{5}$$

$\mathbf{z}$ is later fed into a fully-connected layer followed by a softmax layer for relation classification.

Note that our model significantly differs from the attention mechanism in Bahdanau et al. (2015) and Zhou et al. (2016) in our use of the summary vector and position embeddings, and the way our attention weights are computed. An intuitive way to understand the model is to view the attention calculation as a selection process, where the goal is to select relevant contexts over irrelevant ones.

Dataset	# Rel.	# Ex.	% Neg.
SemEval-2010 Task 8	19	10,717	17.4%
ACE 2003–2004	24	16,771	N/A
TACRED	42	119,474	78.7%

Table 2: A comparison of existing datasets and our proposed TACRED dataset. % Neg. denotes the percentage of negative examples (no relation).

Here the summary vector ($\mathbf{q}$) helps the model to base this selection on the semantic information of the entire sentence (rather than on each word only), while the position vectors ($\mathbf{p}_i^s$ and $\mathbf{p}_i^o$) provides important spatial information between each word and the entities.

3 The TAC Relation Extraction Dataset

Previous research has shown that slot filling systems can greatly benefit from supervised data. For example, Angeli et al. (2014b) showed that even a small amount of supervised data can boost the end-to-end F_1 score by 3.9% on the TAC KBP tasks. However, existing relation extraction datasets such as the SemEval-2010 Task 8 dataset (Hendrickx et al., 2009) and the Automatic Content Extraction (ACE) (Strassel et al., 2008) dataset are less useful for this purpose. This is mainly because: (1) these datasets are relatively small for effectively training high-capacity models (see Table 2), and (2) they capture very different types of relations. For example, the SemEval dataset focuses on semantic relations (e.g., *Cause-Effect*, *Component-Whole*) between two nominals.

One can further argue that it is easy to obtain a large amount of training data using distant supervision (Mintz et al., 2009). In practice, however, due to the large amount of noise in the induced data, training relation extractors that perform well becomes very difficult. For example, Riedel et al. (2010) show that up to 31% of the distantly supervised labels are wrong when creating training data from aligning Freebase to newswire text.

To tackle these challenges, we collect a large supervised dataset TACRED, targeted towards the TAC KBP relations.

Data collection. We create TACRED based on query entities and annotated system responses in the yearly TAC KBP evaluations. In each year of the TAC KBP evaluation (2009–2015), 100 entities (people or organizations) are given as queries, for which participating systems should find associated relations and object entities. We make use of Mechanical Turk to annotate each sentence in the source corpus that contains one of these query entities. For each sentence, we ask crowd workers to annotate both the subject and object entity spans and the relation types.

Data Split	# Ex.	Years
Train	75,050	2009–2012
Dev	25,764	2013
Test	18,660	2014

Table 3: Statistics on TACRED: number of examples and the source of each portion.

Dataset stratification. In total we collect 119,474 examples. We stratify TACRED across years in which the TAC KBP challenge was run, and use examples corresponding to query entities from 2009 to 2012 as training split, 2013 as development split, and 2014 as test split. We reserve the TAC KBP 2015 evaluation data for running slot filling evaluations, as presented in Section 4. Detailed statistics are given in Table 3.

Discussion. Table 1 presents sampled examples from TACRED. Compared to existing datasets, TACRED has four advantages. First, it contains an order of magnitude more relation instances (Table 2), enabling the training of expressive models. Second, we reuse the entity and relation types of the TAC KBP tasks. We believe these relation types are of more interest to downstream applications. Third, we fully annotate all negative instances that appear in our data collection process, to ensure that models trained on TACRED are not biased towards predicting false positives on real-world text. Lastly, the average sentence length in TACRED is 36.2, compared to 19.1 in the SemEval dataset, reflecting the complexity of contexts in which relations occur in real-world text.

Due to space constraints, we describe the data collection and validation process, system interfaces, and more statistics and examples of TACRED in the supplementary material. We will make TACRED publicly available through the LDC.

4 Experiments

In this section we evaluate the effectiveness of our proposed model and TACRED on improving slot filling systems. Specifically, we run two sets of experiments: (1) we evaluate model performance on the relation extraction task using TACRED, and (2) we evaluate model performance on the TAC KBP 2015 cold start slot filling task, by training the models on TACRED.

4.1 Baseline Models

We compare our model against the following baseline models for relation extraction and slot filling:

TAC KBP 2015 winning system. To judge our proposed model against a strong baseline, we compare against Stanford's top performing system on the TAC KBP 2015 cold start slot filling task (Angeli et al., 2015). At the core of this system are two relation extractors: a pattern-based extractor and a logistic regression (LR) classifier. The pattern-based system uses a total of 4,528 surface patterns and 169 dependency patterns. The logistic regression model was trained on approximately 2 million bootstrapped examples (using a small annotated dataset and high-precision pattern system output) that are carefully tuned for TAC KBP slot filling evaluation. It uses a comprehensive feature set similar to the MIML-RE system for relation extraction (Surdeanu et al., 2012), including lemmatized n-grams, sequence NER tags and POS tags, positions of entities, and various features over dependency paths, etc.

Convolutional neural networks. We follow the 1-dimensional CNN architecture by Nguyen and Grishman (2015) for relation extraction. This model learns a representation of the input sentence, by first running a series of convolutional operations on the sentence with various filters, and then feeding the output into a max-pooling layer to reduce the dimension. The resulting representation is then fed into a fully-connected layer followed by a softmax layer for relation classification. As an extension, positional embeddings are also introduced into this model to better capture the relative position of each word to the subject and object entities and were shown to achieve improved results. We use "CNN-PE" to represent the CNN model with positional embeddings.

Dependency-based recurrent neural networks. In dependency-based neural models, shortest dependency paths between entities are often used as input to the neural networks. The intuition is to eliminate tokens that are potentially less relevant to the classification of the relation. For the example in Figure 1, the shortest dependency path between the two entities is:

$$\text{[Penner]} \leftarrow \text{survived} \rightarrow \text{brother}$$
$$\rightarrow \text{wife} \rightarrow \text{[Lisa Dillman]}$$

We follow the SDP-LSTM model proposed by Xu et al. (2015b). In this model, each shortest dependency path is divided into two separate sub-paths from the subject entity and the object entity to the lowest common ancestor node. Each sub-path is fed into an LSTM network, and the resulting hidden units at each word position are passed into a max-over-time pooling layer to form the output of this sub-path. Outputs from the two sub-paths are then concatenated to form the final representation.

In addition to the above models, we also compare our proposed model against an LSTM sequence model without attention mechanism.

4.2 Implementation Details

We map words that occur less than 2 times in the training set to a special <*UNK*> token. We use the pre-trained GloVe vectors (Pennington et al., 2014) to initialize word embeddings. For all the LSTM layers, we find that 2-layer stacked LSTMs generally work better than one-layer LSTMs. We minimize cross-entropy loss over all 42 relations using *AdaGrad* (Duchi et al., 2011). We apply Dropout with $p = 0.5$ to CNNs and LSTMs. During training we also find a word dropout strategy to be very effective: we randomly set a token to be <*UNK*> with a probability p. We set p to be 0.06 for the SDP-LSTM model and 0.04 for all other models.

Entity masking. We replace each subject entity in the original sentence with a special <*NER*>-*SUBJ* token where <*NER*> is the corresponding NER signature of the subject as provided in TACRED. We do the same processing for object entities. This processing step helps (1) provide a model with entity type information, and (2) prevent a model from overfitting its predictions to specific entities.

Multi-channel augmentation. Instead of using only word vectors as input to the network, we augment the input with part-of-speech (POS) and named entity recognition (NER) embeddings. We run Stanford CoreNLP (Manning et al., 2014) to obtain the POS and NER annotations.

	Model	P	R	F_1
Traditional	Patterns	**85.3**	23.4	36.8
	LR	72.0	47.8	57.5
	LR + Patterns	71.4	50.1	58.9
Neural	CNN	72.1	50.3	59.2
	CNN-PE	68.2	55.4	61.1
	SDP-LSTM	62.0	54.8	58.2
	LSTM	61.4	61.7	61.5
	Our model	67.7	**63.2**	**65.4**
	Ensemble	69.4	**64.8**	**67.0**

Table 4: Model performance on the test set of TACRED, micro-averaged over instances. LR = Logistic Regression.

We describe our model hyperparameters and training in detail in the supplementary material.

4.3 Evaluation on TACRED

We first evaluate all models on TACRED. We train each model for 5 separate runs with independent random initializations. For each run we perform early stopping using the dev set. We then select the run (among 5) that achieves the *median* F_1 score on the dev set, and report its test set performance.

Table 4 summarizes our results. We observe that all neural models achieve higher F_1 scores than the logistic regression and patterns systems, which demonstrates the effectiveness of neural models for relation extraction. Although positional embeddings help increase the F_1 by around 2% over the plain CNN model, a simple (2-layer) LSTM model performs surprisingly better than CNN and dependency-based models. Lastly, our proposed position-aware mechanism is very effective and achieves an F_1 score of 65.4%, with an absolute increase of 3.9% over the best baseline neural model (LSTM) and 7.9% over the baseline logistic regression system. We also run an ensemble of our position-aware attention model which takes majority votes from 5 runs with random initializations and it further pushes the F_1 score up by 1.6%.

We find that different neural architectures show a different balance between precision and recall. CNN-based models tend to have higher precision; RNN-based models have better recall. This can be explained by noting that the filters in CNNs are essentially a form of "fuzzy n-gram patterns".

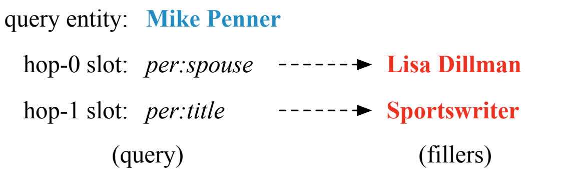

Figure 3: An example query and corresponding fillers in the TAC KBP cold start slot filling task.

4.4 Evaluation on TAC KBP Slot Filling

Second, we evaluate the slot filling performance of all models using the TAC KBP 2015 cold start slot filling task (Ellis et al., 2015). In this task, about 50k newswire and Web forum documents are selected as the evaluation corpus. A slot filling system is asked to answer a series of queries with two-hop slots (Figure 3): The first slot asks about fillers of a relation with the query entity as the subject (Mike Penner), and we term this a **hop-0** slot; the second slot asks about fillers with the system's hop-0 output as the subject, and we term this a **hop-1** slot. System predictions are then evaluated against gold annotations, and micro-averaged precision, recall and F_1 scores are calculated at the hop-0 and hop-1 levels. Lastly **hop-all** scores are calculated by combining hop-0 and hop-1 scores.[2]

Evaluating relation extraction systems on slot filling is particularly challenging in that: (1) End-to-end cold start slot filling scores conflate the performance of all modules in the system (i.e., entity recognizer, entity linker and relation extractor). (2) Errors in hop-0 predictions can easily propagate to hop-1 predictions. To fairly evaluate each relation extraction model on this task, we use Stanford's 2015 slot filling system as our basic pipeline.[3] It is a very strong baseline specifically tuned for TAC KBP evaluation and ranked top in the 2015 evaluation. We then plug in the corresponding relation extractor trained on TACRED, keeping all other modules unchanged.

Table 5 presents our results. We find that: (1) by only training our logistic regression model on TACRED (in contrast to on the 2 million bootstrapped examples used in the 2015 Stanford system) and combining it with patterns, we obtain a higher hop-0 F_1 score than the 2015 Stanford sys-

[2] In the TAC KBP cold start slot filling evaluation, a hop-1 slot is transferred to a pseudo-slot which is treated equally as a hop-0 slot. Hop-all precision, recall and F1 are then calculated by combining these pseudo-slot predictions and hop-0 predictions.

[3] This system uses the fine-grained NER system in Stanford CoreNLP (Manning et al., 2014) for entity detection and the Illinois Wikifier (Ratinov et al., 2011) for entity linking.

Model	Hop-0			Hop-1			Hop-all		
	P	R	F_1	P	R	F_1	P	R	F_1
Patterns	**63.8**	17.7	27.7	**49.3**	8.6	14.7	**58.9**	13.3	21.8
LR	36.6	21.9	27.4	15.1	10.1	12.2	25.6	16.3	19.9

Table 6: An ablation test of our position-aware attention model, evaluated on TACRED dev set. Scores are median of 5 models.

tem, and a similar hop-all F_1; (2) our proposed position-aware attention model substantially outperforms the 2015 Stanford system on all hop-0, hop-1 and hop-all F_1 scores. Combining it with the patterns, we achieve a hop-all F_1 of 26.7%, an absolute improvement of 4.5% over the previous state-of-the-art result.

4.5 Analysis

Model ablation. Table 6 presents the results of an ablation test of our position-aware attention model on the development set of TACRED. The entire attention mechanism contributes about 1.5% F_1, where the position-aware term in Eq. (3) alone contributes about 1% F_1 score.

Impact of negative examples. Figure 4 shows how the slot filling evaluation scores change as we change the amount of negative (i.e., *no_relation*) training data provided to our proposed model. We find that: (1) At hop-0 level, precision increases as we provide more negative examples, while recall stays almost unchanged. F_1 score keeps increasing. (2) At hop-all level, F_1 score increases by about 10% as we change the amount of negative examples from 20% to 100%.

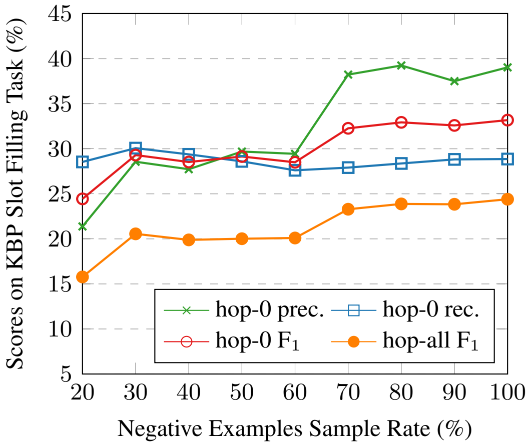

Figure 4: Change of slot filling hop-0 and hop-all scores as number of negative training examples changes. 100% is with all the negative examples included in the training set; the left side scores have positives and negatives roughly balanced.

Performance by sentence length. Figure 5 shows performance on varying sentence lengths. We find that: (1) Performance of all models degrades substantially as the sentences get longer. (2) Compared to the baseline Logistic Regression model, all neural models handle long sentences better. (3) Compared to CNN-PE model, RNN-based models are more robust on long sentences, and notably SDP-LSTM model is least sensitive to sentence length. (4) Our proposed model achieves equal or better results on sentences of all lengths, except for sentences with more than 60 tokens where SDP-LSTM model achieves the best result.

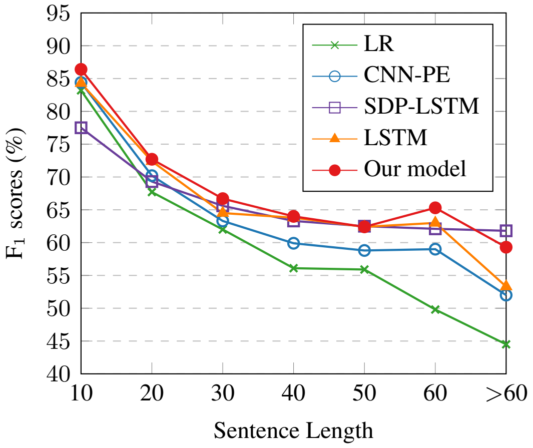

Figure 5: TACRED development set F_1 scores for sentences of varying lengths.

Improvement by slot types. We calculate the F_1 score for each slot type and compare the improvement from using our proposed model across slot types. When compared with the CNN-PE model, our position-aware attention model achieves improved F_1 scores on 30 out of the 41 slot types, with the top 5 slot types being *org:members*, *per:country_of_death*, *org:shareholders*, *per:children* and *per:religion*. When compared with SDP-LSTM model, our model achieves improved F_1 scores on 26 out of the 41 slot types, with the top 5 slot types being *org:political/religious_affiliation*, *per:country_of_death*, *org:alternate_names*, *per:religion* and *per:alternate_names*. We observe that slot types with relatively sparse training examples tend to be improved by using the position-aware attention model.

Attention visualization. Lastly, Figure 6 shows the visualization of attention weights assigned by our model on sampled sentences from the development set. We find that the model learns to pay more attention to words that are informative for the relation (e.g., "graduated from", "niece" and "chairman"), though it still makes mistakes (e.g., "refused to name the three"). We also observe that the model tends to put a lot of weight onto object entities, as the object NER signatures are very informative to the classification of relations.

5 Related Work

Relation extraction. There are broadly three main lines of work on relation extraction: first, fully-supervised approaches (Zelenko et al., 2003; Bunescu and Mooney, 2005), where a statistical classifier is trained on an annotated dataset; second, distant supervision (Mintz et al., 2009; Surdeanu et al., 2012), where a training set is formed by projecting the relations in an existing knowledge base onto textual instances that contain the entities that the relation connects; and third, Open IE (Fader et al., 2011; Mausam et al., 2012), which views its goal as producing subject-relation-object triples and expressing the relation in text.

Slot filling and knowledge base population. The most widely-known effort to evaluate slot filling and KBP systems is the yearly TAC KBP slot filling tasks, starting from 2009 (McNamee and Dang, 2009). Participants in slot filling tasks usually make use of hybrid systems that combine patterns, Open IE, distant supervision and supervised systems for relation extraction (Kisiel et al., 2015; Finin et al., 2015; Zhang et al., 2016).

Datasets for relation extraction. Popular general-domain datasets include the ACE dataset (Strassel et al., 2008) and the SemEval-2010 task 8 dataset (Hendrickx et al., 2009). In addition, the BioNLP Shared Tasks (Kim et al., 2009) are yearly efforts on creating datasets and evaluations for biomedical information extraction systems.

Deep learning models for relation extraction. Many deep learning models have been proposed for relation extraction, with a focus on end-to-end training using CNNs (Zeng et al., 2014; Nguyen and Grishman, 2015) and RNNs (Zhang et al., 2015). Other popular approaches include using CNN or RNN over dependency paths between entities (Xu et al., 2015a,b), augmenting RNNs with different components (Xu et al., 2016; Zhou et al., 2016), and combining RNNs and CNNs (Vu et al., 2016; Wang et al., 2016). Adel et al. (2016) compares the performance of CNN models against traditional approaches on slot filling using a portion of the TAC KBP evaluation data.

6 Conclusion

We introduce a state-of-the-art position-aware neural sequence model for relation extraction, as well as TACRED, a large-scale, crowd-sourced dataset that is orders of magnitude larger than previous relation extraction datasets. Our proposed model outperforms a strong feature-based classifier and all baseline neural models. In combination with the new dataset, it improves the state-of-the-

Abstract

Relation extraction is a fundamental task in information extraction. Most existing methods have heavy reliance on annotations labeled by human experts, which are costly and time-consuming. To overcome this drawback, we propose a novel framework, REHESSION, to conduct relation extractor learning using annotations from heterogeneous information source, e.g., knowledge base and domain heuristics. These annotations, referred as *heterogeneous supervision*, often conflict with each other, which brings a new challenge to the original relation extraction task: how to infer the true label from noisy labels for a given instance. Identifying context information as the backbone of both relation extraction and true label discovery, we adopt embedding techniques to learn the distributed representations of context, which bridges all components with mutual enhancement in an iterative fashion. Extensive experimental results demonstrate the superiority of REHESSION over the state-of-the-art.

1 Introduction

One of the most important tasks towards text understanding is to detect and categorize semantic relations between two entities in a given context. For example, in Fig. 1, with regard to the sentence of c_1, relation between *Jesse James* and *Missouri* should be categorized as `died_in`. With accurate identification, relation extraction systems can provide essential support for many applications. One example is question answering, regarding a specific question, relation among entities can provide valuable information, which helps to seek better answers (Bao et al., 2014). Similarly, for medical science literature, relations like protein-protein interactions (Fundel et al., 2007) and gene disease associations (Chun et al., 2006) can be extracted and used in knowledge base population. Additionally, relation extractors can be used in ontology construction (Schutz and Buitelaar, 2005).

Typically, existing methods follow the supervised learning paradigm, and require extensive annotations from domain experts, which are costly and time-consuming. To alleviate such drawback, attempts have been made to build relation extractors with a small set of seed instances or human-crafted patterns (Nakashole et al., 2011; Carlson et al., 2010), based on which more patterns and instances will be iteratively generated by bootstrap learning. However, these methods often suffer from semantic drift (Mintz et al., 2009). Besides, knowledge bases like Freebase have been leveraged to automatically generate training data and provide *distant supervision* (Mintz et al., 2009). Nevertheless, for many domain-specific applications, distant supervision is either non-existent or insufficient (usually less than 25% of relation mentions are covered (Ren et al., 2015; Ling and Weld, 2012)).

Only recently have preliminary studies been developed to unite different supervisions, including knowledge bases and domain specific patterns, which are referred as *heterogeneous supervision*. As shown in Fig. 1, these supervisions often conflict with each other (Ratner et al., 2016). To address these conflicts, data programming (Ratner et al., 2016) employs a generative model, which encodes supervisions as *labeling functions*, and adopts the source consistency assumption: *a source is likely to provide true information with*

Figure 2: Relation Mention Representation

the same probability for all instances. This assumption is widely used in true label discovery literature (Li et al., 2016) to model reliabilities of information sources like crowdsourcing and infer the true label from noisy labels. Accordingly, most true label discovery methods would trust a human annotator on all instances to the same level.

However, labeling functions, unlike human annotators, do not make casual mistakes but follow certain "error routine". Thus, the reliability of a labeling function is not consistent among different pieces of instances. In particular, a labeling function could be more reliable for a certain subset (Varma et al., 2016) (also known as its *proficient subset*) comparing to the rest. We identify these proficient subsets based on context information, only trust labeling functions on these subsets and avoid assuming global source consistency.

Meanwhile, embedding methods have demonstrated great potential in capturing semantic meanings, which also reduce the dimension of overwhelming text features. Here, we present REHESSION, a novel framework capturing context's semantic meaning through representation learning, and conduct both relation extraction and true label discovery in a context-aware manner. Specifically, as depicted in Fig. 1, we embed relation mentions in a low-dimension vector space, where similar relation mentions tend to have similar relation types and annotations. 'True' labels are further inferred based on reliabilities of labeling functions, which are calculated with their proficient subsets' representations. Then, these inferred true labels would serve as supervision for all components, including context representation, true label discovery and relation extraction. Besides, the context representation bridges relation extraction with true label discovery, and allows them to enhance each other.

To the best of our knowledge, the framework proposed here is the first method that utilizes representation learning to provide heterogeneous supervision for relation extraction. The high-quality context representations serve as the backbone of true label discovery and relation extraction. Extensive experiments on benchmark datasets demonstrate significant improvements over the state-of-the-art.

The remaining of this paper is organized as follows. Section 2 gives the definition of relation extraction with heterogeneous supervision. We then present the REHESSION model and the learning algorithm in Section 3, and report our experimental evaluation in Section 4. Finally, we briefly survey related work in Section 5 and conclude this study in Section 6.

2 Preliminaries

In this section, we would formally define relation extraction and heterogeneous supervision, including the format of labeling functions.

2.1 Relation Extraction

Here we conduct relation extraction in *sentence-level* (Bao et al., 2014). For a sentence d, an entity mention is a token span in d which represents an entity, and a relation mention is a triple (e_1, e_2, d) which consists of an ordered entity pair (e_1, e_2) and d. And the relation extraction task is to categorize relation mentions into a given set of relation types $\mathcal{R}$, or Not-Target-Type (`None`) which means the type of the relation mention does not belong to $\mathcal{R}$.

2.2 Heterogeneous Supervision

Similar to (Ratner et al., 2016), we employ labeling functions as basic units to encode supervision information and generate annotations. Since different supervision information may have different proficient subsets, we require each labeling function to encode only one elementary supervision information. Specifically, in the relation extraction scenario, we require each labeling function to only annotate one relation type based on one elementary piece of information, e.g., four examples are listed in Fig. 1.

Notice that knowledge-based labeling functions are also considered to be noisy because relation extraction is conducted in sentence-level, e.g. although `president_of` (*Obama*, *USA*) exists in KB, it should not be assigned with "*Obama* was born in Honolulu, Hawaii, *USA*", since `president_of` is irrelevant to the context.

2.3 Problem Definition

For a POS-tagged corpus $\mathcal{D}$ with detected entities, we refer its relation mentions as $\mathcal{C} = \{c_i = (e_{i,1}, e_{i,2}, d), \forall d \in \mathcal{D}\}$. Our goal is to annotate entity mentions with relation types of interest ($\mathcal{R} = \{r_1, \ldots, r_K\}$) or `None`. We require users to provide heterogeneous supervision in the form of labeling function $\Lambda = \{\lambda_1, \ldots, \lambda_M\}$, and mark the annotations generated by Λ as $\mathcal{O} = \{o_{c,i} | \lambda_i$ generate annotation $o_{c,i}$ for $c \in \mathcal{C}\}$. We record relation mentions annotated by Λ as $\mathcal{C}_l$, and refer relation mentions without annotation as $\mathcal{C}_u$. Then, our task is to train a relation extractor based on $\mathcal{C}_l$ and categorize relation mentions in $\mathcal{C}_u$.

$\mathbf{f}_c$	c's text features set, where $c \in \mathcal{C}$
$\mathbf{v}_i$	text feature embedding for $f_i \in \mathcal{F}$
$\mathbf{z}_c$	relation mention embedding for $c \in \mathcal{C}$
$\mathbf{l}_i$	embedding for λ_i's proficient subset, $\lambda_i \in \Lambda$
$o_{c,i}$	annotation for c, generated by labeling function λ_i
o_c^*	underlying true label for c
$\rho_{c,i}$	identify whether $o_{c,i}$ is correct
$\mathcal{S}_i$	the proficient subset of labeling function λ_i
$s_{c,i}$	identify whether c belongs to λ_i's proficient subset
$\mathbf{t}_i$	relation type embedding for $r_i \in \mathcal{R}$

Table 1: Notation Table.

3 The REHession Framework

Here, we present REHession, a novel framework to infer true labels from automatically generated noisy labels, and categorize unlabeled instances into a set of relation types. Intuitively, errors of annotations ($\mathcal{O}$) come from mismatch of contexts, e.g., in Fig. 1, λ_1 annotates c_1 and c_2 with 'true' labels but for mismatched contexts 'killing' and 'killed'. Accordingly, we should only trust labeling functions on *matched* context, e.g., trust λ_1 on c_3 due to its context 'was born in', but not on c_1 and c_2. On the other hand, relation extraction can be viewed as *matching* appropriate relation type to a certain context. These two *matching* processes are closely related and can enhance each other, while context representation plays an important role in both of them.

Framework Overview. We propose a general framework to learn the relation extractor from automatically generated noisy labels. As plotted in Fig. 1, distributed representation of context bridges relation extraction with true label discovery, and allows them to enhance each other. Specifically, it follows the steps below:

1. After being extracted from context, text features are embedded in a low dimension space by representation learning (see Fig. 2);
2. Text feature embeddings are utilized to calculate relation mention embeddings (see Fig. 2);
3. With relation mention embeddings, true labels are inferred by calculating labeling functions' reliabilities in a context-aware manner (see Fig. 1);
4. Inferred true labels would 'supervise' all components to learn model parameters (see Fig. 1).

We now proceed by introducing these components of the model in further details.

3.1 Modeling Relation Mention

As shown in Table 2, we extract abundant lexical features (Ren et al., 2016; Mintz et al., 2009) to characterize relation mentions. However, this abundance also results in the gigantic dimension of original text features ($\sim 10^7$ in our case). In

Feature	**Description**	**Example**
Entity mention (EM) head	Syntactic head token of each entity mention	“*HEAD_EM1_Hussein*”, ...
Entity Mention Token	Tokens in each entity mention	“*TKN_EM1_Hussein*”, ...
Tokens between two EMs	Tokens between two EMs	“*was*”, “*born*”, “*in*”
Part-of-speech (POS) tag	POS tags of tokens between two EMs	“*VBD*”, “*VBN*”, “*IN*”
Collocations	Bigrams in left/right 3-word window of each EM	“*Hussein was*”, “*in Amman*”
Entity mention order	Whether EM 1 is before EM 2	“*EM1_BEFORE_EM2*”
Entity mention distance	Number of tokens between the two EMs	“*EM_DISTANCE_3*”
Body entity mentions numbers	Number of EMs between the two EMs	“*EM_NUMBER_0*”
Entity mention context	Unigrams before and after each EM	“*EM_AFTER_was*”, ...
Brown cluster (learned on $\mathcal{D}$)	Brown cluster ID for each token	“*BROWN_010011001*”, ...

Table 2: Text features $\mathcal{F}$ used in this paper. (“*Hussein*”, “*Amman*”,“***Hussein** was born in **Amman***”) is used as an example.

order to achieve better generalization ability, we represent relation mentions with low dimensional ($\sim 10^2$) vectors. In Fig. 2, for example, relation mention c_3 is first represented as bag-of-features. After learning text feature embeddings, we use the average of feature embedding vectors to derive the embedding vector for c_3.

Text Feature Representation. Similar to other principles of embedding learning, we assume text features occurring in the same contexts tend to have similar meanings (also known as distributional hypothesis(Harris, 1954)). Furthermore, we let each text feature's embedding vector to predict other text features occurred in the same relation mentions or context. Thus, text features with similar meaning should have similar embedding vectors. Formally, we mark text features as $\mathcal{F} = \{f_1, \cdots, f_{|\mathcal{F}|}\}$, record the feature set for $\forall c \in \mathcal{C}$ as $\mathbf{f}_c$, and represent the embedding vector for f_i as $\mathbf{v}_i \in \mathbb{R}^{n_v}$, and we aim to maximize the following log likelihood: $\sum_{c \in \mathcal{C}_l} \sum_{f_i, f_j \in \mathbf{f}_c} \log\, p(f_i|f_j)$, where $p(f_i|f_j) = \exp(\mathbf{v}_i^T \mathbf{v}_j^*) / \sum_{f_k \in \mathcal{F}} \exp(\mathbf{v}_i^T \mathbf{v}_k^*)$.

However, the optimization of this likelihood is impractical because the calculation of $\nabla p(f_i|f_j)$ requires summation over all text features, whose size exceeds 10^7 in our case. In order to perform efficient optimization, we adopt the negative sampling technique (Mikolov et al., 2013) to avoid this summation. Accordingly, we replace the log likelihood with Eq. 1 as below:

$$\mathcal{J}_E = \sum_{\substack{c \in \mathcal{C}_l \\ f_i, f_j \in \mathbf{f}_c}} (\log \sigma(\mathbf{v}_i^T \mathbf{v}_j^*) - \sum_{k=1}^{V} \mathbb{E}_{f_{k'} \sim \hat{P}} [\log \sigma(-\mathbf{v}_i^T \mathbf{v}_{k'}^*)]) \tag{1}$$

where $\hat{P}$ is noise distribution used in (Mikolov et al., 2013), σ is the sigmoid function and V is number of negative samples.

Relation Mention Representation. With text feature embeddings learned by Eq. 1, a naive method to represent relation mentions is to concatenate or average its text feature embeddings. However, text features embedding may be in a different semantic space with relation types. Thus, we directly learn a mapping g from text feature representations to relation mention representations (Van Gysel et al., 2016a,b) instead of simple heuristic rules like concatenate or average (see Fig. 2):

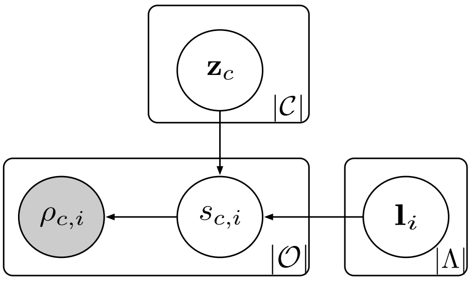

Figure 3: Graphical model of $o_{c,i}$'s correctness

$$\mathbf{z}_c = g(\mathbf{f}_c) = \tanh(W \cdot \frac{1}{|\mathbf{f}_c|} \sum_{f_i \in \mathbf{f}_c} \mathbf{v}_i) \tag{2}$$

where $\mathbf{z}_c$ is the representation of $c \in \mathcal{C}_l$, W is a $n_z \times n_v$ matrix, n_z is the dimension of relation mention embeddings and tanh is the element-wise hyperbolic tangent function.

In other words, we represent bag of text features with their average embedding, then apply linear map and hyperbolic tangent to transform the embedding from text feature semantic space to relation mention semantic space. The non-linear tanh function allows non-linear class boundaries in other components, and also regularize relation mention representation to range $[-1, 1]$ which avoids numerical instability issues.

3.2 True Label Discovery

Because heterogeneous supervision generates labels in a discriminative way, we suppose its errors follow certain underlying principles, i.e., if a

Datasets	NYT	Wiki-KBP
% of `None` in Training	0.6717	0.5552
% of `None` in Test	0.8972	0.8532

Table 3: Proportion of `None` in Training/Test Set

labeling function annotates a instance correctly / wrongly, it would annotate other similar instances correctly / wrongly. For example, λ_1 in Fig. 1 generates wrong annotations for two similar instances c_1, c_2 and would make the same errors on other similar instances. Since context representation captures the semantic meaning of relation mention and would be used to identify relation types, we also use it to identify the mismatch of context and labeling functions. Thus, we suppose for each labeling function λ_i, there exists an proficient subset $\mathcal{S}_i$ on $\mathcal{R}^{n_z}$, containing instances that λ_i can precisely annotate. In Fig. 1, for instance, c_3 is in the proficient subset of λ_1, while c_1 and c_2 are not. Moreover, the generation of annotations are not really random, and we propose a probabilistic model to describe the level of mismatch from labeling functions to real relation types instead of annotations' generation.

As shown in Fig. 3, we assume the indicator of whether c belongs to $\mathcal{S}_i$, $s_{c,i} = \delta(c \in \mathcal{S}_i)$, would first be generated based on context representation

$$p(s_{c,i} = 1|\mathbf{z}_c, \mathbf{l}_i) = p(c \in \mathcal{S}_i) = \sigma(\mathbf{z}_c^T \mathbf{l}_i) \quad (3)$$

Then the correctness of annotation $o_{c,i}$, $\rho_{c,i} = \delta(o_{c,i} = o_c^*)$, would be generated. Furthermore, we assume $p(\rho_{c,i} = 1|s_{c,i} = 1) = \phi_1$ and $p(\rho_{c,i} = 1|s_{c,i} = 0) = \phi_0$ to be constant for all relation mentions and labeling functions.

Because $s_{c,i}$ would not be used in other components of our framework, we integrate out $s_{c,i}$ and write the log likelihood as

$$\mathcal{J}_T = \sum_{o_{c,i} \in \mathcal{O}} \log(\sigma(\mathbf{z}_c^T \mathbf{l}_i)\phi_1^{\delta(o_{c,i}=o_c^*)}(1-\phi_1)^{\delta(o_{c,i}\neq o_c^*)} + (1-\sigma(\mathbf{z}_c^T \mathbf{l}_i))\phi_0^{\delta(o_{c,i}=o_c^*)}(1-\phi_0)^{\delta(o_{c,i}\neq o_c^*)}) \quad (4)$$

Note that o_c^* is a hidden variable but not a model parameter, and $\mathcal{J}_T$ is the likelihood of $\rho_{c,i} = \delta(o_{c,i} = o_c^*)$. Thus, we would first infer $o_c^* = \text{argmax}_{o_c^*} \mathcal{J}_T$, then train the true label discovery model by maximizing $\mathcal{J}_T$.

3.3 Modeling Relation Type

We now discuss the model for identifying relation types based on context representation. For each relation mention c, its representation $\mathbf{z}_c$ implies its relation type, and the distribution of relation type can be described by the soft-max function:

$$p(r_i|\mathbf{z}_c) = \frac{\exp(\mathbf{z}_c^T \mathbf{t}_i)}{\sum_{r_j \in \mathcal{R}\cup\{\texttt{None}\}} \exp(\mathbf{z}_c^T \mathbf{t}_j)} \quad (5)$$

where $\mathbf{t}_i \in \mathbb{R}^{v_z}$ is the representation for relation type r_i. Moreover, with the inferred true label o_c^*, the relation extraction model can be trained as a multi-class classifier. Specifically, we use Eq. 5 to approach the distribution

$$p(r_i|o_c^*) = \begin{cases} 1 & r_i = o_c^* \\ 0 & r_i \neq o_c^* \end{cases} \quad (6)$$

Moreover, we use KL-divergence to measure the dissimilarity between two distributions, and formulate model learning as maximizing $\mathcal{J}_R$:

$$\mathcal{J}_R = -\sum_{c \in \mathcal{C}_l} KL(p(.|\mathbf{z}_c)||p(.|o_c^*)) \quad (7)$$

where $KL(p(.|\mathbf{z}_c)||p(.|o_c^*))$ is the KL-divergence from $p(r_i|o_c^*)$ to $p(r_i|\mathbf{z}_c)$, $p(r_i|\mathbf{z}_c)$ and $p(r_i|o_c^*)$ has the form of Eq. 5 and Eq. 6.

3.4 Model Learning

Based on Eq. 1, Eq. 4 and Eq. 7, we form the joint optimization problem for model parameters as

$$\min_{W,\mathbf{v},\mathbf{v}^*,\mathbf{l},\mathbf{t},o^*} \mathcal{J} = -\mathcal{J}_R - \lambda_1 \mathcal{J}_E - \lambda_2 \mathcal{J}_T$$
$$\text{s.t. } \forall c \in \mathcal{C}_l, o_c^* = \underset{o_c^*}{\text{argmax}}\, \mathcal{J}_T, \mathbf{z}_c = g(\mathbf{f}_c) \quad (8)$$

Collectively optimizing Eq. 8 allows heterogeneous supervision guiding all three components, while these components would refine the context representation, and enhance each other.

In order to solve the joint optimization problem in Eq. 8 efficiently, we adopt the stochastic gradient descent algorithm to update $\{W, \mathbf{v}, \mathbf{v}^*, \mathbf{l}, \mathbf{t}\}$ iteratively, and o_c* is estimated by maximizing $\mathcal{J}_T$ after calculating $\mathbf{z}_c$. Additionally, we apply the widely used dropout techniques (Srivastava et al., 2014) to prevent overfitting and improve generalization performance.

The learning process of REHESSION is summarized as below. In each iteration, we would sample a relation mention c from $\mathcal{C}_l$, then sample c's text features and conduct the text features' representation learning. After calculating the representation of c, we would infer its true label o_c^* based on our true label discovery model, and finally update model parameters based on o_c^*.

3.5 Relation Type Inference

We now discuss the strategy of performing type inference for $\mathcal{C}_u$. As shown in Table 3, the proportion of None in $\mathcal{C}_u$ is usually much larger than in $\mathcal{C}_l$. Additionally, not like other relation types in $\mathcal{R}$, None does not have a coherent semantic meaning. Similar to (Ren et al., 2016), we introduce a heuristic rule: identifying a relation mention as None when (1) our relation extractor predict it as None, or (2) the entropy of $p(.|\mathbf{z}_c)$ over $\mathcal{R}$ exceeds a pre-defined threshold η. The entropy is calculated as $H(p(.|\mathbf{z}_c)) = -\sum_{r_i \in \mathcal{R}} p(r_i|\mathbf{z}_c) log(p(r_i|\mathbf{z}_c))$. And the second situation means based on relation extractor this relation mention is not likely belonging to any relation types in $\mathcal{R}$.

4 Experiments

In this section, we empirically validate our method by comparing to the state-of-the-art relation extraction methods on news and Wikipedia articles.

4.1 Datasets and settings

In the experiments, we conduct investigations on two benchmark datasets from different domains:[1]
NYT (Riedel et al., 2010) is a news corpus sampled from $\sim$ 294k 1989-2007 New York Times news articles. It consists of 1.18M sentences, while 395 of them are annotated by authors of (Hoffmann et al., 2011) and used as test data;
Wiki-KBP utilizes 1.5M sentences sampled from 780k Wikipedia articles (Ling and Weld, 2012) as training corpus, while test set consists of the 2k sentences manually annotated in 2013 KBP slot filling assessment results (Ellis et al., 2012).

For both datasets, the training and test sets partitions are maintained in our experiments. Furthermore, we create validation sets by randomly sampling 10% mentions from each test set and used the remaining part as evaluation sets.

Feature Generation. As summarized in Table 2, we use a 6-word window to extract context features for each entity mention, apply the Stanford CoreNLP tool (Manning et al., 2014) to generate entity mentions and get POS tags for both datasets. Brown clusters(Brown et al., 1992) are derived for each corpus using public implementation[2]. All these features are shared with all compared methods in our experiments.

Kind	Wiki-KBP		NYT	
	#Types	#LF	#Types	#LF
Pattern	13	147	16	115
KB	7	7	25	26

Table 4: Number of labeling functions and the relation types they can annotated w.r.t. two kinds of information

Labeling Functions. In our experiments, labeling functions are employed to encode two kinds of supervision information. One is knowledge base, the other is handcrafted domain-specific patterns. For domain-specific patterns, we manually design a number of labeling functions[3]; for knowledge base, annotations are generated following the procedure in (Ren et al., 2016; Riedel et al., 2010).

Regarding two kinds of supervision information, the statistics of the labeling functions are summarized in Table 4. We can observe that heuristic patterns can identify more relation types for KBP datasets, while for NYT datasets, knowledge base can provide supervision for more relation types. This observation aligns with our intuition that single kind of information might be insufficient while different kinds of information can complement each other.

We further summarize the statistics of annotations in Table 6. It can be observed that a large portion of instances is only annotated as None, while lots of conflicts exist among other instances. This phenomenon justifies the motivation to employ true label discovery model to resolve the conflicts among supervision. Also, we can observe most conflicts involve None type, accordingly, our proposed method should have more advantages over traditional true label discovery methods on the relation extraction task comparing to the relation classification task that excludes None type.

4.2 Compared Methods

We compare REHESSION with below methods:
FIGER (Ling and Weld, 2012) adopts multi-label

learning with Perceptron algorithm.

BFK (Bunescu and Mooney, 2005) applies bag-of-feature kernel to train a support vector machine;

DSL (Mintz et al., 2009) trains a multi-class logistic classifier[4] on the training data;

MultiR (Hoffmann et al., 2011) models training label noise by multi-instance multi-label learning;

FCM (Gormley et al., 2015) performs compositional embedding by neural language model.

CoType-RM (Ren et al., 2016) adopts partial-label loss to handle label noise and train the extractor.

Moreover, two different strategies are adopted to feed heterogeneous supervision to these methods. The first is to keep all noisy labels, marked as 'NL'. Alternatively, a true label discovery method, Investment (Pasternack and Roth, 2010), is applied to resolve conflicts, which is based on the source consistency assumption and iteratively updates inferred true labels and label functions' reliabilities. Then, the second strategy is to only feed the inferred true labels, referred as 'TD'.

Universal Schemas (Riedel et al., 2013) is proposed to unify different information by calculating a low-rank approximation of the annotations $\mathcal{O}$. It can serve as an alternative of the Investment method, i.e., selecting the relation type with highest score in the low-rank approximation as the true type. But it doesnt explicitly model noise and not fit our scenario very well. Due to the constraint of space, we only compared our method to Investment in most experiments, and Universal Schemas is listed as a baseline in Sec. 4.4. Indeed, it performs similarly to the Investment method.

Evaluation Metrics. For relation classification task, which excludes None type from training / testing, we use the classification accuracy (Acc) for evaluation, and for relation extraction task, precision (Prec), recall (Rec) and F1 score (Bunescu and Mooney, 2005; Bach and Badaskar, 2007) are employed. Notice that both relation extraction and relation classification are conducted and evaluated in *sentence-level* (Bao et al., 2014).

Parameter Settings. Based on the semantic meaning of proficient subset, we set ϕ_2 to $1/|\mathcal{R}\cup\{\texttt{None}\}|$, i.e., the probability of generating right label with random guess. Then we set ϕ_1 to $1-\phi_2$, $\lambda_1 = \lambda_2 = 1$, and the learning rate $\alpha = 0.025$. As for other parameters, they are tuned on the validation sets for each dataset. Similarly, all parameters of compared methods are tuned on validation set, and the parameters achieving highest F1 score are chosen for relation extraction.

Table 8: Comparison among REHession (Ori), REHession-US (US) and REHession-TD (TD) on relation extraction and relation classification

4.3 Performance Comparison

Given the experimental setup described above, the averaged evaluation scores in 10 runs of relation classification and relation extraction on two datasets are summarized in Table 5.

From the comparison, it shows that NL strategy yields better performance than TD strategy, since the true labels inferred by Investment are actually wrong for many instances. On the other hand, as discussed in Sec. 4.4, our method introduces context-awareness to true label discovery, while the inferred true label guides the relation extractor achieving the best performance. This observation justifies the motivation of avoiding the source consistency assumption and the effectiveness of proposed true label discovery model.

One could also observe the difference between REHession and the compared methods is more significant on the NYT dataset than on the Wiki-KBP dataset. This observation accords with the fact that the NYT dataset contains more conflicts than KBP dataset (see Table 6), and the intuition is that our method would have more advantages on more conflicting labels.

Among four tasks, the relation classification of Wiki-KBP dataset has highest label quality, i.e. conflicting label ratio, but with least number of training instances. And CoType-RM and DSL reach relatively better performance among all compared methods. CoType-RM performs much better than DSL on Wiki-KBP relation classification task, while DSL gets better or similar performance with CoType-RM on other tasks. This may be because the representation learning method is able to generalize better, thus performs better when the training set size is small. However, it is rather vulnerable to the noisy labels compared to DSL. Our method employs embedding techniques, and also integrates context-aware true label discovery to de-noise labels, making the embedding method rather robust, thus achieves the best performance on all tasks.

4.4 Case Study

Context Awareness of True Label Discovery.

Although Universal Schemas does not adopted the source consistency assumption, but it's conducted in document-level, and is context-agnostic in our sentence-level setting. Similarly, most true label discovery methods adopt the source consistency assumption, which means if they trust a labeling function, they would trust it on all annotations. And our method infers true labels in a context-aware manner, which means we only trust labeling functions on matched contexts.

For example, Investment and Universal Schemas refer None as true type for all four instances in Table 7. And our method infers born-in as the true label for the first two relation mentions; after replacing the matched contexts (**born**) with other words (**elected** and **examined**), our method no longer trusts born-in since the modified contexts are no longer matched, then infers None as the true label. In other words, our proposed method infer the true label in a context aware manner.

Effectiveness of True Label Discovery. We explore the effectiveness of the proposed context-aware true label discovery component by comparing REHession to its variants REHession-TD and REHession-US, which uses Investment or Universal Schemas to resolve conflicts. The averaged evaluation scores are summarized in Table 8. We can observe that REHession significantly outperforms its variants. Since the only difference between REHession and its variants is the model employed to resolve conflicts, this gap verifies the effectiveness of the proposed context-aware true label discovery method.

5 Related Work

5.1 Relation Extraction

Relation extraction aims to detect and categorize semantic relations between a pair of entities. To alleviate the dependency of annotations given by human experts, weak supervision (Bunescu and Mooney, 2007; Etzioni et al., 2004) and distant supervision (Ren et al., 2016) have been employed to automatically generate annotations based on knowledge base (or seed patterns/instances). Universal Schemas (Riedel et al., 2013; Verga et al., 2015; Toutanova et al., 2015) has been proposed to unify patterns and knowledge base, but it's designed for document-level relation extraction, i.e., not to categorize relation types based on a specific context, but based on the whole corpus. Thus, it allows one relation mention to have multiple true relation types; and does not fit our scenario very well, which is sentence-level relation extraction and assumes one instance has only one relation type. Here we propose a more general framework to consolidate heterogeneous information and further refine the true label from noisy labels, which gives the relation extractor potential to detect more types of relations in a more precise way.

Word embedding has demonstrated great potential in capturing semantic meaning (Mikolov et al., 2013), and achieved great success in a wide range of NLP tasks like relation extraction (Zeng et al., 2014; Takase and Inui, 2016; Nguyen and Grishman, 2015). In our model, we employed the embedding techniques to represent context information, and reduce the dimension of text features, which allows our model to generalize better.

5.2 Truth Label Discovery

True label discovery methods have been developed to resolve conflicts among multi-source information under the assumption of source consistency (Li et al., 2016; Zhi et al., 2015). Specifically, in the *spammer-hammer* model (Karger et al., 2011), each source could either be a spammer, which annotates instances randomly; or a hammer, which annotates instances precisely. In this paper, we assume each labeling function would be a hammer on its proficient subset, and would be a spammer otherwise, while the proficient subsets are identified in the embedding space.

Besides data programming, socratic learning (Varma et al., 2016) has been developed to conduct binary classification under heterogeneous supervision. Its true label discovery module supervises the discriminative module in label level, while the discriminative module influences the true label discovery module by selecting a feature subset. Although delicately designed, it fails to make full use of the connection between these modules, i.e., not refine the context representation for classifier. Thus, its discriminative module might suffer from the overwhelming size of text features.

6 Conclusion and Future Work

In this paper, we propose REHESSION, an embedding framework to extract relation under heterogeneous supervision. When dealing with heterogeneous supervisions, one unique challenge is how to resolve conflicts generated by different labeling functions. Accordingly, we go beyond the "source consistency assumption" in prior works and leverage context-aware embeddings to induce proficient subsets. The resulting framework bridges true label discovery and relation extraction with context representation, and allows them to mutually enhance each other. Experimental evaluation justifies the necessity of involving context-awareness, the quality of inferred true label, and the effectiveness of the proposed framework on two real-world datasets.

There exist several directions for future work. One is to apply transfer learning techniques to handle label distributions' difference between training set and test set. Another is to incorporate OpenIE methods to automatically find domain-specific patterns and generate pattern-based labeling functions.

Abstract

There has been a recent line of work automatically learning scripts from unstructured texts, by modeling narrative event chains. While the dominant approach group events using event pair relations, LSTMs have been used to encode full chains of narrative events. The latter has the advantage of learning long-range *temporal orders*[1], yet the former is more adaptive to partial orders. We propose a neural model that leverages the advantages of both methods, by using LSTM hidden states as features for event pair modelling. A dynamic memory network is utilized to automatically induce weights on existing events for inferring a subsequent event. Standard evaluation shows that our method significantly outperforms both methods above, giving the best results reported so far.

1 Introduction

Frequently recurring sequences of events in prototypical scenarios, such as visiting a restaurant and driving to work, are a useful source of world knowledge. Two examples are shown in Figure 1, which are different variations of the "restaurant visiting" scenario, where events are partially ordered and can be flexible. Such knowledge is useful for natural language understanding because texts typically do not include event details when mentioning a scenario. For example, the reader is expected to infer that the narrator could have been driving or cycling given the text "I got flat tire". Another typical use of event chain knowledge is to help infer what is likely to happen next given a previous event sequence in a scenario. We investigate the modeling of stereotypical event chains, which is remotely similar to language modeling, but with events being more sparse and flexibly ordered than words.

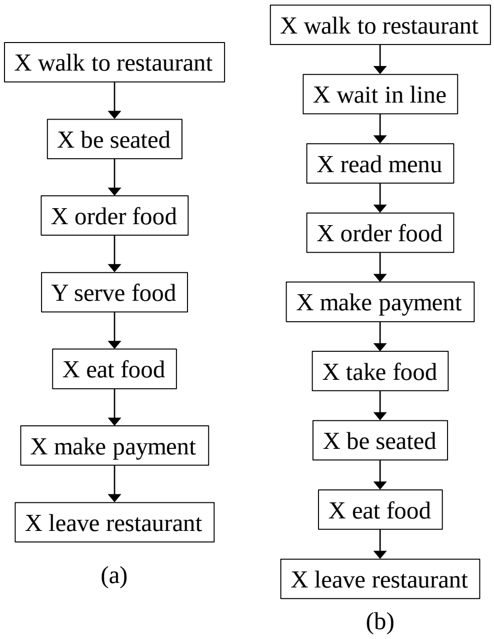

Figure 1: Event sequences for restaurant visiting.

Our work follows a recent line of NLP research on *script learning*. Stereotypical knowledge about partially-ordered *events*, together with their participant *roles* such as "customer", "waiter", and "table", is conventionally referred to as *scripts* (Schank et al., 1977). NLP algorithms have been investigated for automatically inducing scripts from unstructured texts (Mooney and DeJong, 1985; Chambers and Jurafsky, 2008). In particular, Chambers and Jurafsky (2008) made a first attempt to learn scripts from test inducing event

[*] This work has been done when the first author worked at SUTD.

[1] The term "temporal order" is used throughout this work to indicate the narrative order in texts, following Chambers and Jurafsky (2008). Strictly speaking, the event order we extract is the narrative order.

Proceedings of the 2017 Conference on Empirical Methods in Natural Language Processing, pages 57–67
Copenhagen, Denmark, September 7–11, 2017. ©2017 Association for Computational Linguistics

chains by grouping events based on their narrative coherence, calculated based on Pairwise Mutual Information (PMI). Jans et al. (2012) showed that the method can be improved by calculating event relations using skip bi-gram probabilities, which explicitly model the temporal order of pairs event. Jans et al. (2012)'s model is adopted by a line of subsequent methods on inducing event chains from text (Orr et al., 2014; Pichotta and Mooney, 2014; Rudinger et al., 2015).

While the above methods are statistical, neural network models have recently been used for event sequence modeling. Granroth-Wilding and Clark (2016) used a Siamese Network instead of PMI to calculate the coherence between two events. Rudinger et al. (2015) extended the idea of Jans et al. (2012) by using a log-bilinear neural language model (Mnih and Hinton, 2007) to calculate event probabilities. By learning embeddings for reducing sparsity, the above models give much better results compared to the models of Chambers and Jurafsky (2008) and Jans et al. (2012). Similar in spirit, Modi (2016) predicted the probability of an event belonging to a certain event chain by modeling known events in the chain as a bag of vectors, showing that it outperforms discrete statistical methods. These neural methods are consistent with the earlier statistical models in leveraging event-pair relations.

Pichotta and Mooney (2016) experimented with LSTM for script learning, using an existing sequence of events to predict the probability of a next event, which outperformed strong discrete baselines. One advantage of LSTMs is that they can encode unbounded time sequences without losing long-term historical information. LSTMs capture significantly more order information compared to the methods of Granroth-Wilding and Clark (2016), Rudinger et al. (2015), and Modi (2016), which model the temporal order of only pairs of events. On the other hand, a strong-order LSTM model can also suffer the disadvantage of over-fitting, given the flexible order of event chains in a script, as demonstrated by the cases of Figure 1. In this aspect, event-pair models are more adaptive for flexible orders. However, no direct comparisons have been reported between LSTM and various existing neural network methods that model event-pairs.

We make such comparisons using the same benchmark, finding that the method of Pichotta and Mooney (2016) does not necessarily outperform event-pair models, such as Granroth-Wilding and Clark (2016). LSTM temporal ordering and event pair modeling have their respective strength. To leverage the advantages of both methods, we propose to integrate chain temporal order information into event relation measuring. In particular, we calculate event pair relations by representing events in a chain using LSTM hidden states, which encode temporal information. The LSTM over-fitting issue is mitigated by using the temporal-order in a chain as a *feature* for event pair modeling, rather than the direct model *output*. In addition, observing that the importance of existing events can vary for inferring a subsequent event, we use a dynamic memory network model to automatically induce event weights for each event for inferring the next event. In contrast, previous methods give equal weights to existing events (Chambers and Jurafsky, 2008; Modi, 2016; Granroth-Wilding and Clark, 2016).

Results on a multi-choice narrative cloze benchmark show that our model significantly outperforms both Granroth-Wilding and Clark (2016) and Pichotta and Mooney (2016), improving the state-of-the-art accuracy from 49.57% to 55.12%. Our contributions can be summarized as follows:

- We make a systematic comparison of LSTM and pair-based event sequence learning methods using the same benchmarks.
- We propose a novel dynamic memory network model, which combines the advantages of both LSTM temporal order learning and traditional event pair coherence learning.
- We obtain the best results in the standard multi-choice narrative cloze test.

Our code is released at `https://github.com/wangzq870305/event_chain`.

2 Related Work

Scripts have been a traditional subject in AI research (Schank et al., 1977), where event sequences are manually encoded in knowledge bases, and used for end tasks such as inference. They are also connected with research in linguistics and psychology, and sometimes referred to as *frames* (Minsky, 1975; Fillmore, 1982) and *schemata* (Rumelhart, 1975). The same concept is also studied as *templates* in information extraction (Sundheim, 1991). Chambers and Jurafsky (2008) pioneered the recent line of work on script induction (Jans et al., 2012; Pichotta and Mooney, 2016; Granroth-Wilding and Clark, 2016), where the focus is on modeling narrative event chains, a crucial subtask for script modeling from raw text. Below we summarize such investigations.

With respect to **event representation**, Chambers and Jurafsky (2008) casted narrative events as triples of the form $\langle event, dependency \rangle$, where the event is typically represented by a verb and the dependency represents typed dependency relations between the event and a protagonist, such as "subject" and "object". Chambers and Jurafsky (2008) organized narrative chains around a central actor, or protagonist, mining events that share a common protagonist from texts by using a syntactic parser and a coreference resolver. Balasubramanian et al. (2013) observed that the protagonist representation of event chains can suffer from weaknesses such as lack of coherence, and proposed to represent events as $\langle arg_1, relation, arg_2 \rangle$, where arg_1 and arg_2 represent the subject and object, respectively. Such representation is inspired by open information extraction (Mausam et al., 2012), and offers richer features for event pair modeling. Pichotta and Mooney (2014) adpoted a similar idea, using $v(e_s, e_o, e_p)$ to represent an event, where v is a verb lemma, e_s is the subject, e_o is the object, and e_p is an entity with prepositional relation to v. Their representation is used by subsequent work such as Modi (2016) and Granroth-Wilding and Clark (2016). We follow Pichotta and Mooney (2016) in our event representation form.

With respect to **modeling**, existing methods can be classified into two main categories, namely *weak-order* models, which calculate relations between pairs of events, and *strong-order* models, which consider the temporal order of events in a full sequence. Event-pair models have so far been the dominant method in the literature. Earlier work used discrete event representations and estimated event relations by statistical counting. As mentioned earlier, Chambers and Jurafsky (2008) used PMI to calculate event relations, and Jans et al. (2012) used skip bigram probabilites to the same end, which is order-sensitive. Most subsequent methods followed Jans et al. (2012) in using skip n-grams (Pichotta and Mooney, 2014; Rudinger et al., 2015).

Events being multi-argument structures, counting-based methods can suffer from sparsity issues. Recent work employed embeddings to address this disadvantage. Rudinger et al. (2015) learned event embeddings as a by-product of training a log-bilinear language model for events; Granroth-Wilding and Clark (2016) leveraged the skip-gram model of Mikolov et al. (2013) for training the embeddings of event and arguments by ordering them into a pseudo sentence. Modi (2016) utilized *word embeddings* of verbs and arguments directly, using a hidden layer to automatically consolidate word embedding into a single structured *event embeddings*. We follow Modi (2016) and use a hidden layer to learn event argument compositions given word embeddings, training the composition function as a part of the event chain learning process.

Mitigating the sparsity issue of event representations, neural methods can capture temporal orders between events beyond skip n-grams. Our model integrates the advantages of strong-order learning and event-pair learning by using LSTM hidden states as feature representation of existing events in the calculation of event pair relationships. In addition, we use a memory network model to weigh existing events, which gives better results compared to the equal weighting method of existing models.

With respect to **evaluation**, Chambers and Jurafsky (2008) proposed the *Narrative Cloze Test*, which asks for a missing event in a given event chain with a gap. The task has been adopted by various subsequent work for comparing results with Chambers and Jurafsky (2008) (Jans et al., 2012; Pichotta and Mooney, 2014; Rudinger et al., 2015). One issue of the narrative cloze test is that there can sometimes be multiple plausible answers, but only one gold-standard answer, which can make it overly expensive to manually evaluate system outputs. To address this issue, Modi (2016) proposed the *Adversarial Narrative Cloze* (ANC) task, which is to discriminate between pairs of real and corrupted event chains. Granroth-Wilding and Clark (2016) proposed the *Multi-Choice Narrative Cloze* (MCNC) task, which is to choose the most likely next event from a set of candidates given a chain of events. We choose MCNC for comparing different models.

Other related work includes learning temporal relations of events (Modi and Titov, 2014; Uz-

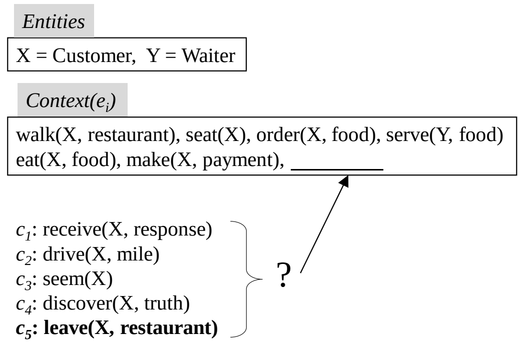

Figure 2: Multiple choice narrative cloze. The gold subsequent event is marked in bold.

Zaman et al., 2013; Abend et al., 2015), evaluated using different metrics. There has also been work using graph models to induce frames, which emphasize more on learning event structures and less on temporal orders (Chambers, 2013; Cheung et al., 2013). The above methods focus on one of the two subtasks we consider here. Frermann et al. (2014) used a Bayesian model to jointly cluster web collections of explicit event sequence and learn input event-pair temporal orders. However, their work is under a different input setting (Regneri et al., 2010), not learning event chains from texts. Mostafazadeh et al. (2016) proposed the story close task (SCT), which is to predict the ending given a unfinished story. Our narrative chain prediction task can be regarded as a sub task in the story close task, which can contribute as a major approach. On the other hand, information beyond event chains can be useful for the story close task.

3 Problem Definition

As shown in Figure 2, given a chain of narrative events e_1, e_2, ..., e_{n-1}, our work is to predict the likelihood of a next event candidate e_n. Formally, an event e is a structure $v(a_0, a_1, a_2)$, where v is a verb describing the event, a_0 and a_1 are its subject and direct object, respectively, and a_2 is a prepositional object. For example, given the sentence "John brought Marry to the restaurant", an event $bring\{John, Marry, to\ the\ restaurant\}$ can be extracted.

We follow the standard script induction setting (Chambers and Jurafsky, 2008; Granroth-Wilding and Clark, 2016), extracting events from a text corpus using a syntactic parser and a named entity resolver. A neural network is used to model chains of extracted events for script learning. In particular, we model the probability of a subsequent event given a chain of events. For evaluation, we solve the multi-choice narrative cloze task: given a chain of events and a set of candidate next events, the most likely candidate is chosen as the output.

4 Model

The overall structure of our model is shown in Figure 3, which has three main components. First, given an event $v(a_0, a_1, a_2)$, a representation layer is used to compose the embeddings of v, a_0, a_1, and a_2 into a single event vector e. Second, a LSTM is used to map a sequence of existing events e_1, e_2, ..., e_{n-1} into a sequence of hidden vectors h_1, h_2, ..., h_{n-1}, which encode the temporal order. Given a next event candidate e_c, the recurrent network takes one further step from h_{n-1} to derive its hidden vector h_c, which encodes e_c. Third, h_c is paired with h_1, h_2, ..., h_{n-1} individually, and passed to a dynamic memory network to learn the relatedness score s. s is used to denote the connectedness between the candidate subsequent event and the context event chain.

4.1 Event Representation

We learn vector representations of standard events by composing pre-trained word embeddings of its verb and arguments. The skipgram model (Mikolov et al., 2013) is used to train word vectors. For arguments that consist of more than one word, we use the averaged word for the representation. OOV words are represented simply using zero vectors. For events with less than 3 arguments, such as "John fell", where v = fall, a_0 = John, a_1 = NULL, and a_2 = NULL, the NULL arguments are represented using all-zero vectors.

Denoting the embeddings of v, a_0, a_1, and a_2 as $e(v)$, $e(a_0)$, $e(a_1)$, and $e(a_2)$, respectively, the embedding of e is calculated using a $\tanh$ composition layer

$$\begin{aligned} e(e) = &\tanh(W_e^v \cdot e(v) + W_e^0 \cdot e(a_0) + \\ &W_e^1 \cdot e(a_1) + W_e^2 \cdot e(a_2) + b_e) \end{aligned} \quad (1)$$

Here W_e^v, W_e^0, W_e^1, W_e^2, and b are model parameters, which are randomly initialized and tuned during the training of the main network.

4.2 Modeling Temporal Orders

Given the embeddings of the existing chain of events e_1, e_2, ..., e_{n-1}, we use a standard LSTM (Hochreiter and Schmidhuber, 1997) without

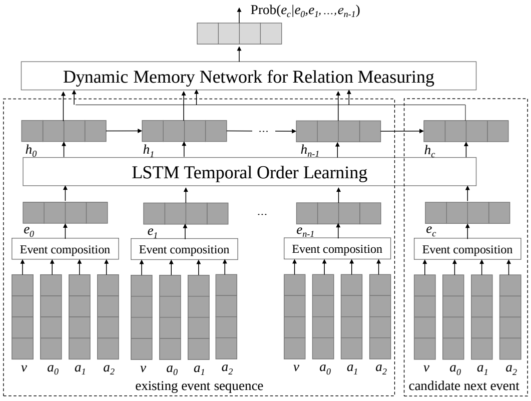

Figure 3: Overview of proposed model.

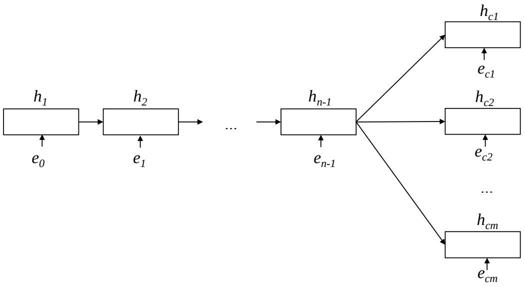

Figure 4: Temporal order modeling.

coupled input and forget gates or peephole connections to model the temporal order. We obtain a sequence of hidden state vectors h_1, h_2, ..., h_{n-1} by recurrently feeding $e(e_1)$, $e(e_2)$, ..., $e(e_{n-1})$ as inputs to the LSTM, where $h_i = \mathrm{LSTM}(e(e_i), h_{i-1})$. The initial state h_s and all stand LSTM parameters are randomly initialized and tuned during training.

Now for each candidate next event e_c, we obtain its vector representation $e(e_c)$ in the same way as for e_1 to e_{n-1}. $e(e_c)$ is then appended to the existing event chain to obtain a temporal-order-sensitive feature vector h_c, by advancing the recurrent encoding process for one step from h_{n-1}: $h_c = \mathrm{LSTM}(e(e_c), h_{n-1})$. With multiple next event candidates e_c^1, e_c^2, ..., e_c^m ($m \in [1, \infty]$), m feature vectors are obtained, as shown in Figure 4, each being used as a basis for estimating the probability of the corresponding event candidate.

4.3 Modeling Pairwise Event Relations

After obtaining the hidden states for events, we model event pair relations using these hidden state vectors. A straightforward approach to model the relation between two events is using a Siamese network (Granroth-Wilding and Clark, 2016). The order-sensitive LSTM features for existing events h_1, h_2, ..., h_{n-1} and the candidate event h_c are used as event representations. Given a pair of events h_i ($i \in [1..n-1]$) and h_c, the relatedness score is calculated by

$$s_i = \mathrm{sigmoid}(W_{si}h_i + W_{sc}h_c + b_s), \qquad (2)$$

where W_{si}, W_{sc} and b_s are model parameters.

Given the relation score s_i between h_c and each existing event h_i, the likelihood of e_c given e_1, e_2, ..., e_{n-1} can be calculated as the average of s_i:

$$s = \frac{\sum_{i=1}^{n-1} s_i}{n-1} \qquad (3)$$

Weighting existing events. The drawback of above approach is that it considers the contribution of each event on the chain is same. However, given a chain of existing events, some are more informative for inferring a subsequent event than others. For example, given the events "wait in queue", "getting seated" and "order food", "order food" is more relevant for inferring "eat food" compared with the other two given events. Given information over the full event chain, this link can be more evident since the scenario is likely restaurant visiting.

We use an attentional neural network to calculate the relative importance of each existing event according to the subsequent event candidate, using h_i ($i \in [1..n-1]$) and h_c for event representations:

$$u_i = \tanh(W_{ei}h_i + W_c h_c + b_u) \qquad (4)$$

$$\alpha_i = \frac{\exp(u_i)}{\sum_j \exp(u_j)} \qquad (5)$$

where $\alpha_i \in [0, 1]$ is the weight of h_i, and $\sum_i \alpha_i^t = 1$. W_{ei}, W_c, and b_u are model parameters.

After obtaining the weight α_i of each existing event h_i, the relatedness of e_c with the existing events can be calculated as:

$$s = \sum_{i=1}^{n-1} \alpha_i \cdot s_i \qquad (6)$$

Multi-layer attention using Deep memory network. Memory network (Weston et al., 2014; Mikolov et al., 2014) has been used for exploring deep semantic information for semantic tasks. Such as question answering (Sukhbaatar et al., 2015; Kumar et al., 2016) and reading comprehension (Hermann et al., 2015; Weston et al., 2015). Our task is analogous to such semantic tasks in

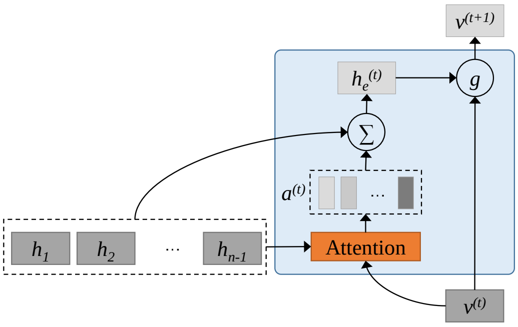

Figure 5: Memory network at hop t. h_i is the hidden variable of the existing event chain, v^t is the semantic representation between context events and candidate event. a^t is the weight of context events, and g is the gated recurrent network on Eq.10.

the sense that deep semantic information can be necessary for making the most rational inference. Hence, we are motivated to use a deep memory network model to refine event weight and event relation calculation by recurrently modeling more abstract representations of the scenario. Different from the previous researches, we use the memory network to model the event chain, refining the attention mechanism used to explore the pair-wise relation between events.

The memory model consists of multiple dynamic computational layers (hops). For the first layer (hop 1), the weights α for existing events e_1, e_2, ..., e_{n-1} can be calculated using the same attention mechanism as Eq.4 and Eq.5. Given the weights α, we build a consolidated representation of context event chain $e_1, e_2, ..., e_{n-1}$ as a weighted sum of $h_1, h_2, ..., h_{n-1}$:

$$h_e = \sum_{i-1}^{n-1} \alpha_i \cdot h_i \tag{7}$$

The event candidate h_c and the new representation of the existing chain h_e can be further integrated to deduce a deeper representation of the full event chain hypothesis to the next layer (hop 2), denoted as v. v contains deeper semantic information compared with h_c, which encode the temporal order of the event chain $[h_1, h_2, ..., h_{n-1}, h_c]$ without differentiating the weights of each event. As a result, in the next hop, better event weights can potentially be deduced by using v instead of h_c in the calculation of attention:

$$u_i^t = \tanh(W_{ei}h_i + W_v v^t + b_u) \tag{8}$$

$$\alpha_i^t = \frac{\exp(u_i^t)}{\sum_j \exp(u_j^t)} \tag{9}$$

In the same way, we stack multiple hops and repeat the steps multiple times, so that more abstract evidences can be extracted according to the chain of existing events. The above process can be performed recurrently, by taking h_c as an initial scenario representation v_0, and then repeatedly calculating h_e^t given h_1, h_2, ..., h_{n-1} and v^t, and using h_e^t and v_t to find a deeper scenario representation v^{t+1}. Following Chung et al. (2014) and Tran et al. (2016), a gated recurrent network is used to this end:

$$\begin{aligned} z &= \sigma(W_z h_e^t + U_z v^t) \\ r &= \sigma(W_r h_e^t + U_r v^t) \\ \hat{h} &= \tanh(W h_e^t + U(r \odot v^t)) \\ v^{t+1} &= (1-z) \odot v^t + z \odot \hat{h} \end{aligned} \tag{10}$$

At any step, if the value of $|v^{t+1} - v^t|$ is less than the threshold μ, we consider that the progress has reached convergence. Figure 5 shows an overview of the memory network at hop t.

4.4 Training

Given a set of event chains, each with a gold-standard subsequent event and a number of non-subsequent events, our training objective is to minimize the cross-entropy loss between the gold subsequent event and the set of non-subsequent events. The loss function of event chain prediction is that:

$$L(\Theta) = \sum_{i=1}^{N} (s_i - y_i)^2 + \frac{\lambda}{2}||\Theta||^2 \tag{11}$$

where s_i is the relation score, y_i is the label of the candidate ($y_i = 1$ for positive sample, and $y_i = 0$ for negative sample), Θ is the set of model parameters and λ is a parameter for L2 regularization. We apply online training, where model parameters are optimized by using AdaGrad (Duchi et al., 2011). We train word embedding using the *Skip-gram* algorithm (Mikolov et al., 2013)[2].

5 Experiments

5.1 Datasets

Following Granroth-Wilding and Clark (2016), we extract events from the NYT portion of the Gigaword corpus (Graff et al., 2003). The C&C

[2] https://code.google.com/p/word2vec/

tools (Curran et al., 2007) are used for POS tagging and dependency parsing, and OpenNLP[3] for phrase structure parsing and coreference resolution. The training set consists of 1,500,000 event chains. We follow Granroth-Wilding and Clark (2016) and use 10,000 event chains as the test set, and 1,000 event chains for development. There are 5 choices of output event for event input chain, which are given by Granroth-Wilding and Clark (2016). This dataset is referred to as **G&C16**.

We also adapt the Chambers and Jurafsky (2008)'s dataset to the multiple choice setting, and use this dataset as the second benchmark. The dataset contains 69 documents, with 346 multiple choice event chain samples. We randomly sample 4 negative subsequent events for each event chain to make multiple-choice candidates. This dataset is referred to as **C&J08**. For both datasets, accuracy (Acc.) of the chosen subsequent event is used to measure the performance of our model.

5.2 Hyper-parameters

There are several important hyper-parameters in our models, and we tune their values using the development dataset. We set the regularization weight $\lambda = 10^{-8}$ and the initial learning rate to 0.01. The size of word vectors is set to 300, and the size of hidden vectors in LSTM to 128. In order to avoid over-fitting, dropout (Hinton et al., 2012) is used for word embedding with a ratio of 0.2. The neighbor similarity threshold η is set to 0.25. The threshold μ of the memory network sets to 0.1.

5.3 Development Experiments

We conduct a set of development experiments on the G&C16 development set to study the influence of event argument representations and network configurations of the proposed *MemNet* model.

5.3.1 Influence of Event Structure

Existing literature discussed various structures to denote events, such as $v(a_0, a_1)$ and $v(a_0, a_1, a_2)$. We investigate the influence of integrating argument values of the subject a_0, object a_1 and preposition a_2, by doing ablation experiments on the development data. The results are shown in Table 1, where the system using all arguments gives a 54.36% accuracy. By removing a_2, which exists in 17.6% of the events in our developmental data, the accuracy drops to 54.02%. In contrast, by removing a_0 and a_1, which exist in 87.6% and 64.6% of the events in the development data, respectively, the accuracies drop to 53.43% and 53.57%, respectively, which demonstrates the relative importance of a_0 (i.e., the subject) and a_1 (i.e., the object) for event modelling. While most previous work (Chambers and Jurafsky, 2008; Balasubramanian et al., 2013; Pichotta and Mooney, 2014) modelled only a_0 and a_1, recent work (Pichotta and Mooney, 2016; Granroth-Wilding and Clark, 2016) modelled a_2 also.

Method	**Acc. (%)**
MemNet	**54.36**
-$verb$	42.63
-(a_0, a_1)	52.32
-(a_0)	53.43
-(a_1)	53.57
-(a_2)	54.02

Table 1: Influence of event arguments.

By removing both a_1 and a_2, the accuracy drops further to 53.32%. Interestingly, by removing the verb while keeping only the arguments, the accuracy drops to 42.63%. While this demonstrates the central value of the verb in denoting a event, it also suggests that the arguments themselves play a useful role in inferring the stereotypical scenario.

5.3.2 Influence of Network Configurations

We study the influence of various network configurations by performing ablation experiments, as shown in Table 2. *MemNet* is the full model of this paper; *-LSTM* denotes ablation of the LSTM layer, using $e(e_1)$, $e(e_2)$, ..., $e(e_{n-1})$ instead of h_1, h_2, ..., h_{n-1} to represent events; *-Hop* denotes ablation of the dynamic network model, using only attention mechanism to calculate the weights of each existing event; *-Attention* denotes ablation of the attention mechanism, using the same weight on each existing event when inferring e_c. The model "*-Attention, -LSTM*" is hence similar to the method of Granroth-Wilding and Clark (2016), although we used a different way of deriving event embeddings. The model "*LSTM-only*" shows a based by using LSTM hidden vector h_{n-1} to directly predict the next event, which is similar to the method of Pichotta and Mooney (2016).

Influence of Temporal Order. By comparing "MemNet" and "-LSTM", and comparing "-

[3] https://opennlp.apache.org/

Method	Acc. (%)
MemNet	**54.36**
-Hop	52.03
-Attention	50.76
-LSTM	51.72
-Hop,-LSTM	50.65
-Attention,-LSTM	48.26
LSTM-Only	46.72

Table 2: Analysis of network structure.

Attention" with "-Attention, -LSTM", one can find that temporal order information over the whole event chain does have significant influence on the results ($p - value < 0.01$ using t-test). On the other hand, using LSTM to directly predict the subsequent event ("LSTM-only") does not give better accuracies compared to model event pairs ("-Attention, -LSTM"). This confirms our intuition that strong-oder modelling and event-pair modelling each have their own strength.

Influence of Attention. Comparison between "-Attention" and "-Hop", and between "-Attention, -LSTM" and "-Hop, -LSTM" shows that giving different weights to different events does lead to improving results. Our analysis in Section 4.3 gives more intuitions to this observation. Finally, comparison between "-Hop" and "MemNet" and between "-Hop, -LSTM" and "-LSTM" shows that a multi-hop deep memory network can indeed enhance the model with single level attention by offering more effective semantic representation of the scenarios.

5.4 Final Results

Table 3 shows the final results on the C&C 16 and C&J08 datasets, respectively. We compare the results of our final model with the following baselines:

- **PMI** is the co-occurrence based model of Chambers and Jurafsky (2008), who calculate event pair relations based on Pointwise Mutual Information (PMI), scoring each candidate event e_c by the sum of PMI scores between the given events e_0, e_1, ..., e_{n-1} and the candidate.

- **Bigram** is the counting based model of Jans et al. (2012), calculating event pair relations based on skip bigram probabilities, trained using maximum likelihood estimation.

Method	G&C16	C&J08
PMI	30.52	30.92
Bigram	29.67	25.43
Event-Comp	49.57	43.28
RNN	45.74	43.17
MemNet	**55.12**	**46.67**

Table 3: Final results.

- **Event-Comp** is the neural event relation model proposed by Granroth-Wilding and Clark (2016). They learn event representations by calculating pair-wise event scores using a Siamese network.

- **RNN** is the method of Pichotta and Mooney (2016), who model event chains by directly using h_c in Section 4.2 to predict the output, rather than taking them as features for event pair relation modeling.

- **MemNet** is the proposed deep memory network model.

Our reimplementation of PMI and Bigrams follows (Granroth-Wilding and Clark, 2016). It can be seen from the table that the statistical counting-based models PMI and Bigram significantly underperform the neural network models Event-Comp, RNN and MemNet, which is largely due to their sparsity and lack of semantic representation power. Under our event representation, Bigram does not outperform PMI significantly either, although considering the order of event pairs. This is likely due to sparsity of events when all arguments are considered.

Direct comparison between Event-Comp and RNN shows that the event-pair model gives comparable results to the strong-order LSTM model. Although Granroth-Wilding and Clark (2016) and Pichotta and Mooney (2016) both compared with statistical baselines, they did not make direct comparisons between their methods, which represent two different approaches to the task. Our results show that they each have their unique advantages, which confirm our intuition in the introduction. By considering both pairwise relations and chain temporal orders, our method significantly outperform both Event-Comp and RNN ($p - value < 0.01$ using t-test), giving the best reported results on both datasets.

6 Conclusion

We proposed a dynamic memory network to integrate chain order information into event relation measuring, calculating event pair relations by representing events in a chain using LSTM hidden states, which encode temporal orders, and using a dynamic memory model to automatically induce event weights for each event. Standard evaluation showed that our method significantly outperforms state-of-the-art event pair models and event chain models, giving the best results reported so far.

Abstract

We present a simple yet effective approach for linking entities in queries. The key idea is to search sentences similar to a query from Wikipedia articles and directly use the human-annotated entities in the similar sentences as candidate entities for the query. Then, we employ a rich set of features, such as link-probability, context-matching, word embeddings, and relatedness among candidate entities as well as their related entities, to rank the candidates under a regression based framework. The advantages of our approach lie in two aspects, which contribute to the ranking process and final linking result. First, it can greatly reduce the number of candidate entities by filtering out irrelevant entities with the words in the query. Second, we can obtain the query sensitive prior probability in addition to the static link-probability derived from all Wikipedia articles. We conduct experiments on two benchmark datasets on entity linking for queries, namely the ERD14 dataset and the GERDAQ dataset. Experimental results show that our method outperforms state-of-the-art systems and yields 75.0% in F1 on the ERD14 dataset and 56.9% on the GERDAQ dataset.

1 Introduction

Query understanding has been an important research area in information retrieval and natural language processing (Croft et al., 2010). A key part of this problem is entity linking, which aims to annotate the entities in the query and link them to a knowledge base such as Freebase and Wikipedia. This problem has been extensively studied over the recent years (Ling et al., 2015; Usbeck et al., 2015; Cornolti et al., 2016).

The mainstream methods of entity linking for queries can be summed up in three steps: mention detection, candidate generation, and entity disambiguation. The first step is to recognize candidate mentions in the query. The most common method to detect mentions is to search a dictionary collected by the entity alias in a knowledge base and the human-maintained information in Wikipedia (such as anchors, titles and redirects) (Laclavik et al., 2014). The second step is to generate candidates by mapping mentions to entities. It usually uses all possible senses of detected mentions as candidates. Hereafter, we refer to these two steps of generating candidate entities as entity search. Finally, they disambiguate and prune candidate entities, which is usually implemented with a ranking framework.

There are two main issues in entity search. First, a mention may be linked to many entities. The methods using entity search usually leverage little context information in the query. Therefore it may generate many completely irrelevant entities for the query, which brings challenges to the ranking phase. For example, the mention “Austin” usually represents the capital of Texas in the United States. However, it can also be linked to “Austin, Western Australia”, “Austin, Quebec”, “Austin (name)”, “Austin College”, “Austin (song)” and 31 other entities in the Wikipedia page of “Austin (disambiguation)”. For the query “blake shelton austin lyrics”, Blake Shelton is a singer and made his debut with the song “Austin”. The entity search method detects the mention “austin” using the dictionary. However, while “Austin (song)” is most related to the context “blake shelton” and “lyrics”, the mention “austin” may be linked to all the above entities as candidates. Therefore candidate gener-

[*] Contribution during internship at Microsoft Research.

Proceedings of the 2017 Conference on Empirical Methods in Natural Language Processing, pages 68–77
Copenhagen, Denmark, September 7–11, 2017.

ation with entity search generates too many candidates especially for a common anchor text with a large number of corresponding entities. Second, it is hard to recognize entities with common surface names. The common methods usually define a feature called "link-probability" as the probability that a mention is annotated in all documents. There is an issue with this probability being static whatever the query is. We show an example with the query "her film". "Her (film)" is a film while its surface name is usually used as a possessive pronoun. Since the static link-probability of "her" from all Wikipedia articles is very low, "her" is usually not treated as a mention linked to the entity "Her (film)".

In this paper, we propose a novel approach to generating candidates by searching sentences from Wikipedia articles and directly using the human-annotated entities as the candidates. Our approach can greatly reduce the number of candidate entities and obtain the query sensitive prior probability. We take the query "blake shelton austin lyrics" as an example. Below we show a sentence in the Wikipedia page of "Austin (song)".

[[Austin (song)|Austin]] is the title of a debut song written by David Kent and Kirsti Manna, and performed by American country music artist [[Blake Shelton]].

Table 1: A sentence in the page "Austin (song)".

In the above sentence, the mentions "Austin" and "Blake Shelton" in square brackets are annotated to the entity "Austin (song)" and "Blake Shelton", respectively. We generate candidates by searching sentences and thus obtain "Blake Shelton" as well as "Austin (song)" from this example. We reduce the number of candidates because many irrelevant entities linked by "austin" do not occur in returned sentences. In addition, as previous methods generate candidates by searching entities without the query information, "austin" can be linked to "Austin, Texas" with much higher static link-probability than all other senses of "austin". However, the number of returned sentences that contain "Austin, Texas" is close to the number of sentences that contain "Austin (song)" in our system. We show another example with the query "her film" in Table 2. In this sentence, "Her", "romantic", "science fiction", "comedy-drama" and "Spike Jonze" are annotated to corresponding entities. As "Her" is annotated to "Her (film)" by humans in this example, we have strong evidence to annotate it even if it is usually used as a possessive pronoun with very low static link-probability.

[[Her (film)|Her]] is a 2013 American [[romantic]] [[science fiction]] [[comedy-drama]] film written, directed, and produced by [[Spike Jonze]].

Table 2: A sentence in the page "Her (film)".

We obtain the anchors as well as corresponding entities and map them to the query after searching similar sentences. Then we build a regression based framework to rank the candidates. We use a rich set of features, such as link-probability, context-matching, word embeddings, and relatedness among candidate entities as well as their related entities. We evaluate our method on the ERD14 and GERDAQ datasets. Experimental results show that our method outperforms state-of-the-art systems and yields 75.0% and 56.9% in terms of F1 metric on the ERD14 dataset and the GERDAQ dataset respectively.

2 Related Work

Recognizing entity mentions in text and linking them to the corresponding entries helps to understand documents and queries. Most work uses the knowledge base including Freebase (Chiu et al., 2014), YAGO (Yosef et al., 2011) and Dbpedia (Olieman et al., 2014). Wikify (Mihalcea and Csomai, 2007) is the very early work on linking anchor texts to Wikipedia pages. It extracts all n-grams that match Wikipedia concepts such as anchors and titles as candidates. They implement a voting scheme based on the knowledge-based and data-driven method to disambiguate candidates. Cucerzan (2007) uses four recourses to generate candidates, namely entity pages, redirecting pages, disambiguation pages, and list pages. Then they disambiguate candidates by calculating the similarity between the contextual information and the document as well as category tags on Wikipedia pages. Milne and Witten (2008) generate candidates by gathering all n-grams in the document, and retaining those whose probability exceeds a low threshold. Then they define commonness and relatedness on the hyper-link structure of Wikipedia to disambiguate candidates.

The work on linking entities in queries has been extensively studied in recent years. TagME (Ferragina and Scaiella, 2010) is a very early work on entity linking in queries. It generates candidates by searching Wikipedia page titles, anchors and redirects. Then disambiguation exploits the structure of the Wikipedia graph, according to a voting scheme based on a relatedness measure inspired by Milne and Witten (2008). The improved version of TagME, named WAT (Piccinno and Ferragina, 2014), uses Jaccard-similarity between two pages' in-links as a measure of relatedness and uses PageRank to rank the candidate entities. Moreover, Meij (2012) proposes a two step approach for linking tweets to Wikipedia articles. They first extract candidate concepts for each n-gram, and then use a supervised learning algorithm to classify relevant concepts.

Unlike the work which revolves around ranking entities for query spans, the Entity Recognition and Disambiguation (ERD) Challenge (Carmel et al., 2014) views entity linking in queries as the problem of finding multiple query interpretations. The SMAPH system (Cornolti et al., 2014) which wins the short-text track works in three phases: fetching, candidate-entity generation and pruning. First, they fetch the snippets returned by a commercial search engine. Next, snippets are parsed to identify candidate entities by looking at the boldfaced parts of the search snippets. Finally, they implement a binary classifier using a set of features such as the coherence and robustness of the annotation process and the ranking as well as composition of snippets. They further extend SMAPH-1 to SMAPH-2 (Cornolti et al., 2016). They use the annotator WAT to annotate the snippets of search results to generate candidates and joint the additionally link-back step as well as the pruning step in the ranking phase, which gets the state-of-the-art results on the ERD14 dataset and their released dataset GERDAQ. There is another work closed to SMAPH that uses information of query logs and anchor texts (Blanco et al., 2015), which gives a ranked list of entities and is evaluated by means of typical ranking metrics.

Our work is different from using search engines to generate candidates. We firstly propose to search Wikipedia sentences and take advantage of human annotations to generate candidates. The previous work, such as SMAPH, employs search engine for candidate generation, which puts queries in a larger context in which it is easier to make sense of them. However, it uses WAT, an entity search based tool, to pre-annotate the snippets for candidate generation, which falls back the issues of entity search.

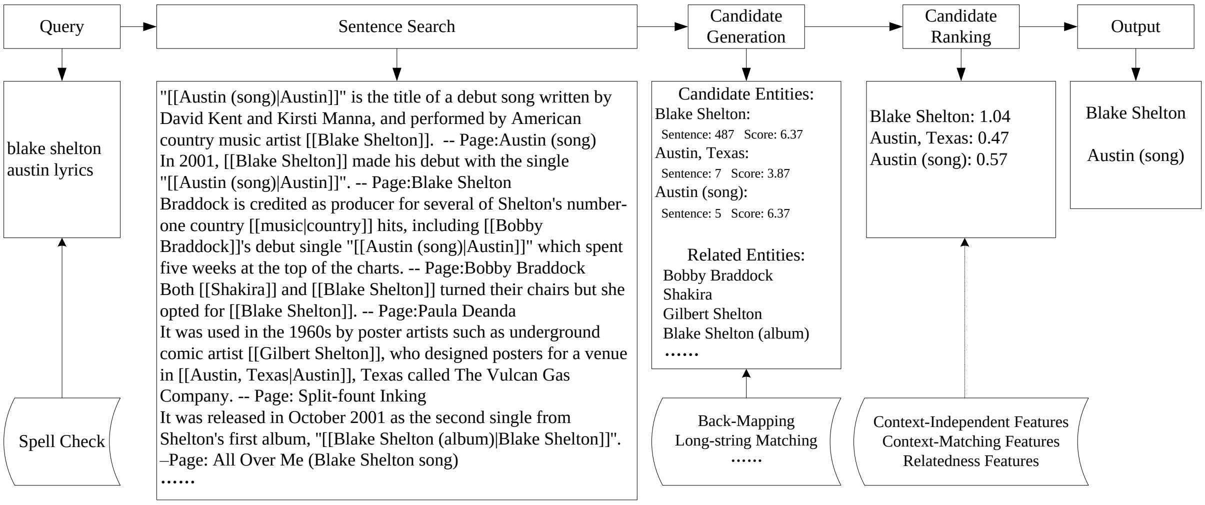
3 Our Approach

As shown in Figure 1, we introduce our approach with the query "blake shelton austin lyrics". Our approach consists of three main phases: sentence search, candidate generation, and candidate ranking. First, we search the query in all Wikipedia articles to obtain the similar sentences. Second, we extract human-annotated entities from these sentences. We keep the entities whose corresponding anchor texts occur in the query as candidates, and treat others as related entities. Specifically, we obtain three candidates in this example, namely "Blake Shelton", "Austin, Texas", and "Austin (song)". Finally, we use a regression based model to rank the candidate entities. We get the final annotations of "Blake Shelton" and "Austin (song)" whose scores are higher than the threshold selected on the development set. In the following sections, we describe these three phases in detail.

3.1 Sentence Search

Sentences in Wikipedia articles usually contain anchors linking to entities. We are therefore motivated to generate the candidate entities based on the sentence search instead of the common method using entity search. There are some issues in the original annotations because of the annotation regulation. First, entities in their own pages are usually not annotated. Thus we annotate these entities with matching between the text and the page title. Second, entities are usually annotated only in their first appearance. We annotate these entities if they are annotated in previous sentences in the page. Moreover, pronouns are widely used in Wikipedia sentences and are usually not annotated. We use the Stanford CoreNLP toolkit (Manning et al., 2014) to do the coreference resolution. In addition, we use the content in the disambiguation page and the infobox. Although these two kinds of information may have incomplete grammatical structure, it contains enough context information for the sentence search in our task.

We use the Wikipedia snapshot of May 1, 2016, which contains 4.45 million pages and 120 million sentences. We extract sentences that contain at least one anchor in the Wikipedia articles, and



"[[Austin (song)|Austin]]" is the title of a debut song written by David Kent and Kirsti Manna, and performed by American country music artist [[Blake Shelton]]. -- Page:Austin (song)
In 2001, [[Blake Shelton]] made his debut with the single "[[Austin (song)|Austin]]". -- Page:Blake Shelton
Braddock is credited as producer for several of Shelton's number-one country [[music|country]] hits, including [[Bobby Braddock]]'s debut single "[[Austin (song)|Austin]]" which spent five weeks at the top of the charts. -- Page:Bobby Braddock
Both [[Shakira]] and [[Blake Shelton]] turned their chairs but she opted for [[Blake Shelton]]. -- Page:Paula Deanda
It was used in the 1960s by poster artists such as underground comic artist [[Gilbert Shelton]], who designed posters for a venue in [[Austin, Texas|Austin]], Texas called The Vulcan Gas Company. -- Page: Split-fount Inking
It was released in October 2001 as the second single from Shelton's first album, "[[Blake Shelton (album)|Blake Shelton]]". –Page: All Over Me (Blake Shelton song)
……

Figure 1: Example of the linking process of the query "blake shelton austin lyrics"

extract human-annotated anchors as well as corresponding entities in the sentences. The original annotation contains 82.6 million anchors. We obtain 110 million annotated anchors in 48.4 million sentences after the incrementally annotation. All of above annotations are indexed by Lucene[1] by building documents consisting of two fields: the first one contains the sentence and the second one contains all anchors with their corresponding entities. For each query, we search it with Lucene using its default ranker[2] based on the vector space model and tf-idf to obtain the top K sentences (K is selected on the development set). We extract all entities as the related entities and use these sentences as their support sentences.

3.2 Candidate Generation

We back-map anchors and corresponding entities extracted in sentences to generate candidates. We use (a, e) to denote the pair of the anchor text and corresponding entity and use $w(a, e)$ to denote the number of sentences containing the pair (a, e). Then, we prune the candidate pairs according to following rules.

First, we only keep the pair whose corresponding anchor text a occurs in the query as a candidate, which has been used in previous work (Ferragina and Scaiella, 2010). Second, we follow the long-string match strategy. If we have two pairs (a_1, e_1) and (a_2, e_2) while a_1 is a substring of a_2, we drop (a_1, e_1) if $w(a_1, e_1) < w(a_2, e_2)$. This is because a_2 is typically less ambiguous than a_1. For example, for the query "mesa community college football", we can obtain the anchor "mesa", "college", "community college", and "mesa community college". We only keep "mesa community college" because it is longest and occurs most times in returned sentences. However, if $w(a_1, e_1) > w(a_2, e_2)$, we keep both candidate pairs because a_1 is more common in the query.

In addition, we keep the entity whose surface form is the same with the anchor text and prune others. If we have two pairs (a, e_1) and (a, e_2) with the same anchor, and only e_2 occurs in the query, we drop the pair (a, e_1) if $w(a, e_1) < w(a, e_2)$. For example, for the query "business day south africa", the anchor "south africa" can be linked to "south africa", "union of south africa", and "south africa cricket team". We only keep the entity "south africa".

3.3 Candidate Ranking

We build a regression based framework to rank the candidate entities. In the training phase, we treat the candidates that are equal to the ground truth as the positive samples and the others as negative samples. The regression object of the positive sample is set to the score 1.0. The negative sample is set to the maximum score of overlapping ratio of tokens between its text and each gold answer. The regression object of the negative sample is not simply set to 0 in order to give a small score if the candidate is very closed to the ground truth. We find it benefits the final results. We use LIBLIN-

[1] `http://lucene.apache.org`

[2] Details can be found in `https://lucene.apache.org/core/2_9_4/api/core/org/apache/lucene/search/Similarity.html`

EAR (Fan et al., 2008) with L2-regularized L2-loss support vector regression to train the regression model. The object function is to minimize

$$w^T w/2 + C \sum \max(0, |y_i - w^T x_i| - eps)^2 \quad (1)$$

where x_i is the feature set, y_i is the object score and w is the parameter to be learned. We follow the default setting that C is set to 1 and eps is set to 0.1.

In the test phase, each candidate gets a score of $w^T x_i$ and then we only output the candidate whose score is higher than the threshold selected on the development set.

We employ four different feature sets to capture the quality of a candidate from different aspects. All features are shown in Table 3.

Context-Independent Features This feature set measures each annotation pair (a, e) without context information. Feature 1-4 catch the syntactic properties of the candidate. Feature 5 is the number of returned sentences that contain (a, e). Feature 6 is the maximum search score (returned by Lucene) in its support sentences. Moreover, inspired by TagME (Ferragina and Scaiella, 2010), we denote $freq(a)$ as the number of times the text a occurs in Wikipedia. We use $link(a)$ to denote the number of times the text a occurs as an anchor. We use $lp(a) = link(a)/freq(a)$ to denote the static link-probability that an occurrence of a has been set as an anchor. We use $freq(a, e)$ to denote the number of times that the anchor text a links to the entity e, and use $pr(e|a) = freq(a, e)/link(a)$ to denote the static prior-probability that the anchor text a links to e. Features 7 and 8 are these two probabilities.

Context-Matching Features We treat the other words except for the anchor text as the context. This feature set measures the context matching to the query. Feature 9 is the context matching score calculated by tokens. We denote c as the set of context words. For each c_i in c, the $cm\_sc(c_i)$ is the ratio of times that c_i occurs in the support sentences, and $cm\_sc(c) = \frac{1}{N} \sum cm\_sc(c_i)$. Features 10 and 11 are the ratio of context words occurring in the first sentence in the entity page and the description of entity's disambiguation page (if existed), respectively. Moreover, we train a 300-dimensional word embeddings on all Wikipedia articles by word2vec (Mikolov et al., 2013) and use the average embedding of each word as the sentence representation. Feature 12 is the maximum cosine score between the query and each support sentence. Features 13 and 14 are calculated with the first sentence in the entity's page and the description in the disambiguation page.

ID	Name	Description
1	in_query	1 if e is in the query, 0 otherwise
2	is_pt	1 if e contains parenthesis, 0 otherwise
3	is_cm	1 if e contains comma, 0 otherwise
4	len	len(e) by tokens
5	$w(a, e)$	number of support sentences
6	$sc(a, e)$	maximum search score of support sentences
7	$lp(a)$	static link-probability that a is an anchor
8	$pr(a, e)$	static prior-probability that a links to e
9	cm_sc	context matching score to the support sentences
10	cm_fs	context matching score to the first sentence of e's page
11	cm_dd	context matching score to the description in e's disambiguation page
12	$embed\_sc$	maximum embedding similarity of the query and each support sentence
13	$embed\_fs$	embedding similarity of the query and the first sentence of e's page
14	$embed\_dd$	embedding similarity of the query and the description in e's disambiguation page
15	rel_cd_sc	number of candidates that occur in the support sentences
16	rel_cd_sp	number of candidates that occur in the same Wikipedia page
17	rel_re_sc	number of related entities that occur in the support sentences
18	rel_re_sp	number of related entities that occur in the same Wikipedia page

Table 3: Feature Set for Candidate Ranking

Relatedness Features of Candidate Entities This set of features measures how much an entity is supported by other candidates. Feature 15 is the number of other candidate entities occurring in the support sentences. Feature 16 is the number of candidate entities occurring in the same Wikipedia page with the current entity.

Relatedness Features to Related Entities This set of features measures the relatedness between candidates and related entities outside of queries. Related entities can provide useful signals for disambiguating the candidates. Features 17 and 18 are analogous features with features 15 and 16, which are calculated by the related entities.

4 Experiment

We conduct experiments on the ERD14 and GERDAQ datasets. We compare with several baseline annotators and experimental results show that our method outperforms the baseline on these two datasets. We also report the parameter selection on each dataset and analyze the quality of the candidates using different methods.

4.1 Dataset

ERD14[3] is a benchmark dataset in the ERD Challenge (Carmel et al., 2014), which contains both long-text track and short-text track. In this paper we only focus on the short-text track. It contains 500 queries as the development set and 500 queries as the test set. Due to the lack of training set, we use the development set to do the model training and tuning. This dataset can be evaluated by both Freebase and Wikipedia as the ERD Challenge Organizers provide the Freebase Wikipedia Mapping with one-to-one correspondence of entities between two knowledge bases. We use Wikipedia to evaluate our results.

GERDAQ[4] is a benchmark dataset to annotate entities to Wikipedia built by Cornolti et al. (2016). It contains 500 queries for training, 250 for development, and 250 for test. The query in this dataset is sampled from the KDD-Cup 2005 and then annotated manually. Both name entities and common concepts are annotated in this dataset.

4.2 Evaluation Metric

We use average F1 designed by ERD Challenge (Carmel et al., 2014) as the evaluation metrics. Specifically, given a query q, with labeled entities $\hat{A} = \{\hat{E_1}, \ldots, \hat{E_n}\}$. We define the F-measure of a set of hypothesized interpretations $A = \{E_1, \ldots, E_m\}$ as follows:

$$Precision = \frac{|\hat{A} \cap A|}{|A|}, Recall = \frac{|\hat{A} \cap A|}{|\hat{A}|} \quad (2)$$

$$F_1 = \frac{2 \times Precision \times Recall}{Precision + Recall} \quad (3)$$

The average F1 of the evaluation set is the average of the F1 for each query:

$$AverageF_1 = \frac{1}{N} \sum_{i=1}^{N} F_1(q_i) \quad (4)$$

Following the evaluation guideline in ERD14 and GERDAQ, we define recall to be 1.0 if the gold binding of a query is empty and define precision to be 1.0 if the hypothesized interpretation is empty.

4.3 Baseline Methods

We compare with several baselines and use the results reported by the ERD organizer and Cornolti et al. (2016).

AIDA (Hoffart et al., 2011) searches the mention using Stanford NER Tagger based on YAGO2. We select AIDA as a representative system aiming to entity linking for documents following the work in Cornolti et al. (2016).

WAT (Piccinno and Ferragina, 2014) is the improved version of TagME (Ferragina and Scaiella, 2010).

Magnetic IISAS (Laclavik et al., 2014) retrieves the index extracted from Wikipedia, Freebase and Dbpedia. Then it exploits Wikipedia link graph to assess the similarity of candidate entities for disambiguation and filtering.

Seznam (Eckhardt et al., 2014) uses Wikipedia and DBpedia to generate candidates. The disambiguation step is based on PageRank over the graph.

NTUNLP (Chiu et al., 2014) searches the query to match Freebase surface forms. The disambiguation step is built on top of TagME and Wikipedia.

SMAPH-1 (Cornolti et al., 2014) is the winner in the short-text track in the ERD14 Challenge.

SMAPH-2 (Cornolti et al., 2016) is the improved version of SMAPH-1. It generates candidates from the snippets of search results returned by the Bing search engine.

4.4 Result

We report results on the ERD datset and GERDAQ dataset in Table 4 and Table 5, respectively. On the ERD14 dataset, WAT is superior to AIDA but it is still up to 10% than SMAPH-1 that wins the ERD Challenge. SMAPH-2 improves 2% than SMAPH-1. Our system significantly outperforms the state-of-the-art annotator SMAPH-2 by 4.2%. On the GERDAQ dataset, our system is 2.5% superior to the state-of-the-art annotator SMAPH-2. The F1 score in this dataset is much lower than the ERD dataset because common concepts such as “Week” and “Game” that are not annotated in the ERD dataset are annotated in the GERDAQ dataset.

Spell checking has been widely used in the baseline annotators as it is not uncommon in queries (Laclavik et al., 2014). The SMAPH system that generates candidates by search results implicitly leverages the spell-checking embedded in

Table 5: Results on the GERDAQ dataset. Results of the baseline systems are taken from Table 10 in Cornolti et al. (2016).

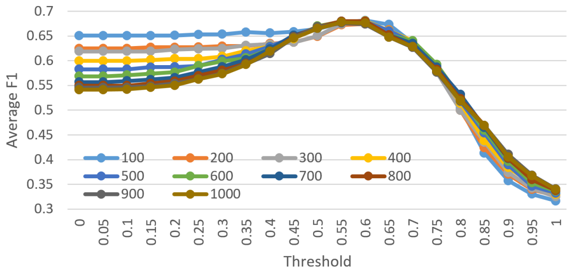

Figure 2: F1 scores with different search numbers and thresholds on the ERD development set

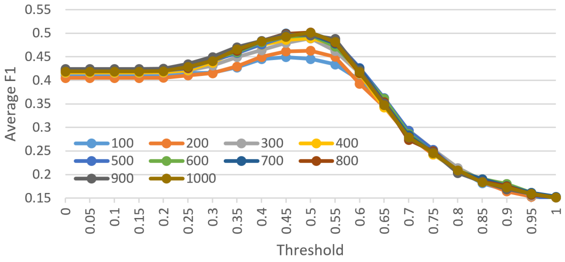

Figure 3: F1 scores with different search numbers and thresholds on the GERDAQ development set

search engines. In our experiments, spell checking improves 1.0% on the ERD dataset and 7.6% on the GERDAQ dataset. Furthermore, only 6.9% of queries in the ERD14 dataset have spelling mistakes, whereas the number in the GERDAQ dataset is 23.0%. Thus spell-checking is more important in the GERDAQ dataset.

The result decreases 0.6% on the ERD dataset and 1.1% on the GERDAQ dataset without the additional annotation. Furthermore, while the F1 score decreases 2.4% on the ERD dataset and 1.4% on the GERDAQ dataset without the context features, the score only decreases 0.5% on the ERD dataset and 0.2% on the GERDAQ dataset without the relatedness features. Unlike the work on entity linking for documents (Eckhardt et al., 2014; Witten and Milne, 2008) that features derived from entity relations get promising results, the context features play a more important role than the relatedness features on entity linking for queries as search queries are short and contain fewer entities than documents.

4.5 Parameter Selection

There are two parameters in our framework, namely the number of search sentences and the threshold for final output. We select these two parameters on the development set. We show the F1 score with different numbers of search sentences and thresholds in Figure 2 and Figure 3. On the ERD development set, better results occur in the search number between 600 and 800 as well as the threshold 0.55 and 0.6. On the GERDAQ development set, better results occur in the search number between 700 and 1000 as well as the threshold between 0.45 and 0.5. In our experiment, we set the number of sentences to 700 and the threshold to 0.56 on the ERD dataset as well as 800 and 0.48 on the GERDAQ dataset according to the F1 scores on the development set.

4.6 Model Analysis

The main difference between our method and most previous work is that we generate candidates by searching Wikipedia sentences instead of searching entities. For generating candidates with entity search, we build a dictionary containing all anchors, titles, and redirects in Wikipedia. Then we query the dictionary to get the mention and obtain corresponding entities as candidates. We use the

Method	Number of anchors	Number of candidates	$F1_{avg}$
Entity Search ES + RF	1.96	6.84	66.46 69.00
Sentence Search SS + RF	1.12	1.49	73.81 75.01

Table 6: Comparison with different candidate generation methods on the ERD dataset. +RF: integrating ranking features extracted by Sentence Search.

Method	C_{avg}	P_{avg}	R_{avg}
Entity Search	78.87	77.56	66.04
Sentence Search	74.42	89.61	69.08

Table 7: Results for the 398 queries which have at least one labeled entity on the ERD dataset using different candidate generation methods. C_{avg} is the average recall of candidates per query. P_{avg} and R_{avg} are calculated on the final results.

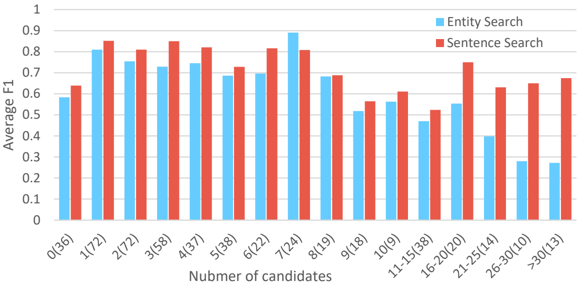

Figure 4: F1 scores with number of candidates using different methods on the ERD dataset. The number of queries is shown in the parentheses.

same pruning rules and ranking framework in our experiments, but exclude the features from support sentences because the entity search method does not contain the information. The F1 score is shown in Table 6. We achieve similar results in our implementation of the method using entity search on the ERD dataset as Magnetic IISAS (Laclavik et al., 2014) which uses a similar method and ranks 4th with the F1 of 65.57 in the ERD14 Challenge.

We compare the two candidate generation methods in several aspects. First, we show the overall results in Table 6. The average number of candidates from our method is much smaller. It is noted that the anchors from sentence search can also be found in entity search. However, we only extract the entities in the returned sentences while the methods by entity search use all entities linked by the anchors. In addition, features such as the number of sentences containing the entity from sentence search which provide query sensitive prior probability contribute to the ranking process. It improves the F1 score from 73.81 to 75.01 for sentence search and from 66.46 to 69.00 for entity search. More important, the result of "ES+RF" is still significantly worse than the result of both small candidate set and Wikipedia related features that prunes irrelevant candidates at the beginning, which proves that the high-quality candidate set is very important since the larger candidate set brings in lots of noise in training a ranking model. Moreover, there are 102 queries (20.4%) without labeled entities in the ERD dataset. We only give 7 incorrect annotations in these queries while the number is 13 from entity search. Furthermore, as shown in Table 7, the coverage of our method is lower in queries with at least one entity, but we obtain better results on precision, recall and F1 in the final stage.

Figure 4 illustrates the F1 score grouped by the number of candidates using entity search. In almost all columns the F1 score of our method is better than the baseline. In left columns (the number of candidates is less than 10), both methods generate few candidates. The F1 score of our method is higher, which proves that we train a better ranking model because of our small but quality candidate set. Moreover, the right columns (the number of candidates is more than 10) show that the F1 score using entity search gradually decreases with the incremental candidates. However, our method based on sentence search takes advantage of context information to keep a small set of candidates, which keeps a consistent result and outperforms the baseline.

5 Conclusion

In this paper we address the problem of entity linking for open-domain queries. We introduce a novel approach to generating candidate entities by searching sentences in the Wikipedia to the query, then we extract the human-annotated entities as the candidates. We implement a regression model to rank these candidates for the final output. Two experiments on the ERD dataset and the GERDAQ dataset show that our approach outperforms the baseline systems. In this work we directly use the default ranker in Lucene for similar sentences, which can be improved in future work.

Acknowledgments

We thank Ming-Wei Chang for sharing the ERD14 dataset. Chuanqi Tan and Weifeng Lv are supported by the National Natural Science Foundation of China (Grant No. 61421003). Weifeng Lv is the corresponding author of this paper.

Train-O-Matic: Large-Scale Supervised Word Sense Disambiguation in Multiple Languages without Manual Training Data

Tommaso Pasini and **Roberto Navigli**
Department of Computer Science
Sapienza University of Rome
{pasini,navigli}@di.uniroma1.it

Abstract

Annotating large numbers of sentences with senses is the heaviest requirement of current Word Sense Disambiguation. We present Train-O-Matic, a language-independent method for generating millions of sense-annotated training instances for virtually all meanings of words in a language's vocabulary. The approach is fully automatic: no human intervention is required and the only type of human knowledge used is a WordNet-like resource. Train-O-Matic achieves consistently state-of-the-art performance across gold standard datasets and languages, while at the same time removing the burden of manual annotation. All the training data is available for research purposes at http://trainomatic.org.

1 Introduction

Word Sense Disambiguation (WSD) is a key task in computational lexical semantics, inasmuch as it addresses the lexical ambiguity of text by making explicit the meaning of words occurring in a given context (Navigli, 2009). Anyone who has struggled with frustratingly unintelligible translations from an automatic system, or with the meaning bias of search engines, can understand the importance for an intelligent system to go beyond the surface appearance of text.

There are two mainstream lines of research in WSD: supervised and knowledge-based WSD. Supervised WSD frames the problem as a classical machine learning task in which, first a training phase occurs aimed at learning a classification model from sentences annotated with word senses and, second the model is applied to previously-unseen sentences focused on a target word. A key difference from many other problems, however, is that the classes to choose from (i.e., the senses of a target word) vary for each word, therefore requiring a separate training process to be performed on a word by word basis. As a result, hundreds of training instances are needed for each ambiguous word in the vocabulary. This would necessitate a million-item training set to be manually created for each language of interest, an endeavour that is currently beyond reach even in resource-rich languages like English.

The second paradigm, i.e., knowledge-based WSD, takes a radically different approach: the idea is to exploit a general-purpose knowledge resource like WordNet (Fellbaum, 1998) to develop an algorithm which can take advantage of the structural and lexical-semantic information in the resource to choose among the possible senses of a target word occurring in context. For example, a PageRank-based algorithm can be developed to determine the probability of a given sense being reached starting from the senses of its context words. Recent approaches of this kind have been shown to obtain competitive results (Agirre et al., 2014; Moro et al., 2014). However, due to its inherent nature, knowledge-based WSD tends to adopt bag-of-word approaches which do not exploit the local lexical context of a target word, including function and collocation words, which limits this approach in some cases.

In this paper we get the best of both worlds and present Train-O-Matic, a novel method for generating huge high-quality training sets for all the words in a language's vocabulary. The approach is language-independent, thanks to its use of a multilingual knowledge resource, BabelNet (Navigli and Ponzetto, 2012), and it can be applied to any kind of corpus. The training sets produced with Train-O-Matic are shown to provide competitive performance with those of manually and semi-

Proceedings of the 2017 Conference on Empirical Methods in Natural Language Processing, pages 78–88
Copenhagen, Denmark, September 7–11, 2017.

automatically tagged corpora. Moreover, state-of-the-art performance is also reported for low resourced languages (i.e., Italian and Spanish) and domains, where manual training data is not available.

2 Building a Training Set from Scratch

In this Section we present Train-O-Matic, a language-independent approach to the automatic construction of a sense-tagged training set. Train-O-Matic takes as input a corpus C (e.g., Wikipedia) and a semantic network $G = (V, E)$. We assume a WordNet-like structure of G, i.e., V is the set of concepts (i.e., synsets) such that, for each word w in the vocabulary, $Senses(w)$ is the set of vertices in V that are expressed by w, e.g., the WordNet synsets that include w as one of their senses.

Train-O-Matic consists of three steps:

- **Lexical profiling:** for each vertex in the semantic network, we compute its Personalized PageRank vector, which provides its lexical-semantic profile (Section 2.1).
- **Sentence scoring:** For each sentence containing a word w, we compute a probability distribution over all the senses of w based on its context (Section 2.2).
- **Sentence ranking and selection:** for each sense s of a word w in the vocabulary, we select those sentences that are most likely to use w in the sense of s (Section 2.3).

2.1 Lexical profiling

In terms of semantic networks the probability of reaching a node v' starting from v can be interpreted as a measure of relatedness between the synsets v and v'. Thus we define the lexical profile of a vertex v in a graph $G = (V, E)$ as the probability distribution over all the vertices v' in the graph. Such distribution is computed by applying the Personalized PagaRank algorithm, a variant of the traditional PageRank (Brin and Page, 1998). While the latter is equivalent to performing random walks with uniform restart probability on every vertex at each step, PPR, on the other hand, makes the restart probability non-uniform, thereby concentrating more probability mass in the surroundings of those vertices having higher restart probability. Formally, (P)PR is computed as follows:

$$v^{(t+1)} = (1 - \alpha)v^{(0)} + \alpha M v^{(t)} \tag{1}$$

where M is the row-normalized adjacency matrix of the semantic network, the restart probability distribution is encoded by vector $v^{(0)}$, and α is the well-known damping factor usually set to 0.85 (Brin and Page, 1998). If we set $v^{(0)}$ to a unit probability vector $(0, \ldots, 0, 1, 0, \ldots, 0)$, i.e., restart is always on a given vertex, PPR outputs the probability of reaching every vertex starting from the restart vertex after a certain number of steps. This approach has been used in the literature to create semantic signatures (i.e., profiles) of individual concepts, i.e., vertices of the semantic network (Pilehvar et al., 2013), and then to determine the semantic similarity of concepts. As also done by Pilehvar and Collier (2016), we instead use the PPR vector as an estimate of the conditional probability of a word w' given the target sense[1] $s \in V$ of word w:

$$P(w'|s, w) = \frac{\max_{s' \in Senses(w')} v_s(s')}{Z} \tag{2}$$

where $Z = \sum_{w"} P(w"|s, w)$ is a normalization constant, v_s is the vector resulting from an adequate number of random walks used to calculate PPR, and $v_s(s')$ is the vector component corresponding to sense s'. To fix the number of iterations needed to have a sufficiently accurate vector, we follow Lofgren et al. (2014) and set the error $\delta = 0.00001$ and the number of iterations to $\frac{1}{\delta} = 100,000$.

As a result of this lexical profiling step we have a probability distribution over vocabulary words for each given word sense of interest.

2.2 Sentence scoring

The objective of the second step is to score the importance of word senses for each of the corpus sentences which contain the word of interest. Given a sentence $\sigma = w_1, w_2, \ldots, w_n$, for a given target word w in the sentence ($w \in \sigma$), and for each of its senses $s \in Senses(w)$, we compute the probability $P(s|\sigma, w)$. Thanks to Bayes' theorem we can determine the probability of sense s of w given the

[1] Note that we use senses and concepts (synsets) interchangeably, because – given a word – a word sense unambiguously determines a concept (i.e., the synset it is contained in) and vice versa.

sentence as follows:

$$P(s|\sigma, w) = \frac{P(\sigma|s, w)P(s|w)}{P(\sigma|w)} \quad (3)$$

$$= \frac{P(w_1, \dots, w_n|s, w)P(s|w)}{P(w_1, \dots, w_n|w)}$$

$$\propto P(w_1, \dots, w_n|s, w)P(s|w) \quad (4)$$

$$\approx P(w_1|s, w) \dots P(w_n|s, w)P(s|w) \quad (5)$$

where Formula 4 is proportional to the original probability (due to removing the constant in the denominator) and is approximated with Formula 5 due to the assumption of independence of the words in the sentence. $P(w_i|s, w)$ is calculated as in Formula 2 and $P(s|w)$ is set to $1/|Senses(w)|$ (recall that s is a sense of w). For example, given the sentence $\sigma =$"A match is a tool for starting a fire", the target word $w = match$ and its set of senses $S_{match} = \{s^1_{match}, s^2_{match}\}$, where s^1_{match} is the sense of *lighter* and s^2_{match} is the sense of *game match*, we want to calculate the probability of each $s^i_{match} \in S_{match}$ of being the correct sense of *match* in the sentence σ. Following Formula 5 we have:

$$\begin{aligned} P(s^1_{match}|\sigma, match) \approx{} & \\ & P(\text{tool}|s^1_{match}, match) \\ & \cdot P(\text{start}|s^1_{match}, match) \\ & \cdot P(\text{fire}|s^1_{match}, match) \\ & \cdot P(s^1_{match}|match) \\ & = 2.1 \cdot 10^{-4} \cdot 2 \cdot 10^{-3} \cdot 10^{-2} \cdot 5 \cdot 10^{-1} \\ & = 2.1 \cdot 10^{-9} \end{aligned}$$

$$\begin{aligned} P(s^2_{match}|\sigma, match) \approx{} & \\ & P(\text{tool}|s^2_{match}, match) \\ & \cdot P(\text{start}|s^2_{match}, match) \\ & \cdot P(\text{fire}|s^2_{match}, match) \\ & \cdot P(s^2_{match}|match) \\ & = 10^{-5} \cdot 2.9 \cdot 10^{-4} \cdot 10^{-6} \cdot 5 \cdot 10^{-1} \\ & = 1.45 \cdot 10^{-15} \end{aligned}$$

As can be seen, the first sense of *match* has a much higher probability due to its stronger relatedness to the other words in the context (i.e. *start*, *fire* and *tool*). Note also that all the probabilities for the second sense are at least one magnitude less than the probability of the first sense.

2.3 Sense-based sentence ranking and selection

Finally, for a given word w and a given sense $s_1 \in Senses(w)$, we score each sentence σ in which w appears and s_1 is its most likely sense according to a formula that takes into account the difference between the first (i.e., s_1) and the second most likely sense of w in σ:

$$\Delta_{s_1}(\sigma) = P(s_1|\sigma, w) - P(s_2|\sigma, w) \quad (6)$$

where $s_1 = \arg\max_{s \in Senses(w)} P(s|\sigma, w)$, and $s_2 = \arg\max_{s \in Senses(w) \setminus \{s_1\}} P(s|\sigma, w)$. We then sort all sentences based on $\Delta_{s_1}(\cdot)$ and return a ranked list of sentences where word w is most likely to be sense-annotated with s_1. Although we recognize that other scoring strategies could have been used, this was experimentally the most effective one when compared to alternative strategies, i.e., the sense probability, the number of words related to the target word w, the sentence length or a combination thereof.

3 Creating a Denser and Multilingual Semantic Network

In the previous Section we assumed that WordNet was our semantic network, with synsets as vertices and edges represented by its semantic relations. However, while its lexical coverage is high, with a rich set of fine-grained synsets, at the relation level WordNet provides mainly paradigmatic information, i.e., relations like hypernymy (is-a) and meronymy (part-of). It lacks, on the other hand, syntagmatic relations, such as those that connect verb synsets to their arguments (e.g., the appropriate senses of eat_v and $food_n$), or pairs of noun synsets (e.g., the appropriate senses of bus_n and $driver_n$).

Intuitively, Train-O-Matic would suffer from such a lack of syntagmatic relations, as the relevance of a sense for a given word in a sentence depends directly on the possibility of visiting senses of the other words in the same sentence (cf. Formula 5) via random walks as calculated with Formula 1. Such reachability depends on the connections available between synsets. Because syntagmatic relations are sparse in WordNet, if it was used on its own, we would end up with a poor ranking of sentences for any given word sense. Moreover, even though the methodology presented in Section 2 is language-independent, Train-O-Matic would lack informa-

tion (e.g. senses for a word in an arbitrary vocabulary) for languages other than English.

To cope with these issues, we exploit BabelNet,[2] a huge multilingual semantic network obtained from the automatic integration of WordNet, Wikipedia, Wiktionary and other resources (Navigli and Ponzetto, 2012), and create the BabelNet subgraph induced by the WordNet vertices. The result is a graph whose vertices are BabelNet synsets that contain at least one WordNet synset and whose edge set includes all those relations in BabelNet coming either from WordNet itself or from links in other resources mapped to WordNet (such as hyperlinks in a Wikipedia article connecting it to other articles). The greatest contribution of syntagmatic relations comes, indeed, from Wikipedia, as its articles are linked to related articles (e.g., the English Wikipedia *Bus* article[3] is linked to *Passenger*, *Tourism*, *Bus lane*, *Timetable*, *School*, and many more).

Because not all Wikipedia (and other resources') pages are connected with the same degree of relatedness (e.g., countries are often linked, but they are not necessarily closely related to the source article in which the link occurs), we apply the following weighting strategy to each edge $(s, s') \in E$ of our WordNet-induced subgraph of BabelNet $G = (V, E)$:

$$w(s, s') = \begin{cases} 1 & (s, s') \in E(\text{WordNet}) \\ WO(s, s') & \text{otherwise} \end{cases} \tag{7}$$

where E(WordNet) is the edge set of the original WordNet graph and $WO(s, s')$ is the weighted overlap measure which calculates the similarity between two synsets:

$$WO(s, s') = \frac{\sum_{i=1}^{|S|}(r_i^1 + r_i^2)^{-1}}{\sum_{i=1}^{|S|}(2i)^{-1}}$$

where r_i^1 and r_i^2 are the rankings of the i-th synsets in the set S of the components in common between the vectors associated with s and s', respectively. Because at this stage we still have to calculate our synset vector representation, we use the precomputed NASARI vectors (Camacho-Collados et al., 2015) to calculate WO. This choice is due to WO's higher performance over cosine similarity for vectors with explicit dimensions (Pilehvar et al., 2013).

As a result, each row of the original adjacency matrix M of G will be replaced with the weights calculated in Formula 7 and then normalized in order to be ready for PPR calculation (see Formula 1). An idea of why a denser semantic network has more useful connections and thus leads to better results is provided by the example in Table 1[4], where we show the highest-probability synsets in the PPR vectors calculated with Formula 1 for two different senses of *mouse* (its animal and device senses) when WordNet (left) and our WordNet-induced subgraph of BabelNet (WordNet$_{BN}$, right) are used as the underlying semantic network for PPR computation. Note that WordNet's top synsets are related to the target synset via paradigmatic (i.e., hypernymy and meronymy) relations, while WordNet$_{BN}$ includes many syntagmatically-related synsets (e.g., *exper-*

iment for the animal, and *operating system* and *Windows* for the device sense, among others).

4 Experimental Setup

Corpora for sense annotation We used two different corpora to extract sentences: Wikipedia and the United Nations Parallel Corpus (Ziemski et al., 2016). The first is the largest and most up-to-date encyclopedic resource, containing definitional information, the second, on the other hand, is a public collection of parliamentary documents of the United Nations. The application of Train-O-Matic to the two corpora produced two sense-annotated datasets, which we named T-O-M$_{Wiki}$ and T-O-M$_{UN}$, respectively.

Semantic Network We created sense-annotated corpora with Train-O-Matic both when using PPR vectors computed from vanilla WordNet and when using WordNet$_{BN}$, our denser network obtained from the WordNet-induced subgraph of BabelNet (see Section 3).

Gold standard datasets We performed our evaluations using the framework made available by Raganato et al. (2017a) on five different all-words datasets, namely: the Senseval-2 (Edmonds and Cotton, 2001), Senseval-3 (Snyder and Palmer, 2004), SemEval-2007 (Pradhan et al., 2007), SemEval-2013 (Navigli et al., 2013) and SemEval-2015 (Moro and Navigli, 2015) WSD datasets. We focused on nouns only, given the fact that Wikipedia provides connections between nominal synsets only, and therefore contributes mainly to syntagmatic relations between nouns.

Comparison sense-annotated corpora To show the impact of our T-O-M corpora in WSD, we compared its performance on the above gold standard datasets, against training with:

- **SemCor** (Miller et al., 1993), a corpus containing about 226,000 words annotated manually with WordNet senses.

- **One Million Sense-Tagged Instances** (Taghipour and Ng, 2015, OMSTI), a sense-annotated dataset obtained via a semi-automatic approach based on the disambiguation of a parallel corpus, i.e., the United Nations Parallel Corpus, performed by exploiting manually translated word senses. Because OMSTI integrates SemCor to increase coverage, to keep a level playing field we excluded the latter from the corpus.

We note that T-O-M, instead, is fully automatic and does not require any WSD-specific human intervention nor any aligned corpus.

Reference system In all our experiments, we used It Makes Sense (Zhong and Ng, 2010, IMS), a state-of-the-art WSD system based on linear Support Vector Machines, as our reference system for comparing its performance when trained on T-O-M, against the same WSD system trained on other sense-annotated corpora (i.e., SemCor and OMSTI). Following the WSD literature, unless stated otherwise, we report performance in terms of F1, i.e., the harmonic mean of precision and recall.

We note that it is not the purpose of this paper to show that T-O-M, when integrated into IMS, beats all other configurations or alternative systems, but rather to fully automatize the WSD pipeline with performances which are competitive with the state of the art.

Baseline As a traditional baseline in WSD, we used the Most Frequent Sense (MFS) baseline given by the first sense in WordNet. The MFS is a very competitive baseline, due to the sense skewness phenomenon in language (Navigli, 2009).

Number of training sentences per sense Given a target word w, we sorted its senses $Senses(w)$ following the WordNet ordering and selected the top k_i training sentences for the i-th sense according to Formula 6, where:

$$k_i = \frac{1}{i^z} * K \tag{8}$$

with $K = 500$ and $z = 2$ which were tuned on a separate small in-house development dataset[5].

5 Results

5.1 Impact of syntagmatic relations

The first result we report regards the impact of vanilla WordNet vs. our WordNet-induced subgraph of BabelNet (WordNet$_{BN}$) when calculating PPR vectors. As can be seen from Table 2 – which shows the performance of the T-O-M$_{Wiki}$ corpora generated with the two semantic networks – using WordNet for PPR computation decreases

[5] 50 word-sense pairs annotated manually.

Dataset	T-O-M$_{Wiki}$ BN	T-O-M$_{Wiki}$ WN
Senseval-2	**70.5**	70.0
Senseval-3	**67.4**	63.1
SemEval-07	**59.8**	57.9
SemEval-13	**65.5**	63.7
SemEval-15	68.6	**69.5**
ALL	**67.3**	65.7

Table 2: F1 of IMS trained on T-O-M when PPR is obtained from the WordNet graph (WN) and from the WordNet-induced subgraph of BabelNet (BN).

the overall performance of IMS from 0.5 to around 4 points across the five datasets, with an overall loss of 1.6 F1 points. Similar performance losses were observed when using T-O-M$_{UN}$ (see Table 3). This corroborates our hunch discussed in Section 3 that a resource like BabelNet can contribute important syntagmatic relations that are beneficial for identifying (and ranking high) sentences which are semantically relevant for the target word sense. In the following experiments, we report only results using WordNet$_{BN}$.

5.2 Comparison against sense-annotated corpora

We now move to comparing the performance of T-O-M, which is fully automatic, against corpora which are annotated manually (SemCor) and semi-automatically (OMSTI). In Table 3 we show the F1-score of IMS on each gold standard dataset in the evaluation framework and on all datasets merged together (last row), when it is trained with the various corpora described above.

As can be seen, T-O-M$_{Wiki}$ and T-O-M$_{UN}$ obtain higher performance than OMSTI (up to 5.5 points above) on 3 out of 5 datasets, and, overall, T-O-M$_{Wiki}$ scores 1 point above OMSTI. The MFS is in the same ballpark as T-O-M$_{Wiki}$, performing better on some datasets and worse on others. We note that IMS trained on T-O-M$_{Wiki}$ succeeds in surpassing or obtaining the same results as IMS trained on SemCor on SemEval-15 and SemEval-13. We view this as a significant achievement given the total absence of manual effort involved in T-O-M. Because overall T-O-M$_{Wiki}$ outperforms T-O-M$_{UN}$, in what follows we report all the results with T-O-M$_{Wiki}$, except for the domain-oriented evaluation (see Section 5.4).

5.3 Performance without backoff strategy

IMS uses the MFS as a backoff strategy when no sense can be output for a target word in context (Zhong and Ng, 2010). Consequently, the performance of the MFS is mixed up with that of the SVM classifier. As shown in Table 4, OMSTI is able to provide annotated sentences for roughly half of the tokens in the datasets. Train-O-Matic, on the other hand, is able to cover almost all words in each dataset with at least one training sentence. This means that in around 50% of cases OMSTI gives an answer based on the IMS backoff strategy.

To determine the real impact of the different training data, we therefore decided to perform an additional analysis of the IMS performance when the MFS backoff strategy is disabled. Because we suspected the system would not always return a sense for each target word, in this experiment we measured precision, recall and their harmonic mean, i.e., F1. The results in Table 5 confirm our hunch, showing that OMSTI's recall drops heavily, thereby affecting F1 considerably. T-O-M performances, instead, remain high in terms of precision, recall and F1. This confirms that OMSTI relies heavily on data (those obtained for the MFS and from SemCor) that are produced manually, rather than semi-automatically.

5.4 Domain-oriented WSD

To further inspect the ability of T-O-M to enable disambiguation in different domains, we decided to evaluate on specific documents from the various gold standard datasets which could be clearly assigned a domain label. Specifically, we tested on 13 SemEval-13 documents from various domains[6] and 2 SemEval-15 documents (namely, maths & computers, and biomedicine) and carried out two separate tests and evaluations of T-O-M on each domain: once using the MFS backoff strategy, and once not using it. In Tables 6 and 7 we report the results of both T-O-M$_{Wiki}$ and T-O-M$_{UN}$ to determine the impact of the corpus type.

As can be seen in the tables, T-O-M$_{Wiki}$ systematically attains higher scores than OMSTI (except for the biology domain), and, in most cases, attains higher scores than MFS when the backoff is used, with a drastic, systematic increase over OMSTI with both Train-O-Matic configurations

[6] Namely biology, climate, finance, health care, politics, social issues and sport.

in recall and F1 when the backoff strategy is disabled. This demonstrates the usefulness of the corpora annotated by Train-O-Matic not only on open text, but also on specific domains. We note that T-O-M$_{UN}$ obtains the best results in the politics domain, which is the closest domain to the UN corpus from which its training sentences are obtained.

6 Scaling up to Multiple Languages

Experimental Setup In this section we investigate the ability of Train-O-Matic to scale to low-resourced languages, such as Italian and Spanish, for which training data for WSD is not available.

Thanks to BabelNet, in fact, Train-O-Matic can be used to generate sense-annotated data for any language supported by the knowledge base. Thus, in order to build new training datasets for the two languages, we ran Train-O-Matic on their corresponding versions of Wikipedia, then we tuned the two parameters K and z on an in-house development dataset[7]. In contrast to the English setting, in order to calculate Formula 8 we sorted the senses of each word by vertex degree. Finally we used the output data to train IMS.

Results To perform our evaluation we chose the most recent multilingual task (SemEval 2015 task 13) which includes gold data for Italian and Spanish. As can be seen from Table 8 Train-O-Matic enabled IMS to perform better than the best participating system (Manion and Sainudiin, 2014, SUDOKU) in all three settings (All domains, Maths & Computer and Biomedicine). Its performance was in fact, 1 to 3 points higher, with a 6-point peak on Maths & Computer in Spanish and on Biomedicine in Italian. This demonstrates the ability of Train-O-Matic to enable supervised WSD systems to surpass state-of-the-art knowledge-based WSD approaches in low-resourced languages without relying on manually curated data for training.

7 Related Work

There are two mainstream approaches to Word Sense Disambiguation: supervised and knowledge-based approaches. Both suffer in different ways from the so-called knowledge acquisition bottleneck, that is, the difficulty in obtaining an adequate amount of lexical-semantic data: for training in the case of supervised systems, and for enriching semantic networks in the case of knowledge-based ones (Pilehvar and

[7] We set $K = 100$ and $z = 2.3$ for Spanish and $K = 100$ and $z = 2.5$ for Italian.

Navigli, 2014; Navigli, 2009).

State-of-the-art supervised systems include Support Vector Machines such as IMS (Zhong and Ng, 2010) and, more recently, LSTM neural networks with attention and multitask learning (Raganato et al., 2017b) as well as LSTMs paired with nearest neighbours classification (Melamud et al., 2016; Yuan et al., 2016). The latter also integrates a label propagation algorithm in order to enrich the sense annotated dataset. The main difference from our approach is its need for a manually annotated dataset to start the label propagation algorithm, whereas Train-O-Matic is fully automatic. An evaluation against this system would have been interesting, but neither the proprietary training data nor the code are available at the time of writing.

In order to generalize effectively, these supervised systems require large numbers of training instances annotated with senses for each target word occurrence. Overall, this amounts to millions of training instances for each language of interest, a number that is not within reach for any language. In fact, no supervised system has been submitted in major multilingual WSD competitions for languages other than English (Navigli et al., 2013; Moro and Navigli, 2015). To overcome this problem, new methodologies have recently been developed which aim to create sense-tagged corpora automatically. Raganato et al. (2016) developed 7 heuristics to grow the number of hyperlinks in Wikipedia pages. Otegi et al. (2016) applied a different disambiguation pipeline for each language to parallel text in Europarl (Koehn, 2005) and QTLeap (Agirre et al., 2015) in order to enrich them with semantic annotations. Taghipour and Ng (2015), the work closest to ours, exploits the alignment from English to Chinese sentences of the United Nation Parallel Corpus (Ziemski et al., 2016) to reduce the ambiguity of English words and sense-tag English sentences. The assumption is that the second language is less ambiguous than the first one and that hand-made translations of senses are available for each WordNet synset. This approach is, therefore, semi-automatic and relies on certain assumptions, in contrast to Train-O-Matic which is, instead, fully automatic and can be applied to any kind of corpus (and language) depending on the specific need. Earlier attempts at the automatic extraction of training samples were made by Agirre and De Lacalle (2004) and Fernández et al. (2004). Both exploited the monosemous relatives method (Leacock et al., 1998) in order to retrieve sentences from the Web which contained a given monosemous noun or a relative monosemous word (e.g., a synonym, a hypernym, etc.). As can be seen in (Fernández et al., 2004) this approach can lead to the retrieval of very accurate examples, but its main drawback lies in the number of senses covered. In fact, for all those synsets that do not have any monosemous relative, the system is unable to retrieve examples, thus heavily affecting the performance in terms of recall and F1.

Knowledge-based WSD, instead, bypasses the heavy requirement of sense-annotated corpora by applying algorithms that exploit a general-purpose semantic network, such as WordNet, which encodes the relational information that interconnects synsets via different kinds of relation. Approaches include variants of Personalized PageRank (Agirre et al., 2014) and densest subgraph approximation algorithms (Moro et al., 2014) which, thanks to the availability of multilingual resources such as BabelNet, can easily be extended to perform WSD in arbitrary languages. Other approaches to knowledge-based WSD exploit the definitional knowledge contained in a dictionary. The Lesk algorithm (Lesk, 1986) and its variants (Banerjee and Pedersen, 2002; Kilgarriff and Rosenzweig, 2000; Vasilescu et al., 2004) aim to determine the correct sense of a word by comparing each word-sense definition with the context in which the target word appears. The limit of knowledge-based WSD, however, lies in the absence of mechanisms that can take into account the very local context of a target word occurrence, including non-content words such as prepositions and articles. Furthermore, recent studies seem to suggest that such approaches are barely able to surpass supervised WSD systems when they enrich their networks starting from a comparable amount of annotated data (Pilehvar and Navigli, 2014). With T-O-M, rather than further enriching an existing semantic network, we exploit the information available in the network to annotate raw sentences with sense information and train a state-of-the-art supervised WSD system without task-specific human annotations.

8 Conclusion

In this paper we presented Train-O-Matic, a novel approach to the automatic construction of large training sets for supervised WSD in an arbitrary language. Train-O-Matic removes the burden of manual intervention by leveraging the structural semantic information available in the WordNet graph enriched with additional relational information from BabelNet, and achieves performance competitive to that of semi-automatic approaches and, in some cases, of manually-curated training data. T-O-M was shown to provide training data for virtually all the target ambiguous nouns, in marked contrast to alternatives like OMSTI, which covers in many cases around half of the tokens, resorting to the MFS otherwise. Moreover Train-O-Matic has proven to scale well to low-resourced languages, for which no manually annotated dataset exists, surpassing the current state of the art of knowledge-based systems.

We believe that the ability of T-O-M to overcome the current paucity of annotated data for WSD, coupled with video games with a purpose for validation purposes (Jurgens and Navigli, 2014; Vannella et al., 2014), paves the way for high-quality multilingual supervised WSD. All the training corpora, including approximately one million sentences which cover English, Italian and Spanish, are made available to the community at `http://trainomatic.org`.

As future work we plan to extend our approach to verbs, adjectives and adverbs. Following Bennett et al. (2016) we will also experiment on more realistic estimates of $P(s|w)$ in Formula 5 as well as other assumptions made in our work.

Abstract

Universal Dependencies (UD) offer a uniform cross-lingual syntactic representation, with the aim of advancing multilingual applications. Recent work shows that semantic parsing can be accomplished by transforming syntactic dependencies to logical forms. However, this work is limited to English, and cannot process dependency graphs, which allow handling complex phenomena such as control. In this work, we introduce UDEPLAMBDA, a semantic interface for UD, which maps natural language to logical forms in an almost language-independent fashion and can process dependency graphs. We perform experiments on question answering against Freebase and provide German and Spanish translations of the WebQuestions and GraphQuestions datasets to facilitate multilingual evaluation. Results show that UDEPLAMBDA outperforms strong baselines across languages and datasets. For English, it achieves a 4.9 F_1 point improvement over the state-of-the-art on GraphQuestions.

1 Introduction

The Universal Dependencies (UD) initiative seeks to develop cross-linguistically consistent annotation guidelines as well as a large number of uniformly annotated treebanks for many languages (Nivre et al., 2016). Such resources could advance multilingual applications of parsing, improve comparability of evaluation results, enable cross-lingual learning, and more generally support natural language understanding.

Seeking to exploit the benefits of UD for natural language understanding, we introduce UDEPLAMBDA, a semantic interface for UD that maps natural language to logical forms, representing underlying predicate-argument structures, in an almost language-independent manner. Our framework is based on DEPLAMBDA (Reddy et al., 2016) a recently developed method that converts English Stanford Dependencies (SD) to logical forms. The conversion process is illustrated in Figure 1 and discussed in more detail in Section 2. Whereas DEPLAMBDA works only for English, UDEPLAMBDA applies to any language for which UD annotations are available.[1] Moreover, DEPLAMBDA can only process tree-structured inputs whereas UDEPLAMBDA can also process dependency graphs, which allow to handle complex constructions such as control. The different treatments of various linguistic constructions in UD compared to SD also require different handling in UDEPLAMBDA (Section 3.3).

Our experiments focus on Freebase semantic parsing as a testbed for evaluating the framework's multilingual appeal. We convert natural language to logical forms which in turn are converted to machine interpretable formal meaning representations for retrieving answers to questions from Freebase. To facilitate multilingual evaluation, we provide translations of the English WebQuestions (Berant et al., 2013) and GraphQuestions (Su et al., 2016) datasets to German and Spanish. We demonstrate that UDEPLAMBDA can be used to derive logical forms for these languages using a minimal amount of language-specific knowledge. Aside from developing the first multilingual semantic parsing tool for Freebase, we also experimentally show that UDEPLAMBDA outperforms strong baselines across

[*] Work done at the University of Edinburgh

[1] As of v1.3, UD annotations are available for 47 languages at http://universaldependencies.org.

Proceedings of the 2017 Conference on Empirical Methods in Natural Language Processing, pages 89–101
Copenhagen, Denmark, September 7–11, 2017.

languages and datasets. For English, it achieves the strongest result to date on GraphQuestions, with competitive results on WebQuestions. Our implementation and translated datasets are publicly available at https://github.com/sivareddyg/udeplambda.

2 DepLambda

Before describing UDepLambda, we provide an overview of DepLambda (Reddy et al., 2016) on which our approach is based. DepLambda converts a dependency tree to its logical form in three steps: *binarization*, *substitution*, and *composition*, each of which is briefly outlined below. Algorithm 1 describes the steps of DepLambda in lines 4-6, whereas lines 2 and 3 are specific to UDepLambda.

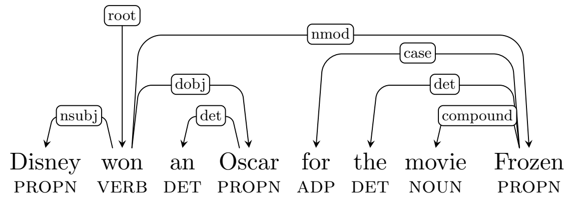
Binarization A dependency tree is first mapped to a Lisp-style s-expression indicating the order of semantic composition. Figure 1(b) shows the s-expression for the sentence *Disney won an Oscar for the movie Frozen*, derived from the dependency tree in Figure 1(a). Here, the sub-expression (dobj won (det Oscar an)) indicates that the logical form of the phrase *won an Oscar* is derived by composing the logical form of the label `dobj` with the logical form of the word *won* and the logical form of the phrase *an Oscar*, derived analogously. The s-expression can also be interpreted as a binarized tree with the dependency label as the root node, and the left and right expressions as subtrees.

A composition hierarchy is employed to impose a strict traversal ordering on the modifiers to each head in the dependency tree. As an example, *won* has three modifiers in Figure 1(a), which according to the composition hierarchy are composed in the order `dobj` > `nmod` > `nsubj`. In constructions like coordination, this ordering is crucial to arrive at the correct semantics. Lines 7-17 in Algorithm 1 describe the binarization step.

Substitution Each symbol in the s-expressions is substituted for a lambda expression encoding its semantics. Words and dependency labels are assigned different types of expressions. In general, words have expressions of the following kind:

ENTITY $\Rightarrow \lambda x.\,\text{word}(x_a)$; e.g. Oscar $\Rightarrow \lambda x.\,\text{Oscar}(x_a)$
EVENT $\Rightarrow \lambda x.\,\text{word}(x_e)$; e.g. won $\Rightarrow \lambda x.\,\text{won}(x_e)$
FUNCTIONAL $\Rightarrow \lambda x.\,\text{TRUE}$; e.g. an $\Rightarrow \lambda x.\,\text{TRUE}$

Here, the subscripts $\cdot_a$ and $\cdot_e$ denote the types of individuals (**Ind**) and events (**Event**), respectively, whereas x denotes a paired variable (x_a, x_e) of type **Ind** × **Event**. Roughly speaking, proper nouns and adjectives invoke ENTITY expressions, verbs and adverbs invoke EVENT expressions, and common nouns invoke both ENTITY and EVENT expressions (see Section 3.3), while remaining words invoke FUNCTIONAL expressions. DepLambda enforces the constraint that every s-expression is of the type $\eta = \textbf{Ind} \times \textbf{Event} \rightarrow \textbf{Bool}$, which simplifies the type system considerably.



(a) The dependency tree for *Disney won an Oscar for the movie Frozen* in the Universal Dependencies formalism.

(nsubj (nmod (dobj won (det Oscar an))
(case (det (comp. Frozen movie) the) for)) Disney)

(b) The binarized s-expression for the dependency tree.

$$\lambda x.\,\exists yzw.\,\text{won}(x_e) \wedge \text{Disney}(y_a) \wedge \text{Oscar}(z_a) \wedge \text{Frozen}(w_a) \wedge \text{movie}(w_a) \wedge \text{arg}_1(x_e, y_a) \wedge \text{arg}_2(x_e, z_a) \wedge \text{nmod.for}(x_e, w_a)$$

(c) The composed lambda-calculus expression.

Figure 1: The mapping of a dependency tree to its logical form with the intermediate s-expression.

Expressions for dependency labels glue the semantics of heads and modifiers to articulate predicate-argument structure. These expressions in general take one of the following forms:

COPY $\Rightarrow \lambda f g x.\,\exists y.\, f(x) \wedge g(y) \wedge \text{rel}(x, y)$
e.g. `nsubj`, `dobj`, `nmod`, `advmod`
INVERT $\Rightarrow \lambda f g x.\,\exists y.\, f(x) \wedge g(y) \wedge \text{rel}^{\text{i}}(y, x)$
e.g. `amod`, `acl`
MERGE $\Rightarrow \lambda f g x.\, f(x) \wedge g(x)$
e.g. `compound`, `appos`, `amod`, `acl`
HEAD $\Rightarrow \lambda f g x.\, f(x)$
e.g. `case`, `punct`, `aux`, `mark` .

As an example of COPY, consider the lambda expression for `dobj` in (dobj won (det Oscar an)): $\lambda f g x.\,\exists y.\, f(x) \wedge g(y) \wedge \text{arg}_2(x_e, y_a)$. This expression takes two functions f and g as input, where f represents the logical form of *won* and g represents the logical form of *an Oscar*. The predicate-argument structure $\text{arg}_2(x_e, y_a)$ indicates that the arg_2 of the event x_e, i.e. *won*, is the individual y_a, i.e. the entity *Oscar*. Since $\text{arg}_2(x_e, y_a)$ mimics the dependency structure dobj(won, Oscar), we refer to the expression kind evoked by `dobj` as COPY.

Expressions that invert the dependency direction are referred to as INVERT (e.g. `amod` in *running horse*); expressions that merge two subexpressions without introducing any relation predicates are referred to as MERGE (e.g. `compound` in *movie Frozen*); and expressions that simply return the parent expression semantics are referred to as HEAD (e.g. `case` in *for Frozen*). While this generalization applies to most dependency labels, several labels take a different logical form not listed here, some of which are discussed in Section 3.3. Sometimes the mapping of dependency label to lambda expression may depend on surrounding part-of-speech tags or dependency labels. For example, `amod` acts as INVERT when the modifier is a verb (e.g. in *running horse*), and as MERGE when the modifier is an adjective (e.g. in *beautiful horse*).[2] Lines 26-32 in Algorithm 1 describe the substitution procedure.

Composition The final logical form is computed by beta-reduction, treating expressions of the form (f x y) as the function f applied to the arguments x and y. For example, (dobj won (det Oscar an)) results in $\lambda x. \exists z. \text{won}(x_e) \wedge \text{Oscar}(z_a) \wedge \text{arg}_2(x_e, z_a)$ when the expression for `dobj` is applied to those for *won* and *(det Oscar an)*. Figure 1(c) shows the logical form for the s-expression in Figure 1(b). The binarized s-expression is recursively converted to a logical form as described in lines 18-25 in Algorithm 1.

3 UDepLambda

We now introduce UDepLambda, a semantic interface for Universal Dependencies.[3] Whereas DepLambda only applies to English Stanford Dependencies, UDepLambda takes advantage of the cross-lingual nature of UD to facilitate an (almost) language independent semantic interface. This is accomplished by restricting the binarization, substitution, and composition steps described above to rely solely on information encoded in the UD representation. As shown in Algorithm 1, lines 4-6 are common to both DepLambda and UDepLambda, whereas lines 2 and 3 applies only to UDepLambda. Importantly, UDepLambda is designed to not rely on lexical forms in a language to assign lambda expressions, but only on information contained in dependency labels and postags.

Algorithm 1: UDepLambda Steps

```
1  Function UDepLambda (depTree):
2      depGraph = Enhancement (depTree)
         #See Figure 2(a) for a depGraph.

However, some linguistic phenomena are language specific (e.g. pronoun-dropping) or lexicalized (e.g. *every* and *the* in English have different semantics, despite being both determiners) and are not encoded in the UD schema. Furthermore, some cross-linguistic phenomena, such as long-distance dependencies, are not part of the core UD representation. To circumvent this limitation, a simple *enhancement* step enriches the original UD representation before binarization takes place (Section 3.1). This step adds to the dependency tree missing syntactic information and long-distance dependencies, thereby creating a graph. Whereas DepLambda is not able to handle graph-structured input, UDep-

[2] We use Tregex (Levy and Andrew, 2006) for substitution mappings and Cornell SPF (Artzi, 2013) as the lambda-calculus implementation. For example, in *running horse*, the tregex */label:amod/=target < /postag:verb/* matches `amod` to its INVERT expression $\lambda f g x. \exists y. f(x) \wedge g(y) \wedge \text{amod}^{\text{i}}(y_e, x_a)$.

[3] In what follows, all references to UD are to UD v1.3.

LAMBDA is designed to work with dependency graphs as well (Section 3.2). Finally, several constructions differ in structure between UD and SD, which requires different handling in the semantic interface (Section 3.3).

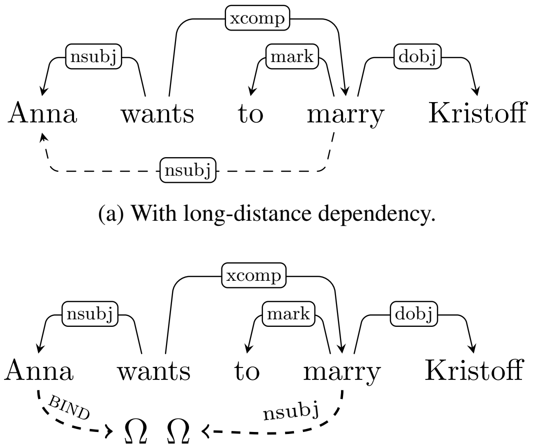
3.1 Enhancement

Both Schuster and Manning (2016) and Nivre et al. (2016) note the necessity of an enhanced UD representation to enable semantic applications. However, such enhancements are currently only available for a subset of languages in UD. Instead, we rely on a small number of enhancements for our main application—semantic parsing for question-answering—with the hope that this step can be replaced by an enhanced UD representation in the future. Specifically, we define three kinds of enhancements: (1) long-distance dependencies; (2) types of coordination; and (3) refined question word tags. These correspond to line 2 in Algorithm 1.

First, we identify long-distance dependencies in relative clauses and control constructions. We follow Schuster and Manning (2016) and find these using the labels `acl` (relative) and `xcomp` (control). Figure 2(a) shows the long-distance dependency in the sentence *Anna wants to marry Kristoff.* Here, *marry* is provided with its missing `nsubj` (dashed arc). Second, UD conflates all coordinating constructions to a single dependency label, `conj`. To obtain the correct coordination scope, we refine `conj` to `conj:verb`, `conj:vp`, `conj:sentence`, `conj:np`, and `conj:adj`, similar to Reddy et al. (2016). Finally, unlike the PTB tags (Marcus et al., 1993) used by SD, the UD part-of-speech tags do not distinguish question words. Since these are crucial to question-answering, we use a small lexicon to refine the tags for determiners (DET), adverbs (ADV) and pronouns (PRON) to DET:WH, ADV:WH and PRON:WH, respectively. Specifically, we use a list of 12 (English), 14 (Spanish) and 35 (German) words, respectively. This is the only part of UDEPLAMBDA that relies on language-specific information. We hope that, as the coverage of morphological features in UD improves, this refinement can be replaced by relying on morphological features, such as the interrogative feature (INT).

3.2 Graph Structures and BIND

To handle graph structures that may result from the enhancement step, such as those in Figure 2(a), we propose a variable-binding mechanism that differs from that of DEPLAMBDA. This is indicated in line 3 of Algorithm 1. First, each long-distance dependency is split into independent arcs as shown in Figure 2(b). Here, Ω is a placeholder for the subject of *marry*, which in turn corresponds to *Anna* as indicated by the binding of Ω via the pseudo-label BIND. We treat BIND like an ordinary dependency label with semantics MERGE and process the resulting tree as usual, via the s-expression:



(a) With long-distance dependency.

(b) With variable binding.

Figure 2: The original and enhanced dependency trees for *Anna wants to marry Kristoff.*

(nsubj (xcomp wants (nsubj (mark
(dobj marry Kristoff) to) Ω) (BIND Anna Ω)) ,

with the lambda-expression substitutions:

wants, *marry* ∈ EVENT; *to* ∈ FUNCTIONAL;
Anna, *Kristoff* ∈ ENTITY;
mark ∈ HEAD; BIND ∈ MERGE;
$\text{xcomp} = \lambda f g x. \exists y. f(x) \wedge g(y) \wedge \text{xcomp}(x_e, y_e)$.

These substitutions are based solely on unlexicalized context. For example, the part-of-speech tag PROPN of *Anna* invokes an ENTITY expression.

The placeholder Ω has semantics $\lambda x.\text{EQ}(x, \omega)$, where $\text{EQ}(u, \omega)$ is true iff u and ω are equal (have the same denotation), which unifies the subject variable of *wants* with the subject variable of *marry*.

After substitution and composition, we get:

$$\lambda z. \exists xywv. \text{wants}(z_e) \wedge \text{Anna}(x_a) \wedge \text{arg}_1(z_e, x_a) \wedge \text{EQ}(x, \omega) \\ \wedge \text{marry}(y_e) \wedge \text{xcomp}(z_e, y_e) \wedge \text{arg}_1(y_e, v_a) \wedge \text{EQ}(v, \omega) \\ \wedge \text{Kristoff}(w_a) \wedge \text{arg}_2(y_e, w_a) \,,$$

This expression may be simplified further by replacing all occurrences of v with x and removing the unification predicates EQ, which results in:

$$\lambda z. \exists xyw. \text{wants}(z_e) \wedge \text{Anna}(x_a) \wedge \text{arg}_1(z_e, x_a) \\ \wedge \text{marry}(y_e) \wedge \text{xcomp}(z_e, y_e) \wedge \text{arg}_1(y_e, x_a) \\ \wedge \text{Kristoff}(w_a) \wedge \text{arg}_2(y_e, w_a) \,.$$

This expression encodes the fact that *Anna* is the arg_1 of the *marry* event, as desired. DEPLAMBDA, in contrast, cannot handle graph-structured input, since it lacks a principled way of generating s-expressions from graphs. Even given the above s-expression, BIND in DEPLAMBDA is defined in a way such that the composition fails to unify v and x, which is crucial for the correct semantics. Moreover, the definition of BIND in DEPLAMBDA does not have a formal interpretation within the lambda calculus, unlike ours.

3.3 Linguistic Constructions

Below, we highlight the most pertinent differences between UDEPLAMBDA and DEPLAMBDA, stemming from the different treatment of various linguistic constructions in UD versus SD.

Prepositional Phrases UD uses a content-head analysis, in contrast to SD, which treats function words as heads of prepositional phrases, Accordingly, the s-expression for the phrase *president in 2009* is (nmod president (case 2009 in)) in UDEPLAMBDA and (prep president (pobj in 2009)) in DEPLAMBDA. To achieve the desired semantics,

$$\lambda x.\, \exists y.\, \text{president}(x_a) \wedge \text{president\_event}(x_e) \wedge \\ \text{arg}_1(x_e, x_a) \wedge \text{2009}(y_a) \wedge \text{prep.in}(x_e, y_a)\,,$$

DEPLAMBDA relies on an intermediate logical form that requires some post-processing, whereas UDEPLAMBDA obtains the desired logical form directly through the following entries:

$$\textit{in} \in \text{FUNCTIONAL};\ \textit{2009} \in \text{ENTITY};\ \text{case} \in \text{HEAD};\\ \textit{president} = \lambda x.\, \text{president}(x_a) \wedge \text{president\_event}(x_e) \\ \wedge\, \text{arg}_1(x_e, x_a)\,;\\ \text{nmod} = \lambda f g x.\, \exists y.\, f(x) \wedge g(y) \wedge \text{nmod.in}(x_e, y_a)\,.$$

Other `nmod` constructions, such as possessives (`nmod:poss`), temporal modifiers (`nmod:tmod`) and adverbial modifiers (`nmod:npmod`), are handled similarly. Note how the common noun *president*, evokes both entity and event predicates above.

Passives DEPLAMBDA gives special treatment to passive verbs, identified by the fine-grained part-of-speech tags in the PTB tag together with dependency context. For example, *An Oscar was won* is analyzed as $\lambda x.\, \text{won.pass}(x_e) \wedge \text{Oscar}(y_a) \wedge \text{arg}_1(x_e, y_a)$, where won.pass represents a passive event. However, UD does not distinguish between active and passive forms.[4] While the labels `nsubjpass` or `auxpass` indicate passive constructions, such clues are sometimes missing, such as in reduced relatives. We therefore opt to not have separate entries for passives, but aim to produce identical logical forms for active and passive forms when possible (for example, by treating `nsubjpass` as direct object). With the following entries,

$$\textit{won} \in \text{EVENT};\ \textit{an, was} \in \text{FUNCTIONAL};\ \text{auxpass} \in \text{HEAD};\\ \text{nsubjpass} = \lambda f g x.\, \exists y.\, f(x) \wedge g(y) \wedge \text{arg}_2(x_e, y_a)\,,$$

the lambda expression for *An Oscar was won* becomes $\lambda x.\, \text{won}(x_e) \wedge \text{Oscar}(y_a) \wedge \text{arg}_2(x_e, y_a)$, identical to that of its active form. However, not having a special entry for passive verbs may have undesirable side-effects. For example, in the reduced-relative construction *Pixar claimed the Oscar won for Frozen*, the phrase *the Oscar won ...* will receive the semantics $\lambda x.\, \text{Oscar}(y_a) \wedge \text{won}(x_e) \wedge \mathbf{arg_1}(x_e, y_a)$, which differs from that of *an Oscar was won*. We leave it to the target application to disambiguate the interpretation in such cases.

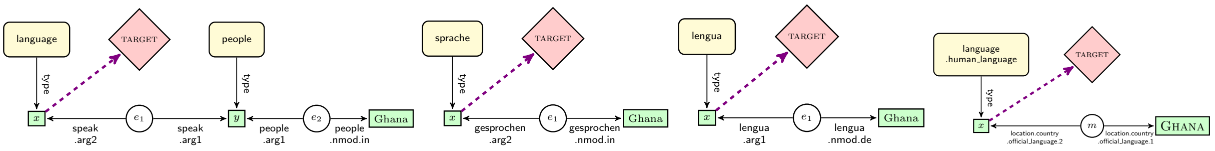
Long-Distance Dependencies As discussed in Section 3.2, we handle long-distance dependencies evoked by clausal modifiers (`acl`) and control verbs (`xcomp`) with the BIND mechanism, whereas DEPLAMBDA cannot handle control constructions. For `xcomp`, as seen earlier, we use the mapping $\lambda f g x.\, \exists y.\, f(x) \wedge g(y) \wedge \text{xcomp}(x_e, y_e)$. For `acl` we use $\lambda f g x.\, \exists y.\, f(x) \wedge g(y)$, to conjoin the main clause and the modifier clause. However, not all `acl` clauses evoke long-distance dependencies, e.g. in *the news that Disney won an Oscar*, the clause *that Disney won an Oscar* is a subordinating conjunction of *news*. In such cases, we instead assign `acl` the INVERT semantics.

Questions Question words are marked with the enhanced part-of-speech tags DET:WH, ADV:WH and PRON:WH, which are all assigned the semantics $\lambda x.\, \$\{\text{word}\}(x_a) \wedge \text{TARGET}(x_a)$. The predicate TARGET indicates that x_a represents the variable of interest, that is the answer to the question.

3.4 Limitations

In order to achieve language independence, UDEPLAMBDA has to sacrifice semantic specificity, since in many cases the semantics is carried by lexical information. Consider the sentences *John broke the window* and *The window broke*. Although it is the *window* that broke in both cases, our inferred logical forms do not canonicalize the relation between *broke* and *window*. To achieve this, we

[4] UD encodes voice as a morphological feature, but most syntactic analyzers do not produce this information yet.



(a) English (b) German (c) Spanish (d) Freebase

Figure 3: The ungrounded graphs for *What language do the people in Ghana speak?*, *Welche Sprache wird in Ghana gesprochen?* and *Cuál es la lengua de Ghana?*, and the corresponding grounded graph.

would have to make the substitution of `nsubj` depend on lexical context, such that when *window* occurs as `nsubj` with *broke*, the predicate arg_2 is invoked rather than arg_1. UDEPLAMBDA does not address this problem, and leave it to the target application to infer context-sensitive semantics of arg_1 and arg_2. To measure the impact of this limitation, we present UDEPLAMBDASRL in Section 4.4 which addresses this problem by relying on semantic roles from semantic role labeling (Palmer et al., 2010).

Other constructions that require lexical information are quantifiers like *every*, *some* and *most*, negation markers like *no* and *not*, and intentional verbs like *believe* and *said*. UD does not have special labels to indicate these. We discuss how to handle quantifiers in this framework in the supplementary material.

Although in the current setup UDEPLAMBDA rules are hand-coded, the number of rules are only proportional to the number of UD labels, making rule-writing manageable.[5] Moreover, we view UDEPLAMBDA as a first step towards learning rules for converting UD to richer semantic representations such as PropBank, AMR, or the Parallel Meaning Bank (Palmer et al., 2005; Banarescu et al., 2013; Abzianidze et al., 2017)..

4 Cross-lingual Semantic Parsing

To study the multilingual nature of UDEPLAMBDA, we conduct an empirical evaluation on question answering against Freebase in three different languages: English, Spanish, and German. Before discussing the details of this experiment, we briefly outline the semantic parsing framework employed.

4.1 Semantic Parsing as Graph Matching

UDEPLAMBDA generates *ungrounded* logical forms that are independent of any knowledge base, such as Freebase. We use GRAPHPARSER (Reddy et al., 2016) to map these logical forms to their grounded Freebase graphs, via corresponding ungrounded graphs. Figures 3(a) to 3(c) show the ungrounded graphs corresponding to logical forms from UDEPLAMBDA, each grounded to the same Freebase graph in Figure 3(d). Here, rectangles denote entities, circles denote events, rounded rectangles denote entity types, and edges between events and entities denote predicates or Freebase relations. Finally, the TARGET node represents the set of values of x that are consistent with the Freebase graph, that is the answer to the question.

GRAPHPARSER treats semantic parsing as a graph-matching problem with the goal of finding the Freebase graphs that are structurally isomorphic to an ungrounded graph and rank them according to a model. To account for structural mismatches, GRAPHPARSER uses two graph transformations: CONTRACT and EXPAND. In Figure 3(a) there are two edges between x and *Ghana*. CONTRACT collapses one of these edges to create a graph isomorphic to Freebase. EXPAND, in contrast, adds edges to connect the graph in the case of disconnected components. The search space is explored by beam search and model parameters are estimated with the averaged structured perceptron (Collins, 2002) from training data consisting of question-answer pairs, using answer F_1-score as the objective.

4.2 Datasets

We evaluate our approach on two public benchmarks of question answering against Freebase: WebQuestions (Berant et al., 2013), a widely used benchmark consisting of English questions and their answers, and GraphQuestions (Su et al., 2016), a recently released dataset of English questions with both their answers and grounded logical forms.

[5] UD v1.3 has 40 dependency labels, and the number of substitution rules in UDEPLAMBDA are 61, with some labels having multiple rules, and some representing lexical semantics.

While WebQuestions is dominated by simple entity-attribute questions, GraphQuestions contains a large number of compositional questions involving aggregation (e.g. *How many children of Eddard Stark were born in Winterfell?*) and comparison (e.g. *In which month does the average rainfall of New York City exceed 86 mm?*). The number of training, development and test questions is 2644, 1134, and 2032, respectively, for WebQuestions and 1794, 764, and 2608 for GraphQuestions.

To support multilingual evaluation, we created translations of WebQuestions and GraphQuestions to German and Spanish. For WebQuestions two professional annotators were hired per language, while for GraphQuestions we used a trusted pool of 20 annotators per language (with a single annotator per question). Examples of the original questions and their translations are provided in Table 1.

	WebQuestions
en	What language do the people in Ghana speak?
de	Welche Sprache wird in Ghana gesprochen?
es	¿Cuál es la lengua de Ghana?
en	Who was Vincent van Gogh inspired by?
de	Von wem wurde Vincent van Gogh inspiriert?

1	89.6	82.8	86.7	47.2	39.9	39.5
10	95.7	91.2	94.0	56.9	48.4	51.6

Table 2: Structured perceptron *k*-best entity linking accuracies on the development sets.

4.3 Implementation Details

Here we provide details on the syntactic analyzers employed, our entity resolution algorithm, and the features used by the grounding model.

Dependency Parsing The English, Spanish, and German Universal Dependencies (UD) treebanks (v1.3; Nivre et al 2016) were used to train part of speech taggers and dependency parsers. We used a bidirectional LSTM tagger (Plank et al., 2016) and a bidirectional LSTM shift-reduce parser (Kiperwasser and Goldberg, 2016). Both the tagger and parser require word embeddings. For English, we used GloVe embeddings (Pennington et al., 2014) trained on Wikipedia and the Gigaword corpus. For German and Spanish, we used SENNA embeddings (Collobert et al., 2011; Al-Rfou et al., 2013) trained on Wikipedia corpora (589M words German; 397M words Spanish).[6] Measured on the UD test sets, the tagger accuracies are 94.5 (English), 92.2 (German), and 95.7 (Spanish), with corresponding labeled attachment parser scores of 81.8, 74.7, and 82.2.

Entity Resolution We follow Reddy et al. (2016) and resolve entities in three steps: (1) potential entity spans are identified using seven handcrafted part-of-speech patterns; (2) each span is associated with potential Freebase entities according to the Freebase/KG API; and (3) the 10-best entity linking lattices, scored by a structured perceptron, are input to GRAPHPARSER, leaving the final disambiguation to the semantic parsing problem. Table 2 shows the 1-best and 10-best entity disambiguation F_1-scores for each language and dataset.

Features We use features similar to Reddy et al. (2016): *basic* features of words and Freebase relations, and *graph* features crossing ungrounded events with grounded relations, ungrounded types with grounded relations, and ungrounded answer type crossed with a binary feature indicating if the answer is a number. In addition, we add features encoding the *semantic* similarity of ungrounded events and Freebase relations. Specifically, we used the cosine similarity of the translation-invariant embeddings of Huang et al. (2015).[7]

4.4 Comparison Systems

We compared UDEPLAMBDA to four versions of GRAPHPARSER that operate on different representations, in addition to prior work.

SINGLEEVENT This model resembles the learning-to-rank model of Bast and Haussmann (2015). An ungrounded graph is generated by connecting all entities in the question with the TARGET node, representing a single event. Note that this

[6] https://sites.google.com/site/rmyeid/projects/polyglot.

[7] http://128.2.220.95/multilingual/data/.

Method	WebQuestions en	de	es	GraphQuestions en	de	es
SINGLEEVENT	48.5	45.6	46.3	15.9	8.8	11.4
DEPTREE	48.8	45.9	46.4	16.0	8.3	11.3
CCGGRAPH	49.5	–	–	15.9	–	–
UDEPLAMBDA	49.5	46.1	47.5	17.7	9.5	12.8
UDEPLAMBDASRL	49.8	46.2	47.0	17.7	9.1	12.7

Table 3: F_1-scores on the test data.

baseline cannot handle compositional questions, or those with aggregation or comparison.

DEPTREE An ungrounded graph is obtained directly from the original dependency tree. An event is created for each parent and its dependents in the tree. Each dependent is linked to this event with an edge labeled with its dependency relation, while the parent is linked to the event with an edge labeled arg_0. If a word is a question word, an additional TARGET predicate is attached to its entity node.

CCGGRAPH This is the CCG-based semantic representation of Reddy et al. (2014). Note that this baseline exists only for English.

UDEPLAMBDASRL This is similar to UDEPLAMBDA except that instead of assuming `nsubj`, `dobj` and `nsubjpass` correspond to arg_1, arg_2 and arg_2, we employ semantic role labeling to identify the correct interpretation. We used the systems of Roth and Woodsend (2014) for English and German and Bjrkelund et al. (2009) for Spanish trained on the CoNLL-2009 dataset (Haji et al., 2009).[8]

4.5 Results

Table 3 shows the performance of GRAPHPARSER with these different representations. Here and in what follows, we use average F_1-score of predicted answers (Berant et al., 2013) as the evaluation metric. We first observe that UDEPLAMBDA consistently outperforms the SINGLEEVENT and DEPTREE representations in all languages.

For English, performance is on par with CCGGRAPH, which suggests that UDEPLAMBDA does not sacrifice too much specificity for universality. With both datasets, results are lower for German compared to Spanish. This agrees with the lower performance of the syntactic parser on the German portion of the UD treebank. While UDEPLAMBDASRL performs better than UDEPLAMBDA on WebQuestions for English, we do not see large performance gaps in other settings, suggesting that GRAPHPARSER is either able to learn context-sensitive semantics of ungrounded predicates or that the datasets do not contain ambiguous `nsubj`, `dobj` and `nsubjpass` mappings. Finally, while these results confirm that GraphQuestions is much harder compared to WebQuestions, we note that both datasets predominantly contain single-hop questions, as indicated by the competitive performance of SINGLEEVENT on both datasets.

Method	GraphQ.	WebQ.
SEMPRE (Berant et al., 2013)	10.8	35.7
JACANA (Yao and Van Durme, 2014)	5.1	33.0
PARASEMPRE (Berant and Liang, 2014)	12.8	39.9
QA (Yao, 2015)	–	44.3
AQQU (Bast and Haussmann, 2015)	–	49.4
AGENDAIL (Berant and Liang, 2015)	–	49.7

UDEPLAMBDA	17.7	49.5

Table 4: F_1-scores on the English GraphQuestions and WebQuestions test sets (results with additional task-specific resources in parentheses).

Table 4 compares UDEPLAMBDA with previously published models which exist only for English and have been mainly evaluated on WebQuestions. These are either symbolic like ours (first block) or employ neural networks (second block). Results for models using additional task-specific training resources, such as ClueWeb09, Wikipedia, or SimpleQuestions (Bordes et al., 2015) are shown in parentheses. On GraphQuestions, we achieve a new state-of-the-art result with a gain of 4.8 F_1-points over the previously reported best result. On WebQuestions we are 2.1 points below the best model using comparable resources, and 3.8 points below the state of the art. Most related to our work is the English-specific system of Reddy et al. (2016). We attribute the 0.8 point difference in F_1-score to their use of the more fine-grained PTB tag set and Stanford Dependencies.

5 Related Work

Our work continues the long tradition of building logical forms from syntactic representations initiated by Montague (1973). The literature is rife with

[8] The parser accuracies (%) are 87.33, 81.38 and 79.91for English, German and Spanish respectively.

attempts to develop semantic interfaces for HPSG (Copestake et al., 2005), LFG (Kaplan and Bresnan, 1982; Dalrymple et al., 1995; Crouch and King, 2006), TAG (Kallmeyer and Joshi, 2003; Gardent and Kallmeyer, 2003; Nesson and Shieber, 2006), and CCG (Baldridge and Kruijff, 2002; Bos et al., 2004; Artzi et al., 2015). Unlike existing semantic interfaces, UDEPLAMBDA uses dependency syntax, a widely available syntactic resource.

A common trend in previous work on semantic interfaces is the reliance on rich typed feature structures or semantic types coupled with strong type constraints, which can be very informative but unavoidably language specific. Instead, UDEPLAMBDA relies on generic unlexicalized information present in dependency treebanks and uses a simple type system (one type for dependency labels, and one for words) along with a combinatory mechanism, which avoids type collisions. Earlier attempts at extracting semantic representations from dependencies have mainly focused on language-specific dependency representations (Spreyer and Frank, 2005; Simov and Osenova, 2011; Hahn and Meurers, 2011; Reddy et al., 2016; Falke et al., 2016; Beltagy, 2016), and multi-layered dependency annotations (Jakob et al., 2010; Bédaride and Gardent, 2011). In contrast, UDEPLAMBDA derives semantic representations for multiple languages in a common schema directly from Universal Dependencies. This work parallels a growing interest in creating other forms of multilingual semantic representations (Akbik et al., 2015; Vanderwende et al., 2015; White et al., 2016; Evang and Bos, 2016).

We evaluate UDEPLAMBDA on semantic parsing for question answering against a knowledge base. Here, the literature offers two main modeling paradigms: (1) learning of task-specific grammars that directly parse language to a grounded representation (Zelle and Mooney, 1996; Zettlemoyer and Collins, 2005; Berant et al., 2013; Flanigan et al., 2014; Pasupat and Liang, 2015; Groschwitz et al., 2015); and (2) converting language to a linguistically motivated task-independent representation that is then mapped to a grounded representation (Kwiatkowski et al., 2013; Reddy et al., 2014; Krishnamurthy and Mitchell, 2015; Gardner and Krishnamurthy, 2017). Our work belongs to the latter paradigm, as we map natural language to Freebase indirectly via logical forms. Capitalizing on natural-language syntax affords interpretability, scalability, and reduced duplication of effort across applications (Bender et al., 2015). Our work also relates to literature on parsing multiple languages to a common executable representation (Cimiano et al., 2013; Haas and Riezler, 2016). However, existing approaches still map to the target meaning representations (more or less) directly (Kwiatkowksi et al., 2010; Jones et al., 2012; Jie and Lu, 2014).

6 Conclusions

We introduced UDEPLAMBDA, a semantic interface for Universal Dependencies, and showed that the resulting semantic representation can be used for question-answering against a knowledge base in multiple languages. We provided translations of benchmark datasets in German and Spanish, in the hope to stimulate further multilingual research on semantic parsing and question answering in general. We have only scratched the surface when it comes to applying UDEPLAMBDA to natural language understanding tasks. In the future, we would like to explore how this framework can benefit applications such as summarization (Liu et al., 2015) and machine reading (Sachan and Xing, 2016).

Acknowledgements

This work greatly benefited from discussions with Michael Collins, Dipanjan Das, Federico Fancellu, Julia Hockenmaier, Tom Kwiatkowski, Adam Lopez, Valeria de Paiva, Martha Palmer, Fernando Pereira, Emily Pitler, Vijay Saraswat, Nathan Schneider, Bonnie Webber, Luke Zettlemoyer, and the members of ILCC Edinburgh University, the Microsoft Research Redmond NLP group, the Stanford NLP group, and the UW NLP and Linguistics group. We thank Reviewer 2 for useful feedback. The authors would also like to thank the Universal Dependencies community for the treebanks and documentation. This research is supported by a Google PhD Fellowship to the first author. We acknowledge the financial support of the European Research Council (Lapata; award number 681760).

Mimicking Word Embeddings using Subword RNNs

Yuval Pinter **Robert Guthrie** **Jacob Eisenstein**

School of Interactive Computing
Georgia Institute of Technology
{uvp,rguthrie3,jacobe}@gatech.edu

Abstract

Word embeddings improve generalization over lexical features by placing each word in a lower-dimensional space, using distributional information obtained from unlabeled data. However, the effectiveness of word embeddings for downstream NLP tasks is limited by out-of-vocabulary (OOV) words, for which embeddings do not exist. In this paper, we present MIMICK, an approach to generating OOV word embeddings compositionally, by learning a function from spellings to distributional embeddings. Unlike prior work, MIMICK does not require re-training on the original word embedding corpus; instead, learning is performed at the type level. Intrinsic and extrinsic evaluations demonstrate the power of this simple approach. On 23 languages, MIMICK improves performance over a word-based baseline for tagging part-of-speech and morphosyntactic attributes. It is competitive with (and complementary to) a supervised character-based model in low-resource settings.

1 Introduction

One of the key advantages of word embeddings for natural language processing is that they enable generalization to words that are unseen in labeled training data, by embedding lexical features from large unlabeled datasets into a relatively low-dimensional Euclidean space. These low-dimensional embeddings are typically trained to capture distributional similarity, so that information can be shared among words that tend to appear in similar contexts.

However, it is not possible to enumerate the entire vocabulary of any language, and even large unlabeled datasets will miss terms that appear in later applications. The issue of how to handle these *out-of-vocabulary* (OOV) words poses challenges for embedding-based methods. These challenges are particularly acute when working with low-resource languages, where even unlabeled data may be difficult to obtain at scale. A typical solution is to abandon hope, by assigning a single OOV embedding to all terms that do not appear in the unlabeled data.

We approach this challenge from a quasi-generative perspective. Knowing nothing of a word except for its embedding and its written form, we attempt to learn the former from the latter. We train a recurrent neural network (RNN) on the character level with the embedding as the target, and use it later to predict vectors for OOV words in any downstream task. We call this model the MIMICK-RNN, for its ability to read a word's spelling and mimick its distributional embedding.

Through nearest-neighbor analysis, we show that vectors learned via this method capture both word-shape features and lexical features. As a result, we obtain reasonable near-neighbors for OOV abbreviations, names, novel compounds, and orthographic errors. Quantitative evaluation on the Stanford RareWord dataset (Luong et al., 2013) provides more evidence that these character-based embeddings capture word similarity for rare and unseen words.

As an extrinsic evaluation, we conduct experiments on joint prediction of part-of-speech tags and morphosyntactic attributes for a diverse set of 23 languages, as provided in the Universal Dependencies dataset (De Marneffe et al., 2014). Our model shows significant improvement

Proceedings of the 2017 Conference on Empirical Methods in Natural Language Processing, pages 102–112
Copenhagen, Denmark, September 7–11, 2017. ©2017 Association for Computational Linguistics

across the board against a single *UNK*-embedding backoff method, and obtains competitive results against a supervised character-embedding model, which is trained end-to-end on the target task. In low-resource settings, our approach is particularly effective, and is complementary to supervised character embeddings trained from labeled data. The MIMICK-RNN therefore provides a useful new tool for tagging tasks in settings where there is limited labeled data. Models and code are available at `www.github.com/yuvalpinter/mimick`.

2 Related Work

Compositional models for embedding rare and unseen words. Several studies make use of morphological or orthographic information when training word embeddings, enabling the prediction of embeddings for unseen words based on their internal structure. Botha and Blunsom (2014) compute word embeddings by summing over embeddings of the morphemes; Luong et al. (2013) construct a recursive neural network over each word's morphological parse; Bhatia et al. (2016) use morpheme embeddings as a prior distribution over probabilistic word embeddings. While morphology-based approaches make use of meaningful linguistic substructures, they struggle with names and foreign language words, which include out-of-vocabulary morphemes. Character-based approaches avoid these problems: for example, Kim et al. (2016) train a recurrent neural network over words, whose embeddings are constructed by convolution over character embeddings; Wieting et al. (2016) learn embeddings of character n-grams, and then sum them into word embeddings. In all of these cases, the model for composing embeddings of subword units into word embeddings is learned by optimizing an objective over a large unlabeled corpus. In contrast, our approach is a post-processing step that can be applied to any set of word embeddings, regardless of how they were trained. This is similar to the "retrofitting" approach of Faruqui et al. (2015), but rather than smoothing embeddings over a graph, we learn a function to build embeddings compositionally.

Supervised subword models. Another class of methods learn task-specific character-based word embeddings within end-to-end supervised systems. For example, Santos and Zadrozny (2014) build word embeddings by convolution over characters, and then perform part-of-speech (POS) tagging using a local classifier; the tagging objective drives the entire learning process. Ling et al. (2015) propose a multi-level long short-term memory (LSTM; Hochreiter and Schmidhuber, 1997), in which word embeddings are built compositionally from an LSTM over characters, and then tagging is performed by an LSTM over words. Plank et al. (2016) show that concatenating a character-level or bit-level LSTM network to a word representation helps immensely in POS tagging. Because these methods learn from labeled data, they can cover only as much of the lexicon as appears in their labeled training sets. As we show, they struggle in several settings: low-resource languages, where labeled training data is scarce; morphologically rich languages, where the number of morphemes is large, or where the mapping from form to meaning is complex; and in Chinese, where the number of characters is orders of magnitude larger than in non-logographic scripts. Furthermore, supervised subword models can be combined with MIMICK, offering additive improvements.

Morphosyntactic attribute tagging. We evaluate our method on the task of tagging word tokens for their morphosyntactic attributes, such as gender, number, case, and tense. The task of morpho-syntactic tagging dates back at least to the mid 1990s (Oflazer and Kuruöz, 1994; Hajič and Hladká, 1998), and interest has been rejuvenated by the availability of large-scale multilingual morphosyntactic annotations through the Universal Dependencies (UD) corpus (De Marneffe et al., 2014). For example, Faruqui et al. (2016) propose a graph-based technique for propagating type-level morphological information across a lexicon, improving token-level morphosyntactic tagging in 11 languages, using an SVM tagger. In contrast, we apply a neural sequence labeling approach, inspired by the POS tagger of Plank et al. (2016).

3 MIMICK Word Embeddings

We approach the problem of out-of-vocabulary (OOV) embeddings as a **generation** problem: regardless of how the original embeddings were created, we assume there is a generative wordform-based protocol for creating these embeddings. By training a model over the existing vocabulary, we can later use that model for predicting the embedding of an unseen word.

Formally: given a language $\mathcal{L}$, a vocabulary $\mathcal{V} \subseteq \mathcal{L}$ of size V, and a pre-trained embeddings table $\mathcal{W} \in \mathbb{R}^{V \times d}$ where each word $\{w_k\}_{k=1}^{V}$ is assigned a vector $\boldsymbol{e}_k$ of dimension d, our model is trained to find the function $f : \mathcal{L} \rightarrow \mathbb{R}^d$ such that the projected function $f|_{\mathcal{V}}$ approximates the assignments $f(w_k) \approx \boldsymbol{e}_k$. Given such a model, a new word $w_{k^*} \in \mathcal{L} \setminus \mathcal{V}$ can now be assigned an embedding $\boldsymbol{e}_{k^*} = f(w_{k^*})$.

Our predictive function of choice is a **Word Type Character Bi-LSTM**. Given a word with character sequence $w = \{c_i\}_1^n$, a forward-LSTM and a backward-LSTM are run over the corresponding character embeddings sequence $\{\boldsymbol{e}_i^{(c)}\}_1^n$. Let $\boldsymbol{h}_f^n$ represent the final hidden vector for the forward-LSTM, and let $\boldsymbol{h}_b^0$ represent the final hidden vector for the backward-LSTM. The word embedding is computed by a multilayer perceptron:

$$f(w) = \mathbf{O}_T \cdot g(\mathbf{T}_h \cdot [\boldsymbol{h}_f^n; \boldsymbol{h}_b^0] + \boldsymbol{b}_h) + \boldsymbol{b}_T, \quad (1)$$

where $\mathbf{T}_h, \boldsymbol{b}_h$ and $\mathbf{O}_T, \boldsymbol{b}_T$ are parameters of affine transformations, and g is a nonlinear elementwise function. The model is presented in Figure 1.

The training objective is similar to that of Yin and Schütze (2016). We match the predicted embeddings $f(w_k)$ to the pre-trained word embeddings e_{w_k}, by minimizing the squared Euclidean distance,

$$\mathcal{L} = \|f(w_k) - \boldsymbol{e}_{w_k}\|_2^2 . \quad (2)$$

By backpropagating from this loss, it is possible to obtain local gradients with respect to the parameters of the LSTMs, the character embeddings, and the output model. The ultimate output of the training phase is the character embeddings matrix $\mathbf{C}$ and the parameters of the neural network: $\mathcal{M} = \{\mathbf{C}, \mathbf{F}, \mathbf{B}, \mathbf{T}_h, \boldsymbol{b}_h, \mathbf{O}_T, \boldsymbol{b}_T\}$, where $\mathbf{F}, \mathbf{B}$ are the forward and backward LSTM component parameters, respectively.

3.1 MIMICK Polyglot Embeddings

The pretrained embeddings we use in our experiments are obtained from Polyglot (Al-Rfou et al., 2013), a multilingual word embedding effort. Available for dozens of languages, each dataset contains 64-dimension embeddings for the 100,000 most frequent words in a language's training corpus (of variable size), as well as an *UNK* embedding to be used for OOV words. Even with this vocabulary size, querying words from respective UD corpora (train + dev + test) yields high OOV rates: in at least half of the 23 languages in our experiments (see Section 5), 29.1% or more of the word types do not appear in the Polyglot vocabulary. The token-level median rate is 9.2%.[1]

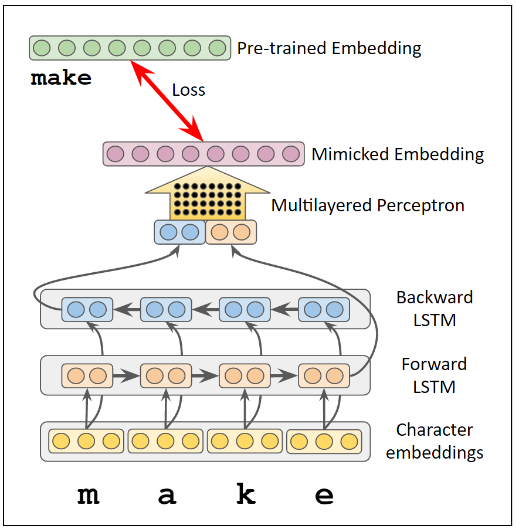

Figure 1: MIMICK model architecture.

Applying our MIMICK algorithm to Polyglot embeddings, we obtain a prediction model for each of the 23 languages. Based on preliminary testing on randomly selected held-out development sets of 1% from each Polyglot vocabulary (with error calculated as in Equation 2), we set the following hyper-parameters for the remainder of the experiments: character embedding dimension = 20; one LSTM layer with 50 hidden units; 60 training epochs with no dropout; nonlinearity function $g = \tanh$.[2] We initialize character embeddings randomly, and use DyNet to implement the model (Neubig et al., 2017).

Nearest-neighbor examination. As a preliminary sanity check for the validity of our protocol, we examined nearest-neighbor samples in languages for which speakers were available: English, Hebrew, Tamil, and Spanish. Table 1 presents selected English OOV words with

[1] Some OOV counts, and resulting model performance, may be adversely affected by tokenization differences between Polyglot and UD. Notably, some languages such as Spanish, Hebrew and Italian exhibit **relational synthesis** wherein words of separate grammatical phrases are joined into one form (e.g. Spanish *del* = *de* + *el*, 'from the-masc.-sg.'). For these languages, the UD annotations adhere to the sub-token level, while Polyglot does not perform sub-tokenization. As this is a real-world difficulty facing users of out-of-the-box embeddings, we do not patch it over in our implementations or evaluation.

[2] Other settings, described below, were tuned on the supervised downstream tasks.

OOV word	Nearest neighbors	OOV word	Nearest neighbors
MCT	AWS OTA APT PDM SMP	compartmentalize	formalize rationalize discern prioritize validate
McNeally	Howlett Gaughan McCallum Blaney	pesky	euphoric disagreeable horrid ghastly horrifying
Vercellotti	Martinelli Marini Sabatini Antonelli	lawnmower	tradesman bookmaker postman hairdresser
Secretive	Routine Niche Turnaround Themed	developiong	compromising inflating shrinking straining
corssing	slicing swaying pounding grasping	hurtling	splashing pounding swaying slicing rubbing
flatfish	slimy jerky watery glassy wrinkle	expectedly	legitimately profoundly strangely energetically

Table 1: Nearest-neighbor examples for the English MIMICK model.

their nearest in-vocabulary Polyglot words computed by cosine similarity. These examples demonstrate several properties: (a) word shape is learned well (acronyms, capitalizations, suffixes); (b) the model shows robustness to typos (e.g., *develop**iong***, *c**or**ssing*); (c) part-of-speech is learned across multiple suffixes (*pesky – euphoric, ghastly*); (d) word compounding is detected (e.g., *lawnmower – bookmaker, postman*); (e) semantics are not learned well (as is to be expected from the lack of context in training), but there are surprises (e.g., *flatfish – slimy, watery*). Table 2 presents examples from Hebrew that show learned properties can be extended to nominal morphosyntactic attributes (gender, number – first two examples) and even relational syntactic subword forms such as genetive markers (third example). Names are learned (fourth example) despite the lack of casing in the script. Spanish examples exhibit word-shape and part-of-speech learning patterns with some loose semantics: for example, the plural adjective form *prenatales* is similar to other family-related plural adjectives such as *patrimoniales* and *generacionales*. Tamil displays some semantic similarities as well: e.g. *enjineer* ('engineer') predicts similarity to other professional terms such as *kalviyiyal* ('education'), *thozhilnutpa* ('technical'), and *iraanuva* ('military').

Stanford RareWords. The Stanford RareWord evaluation corpus (Luong et al., 2013) focuses on predicting word similarity between pairs involving low-frequency English words, predominantly ones with common morphological affixes. As these words are unlikely to be above the cutoff threshold for standard word embedding models, they emphasize the performance on OOV words.

For evaluation of our MIMICK model on the RareWord corpus, we trained the Variational Embeddings algorithm (VarEmbed; Bhatia et al., 2016) on a 20-million-token, 100,000-type Wikipedia corpus, obtaining 128-dimension word embeddings for all words in the test corpus. VarEmbed estimates a prior distribution over word embeddings, conditional on the morphological composition. For in-vocabulary words, a posterior is estimated from unlabeled data; for out-of-vocabulary words, the expected embedding can be obtained from the prior alone. In addition, we compare to FastText (Bojanowski et al., 2016), a high-vocabulary, high-dimensionality embedding benchmark.

The results, shown in Table 3, demonstrate that the MIMICK RNN recovers about half of the loss in performance incurred by the original Polyglot training model due to out-of-vocabulary words in the "All pairs" condition. MIMICK also outperforms VarEmbed. FastText can be considered an upper bound: with a vocabulary that is 25 times larger than the other models, it was missing words from only 44 pairs on this data.

4 Joint Tagging of Parts-of-Speech and Morphosyntactic Attributes

The Universal Dependencies (UD) scheme (De Marneffe et al., 2014) features a minimal set of 17 POS tags (Petrov et al., 2012) and supports tagging further language-specific features using attribute-specific inventories. For example, a verb in Turkish could be assigned a value for the evidentiality attribute, one which is absent from Danish. These additional morphosyntactic attributes are marked in the UD dataset as optional per-token attribute-value pairs.

Our approach for tagging morphosyntactic attributes is similar to the part-of-speech tagging model of Ling et al. (2015), who attach a projection layer to the output of a sentence-level bidirectional LSTM. We extend this approach to morphosyntactic tagging by duplicating this projection layer for each attribute type. The input to our multilayer perceptron (MLP) projection network is the hidden state produced for each token in the sentence by an underlying LSTM, and the output is

OOV word	Nearest neighbors
TTGFM '(s/y) will come true',	TPTVR '(s/y) will solve', TBTL '(s/y) will cancel', TSIR '(s/y) will remove'
GIAVMTRIIM 'geometric(m-pl)'$_2$	ANTVMIIM 'anatomic(m-pl)', GAVMTRIIM 'geometric(m-pl)'$_1$
BQFTNV 'our request'	IVFBIHM 'their(m) residents', XTAIHM 'their(m) sins', IRVFTV 'his inheritance'
RIC'RDSVN 'Richardson'	AVISTRK 'Eustrach', QMINQA 'Kaminka', GVLDNBRG 'Goldenberg'

Table 2: Nearest-neighbor examples for Hebrew (Transcriptions per Sima'an et al. (2001)). 's/y' stands for 'she/you-m.sg.'; subscripts denote alternative spellings, standard form being 'X'$_1$.

	Emb. dim	Vocab size	Polyglot in-vocab $N = 862$	All pairs $N = 2034$

attribute-specific probability distributions over the possible values for each attribute on each token in the sequence. Formally, for a given attribute a with possible values $v \in V_a$, the tagging probability for the i'th word in a sentence is given by:

$$\Pr(a_{w_i} = v) = (\text{Softmax}(\phi(\boldsymbol{h}_i)))_v\ , \qquad (3)$$

with

$$\phi(\boldsymbol{h}_i) = \mathbf{O}_W^a \cdot \tanh(\mathbf{W}_h^a \cdot \boldsymbol{h}_i + \boldsymbol{b}_h^a) + \boldsymbol{b}_W^a, \qquad (4)$$

where $\boldsymbol{h}_i$ is the i'th hidden state in the underlying LSTM, and $\phi(\boldsymbol{h}_i)$ is a two-layer feedforward neural network, with weights $\mathbf{W}_h^a$ and $\mathbf{O}_W^a$. We apply a softmax transformation to the output; the value at position v is then equal to the probability of attribute v applying to token w_i. The input to the underlying LSTM is a sequence of word embeddings, which are initialized to the Polyglot vectors when possible, and to MIMICK vectors when necessary. Alternative initializations are considered in the evaluation, as described in Section 5.2.

Each tagged attribute sequence (including POS tags) produces a loss equal to the sum of negative log probabilities of the true tags. One way to combine these losses is to simply compute the **sum loss**. However, many languages have large differences in sparsity across morpho-syntactic attributes, as apparent from Table 4 (rightmost column). We therefore also compute a **weighted sum loss**, in which each attribute is weighted by the proportion of training corpus tokens on which it is assigned a non-*NONE* value. Preliminary experiments on development set data were inconclusive across languages and training set sizes, and so we kept the simpler sum loss objective for the remainder of our study. In all cases, part-of-speech tagging was less accurate when learned jointly with morphosyntactic attributes. This may be because the attribute loss acts as POS-unrelated "noise" affecting the common LSTM layer and the word embeddings.

5 Experimental Settings

The morphological complexity and compositionality of words varies greatly across languages. While a morphologically-rich agglutinative language such as Hungarian contains words that carry many attributes as fully separable morphemes, a sentence in an analytic language such as Vietnamese may have not a single polymorphemic or inflected word in it. To see whether this property is influential on our MIMICK model and its performance in the downstream tagging task, we select languages that comprise a sample of multiple morphological patterns. Language family and script type are other potentially influential factors in an orthography-based approach such as ours, and so we vary along these parameters as well. We also considered language selection recommendations from de Lhoneux and Nivre (2016) and Schluter and Agić (2017).

As stated above, our approach is built on the Polyglot word embeddings. The intersection of the Polyglot embeddings and the UD dataset (version 1.4) yields 44 languages. Of these, many are under-annotated for morphosyntactic attributes; we select twenty-three sufficiently-tagged languages, with the exception of Indonesian.[3] Table 4 presents the selected languages and their typological properties. As an additional proxy for mor-

[3] Vietnamese has no attributes by design; it is a pure analytic language.

phological expressiveness, the rightmost column shows the proportion of UD tokens which are annotated with any morphosyntactic attribute.

5.1 Metrics

As noted above, we use the UD datasets for testing our MIMICK algorithm on 23 languages[4] with the supplied train/dev/test division. We measure part-of-speech tagging by overall token-level accuracy.

For morphosyntactic attributes, there does not seem to be an agreed-upon metric for reporting performance. Dzeroski et al. (2000) report per-tag accuracies on a morphosyntactically tagged corpus of Slovene. Faruqui et al. (2016) report macro-averages of F1 scores of 11 languages from UD 1.1 for the various attributes (e.g., part-of-speech, case, gender, tense); recall and precision were calculated for the full set of each attribute's values, pooled together.[5] Agić et al. (2013) report separately on parts-of-speech and morphosyntactic attribute accuracies in Serbian and Croatian, as well as precision, recall, and F1 scores per tag. Georgiev et al. (2012) report token-level accuracy for exact all-attribute tags (e.g. 'Ncmsh' for "Noun short masculine singular definite") in Bulgarian, reaching a tagset of size 680. Müller et al. (2013) do the same for six other languages. We report **micro F1**: each token's value for each attribute is compared separately with the gold labeling, where a correct prediction is a matching non-*NONE* attribute/value assignment. Recall and precision are calculated over the entire set, with F1 defined as their harmonic mean.

5.2 Models

We implement and test the following models:

No-Char. Word embeddings are initialized from Polyglot models, with unseen words assigned the Polyglot-supplied *UNK* vector. Following tuning experiments on all languages with cased script, we found it beneficial to first back off to the lowercased form for an OOV word if its embedding exists, and only otherwise assign *UNK*.

MIMICK. Word embeddings are initialized from Polyglot, with OOV embeddings inferred from a MIMICK model (Section 3) trained on the Polyglot embeddings. Unlike the No-Char case, backing off to lowercased embeddings before using the MIMICK output did not yield conclusive benefits and thus we report results for the more straightforward no-backoff implementation.

CHAR→TAG. Word embeddings are initialized from Polyglot as in the No-Char model (with lowercase backoff), and appended with the output of a character-level LSTM updated during training (Plank et al., 2016). This additional module causes a threefold increase in training time.

Both. Word embeddings are initialized as in MIMICK, and appended with the CHAR→TAG LSTM.

Other models. Several non-Polyglot embedding models were examined, all performed substantially worse than Polyglot. Two of these

[4] When several datasets are available for a language, we use the unmarked corpus.

[5] Details were clarified in personal communication with the authors.

are notable: a random-initialization baseline, and a model initialized from FastText embeddings (tested on English). FastText supplies 300-dimension embeddings for 2.51 million lowercase-only forms, and no *UNK* vector.[6] Both of these embedding models were attempted with and without CHAR→TAG concatenation. Another model, initialized from only MIMICK output embeddings, performed well only on the language with smallest Polyglot training corpus (Latvian). A Polyglot model where OOVs were initialized using an averaged embedding of all Polyglot vectors, rather than the supplied *UNK* vector, performed worse than our No-Char baseline on a great majority of the languages.

Last, we do not employ type-based tagset restrictions. All tag inventories are computed from the training sets and each tag selection is performed over the full set.

5.3 Hyperparameters

Based on development set experiments, we set the following hyperparameters for all models on all languages: two LSTM layers of hidden size 128, MLP hidden layers of size equal to the number of each attribute's possible values; momentum stochastic gradient descent with 0.01 learning rate; 40 training epochs (80 for 5K settings) with a dropout rate of 0.5. The CHAR→TAG models use 20-dimension character embeddings and a single hidden layer of size 128.

6 Results

We report performance in both low-resource and full-resource settings. Low-resource training sets were obtained by randomly sampling training sentences, without replacement, until a predefined token limit was reached. We report the results on the full sets and on $N = 5000$ tokens in Table 5 (part-of-speech tagging accuracy) and Table 6 (morphosyntactic attribute tagging micro-F1). Results for additional training set sizes are shown in Figure 2; space constraints prevent us from showing figures for all languages.

MIMICK as OOV initialization. In nearly all experimental settings on both tasks, across languages and training corpus sizes, the MIMICK embeddings significantly improve over the Polyglot *UNK* embedding for OOV tokens on both POS and morphosyntactic tagging. For POS, the largest margins are in the Slavic languages (Russian, Czech, Bulgarian), where word order is relatively free and thus rich word representations are imperative. Chinese also exhibits impressive improvement across all settings, perhaps due to the large character inventory (> 12,000), for which a model such as MIMICK can learn well-informed embeddings using the large Polyglot vocabulary dataset, overcoming both word- and character-level sparsity in the UD corpus.[7] In morphosyntactic tagging, gains are apparent for Slavic languages and Chinese, but also for agglutinative languages — especially Tamil and Turkish — where the stable morpheme representation makes it easy for subword modeling to provide a type-level signal.[8] To examine the effects on Slavic and agglutinative languages in a more fine-grained view, we present results of multiple training-set size experiments for each model, averaged over five repetitions (with different corpus samples), in Figure 2.

MIMICK vs. CHAR→TAG. In several languages, the MIMICK algorithm fares better than the CHAR→TAG model on part-of-speech tagging in low-resource settings. Table 7 presents the POS tagging improvements that MIMICK achieves over the pre-trained Polyglot models, with and without CHAR→TAG concatenation, with 10,000 tokens of training data. We obtain statistically significant improvements in most languages, even when CHAR→TAG is included. These improvements are particularly substantial for test-set tokens outside the UD training set, as shown in the right two columns. While test set OOVs are a strength of the CHAR→TAG model (Plank et al., 2016), in many languages there are still considerable improvements to be obtained from the application of MIMICK initialization. This suggests that with limited training data, the end-to-end CHAR→TAG model is unable to learn a sufficiently accurate representational mapping from orthography.

7 Conclusion

We present a straightforward algorithm to infer OOV word embedding vectors from pre-trained,

[6] Vocabulary type-level coverage for the English UD corpus: 55.6% case-sensitive, 87.9% case-insensitive.

[7] Character coverage in Chinese Polyglot is surprisingly good: only eight characters from the UD dataset are unseen in Polyglot, across more than 10,000 unseen word types.

[8] Persian is officially classified as agglutinative but it is mostly so with respect to derivations. Its word-level inflections are rare and usually fusional.

limited-vocabulary models, without need to access the originating corpus. This method is particularly useful for low-resource languages and tasks with little labeled data available, and in fact is task-agnostic. Our method improves performance over word-based models on annotated sequence-tagging tasks for a large variety of languages across dimensions of family, orthography, and morphology. In addition, we present a Bi-LSTM approach for tagging morphosyntactic attributes at the token level. In this paper, the MIMICK model was trained using characters as input, but future work may consider the use of other subword units, such as morphemes, phonemes, or even bitmap representations of ideographic characters (Costa-jussà et al., 2017).

8 Acknowledgments

We thank Umashanthi Pavalanathan, Sandeep Soni, Roi Reichart, and our anonymous reviewers for their valuable input. We thank Manaal Faruqui and Ryan McDonald for their help in understanding the metrics for morphosyntactic tagging. The project was supported by project HDTRA1-15-1-0019 from the Defense Threat Reduction Agency.

Abstract

We present SuperPivot, an analysis method for low-resource languages that occur in a superparallel corpus, i.e., in a corpus that contains an order of magnitude more languages than parallel corpora currently in use. We show that SuperPivot performs well for the crosslingual analysis of the linguistic phenomenon of tense. We produce analysis results for more than 1000 languages, conducting – to the best of our knowledge – the largest crosslingual computational study performed to date. We extend existing methodology for leveraging parallel corpora for typological analysis by overcoming a limiting assumption of earlier work: We only require that a linguistic feature is overtly marked in a *few* of thousands of languages as opposed to requiring that it be marked in *all* languages under investigation.

1 Introduction

Significant linguistic resources such as machine-readable lexicons and part-of-speech (POS) taggers are available for at most a few hundred languages. This means that the majority of the languages of the world are low-resource. Low-resource languages like Fulani are spoken by tens of millions of people and are politically and economically important; e.g., to manage a sudden refugee crisis, NLP tools would be of great benefit. Even "small" languages are important for the preservation of the common heritage of humankind that includes natural remedies and linguistic and cultural diversity that can potentially enrich everybody. Thus, developing analysis methods for low-resource languages is one of the most important challenges of NLP today.

We address this challenge by proposing a new method for analyzing what we call *superparallel corpora*, corpora that are by an order of magnitude more parallel than corpora that have been available in NLP to date. The corpus we work with in this paper is the Parallel Bible Corpus (PBC) that consists of translations of the New Testament in 1169 languages. Given that no NLP analysis tools are available for most of these 1169 languages, how can we extract the rich information that is potentially hidden in such superparallel corpora?

The method we propose is based on two hypotheses. **H1 Existence of overt encoding.** For any important linguistic distinction f that is frequently encoded across languages in the world, there are a few languages that encode f overtly on the surface. **H2 Overt-to-overt and overt-to-non-overt projection.** For a language l that encodes f, a projection of f from the "overt languages" to l in the superparallel corpus will identify the encoding that l uses for f, both in cases in which the encoding that l uses is overt and in cases in which the encoding that l uses is non-overt. Based on these two hypotheses, our method proceeds in 5 steps.

1. Selection of a linguistic feature. We select a linguistic feature f of interest. Running example: We select past tense as feature f.

2. Heuristic search for head pivot. Through a heuristic search, we find a language l^h that contains a *head pivot* p^h that is highly correlated with the linguistic feature of interest.

Running example: "ti" in Seychelles Creole (CRS). CRS "ti" meets our requirements for a head pivot well as will be verified empirically in §3. First, "ti" is a surface marker: it is easily identifable through whitespace tokenization and it is not ambiguous, e.g., it does not have a second meaning apart from being a grammatical marker. Second, "ti" is a good marker for past tense in

Proceedings of the 2017 Conference on Empirical Methods in Natural Language Processing, pages 113–124
Copenhagen, Denmark, September 7–11, 2017. ©2017 Association for Computational Linguistics

terms of both "precision" and "recall". CRS has mandatory past tense marking (as opposed to languages in which tense marking is facultative) and "ti" is highly correlated with the general notion of past tense.

This does not mean that every clause that a linguist would regard as past tense is marked with "ti" in CRS. For example, some tense-aspect configurations that are similar to English present perfect are marked with "in" in CRS, not with "ti" (e.g., ENG "has commanded" is translated as "in ordonn").

Our goal is not to find a head language and a head pivot that is a perfect marker of f. Such a head pivot probably does not exist; or, more precisely, linguistic features are not completely rigorously defined. In a sense, one of the contributions of this work is that we provide more rigorous definitions of past tense across languages; e.g., "ti" in CRS is one such rigorous definition of past tense and it automatically extends (through projection) to 1000 languages in the superparallel corpus.

3. Projection of head pivot to larger pivot set. Based on an alignment of the head language to the other languages in the superparallel corpus, we project the head pivot to all other languages and search for highly correlated surface markers, i.e., we search for additional pivots in other languages. This projection to more pivots achieves three goals. First, it makes the method more *robust*. Relying on a single pivot would result in many errors due to the inherent noisiness of linguistic data and because several components we use (e.g., alignment of the languages in the superparallel corpus) are imperfect. Second, as we discussed above, the head pivot does not necessarily have high "recall"; our example was that CRS "ti" is not applied to certain clauses that would be translated using present perfect in English. Thus, moving to a larger pivot set *increases recall*. Third, as we will see below, the pivot set can be leveraged to create a *fine-grained map of the linguistic feature*. Consider clauses referring to eventualities in the past that English speakers would render in past progressive, present perfect and simple past tense. Our hope is that the pivot set will cover these distinctions, i.e., one of the pivots marks past progressive, but not present prefect and simple past, another pivot marks present perfect, but not the other two and so on. An example of this type of map, including distinctions like progressive and perfective aspect, is given in §4.

Running example: We compute the correlation of "ti" with words in other languages and select the 100 most highly correlated words as pivots. Examples of pivots we find this way are Torres Strait Creole "bin" (from English "been") and Tzotzil "laj". "laj" is a perfective marker, e.g., "Laj meltzaj -uk" 'LAJ be-made subj' means "It's done being built" (Aissen, 1987).

4. Projection of pivot set to all languages. Now that we have a large pivot set, we project the pivots to all other languages to search for linguistic devices that express the linguistic feature f. Up to this point, we have made the assumption that it is easy to segment text in all languages into pieces of a size that is not too small (individual characters of the Latin alphabet would be too small) and not too large (entire sentences as tokens would be too large). Segmentation on standard delimiters is a good approximation for the majority of languages – but not for all: it undersegments some (e.g., the polysynthetic language Inuit) and oversegments others (e.g., languages that use punctuation marks as regular characters).

For this reason, we do not employ tokenization in this step. Rather we search for character n-grams ($2 \leq n \leq 6$) to find linguistic devices that express f. This implementation of the search procedure is a limitation – there are many linguistic devices that cannot be found using it, e.g., templates in templatic morphology. We leave addressing this for future work (§7).

Running example: We find "-ed" for English and "-te" for German as surface features that are highly correlated with the 100 past tense pivots.

5. Linguistic analysis. The result of the previous steps is a superparallel corpus that is richly annotated with information about linguistic feature f. This structure can be exploited for *the analysis of a single language* l^i that may be the focus of a linguistic investigation. Starting with the character n-grams that were found in the step "projection of pivot set to all languages", we can explore their use and function, e.g, for the mined n-gram "-ed" in English (assuming English is the language l^i and it is unfamiliar to us). Many of the other 1000 languages provide annotations of linguistic feature f for l^i: both the languages that are part of the pivot set (e.g., Tzotzil "laj") and the mined n-grams in other languages that we may have some knowledge about (e.g., "-te" in German).

We can also use the structure we have generated for *typological analysis across languages* following the work of Michael Cysouw ((Cysouw, 2014), §5). Our method is an advancement computationally over Cysouw's work because our method scales to thousands of languages as we demonstrate below.

Running example: We sketch the type of analysis that our new method makes possible in §4.

The above steps "1. heuristic search for head pivot" and "2. projection of head pivot to larger pivot set" are based on H1: we assume the **existence of overt coding** in a subset of languages.

The above steps "2. projection of head pivot to larger pivot set" and "3. projection of pivot set to all languages" are based on H2: we assume that **overt-to-overt and overt-to-non-overt projection** is possible.

In the rest of the paper, we will refer to the method that consists of steps 1 to 5 as *SuperPivot*: "linguistic analysis of SUPERparallel corpora using surface PIVOTs".

We make three contributions. (i) Our basic hypotheses are H1 and H2. (H1) For an important linguistic feature, there exist a few languages that mark it overtly and easily recognizably. (H2) It is possible to project overt markers to overt and non-overt markers in other languages. Based on these two hypotheses we design SuperPivot, a new method for analyzing highly parallel corpora, and show that it performs well for the crosslingual analysis of the linguistic phenomenon of tense. (ii) Given a superparallel corpus, SuperPivot can be used for the analysis of *any low-resource language* represented in that corpus. In the supplementary material, we present results of our analysis for three tenses (past, present, future) for 1163[1] languages. An evaluation of accuracy is presented in Table 3.2. (iii) We extend Michael Cysouw's method of typological analysis using parallel corpora by overcoming several limiting factors. The most important is that Cysouw's method is only applicable if markers of the relevant linguistic feature are recognizable on the surface in *all* languages. In contrast, we only assume that markers of the relevant linguistic feature are recognizable on the surface in *a small number of* languages.

2 SuperPivot: Description of method

1. Selection of a linguistic feature. The linguistic feature of interest f is selected by the person who performs a SuperPivot analysis, i.e., by a linguist, NLP researcher or data scientist. Henceforth, we will refer to this person as the linguist.

In this paper, $f \in F = \{\text{past}, \text{present}, \text{future}\}$.

2. Heuristic search for head pivot. There are several ways for finding the head language and the head pivot. Perhaps the linguist knows a language that has a good head pivot. Or she is a trained typologist and can find the head pivot by consulting the typological literature.

In this paper, we use our knowledge of English and an alignment from English to all other languages to find head pivots. (See below for details on alignment.) We define a "query" in English and search for words that are highly correlated to the query in other languages. For future tense, the query is simply the word "will", so we search for words in other languages that are highly correlated with "will". For present tense, the query is the union of "is", "are" and "am". So we search for words in other languages that are highly correlated with the "merger" of these three words. For past tense, we POS tag the English part of PBC and merge all words tagged as past tense into one past tense word.[2] We then search for words in other languages that are highly correlated with this artificial past tense word.

As an additional constraint, we do not select the most highly correlated word as the head pivot, but the most highly correlated word in a Creole language. Our rationale is that Creole languages are more regular than other languages because they are young and have not accumulated "historical baggage" that may make computational analysis more difficult.

Table 1 lists the three head pivots for F.

3. Projection of head pivot to larger pivot set. We first use fast_align (Dyer et al., 2013) to align the head language to all other languages in the corpus. This alignment is on the word level.

We compute a score for each word in each language based on the number of times it is aligned to the head pivot, the number of times it is aligned to another word and the total frequencies of head pivot and word. We use χ^2 (Casella and Berger, 2008) as the score throughout this paper. Finally,

[1] We exclude six of the 1169 languages because they do not share enough verses with the rest.

[2] Past tense is defined as tags BED, BED*, BEDZ, BEDZ*, DOD*, VBD, DOD. We use NLTK (Bird, 2006).

we select the k words as pivots that have the highest association score with the head pivot.

We impose the constraint that we only select one pivot per language. So as we go down the list, we skip pivots from languages for which we already have found a pivot. We set $k = 100$ in this paper. Table 1 gives the top 10 pivots.

4. Projection of pivot set to all languages. As discussed above, the process so far has been based on tokenization. To be able to find markers that cannot be easily detected on the surface (like "-ed" in English), we identify non-tokenization-based character n-gram features in step 4.

The immediate challenge is that without tokens, we have no alignment between the languages anymore. We could simply assume that the occurrence of a pivot has scope over the entire verse. But this is clearly inadequate, e.g., for the sentence "I arrived yesterday, I'm staying today, and I will leave tomorrow", it is incorrect to say that it is marked as past tense (or future tense) in its entirety. Fortunately, the verses in the New Testament mostly have a simple structure that limits the variation in where a particular piece of content occurs in the verse. We therefore make the assumption that a particular relative position in language l_1 (e.g., the character at relative position 0.62) is aligned with the same relative position in l_2 (i.e., the character at relative position 0.62). This is likely to work for a simple example like "I arrived yesterday, I'm staying today, and I will leave tomorrow" across languages.

In our analysis of errors, we found many cases where this assumption breaks down. A well-known problematic phenomenon for our method is the difference between, say, VSO and SOV languages: the first class puts the verb at the beginning, the second at the end. However, keep in mind that we accumulate evidence over $k = 100$ pivots and then compute aggregate statistics over the entire corpus. As our evaluation below shows, the "linear alignment" assumption does not seem to do much harm given the general robustness of our method.

One design element that increases robustness is that we find the two positions in each verse that are most highly (resp. least highly) correlated with the linguistic feature f. Specifically, we compute the relative position x of each pivot that occurs in the verse and apply a Gaussian filter ($\sigma = 6$ where the unit of length is the character), i.e., we set $p(x) \approx 0.066$ (0.066 is the density of a Gaussian with $\sigma = 6$ at $x = 0$) and center a bell curve around x. The total score for a position x is then the sum of the filter values at x summed over all occurring pivots. Finally, we select the positions x_{min} and x_{max} with lowest and highest values for each verse.

χ^2 is then computed based on the number of times a character n-gram occurs in a window of size w around x_{max} (positive count) and in a window of size w around x_{min} (negative count). Verses in which no pivot occurs are used for the negative count in their entirety. The top-ranked character n-grams are then output for analysis by the linguist. We set $w = 20$.

5. Linguistic analysis. We now have created a structure that contains rich information about the linguistic feature: for each verse we have relative positions of pivots that can be projected across languages. We also have maximum positions within a verse that allow us to pinpoint the most likely place in the vicinity of which linguistic feature f is marked in all languages. This structure can be used for the analysis of individual low-resource languages as well as for typological analysis. We will give an example of such an analysis in §4.

3 Data, experiments and results

3.1 Data

We use a New Testament subset of the Parallel Bible Corpus (PBS) (Mayer and Cysouw, 2014) that consists of 1556 translations of the Bible in 1169 unique languages. We consider two languages to be different if they have different ISO 639-3 codes.

The translations are aligned on the verse level. However, many translations do not have complete coverage, so that most verses are not present in at least one translation. One reason for this is that sometimes several consecutive verses are merged, so that one verse contains material that is in reality not part of it and the merged verses may then be missing from the translation. Thus, there is a trade-off between number of parallel translations and number of verses they have in common. Although some preprocessing was done by the authors of the resource, many translations are not preprocessed. For example, Japanese is not tokenized. We also observed some incorrectness and sparseness in the metadata. One example is that one Fijian translation (see §4) is tagged fij_hindi, but it is Fijian, not Fiji Hindi.

We use the 7958 verses with the best coverage across languages.

3.2 Experiments

1. Selection of a linguistic feature. We conduct three experiments for the linguistic features past tense, present tense and future tense.

2. Heuristic search for head pivot. We use the queries described in §2 for finding the following three head pivots. (i) Past tense head pivot: "ti" in Seychellois Creole (CRS) (McWhorter, 2005). (ii) Present tense head pivot: "ta" in Papiamentu (PAP) (Andersen, 1990). (iii) Future tense head pivot: "bai" in Tok Pisin (TPI) (Traugott, 1978; Sankoff, 1990).

3. Projection of head pivot to larger pivot set. Using the method described in §2, we project each head pivot to a set of $k = 100$ pivots. Table 1 gives the top 10 pivots for each tense.

4. Projection of pivot set to all languages. Using the method described in §2, we compute highly correlated character n-gram features, $2 \leq n \leq 6$, for all 1163 languages.

See §4 for the last step of SuperPivot: **5. Linguistic analysis.**

3.3 Evaluation

We rank n-gram features and retain the top 10, for each linguistic feature, for each language and for each n-gram size. We process 1556 translations. Thus, in total, we extract 1556 × 5 × 10 n-grams.

Table 3.2 shows Mean Reciprocal Rank (MRR) for 10 languages. The rank for a particular ranking of n-grams is the first n-gram that is highly correlated with the relevant tense; e.g., character subsequences of the name "Paulus" are evaluated as incorrect, the subsequence "-ed" in English as correct for past. MRR is averaged over all n-gram sizes, $2 \leq n \leq 6$. Chinese has consistent tense marking only for future, so results are poor. Russian and Polish perform poorly because their central grammatical category is aspect, not tense. The poor performance on Arabic is due to the limits of character n-gram features for a "templatic" language.

During this evaluation, we noticed a surprising amount of variation within translations of one language; e.g., top-ranked n-grams for some German translations include names like "Paulus". We suspect that for literal translations, linear alignment (§2) yields good n-grams. But many translations are free, e.g., they change the sequence of clauses. This deteriorates mined n-grams. See §7.

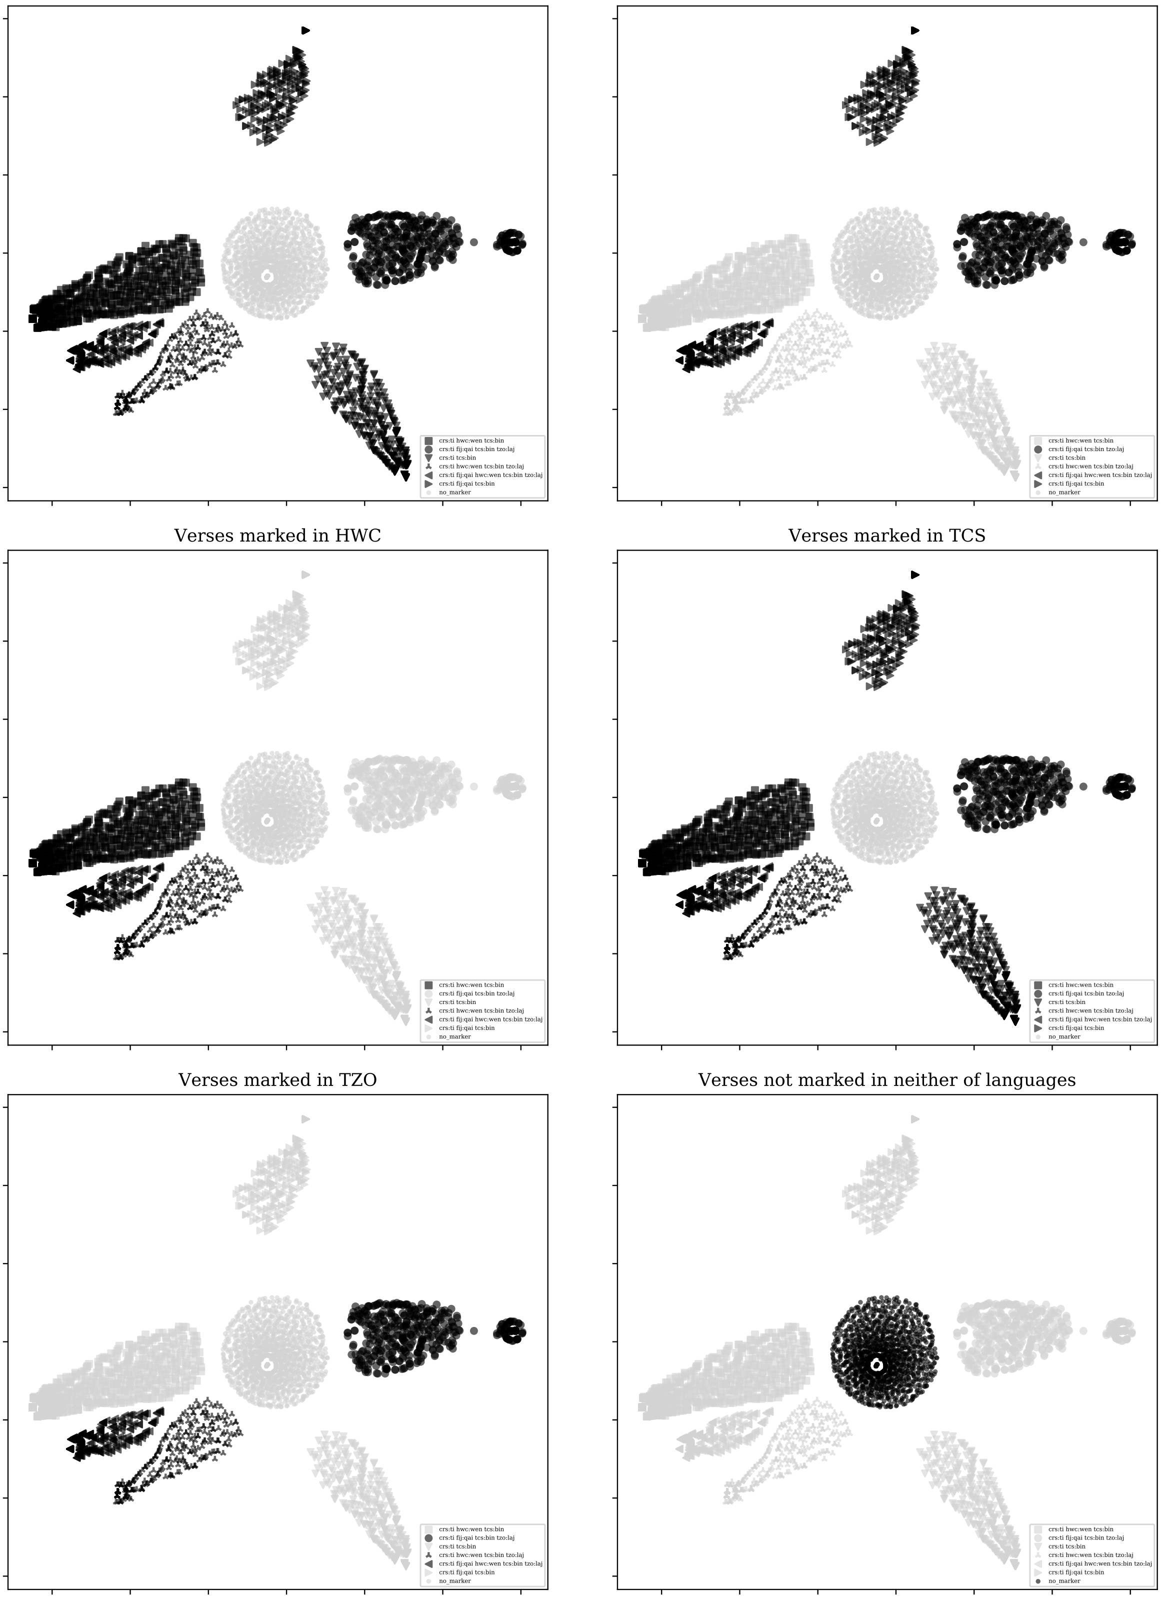
A reviewer points out that simple baselines may be available if all we want to do is compute features highly associated with past tense as evaluated in Table 3.2. As one such baseline, they suggested to first perform a word alignment with the head pivot and then search for highly associated features in the words that were aligned with the head pivot. We implemented this baseline and measured its performance. Indeed, the results were roughly comparable to the more complex method that we evaluate in Table 3.2.

However, our evaluation was not designed to be a direct evaluation of our method, but only meant as a relatively easy way of getting a quantitative sense of the accuracy of our results. The core result of our method is a corpus in which each language annotates each other language. This is only meaningful on the token or context level, not on the word level. For example, recognizing "-ed" as a possible past tense marker in English and applying it uniformly throughout the corpus would result in the incorrect annotation of the adjective "red" as a past tense form. In our proposed method, this will not happen since the annotation proceeds from reliable pivots to less reliable features, not the other way round. Nevertheless, we agree with the reviewer that we do not make enough use of "type-level" features in our method (type-level features of non-pivot languages) and this is something we plan to address in the future.

4 A map of past tense

To illustrate the potential of our method we select five out of the 100 past tense pivots that give rise to large clusters of distinct combinations. Specifically, starting with CRS, we find other pivots that "split" the set of verses that contain the CRS past tense pivot "ti" into two parts that have about the same size. This gives us two sets. We now look for a pivot that splits one of these two sets about evenly and so on. After iterating four times, we arrive at five pivots: CRS "ti", Fijian (FIJ) "qai", Hawaiian Creole (HWC) "wen", Torres Strait Creole (TCS) "bin" and Tzotzil (TZO) "laj".

Figure 1 shows a t-SNE (Maaten and Hinton, 2008) visualization of the large clusters of combinations that are found for these five languages, including one cluster of verses that do not contain any of the five pivots.



Verses marked in HWC

Verses marked in TCS

Verses marked in TZO

Verses not marked in neither of languages

Figure 1: A map of past tense based on the largest clusters of verses with particular combinations of the past tense pivots from Seychellois Creole (CRS), Fijian (FIJ), Hawaiian Creole (HWC), Torres Strait Creole (TCS) and Tzotzil (TZO). For each of the five languages, we present a subfigure that highlights the subset of verse clusters that are marked by the pivot of that language. The sixth subfigure highlights verses not marked by any of the five pivots.

		past			present			future

all	0.88	0.79	0.88	0.85

Table 2: MRR results for step 4. See text for details.

This figure is a map of past tense for all 1163 languages, not just for CRS, FIJ, HWC, TCS and TZO: once the interpretation of a particular cluster has been established based on CRS, FIJ, HWC, TCS and TZO, we can investigate this cluster in the 1164 other languages by looking at the verses that are members of this cluster. This methodology supports the empirical investigation of questions like "how is progressive past tense expressed in language X"? We just need to look up the cluster(s) that correspond to progressive past tense, look up the verses that are members and retrieve the text of these verses in language X.

To give the reader a flavor of the distinctions that are reflected in these clusters, we now list phenomena that are characteristic of verses that contain only one of the five pivots; these phenomena identify properties of one language that the other four do not have.

CRS "ti". CRS has a set of markers that can be systematically combined, in particular, a progressive marker "pe" that can be combined with the past tense marker "ti". As a result, past progressive sentences in CRS are generally marked with "ti". Example: "43004031 Meanwhile, the disciples were urging Jesus, 'Rabbi, eat something.'" "crs_bible 43004031 Pandan sa letan, bann disip ti pe sipliy Zezi, 'Met! Manz en pe.'"

The other four languages do not consistently use the pivot for marking the past progressive; e.g., HWC uses "was begging" in 43004031 (instead of "wen") and TCS uses "kip tok strongwan" 'keep talking strongly' in 43004031 (instead of "bin").

FIJ "qai". This pivot means "and then". It is highly correlated with past tense in the New Testament because most sequential descriptions of events are descriptions of past events. But there are also some non-past sequences. Example: "eng_newliving 44009016 And I will show him how much he must suffer for my name's sake." "fij_hindi 44009016 Au na qai vakatakila vua na levu ni ka e na sota kaya e na vukuqu." This verse is future tense, but it continues a temporal sequence (it starts in the preceding verse) and therefore FIJ uses "qai". The pivots of the other four languages are not general markers of temporal sequentiality, so they are not used for the future.

HWC "wen". HWC is less explicit than the other four languages in some respects and more explicit in others. It is less explicit in that not all sentences in a sequence of past tense sentences need to be marked explicitly with "wen", resulting in some sentences that are indistinguishable from present tense. On the other hand, we found many cases of noun phrases in the other four languages that refer implicitly to the past, but are translated as a verb with explicit past tense marking in HWC. Examples: "hwc_2000 40026046 Da guy who wen set me up . . . " 'the guy who WEN set me up', "eng_newliving 40026046 . . . my betrayer . . . "; "hwc_2000 43008005 . . . Moses wen tell us in da Rules . . . " 'Moses WEN tell us in the rules', "eng_newliving 43008005 The law of Moses says . . . "; "hwc_2000 47006012 We wen give you guys our love . . . ", "eng_newliving 47006012 There is no lack of love on our part . . . ". In these cases, the other four languages (and English too) use a noun phrase with no tense marking that is translated as a tense-marked clause in HWC.

While preparing this analysis, we realized that HWC "wen" unfortunately does not meet one of the criteria we set out for pivots: it is not unambiguous. In addition to being a past tense marker (derived from standard English "went"), it can also be a conjunction, derived from "when". This ambiguity is the cause for some noise in the clusters marked for presence of HWC "wen" in the figure.

TCS "bin". Conditionals is one pattern we found in verses that are marked with TCS "bin", but are not marked for past tense in the other four languages. Example: "tcs_bible 46015046 Wanem i bin kam pas i da nomal bodi ane den da spiritbodi i bin kam apta." 'what came first is the normal body and then the spirit body came after', "eng_newliving 46015046 What comes first is the natural body, then the spiritual body comes later." Apparently, "bin" also has a modal aspect in TCS: generic statements that do not refer to specific events are rendered using "bin" in TCS whereas the other four languages (and also English) use the default unmarked tense, i.e., present tense.

TZO "laj". This pivot indicates perfective aspect. The other four past tense pivots are not perfective markers, so that there are verses that are marked with "laj", but not marked with the past tense pivots of the other four languages. Example: "tzo_huixtan 40010042 . . . ja'ch-ac'bat bendición yu'un hech laj spas . . . " (literally "a blessing . . . LAJ make"), "eng_newliving 40010042 . . . you will surely be rewarded." Perfective aspect and past are correlated in the real world since most events that are viewed as simple wholes are in the past. But future events can also be viewed this way as the example shows.

Similar maps for present and future tenses are presented in the supplementary material.

5 Related work

Our work is inspired by (Cysouw, 2014; Cysouw and Wälchli, 2007); see also (Dahl, 2007; Wälchli, 2010). Cysouw creates maps like Figure 1 by manually identifying occurrences of the proper noun "Bible" in a parallel corpus of Jehovah's Witnesses' texts. Areas of the map correspond to semantic roles, e.g., the Bible as actor (it tells you to do something) or as object (it was printed). This is a definition of semantic roles that is complementary to and different from prior typological research because it is empirically grounded in real language use across a large number of languages. It allows typologists to investigate traditional questions from a new perspective.

The field of **typology** is important for both theoretical (Greenberg, 1960; Whaley, 1996; Croft, 2002) and computational (Heiden et al., 2000; Santaholma, 2007; Bender, 2009, 2011) linguistics. Typology is concerned with all areas of linguistics: morphology (Song, 2014), syntax (Comrie, 1989; Croft, 2001; Croft and Poole, 2008; Song, 2014), semantic roles (Hartmann et al., 2014; Cysouw, 2014), semantics (Koptjevskaja-Tamm et al., 2007; Dahl, 2014; Wälchli and Cysouw, 2012; Sharma, 2009), etc. Typological information is important for many NLP tasks including discourse analysis (Myhill and Myhill, 1992), information retrieval (Pirkola, 2001), POS tagging (Bohnet and Nivre, 2012), parsing (Bohnet and Nivre, 2012; McDonald et al., 2013), machine translation (Hajič et al., 2000; Kunchukuttan and Bhattacharyya, 2016) and morphology (Bohnet et al., 2013).

Tense is a central phenomenon in linguistics and the languages of the world differ greatly in whether and how they express tense (Traugott, 1978; Bybee and Dahl, 1989; Dahl, 2000, 1985; Santos, 2004; Dahl, 2007; Santos, 2004; Dahl, 2014).

Low resource. Even resources with the widest coverage like World Atlas of Linguistic Structures (WALS) (Dryer et al., 2005) have little information for hundreds of languages. Many researchers have taken advantage of parallel information for extracting linguistic knowledge in low-resource settings (Resnik et al., 1997; Resnik, 2004; Mihalcea and Simard, 2005; Mayer and Cysouw, 2014;

Christodouloupoulos and Steedman, 2015; Lison and Tiedemann, 2016).

Parallel projection. Parallel projection across languages has been used for a variety of NLP tasks. Machine translation aside, which is the most natural task on parallel corpora (Brown et al., 1993), parallel projection has been used for sense disambiguation (Ide, 2000), parsing (Hwa et al., 2005), paraphrasing (Bannard and Callison-Burch, 2005), part-of-speech tagging (Mukerjee et al., 2006), coreference resolution (de Souza and Orăsan, 2011), event marking (Nordrum, 2015), morphological segmentation (Chung et al., 2016), bilingual analysis of linguistic marking (McEnery and Xiao, 1999; Xiao and McEnery, 2002), as well as language classification (Asgari and Mofrad, 2016; Östling and Tiedemann, 2017).

6 Discussion

Our motivation is not to develop a method that can then be applied to many other corpora. Rather, our motivation is that many of the more than 1000 languages in the Parallel Bible Corpus are low-resource and that providing a method for creating the first richly annotated corpus (through the projection of annotation we propose) for many of these languages is a significant contribution.

The original motivation for our approach is provided by the work of the typologist Michael Cysouw. He created the same type of annotation as we, but he produced it manually whereas we use automatic methods. But the structure of the annotation and its use in linguistic analysis is the same as what we provide.

The basic idea of the utility of the final outcome of SuperPivot is that the 1163 languages all richly annotate each other. As long as there are a few among the 1163 languages that have a clear marker for linguistic feature f, then this marker can be projected to all other languages to richly annotate them. For any linguistic feature, there is a good chance that a few languages clearly mark it. Of course, this small subset of languages will be different for every linguistic feature.

Thus, even for extremely resource-poor languages for which at present no annotated resources exist, SuperPivot will make available richly annotated corpora that should advance linguistic research on these languages.

7 Conclusion

We presented SuperPivot, an analysis method for low-resource languages that occur in a superparallel corpus, i.e., in a corpus that contains an order of magnitude more languages than parallel corpora currently in use. We showed that SuperPivot performs well for the crosslingual analysis of the linguistic phenomenon of tense. We produced analysis results for more than 1000 languages, conducting – to the best of our knowledge – the largest crosslingual computational study performed to date. We extended existing methodology for leveraging parallel corpora for typological analysis by overcoming a limiting assumption of earlier work. We only require that a linguistic feature is overtly marked in a *few* of thousands of languages as opposed to requiring that it be marked in *all* languages under investigation.

8 Future directions

There are at least two future directions that seem promising to us.

- Creating a common map of tense along the lines of Figure 1, but unifying the three tenses
- Addressing shortcomings of the way we compute alignments: (i) generalizing character n-grams to more general features, so that templates in templatic morphology, reduplication and other more complex manifestations of linguistic features can be captured; (ii) use n-gram features of different lengths to account for differences among languages, e.g., shorter ones for Chinese, longer ones for English; (iii) segmenting verses into clauses and performing alignment not on the verse level (which caused many errors in our experiments), but on the clause level instead; (iv) using global information more effectively, e.g., by extracting alignment features from automatically induced bi- or multilingual lexicons.

Acknowledgments

We gratefully acknowledge financial support from Volkswagenstiftung and fruitful discussions with Fabienne Braune, Michael Cysouw, Alexander Fraser, Annemarie Friedrich, Mohsen Mahdavi Mazdeh, Mohammad R.K. Mofrad, and Benjamin Roth. We are indebted to Michael Cysouw for the Parallel Bible Corpus.

Neural Machine Translation with Source-Side Latent Graph Parsing

Kazuma Hashimoto and Yoshimasa Tsuruoka
The University of Tokyo, 7-3-1 Hongo, Bunkyo-ku, Tokyo, Japan
{hassy,tsuruoka}@logos.t.u-tokyo.ac.jp

Abstract

This paper presents a novel neural machine translation model which jointly learns translation and source-side latent graph representations of sentences. Unlike existing pipelined approaches using syntactic parsers, our end-to-end model learns a latent graph parser as part of the encoder of an attention-based neural machine translation model, and thus the parser is optimized according to the translation objective. In experiments, we first show that our model compares favorably with state-of-the-art sequential and pipelined syntax-based NMT models. We also show that the performance of our model can be further improved by pretraining it with a small amount of treebank annotations. Our final ensemble model significantly outperforms the previous best models on the standard English-to-Japanese translation dataset.

1 Introduction

Neural Machine Translation (NMT) is an active area of research due to its outstanding empirical results (Bahdanau et al., 2015; Luong et al., 2015; Sutskever et al., 2014). Most of the existing NMT models treat each sentence as a sequence of tokens, but recent studies suggest that syntactic information can help improve translation accuracy (Eriguchi et al., 2016b, 2017; Sennrich and Haddow, 2016; Stahlberg et al., 2016). The existing syntax-based NMT models employ a syntactic parser trained by supervised learning in advance, and hence the parser is not adapted to the translation tasks. An alternative approach for leveraging syntactic structure in a language processing task is to jointly learn syntactic trees of the sentences along with the target task (Socher et al., 2011; Yogatama et al., 2017).

Figure 1: An example of the learned latent graphs. Edges with a small weight are omitted.

Motivated by the promising results of recent joint learning approaches, we present a novel NMT model that can learn a task-specific latent graph structure for each source-side sentence. The graph structure is similar to the dependency structure of the sentence, but it can have cycles and is learned specifically for the translation task. Unlike the aforementioned approach of learning single syntactic trees, our latent graphs are composed of "soft" connections, i.e., the edges have real-valued weights (Figure 1). Our model consists of two parts: one is a task-independent parsing component, which we call a *latent graph parser*, and the other is an attention-based NMT model. The latent parser can be independently pre-trained with human-annotated treebanks and is then adapted to the translation task.

In experiments, we demonstrate that our model can be effectively pre-trained by the treebank annotations, outperforming a state-of-the-art sequential counterpart and a pipelined syntax-based model. Our final ensemble model outperforms the previous best results by a large margin on the WAT English-to-Japanese dataset.

2 Latent Graph Parser

We model the latent graph parser based on dependency parsing. In dependency parsing, a sentence is represented as a tree structure where each node corresponds to a word in the sentence and

Proceedings of the 2017 Conference on Empirical Methods in Natural Language Processing, pages 125–135
Copenhagen, Denmark, September 7–11, 2017. ©2017 Association for Computational Linguistics

a unique *root* node (ROOT) is added. Given a sentence of length N, the parent node $H_{w_i} \in \{w_1, \dots, w_N, \text{ROOT}\}$ ($H_{w_i} \neq w_i$) of each word w_i ($1 \leq i \leq N$) is called its *head*. The sentence is thus represented as a set of tuples $(w_i, H_{w_i}, \ell_{w_i})$, where ℓ_{w_i} is a dependency label.

In this paper, we remove the constraint of using the tree structure and represent a sentence as a set of tuples $(w_i, p(H_{w_i}|w_i), p(\ell_{w_i}|w_i))$, where $p(H_{w_i}|w_i)$ is the probability distribution of w_i's parent nodes, and $p(\ell_{w_i}|w_i)$ is the probability distribution of the dependency labels. For example, $p(H_{w_i} = w_j|w_i)$ is the probability that w_j is the parent node of w_i. Here, we assume that a special token ⟨EOS⟩ is appended to the end of the sentence, and we treat the ⟨EOS⟩ token as ROOT. This approach is similar to that of graph-based dependency parsing (McDonald et al., 2005) in that a sentence is represented with a set of weighted arcs between the words. To obtain the *latent graph* representation of the sentence, we use a dependency parsing model based on multi-task learning proposed by Hashimoto et al. (2017).

2.1 Word Representation

The i-th input word w_i is represented with the concatenation of its d_1-dimensional word embedding $v_{dp}(w_i) \in \mathbb{R}^{d_1}$ and its character n-gram embedding $c(w_i) \in \mathbb{R}^{d_1}$: $x(w_i) = [v_{dp}(w_i); c(w_i)]$. $c(w_i)$ is computed as the average of the embeddings of the character n-grams in w_i.

2.2 POS Tagging Layer

Our latent graph parser builds upon multi-layer bi-directional Recurrent Neural Networks (RNNs) with Long Short-Term Memory (LSTM) units (Graves and Schmidhuber, 2005). In the first layer, POS tagging is handled by computing a hidden state $h_i^{(1)} = [\overrightarrow{h}_i^{(1)}; \overleftarrow{h}_i^{(1)}] \in \mathbb{R}^{2d_1}$ for w_i, where $\overrightarrow{h}_i^{(1)} = \text{LSTM}(\overrightarrow{h}_{i-1}^{(1)}, x(w_i)) \in \mathbb{R}^{d_1}$ and $\overleftarrow{h}_i^{(1)} = \text{LSTM}(\overleftarrow{h}_{i+1}^{(1)}, x(w_i)) \in \mathbb{R}^{d_1}$ are hidden states of the forward and backward LSTMs, respectively. $h_i^{(1)}$ is then fed into a softmax classifier to predict a probability distribution $p_i^{(1)} \in \mathbb{R}^{C^{(1)}}$ for word-level tags, where $C^{(1)}$ is the number of POS classes. The model parameters of this layer can be learned not only by human-annotated data, but also by backpropagation from higher layers, which are described in the next section.

2.3 Dependency Parsing Layer

Dependency parsing is performed in the second layer. A hidden state $h_i^{(2)} \in \mathbb{R}^{2d_1}$ is computed by $\overrightarrow{h}_i^{(2)} = \text{LSTM}(\overrightarrow{h}_{i-1}^{(2)}, [x(w_i); y(w_i); \overrightarrow{h}_i^{(1)}])$ and $\overleftarrow{h}_i^{(2)} = \text{LSTM}(\overleftarrow{h}_{i+1}^{(2)}, [x(w_i); y(w_i); \overleftarrow{h}_i^{(1)}])$, where $y(w_i) = W_\ell^{(1)} p_i^{(1)} \in \mathbb{R}^{d_2}$ is the POS information output from the first layer, and $W_\ell^{(1)} \in \mathbb{R}^{d_2 \times C^{(1)}}$ is a weight matrix.

Then, (soft) edges of our latent graph representation are obtained by computing the probabilities

$$p(H_{w_i} = w_j|w_i) = \frac{\exp(m(i,j))}{\sum_{k \neq i} \exp(m(i,k))}, \quad (1)$$

where $m(i,k) = h_k^{(2)\mathrm{T}} W_{dp} h_i^{(2)}$ ($1 \leq k \leq N+1, k \neq i$) is a scoring function with a weight matrix $W_{dp} \in \mathbb{R}^{2d_1 \times 2d_1}$. While the models of Hashimoto et al. (2017), Zhang et al. (2017), and Dozat and Manning (2017) learn the model parameters of their parsing models only by human-annotated data, we allow the model parameters to be learned by the translation task.

Next, $[h_i^{(2)}; z(H_{w_i})]$ is fed into a softmax classifier to predict the probability distribution $p(\ell_{w_i}|w_i)$, where $z(H_{w_i}) \in \mathbb{R}^{2d_1}$ is the weighted average of the hidden states of the parent nodes: $\sum_{j \neq i} p(H_{w_i} = w_j|w_i) h_j^{(2)}$. This results in the latent graph representation $(w_i, p(H_{w_i}|w_i), p(\ell_{w_i}|w_i))$ of the input sentence.

3 NMT with Latent Graph Parser

The latent graph representation described in Section 2 can be used for any sentence-level tasks, and here we apply it to an Attention-based NMT (ANMT) model (Luong et al., 2015). We modify the encoder and the decoder in the ANMT model to learn the latent graph representation.

3.1 Encoder with Dependency Composition

The ANMT model first encodes the information about the input sentence and then generates a sentence in another language. The encoder represents the word w_i with a word embedding $v_{enc}(w_i) \in \mathbb{R}^{d_3}$. It should be noted that $v_{enc}(w_i)$ is different from $v_{dp}(w_i)$ because each component is separately modeled. The encoder then takes the word embedding $v_{enc}(w_i)$ and the hidden state $h_i^{(2)}$ as the input to a uni-directional LSMT:

$$h_i^{(enc)} = \text{LSTM}(h_{i-1}^{(enc)}, [v_{enc}(w_i); h_i^{(2)}]), \quad (2)$$

where $h_i^{(enc)} \in \mathbb{R}^{d_3}$ is the hidden state corresponding to w_i. That is, the encoder of our model is a three-layer LSTM network, where the first two layers are bi-directional.

In the sequential LSTMs, relationships between words in distant positions are not *explicitly* considered. In our model, we explicitly incorporate such relationships into the encoder by defining a dependency composition function:

$$dep(w_i) = \tanh(W_{dep}[h_i^{enc}; \overline{h}(H_{w_i}); p(\ell_{w_i}|w_i)]), \tag{3}$$

where $\overline{h}(H_{w_i}) = \sum_{j \neq i} p(H_{w_i} = w_j|w_i) h_j^{(enc)}$ is the weighted average of the hidden states of the parent nodes.

Note on character n-gram embeddings In NMT models, sub-word units are widely used to address rare or unknown word problems (Sennrich et al., 2016). In our model, the character n-gram embeddings are fed through the latent graph parsing component. To the best of our knowledge, the character n-gram embeddings have never been used in NMT models. Wieting et al. (2016), Bojanowski et al. (2017), and Hashimoto et al. (2017) have reported that the character n-gram embeddings are useful in improving several NLP tasks by better handling unknown words.

3.2 Decoder with Attention Mechanism

The decoder of our model is a single-layer LSTM network, and the initial state is set with $h_{N+1}^{(enc)}$ and its corresponding memory cell. Given the t-th hidden state $h_t^{(dec)} \in \mathbb{R}^{d_3}$, the decoder predicts the t-th word in the target language using an attention mechanism. The attention mechanism in Luong et al. (2015) computes the weighted average of the hidden states $h_i^{(enc)}$ of the encoder:

$$s(i,t) = \frac{\exp(h_t^{(dec)} \cdot h_i^{(enc)})}{\sum_{j=1}^{N+1} \exp(h_t^{(dec)} \cdot h_j^{(enc)})}, \tag{4}$$

$$a_t = \sum_{i=1}^{N+1} s(i,t) h_i^{(enc)}, \tag{5}$$

where $s(i,t)$ is a scoring function which specifies how much each source-side hidden state contributes to the word prediction.

In addition, like the attention mechanism over constituency tree nodes (Eriguchi et al., 2016b), our model uses attention to the dependency composition vectors:

$$s'(i,t) = \frac{\exp(h_t^{(dec)} \cdot dep(w_i))}{\sum_{j=1}^{N} \exp(h_t^{(dec)} \cdot dep(w_j))}, \tag{6}$$

$$a'_t = \sum_{i=1}^{N} s'(i,t) dep(w_i), \tag{7}$$

To predict the target word, a hidden state $\tilde{h}_t^{(dec)} \in \mathbb{R}^{d_3}$ is then computed as follows:

$$\tilde{h}_t^{(dec)} = \tanh(\tilde{W}[h_t^{(dec)}; a_t; a'_t]), \tag{8}$$

where $\tilde{W} \in \mathbb{R}^{d_3 \times 3d_3}$ is a weight matrix. $\tilde{h}_t^{(dec)}$ is fed into a softmax classifier to predict a target word distribution. $\tilde{h}_t^{(dec)}$ is also used in the transition of the decoder LSTMs along with a word embedding $v_{dec}(w_t) \in \mathbb{R}^{d_3}$ of the target word w_t:

$$h_{t+1}^{(dec)} = \mathrm{LSTM}(h_t^{(dec)}, [v_{dec}(w_t); \tilde{h}_t^{(dec)}]), \tag{9}$$

where the use of $\tilde{h}_t^{(dec)}$ is called *input feeding* proposed by Luong et al. (2015).

The overall model parameters, including those of the latent graph parser, are jointly learned by minimizing the negative log-likelihood of the prediction probabilities of the target words in the training data. To speed up the training, we use BlackOut sampling (Ji et al., 2016). By this joint learning using Equation (3) and (7), the latent graph representations are automatically learned according to the target task.

Implementation Tips Inspired by Zoph et al. (2016), we further speed up BlackOut sampling by sharing noise samples across words in the same sentences. This technique has proven to be effective in RNN language modeling, and we have found that it is also effective in the NMT model. We have also found it effective to share the model parameters of the target word embeddings and the softmax weight matrix for word prediction (Inan et al., 2016; Press and Wolf, 2017). Also, we have found that a parameter averaging technique (Hashimoto et al., 2013) is helpful in improving translation accuracy.

Translation At test time, we use a novel beam search algorithm which combines statistics of sentence lengths (Eriguchi et al., 2016b) and length normalization (Cho et al., 2014). During the beam search step, we use the following scoring function for a generated word sequence $y = (y_1, y_2, \dots, y_{L_y})$ given a source word sequence $x = (x_1, x_2, \dots, x_{L_x})$:

$$\frac{1}{L_y}\left(\sum_{i=1}^{L_y} \log p(y_i|x, y_{1:i-1}) + \log p(L_y|L_x)\right), \tag{10}$$

where $p(L_y|L_x)$ is the probability that sentences of length L_y are generated given source-side sentences of length L_x. The statistics are taken by using the training data in advance. In our experiments, we have empirically found that this beam search algorithm helps the NMT models to avoid generating translation sentences that are too short.

4 Experimental Settings

4.1 Data

We used an English-to-Japanese translation task of the Asian Scientific Paper Excerpt Corpus (ASPEC) (Nakazawa et al., 2016b) used in the Workshop on Asian Translation (WAT), since it has been shown that syntactic information is useful in English-to-Japanese translation (Eriguchi et al., 2016b; Neubig et al., 2015). We followed the data preprocessing instruction for the English-to-Japanese task in Eriguchi et al. (2016b). The English sentences were tokenized by the tokenizer in the Enju parser (Miyao and Tsujii, 2008), and the Japanese sentences were segmented by the KyTea tool[1]. Among the first 1,500,000 translation pairs in the training data, we selected 1,346,946 pairs where the maximum sentence length is 50. In what follows, we call this dataset the *large* training dataset. We further selected the first 20,000 and 100,000 pairs to construct the *small* and *medium* training datasets, respectively. The development data include 1,790 pairs, and the test data 1,812 pairs.

For the small and medium datasets, we built the vocabulary with words whose minimum frequency is two, and for the large dataset, we used words whose minimum frequency is three for English and five for Japanese. As a result, the vocabulary of the target language was 8,593 for the small dataset, 23,532 for the medium dataset, and 65,680 for the large dataset. A special token $\langle$UNK$\rangle$ was used to replace words which were not included in the vocabularies. The character n-grams ($n = 2, 3, 4$) were also constructed from each training dataset with the same frequency settings.

4.2 Parameter Optimization and Translation

We turned hyper-parameters of the model using development data. We set $(d_1, d_2) = (100, 50)$ for the latent graph parser. The word and character n-gram embeddings of the latent graph parser were initialized with the pre-trained embeddings in Hashimoto et al. (2017).[2] The weight matrices in the latent graph parser were initialized with uniform random values in $[-\frac{\sqrt{6}}{\sqrt{row+col}}, +\frac{\sqrt{6}}{\sqrt{row+col}}]$, where row and col are the number of rows and columns of the matrices, respectively. All the bias vectors and the weight matrices in the softmax layers were initialized with zeros, and the bias vectors of the forget gates in the LSTMs were initialized by ones (Jozefowicz et al., 2015).

We set $d_3 = 128$ for the small training dataset, $d_3 = 256$ for the medium training dataset, and $d_3 = 512$ for the large training dataset. The word embeddings and the weight matrices of the NMT model were initialized with uniform random values in $[-0.1, +0.1]$. The training was performed by mini-batch stochastic gradient descent with momentum. For the BlackOut objective (Ji et al., 2016), the number of the negative samples was set to 2,000 for the small and medium training datasets, and 2,500 for the large training dataset. The mini-batch size was set to 128, and the momentum rate was set to 0.75 for the small and medium training datasets and 0.70 for the large training dataset. A gradient clipping technique was used with a clipping value of 1.0. The initial learning rate was set to 1.0, and the learning rate was halved when translation accuracy decreased. We used the BLEU scores obtained by greedy translation as the translation accuracy and checked it at every half epoch of the model training. We saved the model parameters at every half epoch and used the saved model parameters for the parameter averaging technique. For regularization, we used L2-norm regularization with a coefficient of 10^{-6} and applied dropout (Hinton et al., 2012) to Equation (8) with a dropout rate of 0.2.

The beam size for the beam search algorithm was 12 for the small and medium training datasets, and 50 for the large training dataset. We used BLEU (Papineni et al., 2002), RIBES (Isozaki et al., 2010), and perplexity scores as our evaluation metrics. Note that lower perplexity scores indicate better accuracy.

4.3 Pre-Training of Latent Graph Parser

The latent graph parser in our model can be optionally pre-trained by using human annotations for dependency parsing. In this paper we used

[1] http://www.phontron.com/kytea/.

[2] The pre-trained embeddings can be found at https://github.com/hassyGo/charNgram2vec.

the widely-used Wall Street Journal (WSJ) training data to jointly train the POS tagging and dependency parsing components. We used the standard training split (Section 0-18) for POS tagging. We followed Chen and Manning (2014) to generate the training data (Section 2-21) for dependency parsing. From each training dataset, we selected the first K sentences to pre-train our model. The training dataset for POS tagging includes 38,219 sentences, and that for dependency parsing includes 39,832 sentences.

The parser including the POS tagger was first trained for 10 epochs in advance according to the multi-task learning procedure of Hashimoto et al. (2017), and then the overall NMT model was trained. When pre-training the POS tagging and dependency parsing components, we did not apply dropout to the model and did not fine-tune the word and character n-gram embeddings to avoid strong overfitting.

4.4 Model Configurations

LGP-NMT is our proposed model that learns the Latent Graph Parsing for NMT.

LGP-NMT+ is constructed by pre-training the latent parser in LGP-NMT as described in Section 4.3.

SEQ is constructed by removing the dependency composition in Equation (3), forming a sequential NMT model with the multi-layer encoder.

DEP is constructed by using pre-trained dependency relations rather than learning them. That is, $p(H_{w_i} = w_j|w_i)$ is fixed to 1.0 such that w_j is the head of w_i. The dependency labels are also given by the parser which was trained by using all the training samples for parsing and tagging.

UNI is constructed by fixing $p(H_{w_i} = w_j|w_i)$ to $\frac{1}{N}$ for all the words in the same sentence. That is, the uniform probability distributions are used for equally connecting all the words.

5 Results on Small and Medium Datasets

We first show our translation results using the small and medium training datasets. We report averaged scores with standard deviations across five different runs of the model training.

5.1 Small Training Dataset

Table 1 shows the results of using the small training dataset. LGP-NMT performs worse than SEQ and UNI, which shows that the small training dataset is not enough to learn useful latent graph structures from scratch. However, LGP-NMT+ (K = 10,000) outperforms SEQ and UNI, and the standard deviations are the smallest. Therefore, the results suggest that pre-training the parsing and tagging components can improve the translation accuracy of our proposed model. We can also see that DEP performs the worst. This is not surprising because previous studies, e.g., Li et al. (2015), have reported that using syntactic structures do not always outperform competitive sequential models in several NLP tasks.

	BLEU	RIBES	Perplexity
LGP-NMT	14.31±1.49	65.96±1.86	41.13±2.66
LGP-NMT+	16.81±0.31	69.03±0.28	38.33±1.18
SEQ	15.37±1.18	67.01±1.55	38.12±2.52
UNI	15.13±1.67	66.95±1.94	39.25±2.98
DEP	13.34±0.67	64.95±0.75	43.89±1.52

All	16.09±0.56	68.19±0.59	39.24±1.88

Table 2: Effects of the size K of the training datasets for POS tagging and dependency parsing.

Now that we have observed the effectiveness of pre-training our model, one question arises naturally:

> how many training samples for parsing and tagging are necessary for improving the translation accuracy?

Table 2 shows the results of using different numbers of training samples for parsing and tagging. The results of K= 0 and K= 10,000 correspond to those of LGP-NMT and LGP-NMT+ in Table 1, respectively. We can see that using the small amount of the training samples performs better than using all the training samples.[3] One possible reason is that the domains of the translation dataset and the parsing (tagging) dataset are considerably different. The parsing and tagging datasets come from WSJ, whereas the translation dataset comes from abstract text of scientific papers in a wide range of domains, such as

[3] We did not observe such significant difference when using the larger datasets, and we used all the training samples in the remaining part of this paper.

	BLEU	RIBES	Perplexity
LGP-NMT	28.70±0.27	77.51±0.13	12.10±0.16
LGP-NMT+	29.06±0.25	77.57±0.24	12.09±0.27
SEQ	28.60±0.24	77.39±0.15	12.15±0.12
UNI	28.25±0.35	77.13±0.20	12.37±0.08
DEP	26.83±0.38	76.05±0.22	13.33±0.23

Table 3: Evaluation on the development data using the medium training dataset (100,000 pairs).

biomedicine and computer science. These results suggest that our model can be improved by a small amount of parsing and tagging datasets in different domains. Considering the recent universal dependency project[4] which covers more than 50 languages, our model has the potential of being applied to a variety of language pairs.

5.2 Medium Training Dataset

Table 3 shows the results of using the medium training dataset. In contrast with using the small training dataset, LGP-NMT is slightly better than SEQ. LGP-NMT significantly outperforms UNI, which shows that our adaptive learning is more effective than using the uniform graph weights. By pre-training our model, LGP-NMT+ significantly outperforms SEQ in terms of the BLEU score. Again, DEP performs the worst among all the models.

By using our beam search strategy, the Brevity Penalty (BP) values of our translation results are equal to or close to 1.0, which is important when evaluating the translation results using the BLEU scores. A BP value ranges from 0.0 to 1.0, and larger values mean that the translated sentences have relevant lengths compared with the reference translations. As a result, our BLEU evaluation results are affected only by the word n-gram precision scores. BLEU scores are sensitive to the BP values, and thus our beam search strategy leads to more solid evaluation for NMT models.

6 Results on Large Dataset

Table 4 shows the BLEU and RIBES scores on the development data achieved with the large training dataset. Here we focus on our models and SEQ because UNI and DEP consistently perform worse than the other models as shown in Table 1 and 3. The averaging technique and attention-based unknown word replacement (Jean et al., 2015; Hashimoto et al., 2016) improve the scores. Again, we see that the translation scores of our model can be further improved by pre-training the model.

B./R.	Single	+Averaging	+UnkRep

Neubig and Duh (2014)	36.58	79.65
Zhu (2015)	36.21	80.91
Lee et al. (2015)	35.75	81.15

Table 5: BLEU and RIBES scores on the test data.

Table 5 shows our results on the test data, and the previous best results summarized in Nakazawa et al. (2016a) and the WAT website[5] are also shown. Our proposed models, LGP-NMT and LGP-NMT+, outperform not only SEQ but also all of the previous best results. Notice also that our implementation of the sequential model (SEQ) provides a very strong baseline, the performance of which is already comparable to the previous state of the art, even without using ensemble techniques. The confidence interval ($p \leq 0.05$) of the RIBES score of LGP-NMT+ estimated by bootstrap resampling (Noreen, 1989) is $(82.27, 83.37)$, and thus the RIBES score of LGP-NMT+ is significantly better than that of SEQ, which shows that our latent parser can be effectively pre-trained with the human-annotated treebank.

The sequential NMT model in Cromieres et al. (2016) and the tree-to-sequence NMT model in Eriguchi et al. (2016b) rely on ensemble techniques while our results mentioned above are obtained using single models. Moreover, our model is more compact[6] than the previous best NMT model in Cromieres et al. (2016). By applying the ensemble technique to LGP-NMT, LGP-NMT+,

LGP-NMT+: アンドロゲンは ImRNA を負に制御している。

(The androgen *negatively* controls ImRNA.)

Google trans: アンドロゲンは負のImRNA を制御する。

LGP-NMT: アンドロゲンは負の ImRNA を制御する。

(The androgen controls *negative* ImRNA.)

SEQ: アンドロゲンは負の ImRNAを負に制御する。

(The androgen *negatively* controls *negative* ImRNA.)

Figure 2: English-to-Japanese translation examples for focusing on the usage of adverbs.

and SEQ, the BLEU and RIBES scores are further improved, and both of the scores are significantly better than the previous best scores.

6.1 Analysis on Translation Examples

Figure 2 shows two translation examples[7] to see how the proposed model works and what is missing in the state-of-the-art sequential NMT model, SEQ. Besides the reference translation, the outputs of our models with and without pre-training, SEQ, and Google Translation[8] are shown.

Selectional Preference In the translation example (1) in Figure 2, we see that the adverb "obliquely" is interpreted differently across the systems. As in the reference translation, "obliquely" is a modifier of the verb "crosses". Our models correctly capture the relationship between the two words, whereas Google Translation and SEQ treat "obliquely" as a modifier of the verb "existed". This error is not a surprise since the verb "existed" is located closer to "obliquely" than the verb "crosses". A possible reason for the correct interpretation by our models is that they can better capture long-distance dependencies and are less susceptible to surface word distances. This is an indication of our models' ability of capturing domain-specific selectional preference that cannot be captured by purely sequential models. It should be noted that simply using standard treebank-based parsers does not necessarily address this error, because our pre-trained dependency parser interprets that "obliquely" is a modifier of the verb "existed".

Adverb or Adjective The translation example (2) in Figure 2 shows another example where the adverb "negatively" is interpreted as an adverb or an adjective. As in the reference translation, "negatively" is a modifier of the verb "controls". Only LGP-NMT+ correctly captures the adverb-verb relationship, whereas "negatively" is interpreted as the adjective "negative" to modify the noun "ImRNA" in the translation results from Google Translation and LGP-NMT. SEQ interprets "negatively" as both an adverb and an adjective, which leads to the repeated translations. This error suggests that the state-of-the-art NMT models are strongly affected by the word order. By contrast, the pre-training strategy effectively embeds the information about the POS tags and the dependency relations into our model.

6.2 Analysis on Learned Latent Graphs

Without Pre-Training We inspected the latent graphs learned by LGP-NMT. Figure 1 shows an example of the learned latent graph obtained for a sentence taken from the development data of the translation task. It has long-range dependencies and cycles as well as ordinary left-to-right dependencies. We have observed that the punctuation mark "." is often pointed to by other words with large weights. This is primarily because the hidden state corresponding to the mark in each sentence has rich information about the sentence.

To measure the correlation between the latent graphs and human-defined dependencies, we parsed the sentences on the development data of the WSJ corpus and converted the graphs into dependency trees by Eisner's algorithm (Eisner, 1996). For evaluation, we followed Chen and Manning (2014) and measured Unlabeled Attachment Score (UAS). The UAS is 24.52%, which shows that the implicitly-learned latent graphs are partially consistent with the human-defined syntactic structures. Similar trends have been reported by Yogatama et al. (2017) in the case of binary constituency parsing. We checked the most dominant gold dependency labels which were assigned for the dependencies detected by LGP-NMT. The labels whose ratio is more than 3% are

[7] These English sentences were created by manual simplification of sentences in the development data.

nn, amod, prep, pobj, dobj, nsubj, num, det, advmod, and poss. We see that dependencies between words in distant positions, such as subject-verb-object relations, can be captured.

With Pre-Training We also inspected the pre-trained latent graphs. Figure 3-(a) shows the dependency structure output by the pre-trained latent parser for the same sentence in Figure 1. This is an ordinary dependency tree, and the head selection is almost deterministic; that is, for each word, the largest weight of the head selection is close to 1.0. By contrast, the weight values are more evenly distributed in the case of LGP-NMT as shown in Figure 1. After the overall NMT model training, the latent parser is adapted to the translation task, and Figure 3-(b) shows the adapted latent graph. Again, we can see that the adapted weight values are also distributed and different from the original pre-trained weight values, which suggests that human-defined syntax is not always optimal for the target task.

The UAS of the pre-trained dependency trees is 92.52%[9], and that of the adapted latent graphs is 18.94%. Surprisingly, the resulting UAS (18.94%) is lower than the UAS of our model without pre-training (24.52%). However, in terms of the translation accuracy, our model with pre-training is better than that without pre-training. These results suggest that human-annotated treebanks can provide useful prior knowledge to guide the overall model training by pre-training, but the resulting sentence structures adapted to the target task do not need to highly correlate with the treebanks.

7 Related Work

While initial studies on NMT treat each sentence as a sequence of words (Bahdanau et al., 2015; Luong et al., 2015; Sutskever et al., 2014), researchers have recently started investigating into the use of syntactic structures in NMT models (Bastings et al., 2017; Chen et al., 2017; Eriguchi et al., 2016a,b, 2017; Li et al., 2017; Sennrich and Haddow, 2016; Stahlberg et al., 2016; Yang et al., 2017). In particular, Eriguchi et al. (2016b) introduced a tree-to-sequence NMT model by building a tree-structured encoder on top of a standard sequential encoder, which motivated the use of the dependency composition vectors in our proposed model. Prior to the advent of NMT, the syntactic structures had been successfully used in statistical machine translation systems (Neubig and Duh, 2014; Yamada and Knight, 2001). These syntax-based approaches are pipelined; a syntactic parser is first trained by supervised learning using a treebank such as the WSJ dataset, and then the parser is used to automatically extract syntactic information for machine translation. They rely on the output from the parser, and therefore parsing errors are propagated through the whole systems. By contrast, our model allows the parser to be adapted to the translation task, thereby providing a first step towards addressing ambiguous syntactic and semantic problems, such as domain-specific selectional preference and PP attachments, in a task-oriented fashion.

Our model learns latent graph structures in a source-side language. Eriguchi et al. (2017) have proposed a model which learns to parse and translate by using automatically-parsed data. Thus, it is also an interesting direction to learn latent structures in a target-side language.

As for the learning of latent syntactic structure, there are several studies on learning task-oriented syntactic structures. Yogatama et al. (2017) used a reinforcement learning method on shift-reduce action sequences to learn task-oriented binary constituency trees. They have shown that the learned trees do not necessarily highly correlate with the human-annotated treebanks, which is consistent with our experimental results. Socher et al. (2011) used a recursive autoencoder model to greedily construct a binary constituency tree for each sentence. The autoencoder objective works as a regularization term for sentiment classification tasks. Prior to these deep learning approaches,

[9] The UAS is significantly lower than the reported score in Hashimoto et al. (2017). The reason is described in Section 4.3.

Wu (1997) presented a method for *bilingual parsing*. One of the characteristics of our model is directly using the soft connections of the graph edges with the real-valued weights, whereas all of the above-mentioned methods use one best structure for each sentence. Our model is based on dependency structures, and it is a promising future direction to jointly learn dependency and constituency structures in a task-oriented fashion.

Finally, more related to our model, Kim et al. (2017) applied their *structured attention networks* to a Natural Language Inference (NLI) task for learning dependency-like structures. They showed that pre-training their model by a parsing dataset did not improve accuracy on the NLI task. By contrast, our experiments show that such a parsing dataset can be effectively used to improve translation accuracy by varying the size of the dataset and by avoiding strong overfitting. Moreover, our translation examples show the concrete benefit of learning task-oriented latent graph structures.

8 Conclusion and Future Work

We have presented an end-to-end NMT model by jointly learning translation and source-side latent graph representations. By pre-training our model using treebank annotations, our model significantly outperforms both a pipelined syntax-based model and a state-of-the-art sequential model. On English-to-Japanese translation, our model outperforms the previous best models by a large margin. In future work, we investigate the effectiveness of our approach in different types of target tasks.

Acknowledgments

We thank the anonymous reviewers and Akiko Eriguchi for their helpful comments and suggestions. We also thank Yuchen Qiao and Kenjiro Taura for their help in speeding up our training code. This work was supported by CREST, JST, and JSPS KAKENHI Grant Number 17J09620.

Abstract

In the encoder-decoder architecture for neural machine translation (NMT), the hidden states of the recurrent structures in the encoder and decoder carry the crucial information about the sentence.These vectors are generated by parameters which are updated by back-propagation of translation errors through time. We argue that propagating errors through the end-to-end recurrent structures are not a direct way of control the hidden vectors. In this paper, we propose to use word predictions as a mechanism for direct supervision. More specifically, we require these vectors to be able to predict the vocabulary in target sentence. Our simple mechanism ensures better representations in the encoder and decoder without using any extra data or annotation. It is also helpful in reducing the target side vocabulary and improving the decoding efficiency. Experiments on Chinese-English and German-English machine translation tasks show BLEU improvements by 4.53 and 1.3, respectively.

1 Introduction

The encoder-decoder based neural machine translation (NMT) models (Sutskever et al., 2014; Cho et al., 2014) have been developing rapidly. Sutskever et al. (2014) propose to encode the source sentence as a fixed-length vector representation, based on which the decoder generates the target sequence, where both the encoder and decoder are recurrent neural networks (RNN) (Sutskever et al., 2014) or their variants (Cho et al., 2014; Chung et al., 2014; Bahdanau et al., 2014). In this framework, the fixed-length vector plays the crucial role of transitioning the information of the sentence from the source side to the target side.

Later, attention mechanisms are proposed to enhance the source side representations (Bahdanau et al., 2014; Luong et al., 2015b). The source side context is computed at each time-step of decoding, based on the attention weights between the source side representations and the current hidden state of the decoder. However, the hidden states in the recurrent decoder still originate from the single fixed-length representation (Luong et al., 2015b), or the average of the bi-directional representations (Bahdanau et al., 2014). Here we refer to the representation as *initial state*.

Interestingly, Britz et al. (2017) find that the value of initial state does not affect the translation performance, and prefer to set the initial state to be a zero vector. On the contrary, we argue that initial state still plays an important role of translation, which is currently neglected. We notice that beside the end-to-end error back propagation for the initial and transition parameters, there is no direct control of the initial state in the current NMT architectures. Due to the large number of parameters, it may be difficult for the NMT system to learn the proper sentence representation as the initial state. Thus, the model is very likely to get stuck in local minimums, making the translation process arbitrary and unstable.

In this paper, we propose to augment the current NMT architecture with a word prediction mechanism. More specifically, we require the initial state of the decoder to be able to predict all the words in the target sentence. In this way, there is a specific objective for learning the initial state. Thus the learnt source side representation will be better constrained. We further extend this idea by applying the word predictions mechanism to all the hidden states of the decoder. So the transition between different decoder states could be controlled

Proceedings of the 2017 Conference on Empirical Methods in Natural Language Processing, pages 136–145
Copenhagen, Denmark, September 7–11, 2017.

as well.

Our mechanism is simple and requires no additional data or annotation. The proposed word predictions mechanism could be used as a training method and brings no extra computing cost during decoding.

Experiments on the Chinese-English and German-English translation tasks show that both the constraining of the initial state and the decoder hidden states bring significant improvement over the baseline systems. Furthermore, using the word prediction mechanism on the initial state as a word predictor to reduce the target side vocabulary could greatly improve the decoding efficiency, without a significant loss on the translation quality.

2 Related Work

Many previous works have noticed the problem of training an NMT system with lots of parameters. Some of them prefer to use the dropout technique (Srivastava et al., 2014; Luong et al., 2015b; Meng et al., 2016). Another possible choice is to ensemble several models with random starting points (Sutskever et al., 2014; Jean et al., 2015; Luong and Manning, 2016). Both techniques could bring more stable and better results. But they are general training techniques of neural networks, which are not specifically targeting the modeling of the translation process like ours. We will make empirical comparison with them in the experiments.

The way we add the word prediction is similar to the research of multi-task learning. Dong et al. (2015) propose to share an encoder between different translation tasks. Luong et al. (2015a) propose to jointly learn the translation task for different languages, the parsing task and the image captioning task, with a shared encoder or decoder. Zhang and Zong (2016) propose to use multitask learning for incorporating source side monolingual data. Different from these attempts, our method focuses solely on the current translation task, and does not require any extra data or annotation.

In the other sequence to sequence tasks, Suzuki and Nagata (2017) propose the idea for predicting words by using encoder information. However, the purpose and the way of our mechanism are different from them.

The word prediction technique has been applied in the research of both statistical machine translation (SMT) (Bangalore et al., 2007; Mauser et al., 2009; Jeong et al., 2010; Tran et al., 2014) and NMT (Mi et al., 2016; L'Hostis et al., 2016). In these research, word prediction mechanisms are employed to decide the selection of words or constrain the target vocabulary, while in this paper, we use word prediction as a control mechanism for neural model training.

3 Notations and Backgrounds

We present a popular NMT framework with the encoder-decoder architecture (Cho et al., 2014; Bahdanau et al., 2014) and the attention networks (Luong et al., 2015b), based on which we propose our word prediction mechanism.

Denote a source-target sentence pair as $\{\mathbf{x}, \mathbf{y}\}$ from the training set, where $\mathbf{x}$ is the source word sequence $(x_1, x_2, \cdots, x_{|\mathbf{x}|})$ and $\mathbf{y}$ is the target word sequence $(y_1, y_2, \cdots, y_{|\mathbf{y}|})$, $|\mathbf{x}|$ and $|\mathbf{y}|$ are the length of $\mathbf{x}$ and $\mathbf{y}$, respectively.

In the encoding stage, a bi-directional recurrent neural network is used (Bahdanau et al., 2014) to encode $\mathbf{x}$ into a sequence of vectors $(\mathbf{h}_1, \mathbf{h}_2, \cdots, \mathbf{h}_{|\mathbf{x}|})$. For each x_i, the representation $\mathbf{h}_i$ is:

$$\mathbf{h}_i = [\overrightarrow{\mathbf{h}}_i; \overleftarrow{\mathbf{h}}_i] \tag{1}$$

where $[\cdot;\cdot]$ denotes the concatenation of column vectors; $\overrightarrow{\mathbf{h}}_i$ and $\overleftarrow{\mathbf{h}}_i$ denote the hidden vectors for the word x_i in the forward and backward RNNs, respectively.

The gated recurrent unit (GRU) is used as the recurrent unit in each RNN, which is shown to have promising results in speech recognition and machine translation (Cho et al., 2014). Formally, the hidden state $\mathbf{h}_i$ at time step i of the forward RNN encoder is defined by the GRU function $g_{\overrightarrow{e}}(\cdot,\cdot)$, as follows:

$$\begin{aligned}\overrightarrow{\mathbf{h}}_i &= g_{\overrightarrow{e}}(\overrightarrow{\mathbf{h}}_{i-1}, \mathbf{emb}_{x_i}) \\ &= (\mathbf{1} - \overrightarrow{\mathbf{z}}_i) \odot \overrightarrow{\mathbf{h}}_{i-1} + \overrightarrow{\mathbf{z}}_i \odot \overrightarrow{\mathbf{h}'}_i\end{aligned} \tag{2}$$

$$\overrightarrow{\mathbf{z}}_i = \sigma(\overrightarrow{\mathbf{W}}_z[\mathbf{emb}_{x_i}; \overrightarrow{\mathbf{h}}_{i-1}]) \tag{3}$$

$$\overrightarrow{\mathbf{h}'}_i = \tanh(\overrightarrow{\mathbf{W}}[\mathbf{emb}_{x_i}; (\overrightarrow{\mathbf{r}}_i \odot \overrightarrow{\mathbf{h}}_{i-1})]) \tag{4}$$

$$\overrightarrow{\mathbf{r}}_i = \sigma(\overrightarrow{\mathbf{W}}_r[\mathbf{emb}_{x_i}; \overrightarrow{\mathbf{h}}_{i-1}]) \tag{5}$$

where $\odot$ denotes element-wise product between vectors and $\mathbf{emb}_{x_i}$ is the word embedding of the x_i. $\tanh(\cdot)$ and $\sigma(\cdot)$ are the tanh and sigmoid transformation functions that can be applied element-wise on vectors, respectively. For simplicity, we

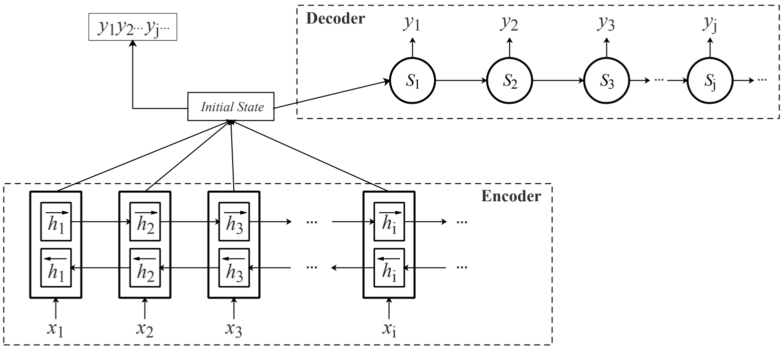

Figure 1: The NMT model with word prediction for the initial state.

omit the bias term in each network layer. The backward RNN encoder is defined likewise.

In the decoding stage, the decoder starts with the initial state $\mathbf{s}_0$, which is the average of source representations (Bahdanau et al., 2014).

$$\mathbf{s}_0 = \sigma(\mathbf{W}_s \frac{1}{|\mathbf{x}|} \sum_{i=1}^{|\mathbf{x}|} \mathbf{h}_i) \tag{6}$$

At each time step j, the decoder maximizes the conditional probability of generating the jth target word, which is defined as:

$$P(y_j|y_{<j}, \mathbf{x}) = f_d(t_d([\mathbf{emb}_{y_{j-1}}; \mathbf{s}_j; \mathbf{c}_j])) \tag{7}$$

$$f_d(\mathbf{u}) = \text{softmax}(\mathbf{W}_f \mathbf{u}) \tag{8}$$

$$t_d(\mathbf{v}) = \tanh(\mathbf{W}_t \mathbf{v}) \tag{9}$$

where $\mathbf{s}_j$ is the decoder's hidden state, which is computed by another GRU (as in Equation 2):

$$\mathbf{s}_j = g_d(\mathbf{s}_{j-1}, [\mathbf{emb}_{y_{j-1}}; \mathbf{c}_j]) \tag{10}$$

and the context vector $\mathbf{c}_j$ is from the attention mechanism (Luong et al., 2015b):

$$\mathbf{c}_j = \sum_{i=1}^{|\mathbf{x}|} a_{ji} \mathbf{h}_i \tag{11}$$

$$a_{ji} = \frac{\exp(e_{ji})}{\sum_{k=1}^{|\mathbf{x}|} \exp(e_{jk})} \tag{12}$$

$$e_{ji} = \tanh(\mathbf{W}_{att_d}[\mathbf{s}_{j-1}; \mathbf{h}_i]). \tag{13}$$

4 NMT with Word Predictions

4.1 Word Prediction for the Initial State

The decoder starts the generation of target sentence from the initial state $\mathbf{s}_0$ (Equation 6) generated by the encoder. Currently, the update for the encoder only happens when a translation error occurs in the decoder. The error is propagated through multiple time steps in the recurrent structure until it reaches the encoder. As there are hundreds of millions of parameters in the NMT system, it is hard for the model to learn the exact representation of source sentences. As a result, the values of initial state may not be exact during the translation process, leading to poor translation performances.

We propose word prediction as a mechanism to control the values of initial state. The intuition is that since the initial state is responsible for the translation of whole target sentence, it should at least contain information of each word in the target sentence. Thus, we optimize the initial state by making prediction for all target words. For simplicity, we assume each target word is independent of each other.

Here the word prediction mechanism is a simpler sub-task of translation, where the order of words is not considered. The prediction task could be trained jointly with the translation task in a multi-task learning way (Luong et al., 2015a; Dong et al., 2015; Zhang and Zong, 2016), where both tasks share the same encoder. In other words, word prediction for the initial state could be interpreted as an improvement for the encoder. We denote this mechanism as WP_E .

As shown in Figure 1, a prediction network is added to the initial state. We define the conditional probability of WP_E as follows:

$$P_{\text{WP}_\text{E}}(\mathbf{y}|\mathbf{x}) = \prod_{j=1}^{|\mathbf{y}|} P_{\text{WP}_\text{E}}(y_j|\mathbf{x}) \tag{14}$$

$$P_{\text{WP}_\text{E}}(y_j|\mathbf{x}) = f_p(t_p([\mathbf{s}_0; \mathbf{c}_p])) \tag{15}$$

where $f_p(\cdot)$ and $t_p(\cdot)$ are the softmax layer and non-linear layer as defined in Equation 8-9, with different parameters; $\mathbf{c}_p$ is defined similar as the

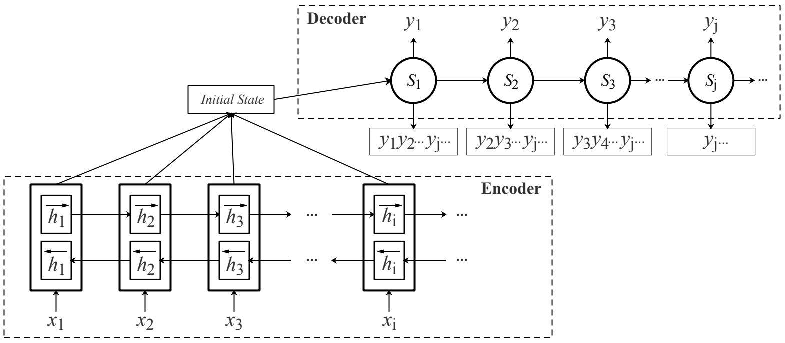

Figure 2: The NMT model with word predictions for the decoder's hidden states.

attention network, so the source side information could be enhanced.

$$\mathbf{c}_p = \sum_{i=1}^{|\mathbf{x}|} a_i \mathbf{h}_i \tag{16}$$

$$a_i = \frac{\exp(e_i)}{\sum_{k=1}^{|\mathbf{x}|} \exp(e_k)} \tag{17}$$

$$e_i = \tanh(\mathbf{W}_{att_p}[\mathbf{s}_0, \mathbf{h}_i]). \tag{18}$$

4.2 Word Predictions for Decoder's Hidden States

Similar intuition is also applied for the decoder. Because the hidden states of the decoder are responsible for the translation of target words, they should be able to predict the target words as well. The only difference is that we remove the already generated words from the prediction task. So each hidden state in the decoder is required to predict the target words which remain untranslated.

For the first state $\mathbf{s}_1$ of the decoder, the prediction task is similar with the task for the initial state. Since then, the prediction is no longer a separate training task, but integrated into each time step of the training process. We denote this mechanism as $\mathrm{WP_D}$.

As shown in Figure 2, for each time step j in the decoder, the hidden state $\mathbf{s}_j$ is used for the prediction of $(y_j, y_{j+1}, \cdots, y_{|\mathbf{y}|})$. The conditional probability of $\mathrm{WP_D}$ is defined as:

$$\begin{aligned} P_{\mathrm{WP_D}}(y_j, y_{j+1}, \cdots, y_{|\mathbf{y}|} | y_{<j}, \mathbf{x}) \\ = \prod_{k=j}^{|\mathbf{y}|} P_{\mathrm{WP_D}}(y_k | y_{<j}, \mathbf{x}) \end{aligned} \tag{19}$$

$$P_{\mathrm{WP_D}}(y_k | y_{<j}, \mathbf{x}) = f_d(p(t_d([\mathbf{emb}_{y_{j-1}}; \mathbf{s}_j; \mathbf{c}_j]))) \tag{20}$$

where $f_d(\cdot)$ and $t_d(\cdot)$ are the softmax layer and non-linear layer as defined in Equation 8-9; $p(\cdot)$ is another non-linear transformation layer, which prepares the current state for the prediction:

$$p(\mathbf{u}) = \tanh(\mathbf{W}_p \mathbf{u}). \tag{21}$$

4.3 Training

NMT models optimize the networks by maximizing the likelihood of the target translation $\mathbf{y}$ given source sentence $\mathbf{x}$, denoted by L_T.

$$L_\mathrm{T} = \frac{1}{|\mathbf{y}|} \sum_{j=1}^{|\mathbf{y}|} \log P(y_j | y_{<j}, \mathbf{x}) \tag{22}$$

where $P(y_j | y_{<j}, \mathbf{x})$ is defined in Equation 7.

To optimize the word prediction mechanism, we propose to add extra likelihood functions $L_{\mathrm{WP_E}}$ and $L_{\mathrm{WP_D}}$ into the training procedure.

For the $\mathrm{WP_E}$, we directly optimize the likelihood of translation and word prediction:

$$L_1 = L_\mathrm{T} + L_{\mathrm{WP_E}} \tag{23}$$

$$L_{\mathrm{WP_E}} = \log P_{\mathrm{WP_E}} \tag{24}$$

where $P_{\mathrm{WP_E}}$ is defined in Equation 14.

For the $\mathrm{WP_D}$, we optimize the likelihood as:

$$L_2 = L_\mathrm{T} + L_{\mathrm{WP_D}} \tag{25}$$

$$L_{\mathrm{WP_D}} = \sum_{j=1}^{|\mathbf{y}|} \frac{1}{|\mathbf{y}| - j + 1} \log P_{\mathrm{WP_D}} \tag{26}$$

where $P_{\mathrm{WP_D}}$ is defined in Equation 19; the coefficient of the logarithm is used to calculate the average probability of each prediction.

The two mechanisms could also work together, so that both the encoder and the decoder could be improved:

$$L_3 = L_\mathrm{T} + L_{\mathrm{WP_E}} + L_{\mathrm{WP_D}}. \tag{27}$$

4.4 Making Use of the Word Predictor

The previously proposed word prediction mechanism could be used only as a extra training objective, which will not be computed during the translation. Thus the computational complexity of our models for translation stays exactly the same.

On the other hand, using a smaller and specific vocabulary for each sentence or batch will improve translation efficiency. If the vocabulary is accurate enough, there is also a chance to improve the translation quality (Jean et al., 2015; Mi et al., 2016; L'Hostis et al., 2016). Our word prediction mechanism $\mathrm{WP_E}$ provides a natural solution for generating a possible set of target words at sentence level. The prediction could be made from the initial state $\mathbf{s}_0$, without using extra resources such as word dictionaries, extracted phrases or frequent word lists, as in Mi et al. (2016).

5 Experiments

5.1 Data

We perform experiments on the Chinese-English (CH-EN) and German-English (DE-EN) machine translation tasks. For the CH-EN, the training data consists of about 8 million sentence pairs [1]. We use NIST MT02 as our validation set, and the NIST MT03, MT04 and MT05 as our test sets. These sets have 878, 919, 1597 and 1082 source sentences, respectively, with 4 references for each sentence. For the DE-EN, the experiments trained on the standard benchmark WMT14, and it has about 4.5 million sentence pairs. We use newstest 2013 (NST13) as validation set, and newstest 2014(NST14) as test set. These sets have 3000 and 2737 source sentences, respectively, with 1 reference for each sentence. Sentences were encoded using byte-pair encoding (BPE) (Britz et al., 2017).

5.2 Systems and Techniques

We implement a baseline system with the bi-directional encoder (Bahdanau et al., 2014) and the attention mechanism (Luong et al., 2015b) as described in Section 3, denoted as baseNMT. Then our proposed word prediction mechanism on initial state and hidden states of decoder are implemented on the baseNMT system, denoted as $\mathrm{WP_E}$ and $\mathrm{WP_D}$, respectively. We denote the system use both techniques as $\mathrm{WP_{ED}}$. We implement systems with variable-sized vocabulary following (Mi et al., 2016). For comparison, we also implement systems with dropout (with dropout rate 0.5 on the output layer) and ensemble (ensemble of 4 systems at the output layer) techniques.

5.3 Implementation Details

Both our CH-EN and DE-EN experiments are implemented on the open source toolkit dl4mt [2], with most default parameter settings kept the same. We train the NMT systems with the sentences of length up to 50 words. The source and target vocabularies are limited to the most frequent 30K words for both Chinese and English, respectively, with the out-of-vocabulary words mapped to a special token UNK.

The dimension of word embedding is set to 512 and the size of the hidden layer is 1024. The recurrent weight matrices are initialized as random orthogonal matrices, and all the bias vectors as zero. Other parameters are initialized by sampling from the Gaussian distribution $\mathcal{N}(0, 0.01)$.

We use the mini-batch stochastic gradient descent (SGD) approach to update the parameters, with a batch size of 32. The learning rate is controlled by AdaDelta (Zeiler, 2012).

For efficient training of our system, we adopt a simple pre-train strategy. Firstly, the baseNMT system is trained. The training results are used as the initial parameters for pre-training our proposed models with word predictions.

For decoding during test time, we simply decode until the end-of-sentence symbol eos occurs, using a beam search with a beam width of 5.

5.4 Translation Experiments

To see the effect of word predictions in translation, we evaluate these systems in case-insensitive IBM-BLEU (Papineni et al., 2002) on both CH-EN and DE-EN tasks.

The detailed results are show in the Table 1 and Table 2. Compared to the baseNMT system, all of our models achieve significant improvements. On the CH-EN experiments, simply adding word predictions to the initial state ($\mathrm{WP_E}$) already brings considerable improvements. The average improvement on test set is 2.53 BLEU, showing that constraining the initial state does lead to a higher translation quality. Adding word predic-

WP$_{\mathrm{ED}}$	21.98	+1.3
baseNMT-dropout	21.62	+0.94
WP$_{\mathrm{ED}}$-dropout	21.71	+1.03
baseNMT-ensemble(4)	21.58	+0.9
WP$_{\mathrm{ED}}$-ensemble(4)	22.47	+1.79

Table 4: Case-insensitive 4-gram BLEU scores on the DE-EN experiments for baseNMT and WP$_{\mathrm{ED}}$ systems, with the dropout and ensemble techniques.

tions to the hidden states in the decoder (WP$_{\mathrm{D}}$) leads to further improvements against baseNMT (4.15 BLEU), because WP$_{\mathrm{D}}$ adds constraints to the state transitions through different time steps in the decoder. Using both techniques improves the baseline by 4.53 BLEU. On the DE-EN experiments, the improvement of WP$_{\mathrm{E}}$ model is 0.41 BLEU and WP$_{\mathrm{D}}$ model is 0.86 BLEU on test set. When use both techniques, the WP$_{\mathrm{ED}}$ improves on the test set is 1.3 BLEU.

We compare our models with systems using dropout and ensemble techniques. The results show in Table 3 and 4. On the CH-EN experiments, the dropout method successfully improves the baseNMT system by 2.06 BLEU. However, it does not work on our WP$_{\mathrm{ED}}$ system. The ensemble technique improves the baseNMT system by 2.75 BLEU. It still improves WP$_{\mathrm{ED}}$ by 1.26 BLEU, but the improvement is smaller than on the baseNMT. On the DE-EN experiments, the phenomenon of experiments is similar to CH-EN experiments. The baseNMT system improves 0.94 through dropout method and 0.9 BLEU through ensemble method. The dropout technique also does not work on WP$_{\mathrm{ED}}$ and the ensemble technique improves 1.79 BLEU. These comparisons suggests that our system already learns better and stable values for the parameters, enjoying some of the benefits of general training techniques like dropout and ensemble. Compared to dropout and ensemble, our method WP$_{\mathrm{ED}}$ achieves the highest improvement against the baseline system on both CH-EN and DE-EN experiments. Along with ensemble method, the improvement could be up to 5.79 BLEU and 1.79 BLEU respectively.

5.5 Word Prediction Experiments

Since we include an explicit word prediction mechanism during the training of NMT systems, we also evaluate the prediction performance on the CH-EN experiments to see how the training is improved.

For each sentence in the test set, we use the initial state of the given model to make prediction about the possible words. We denote the set of top n words as T_n, the set of words in all the references

top-n	baseNMT		WP$_\mathrm{E}$	
	Prec.	Recall	Prec.	Recall
top-10	45%	17%	73%	30%
top-20	33%	21%	63%	43%
top-50	21%	30%	41%	55%
top-100	14%	39%	28%	68%
top-1k	2%	67%	4%	89%
top-5k	0.7%	84%	0.9%	95%
top-10k	0.4%	90%	0.5%	97%

Table 5: Comparison between baseNMT and WP$_\mathrm{E}$ in precision and recall for the different prediction size on the CH-EN experiments.

as R. We define the precision, recall of the word prediction as follows:

$$\text{precision} = \frac{|T_n \cap R|}{|T_n|} * 100\% \tag{28}$$

$$\text{recall} = \frac{|T_n \cap R|}{|R|} * 100\% \tag{29}$$

We compare the prediction performance of baseNMT and WP$_\mathrm{E}$. WP$_\mathrm{ED}$ has similar prediction results with WP$_\mathrm{E}$, so we omit its results. As shown in Table 5, baseNMT system has a relatively lower prediction precision, for example, 45% in top 10 prediction. With an explicit training, the WP$_\mathrm{E}$ could achieve a much higher precision in all conditions. Specifically, the precision reaches 73% in top 10. This indicates that the initial state in WP$_\mathrm{E}$ contains more specific information about the prediction of the target words, which may be a step towards better semantic representation, and leads to better translation quality.

Because the total words in the references are limited (around 50), the precision goes down, as expected, when a larger prediction set is considered. On the other hand, the recall of WP$_\mathrm{E}$ is also much higher than baseNMT. When given 1k predictions, WP$_\mathrm{E}$ could successfully predict 89% of the words in the reference. The recall goes up to 95% with 5k predictions, which is only 1/6 of the current vocabulary.

To analyze the process of word prediction, we draw the attention heatmap (Equation 16) between the initial state $\mathbf{s}_0$ and the bi-directional representation of each source side word $\mathbf{h}_i$ for an example sentence. As shown in Figure 3, both examples show that the initial states have a very strong attention with all the content words in the source sentence. The blank cells are mostly functions words or high frequent tokens such as “的 ('s)”, “是 (is)”, “而 (and)”, “它 (it)”, comma and period. This indicates that the initial state successfully encodes information about most of the content words in the source sentence, which contributes for a high prediction performance and leads to better translation.

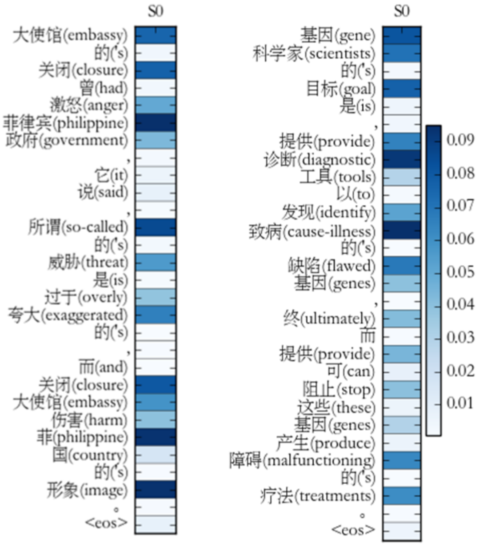

Figure 3: Two examples of the attention heatmap between the initial state $\mathbf{s}_0$ and the bi-directional representation of each source side word $\mathbf{h}_i$ from the CH-EN test sets. (The English translation of each source word is annotated in the parentheses after it.)

5.6 Improving Decoding Efficiency

To make use of the word prediction, we conduct experiments using the predicted vocabulary, with different vocabulary size (1k to 10k) on the CH-EN experiments, denoted as WP$_\mathrm{E}$-V and WP$_\mathrm{ED}$-V. The comparison is made in both translation quality and decoding time. As all our models with fixed vocabulary size have exactly the same number of parameters for decoding (extra mechanism is used only for training), we only plot the decoding time of the WP$_\mathrm{ED}$ for comparison. Figure 4 and 5 show the results.

When we start the experiments with top 1k vocabulary (1/30 of the baseline settings), the translation quality of both WP$_\mathrm{E}$-V and WP$_\mathrm{ED}$-V are already higher than the baseNMT; while their decoding time is less than 1/3 of an NMT system with 30k vocabulary. When the size of vocabulary increases, the translation quality improves as well. With a 6k predicted vocabulary (1/5 of the baseline settings), the decoding time is about 60% of a full-

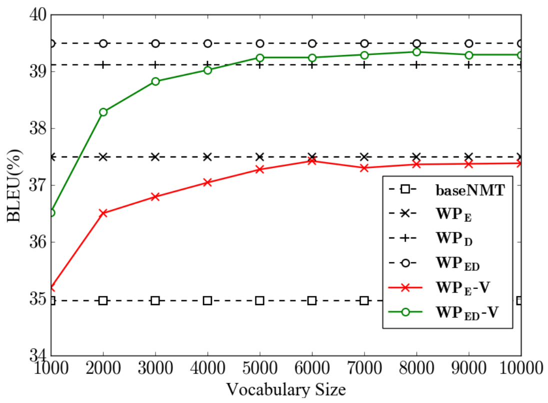

Figure 4: BLEU scores with different vocabulary sizes for each sentence on the CH-EN experiments. (The performance of baseNMT, WP$_E$, WP$_D$, WP$_{ED}$ are plotted as horizontal lines for comparison.)

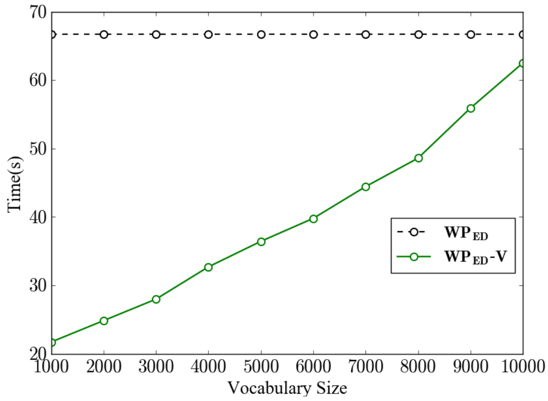

Figure 5: Decoding time with different vocabulary sizes for each sentence on the CH-EN experiments. (The horizontal line shows the decoding time for the systems with fixed vocabulary.)

vocabulary system; the performances of both systems with variable size vocabulary are comparable their corresponding fixed-vocabulary systems, which is higher than the baseNMT by 2.53 and 4.53 BLEU, respectively.

Although the comparison may not be fair enough due to the language pair and training conditions, the above relative improvements (e.g. WP$_{ED}$-V v.s. baseNMT) is much higher than previous research of manipulating the vocabularies (Jean et al., 2015; Mi et al., 2016; L'Hostis et al., 2016). This is because our mechanism is not only about reducing the vocabulary itself for each sentence or batch, it also brings improvement to the overall translation model. Please note that unlike these research, we keep the target vocabulary to be 30k in all our experiments, because we are not focusing on increasing the vocabulary size in this paper. It will be interesting to combine our mechanism with larger vocabulary to further enhance the translation performance. Again, our mechanism requires no extra annotation, dictionary, alignment or separate discriminative predictor, etc.

5.7 Translation Analysis

We also analyze real-case translations to see the difference between different systems (Table 6).

It is easy to see that the baseNMT system misses the translations of several important words, such as "advertising", "1.5", which are marked with underline in the reference. It also wrongly translates the company name "time warner inc." as the redundant information "internet company"; "america online" as "us line".

The results of dropout or ensemble show improvement compared to the baseNMT. But they still make mistakes about the translation of "online" and the company name "time warner inc.".

With WP$_{ED}$, most of these errors no longer exist, because we force the encoder and decoder to carry the exact information during translation.

6 Conclusions

The encoder-decoder architecture provides a general paradigm for learning machine translation from the source language to the target language. However, due to the large amount of parameters and relatively small training data set, the end-to-end learning of an NMT model may not be able to learn the best solution. We argue that at least part of the problem is caused by the long error backpropagation pipeline of the recurrent structures in multiple time steps, which provides no direct control of the information carried by the hidden states in both the encoder and decoder.

Instead of looking for other annotated data, we notice that the words in the target language sentence could be viewed as a natural annotation. We propose to use the word prediction mechanism to enhance the initial state generated by the encoder and extend the mechanism to control the hidden states of decoder as well. Experiments show promising results on the Chinese-English and German-English translation tasks. As a byproduct, the word predictor could be used to improve the efficiency of decoding, which may be

crucial for large scale applications.

Our attempts demonstrate that the learning of the large scale neural network systems is still not good enough. In the future, it might be helpful to analyze the benefits of jointly learning other related tasks together with machine translation, to provide further control of the learning process. It is interesting to demonstrate the effectiveness of the proposed mechanism on other sequence to sequence learning tasks as well.

Abstract

We propose a novel decoding approach for neural machine translation (NMT) based on continuous optimisation. We reformulate decoding, a discrete optimization problem, into a continuous problem, such that optimization can make use of efficient gradient-based techniques. Our powerful decoding framework allows for more accurate decoding for standard neural machine translation models, as well as enabling decoding in intractable models such as intersection of several different NMT models. Our empirical results show that our decoding framework is effective, and can leads to substantial improvements in translations, especially in situations where greedy search and beam search are not feasible. Finally, we show how the technique is highly competitive with, and complementary to, reranking.

1 Introduction

Sequence to sequence learning with neural networks (Graves, 2013; Sutskever et al., 2014; Lipton et al., 2015) is typically associated with two phases: training and decoding (*a.k.a.* inference). Model parameters are learned by optimising the training objective, in order that the model can produce good translations when decoding unseen sentences. The majority of research has focused on the training paradigm or network architecture, however effective means of decoding have been under-investigated. Conventional heuristic-based approaches for approximate inference include greedy, beam, and stochastic search. Greedy and beam search have been empirically proved to be adequate for many sequence to sequence tasks, and are the standard methods for NMT decoding.

However, these inference approaches have several drawbacks. Firstly, although NMT models use a left-to-right generation which would appear to facilitate efficient search, the models themselves use a recurrent architecture, and accordingly are non-Markov. This prevents exact dynamic programming solutions, and moreover, limits the potential to incorporate additional global features or constraints. Global factors can be highly useful in producing better and more diverse translations. Secondly, the sequential decoding of symbols in the target sequence, the inter-dependencies among the target symbols are not fully exploited. For example, when decoding the words of the target sentence in a left-to-right manner, the right context is not exploited leading potentially to inferior performance (see Watanabe and Sumita (2002a) who apply this idea in traditional statistical MT). A natural way to capture this is to intersect left-to-right and right-to-left models, however the resulting model has no natural generation order, and thus standard decoding methods are unsuitable.

We introduce a novel decoding framework (§ 3) that relaxes this *discrete* optimisation problem into a *continuous* optimisation problem. This is akin to linear programming relaxation approach for approximate inference in graphical models with discrete random variables, where the exact inference is NP-hard (Sontag, 2010; Belanger and McCallum, 2016). The resulting continuous optimisation problem is challenging due to the non-linearity and non-convexity of the relaxed decoding objective. We make use of stochastic gradient descent (SGD) and exponentiated gradient (EG) algorithms for decoding based on our relaxation approach.[1] Our decoding framework is powerful and flexible, as it enables us to decode with global constraints involving intersection of multiple NMT

[1] Both methods are mainly used for training in prior work.

Copenhagen, Denmark, September 7–11, 2017.

models (§4). We present experimental results on Chinese-English and German-English translation tasks, confirming the effectiveness of our relaxed optimisation method for decoding (§5).

2 Neural Machine Translation

We briefly review the attentional neural translation model proposed by Bahdanau et al. (2015) as a sequence-to-sequence neural model onto which we apply our decoding framework.

In neural machine translation (NMT), the probability of the target sentence $\boldsymbol{y}$ given a source sentence $\boldsymbol{x}$ is written as:

$$\begin{aligned} \mathrm{P}_{\boldsymbol{\Theta}}(\boldsymbol{y}|\boldsymbol{x}) &= \sum_{i=1}^{|\boldsymbol{y}|} \log \mathrm{P}_{\boldsymbol{\Theta}}(y_i|\boldsymbol{y}_{<i}, \boldsymbol{x}) \qquad (1) \\ y_i|\boldsymbol{y}_{<i}, \boldsymbol{x} &\sim \mathrm{softmax}\left(\boldsymbol{f}(\boldsymbol{\Theta}, \boldsymbol{y}_{<i}, \boldsymbol{x})\right) \end{aligned}$$

where f is a non-linear function of the previously generated sequence of words $\boldsymbol{y}_{<i}$, the source sentence $\boldsymbol{x}$, and the model parameters $\boldsymbol{\Theta}$. In this paper, we realise $\boldsymbol{f}$ as follows:

$$\begin{aligned} \boldsymbol{f}(\boldsymbol{\Theta}, \boldsymbol{y}_{<i}, \boldsymbol{x}) &= \boldsymbol{W}_o \cdot \mathrm{MLP}\left(\boldsymbol{c}_i, \boldsymbol{E}_T^{y_{i-1}}, \boldsymbol{g}_i\right) + \boldsymbol{b}_o \\ \boldsymbol{g}_i &= \mathrm{RNN}_{dec}^{\phi}\left(\boldsymbol{c}_i, \boldsymbol{E}_T^{y_{i-1}}, \boldsymbol{g}_{i-1}\right) \end{aligned}$$

where MLP is a single hidden layer neural network with $\tanh$ activation function, and $\boldsymbol{E}_T^{y_{i-1}}$ is the embedding of the target word y_{i-1} in the embedding matrix $\boldsymbol{E}_T \in \mathbb{R}^{n_e \times |V_T|}$ of the target language vocabulary V_T and n_e is the embedding dimension. The state $\boldsymbol{g}_i$ of the decoder RNN is a function of y_{i-1}, its previous state $\boldsymbol{g}_{i-1}$, and the *context* $\boldsymbol{c}_i = \sum_{j=1}^{|\boldsymbol{x}|} \alpha_{ij} \boldsymbol{h}_j$ summarises parts of the source sentence which are *attended* to, where

$$\begin{aligned} \boldsymbol{\alpha}_i &= \mathrm{softmax}(\boldsymbol{e}_i) \quad ; \quad e_{ij} = \mathrm{MLP}\left(\boldsymbol{g}_{i-1}, \boldsymbol{h}_j\right) \\ \boldsymbol{h}_j &= \mathrm{biRNN}_{enc}^{\theta}\left(\boldsymbol{E}_S^{x_j}, \overrightarrow{\boldsymbol{h}}_{j-1}, \overleftarrow{\boldsymbol{h}}_{j+1}\right) \end{aligned}$$

In above, $\overrightarrow{\boldsymbol{h}}_i$ and $\overleftarrow{\boldsymbol{h}}_i$ are the states of the left-to-right and right-to-left RNNs encoding the source sentence, and $\boldsymbol{E}_S^{x_j}$ is the embedding of the source word x_j in the embedding matrix $\boldsymbol{E}_S \in \mathbb{R}^{n'_e \times |V_S|}$ of the source language vocabulary V_S and n'_e is the embedding dimension.

Given a bilingual corpus $\mathcal{D}$, the model parameters are learned by maximizing the conditional log-likelihood,

$$\boldsymbol{\Theta}^* := \mathrm{argmax}_{\boldsymbol{\Theta}} \sum_{(\boldsymbol{x},\boldsymbol{y}) \in \mathcal{D}} \log \mathrm{P}_{\boldsymbol{\Theta}}(\boldsymbol{y} \mid \boldsymbol{x}). \qquad (2)$$

The model parameters $\boldsymbol{\Theta}$ include the weight matrix $\boldsymbol{W}_o \in \mathbb{R}^{|V_T| \times n_h}$ and the bias $\boldsymbol{b}_o \in \mathbb{R}^{|V_T|}$ – with n_H denoting the hidden dimension size – as well as the RNN encoder $\mathrm{biRNN}_{enc}^{\theta}$ / decoder $\mathrm{RNN}_{dec}^{\phi}$ parameters, word embedding matrices, and the parameters of the attention mechanism. The model is trained end-to-end by optimising the training objective using stochastic gradient descent (SGD) or its variants. In this paper, we focus on the decoding problem, which we turn to in the next section.

3 Decoding as Continuous Optimisation

In decoding, we are interested in finding the highest probability translation for a given source sentence:

$$\mathrm{minimise}_{\boldsymbol{y}} \quad -P_{\boldsymbol{\Theta}}(\boldsymbol{y} \mid \boldsymbol{x}) \quad \text{s.t.} \quad \boldsymbol{y} \in \mathcal{Y}_{\boldsymbol{x}} \qquad (3)$$

where $\mathcal{Y}_{\boldsymbol{x}}$ is the space of possible translations for the source sentence $\boldsymbol{x}$. In general, searching $\mathcal{Y}_{\boldsymbol{x}}$ to find the highest probability translation is intractable due to the recurrent nature of eqn (1) which prevents dynamic programming for efficient search. This is problematic, as the space of translations is exponentially large with respect to the output length $|\boldsymbol{y}|$.

We now formulate this discrete optimisation problem as a continuous one, and then use standard algorithms for continuous optimisation for decoding. Let us assume that the maximum length of a possible translation for a source sentence is known and denote it as ℓ. The best translation for a given source sentence solves the following optimisation problem:

$$\begin{aligned} \boldsymbol{y}^* = &\operatorname*{arg\,min}_{y_1,\ldots,y_\ell} \sum_{i=1}^{\ell} -\log \mathrm{P}_{\boldsymbol{\Theta}}(y_i \mid \boldsymbol{y}_{<i}, \boldsymbol{x}) \qquad (4) \\ &\text{s.t.} \quad \forall i \in \{1 \ldots \ell\} : y_i \in V_T. \end{aligned}$$

where we allow the translation to be padded with sentinel symbols to the right, which are ignored in computing the model probability. Equivalently, we can rewrite the above discrete optimisation problem as follows:

$$\begin{aligned} &\operatorname*{arg\,min}_{\tilde{\boldsymbol{y}}_1,\ldots,\tilde{\boldsymbol{y}}_\ell} -\sum_{i=1}^{\ell} \tilde{\boldsymbol{y}}_i \cdot \log \mathrm{softmax}\left(\boldsymbol{f}\left(\boldsymbol{\Theta}, \tilde{\boldsymbol{y}}_{<i}, \boldsymbol{x}\right)\right) \\ &\text{s.t.} \quad \forall i \in \{1 \ldots \ell\} : \tilde{\boldsymbol{y}}_i \in \mathbb{I}^{|V_T|} \qquad (5) \end{aligned}$$

where $\tilde{\boldsymbol{y}}_i$ are vectors using the one-hot representation of the target words $\mathbb{I}^{|V_T|}$.

Algorithm 1 The EG Algorithm for Decoding by Optimisation

```
For all $i$ initialise $\hat{\boldsymbol{y}}_i^0 \in \Delta_{|V_T|}$
**for** $t = 1, \dots, \text{MaxIter}$ **do**                                   ▷ $Q(.)$ is defined as eqn (6)
    For all $i, w$ : calculate $\nabla_{i,w}^{t-1} = \frac{\partial Q(\hat{\boldsymbol{y}}_1^{t-1}, \dots, \hat{\boldsymbol{y}}_\ell^{t-1})}{\partial \hat{\boldsymbol{y}}_i(w)}$     ▷ using back-propagation
    For all $i, w$ : update $\hat{\boldsymbol{y}}_i^t(w) \propto \hat{\boldsymbol{y}}_i^{t-1}(w) \cdot \exp\left(-\eta \nabla_{i,w}^{t-1}\right)$     ▷ $\eta$ is the step size
**return** $\arg\min_t Q(\hat{\boldsymbol{y}}_1^t, \dots, \hat{\boldsymbol{y}}_\ell^t)$
```

We now convert the optimisation problem (5) to a continuous one by dropping the integrality constraints $\tilde{\boldsymbol{y}}_i \in \mathbb{I}^{|V|}$ and require the variables to take values from the probability simplex:

$$\boxed{\begin{aligned} &\arg\min_{\hat{\boldsymbol{y}}_1, \dots, \hat{\boldsymbol{y}}_\ell} - \sum_{i=1}^{\ell} \hat{\boldsymbol{y}}_i \cdot \log \operatorname{softmax}\left(\boldsymbol{f}\left(\boldsymbol{\Theta}, \hat{\boldsymbol{y}}_{<i}, \boldsymbol{x}\right)\right) \\ &\qquad\text{s.t.} \quad \forall i \in \{1 \dots \ell\} : \hat{\boldsymbol{y}}_i \in \Delta_{|V_T|} \end{aligned}}$$

where $\Delta_{|V_T|}$ is the $|V_T|$-dimensional probability simplex, i.e., $\{\hat{\boldsymbol{y}}_i \in [0, 1]^{|V_T|} : \|\hat{\boldsymbol{y}}_i\|_1 = 1\}$. Intuitively, this amounts to replacing $\boldsymbol{E}_T^{y_i}$ with the *expected* embedding of target language words $\mathbb{E}_{\hat{\boldsymbol{y}}_i(w)}[\boldsymbol{E}_T^w]$ under the distribution $\hat{\boldsymbol{y}}_i$.

After solving the above constrained continuous optimisation problem, there is no guarantee that the resulting solution $\{\hat{\boldsymbol{y}}_i^*\}_{i=1}^{\ell}$ will comprise one-hot vectors, i.,e., target language words. Instead it can find *fractional* solutions, that require 'rounding' in order to to resolve them to lexical items. To solve this problem, we take the $\arg\max$,[2] i.e., take the highest scoring word for each position $\hat{\boldsymbol{y}}_i^*$. We leave exploration of more elaborate projection techniques to the future work.

In the context of graphical models, the above relaxation technique gives rise to linear programming for approximate inference (Sontag, 2010; Belanger and McCallum, 2016). However, our decoding problem is much harder due to the non-linearity and non-convexity of the objective function operating on high dimensional space for deep models. We now turn our attention to optimisation algorithms to effectively solve the decoding optimisation problem.

3.1 Exponentiated Gradient (EG)

Exponentiated gradient (Kivinen and Warmuth, 1997) is an elegant algorithm for solving optimisation problems involving simplex constraints. Recall our constrained optimisation problem:

$$\begin{aligned} &\arg\min_{\hat{\boldsymbol{y}}_1, \dots, \hat{\boldsymbol{y}}_\ell} Q(\hat{\boldsymbol{y}}_1, \dots, \hat{\boldsymbol{y}}_\ell) \\ &\text{s.t.} \quad \forall i \in \{1 \dots \ell\} : \hat{\boldsymbol{y}}_i \in \Delta_{|V_T|} \end{aligned}$$

where $Q(\hat{\boldsymbol{y}}_1, \dots, \hat{\boldsymbol{y}}_\ell)$ is defined as

$$-\sum_{i=1}^{\ell} \hat{\boldsymbol{y}}_i \cdot \log \operatorname{softmax}\left(\boldsymbol{f}\left(\boldsymbol{\Theta}, \hat{\boldsymbol{y}}_{<i}, \boldsymbol{x}\right)\right). \qquad (6)$$

EG is an iterative algorithm, which updates each distribution $\hat{\boldsymbol{y}}_i^t$ in the current time-step t based on the distributions of the previous time-step as follows:

$$\forall w \in V_T : \quad \hat{\boldsymbol{y}}_i^t(w) = \frac{1}{Z_i^t} \hat{\boldsymbol{y}}_i^{t-1}(w) \exp\left(-\eta \nabla_{i,w}^{t-1}\right)$$

where η is the step size, $\nabla_{i,w}^{t-1} = \frac{\partial Q(\hat{\boldsymbol{y}}_1^{t-1}, \dots, \hat{\boldsymbol{y}}_\ell^{t-1})}{\partial \hat{\boldsymbol{y}}_i(w)}$ and Z_i^t is the normalisation constant

$$Z_i^t = \sum_{w \in V_T} \hat{\boldsymbol{y}}_i^{t-1}(w) \exp\left(-\eta \nabla_{i,w}^{t-1}\right).$$

The partial derivatives $\nabla_{i,w}$ are calculated using the back propagation algorithm treating $\{\hat{\boldsymbol{y}}_i\}_{i=1}^{\ell}$ as *parameters* and the original parameters of the model $\boldsymbol{\Theta}$ as constants. Adapting EG to our decoding problem leads to Algorithm 1.

It can be shown that the EG algorithm is a gradient descent algorithm for minimising the following objective function subject to the simplex constraints:

$$\begin{aligned} &Q(\hat{\boldsymbol{y}}_1, \dots, \hat{\boldsymbol{y}}_\ell) - \gamma \sum_{i=1}^{\ell} \sum_{w \in V_T} \hat{\boldsymbol{y}}_i(w) \log \frac{1}{\hat{\boldsymbol{y}}_i(w)} \\ &= Q(\hat{\boldsymbol{y}}_1, \dots, \hat{\boldsymbol{y}}_\ell) - \gamma \sum_{i=1}^{\ell} \text{Entropy}(\hat{\boldsymbol{y}}_i) \qquad (7) \end{aligned}$$

In other words, the algorithm looks for the maximum entropy solution which also maximizes the

[2] Ties are broken arbitrarily.

log likelihood under the model. There are intriguing parallels with the maximum entropy formulation of log-linear models (Berger et al., 1996). In our setting, the entropy term acts as a prior which discourages overly-confident estimates in the absence of sufficient evidence.

3.2 Stochastic Gradient Descent (SGD)

To be able to apply SGD to our optimisation problem, we need to make sure that the simplex constraints are enforced. One way to achieve this is by reparameterising using the softmax transformation, i.e. $\hat{\boldsymbol{y}}_i = \text{softmax}\left(\hat{\boldsymbol{r}}_i\right)$. The resulting *unconstrained* optimisation problem, now over $\hat{\boldsymbol{r}}_i$, becomes

$$\underset{\hat{\boldsymbol{r}}_1,\ldots,\hat{\boldsymbol{r}}_\ell}{\arg\min} - \sum_{i=1}^{\ell} \text{softmax}\left(\hat{\boldsymbol{r}}_i\right) \cdot \log \text{softmax}\left(\mathrm{f}\left(\boldsymbol{\Theta}, \hat{\boldsymbol{y}}_{<i}, \boldsymbol{x}\right)\right)$$

where $\boldsymbol{E}_T^{y_i}$ is replaced with the expected embedding of the target words under the distribution resulted from the $\mathbb{E}_{\text{softmax}(\hat{\boldsymbol{r}}_i)}\left[\boldsymbol{E}_T^{w}\right]$ in the model.

To apply SGD updates, we need the gradient of the objective function with respect to the new variables $\hat{\boldsymbol{r}}_i$ which can be derived with the back-propagation algorithm based on the chain rule:

$$\frac{\partial Q}{\partial \hat{\boldsymbol{r}}_i(w)} = \sum_{w' \in V_T} \frac{\partial Q(.)}{\partial \hat{\boldsymbol{y}}_i(w')} \frac{\partial \hat{\boldsymbol{y}}_i(w')}{\partial \hat{\boldsymbol{r}}_i(w)}$$

The resulting SGD algorithm is summarized in Algorithm 2.

4 Decoding in Extended NMT

Our decoding framework allows us to effectively and flexibly add additional global factors over the output symbols during inference. This enables decoding for richer global models, for which there is no effective means of greedy decoding or beam search. We outline several such models, and their corresponding relaxed objective functions for optimisation-based decoding.

Bidirectional Ensemble. Standard NMT generates the translation in a left-to-right manner, conditioning each target word on its left context. However, the joint probability of the translation can be decomposed in a myriad of different orders; one compelling alternative would be to condition each target word on its right context, i.e., generating the target sentence from right-to-left. We would not expect a right-to-left model to outperform a left-to-right, however, as the left-to-right ordering reflects the natural temporal order of spoken language. However, the right-to-left model is likely to provide a complementary signal in translation, as it will be bringing different biases and making largely independent prediction errors to those of the left-to-right model. For this reason, we propose to use both models, and seek to find translations that have high probability according both models (this mirrors work on bidirectional decoding in classical statistical machine translation by Watanabe and Sumita (2002b).) Decoding under the ensemble of these models leads to an intractable search problem, not well suited to traditional greedy or beam search algorithms, which require a fixed generation order of the target words. This ensemble decoding problem can be formulated simply in our linear relaxation approach, using the following objective function:

$$\begin{aligned} \mathcal{C}_{+\text{bidir}} := & -\alpha \log \mathrm{P}_{\boldsymbol{\Theta}_{\leftarrow}}\left(\boldsymbol{y} \mid \boldsymbol{x}\right) \\ & -(1-\alpha) \log \mathrm{P}_{\boldsymbol{\Theta}_{\rightarrow}}\left(\boldsymbol{y} \mid \boldsymbol{x}\right); \end{aligned} \qquad (8)$$

where α is an interpolation hyper-parameter, which we set to 0.5; $\boldsymbol{\Theta}_{\rightarrow}$ and $\boldsymbol{\Theta}_{\leftarrow}$ are the pre-trained left-to-right and right-to-left models, respectively. This bidirectional agreement may also lead to improvement in translation diversity, as shown in Li and Jurafsky (2016) in a re-ranking evaluation.

Bilingual Ensemble. Another source of complementary information is in terms of the translation direction, that is forward translation from the source to the target language, and reverse translation in the target to source direction. Decoding must find a translation which scores well under both the forward and reverse translation models. This is inspired by the direct and reverse feature functions commonly used in classical discriminative SMT (Och and Ney, 2002) which have been shown to offer some complementary benefits (although see Lopez and Resnik (2006)). More specifically, we decode for the best translation in the intersection of the source-to-target and target-to-source models by minimizing the following objective function:

$$\begin{aligned} \mathcal{C}_{+\text{biling}} := & -\alpha \log \mathrm{P}_{\boldsymbol{\Theta}_{\text{s}\rightarrow\text{t}}}\left(\boldsymbol{y} \mid \boldsymbol{x}\right) \\ & -(1-\alpha) \log \mathrm{P}_{\boldsymbol{\Theta}_{\text{s}\leftarrow\text{t}}}\left(\boldsymbol{x} \mid \boldsymbol{y}\right); \end{aligned} \qquad (9)$$

where α is an interpolation hyper-parameter to be fine-tuned; and $\boldsymbol{\Theta}_{\text{s}\rightarrow\text{t}}$ and $\boldsymbol{\Theta}_{\text{s}\leftarrow\text{t}}$ are the pre-trained

Algorithm 2 The SGD Algorithm for Decoding by Optimisation

```

source-to-target and target-to-source models, respectively. Decoding for the best translation under the above objective function leads to an intractable search problem, as the reverse model is global over the target language, meaning there is no obvious means of search with a greedy algorithm or similar.

Discussion. There are two important considerations on how best to initialise the relaxed optimisation in the above settings, and how best to choose the step size. As the relaxed optimisation problem is, in general, non-convex, finding a plausible initialisation is likely to be important for avoiding local optima. Furthermore, a proper step size is a key in the success of the EG-based and SGD-based optimisation algorithms, and there is no obvious method how to best choose its value. We may also adaptively change the step size using (scheduled) annealing or via the line search. We return to this considerations in the experimental evaluation.

5 Experiments

5.1 Setup

Datasets. We conducted our experiments on datasets with different scales, translating between Chinese→English using the BTEC corpus, and German→English using the IWSLT 2015 TED Talks(Cettolo et al., 2014) and WMT 2016[3] corpora. The statistics of the datasets can be found in Table 1.

NMT Models. We implemented our continuous-optimisation based decoding method on top of the Mantidae toolkit[4] (Cohn et al., 2016), and using the *dynet* deep learning library[5] (Neubig et al., 2017). All neural network models were configured with 512 input embedding and hidden layer dimensions, and 256 alignment dimension, with 1 and 2 hidden layers in the source and target, respectively. We used a LSTM recurrent structure (Hochreiter and Schmidhuber, 1997) for both source and target RNN sequences. For the vocabulary, we use word frequency cut-off of 5, and words rarer than this were mapped to a sentinel. For the large-scale WMT dataset, we applied byte-pair encoding (BPE) method (Sennrich et al., 2016) to better handle unknown words.[6] For training our neural models, we use early stopping based on development perplexity, which usually occurs after 5-8 epochs.

Evaluation Metrics. We evaluated in terms of search error, measured using the model score of the inferred solution (either continuous or discrete), as well as measuring the end translation quality with case-insensitive BLEU (Papineni et al., 2002). The continuous cost measures $-\frac{1}{|\hat{\boldsymbol{y}}|} \log P_{\boldsymbol{\Theta}}(\hat{\boldsymbol{y}} \mid \boldsymbol{x})$ under the model $\boldsymbol{\Theta}$; the discrete model score has the same formulation, albeit using the discrete rounded solution $\boldsymbol{y}$ (see §3). Note the cost can be used as a tool for selecting the best inference solution, as well as assessing convergence, as we illustrate below.

5.2 Results and Analysis

Initialisation and Step Size. As our relaxed optimisation problems are non-convex, local optima are likely to be a problem. We test this empirically, focusing on the effect that initialisation and step size, η, have on the inference quality.

For plausible initialisation states, we evaluate different strategies: *uniform* in which the relaxed variables $\hat{\boldsymbol{y}}$ are initialised to $\frac{1}{|V_T|}$; and *greedy* or *beam* whereby $\hat{\boldsymbol{y}}$ are initialised based on an already good solution produced by a baseline decoder with greedy (gdec) or beam (bdec). Instead of using the Viterbi outputs as a one-hot representation, we initialise to the probability prediction vectors,[7] which serves to limit attraction of the initialisation condition, which is likely to be a local (but not global) optima.

Figure 1 illustrates the effect of initialisation on the EG algorithm, in terms of search error (left and middle) and translation quality (right), as we vary the number of iterations of inference. There is clear evidence of non-convexity: all initialisation methods can be seen to converge using all three measures, however they arrive at highly different solutions. Uniform initialisation is clearly not a viable approach, while greedy and beam initialisation both yield much better results. The best initialisation, beam, outperforms both greedy and beam decoding in terms of BLEU.

Note that the EG algorithm has fairly slow convergence, requiring at least 100 iterations, irrespective of the initialisation. To overcome this, we use momentum (Qian, 1999) to accelerate the convergence by modifying the term $\nabla^t_{i,w}$ in Algorithm 1 with a weighted moving average of past gradients:

$$\nabla^{t-1}_{i,w} = \gamma \nabla^{t-2}_{i,w} + \eta \frac{\partial Q(\hat{\boldsymbol{y}}^{t-1}_1, \ldots, \hat{\boldsymbol{y}}^{t-1}_\ell)}{\partial \hat{\boldsymbol{y}}_i(w)}$$

where we set the momentum term $\gamma = 0.9$. The EG with momentum (**EG-MOM**) converges after fewer iterations (about 35), and results in marginally better BLEU scores. The momentum technique is usually used for SGD involving additive updates; it is interesting to see it also works in EG with multiplicative updates.

The step size, η, is another important hyperparameter for gradient based search. We tune the step size using line search over $[10, 400]$ over the development set. Figure 1 illustrates the effect of changing step size from 50 to 400 (compare **EG** and **EG-400** with **uniform**), which results in a marked difference of about 10 BLEU points, underlining the importance of tuning this value. We found that EG with momentum had less of a reliance on step size, with optimal values in $[10, 50]$; we use this setting hereafter.

Continuous vs Discrete Costs. Another important question is whether the assumption behind continuous relaxation is valid, i.e., if we optimise a continuous cost to solve a discrete problem, do we improve the discrete output? Although the continuous cost diminishes with inference iterations (Figure 1 left), and appears to converge, it is not clear whether this corresponds to a better discrete output (note that the discrete cost and BLEU

[7] Here, EG uses softmax normalization whereas SGD uses the pre-softmax vector.

scores do show improvements Figure 1 centre and right.) Figure 2 illustrates the relation between the two cost measures, showing that in most cases the discrete and continuous costs are identical. Linear relaxation fails only for a handful of cases, where the nearest discrete solution is significantly worse than it would appear using the continuous cost.

EG vs SGD. Both the EG and SGD algorithms are iterative methods for solving the relaxed optimisation problem with simplex constraints. We measure empirically their difference in terms of quality of inference and speed of convergence, as illustrated in Figure 3. Observe that SGD requires 150 iterations for convergence, whereas EG requires many fewer (50). This concurs with previous work on learning structured prediction models with EG (Globerson et al., 2007). Further, the EG algorithm consistently produces better results in terms of both model cost and BLEU.

EG vs Reranking. Reranking is an alternative method for integrating global factors into the existing NMT systems. We compare our EG decoding algorithm against the reranking approach with bidirectional factor where the N-best outputs of a left-to-right decoder is re-scored with the forced decoder operating in a right-to-left fashion. The results are shown in Table 2. Our EG algorithm initialised with the reranked output achieves the best BLEU score. We also compare reranking with EG algorithm initialised with the beam decoder, where for direct comparison we filter out sentences with length greater than that of the beam output in the k-best lists. These results show that the EG algorithm is capable of effectively exploiting the search space.

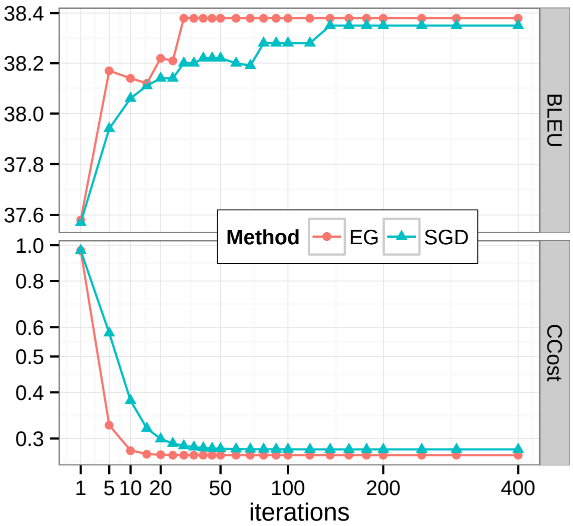

Figure 3: Analysis on convergence and performance comparing SOFTMAX and EG algorithms from BTEC zh→en translation. Both algorithms use momentum and step size 50.

Beyond achieving similar or better translations to re-ranking, note that EG is simpler in implementation, as it does not require $k$best lists, weight tuning and so forth. Instead this is replaced with iterative gradient descent. The run-time of the two methods are comparable, when reranking uses modest k, however EG can be considerably faster when k is large, as is typically done to extract the full benefit from re-ranking. This performance difference is a consequence of GPU acceleration of the dense vector operations in EG inference.

Computational Efficiency. We also quantify the computational efficiency of the proposed decoding approach. Benchmarking on a GPU Titan X for decoding BTEC zh→en, the average time per sentence is 0.02 secs for greedy, 0.07s for beam=5, 0.11s for beam=10, and 3.1s for relaxed EG decoding, which uses an average of 35 EG iterations. The majority of time in the EG algorithm is in the forward and backward passes, taking 30% and 67% of the time, respectively. Our imple-

mentation was not optimised thoroughly, and it is likely that it could be made significantly faster, which we defer to future research.

Main Results. Table 3 shows our experimental results across all datasets, evaluating the EG algorithm and its variants.[8] For the EG algorithm with greedy initialisation (top), we see small but consistent improvements in terms of BLEU. Beam initialisation led to overall higher BLEU scores, and again demonstrating a similar pattern of improvements, albeit of a lower magnitude, over the initialisation values.

Next we evaluate the capability of our inference method with extended NMT models, where approximate algorithms such as greedy or beam search are infeasible. With the **bidirectional** ensemble, we obtained the statistically significant BLEU score improvements compared to the unidirectional models, for either greedy or beam initialisation. This is interesting in the sense that the unidirectional right-to-left model always performs worse than the left-to-right model. However, our method with bidirectional ensemble is capable of combining their strengths in a unified setting. For the **bilingual** ensemble, we see similar effects, with better BLEU score improvements in most cases, albeit of a lower magnitude, over the bidirectional one. This is likely to be due to a disparity with the training condition for the models, which were learned independently of one another.

Overall, decoding in extended NMT models leads to performance improvements compared to baseline methods. This is one of the main findings in this work, and augurs well for its extension to other global model variants.

6 Related Work

Decoding (inference) for neural models is an important task; however, there is limited research in this space perhaps due to the challenging nature of this task, with only a few works exploring some extensions to improve upon them. The most widely-used inference methods include sampling (Cho, 2016), greedy and beam search (Sutskever et al., 2014; Bahdanau et al., 2015, *inter alia*), and reranking (Birch, 2016; Li and Jurafsky, 2016).

Cho (2016) proposed to perturb the neural model by injecting noise(s) in the hidden transition function of the conditional recurrent neural language model during greedy or beam search, and execute multiple parallel decoding runs. This strategy can improves over greedy and beam search; however, it is not clear how, when and where noise should be injected to be beneficial. Recently, Wiseman and Rush (2016) proposed beam search optimisation while *training* neural models, where the model parameters are updated in case the gold standard falls outside of the beam. This exposes the model to its past incorrect predicted labels, hence making the training more robust. This is orthogonal to our approach where we focus on the decoding problem with a pre-trained model.

Reranking has also been proposed as a means of global model combination: Birch (2016) and Li and Jurafsky (2016) re-rank the left-to-right decoded translations based on the scores of a right-to-left model, learning to more diverse translations. Related, Li et al. (2016) learn to adjust the beam diversity with reinforcement learning.

Perhaps most relevant is Snelleman (2016), performed concurrently to this work, who also proposed an inference method for NMT using linear relaxation. Snelleman's method was similar to our SGD approach, however he did not manage to outperform beam search baselines with an encoder-decoder. In contrast we go much further, proposing the EG algorithm, which we show works much more effectively than SGD, and demonstrate how this can be applied to inference in an attentional

[8] Due to the space constraints, we report results for the EG algorithm only. See also translation examples in Figure 4.

encoder-decoder. Moreover, we demonstrate the utility of related optimisation for inference over global ensembles of models, resulting in consistent improvements in search error and end translation quality.

Recently, relaxation techniques have been applied to deep models for training and inference in text classification (Belanger and McCallum, 2016; Belanger et al., 2017), and fully differentiable training of sequence-to-sequence models with scheduled-sampling (Goyal et al., 2017). Our work has applied the relaxation technique specifically for *decoding* in NMT models.

7 Conclusions

This work presents the first attempt in formulating decoding in NMT as a continuous optimisation problem. The core idea is to drop the integrality (i.e. one-hot vector) constraint from the prediction variables and allow them to have soft assignments within the probability simplex while minimising the loss function produced by the neural model. We have provided two optimisation algorithms – exponentiated gradient (EG) and stochastic gradient descent (SGD) – for optimising the resulting contained optimisation problem, where our findings show the effectiveness of EG compared to SGD. Thanks to our framework, we have been able to decode when intersecting left-to-right and right-to-left as well as source-to-target and target-to-source NMT models. Our results show that our decoding framework is effective and leads to substantial improvements in translations generated from the intersected models, where the typical greedy or beam search algorithms are not applicable.

This work raises several compelling possibilities which we intend to address in future work, such as improving decoding speed, integrating additional constraints such as word coverage and fertility into *decoding*,[9] and applying our method to other intractable structured prediction problems.

[9] These constraints have only been used for training in the previous works (Cohn et al., 2016; Mi et al., 2016).

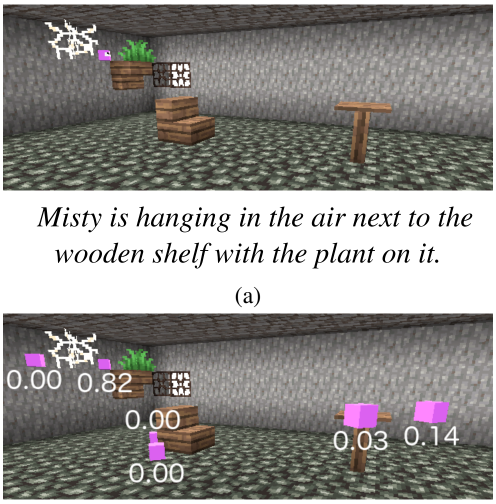
Where is Misty? Interpreting Spatial Descriptors by Modeling Regions in Space

Nikita Kitaev and **Dan Klein**
Computer Science Division
University of California, Berkeley
{kitaev,klein}@cs.berkeley.edu

Abstract

We present a model for locating regions in space based on natural language descriptions. Starting with a 3D scene and a sentence, our model is able to associate words in the sentence with regions in the scene, interpret relations such as *on top of* or *next to,* and finally locate the region described in the sentence. All components form a single neural network that is trained end-to-end without prior knowledge of object segmentation. To evaluate our model, we construct and release a new dataset consisting of Minecraft scenes with crowdsourced natural language descriptions. We achieve a 32% relative error reduction compared to a strong neural baseline.



Misty is hanging in the air next to the wooden shelf with the plant on it.

1 Introduction

In this work, we present a model for grounding spatial descriptors in 3D scenes. Consider interpreting the instructions: *Take the book and put it on the shelf.* One critical element of being able to interpret this sentence is associating the referring expression *the book* with the corresponding object in the world. Another important component of understanding the command above is translating the phrase *on the shelf* to a location in space. We call such phrases spatial descriptors. While spatial descriptors are closely related to referring expressions, they are distinct in that they can refer to locations even when there is nothing there. An intuitive way to model this is to reason over spatial regions as first-class entities, rather than taking an object-centric approach.

Following a long tradition of using game environments for AI, we adopt Minecraft as the setting for our work. Minecraft has previously been used for work on planning and navigation (Oh et al., 2016; Tessler et al., 2016), and we expand on this by using it for grounded language understanding. As a sandbox game, it can be used to construct a wide variety of environments that capture many interesting aspects of the real world. At the same time, it is easy to extract machine-interpretable representations from the game.

We construct a dataset of Minecraft scenes with natural-language annotations, and propose a task that evaluates understanding spatial descriptors. Our task is formulated in terms of locating a pink, cube-shaped character named Misty given a scene, a natural language description, and a set of locations to choose from. An example from our dataset is shown in Figure 1. The Minecraft scene representation does not provide ground-truth information about object identity or segmentation, reflecting the fact that perceptual ambiguity is always

Proceedings of the 2017 Conference on Empirical Methods in Natural Language Processing, pages 157–166
Copenhagen, Denmark, September 7–11, 2017.

present in real-world scenarios. We do, however, assume the availability of 3D depth information (which, for real-world conditions, can be acquired using depth sensors such as RGBD cameras or LiDAR).

We propose and evaluate a neural network that combines convolutional layers operating over 3D regions in space with recurrent layers for processing language. Our model jointly learns to segment objects, associate them with words, and understand spatial relationships – all in an end-to-end manner. We compare with a strong neural baseline and demonstrate a relative error reduction of 32%.

The dataset and model described in this paper are available online.[1]

2 Related Work

Our task includes some of the same elements as referring-expression generation and interpretation. Past work on these tasks includes Golland et al. (2010), Krishnamurthy and Kollar (2013), Socher et al. (2014) and Kazemzadeh et al. (2014). A key difference is that spatial descriptors (as modeled in this paper) refer to locations in space, rather than to objects alone. For example, Krishnamurthy and Kollar (2013) convert natural language to a logical form that is matched against image segments, an approach that is only capable of reasoning about objects already present in the scene (and not skipped over by the segmentation process). Our model's ability to reason over spatial regions also differentiates it from past approaches to tasks beyond referring expressions, such as the work by Tellex et al. (2011) on natural-language commanding of robots. Recent work by Hu et al. (2016) on interpreting referring expressions can capture relationships between objects, relying on the construction of (subject, object, relation) tuples. Their model is limited in that it can only handle one such tuple per utterance. Our model does not have such a restriction, and it additionally expands to a 3D setting.

Our task is also related to work on Visual Question Answering, or VQA (Agrawal et al., 2015). While VQA uses free-form textual answers, our task places targeted emphasis on spatial reasoning by requiring outputs to be locations in the scene. Spatial reasoning remains an important capability for VQA systems, and is one of the elements featured in CLEVR (Johnson et al., 2016), a diagnostic dataset for VQA. Like in our dataset, visual percepts in CLEVR are based on machine-generated scenes. CLEVR also makes use of machine-generated language, while all language in our dataset is written by humans.

Another related task in NLP is spatial role labeling, which includes the identification of spatial descriptors and the assigning of roles to each of their constituent words. This task was studied by Kordjamshidi et al. (2011) and led to the creation of shared tasks such as SpaceEval (Pustejovsky et al., 2015). Our setting differs in that we consider grounded environments instead of studying text in isolation, and evaluate on task performance rather than logical correctness of interpretation.

Spatial descriptors are also present in the task of generating 3D scenes given natural language descriptions. Compared to a recent model by Chang et al. (2017) for scene generation, our model works with lower-level 3D percepts rather than libraries of segmented and tagged objects. We are also able to incorporate learning of vocabulary, perception, and linguistic structure into a single neural network that is trainable end-to-end.

3 Task

At its core, the ability to understand spatial descriptors can be formulated as mapping from a natural-language description to a particular location in space. In Figure 1, we show an instance of our task, which consists of the following components:

- W: a perceptual representation of the world
- x: the natural language description
- $\{y_1, y_2, \ldots, y_n\}$: the candidate set of locations that are under consideration
- $y^\star$: the true location that is being referred to in the scene

Given W and x, a model must select which candidate location y_i best matches the description x.

We will address the particulars of the above representation as we discuss the process for constructing our dataset. Each example $(W, x, \{y_1, \ldots, y_n\}, y^\star)$ in the dataset is made by generating a Minecraft scene (Section 3.1) and selecting a location as the target of description (Section 3.2). We then crowdsource natural language descriptions of the target location in space. To better anchor the language, we populate

[1] https://github.com/nikitakit/voxelworld

the target location with a cube-shaped character we name Misty, and ask workers to describe Misty's location (Section 3.3). We repeat this process for each example in the dataset.

3.1 Scene Generation and Representation

Each of our Minecraft scenes is set in a randomly-generated room. We select a random size for this room, and then populate it with a variety of objects. We include objects that can be placed on the floor (e.g. tables), mounted on the wall (e.g. torches), embedded in the wall (e.g. doors), or hanging from the ceiling (e.g. cobwebs).

We then discard ground-truth knowledge about object segmentation or identity in the process of saving our dataset. This allows our task to evaluate not only models' capacity for understanding language, but also their ability to integrate with perceptual systems. One way of approximating real-world observations would be to take a screenshot of the scene – however, a 2D projection does not provide all of the spatial information that a language user would reasonably have access to. We would like to use a 3D encoding instead, and Minecraft naturally offers a low-level (albeit low-resolution) voxel-based representation that we adopt for this work.

Each Minecraft world W is encoded as a 3D grid of voxels, where a voxel may be empty or contain a particular type of "block," e.g. stone or wood. In general, what humans would interpret as single objects will be made of multiple Minecraft blocks – for example, the table in Figure 1 consists of a "wooden pressure plate" block on top of a "wooden fencepost" block. These same blocks can be used for other purposes as well: the "wooden fencepost" block is also part of fences, lamp-posts, and pillars, while the "wooden pressure plate" block can form shelves, countertops, as well as being placed on the ground to detect when something walks over it. We construct our Minecraft scenes specifically to include examples of such re-use, so that models capable of achieving high performance on this task must demonstrate the capacity to work without ground-truth segmentation or perfect object labeling.

The voxel-grid 3D representation is not specific to the virtual Minecraft setting: it is equally applicable to real-world data where depth information is available. The main difference is that each voxel would need to be associated with a feature vector rather than a block type. One use of such a representation is in Maturana and Scherer (2015)'s work on object classification from data collected with RGBD cameras and LiDAR, which uses a 3D convolutional neural network over a voxel grid. We do not explicitly handle occlusion in this work, but we imagine that real-world extensions can approach it using a combination of multi-viewpoint synthesis, occlusion-aware voxel embeddings, and restricting the set of voxels considered by the model.

3.2 Location Sampling

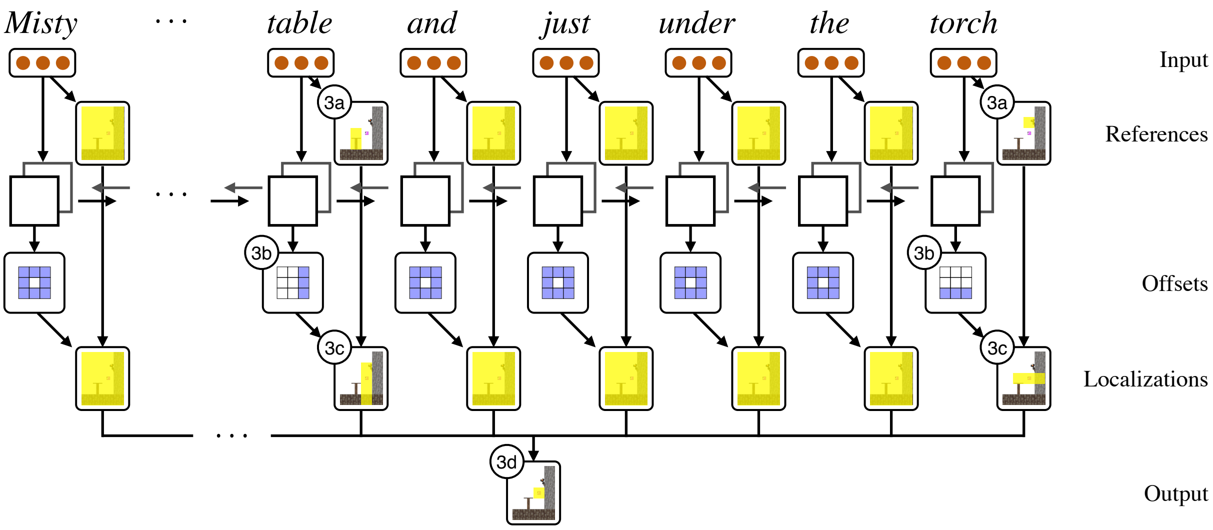
After constructing a scene with representation W, we proceed to sample a location $y^\star$ in the scene. Given our voxel-based scene representation, our location sampling is at voxel granularity. The candidate set we sample from, $\{y_1, \ldots, y_n\}$, consists of empty voxels in the scene. Locations that occur in the middle of a large section of empty space are hard to distinguish visually and to describe precisely, so we require that each candidate y_i be adjacent to at least one object.

3.3 Natural Language Descriptions

For each scene-location pair $(W, y^\star)$ we crowdsource a natural language description x.

The choice of prompt for human annotators is important in eliciting good descriptions. At the location we are asking workers to refer to, we insert a pink-colored cube that we personify and name "Misty." We then ask workers to describe Misty's location such that someone can find her if she were to turn invisible. Having a visually salient target helps anchor human perception, which is why we chose a pink color that contrasts with other visual elements in the scene. We make sure to emphasize the name "Misty" in the instructions, which results in workers almost always referring to Misty by name or with the pronoun *she*. This avoids having to disambiguate a myriad of generic descriptions (*the pink block, the block, the target,* etc.) for what is fundamentally an artificial construct.

To make sure that humans understand the 3D structure of the scene as they describe it, we give them access to a 3D view of the environment and require that they move the camera before submitting a description. This helped increase the quality of our data.



Misty is to the right of the table and just under the torch.

Figure 2: Our model architecture. Note that while the schematic illustrations are shown in 2D, our actual model operates in 3D. Zoomed-in versions of the marked references, offsets, localizations, and output are shown in Figure 3.

4 Model

We next present our model for this task. Our model architecture is shown in Figure 2, with some of the quantities it operates over highlighted in Figure 3. Throughout this section, we will use the example description *Misty is to the right of the table and just under the torch.* Note that while the accompanying scene illustrations are shown in 2D for visual clarity, our actual model operates in 3D and on larger scene sizes.

Our model first associates words with regions in the world. There is no notion of object segmentation in the dataset, so the references it produces are just activations over space given a word. Activations are computed for all words in the sentence, though they will only be meaningful for words such as *table* and *torch* (Figure 3a). Our model next determines the spatial relationships between referenced objects and Misty, using information provided by context words such as *right* and *under.* These relationships are represented as 3D convolutional offset filters (Figure 3b). For each word, its reference and offset filter are convolved to get a localization, i.e. an estimate of Misty's location (Figure 3c). Finally, our model aggregates localizations across all words in the sentence, combining the information provided by the phrases *to the right of the table* and *just under the torch* (Figure 3e).

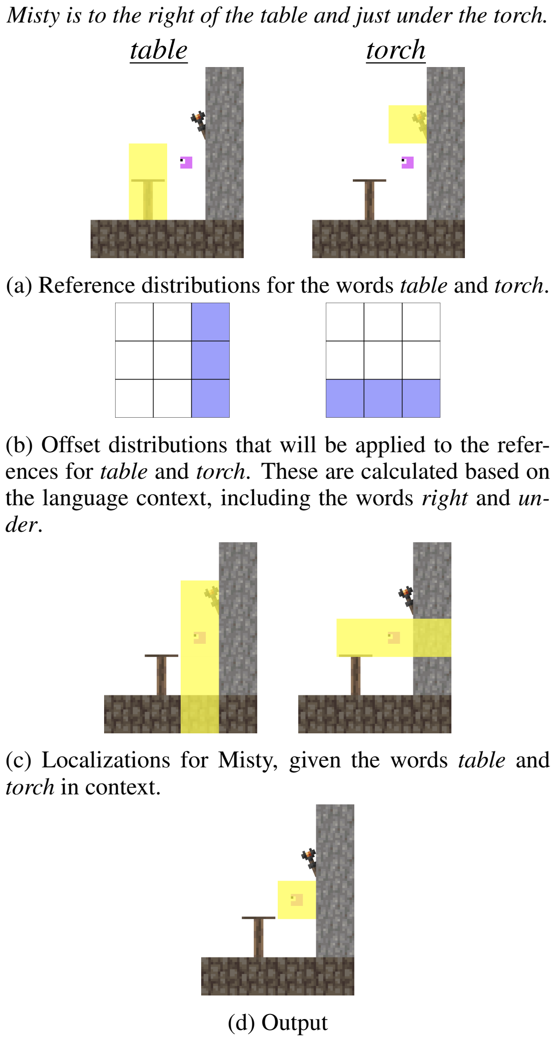
The following sections describe in more detail how references (Section 4.1), offsets (Section 4.2), and localizations (Section 4.3) are computed.

4.1 Input and References

The first component of our model is responsible for associating words with the voxels that they refer to. It assigns a real-valued score $s(x_t, y)$ to each pair consisting of word x_t and voxel coordinate y.

High scores correspond to high compatibility; for any given word, we can visualize the set $s(x_t, \cdot)$ of scores assigned to different voxels by interpreting it as logits that encode a probability distribution over blocks in the scene. In the example, the word *table* would ideally be matched to the uniform reference distribution over blocks that are part of a table, and similarly for the word *torch* (Figure 3a).

The word-voxel scores are computed by combining word and block embeddings. To take advantage of additional unsupervised language and world data, we start with pretrained word embeddings and context-aware location embeddings $f(W, y)$. The function f consists of the first two layers of a convolutional neural network that is pretrained on the task of predicting a voxel's identity given the 5x5x5 neighborhood around it. Since f fails to take into account the actual voxel's identity, we add additional embeddings V that only consider single blocks. The score is then computed as $s(x_t, y) = w_t^\top A f(W, y) + w_t^\top v_y$, where w_t is the word embedding and v_y is the single-block embedding. The parameter matrix



Misty is to the right of the table and just under the torch.
table
torch

(a) Reference distributions for the words *table* and *torch*.

(b) Offset distributions that will be applied to the references for *table* and *torch*. These are calculated based on the language context, including the words *right* and *under*.

(c) Localizations for Misty, given the words *table* and *torch* in context.

(d) Output

(e) Output distribution produced by intersecting the localizations for each word.

Figure 3: A schematic 2D depiction of the representations used throughout our neural network, zoomed in from Figure 2. Our model (a) matches words with objects in the scene, (b) determines offsets from landmark objects to Misty's location, (c) combines these pieces of information to form per-word localizations of Misty, and then (d) uses all localizations to guess Misty's location.

A and the single-block embedding matrix V are trained end-to-end with the rest of the model.

References are computed for all words in the sentence – including function words like *to* or *the*. To signify that a word does not refer to any objects in the world, the next layer of the network expects that we output a uniform distribution over all voxels. Outputting uniform distributions also serves as a good initialization for our model, so we set the elements of A and V to zero at the start of training (our pretrained word embeddings are sufficient to break symmetry).

4.2 Offsets

The per-word references described in Section 4.1 do not themselves indicate Misty's location. Rather, they are used in a spatial descriptor like *to the right of the table*. For every word, our model outputs a distribution over offset vectors that is used to redistribute scores from object locations to possible locations for Misty (Figure 3b). For example, if probability mass is placed on the "one-block-to-the-right" offset vector, this corresponds to predicting that Misty will be one block to the right of the voxels that a word refers to. Offset scores o_t are assigned based on the context the word x_t occurs in, which allows the model to incorporate information from words such as *right* or *under* in its decisions. This is accomplished by running a bidirectional LSTM over the embeddings w_t of the words in the sentence, and using its output to compute offset probabilities:

$$\begin{aligned}[z_0, z_1, \ldots] &= \text{BiLSTM}([w_0, w_1, \ldots]) \\ o'_t &= M z_t \\ o_t(i) &\propto \exp\left(o'_t(i)\right)\end{aligned}$$

Each set of offset scores o_t is reshaped into a 3x3x3 convolutional filter, except that we structurally disallow assigning any probability to the no-offset vector in the center. As a parameter-tying technique, the trainable matrix M is not full-rank; we instead decompose it such that the log-probability of an offset vector factors additively over the components in a cylindrical coordinate system.

4.3 Localizations and Output

For each word, the 3D tensor of word-voxel scores $s(x_t, \cdot)$ is convolved with the offset distribution o_t to produce a distribution of localizations for Misty, $d_t(y)$. A 2D illustration of the result is shown in Figure 3c. Localizations are then summed across all words in the sentence, resulting in a single score for each voxel in the scene (Figure 3e). These scores are interpreted as logits corresponding to a probability distribution over possible locations for Misty:

$$\begin{aligned}d_t(y) &= s(x_t, y) * o_t \\ p(y) &\propto \exp\left\{\sum_t d_t(y)\right\}\end{aligned}$$

Not all words will have localizations that provide information about Misty – for some words the localizations will just be a uniform distribution. We will refer to words that have low-entropy localizations as *landmarks*, with the understanding that being a landmark is actually a soft notion in our model.

Our offset filters o_t are much smaller than our voxel grid, which means that convolving any offset filter with a uniform reference distribution over the voxel grid will also result in a uniform localization distribution (edge effects are immaterial given the small filter size and the fact that Misty is generally not at the immediate edges of the scene). Conversely, given non-uniform references almost any set of offsets will result in a non-uniform localization. The architecture for computing references can output uniform references for function words (like *to* or *the*), but it lacks the linguistic context to determine when words refer to objects but should not be interpreted as landmarks (e.g. when they are part of exposition or a negated expression). We therefore include an additional not-a-landmark class that is softmax-normalized jointly with the offset vector distribution o_t. Probability assigned to this class subtracts from the probability mass for the true offset directions (and therefore from the localizations) – if this class receives a probability of 1, the corresponding localizations will not contribute to the model output.

4.4 Loss and Training

We use a softmax cross-entropy loss for training our model. During training, we find that it helps to not use the candidate set $\{y_1, y_2, \ldots, y_n\}$ and instead calculate a probability $p(y)$ for all blocks in the scene, including solid blocks that cannot possibly contain Misty (perhaps because this penalizes inferring nonsensical spatial relationships).

We run the Adam optimizer (Kingma and Ba, 2014) with step size 0.001 for 100 epochs using batch size 10. We keep an exponential moving average of our trainable parameters, which we save every two epochs. We then select the saved model that has the highest performance on our development set.

We perform several regularization and data augmentation techniques in order to achieve better generalization. Each time we sample a training example, we select a random 19x19x19 crop from the full scene (as long as Misty's location is not cropped out). We also disallow using the context-based block embeddings for the first 20 epochs by holding the parameter matrix A described in Section 4.1 fixed at zero, forcing the model to first learn to associate vocabulary with local features and only later expand to capture the compositional aspects of the environment.

For the natural language descriptions, all tokens are converted to lowercase as part of preprocessing. During training we apply word-level dropout (i.e. replacing words with an UNK token) in the LSTM responsible for computing offsets.

5 Evaluation

5.1 Evaluation Metric

In evaluating this task, we would like to use a metric that can provide meaningful comparison of our model with baseline and human performance. The set of all possible locations for Misty is large enough that it is hard even for a human to guess the correct block on the first try, especially when some descriptions are only precise to within 1 or 2 blocks. The size of this set also varies from scene to scene.

Therefore for our evaluation, we restrict the set $\{y_1, \ldots, y_n\}$ to 6 possible locations: Misty's true location and 5 distractors. This represents a less ambiguous problem that is much easier for humans, while also allowing for the evaluation of future models that may require an expensive computation for each candidate location considered. Our procedure for selecting the distractors is designed to ensure that we test both local and global scene understanding. Each set of six choices is constructed to consist of three clusters of two candidates each. Each cluster location is anchored to a landmark – we sample a landmark block adjacent to Misty and two additional landmark blocks from the entire scene, such that the pairwise distances between landmarks are at least 4 units. We then sample one distractor near Misty's landmark and two distractors near both of the other landmarks.

5.2 Dataset

To make our development and test sets, we construct this six-option variation from a subset of our collected data. For each such example we crowdsource two human solutions using Mechanical Turk. Examples where both humans answered correctly are partitioned into a development and a test set. This filtering procedure serves as our primary method of excluding confusing or uninformative descriptions from the evaluation con-

(a)	*When you come in the door, she's on the floor to the right, just in front of the flower.*
(b)	*Misty is facing to the right of the brown door.*

ditions. We also collect a third human solution to each example in the development and test sets to get an independent estimate of human performance on our task. The final dataset consists of 2321 training examples, 120 dev set examples, and 200 test set examples.

The natural-language descriptions across the full dataset use a vocabulary of 1015 distinct tokens (case-insensitive but including punctuation). The average description length is 19.02 tokens, with a standard deviation of 10.00 tokens. The large spread partially reflects the fact that some people gave short descriptions that referenced a few landmarks, while others gave sequences of instructions on how to find Misty. As a point of comparison, the ReferIt dataset (Kazemzadeh et al., 2014) has a larger vocabulary of 9124 tokens, but a shorter average description length of 3.52 tokens (with a standard deviation of 2.67 tokens).

A random sampling of descriptions from our dataset is shown in Table 1.

5.3 Quantitative Results

Quantitative results are shown in Table 2. Our evaluation metric is constructed such that there is an easily interpretable random baseline. We also evaluate a strong neural baseline that uses an approach we call Seq2Emb. This baseline converts the sentence into a vector using a bidirectional LSTM encoder, and also assigns vector embeddings to each voxel using a two-layer convolutional neural network. The voxel with an embedding that most closely matches the sentence embedding is chosen as the answer.

Our model achieves noticeable gains over the baseline approaches. At the same time, there remains a gap between our model and individual human performance. We see this as an indication that we have constructed a task with appropriate difficulty: it is approachable by building on the current state-of-the-art in machine learning and NLP, while presenting challenges that can motivate continued work on understanding language and how it relates to descriptions of the world.

	Dev Set	Test Set
Random Baseline	16.67	16.67
Seq2Emb Baseline	52.50	44.50
Our Model	67.50	62.50
Human	85.83	87.50

	% correct
Full model	**67.5**
−contextual block embeddings	65.0
−LSTM (use 3-word convolutions instead)	62.5
−language-dependent spatial operators	61.7

Table 3: Development set results for our full model and three independent ablations.

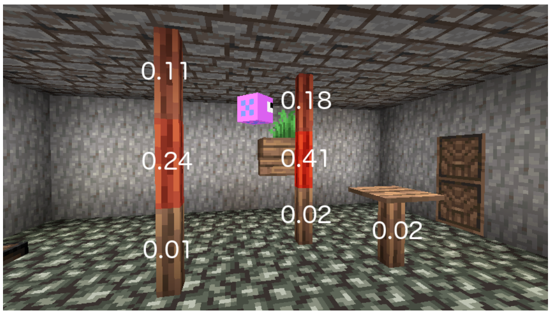
5.4 Ablation Study

We next conduct an ablation study to evaluate the contribution of the individual elements in our model. Our ablation results on the development set are shown in Table 3.

In our first ablation, we remove the compositional block embeddings that make use of multiple blocks. The resulting performance drop of 2.5% reflects the fact that our model uses multi-block information to match words with objects.

We next replace the LSTM in our full model with a 3-word-wide convolutional layer. A single word of left- and right-context provides limited ability to incorporate spatial descriptor words like *left* and *right*, or to distinguish landmarks used to locate Misty from words providing exposition about the scene. This ablation solves 5% fewer examples than our full model, reflecting our LSTM's ability to capture such phenomena.

Finally, we try holding the distribution over offset vectors fixed, by making it a trainable variable rather than a function of the language. This corresponds to enforcing the use of only one spatial



Misty is floating in the middle of the room. She in the upper half of the room, between the two ***poles****.*

Figure 4: Reference distribution representing our model's belief of which blocks the word *poles* refers to. Our model assigns the majority of the probability mass to the poles, while ignoring a table leg that is made of the same block type. Note that the seven numbers overlaid on top account for more than 99% of the total probability mass, and that each of the remaining blocks in the scene has a probability of at most 0.025%.

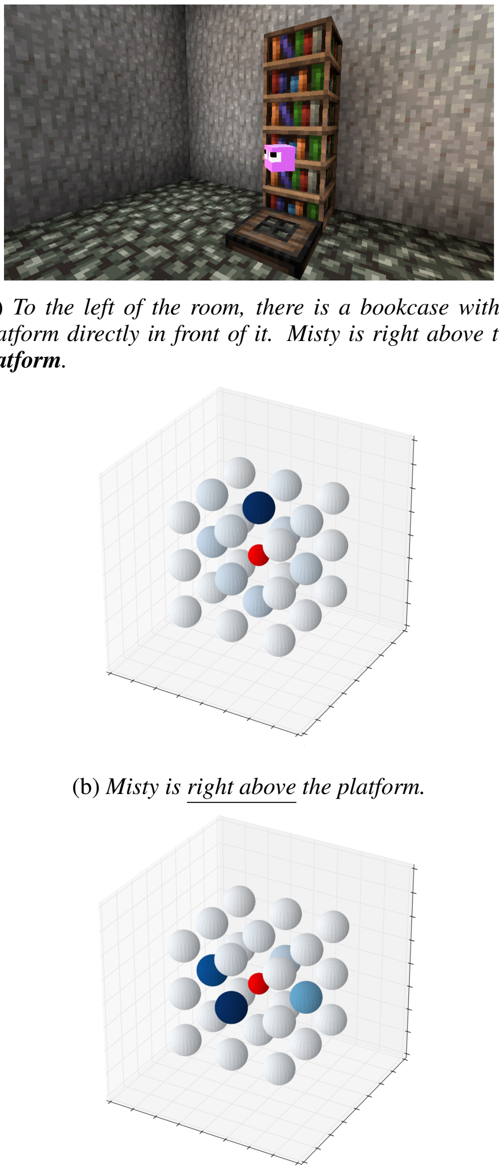
operator that roughly means 'near.' We retain the LSTM for the sole purpose of assigning a score to the not-a-landmark class, meaning that contextual information is still incorporated in the decision of whether to classify a word as a landmark or not. The resulting accuracy is 5.8% lower than our full model, which makes this the worst-performing of our ablations. These results suggest that the ability to infer spatial directions is important to our model's overall performance.

5.5 Qualitative Examination

The modular design of our model allows us to examine the individual behavior of each component in the network, which we explore in this section.

We find that our algorithm is able to learn to associate words with the corresponding voxels in the world. Figure 4 shows the reference distribution associated with the word *poles*, which is constructed by applying a softmax operation to the word-voxel scores for that word. Our algorithm is able to correctly segment out the voxels that are a part of the pole. Moreover, the table on the right side of the scene has a table leg made of the same block type as the pole – and yet, it is is assigned a low probability. This shows that our model is capable of representing compositional objects, and can learn to do so in an end-to-end manner.

We next examine the offset distributions computed by our model. Consider the scene and description shown in Figure 5a. The offset vector distribution at the word *platform*, shown in Figure 5b, shows that the model assigns high proba-

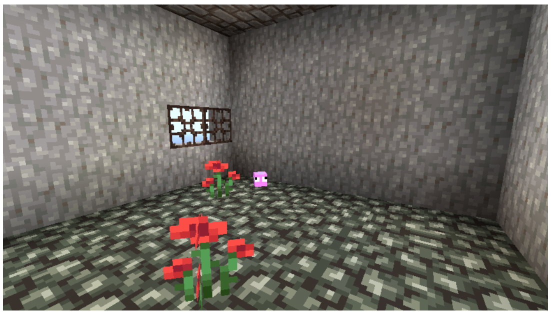


(a) *To the left of the room, there is a bookcase with a platform directly in front of it. Misty is right above the* ***platform****.*

(b) *Misty is right above the platform.*

(c) *Misty is in front of the platform.*

Figure 5: Effects of language context on offset vector distributions. In (a), we show the scene and its description. In (b), we visualize the offset vector distribution at the word *platform*, i.e. the 3D convolutional filter that is applied after finding the platform location. The red dot that indicates the center of the filter will be matched with the platform location. In (c), we have artificially replaced the words *right above* with *in front of*, resulting in a substantial change to this distribution.



Misty is between the wall and the flowers that are close to the corner.

Figure 6: Our algorithm interprets this sentence as *Misty is near the wall and the flowers and close to the corner.* This intersective interpretation is sufficient to correctly guess Misty's location in this scene (as well as others in the dataset).

bility to Misty being above the platform. In Figure 5c, we show the effects of replacing the phrase *right above* with the words *in front of*. This example illustrates our model's capacity for learning spatial directions. We note that the offset distribution given the phrase *in front of* is not as peaked as it is for *right above*, and that distributions for descriptions saying *left* or *right* are even less peaked (and are mostly uniform on the horizontal plane). One explanation for this is the ambiguity between speaker-centric and object-centric reference frames. The reference frame of our convolutional filters is the same as the initial camera frame for our our annotators, but this may not be the true speaker-centric frame because we mandate that annotators move the camera before submitting a description.

We next highlight our model's ability to incorporate multiple landmarks in making its decisions. Consider the scene and description shown in Figure 6. The room has four walls, two flowers, and four corners – no single landmark is sufficient to correctly guess Misty's location. Our model is able to localize the flowers, walls, and corners in this scene and intersect them to locate Misty. Strictly speaking, this approach is not logically equivalent to applying a two-argument *between* operator and recognizing the role of *that* as a relativizer. This is a limitation of our specific model, but the general approach of manipulating spatial region masks need not be constrained in this way. It would be possible to introduce operations into the neural network to model recursive structure in the language. In practice, however, we find that the intersective interpretation suffices for many of the descriptions that occur in our dataset.

6 Conclusion

In this paper, we define the task of interpreting spatial descriptors, construct a new dataset based on Minecraft, and propose a model for this task. We show that convolutional neural networks can be used to reason about regions in space as first-class entities. This approach is trainable end-to-end while also having interpretable values at the intermediate stages of the neural network.

Our architecture handles many of the linguistic phenomena needed to solve this task, including object references and spatial regions. However, there is more work to be done before we can say that the network completely understands the sentences that it reads. Our dataset can be used to investigate future models that expand to handle relativization and other recursive phenomena in language.

Acknowledgments

We thank the many workers on Mechanical Turk who contributed to the creation of our dataset.

This work was made possible by the open source tooling developed around and inspired by Minecraft; in particular we would like to thank the developers of the `voxel.js` project and associated plugins, as well as the developers of `mcedit2`.

Continuous Representation of Location for Geolocation and Lexical Dialectology using Mixture Density Networks

Abstract

We propose a method for embedding two-dimensional locations in a continuous vector space using a neural network-based model incorporating mixtures of Gaussian distributions, presenting two model variants for text-based geolocation and lexical dialectology. Evaluated over Twitter data, the proposed model outperforms conventional regression-based geolocation and provides a better estimate of uncertainty. We also show the effectiveness of the representation for predicting words from location in lexical dialectology, and evaluate it using the DARE dataset.

1 Introduction

Geolocation is an essential component of applications such as traffic monitoring (Emadi et al., 2017), human mobility pattern analysis (McNeill et al., 2016; Dredze et al., 2016) and disaster response (Ashktorab et al., 2014; Wakamiya et al., 2016), as well as targeted advertising (Anagnostopoulos et al., 2016) and local recommender systems (Ho et al., 2012). Although Twitter provides users with the means to geotag their messages, less than 1% of users opt to turn on geotagging, so third-party service providers tend to use profile data, text content and network information to infer the location of users. Text content is the most widely used source of geolocation information, due to its prevalence across social media services.

Text-based geolocation systems use the geographical bias of language to infer the location of a user or message using models trained on geotagged posts. The models often use a representation of text (e.g. based on a bag-of-words, convolutional or recurrent model) to predict the location either in real-valued latitude/longitude coordinate space or in discretised region-based space, using regression or classification, respectively. Regression models, as a consequence of minimising squared loss for a unimodal distribution, predict inputs with multiple targets to lie between the targets (e.g. a user who mentions content in both NYC and LA is predicted to be in the centre of the U.S.). Classification models, while eliminating this problem by predicting a more granular target, don't provide fine-grained predictions (e.g. specific locations in NYC), and also require heuristic discretisation of locations into regions (e.g. using clustering).

Mixture Density Networks ("MDNs": Bishop (1994)) alleviate these problems by representing location as a mixture of Gaussian distributions. Given a text input, an MDN can generate a mixture model in the form of a probability distribution over all location points. In the example of a user who talks about both NYC and LA, e.g., the model will predict a strong Gaussian component in NYC and another one in LA, and also provide an estimate of uncertainty over all the coordinate space.

Although MDNs are not new, they have not found widespread use in *inverse* regression problems where for a single input, multiple correct outputs are possible. Given the integration of NLP technologies into devices (e.g. phones or robots with natural language interfaces) is growing quickly, there is a potential need for interfacing language with continuous variables as input or target. MDNs can also be used in general text regression problems such as risk assessment (Wang and Hua, 2014), sentiment analysis (Joshi et al., 2010) and loan rate prediction (Bitvai and Cohn, 2015), not only to improve prediction but also to use the mixture model as a representation for the continuous variables. We apply MDNs to geotagged Twitter data in two different settings: (a) predicting location given text; and (b) predicting text given location.

Proceedings of the 2017 Conference on Empirical Methods in Natural Language Processing, pages 167–176
Copenhagen, Denmark, September 7–11, 2017. ©2017 Association for Computational Linguistics

Geotagged text content is not only useful in geolocation, but can also be used in lexical dialectology. Lexical dialectology is (in part) the converse of text-based geolocation (Eisenstein, 2015): instead of predicting location from language, language (e.g. dialect terms) are predicted from a given location. This is a much more challenging task as the lexical items are not known beforehand, and there is no notion of dialect regions in the continuous space of latitude/longitude coordinates. A lexical dialectology model should not only be able to predict dialect terms but also be able to automatically learn dialect regions.

In this work, we use bivariate Gaussian mixtures over geotagged Twitter data in two different settings, and demonstrate their use for geolocation and lexical dialectology. Our contributions are as follows: (1) we propose a continuous representation of location using bivariate Gaussian mixtures; (2) we show that our geolocation model outperforms regression-based models and achieves comparable results with classification models, but with added uncertainty over the continuous output space; (3) we show that our lexical dialectology model is able to predict geographical dialect terms from latitude/longitude input with state-of-the-art accuracy; and (4) we show that the automatically learned Gaussian regions match expert-generated dialect regions of the U.S.[1]

2 Related Work

2.1 Text-based Geolocation

Text-based geolocation models are defined as either a regression or a classification problem. In regression geolocation, the model learns to predict a real-valued latitude/longitude from a text input. This is a very challenging task for data types such as Twitter, as they are often heavily biased toward population centres and urban areas, and far from uniform. As an example, *Norwalk* is the name of a few cities in the U.S among which Norwalk, California (West Coast) and Norwalk, Connecticut (East Coast) are the two most populous cities. Assuming that occurrences of the city's name are almost equal in both city regions within the training set, a trained regression-based geolocation model given *Norwalk* as input, would geolocate it to a point in the middle of the U.S. instead of choosing one of the cities. In the machine learning literature, regression problems where there are multiple real-valued outputs for a given input are called *inverse problems* (Bishop, 1994). Here, standard regression models predict an average point in the middle of all training target points to minimise squared error loss. Bishop (1994) proposes density mixture networks to model such inverse problems, as we discuss in detail in Section 3.

In addition, non-Bayesian interpretations of regression models, which are often used in practice, don't produce any prediction of uncertainty, so other than the predicted point, we have little idea where else the term could have high or low probability. Priedhorsky et al. (2014) propose a Gaussian Mixture Model (GMM) approach instead of squared loss regression, whereby they learn a mixture of bivariate Gaussian distributions for each individual n-gram in the training set. During prediction, they add the Gaussian mixture of each n-gram in the input text, resulting in a new Gaussian mixture which can be used to predict a coordinate with associated uncertainty. To add the mixture components they use a weighted sum, where the weight of each n-gram is assigned by several heuristic features. Learning a GMM for each n-gram is resource-intensive if the size of the training set — and thus the number of n-grams — is large.

Assuming sufficient training samples containing the term *Norwalk* in the two main, a trained classification model would, given this term as input, predict a probability distribution over all regions, and assign higher probabilities to the regions containing the two major cities. The challenge, though, is that the coordinates in the training data must first be partitioned into regions using administrative regions (Cheng et al., 2010; Hecht et al., 2011; Kinsella et al., 2011; Han et al., 2012, 2014), a uniform grid (Serdyukov et al., 2009), or a clustering method such as a k-d tree (Wing and Baldridge, 2011) or K-means (Rahimi et al., to appear). The cluster/region labels can then be used as targets. Once we have a prediction about where a user is more likely to be from, there is no more information about the coordinates inside the predicted region. If a region that contains Wyoming is predicted as the home location of a user, we have no idea which city or county within Wyoming the user might be from, unless we retrain the model using a more fine-grained discretisation or a hierarchical discretisation (Wing and Baldridge, 2014), which is both time-consuming and challenging due to data

[1] Code available at https://github.com/afshinrahimi/geomdn

sparseness.

2.2 Lexical Dialectology

The traditional linguistic approach to lexical dialectology is to find the geographical distributions of known contrast sets such as $\{\textit{you}, \textit{yall}, \textit{yinz}\}$: (Labov et al., 2005; Nerbonne et al., 2008; Gonçalves and Sánchez, 2014; Doyle, 2014; Huang et al., 2015; Nguyen and Eisenstein, to appear). This usually involves surveying a large geographically-uniform sample of people from different locations and analysing where each known alternative is used more frequently. Then, the coordinates are clustered heuristically into dialect regions, based on the lexical choices of users in each region relative to the contrast set. This processing is very costly and time-consuming, and relies critically on knowing the lexical alternatives a priori. For example, it would require a priori knowledge of the fact that people in different regions of the US use *pop* and *soda* to refer to the same type of drink, and a posteriori analysis of the empirical geographical distribution of the different terms. Language, particularly in social media and among younger speakers, is evolving so quickly, in ways that can be measured over large-scale data samples such as Twitter, that we ideally want to be able to infer such contrast sets dynamically. The first step in automatically collecting dialect words is to find terms that are disproportionately distributed in different locations. The two predominant approaches to this problem are model-based (Eisenstein et al., 2010; Ahmed et al., 2013; Eisenstein, 2015) and through the use of statistical metrics (Monroe et al., 2008; Cook et al., 2014). Model-based approaches use a topic model, e.g., to extract region-specific topics, and from this, predict the probability of seeing a word given a geographical region (Eisenstein et al., 2010). However, there are scalability issues, limiting the utility of such models.

In this paper, we propose a neural network architecture that learns a mixture of Gaussian distributions as its activation function, and predicts both locations from word-based inputs (geolocation), and words from location-based inputs (lexical dialectology).

3 Model

3.1 Bivariate Gaussian Distribution

A bivariate Gaussian distribution is a probability distribution over 2d space (in our case, a latitude/longitude coordinate pair). The probability mass function is given by:

$$\mathcal{N}(\boldsymbol{x}|\boldsymbol{\mu},\Sigma) = \frac{1}{(2\pi)}\frac{1}{|\Sigma|^{1/2}} \exp\left\{-\frac{1}{2}(\boldsymbol{x}-\boldsymbol{\mu})^{\intercal}\Sigma^{-1}(\boldsymbol{x}-\boldsymbol{\mu})\right\}$$

where $\boldsymbol{\mu}$ is the 2-dimensional mean vector, the matrix $\Sigma = \begin{pmatrix} {\sigma_1}^2 & \rho_{12}\sigma_1\sigma_2 \\ \rho_{12}\sigma_1\sigma_2 & {\sigma_2}^2 \end{pmatrix}$ is the covariance matrix, and $|\Sigma|$ is its determinant. σ_1 and σ_2 are the standard deviations of the two dimensions, and ρ_{12} is the covariance. $\boldsymbol{x}$ is a latitude/longitude coordinate whose probability we are seeking to predict.

3.2 Mixtures of Gaussians

A mixture of Gaussians is a probabilistic model to represent subpopulations within a global population in the form of a weighted sum of K Gaussian distributions, where a higher weight with a component Gaussian indicates stronger association with that component. The probability mass function of a Gaussian mixture model is given by:

$$\mathcal{P}(\boldsymbol{x}) = \sum_{k=1}^{K}\pi_k\mathcal{N}(\boldsymbol{x}|\boldsymbol{\mu_k},\Sigma_k)$$

where $\sum_{k=1}^{K}\pi_k = 1$, and the number of components K is a hyper-parameter.

3.3 Mixture Density Network (MDN)

A mixture density network ("MDN": Bishop (1994)) is a latent variable model where the conditional probability of $p(y|x)$ is modelled as a mixture of K Gaussians where the mixing coefficients π and the parameters of Gaussian distributions $\boldsymbol{\mu}$ and Σ are computed as a function of input using a neural network:

$$\mathcal{P}(y|x) = \sum_{k=1}^{K}\pi_k(x)\mathcal{N}\big(y|\mu_k(x),\Sigma_k(x)\big)$$

In the bivariate case of latitude/longitude, the number of parameters of each Gaussian is 6 $(\pi_k(x), \mu_{1k}(x), \mu_{2k}(x), \rho_k(x), \sigma_{1k}(x), \sigma_{2k}(x))$, which are learnt in the output layer of a regular neural network as a function of input x. The output size of the network for K components would be $6 \times K$. The output of an MDN for N samples (e.g. where N is the mini-batch size) is an $N \times 6K$ matrix which is then sliced and reshaped into $(N \times 2 \times K)$, $(N \times 2 \times K)$, $(N \times 1 \times K)$

and $(N \times 1 \times K)$ matrices, providing the model parameters μ, σ, ρ and π. Each parameter type has its own constraints: σ (the standard deviation) should be positive, ρ (the correlation) should be in the interval $[-1, 1]$ and π should be positive and sum to one, as a probability distribution. To force these constraints, the following transformations are often applied to each parameter set:

$$\sigma \sim \mathrm{SoftPlus}(\sigma\prime) = \log(\exp(\sigma\prime) + 1) \in (0, +\infty)$$
$$\pi \sim \mathrm{SoftMax}(\pi\prime)$$
$$\rho \sim \mathrm{SoftSign}(\rho\prime) = \frac{\rho\prime}{1 + |\rho\prime|} \in [-1, 1]$$

As an alternative, it's possible to use transformations like $\exp$ for σ and $\tanh$ for ρ. After applying the transformations to enforce the range constraints, the negative log likelihood loss of each sample x given a 2d coordinate label y is computed as:

$$\mathcal{L}(y|x) = -\log\left\{\sum_{k=1}^{K} \pi_k(x)\mathcal{N}\big(y|\mu_k(x), \Sigma_k(x)\big)\right\}$$

To predict a location, given an unseen input, the output of the network is reshaped into a mixture of Gaussians and μ_k, one of the K components' μ is chosen as the prediction. The selection criteria is either based on the strongest component with highest π, or the component that maximises the overall mixture probability:

$$\max_{\mu_i \in \{\mu_1 \ldots \mu_K\}} \sum_{k=1}^{K} \pi_k \mathcal{N}(\mu_i|\mu_k, \Sigma_k)$$

For further details on selection criteria, see Bishop (1994).

3.4 Mixture Density Network with Shared Parameters (MDN-SHARED)

In the original MDN model proposed by Bishop (1994), the parameters of the mixture model are separate functions of input, which is appropriate when the inputs and outputs directly relate to each other, but in the case of geolocation or lexical dialectology, the relationship between inputs and outputs is not so obvious. As a result, it might be a difficult task for the model to learn all the parameters of each sample correctly. Instead of using the output to predict all the parameters, we share μ and Σ among all samples as parameters of the output layer, and only use the input to predict π, the mixture probabilities, using a SoftMax layer. We initialise μ by applying K-means clustering to the training coordinates and setting each value of μ to the centroids of the K clusters; we initialise Σ randomly between 0 and 10. We use the original cost function to update the weight matrices, biases and the global shared parameters of the mixture model through backpropagation. Prediction is performed in the same way as for MDN.

3.5 Continuous Representation of Location

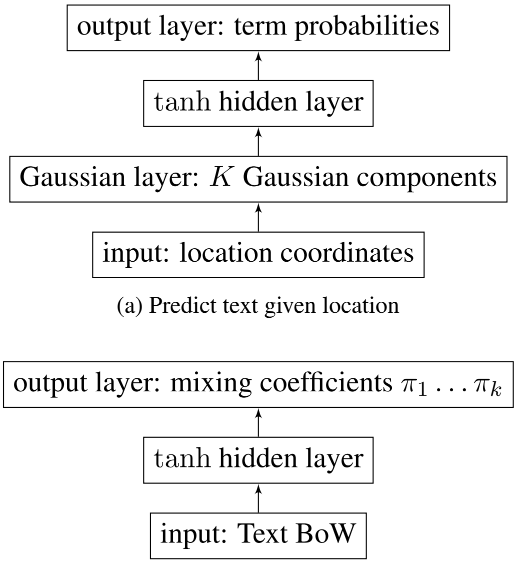
Gaussian mixtures are usually used as the output layer in neural networks (as in MDN) for inverse regression problems. We extend their application by using them as an input representation when the input is a multidimensional continuous variable. In problems such as lexical dialectology, the input is real-valued 2d coordinates, and the goal is to predict dialect words from a given location. Small differences in latitude/longitude may result in big shifts in language use (e.g. in regions such as Switzerland or Gibraltar). One way to model this is to discretise the input space (similar to the discretisation of the output space in classification), with the significant downside that the model is not able to learn/fine-tune regions in a data-driven way. A better solution is to use a K component Gaussian mixture representation of location, where μ and Σ are shared among all samples, and the output of the layer is the probability of input in each of the mixture components. Note that in this representation, there is no need for π parameters as we just need to represent the association of an input location to K regions, which will then be used as input to the next layer of a neural network and used to predict the targets. We use this continuous representation of location to predict dialect words from location input.

4 Experiments

We apply the two described MDN models on two widely-used geotagged Twitter datasets for geolocation, and compare the results with state-of-the-art classification and regression baselines. Also, we use the mixture of Gaussian representation of location to predict dialect terms from coordinates.

4.1 Data

In our experiments, we use two existing Twitter user geolocation datasets: (1) GEOTEXT (Eisenstein et al., 2010), and (2) TWITTER-US (Roller et al., 2012). Each dataset has fixed training, devel-



output layer: term probabilities
tanh hidden layer
Gaussian layer: K Gaussian components
input: location coordinates
output layer: mixing coefficients $\pi_1 \dots \pi_k$
tanh hidden layer
input: Text BoW

(a) Predict text given location

(b) Predict location given text

Figure 1: (a) The lexical dialectology model using a Gaussian representation layer. (b) MDN-SHARED geolocation model where the mixture weights π are predicted for each sample, and μ and Σ are parameters of the output layer, shared between all samples.

opment and test partitions, and a user is represented by the concatenation of their tweets, and labelled with the latitude/longitude of the first collected geotagged tweet.[2] GEOTEXT and TWITTER-US cover the continental US with 9k, 449k users, respectively.[3]

DARE is a dialect-term dataset derived from the Dictionary of American Regional English (Cassidy, 1985) by Rahimi et al. (to appear). DARE consists of dialect regions, terms and the meaning of each term.[4] It represents the aggregation of a number of dialectal surveys over different regions of the U.S., to identify shared dialect regions. Because the dialect regions in DARE maps are not machine readable, populous cities within each dialect region are manually extracted and associated with their dialect region terms. The dataset is made up of around 4.3k dialect terms across 99 U.S. dialect regions.

4.2 Geolocation

We use a 3-layer neural network as shown in Figure 1a where the input is the l_2 normalised bag-of-words model of a given user with stop words, @-mentions and words with document frequency less than 10 removed. The input is fed to a hidden layer with tanh nonlinearity that produces the output of the network (with no nonlinearity applied). The output is the collection of Gaussian mixture parameters (μ, Σ, π) from MDN. For prediction, the μ_k of the mixture component which has the highest probability within the mixture component is selected. In the case of MDN-SHARED, the output is only π, a vector with size K, but the output layer contains extra global parameters μ and Σ $(\sigma_{\text{lat}}, \sigma_{\text{lon}}, \rho)$ which are shared between all the samples. The negative log likelihood objective is optimised using Adam (Kingma and Ba, 2014) and early stopping is used to prevent overfitting. The hidden layer is subject to drop-out and elastic net regularisation (with equal l_1 and l_2 shares). As our baseline, we used a multilayer perceptron regressor with the same input and hidden architecture but with a 2d output with linear activation that predicts the location from text input. The regularisation and drop-out rate, hidden layer size and the number of Gaussian components K (for MDN and MDN-SHARED) are tuned over the development set of each dataset, as shown in Table 1.

We evaluate the predictions of the geolocation models based on three measures (following Cheng et al. (2010) and Eisenstein et al. (2010)):

1. the classification accuracy within a 161km (= 100 mile) radius of the actual location ("Acc@161"); i.e., if the predicted location is within 161km of the actual location, it is considered to be correct
2. the mean error ("Mean") between the predicted location and the actual location of the user, in kilometres
3. the median error ("Median") between the predicted location and the actual location of the user, in kilometres

4.3 Lexical Dialectology

To predict dialect words from location, we use a 4-layer neural network as shown in Figure 1b. The input is a latitude/longitude coordinate, the first hidden layer is a Gaussian mixture with K components which has μ and Σ as its parameters and produces a probability for each component as an

[2] This geolocation representation is naive, but was made by the creators of the original datasets and has been used by others. It has been preserved in this work for comparability with the results of others, despite misgivings about whether this is a faithful representation of the location for a given user.

[3] The datasets can be obtained from https://github.com/utcompling/textgrounder.

[4] http://www.daredictionary.com/

activation function, the second hidden layer with $\tanh$ nonlinearity captures the association between different Gaussians, and the output is a $\mathrm{SoftMax}$ layer which results in a probability distribution over the vocabulary. For a user label, we use an l_1 normalised bag-of-words representation of its text content and use binary tf and idf for term-weighting. The model should learn to predict the probability distribution over the vocabulary and so be capable of predicting dialect words with a higher probability. It also learns regions (parameters of K Gaussians) that represent dialect regions.

We evaluate the lexical dialectology model (`MDN-layer`) using perplexity of the predicted unigram distribution, and compare it with a baseline where the Gaussian mixture layer is replaced with a $\tanh$ hidden layer (`tanh-layer`). Also we retrieve words given points within a region from the DAREDS dataset, and measure recall with respect to relevant dialect terms from DAREDS. To do that, we randomly sample $P = 10000$ latitude/longitude points from the training set and predict the corresponding word distribution. To come up with a ranking over words given region r as query, we use the following measure:

$$
\begin{aligned}
score(w_i|r) = & \frac{1}{N}\sum_{p_j \in r} \log(P(w_i|p_j)) \\
& -\frac{1}{P}\sum_{j=1}^{P} \log(P(w_i|p_j))
\end{aligned}
$$

where N equals the number of points (out of 10000) inside the query dialect region r and P equals the total number of points (here 10000). For example, if we are querying dialect terms from dialect region South (r), N is the number of randomly selected points that fall within the constituent states of South. $score(w_i|r)$ measures the (log) probability ratio of a word w_i inside region r compared to its global score: if a word is local to region r, the ratio will be higher. We use this measure to create a ranking over the vocabulary from which we measure precision and recall at k given gold-standard dialect terms in DAREDS.

5 Results

5.1 Geolocation

The performance of `Regression`, `MDN` and `MDN-SHARED`, along with several state-of-the-art classification models, is shown in Table 2. The `MDN` and `MDN-SHARED` models clearly outperform `Regression`, and achieve competitive or slightly worse results than the classification models but provide uncertainty over the whole output space. The geographical distribution of error for `MDN-SHARED` over the development set of TWITTER-US is shown in Figure 3, indicating larger errors in MidWest and particularly in North Pacific regions (e.g. Oregon).

5.2 Dialectology

The perplexity of the lexical dialectology model using Gaussian mixture representation (`MDN-layer`) is 840 for the 54k vocabulary of TWITTER-US dataset, 1% lower than a similar network architecture with a $\tanh$ hidden layer (`tanh-layer`), which is not a significant improvement. Also we evaluated the model using recall at k and compared it to the `tanh-layer` model which again is competitive with `tanh-layer` but with the advantage of learning dialect regions simultaneously. Because the DARE dialect terms are not used frequently in Twitter, many of the words are not covered in our dataset, despite its size. However, our model is able to retrieve dialect terms that are distinctly associated with regions. The top dialect words for regions New York, Louisiana, Illinois and Pennsylvania are shown in Table 3, and include named entities, dialect words and local hashtags. We also visualised the learned Gaussians of the dialectology model in Figure 2, which as expected show several smaller regions (Gaussians with higher σ) and larger regions in lower populated areas. It is interesting to see that the shape of the learned Gaussians matches natural borders such as coastal regions.

We also visualised the log probability of dialect terms *hella* (an intensifier mainly used in Northern California) and *yall* (means "you all", used in Southern U.S.) resulting from the Gaussian representation model. As shown in Figure 5, the heatmap matches the expected regions.

6 Conclusion

We proposed a continuous representation of location using mixture of Gaussians and applied it to geotagged Twitter data in two different settings: (1) geolocation of social media users, and (2) lexical dialectology. We used `MDN` (Bishop, 1994) in a multilayer neural network as a geolocation model

and showed that it outperforms regression models by a large margin. There is also very recent work (Iso et al., 2017) in tweet-level geolocation that shows the effectiveness of MDN.

We modified MDN by sharing the parameters of the Gaussian mixtures in MDN-SHARED and improved upon MDN, achieving competetive results with state-of-the-art classification models. We also applied the Gaussian mixture representation to predict dialect words from location, and showed that it

is competitive with simple tanh activation in terms of both perplexity of the predicted unigram model and also recall at k at retrieving DARE dialect words by location input. Furthermore we showed that the learned Gaussian mixtures have intereting properties such as covering high population density regions (e.g. NYC and LA) with a larger number of small Gaussians, and a smaller number of larger Gaussians in low density areas (e.g. the midwest).

Although we applied the mixture of Gaussians to location data, it can be used in other settings where the input or output are from a continuous multivariate distribution. For example it can be applied to predict financial risk (Wang and Hua, 2014) and sentiment (Joshi et al., 2010) given text. We showed that when a global structure exists (e.g. population centres, in the case of geolocation) it is better to share the global parameters of the mixture model to improve generalisation. In this work, we used the bivariate Gaussian distribution in the MDN's mixture leaving the use of other distributions which might better suit the geolocation task for future research.

OBJ2TEXT: Generating Visually Descriptive Language from Object Layouts

Xuwang Yin **Vicente Ordonez**
Department of Computer Science, University of Virginia, Charlottesville, VA.
[xy4cm, vicente]@virginia.edu

Abstract

Generating captions for images is a task that has recently received considerable attention. In this work we focus on caption generation for abstract scenes, or object layouts where the only information provided is a set of objects and their locations. We propose OBJ2TEXT, a sequence-to-sequence model that encodes a set of objects and their locations as an input sequence using an LSTM network, and decodes this representation using an LSTM language model. We show that our model, despite encoding object layouts as a sequence, can represent spatial relationships between objects, and generate descriptions that are globally coherent and semantically relevant. We test our approach in a task of object-layout captioning by using only object annotations as inputs. We additionally show that our model, combined with a state-of-the-art object detector, improves an image captioning model from 0.863 to 0.950 (CIDEr score) in the test benchmark of the standard MS-COCO Captioning task.

1 Introduction

Natural Language generation (NLG) is a long standing goal in natural language processing. There have already been several successes in applications such as financial reporting (Kukich, 1983; Smadja and McKeown, 1990), or weather forecasts (Konstas and Lapata, 2012; Wen et al., 2015), however it is still a challenging task for less structured and open domains. Given recent progress in training robust visual recognition models using convolutional neural networks, the task of generating natural language descriptions for arbitrary images has received considerable attention (Vinyals et al., 2015; Karpathy and Fei-Fei, 2015; Mao et al., 2015). In general, generating visually descriptive language can be useful for various tasks such as human-machine communication, accessibility, image retrieval, and search. However this task is still challenging and it depends on developing both a robust visual recognition model, and a reliable language generation model. In this paper, we instead tackle a task of describing object layouts where the categories for the objects in an input scene and their corresponding locations are known. Object layouts are commonly used for story-boarding, sketching, and computer graphics applications. Additionally, using our object layout captioning model on the outputs of an object detector we are also able to improve image caption-

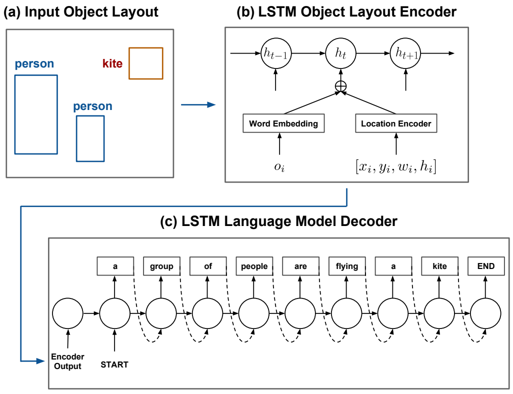

Figure 1: Overview of our proposed model for generating visually descriptive language from object layouts. The input (a) is an object layout that consists of object categories and their corresponding bounding boxes, the encoder (b) uses a two-stream recurrent neural network to encode the input object layout, and the decoder (c) uses a standard LSTM recurrent neural network to generate text.

Proceedings of the 2017 Conference on Empirical Methods in Natural Language Processing, pages 177–187
Copenhagen, Denmark, September 7–11, 2017. ©2017 Association for Computational Linguistics

ing models. Object layouts contain rich semantic information, however they also abstract away several other visual cues such as color, texture, and appearance, thus introducing a different set of challenges than those found in traditional image captioning.

We propose OBJ2TEXT, a sequence-to-sequence model that encodes object layouts using an LSTM network (Hochreiter and Schmidhuber, 1997), and decodes natural language descriptions using an LSTM-based neural language model[1]. Natural language generation systems usually consist of two steps: content planning, and surface realization. The first step decides on the content to be included in the generated text, and the second step connects the concepts using structural language properties. In our proposed model, OBJ2TEXT, content planning is performed by the encoder, and surface realization is performed by the decoder. Our model is trained in the standard MS-COCO dataset (Lin et al., 2014), which includes both object annotations for the task of object detection, and textual descriptions for the task of image captioning. While most previous research has been devoted to any one of these two tasks, our paper presents, to our knowledge, the first approach for learning mappings between object annotations and textual descriptions. Using several lesioned versions of the proposed model we explored the effect of object counts and locations in the quality and accuracy of the generated natural language descriptions.

Generating visually descriptive language requires beyond syntax, and semantics; an understanding of the physical word. We also take inspiration from recent work by Schmaltz et al. (2016) where the goal was to reconstruct a sentence from a bag-of-words (BOW) representation using a simple surface-level language model based on an encoder-decoder sequence-to-sequence architecture. In contrast to this previous approach, our model is grounded on visual data, and its corresponding spatial information, so it goes beyond word re-ordering. Also relevant to our work is Yao et al. (2016a) which previously explored the task of oracle image captioning by providing a language generation model with a list of manually defined visual concepts known to be present in the image. In addition, our model is able to leverage both quantity and spatial information as additional cues associated with each object/concept, thus allowing it to learn about verbosity, and spatial relations in a supervised fashion.

In summary, our contributions are as follows:

- We demonstrate that despite encoding object layouts as a sequence using an LSTM, our model can still effectively capture spatial information for the captioning task. We perform ablation studies to measure the individual impact of object counts, and locations.
- We show that a model relying only on object annotations as opposed to pixel data, performs competitively in image captioning despite the ambiguity of the setup for this task.
- We show that more accurate and comprehensive descriptions can be generated on the image captioning task by combining our OBJ2TEXT model using the outputs of a state-of-the-art object detector with a standard image captioning approach.

2 Task

We evaluate OBJ2TEXT in the task of object layout captioning, and image captioning. In the first task, the input is an object layout that takes the form of a set of object categories and bounding box pairs $\langle \boldsymbol{o}, \boldsymbol{l} \rangle = \{\langle o_i, l_i \rangle\}$, and the output is natural language. This task resembles the second task of image captioning except that the input is an object layout instead of a standard raster image represented as a pixel array. We experiment in the MS-COCO dataset for both tasks. For the first task, object layouts are derived from ground-truth bounding box annotations, and in the second task object layouts are obtained using the outputs of an object detector over the input image.

3 Related Work

Our work is related to previous works that used clipart scenes for visually-grounded tasks including sentence interpretation (Zitnick and Parikh, 2013; Zitnick et al., 2013), and predicting object dynamics (Fouhey and Zitnick, 2014). The cited advantage of abstract scene representations such as the ones provided by the clipart scenes dataset proposed in (Zitnick and Parikh, 2013) is their ability to separate the complexity of pattern recognition from semantic visual representation. Abstract scene representations also maintain

[1] We build on neuraltalk2 and make our Torch code, and an interactive demo of our model available in the following url: http://vision.cs.virginia.edu/obj2text

common-sense knowledge about the world. The works of Vedantam et al. (2015b); Eysenbach et al. (2016) proposed methods to learn common-sense knowledge from clipart scenes, while the method of Yatskar et al. (2016), similar to our work, leverages object annotations for natural images. Understanding abstract scenes has demonstrated to be a useful capability for both language and vision tasks and our work is another step in this direction.

Our work is also related to other language generation tasks such as image and video captioning (Farhadi et al., 2010; Ordonez et al., 2011; Mason and Charniak, 2014; Ordonez et al., 2015; Xu et al., 2015; Donahue et al., 2015; Mao et al., 2015; Fang et al., 2015). This problem is interesting because it combines two challenging but perhaps complementary tasks: visual recognition, and generating coherent language. Fueled by recent advances in training deep neural networks (Krizhevsky et al., 2012) and the availability of large annotated datasets with images and captions such as the MS-COCO dataset (Lin et al., 2014), recent methods on this task perform end-to-end learning from pixels to text. Most recent approaches use a variation of an encoder-decoder model where a convolutional neural network (CNN) extracts visual features from the input image (encoder), and passes its outputs to a recurrent neural network (RNN) that generates a caption as a sequence of words (decoder) (Karpathy and Fei-Fei, 2015; Vinyals et al., 2015). However, the MS-COCO dataset, containing object annotations, is also a popular benchmark in computer vision for the task of object detection, where the objective is to go from pixels to a collection of object locations. In this paper, we instead frame our problem as going from a collection of object categories and locations (object layouts) to image captions. This requires proposing a novel encoding approach to encode these object layouts instead of pixels, and allows for analyzing the image captioning task from a different perspective. Several other recent works use a similar sequence-to-sequence approach to generate text from source code input (Iyer et al., 2016), or to translate text from one language to another (Bahdanau et al., 2015).

There have also been a few previous works explicitly analyzing the role of spatial and geometric relations between objects for vision and language related tasks. The work of Elliott and Keller (2013) manually defined a dictionary of object-object relations based on geometric cues. The work of Ramisa et al. (2015) is focused on predicting preposition given two entities and their locations in an image. Previous works of Plummer et al. (2015) and Rohrbach et al. (2016) showed that switching from classification-based CNN network to detection-based Fast RCNN network improves performance for phrase localization. The work of Hu et al. (2016) showed that encoding image regions with spatial information is crucial for natural language object retrieval as the task explicitly asks for locations of target objects. Unlike these previous efforts, our model is trained end-to-end for the language generation task, and takes as input a holistic view of the scene layout, potentially learning higher order relations between objects.

4 Model

In this section we describe our base OBJ2TEXT model for encoding object layouts to produce text (section 4.1), as well as two further variations to use our model to generate captions for real images: OBJ2TEXT-YOLO which uses the YOLO object detector (Redmon and Farhadi, 2017) to generate layouts of object locations from real images (section 4.2), and OBJ2TEXT-YOLO + CNN-RNN which further combines the previous model with an encoder-decoder image captioning which uses a convolutional neural network to encode the image (section 4.3).

4.1 OBJ2TEXT

OBJ2TEXT is a sequence-to-sequence model that encodes an input object layout as a sequence, and decodes a textual description by predicting the next word at each time step. Given a training data set comprising N observations $\left\{\langle \boldsymbol{o}^{(n)}, \boldsymbol{l}^{(n)} \rangle\right\}$, where $\langle \boldsymbol{o}^{(n)}, \boldsymbol{l}^{(n)} \rangle$ is a pair of sequences of input category and location vectors, together with a corresponding set of target captions $\left\{\boldsymbol{s}^{(n)}\right\}$, the encoder and decoder are trained jointly by minimizing a loss function over the training set using stochastic gradient descent:

$$W^* = \arg\min_W \sum_{n=1}^{N} \mathcal{L}(\langle \boldsymbol{o}^{(n)}, \boldsymbol{l}^{(n)} \rangle, \boldsymbol{s}^{(n)}), \qquad (1)$$

in which $W = \binom{W_1}{W_2}$ is the group of encoder parameters W_1 and decoder parameters W_2. The loss function is a negative log likelihood function of the generated description given the encoded object layout

$$\mathcal{L}(\langle \boldsymbol{o}^{(n)}, \boldsymbol{l}^{(n)} \rangle, \boldsymbol{s}^{(n)}) = -\log p(\boldsymbol{s}^n | h_L^n, W_2), \quad (2)$$

where h_L^n is computed using the LSTM-based encoder (eqs. 3, and 4) from the object layout inputs $\langle \boldsymbol{o}^{(n)}, \boldsymbol{l}^{(n)} \rangle$, and $p(\boldsymbol{s}^n | h_L^n, W_2)$ is computed using the LSTM-based decoder (eqs. 5, 6 and 7).

At inference time we encode an input layout $\langle \boldsymbol{o}, \boldsymbol{l} \rangle$ into its representation h_L, and sample a sentence word by word based on $p(s_t | h_L, \boldsymbol{s}_{<t})$ as computed by the decoder in time-step t. Finding the optimal sentence $\boldsymbol{s}^* = \arg\max_{\boldsymbol{s}} p(\boldsymbol{s}|h_L)$ requires the evaluation of an exponential number of sentences as in each time-step we have K number of choices for a word vocabulary of size K. As a common practice for an approximate solution, we follow (Vinyals et al., 2015) and use beam search to limit the choices for words at each time-step by only using the ones with the highest probabilities.

Encoder: The encoder at each time-step t takes as input a pair $\langle o_t, l_t \rangle$, where o_t is the object category encoded as a one-hot vector of size V, and $l_t = [B_t^x, B_t^y, B_t^w, B_t^h]$ is the location configuration vector that contains left-most position, top-most position, and the width and height of the bounding box corresponding to object o_t, all normalized in the range [0,1] with respect to input image dimensions. o_t and l_t are mapped to vectors with the same size k and added to form the input x_t to one time-step of the LSTM-based encoder as follows:

$$x_t = W_o o_t + (W_l l_t + b_l), \quad x_t \in \mathbb{R}^k, \quad (3)$$

in which $W_o \in \mathbb{R}^{k \times V}$ is a categorical embedding matrix (the word encoder), and $W_l \in \mathbb{R}^{k \times 4}$ and bias $b_l \in \mathbb{R}^k$ are parameters of a linear transformation unit (the object location encoder).

Setting initial value of cell state vector $c_0^e = 0$ and hidden state vector $h_0^e = 0$, the LSTM-based encoder takes the sequence of input $(x_1, ..., x_{T_1})$ and generates a sequence of hidden state vectors $(h_1^e, ..., h_{T_1}^e)$ using the following step function (we omit cell state variables and internal transition gates for simplicity as we use a standard LSTM cell definition):

$$h_t^e = \text{LSTM}(h_{t-1}^e, x_t; W_1). \quad (4)$$

We use the last hidden state vector $h_L = h_{T_1}^e$ as the encoded representation of the input layout $\langle \boldsymbol{o}_t, \boldsymbol{l}_t \rangle$ to generate the corresponding description $\boldsymbol{s}$.

Decoder: The decoder takes the encoded layout h_L as input and generates a sequence of multinomial distributions over a vocabulary of words using an LSTM neural language model. The joint probability distribution of generated sentence $\boldsymbol{s} = (s_1, ..., s_{T_2})$ is factorized into products of conditional probabilities:

$$p(\boldsymbol{s}|h_L) = \prod_{t=1}^{T_2} p(s_t | h_L, \boldsymbol{s}_{<t}), \quad (5)$$

where each factor is computed using a softmax function over the hidden states of the decoder LSTM as follows:

$$p(s_t | h_L, \boldsymbol{s}_{<t}) = \text{softmax}(W_h h_{t-1}^d + b_h), \quad (6)$$

$$h_t^d = \text{LSTM}(h_{t-1}^d, W_s s_t; W_2), \quad (7)$$

where W_s is the categorical embedding matrix for the one-hot encoded caption sequence of symbols. By setting $h_{-1}^d = 0$ and $c_{-1}^d = 0$ for the initial hidden state and cell state, the layout representation is encoded into the decoder network at the 0 time step as a regular input:

$$h_0^d = \text{LSTM}(h_{-1}^d, h_L; W_2). \quad (8)$$

We use beam search to sample from the LSTM as is routinely performed in previous literature in order to generate text.

4.2 OBJ2TEXT-YOLO

For the task of image captioning we propose OBJ2TEXT-YOLO. This model takes an image as input, extracts an object layout (object categories and locations) with a state-of-the-art object detection model YOLO (Redmon and Farhadi, 2017), and uses OBJ2TEXT as described in section 4.1 to generate a natural language description of the input layout and hence, the input image. The model is trained using the standard back-propagation algorithm, but the error is not back-propagated to the object detection module.

4.3 OBJ2TEXT-YOLO + CNN-RNN

For the image captioning task we experiment with a combined model (see Figure 2) where we take an image as input, and then use two separate computation branches to extract visual feature information and object layout information. These two streams of information are then passed to an LSTM neural language model to generate a description. Visual features are extracted using the

Layout Encoding

Figure 2: Image Captioning by joint learning of visual features and object layout encoding.

VGG-16 (Simonyan and Zisserman, 2015) convolutional neural network pre-trained on the ImageNet classification task (Russakovsky et al., 2015). Object layouts are extracted using the YOLO object detection system and its output object locations are encoded using our proposed OBJ2TEXT encoder. These two streams of information are encoded into vectors of the same size and their sum is input to the language model to generate a textual description. The model is trained using the standard back-propagation algorithm where the error is back-propagated to both branches but not the object detection module. The weights of the image CNN model are fine-tuned only after the layout encoding branch is well trained but no significant overall performance improvements were observed.

5 Experimental Setup

We evaluate the proposed models on the MS-COCO (Lin et al., 2014) dataset which is a popular image captioning benchmark that also contains object extent annotations. In the object layout captioning task the model uses the ground-truth object extents as input object layouts, while in the image captioning task the model takes raw images as input. The qualities of generated descriptions are evaluated using both human evaluations and automatic metrics. We train and validate our models based on the commonly adopted split regime (113,287 training images, 5000 validation and 5000 test images) used in (Karpathy et al., 2016), and also test our model in the MS-COCO official test benchmark.

We implement our models based on the open source image captioning system Neuraltalk2 (Karpathy et al., 2016). Other configurations including data preprocessing and training hyper-parameters also follow Neuraltalk2. We trained our models using a GTX1080 GPU with 8GB of memory for 400k iterations using a batch size of 16 and an Adam optimizer with alpha of 0.8, beta of 0.999 and epsilon of 1e-08. Descriptions of the CNN-RNN approach are generated using the publicly available code and model checkpoint provided by Neuraltalk2 (Karpathy et al., 2016). Captions for online test set evaluations are generated using beam search of size 2, but score histories on split validation set are based on captions generated without beam search (i.e. max sampling at each time-step).

Ablation on Object Locations and Counts:. We setup an experiment where we remove the input locations from the OBJ2TEXT encoder to study the effects on the generated captions, and confirm whether the model is actually using spatial information during surface realization. In this restricted version of our model the LSTM encoder at each time step only takes the object category embedding vector as input. The OBJ2TEXT model additionally encodes different instances of the same object category in different time steps, potentially encoding in some of its hidden states information about how many objects of a particular class are in the image. For example, in the object annotation presented in the input in Figure 1, there are two instances of “person”. We perform an additional experiment where our model does not have access neither to object locations, nor the number of object instances by providing only a set of object categories. Note that in this set of experiments the object layouts are given as inputs, thus we assume full access to ground-truth object annotations, even in the test split. In the experimental results section we use the “-GT” postfix to indicate that input object layouts are obtained from ground-truth object annotations provided by the MS-COCO dataset.

Image Captioning Experiment: In this experiment we assess whether the image captioning model OBJ2TEXT-YOLO that only relies on object categories and locations could give comparable performance with a CNN-RNN model based on Neuraltalk2 (Karpathy et al., 2016) that has full access to visual image features. We also explore how much does a combined OBJ2TEXT-YOLO + CNN-RNN model could improve over a CNN-RNN model by fusing object counts and location information that is not explicitly encoded in a traditional CNN-RNN approach.

Human Evaluation Protocol. We use a two-alternative forced-choice evaluation (2AFC) approach to compare two methods that generate captions. For this, we setup a task on Amazon Mechanical Turk where users are presented with an image and two alternative captions, and they have to choose the caption that best describes the image. Users are not prompted to use any single criteria but rather a holistic assessment of the captions, including their semantics, syntax, and the degree to which they describe the image content. In our experiment we randomly sample 500 captions generated by various models for MS COCO online test set images, and use three users per image to obtain annotations. Note that three users choosing randomly between two options have a chance of 25% to select the same caption for a given image. In our experiments comparing method A vs method B, we report the percentage of times A was picked over B (Choice-all), the percentage of times all users selected the same method, either A or B, (Agreement), and the percentage of times A was picked over B only for these cases where all users agreed (Choice-agreement).

6 Results

Impact of Object Locations and Counts: Figure 3a shows the CIDEr (Vedantam et al., 2015a), and BLEU-4 (Papineni et al., 2002) score history on our validation set during 400k iterations of training of OBJ2TEXT, as well as a version of our model that does not use object locations, and a version of our model that does not use neither object locations nor object counts. These results show that our model is effectively using both object locations and counts to generate better captions, and absence of any one of these two cues affects performance. Table 1 confirms these results on the test split after a full round of training.

Furthermore, human evaluation results in the first row of Table 2 show that the OBJ2TEXT model with access to object locations is preferred by users, especially in cases where all evaluators agreed on their choice (62% over the baseline that does not have access to locations). In Figure 4 we additionally present qualitative examples showing predictions side-by-side between OBJ2TEXT-GT and OBJ2TEXT-GT (no obj-locations). These results indicate that 1) perhaps not surprisingly, object counts is useful for generating better quality descriptions, and 2) object location information when properly encoded, is an important cue for generating more accurate descriptions. We additionally implemented a nearest neighbor baseline by representing the objects in the input layout using an orderless bag-of-words representation of object counts and the CIDEr score on the test split was only 0.387.

On top of OBJ2TEXT we additionally experimented with the global attention model proposed in (Luong et al., 2015) so that a weighted combination of the encoder hidden states are forwarded to the decoding neural language model, however we did not notice any overall gains in terms of accuracy from this formulation. We observed that this model provided gains only for larger input sequences where it is more likely that the LSTM network forgets its past history (Bahdanau et al., 2015). However in MS-COCO the average number of objects in each image is rather modest, so the last hidden state can capture well the overall nuances of the visual input.

Object Layout Encoding for Image Captioning: Figure 3b shows the CIDEr, and BLEU-4 score history on the validation set during 400k iterations of training of OBJ2TEXT-YOLO, CNN-RNN, and their combination. These results show that OBJ2TEXT-YOLO performs surprisingly close to CNN-RNN, and the model resulting from combining the two, clearly outperforms each method alone. Table 3 shows MS-COCO evaluation results on the test set using their online benchmark service, and confirms results obtained in the validation split, where CNN-RNN seems to have only a slight edge over OBJ2TEXT-YOLO which lacks access to pixel data after the object detection stage. Human evaluation results in Table 2 rows 2, and 3, further confirm these findings. These results show that meaningful descriptions could be generated solely based on object categories and locations information, even without access to color and texture input.

The combined model performs better than the two models, improving the CIDEr score of the basic CNN-RNN model from 0.863 to 0.950, and human evaluation results show that the combined model is preferred over the basic CNN-RNN model for 65.3% of the images for which all evaluators were in agreement about the selected method. These results show that explicitly encoded object counts and location information, which is often overlooked in traditional image captioning approaches, could boost the performance of existing models. Intuitively, object lay-

Method	Bleu_4	CIDEr	METEOR	ROUGE-L
OBJ2TEXT-GT (no obj-locations, counts)	0.21	0.759	0.215	0.464
OBJ2TEXT-GT (no obj-locations)	0.233	0.837	0.222	0.482
OBJ2TEXT-GT	**0.253**	**0.922**	**0.238**	**0.507**

Table 1: Performance of lesioned versions of the proposed model on the MS COCO split test set.

out and visual features are complementary: neural network models for visual feature extraction are trained on a classification task where object-level information such as number of instances and locations are ignored in the objective. Object layouts on the other hand, contain categories and their bounding-boxes but don't have access to rich image features such as image background, object attributes and objects with categories not present in the object detection vocabulary.

Figure 5 provides a three-way comparison of captions generated by the three image captioning models, with preferred captions by human evaluators annotated in bold text. Analysis on actual outputs gives us insights into the benefits of combing object layout information and visual features obtained using a CNN. Our OBJ2TEXT-YOLO model makes many mistakes because of lack of image context information since it only has access to object layout, while CNN-RNN makes many mistakes because the visual recognition model is imperfect at predicting the correct content. The combined model is usually able to generate more accurate and comprehensive descriptions.

In this work we only explored encoding spatial information with object labels, but object labels could be readily augmented with rich semantic features that are more detailed descriptions of objects or image regions. For example, the work of You et al. (2016) and Yao et al. (2016b) showed that visual features trained with semantic concepts (text entities mentioned in captions) instead of object labels is useful for image captioning, although they didn't consider encoding semantic concepts with spatial information. In case of object annotations the MS-COCO dataset only provides object labels and bounding-boxes, but there are other datasets such as Flick30K Entities (Plummer et al., 2015), and the Visual Genome dataset (Krishna et al., 2017) that provide richer region-to-phrase correspondence annotations. In addition, the fusion of object counts and spatial information with CNN visual features could in principle benefit other vision and language tasks such as visual question answering. We leave these possible extensions as future work.

7 Conclusion

We introduced OBJ2TEXT, a sequence-to-sequence model to generate visual descriptions for object layouts where only categories and locations are specified. Our proposed model

Alternatives	Choice-all	Choice-agreement	Agreement
OBJ2TEXT-GT vs. OBJ2TEXT-GT (no obj-locations)	54.1%	62.1%	40.6%
OBJ2TEXT-YOLO vs. CNN+RNN	45.6%	40.6%	54.7%
OBJ2TEXT-YOLO + CNN-RNN vs. CNN-RNN	58.1%	65.3%	49.5%
OBJ2TEXT-GT vs. HUMAN	23.6%	9.9%	58.8%

Table 2: Human evaluation results using two-alternative forced choice evaluation. Choice-all is percentage the first alternative was chosen. Choice-agreement is percentage the first alternative was chosen only when all annotators agreed. Agreement is percentage where all annotators agreed (random is 25%).

MS COCO Test Set Performance	CIDEr	ROUGE-L	METEOR	B-4	B-3	B-2	B-1

shows that an orderless visual input representation of concepts is not enough to produce good descriptions, but object extents, locations, and object counts, all contribute to generate more accurate image descriptions. Crucially we show that our encoding mechanism is able to capture useful spatial information using an LSTM network to produce image descriptions, even when the input is provided as a sequence rather than as an explicit 2D representation of objects. Additionally, using our proposed OBJ2TEXT model in combination with an existing image captioning model and a robust object detector we showed improved results in the task of image captioning.

Abstract

We introduce the first end-to-end coreference resolution model and show that it significantly outperforms all previous work without using a syntactic parser or hand-engineered mention detector. The key idea is to directly consider all spans in a document as potential mentions and learn distributions over possible antecedents for each. The model computes span embeddings that combine context-dependent boundary representations with a head-finding attention mechanism. It is trained to maximize the marginal likelihood of gold antecedent spans from coreference clusters and is factored to enable aggressive pruning of potential mentions. Experiments demonstrate state-of-the-art performance, with a gain of 1.5 F1 on the OntoNotes benchmark and by 3.1 F1 using a 5-model ensemble, despite the fact that this is the first approach to be successfully trained with no external resources.

1 Introduction

We present the first state-of-the-art coreference resolution model that is learned end-to-end given only gold mention clusters. All recent coreference models, including neural approaches that achieved impressive performance gains (Wiseman et al., 2016; Clark and Manning, 2016b,a), rely on syntactic parsers, both for head-word features and as the input to carefully hand-engineered mention proposal algorithms. We demonstrate for the first time that these resources are not required, and in fact performance can be improved significantly without them, by training an end-to-end neural model that jointly learns which spans are entity mentions and how to best cluster them.

Our model reasons over the space of all spans up to a maximum length and directly optimizes the marginal likelihood of antecedent spans from gold coreference clusters. It includes a *span*-ranking model that decides, for each span, which of the previous spans (if any) is a good antecedent. At the core of our model are vector embeddings representing spans of text in the document, which combine context-dependent boundary representations with a head-finding attention mechanism over the span. The attention component is inspired by parser-derived head-word matching features from previous systems (Durrett and Klein, 2013), but is less susceptible to cascading errors. In our analyses, we show empirically that these learned attention weights correlate strongly with traditional headedness definitions.

Scoring all span pairs in our end-to-end model is impractical, since the complexity would be quartic in the document length. Therefore we factor the model over unary mention scores and pairwise antecedent scores, both of which are simple functions of the learned span embedding. The unary mention scores are used to prune the space of spans and antecedents, to aggressively reduce the number of pairwise computations.

Our final approach outperforms existing models by 1.5 F1 on the OntoNotes benchmark and by 3.1 F1 using a 5-model ensemble. It is not only accurate, but also relatively interpretable. The model factors, for example, directly indicate whether an absent coreference link is due to low mention scores (for either span) or a low score from the mention ranking component. The head-finding attention mechanism also reveals which mention-internal words contribute most to coreference decisions. We leverage this overall interpretability to do detailed quantitative and qualitative analyses, providing insights into the strengths and weaknesses of the approach.

2 Related Work

Machine learning methods have a long history in coreference resolution (see Ng (2010) for a detailed survey). However, the learning problem is challenging and, until very recently, hand-engineered systems built on top of automatically produced parse trees (Raghunathan et al., 2010) outperformed all learning approaches. Durrett and Klein (2013) showed that highly lexical learning approaches reverse this trend, and more recent neural models (Wiseman et al., 2016; Clark and Manning, 2016b,a) have achieved significant performance gains. However, all of these models still use parsers for head features and include highly engineered mention proposal algorithms.[1] Such pipelined systems suffer from two major drawbacks: (1) parsing mistakes can introduce cascading errors and (2) many of the hand-engineered rules do not generalize to new languages or domains. We present the first non-pipelined results, while providing further performance gains.

More generally, a wide variety of approaches for learning coreference models have been proposed. They can typically be categorized as (1) mention-pair classifiers (Ng and Cardie, 2002; Bengtson and Roth, 2008), (2) entity-level models (Haghighi and Klein, 2010; Clark and Manning, 2015, 2016b; Wiseman et al., 2016), (3) latent-tree models (Fernandes et al., 2012; Björkelund and Kuhn, 2014; Martschat and Strube, 2015), or (4) mention-ranking models (Durrett and Klein, 2013; Wiseman et al., 2015; Clark and Manning, 2016a). Our span-ranking approach is most similar to mention ranking, but we reason over a larger space by jointly detecting mentions and predicting coreference.

3 Task

We formulate the task of end-to-end coreference resolution as a set of decisions for every possible span in the document. The input is a document D containing T words along with metadata such as speaker and genre information.

Let $N = \frac{T(T+1)}{2}$ be the number of possible text spans in D. Denote the start and end indices of a span i in D respectively by START(i) and END(i), for $1 \leq i \leq N$. We assume an ordering of the spans based on START(i); spans with the same start index are ordered by END(i).

The task is to assign to each span i an antecedent y_i. The set of possible assignments for each y_i is $\mathcal{Y}(i) = \{\epsilon, 1, \ldots, i-1\}$, a dummy antecedent ϵ and all preceding spans. True antecedents of span i, i.e. span j such that $1 \leq j \leq i-1$, represent coreference links between i and j. The dummy antecedent ϵ represents two possible scenarios: (1) the span is not an entity mention or (2) the span is an entity mention but it is not coreferent with any previous span. These decisions implicitly define a final clustering, which can be recovered by grouping all spans that are connected by a set of antecedent predictions.

4 Model

We aim to learn a conditional probability distribution $P(y_1, \ldots, y_N \mid D)$ whose most likely configuration produces the correct clustering. We use a product of multinomials for each span:

$$\begin{aligned} P(y_1, \ldots, y_N \mid D) &= \prod_{i=1}^{N} P(y_i \mid D) \\ &= \prod_{i=1}^{N} \frac{\exp(s(i, y_i))}{\sum_{y' \in \mathcal{Y}(i)} \exp(s(i, y'))} \end{aligned}$$

where $s(i, j)$ is a pairwise score for a coreference link between span i and span j in document D. We omit the document D from the notation when the context is unambiguous. There are three factors for this pairwise coreference score: (1) whether span i is a mention, (2) whether span j is a mention, and (3) whether j is an antecedent of i:

$$s(i,j) = \begin{cases} 0 & j = \epsilon \\ s_{\mathrm{m}}(i) + s_{\mathrm{m}}(j) + s_{\mathrm{a}}(i,j) & j \neq \epsilon \end{cases}$$

Here $s_{\mathrm{m}}(i)$ is a unary score for span i being a mention, and $s_{\mathrm{a}}(i,j)$ is pairwise score for span j being an antecedent of span i.

By fixing the score of the dummy antecedent ϵ to 0, the model predicts the best scoring antecedent if any non-dummy scores are positive, and it abstains if they are all negative.

A challenging aspect of this model is that its size is $\mathcal{O}(T^4)$ in the document length. As we will see in Section 5, the above factoring enables aggressive pruning of spans that are unlikely to belong to a coreference cluster according the mention score $s_{\mathrm{m}}(i)$.

[1] For example, Raghunathan et al. (2010) use rules to remove pleonastic mentions of *it* detected by 12 lexicalized regular expressions over English parse trees.

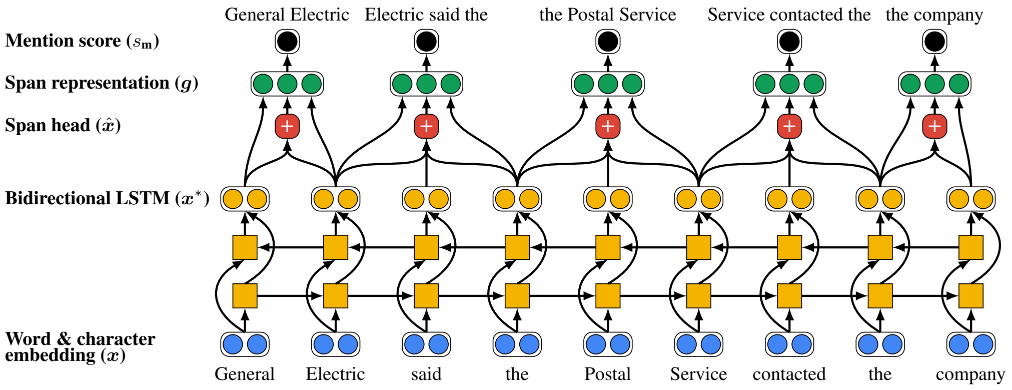

Figure 1: First step of the end-to-end coreference resolution model, which computes embedding representations of spans for scoring potential entity mentions. Low-scoring spans are pruned, so that only a manageable number of spans is considered for coreference decisions. In general, the model considers all possible spans up to a maximum width, but we depict here only a small subset.

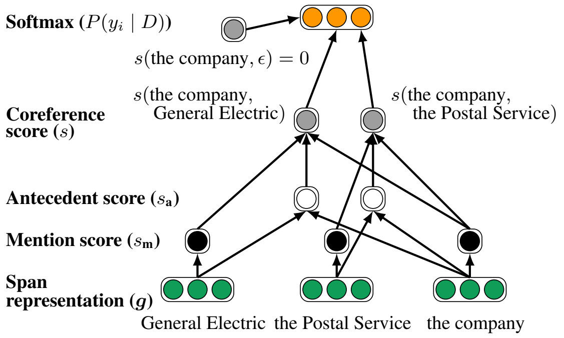

Softmax ($P(y_i \mid D)$)

the Postal Service
the company

Figure 2: Second step of our model. Antecedent scores are computed from pairs of span representations. The final coreference score of a pair of spans is computed by summing the mention scores of both spans and their pairwise antecedent score.

Scoring Architecture We propose an end-to-end neural architecture that computes the above scores given the document and its metadata.

At the core of the model are vector representations $\boldsymbol{g}_i$ for each possible span i, which we describe in detail in the following section. Given these span representations, the scoring functions above are computed via standard feed-forward neural networks:

$$s_\mathrm{m}(i) = \boldsymbol{w}_\mathrm{m} \cdot \mathrm{FFNN}_\mathrm{m}(\boldsymbol{g}_i)$$
$$s_\mathrm{a}(i,j) = \boldsymbol{w}_\mathrm{a} \cdot \mathrm{FFNN}_\mathrm{a}([\boldsymbol{g}_i, \boldsymbol{g}_j, \boldsymbol{g}_i \circ \boldsymbol{g}_j, \phi(i,j)])$$

where $\cdot$ denotes the dot product, $\circ$ denotes element-wise multiplication, and FFNN denotes a feed-forward neural network that computes a non-linear mapping from input to output vectors.

The antecedent scoring function $s_\mathrm{a}(i,j)$ includes explicit element-wise similarity of each span $\boldsymbol{g}_i \circ \boldsymbol{g}_j$ and a feature vector $\phi(i,j)$ encoding speaker and genre information from the metadata and the distance between the two spans.

Span Representations Two types of information are crucial to accurately predicting coreference links: the context surrounding the mention span and the internal structure within the span. We use a bidirectional LSTM (Hochreiter and Schmidhuber, 1997) to encode the lexical information of both the inside and outside of each span. We also include an attention mechanism over words in each span to model head words.

We assume vector representations of each word $\{\boldsymbol{x}_1, \ldots, \boldsymbol{x}_T\}$, which are composed of fixed pretrained word embeddings and 1-dimensional convolution neural networks (CNN) over characters (see Section 7.1 for details)

To compute vector representations of each span, we first use bidirectional LSTMs to encode every word in its context:

$$\begin{aligned}
\boldsymbol{f}_{t,\delta} &= \sigma(\mathbf{W}_\mathrm{f}[\boldsymbol{x}_t, \boldsymbol{h}_{t+\delta,\delta}] + \boldsymbol{b}_\mathrm{i}) \\
\boldsymbol{o}_{t,\delta} &= \sigma(\mathbf{W}_\mathrm{o}[\boldsymbol{x}_t, \boldsymbol{h}_{t+\delta,\delta}] + \boldsymbol{b}_\mathrm{o}) \\
\widetilde{\boldsymbol{c}}_{t,\delta} &= \tanh(\mathbf{W}_\mathrm{c}[\boldsymbol{x}_t, \boldsymbol{h}_{t+\delta,\delta}] + \boldsymbol{b}_\mathrm{c}) \\
\boldsymbol{c}_{t,\delta} &= \boldsymbol{f}_{t,\delta} \circ \widetilde{\boldsymbol{c}}_{t,\delta} + (\mathbf{1} - \boldsymbol{f}_{t,\delta}) \circ \boldsymbol{c}_{t+\delta,\delta} \\
\boldsymbol{h}_{t,\delta} &= \boldsymbol{o}_{t,\delta} \circ \tanh(\boldsymbol{c}_{t,\delta}) \\
\boldsymbol{x}^*_t &= [\boldsymbol{h}_{t,1}, \boldsymbol{h}_{t,-1}]
\end{aligned}$$

where $\delta \in \{-1, 1\}$ indicates the directionality of each LSTM, and $\boldsymbol{x}^*_t$ is the concatenated output of the bidirectional LSTM. We use independent LSTMs for every sentence, since cross-sentence context was not helpful in our experiments.

Syntactic heads are typically included as features in previous systems (Durrett and Klein, 2013; Clark and Manning, 2016b,a). Instead of relying on syntactic parses, our model learns a task-specific notion of headedness using an attention mechanism (Bahdanau et al., 2014) over words in each span:

$$\alpha_t = \boldsymbol{w}_\alpha \cdot \text{FFNN}_\alpha(\boldsymbol{x}^*_t)$$

$$a_{i,t} = \frac{\exp(\alpha_t)}{\sum\limits_{k=\text{START}(i)}^{\text{END}(i)} \exp(\alpha_k)}$$

$$\hat{\boldsymbol{x}}_i = \sum_{t=\text{START}(i)}^{\text{END}(i)} a_{i,t} \cdot \boldsymbol{x}_t$$

where $\hat{\boldsymbol{x}}_i$ is a weighted sum of word vectors in span i. The weights $a_{i,t}$ are automatically learned and correlate strongly with traditional definitions of head words as we will see in Section 9.2.

The above span information is concatenated to produce the final representation $\boldsymbol{g}_i$ of span i:

$$\boldsymbol{g}_i = [\boldsymbol{x}^*_{\text{START}(i)}, \boldsymbol{x}^*_{\text{END}(i)}, \hat{\boldsymbol{x}}_i, \phi(i)]$$

This generalizes the recurrent span representations recently proposed for question-answering (Lee et al., 2016), which only include the boundary representations $\boldsymbol{x}^*_{\text{START}(i)}$ and $\boldsymbol{x}^*_{\text{END}(i)}$. We introduce the soft head word vector $\hat{\boldsymbol{x}}_i$ and a feature vector $\phi(i)$ encoding the size of span i.

5 Inference

The size of the full model described above is $O(T^4)$ in the document length T. To maintain computation efficiency, we prune the candidate spans greedily during both training and evaluation.

We only consider spans with up to L words and compute their unary mention scores $s_\text{m}(i)$ (as defined in Section 4). To further reduce the number of spans to consider, we only keep up to λT spans with the highest mention scores and consider only up to K antecedents for each. We also enforce non-crossing bracketing structures with a simple suppression scheme.[2] We accept spans in decreasing order of the mention scores, unless, when considering span i, there exists a previously accepted span j such that $\text{START}(i) < \text{START}(j) \leq \text{END}(i) < \text{END}(j) \lor \text{START}(j) < \text{START}(i) \leq \text{END}(j) < \text{END}(i)$.

Despite these aggressive pruning strategies, we maintain a high recall of gold mentions in our experiments (over 92% when $\lambda = 0.4$).

For the remaining mentions, the joint distribution of antecedents for each document is computed in a forward pass over a single computation graph. The final prediction is the clustering produced by the most likely configuration.

6 Learning

In the training data, only clustering information is observed. Since the antecedents are latent, we optimize the marginal log-likelihood of all correct antecedents implied by the gold clustering:

$$\log \prod_{i=1}^{N} \sum_{\hat{y} \in \mathcal{Y}(i) \cap \text{GOLD}(i)} P(\hat{y})$$

where $\text{GOLD}(i)$ is the set of spans in the gold cluster containing span i. If span i does not belong to a gold cluster or all gold antecedents have been pruned, $\text{GOLD}(i) = \{\epsilon\}$.

By optimizing this objective, the model naturally learns to prune spans accurately. While the initial pruning is completely random, only gold mentions receive positive updates. The model can quickly leverage this learning signal for appropriate credit assignment to the different factors, such as the mention scores s_m used for pruning.

Fixing score of the dummy antecedent to zero removes a spurious degree of freedom in the overall model with respect to mention detection. It also prevents the span pruning from introducing noise. For example, consider the case where span i has a single gold antecedent that was pruned, so $\text{GOLD}(i) = \{\epsilon\}$. The learning objective will only correctly push the scores of non-gold antecedents lower, and it cannot incorrectly push the score of the dummy antecedent higher.

This learning objective can be considered a span-level, cost-insensitive analog of the learning objective proposed by Durrett and Klein (2013). We experimented with these cost-sensitive alternatives, including margin-based variants (Wiseman et al., 2015; Clark and Manning, 2016a), but a simple maximum-likelihood objective proved to be most effective.

[2] The official CoNLL-2012 evaluation only considers predictions without crossing mentions to be valid. Enforcing this consistency is not inherently necessary in our model.

Table 1: Results on the test set on the English data from the CoNLL-2012 shared task. The final column (Avg. F1) is the main evaluation metric, computed by averaging the F1 of MUC, B^3, and $CEAF_{\phi_4}$. We improve state-of-the-art performance by 1.5 F1 for the single model and by 3.1 F1.

7 Experiments

We use the English coreference resolution data from the CoNLL-2012 shared task (Pradhan et al., 2012) in our experiments. This dataset contains 2802 training documents, 343 development documents, and 348 test documents. The training documents contain on average 454 words and a maximum of 4009 words.

7.1 Hyperparameters

Word representations The word embeddings are a fixed concatenation of 300-dimensional GloVe embeddings (Pennington et al., 2014) and 50-dimensional embeddings from Turian et al. (2010), both normalized to be unit vectors. Out-of-vocabulary words are represented by a vector of zeros. In the character CNN, characters are represented as learned 8-dimensional embeddings. The convolutions have window sizes of 3, 4, and 5 characters, each consisting of 50 filters.

Hidden dimensions The hidden states in the LSTMs have 200 dimensions. Each feed-forward neural network consists of two hidden layers with 150 dimensions and rectified linear units (Nair and Hinton, 2010).

Feature encoding We encode speaker information as a binary feature indicating whether a pair of spans are from the same speaker. Following Clark and Manning (2016b), the distance features are binned into the following buckets [1, 2, 3, 4, 5-7, 8-15, 16-31, 32-63, 64+]. All features (speaker, genre, span distance, mention width) are represented as learned 20-dimensional embeddings.

Pruning We prune the spans such that the maximum span width $L = 10$, the number of spans per word $\lambda = 0.4$, and the maximum number of antecedents $K = 250$. During training, documents are randomly truncated to up to 50 sentences.

Learning We use ADAM (Kingma and Ba, 2014) for learning with a minibatch size of 1. The LSTM weights are initialized with random orthonormal matrices as described in Saxe et al. (2013). We apply 0.5 dropout to the word embeddings and character CNN outputs. We apply 0.2 dropout to all hidden layers and feature embeddings. Dropout masks are shared across timesteps to preserve long-distance information as described in Gal and Ghahramani (2016). The learning rate is decayed by 0.1% every 100 steps. The model is trained for up to 150 epochs, with early stopping based on the development set.

All code is implemented in TensorFlow (Abadi et al., 2015) and is publicly available. [3]

7.2 Ensembling

We also report ensemble experiments using five models trained with different random initializations. Ensembling is performed for both the span pruning and antecedent decisions.

At test time, we first average the mention scores $s_{\mathrm{m}}(i)$ over each model before pruning the spans.

[3] https://github.com/kentonl/e2e-coref

	Avg. F1	Δ
Our model (ensemble)	69.0	+1.3
Our model (single)	67.7	
– distance and width features	63.9	-3.8
– GloVe embeddings	65.3	-2.4
– speaker and genre metadata	66.3	-1.4
– head-finding attention	66.4	-1.3
– character CNN	66.8	-0.9
– Turian embeddings	66.9	-0.8

Table 2: Comparisons of our single model on the development data. The 5-model ensemble provides a 1.3 F1 improvement. The head-finding attention, features, and all word representations contribute significantly to the full model.

Given the same pruned spans, each model then computes the antecedent scores $s_a(i, j)$ separately, and they are averaged to produce the final scores.

8 Results

We report the precision, recall, and F1 for the standard MUC, B^3, and CEAF$_{\phi_4}$metrics using the official CoNLL-2012 evaluation scripts. The main evaluation is the average F1 of the three metrics.

8.1 Coreference Results

Table 1 compares our model to several previous systems that have driven substantial improvements over the past several years on the OntoNotes benchmark. We outperform previous systems in all metrics. In particular, our single model improves the state-of-the-art average F1 by 1.5, and our 5-model ensemble improves it by 3.1.

The most significant gains come from improvements in recall, which is likely due to our end-to-end setup. During training, pipelined systems typically discard any mentions that the mention detector misses, which for Clark and Manning (2016a) consists of more than 9% of the labeled mentions in the training data. In contrast, we only discard mentions that exceed our maximum mention width of 10, which accounts for less than 2% of the training mentions. The contribution of joint mention scoring is further discussed in Section 8.3

8.2 Ablations

To show the importance of each component in our proposed model, we ablate various parts of the architecture and report the average F1 on the development set of the data (see Figure 2).

	Avg. F1	Δ
Our model (joint mention scoring)	67.7	
w/ rule-based mentions	66.7	-1.0
w/ oracle mentions	85.2	+17.5

Table 3: Comparisons of of various mention proposal methods with our model on the development data. The rule-based mentions are derived from the mention detector from Raghunathan et al. (2010), resulting in a 1 F1 drop in performance. The oracle mentions are from the labeled clusters and improve our model by over 17.5 F1.

Features The distance between spans and the width of spans are crucial signals for coreference resolution, consistent with previous findings from other coreference models. They contribute 3.8 F1 to the final result.

Word representations Since our word embeddings are fixed, having access to a variety of word embeddings allows for a more expressive model without overfitting. We hypothesis that the different learning objectives of the GloVe and Turian embeddings provide orthogonal information (the former is word-order insensitive while the latter is word-order sensitive). Both embeddings contribute to some improvement in development F1.

The character CNN provides morphological information and a way to backoff for out-of-vocabulary words. Since coreference decisions often involve rare named entities, we see a contribution of 0.9 F1 from character-level modeling.

Metadata Speaker and genre indicators many not be available in downstream applications. We show that performance degrades by 1.4 F1 without them, but is still on par with previous state-of-the-art systems that assume access to this metadata.

Head-finding attention Ablations also show a 1.3 F1 degradation in performance without the attention mechanism for finding task-specific heads. As we will see in Section 9.4, the attention mechanism should not be viewed as simply an approximation of syntactic heads. In many cases, it is beneficial to pay attention to multiple words that are useful specifically for coreference but are not traditionally considered to be syntactic heads.

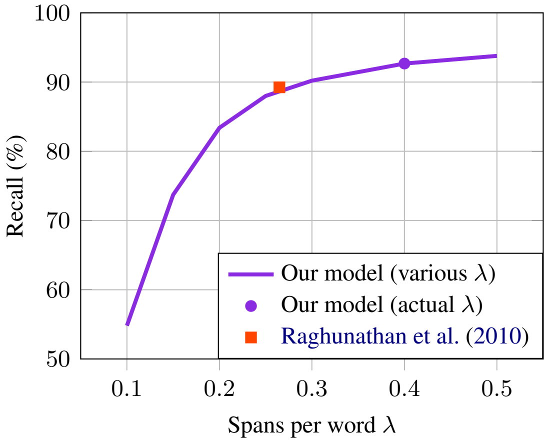

Figure 3: Proportion of gold mentions covered in the development data as we increase the number of spans kept per word. Recall is comparable to the mention detector of previous state-of-the-art systems given the same number of spans. Our model keeps 0.4 spans per word in our experiments, achieving 92.7% recall of gold mentions.

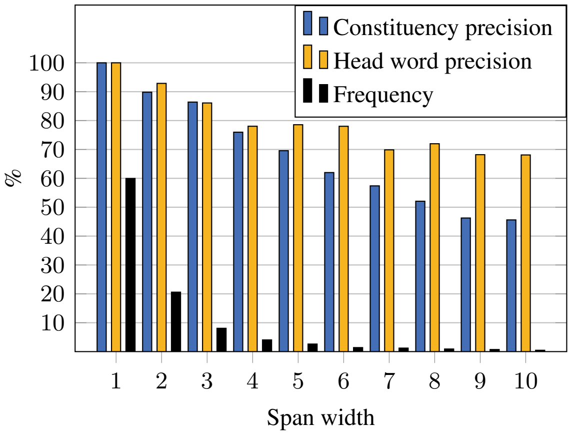

Figure 4: Indirect measure of mention precision using agreement with gold syntax. Constituency precision: % of unpruned spans matching syntactic constituents. Head word precision: % of unpruned constituents whose syntactic head word matches the most attended word. Frequency: % of gold spans with each width.

8.3 Comparing Span Pruning Strategies

To tease apart the contributions of improved mention scoring and improved coreference decisions, we compare the results of our model with alternate span pruning strategies. In these experiments, we use the alternate spans for both training and evaluation. As shown in Table 3, keeping mention candidates detected by the rule-based system over predicted parse trees (Raghunathan et al., 2010) degrades performance by 1 F1. We also provide oracle experiment results, where we keep exactly the mentions that are present in gold coreference clusters. With oracle mentions, we see an improvement of 17.5 F1, suggesting an enormous room for improvement if our model can produce better mention scores and anaphoricity decisions.

9 Analysis

To highlight the strengths and weaknesses of our model, we provide both quantitative and qualitative analyses. In the following discussion, we use predictions from the single model rather than the ensembled model.

9.1 Mention Recall

The training data only provides a weak signal for spans that correspond to entity mentions, since singleton clusters are not explicitly labeled. As a by product of optimizing marginal likelihood, our model automatically learns a useful ranking of spans via the unary mention scores from Section 4.

The top spans, according to the mention scores, cover a large portion of the mentions in gold clusters, as shown in Figure 3. Given a similar number of spans kept, our recall is comparable to the rule-based mention detector (Raghunathan et al., 2010) that produces 0.26 spans per word with a recall of 89.2%. As we increase the number of spans per word (λ in Section 5), we observe higher recall but with diminishing returns. In our experiments, keeping 0.4 spans per word results in 92.7% recall in the development data.

9.2 Mention Precision

While the training data does not offer a direct measure of mention precision, we can use the gold syntactic structures provided in the data as a proxy. Spans with high mention scores should correspond to syntactic constituents.

In Figure 4, we show the precision of top-scoring spans when keeping 0.4 spans per word. For spans with 2–5 words, 75–90% of the predictions are constituents, indicating that the vast majority of the mentions are syntactically plausible. Longer spans, which are all relatively rare, prove more difficult for the model, and precision drops to 46% for spans with 10 words.

1	**(A fire in a Bangladeshi garment factory)** has left at least 37 people dead and 100 hospitalized. Most of the deceased were killed in the crush as workers tried to flee **(the blaze)** in the four-story building.
	A fire in **(a Bangladeshi garment factory)** has left at least 37 people dead and 100 hospitalized. Most of the deceased were killed in the crush as workers tried to flee the blaze in **(the four-story building)**.
2	We are looking for **(a region of central Italy bordering the Adriatic Sea)**. **(The area)** is mostly mountainous and includes Mt. Corno, the highest peak of the Apennines. **(It)** also includes a lot of sheep, good clean-living, healthy sheep, and an Italian entrepreneur has an idea about how to make a little money of them.
3	**(The flight attendants)** have until 6:00 today to ratify labor concessions. **(The pilots')** union and ground crew did so yesterday.
4	**(Prince Charles and his new wife Camilla)** have jumped across the pond and are touring the United States making **(their)** first stop today in New York. It's Charles' first opportunity to showcase his new wife, but few Americans seem to care. Here's Jeanie Mowth. What a difference two decades make. **(Charles and Diana)** visited a JC Penney's on the prince's last official US tour. Twenty years later here's the prince with his new wife.
5	Also such location devices, **(some ships)** have smoke floats **(they)** can toss out so the man overboard will be able to use smoke signals as a way of trying to, let the rescuer locate **(them)**.

Table 4: Examples predictions from the development data. Each row depicts a single coreference cluster predicted by our model. Bold, parenthesized spans indicate mentions in the predicted cluster. The redness of each word indicates the weight of the head-finding attention mechanism ($a_{i,t}$ in Section 4).

9.3 Head Agreement

We also investigate how well the learned head preferences correlate with syntactic heads. For each of the top-scoring spans in the development data that correspond to gold constituents, we compute the word with the highest attention weight.

We plot in Figure 4 the proportion of these words that match syntactic heads. Agreement ranges between 68-93%, which is surprisingly high, since no explicit supervision of syntactic heads is provided. The model simply learns from the clustering data that these head words are useful for making coreference decisions.

9.4 Qualitative Analysis

Our qualitative analysis in Table 4 highlights the strengths and weaknesses of our model. Each row is a visualization of a single coreference cluster predicted by the model. Bolded spans in parentheses belong to the predicted cluster, and the redness of a word indicates its weight from the head-finding attention mechanism ($a_{i,t}$ in Section 4).

Strengths The effectiveness of the attention mechanism for making coreference decisions can be seen in Example 1. The model pays attention to *fire* in the span *A fire in a Bangladeshi garment factory*, allowing it to successfully predict the coreference link with *the blaze*. For a subspan of that mention, *a Bangladeshi garment factory*, the model pays most attention instead to *factory*, allowing it successfully predict the coreference link with *the four-story building*.

The task-specific nature of the attention mechanism is also illustrated in Example 4. The model generally pays attention to coordinators more than the content of the coordination, since coordinators, such as *and*, provide strong cues for plurality.

The model is capable of detecting relatively long and complex noun phrases, such as *a region of central Italy bordering the Adriatic Sea* in Example 2. It also appropriately pays attention to *region*, showing that the attention mechanism provides more than content-word classification. The context encoding provided by the bidirectional LSTMs is critical to making informative head word decisions.

Weaknesses A benefit of using neural models for coreference resolution is their ability to use word embeddings to capture similarity between words, a property that many traditional feature-based models lack. While this can dramatically increase recall, as demonstrated in Example 1, it is also prone to predicting false positive links when the model conflates paraphrasing with relatedness or similarity. In Example 3, the model mistakenly predicts a link between *The flight attendants* and *The pilots'*. The predicted head words *attendants* and *pilots* likely have nearby word embeddings, which is a signal used—and often overused—by the model. The same type of error is made in Example 4, where the model predicts a coreference link between *Prince Charles and his new wife Camilla* and *Charles and Diana*, two non-coreferent mentions that are similar in many ways. These mistakes suggest substantial room for improvement with word or span representations that can cleanly distinguish between equivalence, entailment, and alternation.

Unsurprisingly, our model does little in the uphill battle of making coreference decisions requiring world knowledge. In Example 5, the model incorrectly decides that *them* (in the context of *let the rescuer locate them*) is coreferent with *some ships*, likely due to plurality cues. However, an ideal model that uses common-sense reasoning would instead correctly infer that a rescuer is more likely to look for *the man overboard* rather than the ship from which he fell. This type of reasoning would require either (1) models that integrate external sources of knowledge with more complex inference or (2) a vastly larger corpus of training data to overcome the sparsity of these patterns.

10 Conclusion

We presented a state-of-the-art coreference resolution model that is trained end-to-end for the first time. Our final model ensemble improves performance on the OntoNotes benchmark by over 3 F1 without external preprocessing tools used by previous systems. We showed that our model implicitly learns to generate useful mention candidates from the space of all possible spans. A novel head-finding attention mechanism also learns a task-specific preference for head words, which we empirically showed correlate strongly with traditional head-word definitions.

While our model substantially pushes the state-of-the-art performance, the improvements are potentially complementary to a large body of work on various strategies to improve coreference resolution, including entity-level inference and incorporating world knowledge, which are important avenues for future work.

Neural Net Models of Open-domain Discourse Coherence

Jiwei Li and Dan Jurafsky
Computer Science Department
Stanford University, Stanford, USA
jiweil,jurafsky@stanford.edu

Abstract

Discourse coherence is strongly associated with text quality, making it important to natural language generation and understanding. Yet existing models of coherence focus on measuring individual aspects of coherence (lexical overlap, rhetorical structure, entity centering) in narrow domains.

In this paper, we describe domain-independent neural models of discourse coherence that are capable of measuring multiple aspects of coherence in existing sentences and can maintain coherence while generating new sentences. We study both discriminative models that learn to distinguish coherent from incoherent discourse, and generative models that produce coherent text, including a novel neural latent-variable Markovian generative model that captures the latent discourse dependencies between sentences in a text.

Our work achieves state-of-the-art performance on multiple coherence evaluations, and marks an initial step in generating coherent texts given discourse contexts.

1 Introduction

Modeling discourse coherence (the way parts of a text are linked into a coherent whole) is essential for summarization (Barzilay and McKeown, 2005), text planning (Hovy, 1988; Marcu, 1997) question-answering (Verberne et al., 2007), and even psychiatric diagnosis (Elvevåg et al., 2007; Bedi et al., 2015).

Various frameworks exist, each tackling aspects of coherence. Lexical cohesion (Halliday and Hasan, 1976; Morris and Hirst, 1991) models chains of words and synonyms. Psychological models of discourse (Foltz et al., 1998; Foltz, 2007; McNamara et al., 2010) use LSA embeddings to generalize lexical cohesion. Relational models like RST (Mann and Thompson, 1988; Lascarides and Asher, 1991) define relations that hierarchically structure texts. The entity grid model (Barzilay and Lapata, 2008) and its extensions[1] capture the referential coherence of entities moving in and out of focus across a text. Each captures only a single aspect of coherence, and all focus on scoring existing sentences, rather than on generating coherent discourse for tasks like abstractive summarization.

Here we introduce two classes of neural models for discourse coherence. Our discriminative models induce coherence by treating human generated texts as coherent examples and texts with random sentence replacements as negative examples, feeding LSTM sentence embeddings of pairs of consecutive sentences to a classifier. These achieve state-of-the-art (96% accuracy) on the standard domain-specific sentence-pair-ordering dataset (Barzilay and Lapata, 2008), but suffer in a larger open-domain setting due to the small semantic space that negative sampling is able to cover.

Our generative models are based on augmenting encoder-decoder models with latent variables to model discourse relationships across sentences, including (1) a model that incorporates an HMM-LDA topic model into the generative model and (2) an end-to-end model that introduces a Markov-structured neural latent variable, inspired by recent work on training latent-variable recurrent nets (Bowman et al., 2015; Serban et al., 2016b). These generative models obtain the best result on a large open-domain setting, including on the difficult task of reconstructing the order of every sentence in a paragraph, and our latent variable generative model significantly improves the coherence of text generated by the model.

Our work marks an initial step in building end-to-end systems to evaluate open-domain discourse coherence, and more importantly, generating coherent texts given discourse contexts.

[1] Adding coreference (Elsner and Charniak, 2008), named entities (Eisner and Charniak, 2011), discourse relations (Lin et al., 2011) and entity graphs (Guinaudeau and Strube, 2013).

2 The Discriminative Model

The discriminative model treats cliques (sets of sentences surrounding a center sentence) taken from the original articles as coherent positive examples and cliques with random replacements of the center sentence as negative examples. The discriminative model can be viewed as an extended version of Li and Hovy's (2014) model but is practical at large scale[2]. We thus make this section succinct.

Notations Let C denote a sequence of coherent texts taken from original articles generated by humans. C is comprised of a sequence of sentences $C = \{s_{n-L}, ..., s_{n-1}, s_n, s_{n+1}, ..., s_{n+L}\}$ where L denotes the half size of the context window. Suppose each sentence s_n consists of a sequence of words $w_{n1}, ..., w_{nt}, ..., w_{nM}$, where M is the number of tokens in s_n. Each word w is associated with a K dimensional vector h_w and each sentence is associated with a K dimensional vector x_s.

Each C contains $2L + 1$ sentences, and is associated with a $(2L + 1) \times K$ dimensional vector obtained by concatenating the representations of its constituent sentences. The sentence representation is obtained from LSTMs. After word compositions, we use the representation output from the final time step to represent the entire sentence. Another neural network model with a *sigmoid* function on the very top layer is employed to map the concatenation of representations of its constituent sentences to a scalar, indicating the probability of the current clique being a coherent one or an incoherent one.

Weakness Two problems with the discriminative model stand out: First, it relies on negative sampling to generate negative examples. Since the sentence-level semantic space in the open-domain setting is huge, the sampled instances can only cover a tiny proportion of the possible negative candidates, and therefore don't cover the space of possible meanings. As we will show in the experiments section, the discriminative model performs competitively in specific domains, but not in the open domain setting. Secondly and more importantly, discriminative models are only able to tell whether an already-given chunk of text is coherent or not. While they can thus be used in tasks like extractive summarization for sentence re-ordering, they cannot be used for coherent text generation in tasks like dialogue generation or abstractive text summarization.

3 The Generative Model

We therefore introduce three neural generative models of discourse coherence.

3.1 Model 1: the SEQ2SEQ Model and its Variations

In a coherent context, a machine should be able to guess the next utterance given the preceding ones. A straightforward way to do that is to train a SEQ2SEQ model to predict a sentence given its contexts (Sutskever et al., 2014). Generating sentences based on neighboring sentences resembles skip-thought models (Kiros et al., 2015), which build an encoder-decoder model by predicting tokens in neighboring sentences.

As shown in Figure 1a, given two consecutive sentences $[s_i, s_{i+1}]$, one can measure the coherence by the likelihood of generating s_{i+1} given its preceding sentence s_i (denoted by *uni*). This likelihood is scaled by the number of words in s_{i+1} (denoted by N_{i+1}) to avoid favoring short sequences.

$$L(s_i, s_{i+1}) = \frac{1}{N_{i+1}} \log p(s_{i+1}|s_i) \qquad (1)$$

The probability can be directly computed using a pretrained SEQ2SEQ model (Sutskever et al., 2014) or an attention-based model (Bahdanau et al., 2015; Luong et al., 2015).

In a coherent context, a machine should not only be able to guess the next utterance given the preceding ones, but also the preceding one given the following ones. This gives rise to the coherence model (denoted by *bi*) that measures the bidirectional dependency between the two consecutive sentences:

$$\begin{aligned} L(s_i, s_{i+1}) = &\frac{1}{N_i} \log p_B(s_i|s_{i+1}) \\ &+ \log \frac{1}{N_{i+1}} p_F(s_{i+1}|s_i) \end{aligned} \qquad (2)$$

We separately train two models: a forward model $p_F(s_{i+1}|s_i)$ that predicts the next sentence based on the previous one and a backward model $p_B(s_i|s_{i+1})$ that predicts the previous sentence given the next sentence. $p_B(s_i|s_{i+1})$ can be trained in a way similar to $p_F(s_{i+1}|s_i)$ with sources and targets swapped. It is worth noting that p_B and p_F are separate models and do not share parameters.

[2] Li and Hovy's (2014) recursive neural model operates on parse trees, which does not support batched computation and is therefore hard to scale up.

One problem with the described *uni* and *bi* models is that sentences with higher language model probability (e.g., sentences without rare words) also tend to have higher conditional probability given their preceding or succeeding sentences. We are interested in measuring the informational gain from the contexts rather than how fluent the current sentence is. We thus propose eliminating the influence of the language model, which yields the following coherence score:

$$\begin{aligned} L(s_i, s_{i+1}) \\ &= \frac{1}{N_i}[\log p_B(s_i|s_{i+1}) - \log p_L(s_i)] \\ &+ \frac{1}{N_{i+1}}[\log p_B(s_{i+1}|s_i) - \log p_L(s_{i+1})] \end{aligned} \tag{3}$$

where $p_L(s)$ is the language model probability for generating sentence s. We train an LSTM language model, which can be thought of as a SEQ2SEQ model with an empty source. A closer look at Eq. 3 shows that it is of the same form as the mutual information between s_{i+1} and s_i, namely $\log[p(s_{i+1}, s_i)/p(s_{i+1})p(s_i)]$.

Generation The scoring functions in Eqs. 1, 2, and 3 are discriminative, generating coherence scores for an already-given chunk of text. Eqs. 2 and 3 can not be directly used for generation purposes, since they requires the completion of s_{i+1} before the score can be computed. A normal strategy is to generate a big N-best list using Eq. 1 and then rerank the N-best list using Eq. 2 or 3 (Li et al., 2015a). The N-best list can be generated using standard beam search, or other algorithmic variations that promote diversity, coherence, etc. (Shao et al., 2017).

Weakness (1) The SEQ2SEQ model generates words sequentially based on an evolving hidden vector, which is updated by combining the current word representation with previously built hidden vectors. The generation process is thus not exposed to more global features of the discourse like topics. As the hidden vector evolves, the influence from contexts gradually diminishes, with language models quickly dominating. (2) By predicting a sentence conditioning only on its left or right neighbor, the model lacks the ability to handle the longer-term discourse dependencies across the sentences of a text.

To tackle these two issues, we need a model that is able to constantly remind the decoder about the global meaning that it should convey at each word-generation step, a global meaning which can capture the state of the discourse across the sentences of a text. We propose two models of this global meaning, a pipelined approach based on HMM-based topic models (Blei et al., 2003; Gruber et al., 2007), and an end-to-end generative model with variational latent variables.

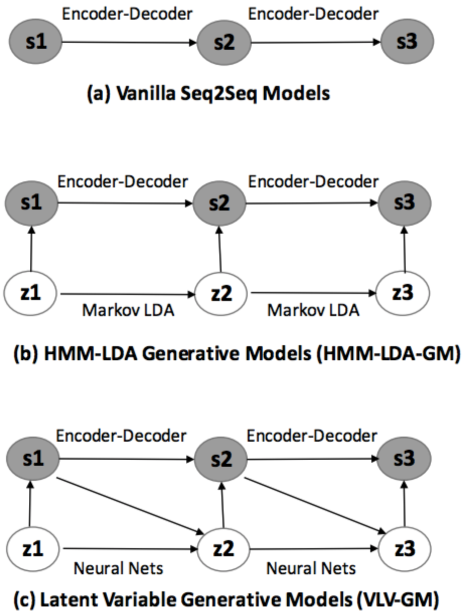

Figure 1: Overview of the proposed generative models for discourse coherence modeling.

3.2 HMM-LDA based Generative Models (HMM-LDA-GM)

In Markov topic models the topic depends on the previous topics in context (Ritter et al., 2010; Paul and Girju, 2010; Wang et al., 2011; Gruber et al., 2007; Paul, 2012). The topic for the current sentence is drawn based on the topic of the preceding sentence (or word) rather than on the global document-level topic distribution in vanilla LDA.

Our first model is a pipelined one (the *HMM-LDA-GM* in Fig. 1b), in which an HMM-LDA model provides the SEQ2SEQ model with global information for token generation, with two components:

(1) **Running HMM-LDA**: we first run a sentence-level HMM-LDA similar to Gruber et al. (2007). Our implementation forces all words in a sentence to be generated from the same topic, and this topic is sampled from a distribution based on the topic from previous sentence. Let t_n denote the distribution of topics for the current sentence, where $t_n \in \mathbb{R}^{1\times T}$. We also associate each LDA

topic with a K dimensional vector, representing the semantics embedded in this topic. The topic-representation matrix is denoted by $V \in \mathbb{R}^{T\times K}$, where T is the pre-specified number of topics in LDA. V is learned in the word predicting process when training encoder-decoder models.

(2) **Training encoder-decoder models**: For the current sentence s_n, given its topic distribution t_n, we first compute the topic representation z_n for s_n using the weighted sum of LDA topic vectors:

$$z_n = t_n \times V \tag{4}$$

z_n can be thought of as a discourse state vector that stores the information the current sentence needs to convey in the discourse, and is used to guide every step of word generation in s_n. We run the encoder-decoder model, which subsequently predicts tokens in s_n given s_{n-1}. This process is the same as the vanilla version of SEQ2SEQ models, the only difference being that z_n is incorporated into each step of decoding for hidden vector updates:

$$p(s_n|z_n, s_{n-1}) = \prod_{t=1}^{M} p(w_t|h_{t-1}, z_n) \tag{5}$$

V is updated along with parameters in the encoder-decoder model.

z_n influences each time step of decoding, and thus addresses the problem that vanilla SEQ2SEQ models gradually lose global information as the hidden representations evolve. z_n is computed based on the topic distribution t_n, which is obtained from the HMM-LDA model, thus modeling the global Markov discourse dependency between sentences of the text.[3] The model can be adapted to the bi-directional setting, in which we separately train two models to handle the forward probability $\log p(t_n|s_{n-1}, ...)$ and the backward one $\log p(t_n|s_{n+1})$. The bi-directional (*bi*) strategy described in Eq. 3 can also be incorporated to remove the influence of language models.

Weakness Topic models (either vanilla or HMM versions) focus on word co-occurrences at the document-level and are thus very lexicon-based. Furthermore, given the diversity of topics in a dataset like Wikipedia but the small number of topic clusters, the LDA model usually produces very coarse-grained topics (politics, sports, history, etc.), assigning very similar topic distributions to consecutive sentences. These topics thus capture topical coherence but are too coarse-grained to capture all the more fine-grained aspects of *discourse* coherence relationships.

3.3 Variational Latent Variable Generative Models (VLV-GM)

We therefore propose instead to train an end-to-end system, in which the meaning transitions between sentences can be naturally learned from the data. Inspired by recent work on generating sentences from a latent space (Serban et al., 2016b; Bowman et al., 2015; Chung et al., 2015), we propose the VSV-GM model in Fig. 1c. Each sentence s_n is again associated with a hidden vector representation $z_n \in \mathbb{R}^K$ which stores the global information that the current sentence needs to talk about, but instead of obtaining z_n from an upstream model like LDA, z_n is learned from the training data. z_n is a stochastic latent variable conditioned on all previous sentences and z_{n-1}:

$$\begin{aligned} &p(z_n|z_{n-1}, s_{n-1}, s_{n-2}, ...) = N(\mu^{\text{true}}_{z_n}, \Sigma^{\text{true}}_{z_n}) \\ &\mu^{\text{true}}_{z_n} = f(z_{n-1}, s_{n-1}, s_{n-2}, ...) \\ &\Sigma^{\text{true}}_{z_n} = g(z_{n-1}, s_{n-1}, s_{n-2}, ...) \end{aligned} \tag{6}$$

where $N(\mu, \Sigma)$ is a multivariate normal distribution with mean $\mu \in \mathbb{R}^K$ and covariance matrix $\Sigma \in \mathbb{R}^{K\times K}$. Σ is a diagonal matrix. As can be seen, the global information z_n for the current sentence depends on the information z_{n-1} for its previous sentence as well as the text of the context sentences. This forms a Markov chain across all sentences. f and g are neural network models that take previous sentences and z_{n-1}, and map them to a real-valued representation using hierarchical LSTMs (Li et al., 2015b)[4].

Each word w_{nt} from s_n is predicted using the concatenation of the representation previously build by the LSTMs (the same vector used in word prediction in vanilla SEQ2SEQ models) and z_n, as shown in Eq.5.

We are interested in the posterior distribution $p(z_n|s_1, s_2, ..., s_{n-1})$, namely, the information that the current sentence needs to convey given the preceding ones. Unfortunately, a highly non-linear mapping from z_n to tokens in s_n results in in-

[3] This pipelined approach is closely related to recent work that incorporates LDA topic information into generation models in an attempt to leverage context information (Ghosh et al., 2016; Xing et al., 2016; Mei et al., 2016)

[4] Sentences are first mapped to vector representations using a LSTM model. Another level of LSTM at the sentence level then composes representations of the multiple sentences to a single vector.

tractable inference of the posterior. A common solution is to use variational inference to learn another distribution, denoted by $q(z_n|s_1, s_2, ..., s_N)$, to approximate the true posterior $p(z_n|s_1, s_2, ..., s_{n-1})$. The model's latent variables are obtained by maximizing the variational lower-bound of observing the dataset:

$$\begin{aligned} & \log p(s_1, .., s_N) \leq \\ & \sum_{t=1}^{N} -D_{KL}(q(z_n|s_n, s_{n-1}, ...)||p(z_n|s_{n-1}, s_{n-2}, ...)) \\ & + E_{q(z_n|s_n, s_{n-1}, ...)} \log p(s_n|z_n, s_{n-1}, s_{n-2}, ...) \end{aligned} \tag{7}$$

This objective to optimize consists of two parts; the first is the KL divergence between the approximate distribution q and the true posterior $p(s_n|z_n, s_{n-1}, s_{n-2}, ...)$, in which we want to approximate the true posterior using q. The second part $E_{q(z_n|s_n, s_{n-1}, ...)} \log p(s_n|z_n, s_{n-1}, s_{n-2}, ...)$, predicts tokens in s_n in the same way as in SEQ2SEQ models with the difference that it considers the global information z_n.

The approximate posterior distribution $q(z_n|s_n, s_{n-1}, ...)$ takes a form similar to $p(z_n|s_{n-1}, s_{n-2}, ...)$:

$$\begin{aligned} & q(z_n|s_n, s_{n-1}, ...) = N(\mu_{z_n}^{\text{approx}}, \Sigma_{z_n}^{\text{approx}}) \\ & \mu_{z_n}^{\text{approx}} = f_q(z_{n-1}, s_n, s_{n-1}, ...) \\ & \Sigma_{z_n}^{\text{approx}} = g_q(z_{n-1}, s_n, s_{n-1}, ...) \end{aligned} \tag{8}$$

f_q and g_q are of similar structures to f and g, using a hierarchical neural network model to map context tokens to vector representations.

Learning and Testing At training time, the approximate posterior $q(z_n|z_{n-1}, s_n, s_{n-1}, ...)$, the true distribution $p(z_n|z_{n-1}, s_{n-1}, s_{n-2}, ...)$, and the generative probability $p(s_n|z_n, s_{n-1}, s_{n-2}, ...)$ are trained jointly by maximizing the variational lower bound with respect to their parameters: a sample z_n is first drawn from the posterior distribution q, namely $N(\mu_{z_n}^{\text{approx}}, \Sigma_{z_n}^{\text{approx}})$. This sample is used to approximate the expectation $E_q \log p(s_n|z_n, s_{n-1}, s_{n-2}, ...)$. Using z_n, we can update the encoder-decoder model using SGD in a way similar to the standard SEQ2SEQ model, the only difference being that the current token to predict not only depends on the LSTM output h_t, but also z_n. Given the sampled z_n, the KL-divergence can be readily computed, and we update the model using standard gradient decent (details shown in the Appendix).

The proposed *VLV-GM* model can be adapted to the bi-directional setting and the *bi* setting similarly to the way LDA-based models are adapted.

The proposed model is closely related to many recent attempts in training variational autoencoders (VAE) (Kingma and Welling, 2013; Rezende et al., 2014), variational or latent-variable recurrent nets (Bowman et al., 2015; Chung et al., 2015; Ji et al., 2016; Bayer and Osendorfer, 2014), hierarchical latent variable encoder-decoder models (Serban et al., 2016b,a).

4 Experimental Results

In this section, we describe experimental results. We first evaluate the proposed models on discriminative tasks such as sentence-pair ordering and full paragraph ordering reconstruction. Then we look at the task of coherent text generation.

Model	Acci	Earthq	Aver
Discriminative Model	**0.930**	**0.992**	**0.956**
SEQ2SEQ (bi)	0.755	0.930	0.842
VLV-GM (bi)	0.770	0.931	0.851
Recursive	0.864	0.976	0.920
Entity Grid Model	0.904	0.872	0.888
HMM	0.822	0.938	0.880
HMM+Entity	0.842	0.911	0.876
HMM+Content	0.742	0.953	0.847
Graph	0.846	0.635	0.740
Foltz et al. (1998)-Glove	0.705	0.682	0.688
Foltz et al. (1998)-LDA	0.660	0.667	0.664

Table 1: Results from different coherence models. Results for the Recursive model is reprinted from Li and Hovy (2014), Entity Grid Model from Louis and Nenkova (2012), HMM, HMM+Entity and HMM+Content from Louis and Nenkova (2012), Graph from Guinaudeau and Strube (2013), and the final two lexical models are recomputed using Glove and LDA to replace the original LSA model of Foltz et al. (1998).

4.1 Sentence Ordering, Domain-specific Data

Dataset We first evaluate the proposed algorithms on the task of predicting the correct ordering of pairs of sentences predicated on the assumption that an article is always more coherent than a random permutation of its sentences (Barzilay and Lapata, 2008). A detailed description of this commonly used dataset and training/testing are found in the Appendix.

We report the performance of the following baselines widely used in the coherence literature.

(1) *Entity Grid Model*: The grid model presented in Barzilay and Lapata (2008). Results are directly taken from Barzilay and Lapata's (2008) paper. We also consider variations of entity grid models, such as Louis and Nenkova (2012) which models the

cluster transition probability and the *Graph Based Approach* which uses a graph to represent the entity transitions needed for local coherence computation (Guinaudeau and Strube, 2013).

(2) Li and Hovy (2014): A recursive neural model computes sentence representations based on parse trees. Negative sampling is used to construct negative incoherent examples. Results are from their papers.

(3) Foltz et al. (1998) computes the semantic relatedness of two text units as the cosine similarity between their LSA vectors. The coherence of a discourse is the average of the cosine of adjacent sentences. We used this intuition, but with more modern embedding models: (1) 300-dimensional Glove word vectors (Pennington et al., 2014), embeddings for a sentence computed by averaging the embeddings of its words (2) Sentence representations obtained from LDA (Blei et al., 2003) with 300 topics, trained on the Wikipedia dataset. Results are reported in Table 2. The extended version of the discriminative model described in this work significantly outperforms the parse-tree based recursive models presented in Li and Hovy (2014) as well as all non-neural baselines. It achieves almost perfect accuracy on the earthquake dataset and 93% on the accident dataset, marking a significant advancement in the benchmark. Generative models (both vanilla SEQ2SEQ and the proposed variational model) do not perform competitively on this dataset. We conjecture that this is due to the small size of the dataset, leading the generative model to overfit.

4.2 Evaluating Ordering on Open-domain

Since the dataset presented in Barzilay and Lapata (2008) is quite domain-specific, we propose testing coherence with a much larger, open-domain dataset: Wikipedia. We created a test set by randomly selecting 984 paragraphs from Wikipedia dump 2014, each paragraph consisting of at least 16 sentences. The training set is 30 million sentences not overlapping with the test set.

4.2.1 Binary Permutation Classification

We adopt the same strategy as in Barzilay and Lapata (2008), in which we generate pairs of sentence permutations from the original Wikipedia paragraphs. We follow the protocols described in the subsection and each pair whose original paragraph's score is higher than its permutation is treated as being correctly classified, else incorrectly classified. Models are evaluated using accuracy. We implement the Entity Grid Model (Barzilay and Lapata, 2008) using the Wikipedia training set as a baseline, the detail of which is presented in the Appendix. Other baselines consist of the Glove and LDA updates of the lexical coherence baselines (Foltz et al., 1998).

Model	Accuracy
VLV-GM (MMI)	**0.873**
VLV-GM (bi)	0.860
VLV-GM (uni)	0.839
LDA-HMM-GM (MMI)	0.847
LDA-HMM-GM (bi)	0.837
LDA-HMM-GM (uni)	0.814
SEQ2SEQ (MMI)	0.840
SEQ2SEQ (bi)	0.821
SEQ2SEQ (uni)	0.803
Discriminative Model	0.715
Entity Grid Model	0.686
Foltz et al. (1998)-Glove	0.597
Foltz et al. (1998)-LDA	0.575

Table 2: Performance on the open-domain binary classification dataset of 984 Wikipedia paragraphs.

Results Table 2 presents results on the binary classification task. Contrary to the findings on the domain specific dataset in the previous subsection, the discriminative model does not yield compelling results, performing only slightly better than the entity grid model. We believe the poor performance is due to the sentence-level negative sampling used by the discriminative model. Due to the huge semantic space in the open-domain setting, the sampled instances can only cover a tiny proportion of the possible negative candidates, and therefore don't cover the space of possible meanings. By contrast the dataset in Barzilay and Lapata (2008) is very domain-specific, and the semantic space is thus relatively small. By treating all other sentences in the document as negative, the discriminative strategy's negative samples form a much larger proportion of the semantic space, leading to good performance.

Generative models perform significantly better than all other baselines. Compared with the dataset in Barzilay and Lapata (2008), overfitting is not an issue here due to the great amount of training data. In line with our expectation, the *MMI* model outperforms the *bidirectional* model, which in turn outperforms the *unidirectional* model across all three generative model settings. We thus only report *MMI* results for experiments below. The *VLV-GM* model outperforms that the *LDA-HMM-GM* model, which is slightly better than the vanila SEQ2SEQ models.

Model	Accuracy
VLV-GM (MMI)	**0.256**
LDA-HMM-GM (MMI)	0.237
SEQ2SEQ (MMI)	0.226
Entity Grid Model	0.143
Foltz et al. (1998) (Glove)	0.084

Table 3: Performances of the proposed models on the open-domain paragraph reconstruction dataset.

Model	adver-1	adver-2	adver-3
VLV-GM (MMI)	**0.174**	**0.120**	**0.054**
LDA-HMM-GM (MMI)	0.130	0.104	0.043
SEQ2SEQ (MMI)	0.120	0.090	0.039
SEQ2SEQ (bi)	0.108	0.078	0.030
SEQ2SEQ (uni)	0.101	0.068	0.024

Table 4: Adversarial Success for different models.

4.2.2 Paragraph Reconstruction

The accuracy of our models on the binary task of detecting the original sentence ordering is very high, on both the prior small task and our large open-domain version. We therefore believe it is time for the community to move to a more difficult task for measuring coherence.

We suggest the task of *reconstructing an original paragraph from a bag of constituent sentences*, which has been previously used in coherence evaluation (Lapata, 2003). More formally, given a set of permuted sentences $s_1, s_2, ..., s_N$ (N the number of sentences in the original document), our goal is return the original (presumably most coherent) ordering of s.

Because the *discriminative model* calculates the coherence of a sentence given the known previous and following sentences, it cannot be applied to this task since we don't know the surrounding context. Hence, we only use the *generative model*. The first sentence of a paragraph is given: for each step, we compute the coherence score of placing each remaining candidate sentence to the right of the partially constructed document. We use beam search with beam size 10. We use the Entity Grid model as a baseline for both the settings.

Evaluating the absolute positions of sentences would be too harsh, penalizing orderings that maintain relative position between sentences through which local coherence can be manifested. We therefore use Kendall's τ (Lapata, 2003, 2006), a metric of rank correlation for evaluation. See the Appendix for details of Kendall's τ computation. We observe a pattern similar to the results on the binary classification task, where the *VLV-GM* model performs the best.

4.3 Adversarial evaluation on Text Generation Quality

Both the tasks above are discriminative ones. We also want to evaluate different models' ability to generate coherent text chunks. The experiment is set up as follow: each encoder-decoder model is first given a set of context sentences (3 sentences). The model then generates a succeeding sentence using beam-search given the contexts. For the *unidirectional* setting, we directly take the most probable sequence and for the *bi-directional* and *MMI*, we rerank the N-best list using the backward probability and language model probability.

We conduct experiments on multi-sentence generation, in which we repeat the generative process described above for N times, where N=1,2,3. At the end of each turn, the context is updated by adding in the newly generated sequence, and this sequence is used as the source input to the encoder-decoder model for next sequence generation. For example, when N is set to 2, given the three context sentences *context-a*, *context-b* and *context-c*, we first generate *sen-d* given the three context sentences and then generate *sen-e* given the sen-d, *context-a*, *context-b* and *context-c*.

For evaluation, standard word overlap metrics such as BLEU or ROUGE are not suited for our task, and we use adversarial evaluation Bowman et al. (2015); Anjuli and Vinyals (2016). In adversarial evaluation, we train a binary discriminant function to classify a sequence as machine generated or human generated, in an attempt to evaluate the model's sentence generation capability. The evaluator takes as input the concatenation of the contexts and the generated sentences (i.e., *context-a*, *context-b* and *context-c*, *sen-d* , *sen-e* in the example described above),[5] and outputs a scalar, indicating the probability of the current text chunk being human-generated. Training/dev/test sets are held-out sets from the one on which generative models are trained. They respectively contain 128,000/12,800/12,800 instances. Since discriminative models cannot generate sentences, and thus cannot be used for adversarial evaluation, they are skipped in this section.

We report Adversarial Success (*AdverSuc* for short), which is the fraction of instances in which a model is capable of fooling the evaluator. *Adver-*

[5] The model uses a hierarchical neural structure that first maps each sentence to a vector representation, with another level of LSTM on top of the constituent sentences, producing a single vector to represent the entire chunk of texts.

Machine Generated Texts

Figure 2: An overview of training the adversarial evaluator using a hierarchical neural model. Green denotes input contexts. Red denotes a sentence from human-generated texts, treated as a positive example. Purple denotes a sentence from machine-decoded texts, treated as a negative example.

Suc is the difference between 1 and the accuracy achieved by the evaluator. Higher values of *AdverSuc* for a dialogue generation model are better. *AdverSuc-N* denotes the adversarial accuracy value on machine-generated texts with N turns.

Table 4 show *AdverSuc* numbers for different models. As can be seen, the latent variable model VLV-GM is able to generate chunk of texts that are most indistinguishable from coherent texts from humans. This is due to its ability to handle the dependency between neighboring sentences. Performance declines as the number of turns increases due to the accumulation of errors and current models' inability to model long-term sentence-level dependency. All models perform poorly on the *adver-3* evaluation metric, with the best adversarial success value being 0.081 (the trained evaluator is able to distinguish between human-generated and machine generated dialogues with greater than 90 percent accuracy for all models).

4.4 Qualitative Analysis

With the aim of guiding future investigations, we also briefly explore our model qualitatively, examining the coherence scores assigned to some artificial miniature discourses that exhibit various kinds of coherence.

Case 1: Lexical Coherence

Pinochet was arrested. His arrest was unexpected. **1.79**
Pinochet was arrested. His death was unexpected. **0.84**
Mary ate some apples. She likes apples. **2.03**
Mary ate some apples. She likes pears. **0.27**
Mary ate some apples. She likes Paris. **-1.35**

The examples suggest that the model handles lexical coherence, correctly favoring the 1st over the 2nd, and the 3rd over the 4th examples. Note that the coherence score for the final example is negative, which means conditioning on the first sentence actually decreases the likelihood of generating the second one.

Case 2: Temporal Order

Washington was unanimously elected president in the first two national elections. He oversaw the creation of a strong, well-financed national government. **1.48**
Washington oversaw the creation of a strong, well-financed national government. He was unanimously elected president in the first two national elections. **0.72**

Case 3: Causal Relationship

Bret enjoys video games; therefore, he sometimes is late to appointments. **0.69**
Bret sometimes is late to appointments; therefore, he enjoys video games. **-0.07**

Cases 2 and 3 suggest the model may, at least in these simple cases, be capable of addressing the much more complex task of dealing with temporal and causal relationships. Presumably this is because the model is exposed in training to the general preference of natural text for temporal order, and even for the more subtle causal links.

Case 4: Centering/Referential Coherence

Mary ate some apples. She likes apples. **3.06**
She ate some apples. Mary likes apples. **2.41**

The model seems to deal with simple cases of referential coherence.

Example3: **2.40**
John went to his favorite music store to buy a piano.
He had frequented the store for many years.
He was excited that he could finally buy a piano.
He arrived just as the store was closing for the day.
Example4: **1.62**
John went to his favorite music store to buy a piano.
It was a store John had frequented for many years
He was excited that he could finally buy a piano..
It was closing just as John arrived.

In these final examples from Miltsakaki and Kukich (2004), the model successfully captures the fact that the second text is less coherent due to *rough shifts*. This suggests that the discourse embedding space may be able to capture a representation of entity focus.

Of course all of these these qualitative evaluations are only suggestive, and a deeper understanding of what the discourse embedding space is capturing will likely require more sophisticated visualizations.

5 Conclusion

We investigate the problem of open-domain discourse coherence, training discriminative models that treating natural texts as coherent and permutations as non-coherent, and Markov generative models that can predict sentences given their neighbors.

Our work shows that the traditional evaluation metric (ordering pairs of sentences in small domains) is completely solvable by our discriminative models, and we therefore suggest the community move to the harder task of open-domain full-paragraph sentence ordering.

The proposed models also offer an initial step in generating coherent texts given contexts, which has the potential to benefit a wide range of generation tasks in NLP. Our latent variable neural models, by offering a new way to learn latent discourse-level features of a text, also suggest new directions in discourse representation that may bring benefits to any discourse-aware NLP task.

6 Supplemental Material

Details for the domain specific dataset (Barzilay and Lapata, 2008) The corpus consists of 200 articles each from two domains: NTSB airplane accident reports (V=4758, 10.6 sentences/document) and AP earthquake reports (V=3287, 11.5 sentences/document), split into training and testing. For each document, pairs of permutations are generated[6]. Each pair contains the original document order and a random permutation of the sentences from the same document.

Training/Testing details for models on the domain specific dataset We use reduced versions of both generative and discriminative models to allow fair comparison with baselines. For the discriminative model, we generate noise negative examples from random replacements in the training set, with the only difference that random replacements only come from the same document. We use 300 dimensional embeddings borrowed from GLOVE (Pennington et al., 2014) to initialize word embeddings. Word embeddings are kept fixed during training and we update LSTM parameters using AdaGrad (Duchi et al., 2011). For the generative model, due to the small size of the dataset, we train a one layer SEQ2SEQ model with word dimensionality and number of hidden neurons set to 100. The model is trained using SGD with AdaGrad (Zeiler, 2012).

The task requires a coherence score for the whole document, which is comprised of multiple cliques. We adopt the strategy described in Li and Hovy (2014) by breaking the document into a series of cliques which is comprised of a sequence of

[6] Permutations downloaded from `people.csail.mit.edu/regina/coherence/CLsubmission/`.

consecutive sentences. The document-level coherence score is attained by averaging its constituent cliques. We say a document is more coherent if it achieves a higher average score within its constituent cliques.

Implementation of Entity Grid Model For each noun in a sentence, we extract its syntactic role (subject, object or other). We use a wikipedia dump parsed using the Fanse Parser (Tratz and Hovy, 2011). Subjects and objects are extracted based on *nsubj* and *dobj* relations in the dependency trees. (Barzilay and Lapata, 2008) define two versions of the Entity Grid Model, one using full coreference and a simpler method using only exact-string coreference; Due to the difficulty of running full coreference resolution tens of millions of Wikipedia sentences, we follow other researchers in using Barzilay and Lapata's simpler method (Feng and Hirst, 2012; Burstein et al., 2010; Barzilay and Lapata, 2008).[7]

Kendall's τ Kendall's τ is computed based on the number of inversions in the rankings as follows:

$$\tau = 1 - \frac{2\text{\# of inversions}}{N \times (N-1)} \tag{9}$$

where N denotes the number of sentences in the original document and inversions denote the number of interchanges of consecutive elements needed to reconstruct the original document. Kendall's τ can be efficiently computed by counting the number of intersections of lines when aligning the original document and the generated document. We refer the readers to Lapata (2003) for more details.

Derivation for Variation Inference For simplicity, we use μ_{post} and Σ_{approx} to denote $\mu^{\text{approx}}(z_n)$ and $\Sigma^{\text{approx}}(z_n)$, μ_{true} and Σ_{true} to denote $\mu^{\text{true}}(z_n)$ and $\Sigma^{\text{true}}(z_n)$. The KL-divergence between the approximate distribution $q(z_n|z_{n-1}, s_n, s_{n-1}, ...)$ and the true distribution $p(z_n|z_{n-1}, s_{n-1}, s_{n-2}, ...)$ in the variational inference is given by:

$$\begin{aligned} & D_{KL}(q(z_n|z_{n-1}, s_n, s_{n-1}, ...)||p(z_n|z_{n-1}, s_{n-1}, s_{n-2}, ...) \\ =& \frac{1}{2}(\text{tr}(\Sigma_{true}^{-1}\Sigma_{approx}) - k + \log\frac{\det\Sigma_{true}}{\det\Sigma_{approx}} \\ +& (\mu_{true} - \mu_{approx})^{-1}\Sigma_{true}^{-1}(\mu_{true} - \mu_{approx})) \end{aligned} \tag{10}$$

where k denotes the dimensionality of the vector. Since z_n has already been sampled and thus known, μ_{approx}, Σ_{approx}, μ_{true}, Σ_{true} and consequently Eq10 can be readily computed. The gradient with respect to μ_{approx}, Σ_{approx}, μ_{true}, Σ_{true} can be respectively computed, and the error is then backpropagated to the hierarchical neural models that are used to compute them. We refer the readers to Doersch (2016) for more details about how a general VAE model can be trained.

Our generate models offer a powerful way to represent the latent discourse structure in a complex embedding space, but one that is hard to visualize. To help understand what the model is doing, we examine some relevant examples, annotated with the (log-likelihood) coherence score from the *MMI* generative model, with the goal of seeing (qualitatively) the kinds of coherence the model seems to be representing. (The MMI can be viewed as the informational gain from conditioning the generation of the current sentence on its neighbors.)

[7] Our implementation of the Entity Grid Model is built upon public available code at https://github.com/karins/CoherenceFramework.

Affinity-Preserving Random Walk for Multi-Document Summarization

Abstract

Multi-document summarization provides users with a short text that summarizes the information in a set of related documents. This paper introduces affinity-preserving random walk to the summarization task, which preserves the affinity relations of sentences by an absorbing random walk model. Meanwhile, we put forward adjustable affinity-preserving random walk to enforce the diversity constraint of summarization in the random walk process. The ROUGE evaluations on DUC 2003 topic-focused summarization task and DUC 2004 generic summarization task show the good performance of our method, which has the best ROUGE-2 recall among the graph-based ranking methods.

1 Introduction

Multi-document summarization provides users with summary that reflects the main information in a set of given documents. The documents are often related and talk about more than one topics. Generic multi-document summarization and topic-focused multi-document summarization are two typical kinds of summarization. The former is a summarization delivering the main information of the documents with no bias while the latter is a one delivering the main information biased to a given topic description (a few sentences or even phrases). Most existing summarization systems are designed for these two kinds of summarization.

There are two goals for generic multi-document summarization. The first one is **saliency**. Summary sentences should be central sentences that capture the majority of information in a document cluster. The sentences with little information about the document cluster should not be included in the summary. The second one is **diversity**. The information overlap between summary sentences should be as minimal as possible due to the length limit of summary. In other words, the information coverage of summary is a determinant, which requires that the summary sentences should cover diverse aspects of information. Besides the two goals, there is another goal for the topic-focused summarization and that is **relevancy**. It requires that the summary sentences be relevant to the topic description. A series of conferences and workshops on automatic text summarization (e.g. NTCIR, DUC), special topic sessions in ACL, EMNLP and SIGIR have advanced the techniques to achieve these goals and many approaches have been proposed so far.

In this paper, we focus on the extractive summarization methods, which extract the summary sentences from the input document cluster. We propose affinity-preserving random walk for multi-document summarization. The method is a graph-based ranking method, which takes into account the global information collectively computed from the entire sentence affinity graph. Different from the previous graph-based ranking methods, our method adopts "global normalization" to transform sentence affinity matrix into sentence transition matrix and formulates the sentence ranking process in an absorbing random walk model. Meanwhile, the adjustable affinity-preserving random walk is proposed to facilitate the diversity of summary by adjusting the sentence transition matrix after each iteration of random walk. Experimental results on DUC generic and topic-focused multi-document summarization tasks show the competitive performance of our method. To our best knowledge, our system has the best ROUGE-2 recall on both tasks among all existing graph-

Proceedings of the 2017 Conference on Empirical Methods in Natural Language Processing, pages 210–220
Copenhagen, Denmark, September 7–11, 2017.

based ranking methods, which defeats most other methods.

We summarize our contributions as follows. (1) We preserve the original affinity relations between sentences in a novel affinity-preserving random walk view for multi-document summarization. The preservation of affinity leads to a more salient summary. And it is applicable to both generic and topic-focused summarization. (2) We propose adjustable affinity-preserving random walk to enforce the diversity constraint of summarization in the random walk process. (3) Experiments on DUC 2003 and DUC 2004 tasks demonstrate the competitive performance of our method.

The rest of the paper is organized as follows. Section 2 discusses the related work. Section 3 describes traditional random walk model for summarization. Section 4 proposes affinity-preserving random walk for the saliency goal of summarization and this section also proposes adjustable affinity-preserving random walk to produce both salient and diverse summary. Section 5 gives our evaluation results and the conclusion is made in Section 6.

2 Related Work

Our method belongs to the graph-based ranking methods to select sentences in the documents to produce the summary. Erkan and Radev (2004) proposed LexPageRank to compute the sentence saliency based on the concept of eigenvector centrality. It constructs the sentence affinity graph and computes the sentence saliency based on an algorithm similar to PageRank (Page et al., 1999). Like PageRank, the affinity matrix is converted into the row-stochastic matrix, which is used as the transition matrix of random walk on the weighted graph. Wan (2007) proposed manifold ranking for topic-focused multi-document summarization. It makes full use of both the relationships among all sentences in the documents and the relationships between the given topic description and the sentences. Manifold ranking conducts a different normalization on the sentence affinity matrix to guarantee the algorithm's convergence. GRASSHOPPER (Zhu et al., 2007) ranks sentences with an emphasis on the diversity constraint of summarization. It turns already ranked sentences into absorbing states, which effectively prevents redundant sentences from receiving a high rank. The algorithm is based on an absorbing random walk and produces only one summary sentence after one particular random walk becomes stationary. And the normalization from sentence affinity matrix to sentence transition matrix is the same as PageRank. DivRank (Mei et al., 2010) is a method to balance the saliency and diversity of the top ranked sentences in a reinforced random walk model. Also, the normalization in DivRank from affinity matrix to transition matrix is the same as PageRank. Another notable diversified graph-based ranking method GCD (Dubey et al., 2011) relies on large amounts of training data to learn edge conductances.

Our method formulates the multi-document summarization as an affinity-preserving random walk and uses the "global normalization" to transform sentence affinity matrix into sentence transition matrix, which is different from all those proposed methods. And the adjustable transition matrix in our method balances the saliency and diversity goals of summarization. Like GRASSHOPPER, our method relies on the absorbing random walk model. The difference is that our method does not turn the sentence vertex into absorbing state but add an absorbing vertex to the original sentence affinity graph. And all summary sentences are extracted after the random walk reaches a stationary state in our method. Like DivRank, the sentence transition matrix is adjustable in our method to enforce the diversity constraint of summarization. However, our method differs from DivRank in the mechanism to adjust the transition matrix.

3 Traditional Random Walk for Summarization

Suppose $G = (S, E)$ is a graph with vertex set S and edge set $E \subset S^2$. Suppose there is a conductance $c(s_i, s_j) > 0$ associated with each edge $(s_i, s_j) \in E$ and $c(s_i, s_j) = 0$ associated with the set $S^2 - E$ (the conductance of nonexistent edge is zero). Let

$$C(s_i) = \sum_{s_j \in S} c(s_i, s_j), \ s_i \in S \tag{1}$$

so that $C(s_i)$ is the total conductance of the edges coming from s_i. And the traditional random walk on graph is defined as

Definition 3.1. *The discrete-time Markov chain $X = (X_0, X_1, X_2, ...)$ with state space and tran-*

sition probability matrix **P** *given by*

$$P(s_i, s_j) = \frac{c(s_i, s_j)}{C(s_i)},\ (s_i, s_j) \in S^2 \qquad (2)$$

is called a random walk on the graph G.

This chain governs a particle moving along the vertices of G. If the particle in the state X_m is at vertex $s_i \in S$, it will be at a neighbor of s_i in the next state X_{m+1}, which is chosen randomly in proportion to the conductance. We can prove that $\sum_{s_j \in S} P(s_i, s_j) = 1$ for any $s_i \in S$ ($C(s_i) \neq 0$) so $\mathbf{P}$ is a row-stochastic matrix by $\mathbf{P} = \mathbf{D}^{-1}\mathbf{W}$, where $\mathbf{D}$ is a diagonal matrix with entries $\mathbf{D}_{ii} = C(s_i)$ and $\mathbf{W}$ is the adjacency matrix of G where $\mathbf{W}_{ij} = c(s_i, s_j)$.

For the summarization task, G is the sentence affinity graph. The vertex set $S = \{s_1, s_2, ..., s_n\}$ contains every sentence in the document cluster and the edge set E contains the pairwise affinity between sentences. We use the $tf{*}isf$ formula to calculate the weight associated with each term occurring in the sentence, where tf is the term frequency in the sentence and isf is the inverse sentence frequency of the term among all sentences. isf is often calculated as $1{+}log(n/n_t)$, where n is the total number of sentences and n_t is the number of sentences containing the term t. $\mathbf{W}_{ij}$ is computed using the standard cosine measure (Baeza-Yates et al., 1999).

$$\mathbf{W}_{ij} = sim_{cosine}(\mathbf{v}_i, \mathbf{v}_j) = \frac{\mathbf{v}_i \cdot \mathbf{v}_j}{\|\mathbf{v}_i\|_2 \times \|\mathbf{v}_j\|_2} \qquad (3)$$

where $\mathbf{v}_i$ and $\mathbf{v}_j$ are the corresponding term vectors of s_i and s_j. Two vertices are connected if their affinity is larger than 0 and $\mathbf{W}_{ii}$ is set as 0 to avoid self transition. We get an undirected graph G as well as a symmetric sentence affinity matrix $\mathbf{W}$ in this way. Then we transform $\mathbf{W}$ into $\mathbf{P}$ by $\mathbf{P} = \mathbf{D}^{-1}\mathbf{W}$ and use the stationary distribution of random walk as sentence ranking scores. The traditional random walk model is a simple practice of PageRank algorithm for multi-document summarization.

4 Affinity-Preserving Random Walk for Summarization

4.1 Prior of Multi-Document Summarization

In the above traditional random walk on graph, the normalization from affinity matrix $\mathbf{W}$ to transition matrix $\mathbf{P}$ is to make $\mathbf{P}$ a row-stochastic matrix. This can be interpreted as a democratic normalization because the surfer of a traditional random walk visits neighbors of a vertex with probability 1. The surfer has to choose a neighbor to visit next although it is a random choice w.r.t. the conductance distribution of the vertex. However this democratic normalization is not suitable for multi-document summarization due to the fact that most sentences are not salient and should not be normalized democratically as the few salient ones. The prior here is that the number ratio of good candidate sentences over bad candidate sentences is very low due to the summary length limit. Good candidate sentences are the sentences highly overlapping with sentences in the reference summary written by humans. And the remaining sentences are bad candidate sentences. The democratic normalization of $\mathbf{P} = \mathbf{D}^{-1}\mathbf{W}$ will extend the adverse effect of bad candidate sentences and suppress the effect of good candidate sentences, because the total conductance of the bad candidate sentence is usually smaller than that of the good candidate sentence. In this case, the random surfer has to choose a neighbor to visit even when she is currently at a bad candidate sentence, which will direct her to visit other bad candidate sentences neighboring to the current sentence. The invariant behavior of the surfer at all vertices in the graph is not consistent with the prior which makes a distinction between good and bad candidate sentences. It may pervert the random walk process to get an ideal distribution in which only few sentences are assigned with a high ranking score.

It is worth noting here that manifold ranking (Wan et al., 2007) for summarization uses a different normalization: $\mathbf{P} = \mathbf{D}^{-\frac{1}{2}}\mathbf{W}\mathbf{D}^{-\frac{1}{2}}$. It is a symmetric normalization on both endpoints of an edge, which makes $\mathbf{P}$ a suitable choice in the manifold ranking process to smooth the scores of neighboring vertices. The symmetric normalization can be deduced from the objective function of manifold ranking (Zhou et al., 2003) and does not make a distinction between the good and bad candidate sentences. It is also not consistent with the prior. We can conclude that existing graph-based ranking methods can not well characterize the prior of multi-document summarization.

4.2 Affinity-Preserving Random Walk

We need a new normalization method that distinguishes between good and bad candidate sen-

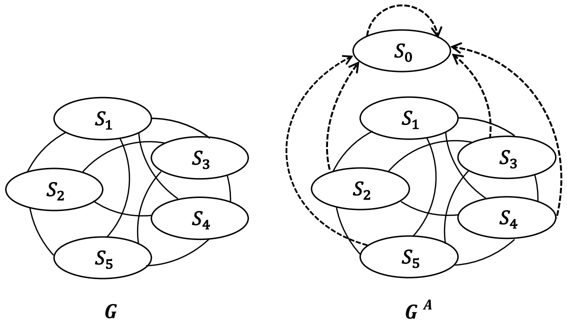

Figure 4.1: Sentence graphs for summarization. G: sentence affinity graph constructed from the document cluster. G^A: sentence augmented graph with an absorbing vertex s_0. C_{max} equals to $C(s_1)$ indicating that sentence s_1 has the maximum conductance, so there is no edge (s_1, s_0).

tences to satisfy the prior of multi-document summarization. Affinity-preserving random walk has an intrinsic mechanism that preserves the original affinity relations between sentences in the documents, which is proposed and defined as follows.

Definition 4.1. *For the graph G, the vertex set S has $(n+1)$ vertices: $s_0, s_1, s_2, ..., s_n$. The maximum conductance $C_{max} = max_{i=1,2,...n} C(s_i)$. Of the $(n+1)$ vertices, s_0 is an absorbing vertex with $c(s_i, s_0) \geqslant 0, c(s_0, s_i) = 0$, and $c(s_0, s_0) = C_{max}$ for $i = 1, 2, ..., n$. The remaining vertices are the normal vertices with $c(s_i, s_j) \geqslant 0$ for $i, j = 1, 2, ..., n$. The discrete-time Markov chain $X = (X_0, X_1, X_2, ...)$ with state space and transition probability matrix **P** given by*

$$\begin{aligned} &P(s_i, s_j) = \frac{c(s_i, s_j)}{C_{max}} \\ &P(s_i, s_0) = 1 - \frac{C(s_i)}{C_{max}}, \; P(s_0, s_i) = 0 \\ &P(s_0, s_0) = 1 \\ &\textit{for } i, j = 1, 2, ..., n \end{aligned} \tag{4}$$

is called an affinity-preserving random walk on the graph G.

For our summarization task, we construct a sentence augmented graph G^A (as shown in Figure 4.1) by adding an absorbing vertex s_0 to the sentence affinity graph G. The unabsorbed vertices s_i $(i = 1, 2, ..., n)$ represent sentences in the documents. The affinity-preserving random walk process as defined above is implemented on G^A to rank sentences in the documents. In the affinity-preserving random walk, once the surfer reaches the absorbing vertex, she cannot walk out of there. Because $P(s_i, s_0)$ is small for the vertex s_i with a large conductance, it is less likely for the surfer at s_i to walk into s_0. As for the vertex with a small conductance, the surfer has a tendency to be absorbed by s_0. The absorbing vertex here plays a role of soaking unreliable ranking scores from large numbers of bad candidate sentences and highlighting the few good candidate sentences. The affinity matrix **W** is normalized by its first norm (equivalent to C_{max}) in the affinity-preserving random walk, which results in a kind of "*soft*" stochastic matrix for n unabsorbed vertices. "*soft*" here means that the sum of row elements in the matrix can be less than 1. By contrast, **P** in the traditional random walk is a "*hard*" stochastic matrix in which every sum of row elements has to be 1. Meanwhile, **P** in this absorbing Markov chain (Seneta, 2006) preserves the original affinity relations in **W** as all sentences are globally normalized by the same factor (i.e. C_{max}). We call this approach an "affinity-preserving random walk" as it is used in (Cho et al., 2010), which deals with a graph matching problem that aims at assigning 1-vs-1 correspondences between two graphs. The similar idea is also applied in the case of ontology matching (Xiang et al., 2015). Transition matrix **P** including the absorbing vertex is formulated in (Cho et al., 2010) as follows

$$\mathbf{P} = \begin{pmatrix} 1 & \mathbf{0}^T \\ \mathbf{e} - \mathbf{c}/\|\mathbf{W}\|_1 & \mathbf{W}/\|\mathbf{W}\|_1 \end{pmatrix} \tag{5}$$

where $\mathbf{0}^T$ is a $1 \times n$ vector with all elements 0, **e** is an $n \times 1$ vector with all elements 1, $\mathbf{c} = [C(s_1), C(s_2), ..., C(s_n)]^T$ is a vector containing the conductances of n sentences and $\mathbf{W}/\|\mathbf{W}\|_1$ is the $n \times n$ soft substochastic matrix. However, the stationary distribution of such a random walk on graph with one absorbing vertex is always $\begin{pmatrix} 1 & \mathbf{0}^T \end{pmatrix}$, which is not a good characterization of the sentence ranking distribution. We turn to the quasi-stationary distribution $\bar{\mathbf{x}}$ (Cho et al., 2010; Darroch and Seneta, 1965) of absorbing random walk for ranking sentences. $\bar{\mathbf{x}}^{(K)}$ is defined as

$$\begin{aligned} \bar{\mathbf{x}}_i^{(K)} &= Prob(X^{(K)} = s_i | X^{(K)} \neq s_0) \\ &= \frac{\mathbf{x}_i^{(K)}}{\sum_j \mathbf{x}_j^{(K)}} \end{aligned} \tag{6}$$

where $X^{(K)}$ denotes the position of random surfer at time K. It can be proven that $\bar{\mathbf{x}}^{(K)}$ has its stationary distribution $\bar{\mathbf{x}}$ if $\mathbf{W}$ is irreducible (Darroch and Seneta, 1965). We remove the sentences that have the total conductance 0 (i.e. the isolated sentences) when constructing the sentence affinity graph G. In this way, G will be strongly connected and has an irreducible adjacency matrix $\mathbf{W}$.

We introduce the teleport vector $\mathbf{y}$ as used in personalized PageRank (Page et al., 1999; Haveliwala, 2002; Jeh and Widom, 2003) for the summarization task. In the generic summarization case, we define the vector $\mathbf{y}$ in a way that reflects the position of each sentence in a document. If the sentence s_{i+1} is right after the sentence s_i in the same document, then

$$\frac{\mathbf{y}_{i+1}}{\mathbf{y}_i} = \lambda^{-1}, \lambda > 1 \qquad (7)$$

where λ is the decay factor. In the topic-focused summarization case, we incorporate the topic description as a vertex in the random walk process, which is a standard way of achieving the relevancy goal of this kind of summarization. Vector $\mathbf{y}$ is defined to be $[y_1, y_2, ..., y_n, y_{n+1}]^T$ in which $y_i = 0 (1 \leqslant i \leqslant n)$ and $y_{n+1} = 1$ when the first n elements represent sentences in the documents and the last one represents the topic description. We normalize $\mathbf{y}$ by its first norm to get a prior sentence ranking for multi-document summarization. Based on $\mathbf{W}$ and $\mathbf{y}$, sentence ranking scores in affinity-preserving random walk can be formulated in a recursive form as follows

$$\mathbf{x} = \frac{\mu \mathbf{W}^T / \|\mathbf{W}\|_1 \mathbf{x} + (1-\mu)\mathbf{y}}{\|\mu \mathbf{W}^T / \|\mathbf{W}\|_1 \mathbf{x} + (1-\mu)\mathbf{y}\|_1} \qquad (8)$$

where $\mathbf{x} = [Score(s_i)]_{n \times 1}$ is the vector of sentence ranking scores. μ is the damping factor that trades off between two actions: the transition according to $\mathbf{W}^T/\|\mathbf{W}\|_1$ and the teleport specified by $\mathbf{y}$. Transpose operation in Eq.(8) can be removed because of symmetry of $\mathbf{W}$. The final transition matrix of affinity-preserving random walk is given by $\mathbf{A} = \mu\mathbf{W}/\|\mathbf{W}\|_1 + (1-\mu)\mathbf{y} \cdot \mathbf{e}^T$ and $\mathbf{x}$ should be normalized by its first norm after each iteration of random walk. Like PageRank, the quasi-stationary distribution is obtained by the normalized principal eigenvector of $\mathbf{A}$.

For implementation, the initial ranking scores of all sentences are set to $1/n$ and the iterative process in Eq.(8) is adopted to compute new ranking scores of sentences. Usually convergence of the iterative algorithm is achieved when the difference between scores computed at two successive iterations falls below a given threshold.

4.3 Adjustable Affinity-Preserving Random Walk for Summarization

Affinity-preserving random walk preserves the affinity relations between sentences and gives high ranking scores to the salient sentences. However, the diversity constraint of summarization has not been taken into account. The surfer of affinity-preserving random walk has no knowledge about what a diverse summary should be. If we just take redundancy removing as the post-processing separate step to improve diversity, sentences that highly overlap with other summary sentences may be chosen and sentences that include information about different topics may be submerged. This phenomenon can be explained by the theorem as follows.

Theorem 4.1. *Suppose $\bar{\boldsymbol{x}}$ is the quasi-stationary distribution of affinity-preserving random walk as defined in Sec.4.2 and $\boldsymbol{x}$ is the solution of a continuous quadratic optimization problem $argmax(\boldsymbol{x}^T \boldsymbol{A}\, \boldsymbol{x})$ s.t. $\boldsymbol{x} \in [0,1]^n$, $\|\boldsymbol{x}\|_2 = 1$ and $\boldsymbol{A}$ has definition in Sec.4.2. The following equation holds*

$$\bar{\boldsymbol{x}} = \boldsymbol{x}/\|\boldsymbol{x}\|_1 \qquad (9)$$

when $\mu = 1$.

Proof. In mathematics, for a given symmetric real matrix $\mathbf{A}$ (when $\mu = 1$) and nonzero real vector $\mathbf{x}$, the Rayleigh quotient $R(\mathbf{A}, \mathbf{x})$ is defined as

$$R(\mathbf{A}, \mathbf{x}) = \frac{\mathbf{x}^T \mathbf{A} \mathbf{x}}{\mathbf{x}^T \mathbf{x}}$$

and it reaches its maximum value when $\mathbf{x}$ is the principal eigenvector of $\mathbf{A}$. If $\|\mathbf{x}\|_2 = 1$, $R(\mathbf{A}, \mathbf{x})$ is equivalent to $\mathbf{x}^T \mathbf{A}\, \mathbf{x}$. So the solution $\mathbf{x}$ is the principal eigenvector of $\mathbf{A}$. From Section 4.2, $\bar{\mathbf{x}}$ is the normalized principal eigenvector of $\mathbf{A}$. $\bar{\mathbf{x}}$ and $\mathbf{x}$ have the relation in Eq.(9). The conclusion is made. □

From Theorem 4.1, affinity-preserving random walk tends to produce a stationary distribution in which the total sum of affinity between sentences (i.e. $\mathbf{x}^T \mathbf{A} \mathbf{x}$) is large if there is a subtle teleporting effect. It will lead to a summary consisting of many sentences overlapping with each other, which clearly violates the diversity constraint of summarization. Good candidate sentences may not have high affinity with other sentences and are likely to be submerged by affinity-preserving random walk. Conversely, some bad candidate sentences could have high affinity with others and will be highlighted by the random walk process. An extreme example is that a cluster of sentences will all get high ranking scores if they are very similar to each other. However, only one sentence in this cluster should be included in the summary and the others should be suppressed. The random surfer is caught in a trap of larger sentence cluster, which operates against the exploration of good candidates in smaller cluster.

We introduce adjustable affinity-preserving random walk to enforce the diversity constraint of summarization. In the original affinity-preserving random walk, sentence transition matrix **A** is fixed and set as $\mu\mathbf{W}/\|\mathbf{W}\|_1+(1-\mu)\mathbf{y}\cdot\mathbf{e}^T$. Edge (s_i, s_0) (if $C(s_i) \neq C_{max}$) always exists and has an invariant conductance $c(s_i, s_0)$, which means that the surfer at s_i walks into s_0 in the same manner for the entire random walk process. The random surfer makes her decision only based on invariant **A** to select salient sentences and form the summary. To equip the surfer with knowledge about what a diverse summary should be, we propose to adjust sentence transition matrix **A** in each iteration of random walk. The key point is that good candidate sentences should be normalized *locally* while bad ones should be normalized *globally* in the transformation from affinity matrix **W** to transition matrix **A**.

A "virtual" summary V is produced based on **x** in each iteration of affinity-preserving random walk. "Virtual" here means that V is a summary based on transient distribution **x**, which differs from the final summary based on quasi-stationary distribution $\bar{\mathbf{x}}$. The method of diversity penalty imposition (Wan et al., 2007) is used to produce V, which is denoted by the *producingSummary* function in Algorithm 4.1. It is a simple greedy algorithm to select sentences that are both salient and diverse, which often plays a role of greedy post-processing step to produce the final summary. Rather, we use it to produce virtual summary V that satisfies both the saliency and diversity constraints based on a specific iteration. V is an indicator for the diversity constraint of summarization.

The sentence transition matrix **A** in the iteration $(K+1)$ is then constructed with help of the virtual summary V in the iteration K. Here, different normalization methods are used to transform **W** into **A**. If V includes the sentence s_i, elements in the corresponding *i*-th row of **W** will be normalized by the sum of the row (i.e. $C(s_i)$). Otherwise, elements will be normalized by the maximum sum of row elements in **W** (i.e. C_{max}). In this way, "local normalization" is adopted for the sentences in V while "global normalization" is adopted for the sentences not in V. We differentiate the normalization methods to lead the surfer of affinity-preserving random walk to explore more in the neighborhood of the sentences in V rather than end in the absorbing vertex s_0. As a result, the sentences that satisfy the saliency and diversity constraints will be highlighted even though they are in a small sentence cluster. We characterize different normalizations in the diagonal matrix **D**. $\mathbf{D}_{ii}$ is $C(s_i)$ if $s_i \in V$ and $\mathbf{D}_{ii}$ is C_{max} if $s_i \notin V$,which is denoted by the *adjustingNormalization* function in Algorithm 4.1. **D** in the current iteration is here dependent on **x** in the previous iteration. We will have different sentence augmented graphs G^A in each iteration. Figure 4.2 shows an example of $G^A(K)$ and $G^A(K+1)$ in the respective iterations K and $(K+1)$. The probability distribution in the adjustable affinity-preserving random walk is updated as follows.

Algorithm 4.1: Adjustable Affinity-Preserving Random Walk for Multi-Document Summarization

```
Input: The sentence affinity matrix, W; The
       starting and maximum number of
       iteration, $B$ and $M$; The teleport
       vector, y; The damping factor, $\mu$;
Output: The multi-document summary, $V$;
$\mathbf{A} \leftarrow \mu\mathbf{W}/C_{max} + (1-\mu)\mathbf{y}\cdot\mathbf{e}^T$
Initialize the starting distribution x as uniform
for $i \leftarrow 1, 2, ..., M$ do
    if $i > B$ then
        $V \leftarrow$ producingSummary(x)
        $\mathbf{D} \leftarrow$ adjustingNormalization($V$)
        $\mathbf{A} \leftarrow \mu(\mathbf{D}^{-1}\mathbf{W})^T + (1-\mu)\mathbf{y}\cdot\mathbf{e}^T$
    $\bar{\mathbf{x}} \leftarrow \mathbf{A}\mathbf{x}$
    $\bar{\mathbf{x}} \leftarrow \bar{\mathbf{x}}/\|\bar{\mathbf{x}}\|_1$
    if $\|\bar{\mathbf{x}} - \mathbf{x}\|_1 < \varepsilon$ then
        break
    $\mathbf{x} \leftarrow \bar{\mathbf{x}}$
$V \leftarrow$ producingSummary(x)
Return $V$
```

$$\mathbf{x} = \frac{\mu(\mathbf{D}^{-1}\mathbf{W})^T\mathbf{x} + (1-\mu)\mathbf{y}}{\|\mu(\mathbf{D}^{-1}\mathbf{W})^T\mathbf{x} + (1-\mu)\mathbf{y}\|_1} \tag{10}$$

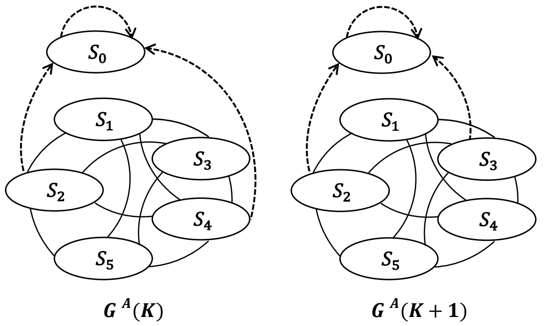

Figure 4.2: Sentence augmented graphs for summarization in two successive iterations. $G^A(K)$: augmented graph in the iteration K. Virtual summary $V = \{s_1, s_3, s_5\}$, which is constructed from $\mathbf{x}$ in the iteration $(K-1)$ by *producingSummary*. $\mathbf{D} = diag([C(s_1), C_{max}, C(s_3), C_{max}, C(s_5)])$. $G^A(K+1)$: augmented graph in the iteration $(K+1)$. $V = \{s_1, s_4, s_5\}$, which is constructed from $\mathbf{x}$ in the iteration K by *producingSummary*. $\mathbf{D} = diag([C(s_1), C_{max}, C_{max}, C(s_4), C(s_5)])$. In both cases, C_{max} equals to $C(s_1)$ indicating that sentence s_1 has the maximum conductance.

This is an adjustable Markov chain for which the transition matrix $\mathbf{A}$ is $\mu(\mathbf{D}^{-1}\mathbf{W})^T + (1-\mu)\mathbf{y} \cdot \mathbf{e}^T$. In this setting, $\mathbf{A}$ is dependent on the transient distribution $\mathbf{x}$ in the previous iteration, which differs from the invariant transition matrix in Eq.(8). As the diversity constraint is embedded in $\mathbf{A}$, subsequent random walks move to the solution that induces a better summary. The algorithm of the adjustable affinity-preserving random walk for multi-document summarization is demonstrated in Algorithm 4.1.

The parameter B in Algorithm 4.1 is used to produce a transient distribution which is reliable enough to adjust the transition matrix. To get the final multi-document summary, we use the same *producingSummary* function.

5 Experiments

5.1 Data Sets

Generic and topic-focused multi-document summarization have been the main tasks in DUC[1]. Task 2 of DUC 2004 is a generic summarization task and task 3 of DUC 2003 is a topic-focused summarization task. Both tasks are used for performance evaluation of our method. In the experiments, task 2 of DUC 2003 is used for the parameter tuning of our method. We preprocess the document data sets by removing stopwords from each sentence and stemming the remaining words using the Porter's stemmer[2]. Also, the sentences containing the said clause (if a said, says, told, tells word and quotation marks appear simultaneously) are filtered out.

For evaluation, four reference summaries generated by human judges for each document cluster are provided by DUC as the ground truth. A brief summary over the evaluation datasets is shown in Table 5.1. According to (Hong et al., 2014), we adjust the length limit of summary in DUC 2004 from 665 bytes to 100 words as it provides the same setting for system evaluations.

	DUC 2003	DUC 2003	DUC 2004
Task	Task 2	Task 3	Task 2
Type	Generic	Topic-focused	Generic
Cluster numbers	30	30	50
Data source	TDT	TREC	TDT
Summary length	100 words	100 words	100 words

Table 5.1: Summary of data sets used in our experiments.

5.2 Evaluation Metric

We use the ROUGE-1.5.5 (Lin and Hovy, 2003) toolkit for evaluation, which has been officially adopted by DUC for automatic summarization evaluation. The toolkit measures summary quality by counting overlapping units such as the n-gram, word sequences and word pairs between the candidate summary and the reference summary. ROUGE-N is an n-gram based measure and the ROUGE-N recall is computed as follows

$$\textit{ROUGE-N}_R = \frac{\sum\limits_{S \in \{\textit{RefSum}\}} \sum\limits_{\textit{n-gram} \in S} \textit{Count}_{\textit{match}}(\textit{n-gram})}{\sum\limits_{S \in \{\textit{RefSum}\}} \sum\limits_{\textit{n-gram} \in S} \textit{Count}(\textit{n-gram})} \quad (11)$$

where n stands for the length of the n-gram, and *Count*$_{match}$*(n-gram)* is the maximum number of n-grams co-occurring in the candidate summary and the set of reference summaries. *Count(n-gram)* is the number of n-grams in the reference summaries.

We conduct our ROUGE experiments following the recommended standard in (Owczarzak et al.,

[1] http://www-nlpir.nist.gov/projects/duc/intro.html

[2] https://tartarus.org/martin/PorterStemmer/

2012; Hong et al., 2014)[3]. We compute ROUGE-2 recall with stemming and stopwords not removed, which provides the best agreement with manual evaluations. We also compute ROUGE-1 recall which has the highest recall of ability to identify the better summary in a pair, and ROUGE-4 recall which has the highest precision of ability to identify the better summary in a pair (Owczarzak et al., 2012).

5.3 Experimental Results

In the experiments, the parameters of our method are set as follows: the decay factor λ is 2, the maximum number of iteration M is 100, the number of starting iteration B is 30, the damping factor μ is 0.85 and the minimum error ε is 1E-30.

System	R-1	R-2	R-4
Cont. LexPageRank*	35.95	7.47	0.82
FreqSum	35.30	8.11	1.00
CLASSY 04	37.62	8.96	1.51
CLASSY 11	37.22	9.20	1.48
GRASSHOPPER*	37.20	9.26	1.50
DivRank*	37.60	9.30	1.52
GCD*	38.68	9.31	1.45
Submodular	39.18	9.35	1.39
APRW*	38.10	9.39	1.35
DPP	39.79	9.62	1.57
ICSISumm	38.41	9.78	1.73
AAPRW*	38.92	10.06	1.61
WFS-NMF	39.24	10.94	1.65

Table 5.2: System comparisons on task 2 of DUC 2004 (%). *: Graph-based ranking methods.

Table 5.2 shows the performance of our method and other eleven well-known systems on task 2 of DUC 2004 according to ROUGE-1,2,4 recall, sorted by ROUGE-2 recall in the ascending order. Some of the results are from (Hong et al., 2014). *Cont. LexPageRank* (Erkan and Radev, 2004) is a graph-based ranking method and a representative of traditional random walk approach. Here we employ the continuous version of LexPageRank. *FreqSum* (Nenkova et al., 2006) is a simple approach to approximate the importance of words with their probability in the input and then select sentences with high average word probability. *CLASSY 04* (Conroy et al., 2004) was the participant of the official DUC 2004 evaluation with the best evaluation score. It employs a Hidden Markov Model using topic signature feature and requires a linguistic preprocessing component. *CLASSY 11* (Conroy et al., 2011) is the successor of *CLASSY 04* and selects the non-redundant sentences using the non-negative matrix factorization algorithm. In the *Submodular* system (Lin and Bilmes, 2011), multi-document summarization is formulated as a submodular set function maximization problem. *DPP* (Lin and Bilmes, 2011) combines a sentence saliency model with a global diversity model encouraging non-overlapping information. *ICSISumm* (Gillick and Favre, 2009) aims at finding the globally optimal summary by formulating the summarization task in Integer Linear Programming. *WFS-NMF* (Wang et al., 2010) extends the non-negative matrix factorization algorithm and provides a good framework for weighting different terms and documents. *GRASSHOPPER*, *DivRank* and *GCD* are the three graph-based ranking models mentioned in Section 2. *APRW* and *AAPRW* are our methods. *APRW* is the method of affinity-preserving random walk described in Section 4.2 and *AAPRW* is the method of adjustable affinity-preserving random walk described in Section 4.3.

System	R-1	R-2	R-4
S17	31.81	4.98	0.47
S13	31.99	5.83	0.73
S16	35.00	7.31	1.04
Manifold Ranking	37.33	7.68	1.26
APRW	35.72	7.72	1.34
AAPRW	36.36	8.21	1.40

Table 5.3: System comparisons on task 3 of DUC 2003 (%).

Table 5.3 shows the evaluation results on task 3 of DUC 2003 according to ROUGE-1,2,4 recall, sorted also by ROUGE-2 recall in the ascending order. *S13*, *S16* and *S17* are the system IDs of the top performing systems in the official DUC 2003 evaluation, whose details are described in DUC publications (Zhou and Hovy, 2003; Chali et al., 2003). *Manifold Ranking* is the method proposed in (Wan et al., 2007) to make use of both the relationships among all sentences in the documents and the relationships between the given topic de-

[3] ROUGE-1.5.5 with the parameters: -n 4 -m -a -l 100 -x -c 95 -r 1000 -f A -p 0.5 -t 0

scription and the sentences. *APRW* and *AAPRW* are our methods.

From Tables 5.2 and 5.3, our method has the best ROUGE-2 score among all graph-based ranking methods for generic multi-document summarization, and it also has the best ROUGE-2 score for topic-focused multi-document summarization. *AAPRW* has the ROUGE-2 score 10.06% on DUC 2004 task 2, which is 0.28% higher than the best system *ICSISumm* reported by (Hong et al., 2014) and 1.1% higher than the official best system *CLASSY 04*. *WFS-NMF* has the overall best score on DUC 2004 task 2 due to the sentence feature selection and the weights on the document side, which is reported by (Wang et al., 2010; Alguliev et al., 2013). *AAPRW* has the ROUGE-2 score 8.21% on DUC 2003 task 3, which is 0.53% higher than *Manifold Ranking* and 0.9% higher than the official best system *S16*. In DUC 2004 *AAPRW* has 0.67% more ROUGE-2 score than *APRW* and the gap is 0.49% in DUC 2003, which proves the effectiveness of the adjustable transition matrix in the random walk process. It is worth mentioning that our method has the best ROUGE-4 score on the DUC 2003 topic-focused summarization task.

We conducted the two-sided Wilcoxon signed-rank tests between each pair of *AAPRW* and other methods. For the generic summarization in DUC 2004, our method provides a significant improvement over the official best system *CLASSY 04* on ROUGE-2 (with p-value lower than 0.05). For the query-focused summarization in DUC 2003, our method also provides a significant improvement over *S17*, *S13* and *S16* on ROUGE-2.

In order to further investigate the influences of the parameter in our proposed method, the damping factor μ is varied from 0 to 1. Figures 5.1 and 5.2 show the ROUGE-1 and ROUGE-2 recall curves of our method on the two data sets, respectively. We can see from the figures that the damping factor has an effect on the performance of multi-document summarization.

6 Conclusion and Future Work

In this paper we propose the adjustable affinity-preserving random walk for generic and topic-focused multi-document summarization, which deals with the saliency and diversity goals in a unified framework. Experiments demonstrate the effectiveness of our method.

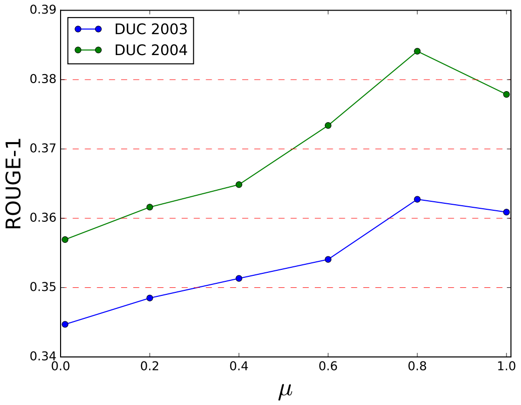

Figure 5.1: ROUGE-1 recall scores vs. μ of our method.

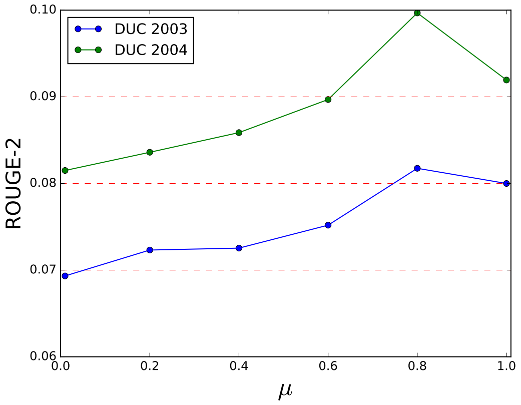

Figure 5.2: ROUGE-2 recall scores vs. μ of our method.

In the future work, we will focus on the self transition of adjustable affinity preserving random walk, which could be used to remove the redundancy between summary sentences.

A Mention-Ranking Model for Abstract Anaphora Resolution

Ana Marasović, Leo Born,[†] Juri Opitz,[†] and Anette Frank[†]

Abstract

Resolving abstract anaphora is an important, but difficult task for text understanding. Yet, with recent advances in representation learning this task becomes a more tangible aim. A central property of *abstract anaphora* is that it establishes a relation between the *anaphor* embedded in the *anaphoric sentence* and its (typically non-nominal) *antecedent*. We propose a mention-ranking model that learns how abstract anaphors relate to their antecedents with an LSTM-Siamese Net. We overcome the lack of training data by generating artificial anaphoric sentence–antecedent pairs. Our model outperforms state-of-the-art results on *shell noun resolution*. We also report first benchmark results on an abstract anaphora subset of the ARRAU corpus. This corpus presents a greater challenge due to a mixture of nominal and pronominal anaphors and a greater range of confounders. We found model variants that outperform the baselines for nominal anaphors, without training on individual anaphor data, but still lag behind for pronominal anaphors. Our model selects syntactically plausible candidates and – if disregarding syntax – discriminates candidates using deeper features.

1 Introduction

Current research in anaphora (or coreference) resolution is focused on resolving noun phrases referring to concrete objects or entities in the real world, which is arguably the most frequently occurring type. Distinct from these are diverse types of *abstract* anaphora (AA) (Asher, 1993) where reference is made to propositions, facts, events or properties. An example is given in (1) below.[1]

While recent approaches address the resolution of selected abstract *shell nouns* (Kolhatkar and Hirst, 2014), we aim to resolve a wide range of abstract anaphors, such as the NP *this trend* in (1), as well as pronominal anaphors (*this*, *that*, or *it*).

Henceforth, we refer to a sentence that contains an abstract anaphor as *the anaphoric sentence (AnaphS)*, and to a constituent that the anaphor refers to as *the antecedent (Antec)* (cf. (1)).

(1) Ever-more powerful desktop computers, designed with one or more microprocessors as their ”brains”, are expected to increasingly take on functions carried out by more expensive minicomputers and mainframes. ”[$_{Antec}$ ***The guys that make traditional hardware are really being obsoleted by microprocessor-based machines***]”, said Mr. Benton. [$_{AnaphS}$ As a result of ***this trend***$_{AA}$, longtime powerhouses HP, IBM and Digital Equipment Corp. are scrambling to counterattack with microprocessor-based systems of their own.]

A major obstacle for solving this task is the lack of sufficient amounts of annotated training data. We propose a method to generate large amounts of training instances covering a wide range of abstract anaphor types. This enables us to use neural methods which have shown great success in related tasks: coreference resolution (Clark and Manning, 2016a), textual entailment (Bowman et al., 2016), learning textual similarity (Mueller and Thyagarajan, 2016), and discourse relation sense classification (Rutherford et al., 2017).

Our model is inspired by the mention-ranking model for coreference resolution (Wiseman et al., 2015; Clark and Manning, 2015, 2016a,b) and combines it with a Siamese Net (Mueller and Thyagarajan, 2016), (Neculoiu et al., 2016) for

[†] Leo Born, Juri Opitz and Anette Frank contributed equally to this work.

[1] Example drawn from ARRAU (Uryupina et al., 2016).

Proceedings of the 2017 Conference on Empirical Methods in Natural Language Processing, pages 221–232
Copenhagen, Denmark, September 7–11, 2017.

learning similarity between sentences. Given an *anaphoric sentence* (AntecS in (1)) and a candidate antecedent (any constituent in a given context, e.g. *being obsoleted by microprocessor-based machines* in (1)), the LSTM-Siamese Net learns representations for the candidate and the anaphoric sentence in a shared space. These representations are combined into a joint representation used to calculate a score that characterizes the relation between them. The learned score is used to select the highest-scoring antecedent candidate for the given anaphoric sentence and hence its anaphor. We consider one anaphor at a time and provide the embedding of the *context of the anaphor* and the embedding of the *head of the anaphoric phrase* to the input to characterize each individual anaphor – similar to the encoding proposed by Zhou and Xu (2015) for individuating multiply occurring predicates in SRL. With deeper inspection we show that the model learns a relation between the anaphor in the anaphoric sentence and its antecedent. Fig. 1 displays our architecture.

In contrast to other work, our method for generating training data is not confined to specific types of anaphora such as shell nouns (Kolhatkar and Hirst, 2014) or anaphoric connectives (Stede and Grishina, 2016). It produces large amounts of instances and is easily adaptable to other languages. This enables us to build a robust, knowledge-lean model for abstract anaphora resolution that easily extends to multiple languages.

We evaluate our model on the shell noun resolution dataset of Kolhatkar et al. (2013b) and show that it outperforms their state-of-the-art results. Moreover, we report results of the model (trained on our newly constructed dataset) on unrestricted abstract anaphora instances from the ARRAU corpus (Poesio and Artstein, 2008; Uryupina et al., 2016). To our knowledge this provides the first state-of-the-art benchmark on this data subset.

Our TensorFlow[2] implementation of the model and scripts for data extraction are available at: `https://github.com/amarasovic/neural-abstract-anaphora`.

2 Related and prior work

Abstract anaphora has been extensively studied in linguistics and shown to exhibit specific properties in terms of semantic antecedent types, their degrees of abstractness, and general discourse properties (Asher, 1993; Webber, 1991). In contrast to nominal anaphora, abstract anaphora is difficult to resolve, given that agreement and lexical match features are not applicable. Annotation of abstract anaphora is also difficult for humans (Dipper and Zinsmeister, 2012), and thus, only few smaller-scale corpora have been constructed. We evaluate our models on a subset of the ARRAU corpus (Uryupina et al., 2016) that contains abstract anaphors and the shell noun corpus used in Kolhatkar et al. (2013b).[3] We are not aware of other freely available abstract anaphora datasets.

Little work exists for the **automatic resolution of abstract anaphora**. Early work (Eckert and Strube, 2000; Strube and Müller, 2003; Byron, 2004; Müller, 2008) has focused on spoken language, which exhibits specific properties. Recently, **event coreference** has been addressed using feature-based classifiers (Jauhar et al., 2015; Lu and Ng, 2016). Event coreference is restricted to a subclass of *events*, and usually focuses on coreference between verb (phrase) and noun (phrase) mentions of similar abstractness levels (e.g. *purchase – acquire*) with no special focus on (pro)nominal anaphora. Abstract anaphora typically involves a full-fledged clausal antecedent that is referred to by a highly abstract (pro)nominal anaphor, as in (1).

Rajagopal et al. (2016) proposed a model for resolution of events in biomedical text that refer to a single or multiple clauses. However, instead of selecting the correct antecedent clause(s) (our task) for a given event, their model is restricted to classifying the event into six abstract categories: this these *changes, responses, analysis, context, finding, observation*, based on its surrounding context. While related, their task is not comparable to the full-fledged abstract anaphora resolution task, since the events to be classified are known to be coreferent and chosen from a set of restricted abstract types.

More related to our work is Anand and Hardt (2016) who present an antecedent ranking account for **sluicing** using classical machine learning based on a small training dataset. They employ features modeling distance, containment, discourse structure, and – less effectively – content and lexical correlates.[4]

Closest to our work is Kolhatkar et al. (2013b)

[2] Abadi et al. (2015)

[3] We thank the authors for making their data available.

[4] Their data set was not publicized.

(KZH13) and Kolhatkar and Hirst (2014) (KH14) on **shell noun resolution**, using classical machine learning techniques. Shell nouns are abstract nouns, such as *fact*, *possibility*, or *issue*, which can only be interpreted jointly with their *shell* content (their embedded clause as in (2) or antecedent as in (3)). KZH13 refer to shell nouns whose antecedent occurs in the prior discourse as *anaphoric shell nouns* (ASNs) (cf. (3)), and *cataphoric shell nouns* (CSNs) otherwise (cf. (2)).[5]

(2) Congress has focused almost solely on ***the fact*** that [*special education is expensive - and that it takes away money from regular education.*]

(3) Environmental Defense [...] notes that [$_{Antec}$ *Mowing the lawn with a gas mower produces as much pollution [...] as driving a car 172 miles.*] [$_{AnaphS}$ ***This fact*** may [...] explain the recent surge in the sales of [...] old-fashioned push mowers [...]].

KZH13 presented an approach for resolving six typical shell nouns following the observation that CSNs are easy to resolve based on their syntactic structure alone, and the assumption that ASNs share linguistic properties with their embedded (CSN) counterparts. They manually developed rules to identify the embedded clause (i.e. cataphoric antecedent) of CSNs and trained SVM^{rank} (Joachims, 2002) on such instances. The trained SVM^{rank} model is then used to resolve ASNs. KH14 generalized their method to be able to create training data for any given shell noun, however, their method heavily exploits the specific properties of shell nouns and does not apply to other types of abstract anaphora.

Stede and Grishina (2016) study a related phenomenon for German. They examine inherently anaphoric connectives (such as *demzufolge – according to which*) that could be used to access their abstract antecedent in the immediate context. Yet, such connectives are restricted in type, and the study shows that such connectives are often ambiguous with nominal anaphors and require sense disambiguation. We conclude that they cannot be easily used to acquire antecedents automatically.

In our work, we explore a different direction: we construct artificial training data using a general pattern that identifies embedded sentence constituents, which allows us to extract relatively secure training data for abstract anaphora that captures a wide range of anaphora-antecedent relations, and apply this data to train a model for the resolution of unconstrained abstract anaphora.

Recent work in entity coreference resolution has proposed powerful neural network-based models that we will adapt to the task of abstract anaphora resolution. Most relevant for our task is the **mention-ranking neural coreference model** proposed in Clark and Manning (2015), and their improved model in Clark and Manning (2016a), which integrates a loss function (Wiseman et al., 2015) which learns distinct feature representations for anaphoricity detection and antecedent ranking.

Siamese Nets distinguish between similar and dissimilar pairs of samples by optimizing a loss over the metric induced by the representations. It is widely used in vision (Chopra et al., 2005), and in NLP for semantic similarity, entailment, query normalization and QA (Mueller and Thyagarajan, 2016; Neculoiu et al., 2016; Das et al., 2016).

3 Mention-Ranking Model

Given an anaphoric sentence s with a marked anaphor (mention) and a candidate antecedent c, the mention-ranking (MR) model assigns the pair (c, s) a score, using representations produced by an LSTM-Siamese Net. The highest-scoring candidate is assigned to the marked anaphor in the anaphoric sentence. Fig. 1 displays the model.

We learn representations of an anaphoric sentence s and a candidate antecedent c using a bi-directional Long Short-Term Memory (Hochreiter and Schmidhuber, 1997; Graves and Schmidhuber, 2005). One bi-LSTM is applied to the anaphoric sentence s and a candidate antecedent c, hence the term siamese. Each word is represented with a vector $\boldsymbol{w_i}$ constructed by concatenating embeddings of the word, of the context of the anaphor (average of embeddings of the anaphoric phrase, the previous and the next word), of the head of the anaphoric phrase[6], and, finally, an embedding of the constituent tag of the candidate, or the S constituent tag if the word is in the anaphoric sentence. For each sequence s or c, the word vectors $\boldsymbol{w_i}$ are sequentially fed into the bi-LSTM, which produces outputs from the forward pass, $\overrightarrow{\boldsymbol{h_i}}$, and outputs $\overleftarrow{\boldsymbol{h_i}}$ from the backward pass. The final output of the i-th word is defined as $\boldsymbol{h_i} = [\overleftarrow{\boldsymbol{h_i}}; \overrightarrow{\boldsymbol{h_i}}]$. To get a representation of the full sequence, $\boldsymbol{h_s}$ or $\boldsymbol{h_c}$, all outputs are averaged, except for those that correspond to padding tokens.

[5] We follow this terminology for their approach and data representation.

[6] Henceforth we refer to it as embedding of the anaphor.

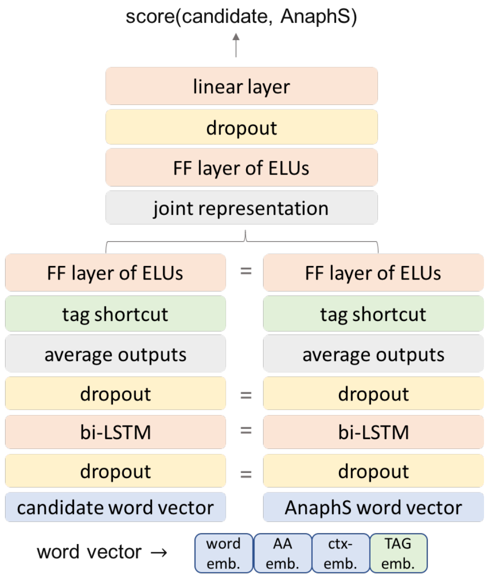

Figure 1: Mention-ranking architecture for abstract anaphora resolution (MR-LSTM).

To prevent forgetting the constituent tag of the sequence, we concatenate the corresponding tag embedding with $\boldsymbol{h_s}$ or $\boldsymbol{h_c}$ (we call this a *shortcut* for the tag information). The resulting vector is fed into a feed-forward layer of exponential linear units (ELUs) (Clevert et al., 2016) to produce the final representation $\tilde{\boldsymbol{h}}_{\boldsymbol{s}}$ or $\tilde{\boldsymbol{h}}_{\boldsymbol{c}}$ of the sequence.

From $\tilde{\boldsymbol{h}}_{\boldsymbol{c}}$ and $\tilde{\boldsymbol{h}}_{\boldsymbol{s}}$ we compute a vector $\boldsymbol{h_{c,s}} = [|\tilde{\boldsymbol{h}}_{\boldsymbol{c}} - \tilde{\boldsymbol{h}}_{\boldsymbol{s}}|; \tilde{\boldsymbol{h}}_{\boldsymbol{c}} \odot \tilde{\boldsymbol{h}}_{\boldsymbol{s}}]$ (Tai et al., 2015), where $|–|$ denotes the absolute values of the element-wise subtraction, and $\odot$ the element-wise multiplication. Then $\boldsymbol{h_{c,s}}$ is fed into a feed-forward layer of ELUs to obtain the final joint representation, $\tilde{\boldsymbol{h}}_{\boldsymbol{c,s}}$, of the pair (c, s). Finally, we compute the score for the pair (c, s) that represents relatedness between them, by applying a single fully connected linear layer to the joint representation:

$$score(c, s) = W\tilde{\boldsymbol{h}}_{\boldsymbol{c,s}} + b \in \mathbb{R}, \qquad (1)$$

where W is a $1 \times d$ weight matrix, and d the dimension of the vector $\tilde{\boldsymbol{h}}_{\boldsymbol{c,s}}$.

We train the described mention-ranking model with the max-margin training objective from Wiseman et al. (2015), used for the antecedent ranking subtask. Suppose that the training set $\mathcal{D} = \{(a_i, s_i, \mathcal{T}(a_i), \mathcal{N}(a_i)\}_{i=1}^{n}$, where a_i is the i-th abstract anaphor, s_i the corresponding anaphoric sentence, $\mathcal{T}(a_i)$ the set of antecedents of a_i and $\mathcal{N}(a_i)$ the set of candidates that are not antecedents (negative candidates). Let $\tilde{t}_i = \arg\max_{t\in\mathcal{T}(a_i)} score(t_i, s_i)$ be the highest scoring antecedent of a_i. Then the loss is given by

$$\sum_{i=1}^{n} \max(0, \max_{c\in\mathcal{N}(a_i)} \{1+score(c, s_i)-score(\tilde{t}_i, s_i)\}).$$

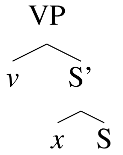

Figure 2: A general pattern for artificially creating anaphoric sentence–antecedent pairs.

4 Training data construction

We create large-scale training data for abstract anaphora resolution by exploiting a common construction, consisting of a verb with an embedded sentence (complement or adverbial) (cf. Fig. 2). We detect this pattern in a parsed corpus, 'cut off' the S′ constituent and replace it with a suitable anaphor to create the anaphoric sentence (AnaphS), while S yields the antecedent (Antec). This method covers a wide range of anaphora-antecedent constellations, due to diverse semantic or discourse relations that hold between the clause hosting the verb and the embedded sentence.

First, the pattern applies to verbs that embed sentential arguments. In (4), the verb *doubt* establishes a specific semantic relation between the embedding sentence and its sentential complement.

(4) He doubts [$_{S'}$ [$_S$ a Bismarckian super state will emerge that would dominate Europe], but warns of "a risk of profound change in the [..] European Community from a Germany that is too strong, even if democratic"].

From this we extract the artificial antecedent *A Bismarckian super state will emerge that would dominate Europe*, and its corresponding anaphoric sentence *He doubts* ***this****, but warns of "a risk of profound change ... even if democratic"*, which we construct by randomly choosing one of a predefined set of appropriate anaphors (here: *this, that, it*), cf. Table 1. The second row in Table 1 is used when the head of S′ is filled by an overt complementizer (*doubts that*), as opposed to (4). The remaining rows in Table 1 apply to adverbial clauses of different types.

Adverbial clauses encode specific discourse relations with their embedding sentences, often indicated by their conjunctions. In (5), for example, the causal conjunction **as** relates a cause (embedded sentence) and its effect (embedding sentence):

type	head of S′	possible anaphoric phrase
empty	∅	this, that
general	that, this	that, this
causal	because, as	therefore, because of this/that,
temporal	while, since, etc.	during this/that
conditional	if, whether	if this/that is true

Table 1: S′-heads and the anaphoric types and phrases they induce (most frequent interpretation).

(5) There is speculation that property casualty firms will sell even more munis [$_{S'}$ **as** [$_S$ they scramble to raise cash to pay claims related to Hurricane Hugo [..]]].

We randomly replace causal conjunctions *because, as* with appropriately adjusted anaphors, e.g. *because of that*, *due to this* or *therefore* that make the causal relation explicit in the anaphor.[7]

Compared to the shell noun corpus of KZH13, who made use of a carefully constructed set of extraction patterns, a downside of our method is that our artificially created antecedents are uniformly of type S. However, the majority of abstract anaphora antecedents found in the existing datasets are of type S. Also, our models are intended to induce semantic representations, and so we expect syntactic form to be less critical, compared to a feature-based model.[8] Finally, the general extraction pattern in Fig. 2, covers a much wider range of anaphoric types.

Using this method we generated a dataset of artificial anaphoric sentence–antecedent pairs from the WSJ part of the PTB Corpus (Marcus et al., 1993), automatically parsed using the Stanford Parser (Klein and Manning, 2003).

5 Experimental setup

5.1 Datasets

We evaluate our model on two types of anaphora: (a) *shell noun anaphora* and (b) (pro)nominal abstract anaphors extracted from ARRAU.

a. Shell noun resolution dataset. For comparability we train and evaluate our model for *shell noun resolution*, using the original training (CSN) and test (ASN) corpus of Kolhatkar et al. (2013a,b).[9] We follow the data preparation and evaluation protocol of Kolhatkar et al. (2013b) (**KZH13**).

The **CSN corpus** was constructed from the NYT corpus using manually developed patterns to identify the antecedent of cataphoric shell nouns (CSNs). In KZH13, all syntactic constituents of the sentence that contains both the CSN and its antecedent were considered as candidates for training a ranking model. Candidates that differ from the antecedent in only one word or one word and punctuation were as well considered as antecedents[10]. To all other candidates we refer to as *negative* candidates. For every shell noun, KZH13 used the corresponding part of the CSN data to train SVM^{rank}.

The **ASN corpus** serves as the test corpus. It was also constructed from the NYT corpus, by selecting anaphoric instances with the pattern "*this* ⟨*shell noun*⟩" for all covered shell nouns. For validation, Kolhatkar et al. (2013a) crowdsourced annotations for the sentence which contains the antecedent, which KZH13 refer to as a *broad region*. Candidates for the antecedent were obtained by using all syntactic constituents of the broad region as candidates and ranking them using the SVM^{rank} model trained on the CSN corpus. The top 10 ranked candidates were presented to the crowd workers and they chose the best answer that represents the ASN antecedent. The workers were encouraged to select *None* when they did not agree with any of the displayed answers and could provide information about how satisfied they were with the displayed candidates. We consider this dataset as gold, as do KZH13, although it may be biased towards the offered candidates.[11]

b. Abstract anaphora resolution data set. We use the automatically constructed data from the WSJ corpus (Section 4) for training.[12] Our test data for unrestricted abstract anaphora resolution is obtained from the **ARRAU corpus** (Uryupina et al., 2016). We extracted all abstract anaphoric instances from the WSJ part of ARRAU that are marked with the category *abstract* or *plan*,[13] and call the subcorpus **ARRAU-AA**.

[7] In case of ambiguous conjunctions (e.g. *as* interpreted as causal or temporal), we generally choose the most frequent interpretation.

[8] This also alleviates problems with languages like German, where (non-)embedded sentences differ in surface position of the finite verb. We can either adapt the order or ignore it, when producing anaphoric sentence – antecedent pairs.

[9] We thank the authors for providing the available data.

[10] We obtained this information from the authors directly.

[11] The authors provided us with the workers' annotations of the broad region, antecedents chosen by the workers and links to the NYT corpus. The extraction of the anaphoric sentence and the candidates had to be redone.

[12] We excluded any documents that are part of ARRAU.

[13] ARRAU distinguishes *abstract* anaphors and (mostly) pronominal anaphors referring to an action or plan, as *plan*.

		shell noun		abstract anaphora	
		CSN train	**ASN** test	**artifical** train	**ARRAU-AA** test
# shell nouns / anaphors		114492	2303	8527	600
median # of tokens	Antec	12.75	13.87	11	20.5
	AnaphS	11.5	24	19	28
median #	Antec	2	4.5	2	1
	negatives	44.5	39	15	48
#	nominal	114492	2303	0	397
	pronominal	0	0	8527	203

Table 2: Data statistics. For the ASN and CSN we report statistics over all shell nouns, but classifiers are trained independently.

Candidates extraction. Following KZH13, for every anaphor we create a list of candidates by extracting all syntactic constituents from sentences which contain antecedents. Candidates that differ from antecedents in only one word, or one word and punctuation, were as well considered as antecedents. Constituents that are not antecedents are considered as negative candidates.

Data statistics. Table 2 gives statistics of the datasets: the number of anaphors (row 1), the median length (in tokens) of antecedents (row 2), the median length (in tokens) for all anaphoric sentences (row 3), the median of the number of antecedents and candidates that are not antecedents (negatives) (rows 4–5), the number of pronominal and nominal anaphors (rows 6–7). Both training sets, artificial and CSN, have only one possible antecedent for which we accept two minimal variants differing in only one word or one word and punctuation. On the contrary, both test sets by design allow annotation of more than one antecedent that differ in more than one word. Every anaphor in the artificial training dataset is pronominal, whereas anaphors in CSN and ASN are nominal only. ARRAU-AA has a mixture of nominal and pronominal anaphors.

Data pre-processing. Other details can be found in Supplementary Materials.

5.2 Baselines and evaluation metrics

Following KZH13, we report *success@n* (*s@n*), which measures whether the antecedent, or a candidate that differs in one word[14], is in the first n ranked candidates, for $n \in \{1, 2, 3, 4\}$. Additionally, we report the preceding sentence baseline (PS$_{BL}$) that chooses the previous sentence for the antecedent and *TAGbaseline* (TAG$_{BL}$) that randomly chooses a candidate with the constituent tag label in {S, VP, ROOT, SBAR}. For TAG$_{BL}$ we report the average of 10 runs with 10 fixed seeds. PS$_{BL}$ always performs worse than the KZH13 model on the ASN, so we report it only for ARRAU-AA.

5.3 Training details for our models

Hyperparameters tuning. We recorded performance with manually chosen HPs and then tuned HPs with Tree-structured Parzen Estimators (TPE) (Bergstra et al., 2011)[15]. TPE chooses HPs for the next (out of 10) trails on the basis of the $s@1$ score on the devset. As devsets we employ the ARRAU-AA corpus for shell noun resolution and the ASN corpus for unrestricted abstract anaphora resolution. For each trial we record performance on the test set. We report the best test $s@1$ score in 10 trials if it is better than the scores from default HPs. The default HPs and prior distributions for HPs used by TPE are given below. The (exact) HPs we used can be found in Supplementary Materials.

Input representation. To construct word vectors $\boldsymbol{w_i}$ as defined in Section 3, we used 100-dim. GloVe word embeddings pre-trained on the Gigaword and Wikipedia (Pennington et al., 2014), and did not fine-tune them. Vocabulary was built from the words in the training data with frequency in $\{3, \mathcal{U}(1, 10)\}$, and OOV words were replaced with an *UNK* token. Embeddings for tags are initialized with values drawn from the uniform distribution $\mathcal{U}\big(-\frac{1}{\sqrt{d+t}}, \frac{1}{\sqrt{d+t}}\big)$, where t is the number of tags[16] and $d \in \{50, \textit{qlog-}\mathcal{U}(30, 100)\}$ the size of the tag embeddings.[17] We experimented with removing embeddings for tag, anaphor and context.

Weights initialization. The size of the LSTMs hidden states was set to $\{100, \textit{qlog-}\mathcal{U}(30, 150)\}$. We initialized the weight matrices of the LSTMs with random orthogonal matrices (Henaff et al., 2016), all other weight matrices with the initialization proposed in He et al. (2015). The first feed-forward layer size is set to a value in $\{400, \textit{qlog-}\mathcal{U}(200, 800)\}$, the second to a value in $\{1024, \textit{qlog-}\mathcal{U}(400, 2000)\}$. Forget biases in the LSTM were initialized with 1s (Józefowicz et al., 2015), all other biases with 0s.

[14] We obtained this information in personal communication with one of the authors.

[15] https://github.com/hyperopt/hyperopt.

[16] We used a list of tags obtained from the Stanford Parser.

[17] *qlog-*$\mathcal{U}$ is the so-called qlog-uniform distribution.

Table 3: Shell noun resolution results.

Optimization. We trained our model in mini-batches using Adam (Kingma and Ba, 2015) with the learning rate of 10^{-4} and maximal batch size 64. We clip gradients by global norm (Pascanu et al., 2013), with a clipping value in $\{1.0, \mathcal{U}(1, 100)\}$. We train for 10 epochs and choose the model that performs best on the devset.

Regularization. We used the l_2-regularization with $\lambda \in \{10^{-5}, log\text{-}\mathcal{U}(10^{-7}, 10^{-2})\}$. Dropout (Srivastava et al., 2014) with a keep probability $k_p \in \{0.8, \mathcal{U}(0.5, 1.0)\}$ was applied to the outputs of the LSTMs, both feed-forward layers and optionally to the input with $k_p \in \mathcal{U}(0.8, 1.0)$.

6 Results and analysis

6.1 Results on shell noun resolution dataset

Table 3 provides the results of the mention-ranking model (MR-LSTM) on the ASN corpus using default HPs. Column 2 states which model produced the results: KZH13 refers to the best reported results in Kolhatkar et al. (2013b) and TAG$_{BL}$ is the baseline described in Section 5.2.

In terms of $s@1$ score, MR-LSTM outperforms both KZH13's results and TAG$_{BL}$ without even necessitating HP tuning. For the outlier *reason* we tuned HPs (on ARRAU-AA) for different variants of the architecture: the full architecture, without embedding of the context of the anaphor (ctx), of the anaphor (aa), of both constituent tag embedding and shortcut (tag,cut), dropping only the shortcut (cut), using only word embeddings as input (ctx,aa,tag,cut), without the first (ffl1) and second (ffl2) layer. From Table 4 we observe: (1) with HPs tuned on ARRAU-AA, we obtain results well beyond KZH13, (2) all ablated model variants perform worse than the full model, (3) a large performance drop when omitting syntactic information (tag,cut) suggests that the model makes good use of it. However, this could also be due to a bias in the tag distribution, given that all candidates stem from the single sentence that contains antecedents. The median occurrence of the S tag among both antecedents and negative candidates is 1, thus the model could achieve 50.00 $s@1$ by picking S-type constituents, just as TAG$_{BL}$ achieves 42.02 for *reason* and 48.66 for *possibility*.

						reason			
ctx	aa	tag	cut	ffl1	ffl2	s@1	s@2	s@ 3	s@ 4
✓	✓	✓	✓	✓	✓	**87.78**	**91.63**	**93.44**	**93.89**
✗	✓	✓	✓	✓	✓	85.97	87.56	89.14	89.82
✓	✗	✓	✓	✓	✓	86.65	88.91	91.18	91.40

✓	✓	✓	✗	✓	✓	85.52	88.24	89.59	90.05
✗	✗	✗	✗	✓	✓	66.97	80.54	85.75	88.24
✓	✓	✓	✓	✗	✓	87.56	91.63	92.76	94.12
✓	✓	✓	✓	✓	✗	85.97	88.69	89.14	90.05

Table 4: Architecture ablation for *reason*.

Tuning of HPs gives us insight into how different model variants cope with the task. For example, without tuning the model with and without syntactic information achieves 71.27 and 19.68 (not shown in table) $s@1$ score, respectively, and with tuning: 87.78 and 68.10. Performance of 68.10 $s@1$ score indicates that the model is able to learn without syntactic guidance, contrary to the 19.68 $s@1$ score before tuning.

6.2 Results on the ARRAU corpus

Table 5 shows the performance of different variants of the MR-LSTM with HPs tuned on the ASN corpus (always better than the default HPs), when evaluated on 3 different subparts of the ARRAU-AA: all 600 abstract anaphors, 397 nominal and 203 pronominal ones. HPs were tuned on the ASN corpus for every variant separately, without shuffling of the training data. For the best performing variant, without syntactic information (tag,cut), we report the results with HPs that yielded the best $s@1$ test score for all anaphors (row 4), when training with those HPs on shuffled training data (row 5), and with HPs that yielded the best $s@1$

						all (600)				nominal (397)				pronominal (203)

score for pronominal anaphors (row 6).

The MR-LSTM is more successful in resolving nominal than pronominal anaphors, although the training data provides only pronominal ones. This indicates that resolving pronominal abstract anaphora is harder compared to nominal abstract anaphora, such as shell nouns. Moreover, for shell noun resolution in KZH13's dataset, the MR-LSTM achieved s@1 scores in the range 76.09–93.14, while the best variant of the model achieves 51.89 s@1 score for nominal anaphors in ARRAU-AA. Although lower performance is expected, since we do not have specific training data for individual nominals in ARRAU-AA, we suspect that the reason for better performance for shell noun resolution in KZH13 is due to a larger number of positive candidates in ASN (cf. Table 2, rows: antecedents/negatives).

We also note that HPs that yield good performance for resolving nominal anaphors are not necessarily good for pronominal ones (cf. rows 4–6 in Table 5). Since the TPE tuner was tuned on the nominal-only ASN data, this suggest that it would be better to tune HPs for pronominal anaphors on a different dataset or stripping the nouns in ASN.

Contrary to shell noun resolution, omitting syntactic information boosts performance in ARRAU-AA. We conclude that when the model is provided with syntactic information, it learns to pick S-type candidates, but does not continue to learn deeper features to further distinguish them or needs more data to do so. Thus, the model is not able to point to exactly one antecedent, resulting in a lower s@1 score, but does well in picking a few good candidates, which yields good s@2-4 scores. This is what we can observe from row 2 vs. row 6 in Table 5: the MR-LSTM without context embedding (ctx) achieves a comparable s@2 score with the variant that omits syntactic information, but better s@3-4 scores. Further, median occurrence of tags not in {S, VP, ROOT, SBAR} among top-4 ranked candidates is 0 for the full architecture, and 1 when syntactic information is omitted. The need for discriminating capacity of the model is more emphasized in ARRAU-AA, given that the median occurrence of S-type candidates among negatives is 2 for nominal and even 3 for pronominal anaphors, whereas it is 1 for ASN. This is in line with the lower TAG$_{BL}$ in ARRAU-AA.

Finally, not all parts of the architecture contribute to system performance, contrary to what is observed for *reason*. For nominal anaphors, the anaphor (aa) and feed-forward layers (ffl1, ffl2) are beneficial, for pronominals only the second ffl.

6.3 Exploring the model

We finally analyze deeper aspects of the model: (1) whether a learned representation between the anaphoric *sentence* and an antecedent establishes a relation between *a specific anaphor we want to resolve* and the antecedent and (2) whether the max-margin objective enforces a separation of the joint representations in the shared space.

(1) We claim that by providing embeddings of both the anaphor and the sentence containing the anaphor we ensure that the learned relation between antecedent and anaphoric sentence is dependent on the anaphor under consideration. Fig. 3 illustrates the heatmap for an anaphoric sentence with two anaphors. The i-th column of the heatmap corresponds to absolute differences between the output of the bi-LSTM for the i-th word in the anaphoric sentence when the first vs. second anaphor is resolved. Stronger color indi-

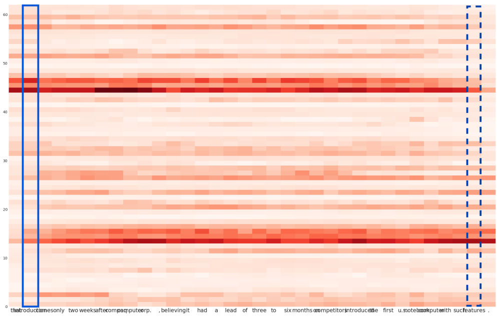

Figure 3: Visualizing the differences between outputs of the bi-LSTM over time for an anaphoric sentence containing two anaphors.

cates larger difference, the blue rectangle represents the column for the head of the first anaphor, the dashed blue rectangle the column for the head of the second anaphor. Clearly, the representations differ when the first vs. second anaphor is being resolved and consequently, joint representations with an antecedent will differ too.

(2) It is known that the max-margin objective separates the best-scoring positive candidate from the best-scoring negative candidate. To investigate what the objective accomplishes in the MR-LSTM model, we analyze the joint representations of candidates and the anaphoric sentence (i.e., outputs of ffl2) after training. For a randomly chosen instance from ARRAU-AA, we plotted outputs of ffl2 with the tSNE algorithm (v.d. Maaten and Hinton, 2008). Fig. 4 illustrates that the joint representation of the first ranked candidate and the anaphoric sentence is clearly separated from other joint representations. This shows that the max-margin objective separates the best scoring positive candidate from the best scoring negative candidate by separating their respective joint representations with the anaphoric sentence.

7 Conclusions

We presented a neural mention-ranking model for the resolution of unconstrained abstract anaphora, and applied it to two datasets with different types of abstract anaphora: the shell noun dataset and a subpart of ARRAU with (pro)nominal abstract anaphora of any type. To our knowledge this work is the first to address the unrestricted abstract anaphora resolution task with a neural network. Our model also outperforms state-of-the-art results on the shell noun dataset.

In this work we explored the use of purely artificially created training data and how far it can bring us. In future work, we plan to investigate mixtures of (more) artificial and natural data from different sources (e.g. ASN, CSN).

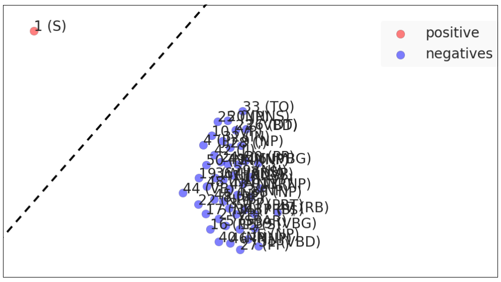

Figure 4: tSNE projection of outputs of ffl2. Labels are the predicted ranks and the constituent tag.

On the more challenging ARRAU-AA, we found model variants that surpass the baselines for the entire and the nominal part of ARRAU-AA, although we do not train models on individual (nominal) anaphor training data like the related work for shell noun resolution. However, our model still lags behind for pronominal anaphors. Our results suggest that models for nominal and pronominal anaphors should be learned independently, starting with tuning of HPs on a more suitable devset for pronominal anaphors.

We show that the model can exploit syntactic information to select plausible candidates, but that when it does so, it does not learn how to distinguish candidates of equal syntactic type. By contrast, if the model is not provided with syntactic information, it learns deeper features that enable it to pick the correct antecedent without narrowing down the choice of candidates. Thus, in order to improve performance, the model should be enforced to first select reasonable candidates and then continue to learn features to distinguish them, using a larger training set that is easy to provide.

In future work we will design such a model, and offer it candidates chosen not only from sentences containing the antecedent, but the larger context.

Abstract

We present a novel neural model *HyperVec* to learn hierarchical embeddings for hypernymy detection and directionality. While previous embeddings have shown limitations on prototypical hypernyms, *HyperVec* represents an unsupervised measure where embeddings are learned in a specific order and capture the hypernym–hyponym distributional hierarchy. Moreover, our model is able to generalize over unseen hypernymy pairs, when using only small sets of training data, and by mapping to other languages. Results on benchmark datasets show that *HyperVec* outperforms both state-of-the-art unsupervised measures and embedding models on hypernymy detection and directionality, and on predicting graded lexical entailment.

1 Introduction

Hypernymy represents a major semantic relation and a key organization principle of semantic memory (Miller and Fellbaum, 1991; Murphy, 2002). It is an asymmetric relation between two terms, a hypernym (superordinate) and a hyponym (subordiate), as in *animal–bird* and *flower–rose*, where the hyponym necessarily implies the hypernym, but not vice versa. From a computational point of view, automatic hypernymy detection is useful for NLP tasks such as taxonomy creation (Snow et al., 2006; Navigli et al., 2011), recognizing textual entailment (Dagan et al., 2013), and text generation (Biran and McKeown, 2013), among many others.

Two families of approaches to identify and discriminate hypernyms are predominent in NLP, both of them relying on word vector representations. ***Distributional count approaches*** make use of either directionally unsupervised measures or of supervised classification methods. Unsupervised measures exploit the *distributional inclusion hypothesis* (Geffet and Dagan, 2005; Zhitomirsky-Geffet and Dagan, 2009), or the *distributional informativeness hypothesis* (Santus et al., 2014; Rimell, 2014). These measures assign scores to semantic relation pairs, and hypernymy scores are expected to be higher than those of other relation pairs. Typically, Average Precision (AP) (Kotlerman et al., 2010) is applied to rank and distinguish between the predicted relations. Supervised classification methods represent each pair of words as a single vector, by using the concatenation or the element-wise difference of their vectors (Baroni et al., 2012; Roller et al., 2014; Weeds et al., 2014). The resulting vector is fed into a Support Vector Machine (SVM) or into Logistic Regression (LR), to predict hypernymy. Across approaches, Shwartz et al. (2017) demonstrated that there is no single unsupervised measure which consistently deals well with discriminating hypernymy from other semantic relations. Furthermore, Levy et al. (2015) showed that supervised methods memorize *prototypical hypernyms* instead of *learning* a relation between two words.

Approaches of hypernymy-specific embeddings utilize neural models to learn vector representations for hypernymy. Yu et al. (2015) proposed a supervised method to learn term embeddings for hypernymy identification, based on pre-extracted hypernymy pairs. Recently, Tuan et al. (2016) proposed a dynamic weighting neural model to learn term embeddings in which the model encodes not only the information of hypernyms vs. hyponyms, but also their contextual information. The performance of this family of models is typically evaluated by using an SVM to discriminate hypernymy from other relations.

Proceedings of the 2017 Conference on Empirical Methods in Natural Language Processing, pages 233–243
Copenhagen, Denmark, September 7–11, 2017.

In this paper, we propose a novel neural model *HyperVec* to learn hierarchical embeddings that **(i)** discriminate hypernymy from other relations (**detection task**), and **(ii)** distinguish between the hypernym and the hyponym in a given hypernymy relation pair (**directionality task**). Our model learns to strengthen the distributional similarity of hypernym pairs in comparison to other relation pairs, by moving hyponym and hypernym vectors close to each other. In addition, we generate a distributional hierarchy between hyponyms and hypernyms. Relying on these two new aspects of hypernymy distributions, the similarity of hypernym pairs receives higher scores than the similarity of other relation pairs; and the distributional hierarchy of hyponyms and hypernyms indicates the directionality of hypernymy.

Our model is inspired by the *distributional inclusion hypothesis*, that prominent context words of hyponyms are expected to appear in a subset of the hypernym contexts. We assume that each context word which appears with both a hyponym and its hypernym can be used as an indicator to determine which of the two words is semantically more general: Common context word vectors which represent distinctive characteristics of a hyponym are expected to be closer to the hyponym vector than to its hypernym vector. For example, the context word *flap* is more characteristic for a *bird* than for its hypernym *animal*; hence, the vector of *flap* should be closer to the vector of *bird* than to the vector of *animal*.

We evaluate our *HyperVec* model on both unsupervised and supervised hypernymy detection and directionality tasks. In addition, we apply the model to the task of graded lexical entailment (Vulić et al., 2016), and we assess the capability of *HyperVec* on generalizing hypernymy by mapping to German and Italian. Results on benchmark datasets of hypernymy show that the hierarchical embeddings outperform state-of-the-art measures and previous embedding models. Furthermore, the implementation of our models is made publicly available.[1]

2 Related Work

Unsupervised hypernymy measures: A variety of directional measures for unsupervised hypernymy detection (Weeds and Weir, 2003; Weeds et al., 2004; Clarke, 2009; Kotlerman et al., 2010; Lenci and Benotto, 2012) all rely on some variation of the *distributional inclusion hypothesis*: If u is a semantically narrower term than v, then a significant number of salient distributional features of u is expected to be included in the feature vector of v as well. In addition, Santus et al. (2014) proposed the *distributional informativeness hypothesis*, that hypernyms tend to be less informative than hyponyms, and that they occur in more general contexts than their hyponyms. All of these approaches represent words as vectors in distributional semantic models (Turney and Pantel, 2010), relying on the *distributional hypothesis* (Harris, 1954; Firth, 1957). For evaluation, these directional models use the AP measure to assess the proportion of hypernyms at the top of a score-sorted list. In a different vein, Kiela et al. (2015) introduced three unsupervised methods drawn from visual properties of images to determine a concept's generality in hypernymy tasks.

Supervised hypernymy methods: The studies in this area are based on word embeddings which represent words as low-dimensional and real-valued vectors (Mikolov et al., 2013b; Pennington et al., 2014). Each hypernymy pair is encoded by some combination of the two word vectors, such as concatenation (Baroni et al., 2012) or difference (Roller et al., 2014; Weeds et al., 2014). Hypernymy is distinguished from other relations by using a classification approach, such as SVM or LR. Because word embeddings are trained for similar and symmetric vectors, it is however unclear whether the supervised methods do actually learn the asymmetry in hypernymy (Levy et al., 2015).

Hypernymy-specific embeddings: These approaches are closest to our work. Yu et al. (2015) proposed a dynamic distance-margin model to learn term embeddings that capture properties of hypernymy. The neural model is trained on the taxonomic relation data which is pre-extracted. The resulting term embeddings are fed to an SVM classifier to predict hypernymy. However, this model only learns term pairs without considering their contexts, leading to a lack of generalization for term embeddings. Tuan et al. (2016) introduced a dynamic weighting neural network to learn term embeddings that encode information about hypernymy and also about their contexts, considering all words between a hypernym and its

[1] www.ims.uni-stuttgart.de/data/hypervec

hyponym in a sentence. The proposed model is trained on a set of hypernym relations extracted from WordNet (Miller, 1995). The embeddings are applied as features to detect hypernymy, using an SVM classifier. Tuan et al. (2016) handles the drawback of the approach by Yu et al. (2015), considering the contextual information between two terms; however the method still is not able to determine the directionality of a hypernym pair. Vendrov et al. (2016) proposed a method to encode order into learned distributed representations, to explicitly model partial order structure of the visual-semantic hierarchy or the hierarchy of hypernymy in WordNet. The resulting vectors are used to predict the transitive hypernym relations in WordNet.

3 Hierarchical Embeddings

In this section, we present our model of hierarchical embeddings *HyperVec*. Section 3.1 describes how we learn the embeddings for hypernymy, and Section 3.2 introduces the unsupervised measure *HyperScore* that is applied to the hypernymy tasks.

3.1 Learning Hierarchical Embeddings

Our approach makes use of a set of hypernyms which could be obtained from either exploiting the transitivity of the hypernymy relation (Fallucchi and Zanzotto, 2011) or lexical databases, to learn hierarchical embeddings. We rely on WordNet, a large lexical database of English (Fellbaum, 1998), and extract all hypernym–hyponym pairs for nouns and for verbs, including both direct and indirect hypernymy, e.g., *animal–bird, bird–robin, animal–robin*. Before training our model, we exclude all hypernym pairs which appear in any datasets used for evaluation.

In the following, Section 3.1.1 first describes the Skip-gram model which is integrated into our model for optimization. Section 3.1.2 then describes the objective functions to train the hierarchical embeddings for hypernymy.

3.1.1 Skip-gram Model

The Skip-gram model is a word embeddings method suggested by Mikolov et al. (2013b). Levy and Goldberg (2014) introduced a variant of the Skip-gram model with negative sampling (SGNS), in which the objective function is defined as follows:

$$\mathrm{J}_{SGNS} = \sum_{w \in V_W} \sum_{c \in V_C} \mathrm{J}_{(w,c)} \tag{1}$$

$$\begin{aligned} \mathrm{J}_{(w,c)} &= \#(w,c) \log \sigma(\vec{w}, \vec{c}) \\ &+ k \cdot \mathbb{E}_{c_N \sim P_D}[\log \sigma(-\vec{w}, \vec{c}_N)] \end{aligned} \tag{2}$$

where the skip-gram with negative sampling is trained on a corpus of words $w \in V_W$ and their contexts $c \in V_C$, with V_W and V_C the word and context vocabularies, respectively. The collection of observed words and context pairs is denoted as D; the term $\#(w,c)$ refers to the number of times the pair (w,c) appeared in D; the term $\sigma(x)$ is the sigmoid function; the term k is the number of negative samples and the term c_N is the sampled context, drawn according to the empirical unigram distribution P.

3.1.2 Hierarchical Hypernymy Model

Vector representations for detecting hypernymy are usually encoded by standard first-order distributional co-occurrences. In this way, they are insufficient to differentiate hypernymy from other paradigmatic relations such as synonymy, meronymy, antonymy, etc. Incorporating directional measures of hypernymy to detect hypernymy by exploiting the common contexts of hypernym and hyponym improves this relation distinction, but still suffers from distinguishing between hypernymy and meronymy.

Our novel approach presents two solutions to deal with these challenges. First of all, the embeddings are learned in a specific order, such that the similarity score for hypernymy is higher than the similarity score for other relations. For example, the hypernym pair *animal–frog* will be assigned a higher cosine score than the co-hyponymy pair *eagle–frog*. Secondly, the embeddings are learned to capture the distributional hierarchy between hyponym and hypernym, as an indicator to differentiate between hypernym and hyponym. For example, given a hyponym–hypernym pair (p, q), we can exploit the Euclidean norms of $\vec{q}$ and $\vec{p}$ to differentiate between the two words, such that the Euclidean norm of the hypernym $\vec{q}$ is larger than the Euclidean norm of the hyponym $\vec{p}$.

Inspired by the distributional lexical contrast model in Nguyen et al. (2016) for distinguishing antonymy from synonymy, this paper proposes two objective functions to learn hierarchical embeddings for hypernymy. Before moving to the details of the two objective functions, we first define the terms as follows: $\mathbb{W}(c)$ refers to the set of words co-occurring with the context c in a certain window-size; $\mathbb{H}(w)$ denotes the set of hypernyms for the word w; the two terms $\mathbb{H}^{+}(w,c)$ and $\mathbb{H}^{-}(w,c)$ are drawn from $\mathbb{H}(w)$, and are defined as follows:

$$\mathbb{H}^{+}(w,c) = \{u \in \mathbb{W}(c) \cap \mathbb{H}(w) : cos(\vec{w},\vec{c}) - cos(\vec{u},\vec{c}) \geq \theta\}$$
$$\mathbb{H}^{-}(w,c) = \{v \in \mathbb{W}(c) \cap \mathbb{H}(w) : cos(\vec{w},\vec{c}) - cos(\vec{v},\vec{c}) < \theta\}$$

where $cos(\vec{x},\vec{y})$ stands for the cosine similarity of the two vectors $\vec{x}$ and $\vec{y}$; θ is the margin. The set $\mathbb{H}^{+}(w,c)$ contains all hypernyms of the word w that share the context c and satisfy the constraint that the cosine similarity of pair (w,c) is higher than the cosine similarity of pair (u,c) within a max-margin framework θ. Similarly, the set $\mathbb{H}^{-}(w,c)$ represents all hypernyms of the word w with respect to the common context c in which the cosine similarity difference between the pair (w,c) and the pair (v,c) is within a min-margin framework θ. The two objective functions are defined as follows:

$$\mathrm{L}_{(w,c)} = \frac{1}{\#(w,u)} \sum\nolimits_{u \in \mathbb{H}^{+}(w,c)} \partial(\vec{w},\vec{u}) \quad (3)$$
$$\mathrm{L}_{(v,w,c)} = \sum\nolimits_{v \in \mathbb{H}^{-}(w,c)} \partial(\vec{v},\vec{w}) \quad (4)$$

where the term $\partial(\vec{x},\vec{y})$ stands for the cosine derivative of $(\vec{x},\vec{y})$; and ∂ then is optimized by the negative sampling procedure.

The objective function in Equation 3 minimizes the distributional difference between the hyponym w and the hypernym u by exploiting the common context c. More specifically, if the common context c is the distinctive characteristic of the hyponym w (i.e. the common context c is closer to the hyponym w than to the hypernym u), the objective function $\mathrm{L}_{(w,c)}$ tries to decrease the distributional generality of hypernym u by moving w closer to u. For example, given a hypernym-hyponym pair *animal–bird*, the context *flap* is a distinctive characteristic of *bird*, because almost every *bird* can flap, but not every *animal* can flap. Therefore, the context *flap* is closer to the hyponym *bird* than to the hypernym *animal*. The model then tries to move *bird* closer to *animal* in order to enforce the similarity between *bird* and *animal*, and to decrease the distributional generality of *animal*.

In contrast to Equation 3, the objective function in Equation 4 minimizes the distributional difference between the hyponym w and the hypernym v by exploiting the common context c, which is a distinctive characteristic of the hypernym v. In this case, the objective function $\mathrm{L}_{(v,w,c)}$ tries to reduce the distributional generality of hyponym w by moving v closer to w. For example, the context word *rights*, a distinctive characteristic of the hypernym *animal*, should be closer to *animal* than to *bird*. Hence, the model tries to move the hypernym *animal* closer to the hyponym *bird*. Given that hypernymy is an asymmetric and also a hierarchical relation, where each hypernym may contain several hyponyms, our objective functions updates simultaneously both the hypernym and all of its hyponyms; therefore, our objective functions are able to capture the hierarchical relations between the hypernym and its hyponyms. Moreover, in our model, the margin framework θ plays a role in learning the hierarchy of hypernymy, and in preventing the model from minimizing the distance of synonymy or antonymy, because synonymy and antonymy share many contexts.

In the final step, the objective function which is used to learn the hierarchical embeddings for hypernymy combines Equations 1, 2, 3, and 4 by the objective function in Equations 5 and 6:

$$\mathrm{J}_{(w,v,c)} = \mathrm{J}_{(w,c)} + \mathrm{L}_{(w,c)} + \mathrm{L}_{(v,w,c)} \quad (5)$$
$$\mathrm{J} = \sum_{w \in V_W} \sum_{c \in V_C} \mathrm{J}_{(w,v,c)} \quad (6)$$

3.2 Unsupervised Hypernymy Measure

HyperVec is expected to show the two following properties: (i) the hyponym and the hypernym are close to each other, and (ii) there exists a distributional hierarchy between hypernyms and their hyponyms. Given a hypernymy pair (u,v) in which u is the hyponym and v is the hypernym, we propose a measure to detect hypernymy and to determine the directionality of hypernymy by using the hierarchical embeddings as follows:

$$HyperScore(u,v) = cos(\vec{u},\vec{v}) * \frac{\|\vec{v}\|}{\|\vec{u}\|} \quad (7)$$

where $cos(\vec{u},\vec{v})$ is the cosine similarity between $\vec{u}$ and $\vec{v}$, and $\|\cdot\|$ is the magnitude of the vector (or the Euclidean norm). The cosine similarity is applied to distinguish hypernymy from other relations, due to the first property of the hierarchical embeddings, while the second property is used to decide about the directionality of hypernymy, assuming that the magnitude of the hypernym is larger than the magnitude of the hyponym. Note that the proposed hypernymy measure is unsupervised when the resource is only used to learn hierarchical embeddings.

4 Experiments

In this section, we first describe the experimental settings in our experiments (Section 4.1). We then evaluate the performance of *HyperVec* on three different tasks: i) unsupervised hypernymy detection and directionality (Section 4.2), where we assess *HyperVec* on ranking and classifying hypernymy; ii) supervised hypernymy detection (Section 4.3), where we apply supervised classification to detect hypernymy; iii) graded lexical entailment (Section 4.4), where we predict the strength of hypernymy pairs.

4.1 Experimental Settings

We use the ENCOW14A corpus (Schäfer and Bildhauer, 2012; Schäfer, 2015) with approx. 14.5 billion tokens for training the hierarchical embeddings and the default SGNS model. We train our model with 100 dimensions, a window size of 5, 15 negative samples, and 0.025 as the learning rate. The threshold θ is set to 0.05. The hypernymy resource for nouns comprises $105,020$ hyponyms, $24,925$ hypernyms, and $1,878,484$ hyponym–hypernym pairs. The hypernymy resource for verbs consists of $11,328$ hyponyms, $4,848$ hypernyms, and $130,350$ hyponym–hypernym pairs.

4.2 Unsupervised Hypernymy Detection and Directionality

In this section, we assess our model on two experimental setups: i) a ranking retrieval setup that expects hypernymy pairs to have a higher similarity score than instances from other semantic relations; ii) a classification setup that requires both hypernymy detection and directionality.

4.2.1 Ranking Retrieval

Shwartz et al. (2017) conducted an extensive evaluation of a large number of unsupervised distributional measures for hypernymy ranking retrieval proposed in previous work (Weeds and Weir, 2003; Santus et al., 2014; Clarke, 2009; Kotlerman et al., 2010; Lenci and Benotto, 2012; Santus et al., 2016). The evaluation was performed on four semantic relation datasets: **BLESS** (Baroni and Lenci, 2011), **WEEDS** (Weeds et al., 2004), **EVALUTION** (Santus et al., 2015), and **LENCI&BENOTTO** (Benotto, 2015). Table 1 describes the detail of these datasets in terms of the semantic relations and the number of instances. The Average Precision (AP) ranking measure is used to evaluate the performance of the measures.

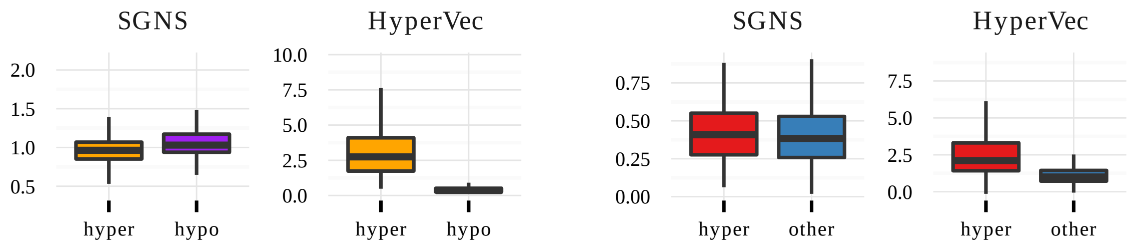
In comparison to the state-of-the-art unsupervised measures compared by Shwartz et al. (2017) (henceforth, baseline models), we apply our unsupervised measure *HyperScore* (Equation 7) to rank hypernymy against other relations. Table 2

Dataset	Relation	#Instance	Total
BLESS	hypernymy	1,337	26,554
	meronymy	2,943	
	coordination	3,565	
	event	3,824	
	attribute	2,731	
	random-n	6,702	
	random-j	2,187	
	random-v	3,265	
EVALution	hypernymy	3,637	13,465
	meronymy	1,819	
	attribute	2,965	
	synonymy	1,888	
	antonymy	3,156	
Lenci&Benotto	hypernymy	1,933	5,010
	synonymy	1,311	
	antonymy	1,766	
Weeds	hypernymy	1,469	2,928
	coordination	1,459	

Table 1: Details of the semantic relations and the number of instances in each dataset.

Dataset	Hypernymy vs.	Baseline	HyperScore
EVALution	other relations	0.353	**0.538**
	meronymy	0.675	**0.811**
	attribute	0.651	**0.800**
	antonymy	0.55	**0.743**
	synonymy	0.657	**0.793**
BLESS	other relations	0.051	**0.454**
	meronymy	0.76	**0.913**
	coordination	0.537	**0.888**
	attribute	0.74	**0.918**
	event	**0.779**	0.620
Lenci&Benotto	other relations	0.382	**0.574**
	antonymy	0.624	**0.696**
	synonymy	0.725	**0.751**
Weeds	coordination	0.441	**0.850**

Table 2: AP results of *HyperScore* in comparison to state-of-the-art measures.



(a) Directionality task: hypernym vs. hyponym.

(b) Hypernymy detection: hypernymy vs. other relations.

Figure 1: Comparing *SGNS* and *HyperVec* on binary classification tasks. The y-axis shows the magnitude values of the vectors.

presents the results of using *HyperScore* vs. the best baseline models, across datasets. When detecting hypernymy among all other relations (which is the most challenging task), *HyperScore* significantly outperforms all baseline variants on all datasets. The strongest difference is reached on the BLESS dataset, where *HyperScore* achieves an improvement of 40% AP score over the best baseline model. When ranking hypernymy in comparison to a single other relation, *HyperScore* also improves over the baseline models, except for the *event* relation in the BLESS dataset. We assume that this is due to the different parts-of-speech (adjective and noun) involved in the relation, where *HyperVec* fails to establish a hierarchy.

4.2.2 Classification

In this setup, we rely on three datasets of semantic relations, which were all used in various state-of-the-art approaches before, and brought together for hypernymy evaluation by Kiela et al. (2015). **(i)** A subset of **BLESS** contains 1,337 hyponym-hypernym pairs. The task is to predict the directionality of hypernymy within a binary classification. Our approach requires no threshold; we only need to compare the magnitudes of the two words and to assign the hypernym label to the word with the larger magnitude. Figure 1a indicates that the magnitude values of the *SGNS* model cannot distinguish between a hyponym and a hypernym, while the hierarchical embeddings provide a larger magnitude for the hypernym. **(ii)** Following Weeds et al. (2014), we conduct a binary classification with a subset of 1,168 BLESS word pairs. In this dataset (**WBLESS**), one class is represented by hyponym–hypernym pairs, and the other class is a combination of reversed hypernym–hyponym pairs, plus additional holonym-meronym pairs, co-hyponyms and randomly matched nouns. For this classification we make use of our *HyperScore* measure that ranks hypernymy pairs higher than other relation pairs. A threshold decides about the splitting point between the two classes: *hyper* vs. *other*. Instead of using a manually defined threshold as done by Kiela et al. (2015), we decided to run 1 000 iterations which randomly sampled only 2% of the available pairs for learning a threshold, using the remaining 98% for test purposes. We present average accuracy results across all iterations. Figure 1b compares the default cosine similarities between the relation pairs (as applied by *SGNS*) and *HyperScore* (as applied by *HyperVec*) on this task. Using *HyperScore*, the class “hyper” can clearly be distinguished from the class “other”. **(iii) BIBLESS** represents the most challenging dataset; the relation pairs from WBLESS are split into three classes instead of two: hypernymy pairs, reversed hypernymy pairs, and other relation pairs. In this case, we perform a three-way classification. We apply the same technique as used for the WBLESS classification, but in cases where we classify *hyper* we additionally classify the hypernymy direction, to decide between hyponym–hypernym pairs and reversed hypernym–hyponym pairs.

	BLESS	WBLESS	BIBLESS
Kiela et al. (2015)	0.88	0.75	0.57
Santus et al. (2014)	0.87	—	—
Weeds et al. (2014)	—	0.75	—
SGNS	0.44	0.48	0.34
HyperVec	**0.92**	**0.87**	**0.81**

Table 3: Accuracy for hypernymy directionality.

Table 3 compares our results against related work. *HyperVec* outperforms all other methods on all three tasks. In addition we see again that an unmodified *SGNS* model cannot solve any of the three tasks.

4.3 Supervised Hypernymy Detection

For supervised hypernymy detection, we make use of the two datasets: the full **BLESS** dataset, and **ENTAILMENT** (Baroni et al., 2012), containing 2,770 relation pairs in total, including 1,385 hypernym pairs and 1,385 other relations pairs. We follow the same procedure as Yu et al. (2015) and Tuan et al. (2016) to assess *HyperVec* on the two datasets. Regarding BLESS, we extract pairs for four types of relations: hypernymy, meronymy, co-hyponymy (or *coordination*), and add the random relation for nouns. For the evaluation, we randomly select one concept and its relatum for testing, and train the supervised model on the 199 remaining concepts and its relatum. We then report the average accuracy across all concepts. For the ENTAILMENT dataset, we randomly select one hypernym pair for testing and train on all remaining hypernym pairs. Again, we report the average accuracy across all hypernyms.

We apply an SVM classifier to detect hypernymy based on *HyperVec*. Given a hyponym–hypernym pair (u, v), we concatenate four components to construct the vector for a pair (u, v) as follows: the vector difference between hypernym and hyponym ($\vec{v} - \vec{u}$); the cosine similarity between the hypernym and hyponym vectors ($cos(\vec{u}, \vec{v})$); the magnitude of the hyponym ($\|\vec{u}\|$); and the magnitude of the hypernym ($\|\vec{v}\|$). The resulting vector is fed into the SVM classifier to detect hypernymy. Similar to the two previous works, we train the SVM classifier with the RBF kernel, $\lambda = 0.03125$, and the penalty $C = 8.0$.

Table 4 shows the performance of *HyperVec* and the two baseline models reported by Tuan et al. (2016). *HyperVec* slightly outperforms the method of Tuan et al. (2016) on the BLESS dataset, and is equivalent to the performance of their method on the ENTAILMENT dataset. In comparison to the method of Yu et al. (2015), *HyperVec* achieves significant improvements.

Models	BLESS	ENTAILMENT
Yu et al. (2015)	0.90	0.87
Tuan et al. (2016)	0.93	0.91
HyperVec	**0.94**	0.91

Table 4: Classification results for BLESS and ENTAILMENT in terms of accuracy.

4.4 Graded Lexical Entailment

In this experiment, we apply *HyperVec* to the dataset of graded lexical entailment, *HyperLex*, as introduced by Vulić et al. (2016). The *HyperLex* dataset provides soft lexical entailment on a continuous scale, rather than simplifying into a binary decision. *HyperLex* contains 2,616 word pairs across seven semantic relations and two word classes (nouns and verbs). Each word pair is rated by a score that indicates the strength of the semantic relation between the two words. For example, the score of the hypernym pair *duck–animal* is 5.9 out of 6.0, while the score of the reversed pair *animal–duck* is only 1.0.

We compared *HyperScore* against the most prominent state-of-the-art hypernymy and lexical entailment models from previous work:

- Directional entailment measures (DEM) (Weeds and Weir, 2003; Weeds et al., 2004; Clarke, 2009; Kotlerman et al., 2010; Lenci and Benotto, 2012)
- Generality measures (SQLS) (Santus et al., 2014)
- Visual generality measures (VIS) (Kiela et al., 2015)
- Consideration of concept frequency ratio (FR) (Vulić et al., 2016)
- WordNet-based similarity measures (WN) (Wu and Palmer, 1994; Pedersen et al., 2004)
- Order embeddings (OrderEmb) (Vendrov et al., 2016)
- Skip-gram embeddings (SGNS) (Mikolov et al., 2013b; Levy and Goldberg, 2014)
- Embeddings fine-tuned to a paraphrase database with linguistic constraints (PARAGRAM) (Mrkšić et al., 2016)
- Gaussian embeddings (Word2Gauss) (Vilnis and McCallum, 2015)

The performance of the models is assessed through Spearman's rank-order correlation coefficient ρ (Siegel and Castellan, 1988), comparing the ranks of the models' scores and the human judgments for the given word pairs.

Measures		Embeddings	
Model	ρ	**Model**	ρ
FR	0.279	SGNS	0.205
DEM	0.180	PARAGRAM	0.320
SLQS	0.228	OrderEmb	0.191
WN	0.234	Word2Gauss	0.206
VIS	0.209	*HyperScore*	**0.540**

Table 5: Results (ρ) of *HyperScore* and state-of-the-art measures and word embedding models on graded lexical entailment.

Table 5 shows that *HyperScore* significantly outperforms both state-of-the-art measures and word embedding models. *HyperScore* outperforms even the previously best word embedding model PARAGRAM by .22, and the previously best measures FR by .27. The reason that *HyperVec* outperforms all other models is that the hierarchy between hypernym and hypornym within *HyperVec* differentiates hyponym–hypernym pairs from hypernym–hyponym pairs. For example, the *HyperScore* for the pairs *duck–animal* and *animal–duck* are 3.02 and 0.30, respectively. Thus, the magnitude proportion of the hypernym–hyponym pair *duck–animal* is larger than that for the pair *animal–duck*.

5 Generalizing Hypernymy

Having demonstrated the general abilities of *HyperVec*, this final section explores its potential for generalization in two different ways, (i) by relying on a small seed set only, rather than using a large set of training data; and (ii) by projecting *HyperVec* to other languages.

Hypernymy Seed Generalization: We utilize only a small hypernym set from the hypernymy resource to train *HyperVec*, relying on 200 concepts from the BLESS dataset. The motivation behind using these concepts is threefold: i) these concepts are distinct and unambiguous noun concepts; ii) the concepts were equally divided between living and non-living entities; iii) concepts have been grouped into 17 broader classes. Based on the seed set, we collected the hyponyms of each concept from WordNet, and then re-trained *HyperVec*. On the hypernymy ranking retrieval task (Section 4.2.1), *HyperScore* outperforms the baselines across all datasets (cf. Table 1) with AP values of 0.39, 0.448, and 0.585 for EVALution, LenciBenotto, and Weeds, respectively. For the graded lexical entailment task (Section 4.4), *HyperScore* obtains a correlation of $\rho = 0.30$, outperforming all models except for PARAGRAM with $\rho = 0.32$. Overall, the results show that *HyperVec* is indeed able to generalize hypernymy from small seeds of training data.

Generalizing Hypernymy across Languages: We assume that hypernymy detection can be improved across languages by projecting representations from any arbitrary language into our modified English *HyperVec* space. We conduct experiments for German and Italian, where the language-specific representations are obtained using the same hyper-parameter settings as for our English *SGNS* model (cf. Section 4.1). As corpus resource we relied on Wikipedia dumps[2]. Note that we do not use any additional resource, such as the German or Italian WordNet, to tune the embeddings for hypernymy detection. Based on the representations, a mapping function between a source language (German, Italian) and our English *HyperVec* space is learned, by relying on the least-squares error method from previous work using cross-lingual data (Mikolov et al., 2013a) and different modalities (Lazaridou et al., 2015).

To learn a mapping function between two languages, a one-to-one correspondence (word translations) between two sets of vectors is required. We obtained these translations by using the parallel Europarl[3] V7 corpus for German–English and Italian–English. Word alignment counts were extracted using *fast_align* (Dyer et al., 2013). We then assigned each source word to the English word with the maximum number of alignments in the parallel corpus. We could match 25,547 pairs for DE→EN and 47,475 pairs for IT→EN.

Taking the aligned subset of both spaces, we assume that X is the matrix obtained by concatenating all source vectors, and likewise Y is the matrix obtained by concatenating all corresponding English elements. Applying the $\ell 2$-regularized least-squares error objective can be described using the following equation:

$$\hat{\mathbf{W}} = \underset{\mathbf{W} \in \mathbb{R}^{d1 \times d2}}{\operatorname{argmin}} \|\mathbf{XW} - \mathbf{Y}\| + \lambda \|\mathbf{W}\| \qquad (8)$$

Although we learn the mapping only on a subset of aligned words, it allows us to project every word in

[2] The Wikipedia dump for German and Italian were both downloaded in January 2017.

[3] http://www.statmt.org/europarl/

a source vocabulary to its English *HyperVec* position by using **W**.

Finally we compare the original representations and the mapped representation on the hypernymy ranking retrieval task (similar to Section 4.2.1). As gold resources we relied on German and Italian nouns pairs. For German we used the 282 German pairs collected via Amazon Mechanical Turk by Scheible and Schulte im Walde (2014). The 1,350 Italian pairs were collected via Crowdflower by Sucameli (2015) in the same way. Both collections contain hypernymy, antonymy and synonymy pairs. As before, we evaluate the ranking by AP, and we compare the cosine of the unmodified default representations against the *HyperScore* of the projected representations.

German	Hyp/All	Hyp/Syn	Hyp/Ant
DE-*SGNS*	0.28	0.48	0.40
DE→EN*HyperVec*	**0.37**	**0.65**	**0.47**
Italian			
IT-*SGNS*	0.38	0.50	0.60
IT→EN*HyperVec*	**0.44**	**0.57**	**0.65**

Table 6: AP results across languages, comparing *SGNS* and the projected representations.

The results are shown in Table 6. We clearly see that for both languages the default *SGNS* embeddings do not provide higher similarity scores for hypernymy pairs (except for Italian Hyp/Ant), but both languages provide higher scores when we map the embeddings into the English *HyperVec* space.

6 Conclusion

This paper proposed a novel neural model *HyperVec* to learn hierarchical embeddings for hypernymy. *HyperVec* has been shown to strengthen hypernymy similarity, and to capture the distributional hierarchy of hypernymy. Together with a newly proposed unsupervised measure *HyperScore* our experiments demonstrated (i) significant improvements against state-of-the-art measures, and (ii) the capability to generalize hypernymy and learn the relation instead of memorizing *prototypical hypernyms*.

Abstract

The existing word representation methods mostly limit their information source to word co-occurrence statistics. In this paper, we introduce ngrams into four representation methods: SGNS, GloVe, PPMI matrix, and its SVD factorization. Comprehensive experiments are conducted on word analogy and similarity tasks. The results show that improved word representations are learned from ngram co-occurrence statistics. We also demonstrate that the trained ngram representations are useful in many aspects such as finding antonyms and collocations. Besides, a novel approach of building co-occurrence matrix is proposed to alleviate the hardware burdens brought by ngrams.

1 Introduction

Recently, deep learning approaches have achieved state-of-the-art results on a range of NLP tasks. One of the most fundamental work in this field is word embedding, where low-dimensional word representations are learned from unlabeled corpora through neural models. The trained word embeddings reflect semantic and syntactic information of words. They are not only useful in revealing lexical semantics, but also used as inputs of various downstream tasks for better performance (Kim, 2014; Collobert et al., 2011; Pennington et al., 2014).

Most of the word embedding models are trained upon <*word, context*> pairs in the local window. Among them, word2vec gains its popularity by its amazing effectiveness and efficiency (Mikolov et al., 2013b,a). It achieves state-of-the-art results on a range of linguistic tasks with only a fraction of time compared with previous techniques. A challenger of word2vec is GloVe (Pennington et al., 2014). Instead of training on <*word, context*> pairs, GloVe directly utilizes word co-occurrence matrix. They claim that the change brings the improvement over word2vec on both accuracy and speed. Levy and Goldberg (2014b) further reveal that the attractive properties observed in word embeddings are not restricted to neural models such as word2vec and GloVe. They use traditional count-based method (PPMI matrix with hyper-parameter tuning) to represent words, and achieve comparable results with the above neural embedding models.

The above models limit their information source to word co-occurrence statistics (Levy et al., 2015). To learn improved word representations, we extend the information source from co-occurrence of ***'word-word'*** type to co-occurrence of ***'ngram-ngram'*** type. The idea of using ngrams is well supported by language modeling, one of the oldest problems studied in statistical NLP. In language models, co-occurrence of words and ngrams is used to predict the next word (Kneser and Ney, 1995; Katz, 1987). Actually, the idea of word embedding models roots in language models. They are closely related but are used for different purposes. Word embedding models aim at learning useful word representations instead of word prediction. Since ngram is a vital part in language modeling, we are inspired to integrate ngram statistical information into the recent word representation methods for better performance.

The idea of using ngrams is intuitive. However, there is still rare work using ngrams in recent representation methods. In this paper, we introduce

Proceedings of the 2017 Conference on Empirical Methods in Natural Language Processing, pages 244–253
Copenhagen, Denmark, September 7–11, 2017.

ngrams into SGNS, GloVe, PPMI, and its SVD factorization. To evaluate the ngram-based models, comprehensive experiments are conducted on word analogy and similarity tasks. Experimental results demonstrate that the improved word representations are learned from ngram co-occurrence statistics. Besides that, we qualitatively evaluate the trained ngram representations. We show that they are able to reflect ngrams' meanings and syntactic patterns (e.g. 'be + past participle' pattern). The high-quality ngram representations are useful in many ways. For example, ngrams in negative form (e.g. 'not interesting') can be used for finding antonyms (e.g. 'boring').

Finally, a novel method is proposed to build ngram co-occurrence matrix. Our method reduces the disk I/O as much as possible, largely alleviating the costs brought by ngrams. We unify different representation methods in a pipeline. The source code is organized as ***ngram2vec*** toolkit and released at `https://github.com/zhezhaoa/ngram2vec`.

2 Related Work

SGNS, GloVe, PPMI, and its SVD factorization are used as baselines. The information used by them does not go beyond word co-occurrence statistics. However, their approaches to using the information are different. We review these methods in the following 3 sections. In section 2.4, we revisit the use of ngrams in the deep learning context.

2.1 SGNS

Skip-gram with negative sampling (SGNS) is a model in word2vec toolkit (Mikolov et al., 2013b,a). Its training procedure follows the majority of neural embedding models (Bengio et al., 2003): (1) *Scan the corpus and use <word, context> pairs in the local window as training samples.* (2) *Train the models to make words useful for predicting contexts (or in reverse).* The details of SGNS is discussed in Section 3.1. Compared to previous neural embedding models, SGNS speeds up the training process, reducing the training time from days or weeks to hours. Also, the trained embeddings possess attractive properties. They are able to reflect relations between two words accurately, which is evaluated by a fancy task called word analogy.

Due to the above advantages, many models are proposed on the basis of SGNS. For example, Faruqui et al. (2015) introduce knowledge in lexical resources into the models in word2vec. Zhao et al. (2016) extend the contexts from the local window to the entire documents. Li et al. (2015) use supervised information to guide the training. Dependency parse-tree is used for defining context in (Levy and Goldberg, 2014a). LSTM is used for modeling context in (Melamud et al., 2016) Sub-word information is considered in (Sun et al., 2016; Soricut and Och, 2015).

2.2 GloVe

Different from typical neural embedding models which are trained on <*word, context*> pairs, GloVe learns word representation on the basis of co-occurrence matrix (Pennington et al., 2014). GloVe breaks traditional 'words predict contexts' paradigm. Its objective is to reconstruct non-zero values in the matrix. The direct use of matrix is reported to bring improved results and higher speed. However, there is still dispute about the advantages of GloVe over word2vec (Levy et al., 2015; Schnabel et al., 2015). GloVe and other embedding models are essentially based on word co-occurrence statistics of the corpus. The <*word, context*> pairs and co-occurrence matrix can be converted to each other. Suzuki and Nagata (2015) try to unify GloVe and SGNS in one framework.

2.3 PPMI & SVD

When we are satisfied with the huge promotions achieved by embedding models on linguistic tasks, a natural question is raised: where the superiorities come from. One conjecture is that it's due to the neural networks. However, Levy and Goldberg (2014c) reveal that SGNS is just factoring PMI matrix implicitly. Also, Levy and Goldberg (2014b) show that positive PMI (PPMI) matrix still rivals the newly proposed embedding models on a range of linguistic tasks. Properties like word analogy are not restricted to neural models. To obtain dense word representations from PPMI matrix, we factorize PPMI matrix with SVD, a classic dimensionality reduction method for learning low-dimensional vectors from sparse matrix (Deerwester et al., 1990).

2.4 Ngram in Deep Learning

In the deep learning literature, ngram has shown to be useful in generating text representations. Recently, convolutional neural networks (CNNs) are reported to perform well on a range of NLP tasks (Blunsom et al., 2014; Hu et al., 2014; Severyn and Moschitti, 2015). CNNs are essentially using ngram information to represent texts. They use 1-D convolutional layers to extract ngram features and the distinct features are selected by max-pooling layers. In (Li et al., 2016), ngram embedding is introduced into Paragraph Vector model, where text embedding is trained to be useful to predict ngrams in the text. In the word embedding literature, a related work is done by Melamud et al. (2014), where word embedding models are used as baselines. They propose to use ngram language models to model the context, showing the effectiveness of ngrams on similarity tasks. Another work that is related to ngram is from Mikolov et al. (2013b), where phrases are embedded into vectors. It should be noted that phrases are different from ngrams. Phrases have clear semantics and the number of phrases is much less than the number of ngrams. Using phrase embedding has little impact on word embedding's quality.

3 Model

In this section, we introduce ngrams into SGNS, GloVe, PPMI, and SVD. Section 3.1 reviews the SGNS. Section 3.2 and 3.3 show the details of introducing ngrams into SGNS. In section 3.4, we show the way of using ngrams in GloVe, PPMI, and SVD, and propose a novel way of building ngram co-occurrence matrix.

3.1 Word Predicts Word: the Revisit of SGNS

First we establish some notations. The raw input is a corpus $T = \{w_1, w_2, ..., w_{|T|}\}$. Let W and C denote word and context vocabularies. θ is the parameters to be optimized. SGNS's parameters involve two parts: word embedding matrix and context embedding matrix. With embedding $\vec{w} \in R^d$, the total number of parameters is $(|W|+|C|)*d$.

The SGNS's objective is to maximize the conditional probabilities of contexts given center words:

$$\sum_{t=1}^{|T|}\left[\sum_{c\in C(w_t)} log\, p(c|w_t;\theta)\right] \qquad (1)$$

where $C(w_t) = \{w_i, t - win \le i \le t + win\, and\, i \ne t\}$ and *win* denotes the window size. As illustrated in figure 1, the center word 'written' predicts its surrounding words 'Potter', 'is', 'by', and 'J.K.'. In this paper, negative sampling (Mikolov et al., 2013b) is used to approximate the conditional probability:

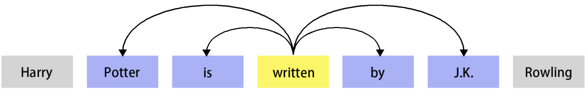

Figure 1: Illustration of 'word predicts word'.

$$p(c|w) = \sigma(\vec{w}^T\vec{c})\prod_{j=1}^{k} E_{c_j\sim P_n(C)}\sigma(-\vec{w}^T\vec{c_j}) \qquad (2)$$

where σ is sigmoid function. k samples (from c_1 to c_k) are drawn from context distribution raised to the power of *n*.

3.2 Word Predicts Ngram

In this section, we introduce ngrams into context vocabulary. We treat each ngram as a normal word and give it a unique embedding. During the training, the center word should not only predict its surrounding words, but also predict its surrounding ngrams. As shown in figure 2, center word 'written' predicts the bigrams in the local window such as 'by J.K.'. The objective of 'word predicts ngram' is similar with the original SGNS. The only difference is the definition of the *C(w)*. In ngram case, *C(w)* is formally defined as follows:

$$C(w_t) = \bigcup_{n=1}^{N}\{w_{i:i+n}|w_{i:i+n}\ is\ not\ w_t\ AND \\ t - win \le i \le t + win - n + 1\} \qquad (3)$$

where $w_{i:i+n}$ denotes the ngram $w_i w_{i+1}...w_{i+n-1}$ and N is the order of context ngram. Two points need to be noticed from the above definition. The first is how to determine the distance between center word and context ngram. In this paper, we use the distance between the word and the ngram's far-end word. As show in figure 2, the distance between 'written' and 'Harry Potter' is 3. As a result, 'Harry Potter' is not included in the center word's context. This distance definition ensures that the ngram models don't use the information beyond the pre-specified window, which guarantees fair comparisons with baselines. Another point is whether the overlap of word and ngram is allowed or not. In the overlap situation, ngrams are used as context even they contain the center word. As the example in figure 2 shows,

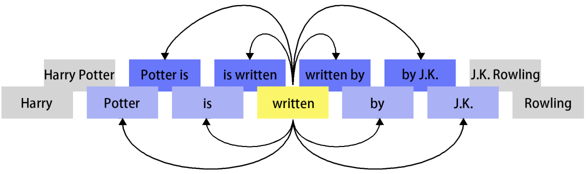

Figure 2: Illustration of ‘word predicts ngram’.

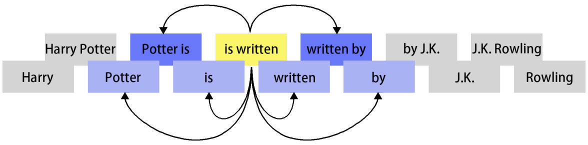

Figure 3: Illustration of ‘ngram predicts ngram’.

ngram ‘is written’ and ‘written by’ are predicted by the center word ‘written’. In the non-overlap case, these ngrams are excluded. The properties of word embeddings are different when overlap is allowed or not, which will be discussed in experiments section.

3.3 Ngram Predicts Ngram

We further extend the model to introduce ngrams into center word vocabulary. During the training, center ngrams (including words) predict their surrounding ngrams. As shown in figure 3, center bigram ‘is written’ predicts its surrounding words and bigrams. The objective of ‘ngram predicts ngram’ is as follows:

$$\sum_{t=1}^{|T|} \sum_{n_w=1}^{N_w} \left[\sum_{c \in C(w_{t:t+n_w})} log\, p(c|w_{t:t+n_w}; \theta) \right] \quad (4)$$

where N_w is the order of center ngram. The definition of $C(w_{t:t+n_w})$ is as follows:

$$\bigcup_{n_c=1}^{N_c} \{w_{i:i+n_c} | w_{i:i+n_c}\ is\ not\ w_{t:t+n_w}\ AND \\ t - win + n_w - 1 \leq i \leq t + win - n_c + 1\} \quad (5)$$

where N_c is the order of context ngram. To this end, the word embeddings are not only affected by the ngrams in the context, but also indirectly affected by co-occurrence statistics of ‘ngram-ngram’ type in the corpus.

SGNS is proven to be equivalent with factorizing pointwise mutual information (PMI) matrix (Levy and Goldberg, 2014c). Following their work, we can easily show that models in section 3.2 and 3.3 are implicitly factoring PMI matrix of ‘word-ngram’ and ‘ngram-ngram’ type. In the next section, we will discuss the content of introducing ngrams into positive PMI (PPMI) matrix.

3.4 Co-occurrence Matrix Construction

Introducing ngrams into GloVe, PPMI, and SVD is straightforward: the only change is to replace word co-occurrence matrices with ngram ones. In the above three sections, we have discussed the way of taking out *<word(ngram), word(ngram)>* pairs from a corpus. Afterwards, we build the co-occurrence matrix upon these pairs. The rest steps are identical with the original baseline models.

Win	Type	#Pairs
2	uni_uni	0.36B
	uni_bi	1.14B
	uni_tri	1.40B
	bi_bi	2.78B
	bi_tri	3.65B
5	uni_uni	0.91B
	uni_bi	2.79B
	uni_tri	3.81B
	bi_bi	7.97B

Table 1: The number of pairs at different settings. The type column lists the order of ngrams considered in center word/context vocabularies. For example, uni_bi denotes that center word vocabulary contains unigrams (words) and context vocabulary contains both unigrams and bigrams. The setting of other hyper-parameters is discussed in Section 4.2.

However, building the co-occurrence matrix is not an easy task as it apparently looks like. The introduction of ngrams brings huge burdens on the hardware. The matrix construction cost is closely related to the number of pairs (**#Pairs**). Table 1 shows the statistics of pairs extracted from corpus wiki2010 [1]. We can observe that **#Pairs** is huge when ngrams are considered.

To speed up the process of building ngram co-occurrence matrix, we take advantages of ‘mixture’ strategy (Pennington et al., 2014) and ‘stripes’ strategy (Dyer et al., 2008; Lin, 2008). The two strategies optimize the process in different aspects. Computational cost is reduced significantly when they are used together.

[1] http://nlp.stanford.edu/data/WestburyLab.wikicorp.201004.txt.bz2

When words (or ngrams) are sorted in descending order by frequency, the co-occurrence matrix's top-left corner is dense while the rest part is sparse. Based on this observation, the 'mixture' of two data structures are used for storing matrix. Elements in the top-left corner are stored in a 2D array, which stays in memory. The rest of the elements are stored in the form of <*ngram, H*>, where *H*<*context, count*> is an associative array recording the number of times the *ngram* and *context* co-occurs ('stripes' strategy). Compared with storing <ngram, context> pairs explicitly, the 'stripes' strategy provides more opportunities to aggregate pairs outside of the top-left corner.

Algorithm 1 shows the way of using the 'mixture' and 'stripes' strategies together. In the first stage, pairs are stored in different data structures according to *topLeft* function. Intermediate results are written to temporary files when memory is full. In the second stage, we merge these sorted temporary files to generate co-occurrence matrix. The *getSmallest* function takes out the pair <*ngram, H*> with the smallest *key* from temporary files. In practice, algorithm 1 is efficient. Instead of using computer clusters (Lin, 2008), we can build the matrix of 'bi_bi' type even in a laptop. It only requires 12GB to store temporary files (win=2, subsampling=0, memory size=4GB), which is much smaller than the implementations in (Pennington et al., 2014; Levy et al., 2015) . More detailed analysis about these strategies can be found in the ***ngram2vec*** toolkit.

Algorithm 1: An algorithm for building n-gram co-occurrence matrix

```
Input  : Pairs $P$, Sorted vocabulary $V$
Output: Sorted and aggregated pairs
The 2D array $A[\,][\,]$;
The dictionary $D < ngram, H >$;
The temporary files array $tfs[\,]$; $fid$=1;
for pair $p < n, c >$ in $P$ do
    if $topLeft(n, c) == 1$ then
        $A[getId(n)][getId(c)]$ += 1;
    else
        $D\{n\}\{c\}$ += 1;
        if Memory is full or $P$ is empty then
            Sort $D$ by key (ngram);
            Write $D$ to $tfs[fid]$;
            $fid$ += 1;
        end
    end
end
Write $A$ to $tfs[0]$ in the form of $< ngram, H >$;
$old = getSmallest(tfs)$ ;
while !(All files in $tfs$ are empty) do
    $new = getSmallest(tfs)$ ;
    if $old.ngram == new.ngram$ then
        $old =$
        $< old.ngram, merge(old.H, new.H) >$;
    else
        Write $old$ to disk;
        $old = new$
    end
end
```

4 Experiments

4.1 Datasets

The tasks used in this paper is the same with the work of Levy et al. (2015), including six similarity and two analogy datasets. In similarity task, a scalar (e.g. a score from 0 to 10) is used to measure the relation between the two words. For example, in a similarity dataset, the 'train, car' pair is given the score of 6.31. A problem of similarity task is that scalar only reflects the strength of the relation, while the type of relation is totally ignored (Schnabel et al., 2015).

Due to the deficiency of similarity task, analogy task is widely used as benchmark recently for evaluation of word embedding models. To answer analogy questions, relations between the two words are reflected by a vector, which is usually obtained by the difference between word embeddings. Different from a scalar, the vector provides more accurate descriptions of relations. For example, capital-country relation is encoded in *vec(Athens)-vec(Greece)*, *vec(Tokyo)-vec(Japan)* and so on. More concretely, the questions in the analogy task are in the form of 'a is to b as c is to d'. 'd' is an unknown word in the test phase. To correctly answer the questions, the models should embed the two relations, *vec(a)-vec(b)* and *vec(c)-vec(d)*, into similar positions in the space. Following the work of Levy and Goldberg (2014b), both additive (add) and multiplicative (mul) functions are used for finding word 'd'. The latter one is more suitable for sparse representation in practice.

4.2 Pipeline and Hyper-parameter Setting

We implement SGNS, GloVe, PPMI, and SVD in a pipeline, allowing the reuse of code and intermediate results. Figure 4 illustrates the overview of the pipeline. Firstly, <*word(ngram), word(ngram)*> pairs are extracted from the corpus as the input of SGNS. Afterwards, we build the co-occurrence matrix upon the pairs. GloVe and PPMI learn word representations on the basis of co-occurrence

Win	Type		Google Tot. / Sem. / Syn.		MSR

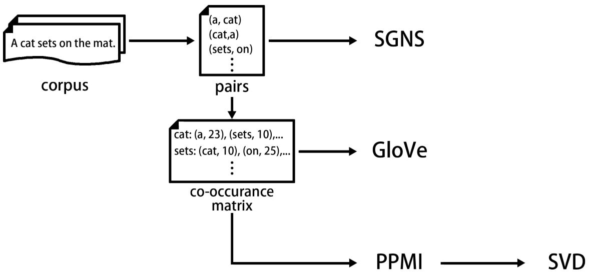

Figure 4: The pipeline.

matrix. SVD factorizes the PPMI matrix to obtain low-dimensional representation.

Most hyper-parameters come from 'corpus to pairs' part and four representation models. 'corpus to pairs' part determines the source of information for the subsequent models and its hyper-parameter setting is as follows: low-frequency words (n-grams) are removed with a threshold of 10. High-frequency words (ngrams) are removed with sub-sampling at the degree of 1e-5 [2]. Window size is set to 2 and 5. Clean strategy (Levy et al., 2015) is used to ensure no information beyond pre-specified window is included. Overlap setting is used in default. For hyper-parameters of four representation models, we use the embeddings of 300 dimensions in dense representations. SGNS is trained by 3 iterations. The rest strictly follow the baseline models [3]. We consider unigrams (words), bigrams, and trigrams in this work. The implementation of higher-order models and their results will be released with ***ngram2vec*** toolkit.

4.3 Ngrams on SGNS

SGNS is a popular word embedding model. Even compared with its challengers such as GloVe, S-GNS is reported to have more robust performance with faster training speed (Levy et al., 2015). Table 2 lists the results on analogy datasets. We can observe that the introduction of bigrams provides significant improvements at different hyper-parameter settings. The SGNS of 'bi_bi' type provides the highest results. It is very effective on capturing semantic information (Google semantic). Around 10 percent improvements are wit-

[2] Sub-sampling is not used in GloVe, which follows its o-riginal setting.

[3] http://bitbucket.org/omerlevy/hyperwords for SGNS, PPMI and SVD; http://nlp.stanford.edu/projects/glove/ for GloVe.

Table 6: Performance of (ngram) SVD on analogy and similarity datasets.

nessed on semantic questions compared with uni_uni baseline. For syntactic questions (Google syntactic and MSR datasets), around 5 percent improvements are obtained on average.

The effect of overlap is large on analogy datasets. Semantic questions prefer the overlap setting. Around 10 and 3 percent improvements are witnessed compared with non-overlap setting at the window size of 2 and 5. While in syntactic case, non-overlap setting performs better by a margin of around 5 percent.

The introduction of trigrams deteriorates the models' performance on analogy datasets (especially at the window size of 2). It is probably because that trigram is sparse on wiki2010, a relatively small corpus with 1 billion tokens. We conjecture that high order ngrams are more suitable for large corpora and will report the results in our future work. It should be noticed that trigram is not included in vocabulary in non-overlap case at the window size of 2. The shortest distance between a word and a trigram is 3, which exceeds the window size.

Table 3 illustrates the SGNS's performance on similarity task. The conclusion is similar with the case in analogy datasets. The use of bigrams is effective while the introduction of trigrams deteriorates the performance in most cases. In general, the bigrams bring significant improvements over SGNS on a range of linguistic tasks. It is generally known that ngram is a vital part in traditional language modeling problem. Results in table 2 and 3 confirm the effectiveness of ngrams again on SGNS, a more advanced word embedding model.

4.4 Ngrams on PPMI, GloVe, SVD

In this section, we only report the results of models of 'uni_uni' and 'uni_bi' types. Using higher order co-occurrence statistics brings immense costs (especially at the window size of 5). Levy and Goldberg (2014b) demonstrate that traditional count-based models can still achieve competitive results on many linguistic tasks, challenging the dominance of neural embedding models. Table 4 lists the results of PPMI matrix on analogy and similarity datasets. PPMI prefers Multiplicative (Mul) evalution. To this end, we focus on analyzing the results on Mul columns. When bigrams are used, significant improvements are witnessed on analogy task. On Google dataset, bigrams bring over 10 percent increase on the total accuracies. At the window size of 2, the accuracy in semantic questions even reaches 0.854, which is the state-of-the-art result to the best of our knowledge. On MSR dataset, around 20 percent improvements are achieved. The use of bigrams does not always bring improvements on similarity datasets. PPMI matrix of 'uni_bi' type improves the results on 5 datasets at the window size of 2. At the window size of 5, using bigrams only improves the results on 2 datasets.

Table 5 and 6 list GloVe and SVD's results. For GloVe, consistent (but minor) improvements are achieved on analogy task with the introduction of bigrams. On similarity datasets, improvements are witnessed on most cases. For SVD, bigrams sometimes lead to worse results in both analogy and similarity tasks. In general, significant improvements are not witnessed on GloVe and SVD. Our preliminary conjecture is that the default hyper-parameter setting should be blamed. We strictly follow the hyper-parameters used in baseline models, making no adjustments to cater to the introduction of ngrams. Besides that, some common techniques such as dynamic window, decreasing weighting function, dirty sub-sampling are discarded. The relationships between ngrams and various hyper-parameters require further exploration. Though trivial, it may lead to much better results and give researchers better understanding of different representation methods. That will be the focus of our future work.

4.5 Qualitative Evaluations of Ngram Embedding

In this section, we analyze the properties of ngram embeddings trained by SGNS of 'bi_bi' type. Ideally, the trained ngram embeddings should reflect ngrams' semantic meanings. For example, *vec(wasn't able)* should be close to *vec(unable)*. *vec(is written)* should be close to *vec(write)* and *vec(book)*. Also, the trained ngram embeddings should preserve ngrams' syntactic patterns. For example, 'was written' is in the form of 'be + past participle' and the nearest neighbors should possess similar patterns, such as 'is written' and 'was transcribed'.

Table 7 lists the target ngrams and their top nearest neighbours. We divide the target ngrams into six groups according to their patterns. We can observe that the returned words and ngrams are very intuitive. As might be expected, synonyms of the target ngrams are returned in top positions (e.g. 'give off' and 'emit'; 'heavy rain' and 'downpours'). From the results of the first group, it can be observed that bigram in negative form 'not X' is useful for finding the antonym of word 'X'. Besides that, the trained ngram embeddings also preserve some common sense. For example, the returned result of 'highest mountain' is a list of mountain names (with a few exceptions such as 'unclimbed'). In terms of syntactic patterns, we can observe that in most cases, the returned ngrams are in the similar form with target ngrams. In general, the trained embeddings basically reflect semantic meanings and syntactic patterns of ngrams.

With high-quality ngram embeddings, we have the opportunity to do more interesting things in our future work. For example, we will construct a antonym dataset to evaluate ngram embeddings systematically. Besides that, we will find more scenarios for using ngram embeddings. In our view, ngram embeddings have potential to be used in many NLP tasks. For example, Johnson and Zhang (2015) use one-hot ngram representation as the input of CNN. Li et al. (2016) use ngram embeddings to represent texts. Intuitively, initializing these models with pre-trained ngram embeddings may further improve the accuracies.

5 Conclusion

We introduce ngrams into four representation methods. The experimental results demonstrate ngrams' effectiveness for learning improved word representations. In addition, we find that the trained ngram embeddings are able to reflect their semantic meanings and syntactic patterns. To alleviate the costs brought by ngrams, we propose a novel way of building co-occurrence matrix, enabling the ngram-based models to run on cheap hardware.

`Dict2vec` : Learning Word Embeddings using Lexical Dictionaries

Abstract

Learning word embeddings on large unlabeled corpus has been shown to be successful in improving many natural language tasks. The most efficient and popular approaches learn or retrofit such representations using additional external data. Resulting embeddings are generally better than their corpus-only counterparts, although such resources cover a fraction of words in the vocabulary. In this paper, we propose a new approach, `Dict2vec`, based on one of the largest yet refined datasource for describing words – natural language dictionaries. `Dict2vec` builds new word pairs from dictionary entries so that semantically-related words are moved closer, and negative sampling filters out pairs whose words are unrelated in dictionaries. We evaluate the word representations obtained using `Dict2vec` on eleven datasets for the word similarity task and on four datasets for a text classification task.

1 Introduction

Learning word embeddings usually relies on the distributional hypothesis – words appearing in similar contexts must have similar meanings, and thus close representations. Finding such representations for words and sentences has been one hot topic over the last few years in Natural Language Processing (NLP) (Mikolov et al., 2013; Pennington et al., 2014) and has led to many improvements in core NLP tasks such as Word Sense Disambiguation (Iacobacci et al., 2016), Machine Translation (Devlin et al., 2014), Machine Comprehension (Hewlett et al., 2016), and Semantic Role Labeling (Zhou and Xu, 2015; Collobert et al., 2011) – to name a few.

These methods suffer from a classic drawback of unsupervised learning: the lack of supervision between a word and those appearing in the associated contexts. Indeed, it is likely that some terms of the context are not related to the considered word. On the other hand, the fact that two words do not appear together – or more likely, not often enough together – in any context of the training corpora is not a guarantee that these words are not semantically related. Recent approaches have proposed to tackle this issue using an attentive model for context selection (Ling et al., 2015), or by using external sources – like knowledge graphs – in order to improve the embeddings (Wang et al., 2014). Similarities derived from such resources are part of the objective function during the learning phase (Yu and Dredze, 2014; Kiela et al., 2015) or used in a retrofitting scheme (Faruqui et al., 2015). These approaches tend to specialize the embeddings to the resource used and its associated similarity measures – while the construction and maintenance of these resources are a set of complex, time-consuming, and error-prone tasks.

In this paper, we propose a novel word embedding learning strategy, called `Dict2vec`, that leverages existing online natural language dictionaries. We assume that dictionary entries (a definition of a word) contain latent word similarity and relatedness information that can improve language representations. Such entries provide, in essence, an additional context that conveys general semantic coverage for most words. `Dict2vec` adds new co-occurrences information based on the terms occurring in the definitions of a word. This information introduces weak supervision that can be used to improve the embeddings. We can indeed distinguish word pairs for which each word appears in the definition of the other (strong pairs) and pairs where only one appears in the definition of the other (weak pairs) – each

Proceedings of the 2017 Conference on Empirical Methods in Natural Language Processing, pages 254–263
Copenhagen, Denmark, September 7–11, 2017.

having their own weight as two hyperparameters. Not only this information is useful at learning time to control words vectors to be close for such word pairs, but also it becomes possible to devise a controlled negative sampling. Controlled negative sampling as introduced in `Dict2vec` consists in filtering out random negative examples in conventional negative sampling that forms a (strong or weak) pair with the target word – they are obviously non-negative examples. Processing online dictionaries in `Dict2vec` does not require a human-in-the-loop – it is fully automated. The neural network architecture from `Dict2vec` (Section 3) extends `Word2vec` (Mikolov et al., 2013) approach which uses a Skip-gram model with negative sampling.

Our main results are as follows :

- `Dict2vec` exhibits a statistically significant improvement around 12.5% against state-of-the-art solutions on eleven most common evaluation datasets for the word similarity task when embeddings are learned using the full Wikipedia dump.
- This edge is even more significant for small training datasets (50 millions first tokens of Wikipedia) than using the full dataset, as the average improvement reaches 30%.
- Since `Dict2vec` does significantly better than competitors for small dimensions (in the $[20;100]$ range) for small corpus, it can yield smaller yet efficient embeddings – even when trained on smaller corpus – which is one of the utmost practical interest for the working natural language processing practitioners.
- We also show that the embeddings learned by `Dict2vec` perform similarly to other baselines on an extrinsic text classification task.

Dict2vec software is an extension and an optimization from the original Word2vec framework leading to a more efficient learning. Source code to fetch dictionaries, train Dict2vec models and evaluate word embeddings are publicly availabe[1] and can be used by the community as a seed for future works.

The paper is organized as follows. Section 2 presents related works, along with a special focus on Word2vec, which we later derive in our approach presented in Section 3. Our experimental setup and evaluation settings are introduced in Section 4 and we discuss the results in Section 5. Section 6 concludes the paper.

2 Learning Word Embeddings

2.1 The Neural Network Approach

In the original model from Collobert and Weston (2008), a window approach was used to feed a neural network and learn word embeddings. Since there are long-range relations between words, the window-based approach was later extended to a sentence-based approach (Collobert et al., 2011) leading to capture more semantic similarities into word vectors. Recurrent neural networks are another way to exploit the context of a word by considering the sequence of words preceding it (Mikolov et al., 2010; Sutskever et al., 2011). Each neuron receives the current window as an input, but also its own output from the previous step.

Mikolov et al. (2013) introduced the Skip-gram architecture built on a single hidden layer neural network to learn efficiently a vector representation for each word w of a vocabulary V from a large corpora of size C. Skip-gram iterates over all (target, context) pairs (w_t,w_c) from every window of the corpus and tries to predict w_c knowing w_t. The objective function is therefore to maximize the log-likelihood :

$$\sum_{t=1}^{C} \sum_{k=-n}^{n} \log p(w_{t+k}|w_t) \tag{1}$$

where n represents the size of the window (composed of n words around the central word w_t) and the probability can be expressed as :

$$p(w_{t+k}|w_t) = \frac{e^{v_{t+k} \cdot v_t}}{\sum_{w \in V} e^{v \cdot v_t}} \tag{2}$$

with v_{t+k} (resp. v_t) the vector associated to w_{t+k} (resp. w_t).

This model relies on the principle "You shall know a word by the company it keeps" – Firth (1957). Thus, words that are frequent within the context of the target word will tend to have close representations, as the model will update their vectors so that they will be closer. Two main drawbacks can be said about this approach. First, words within the same window are not always related. Consider the sentence "Turing is widely considered to be the father of theoretical

[1] https://github.com/tca19/dict2vec

computer science and artificial intelligence."[2], the words (Turing,widely) and (father,theoretical) will be moved closer while they are not semantically related. Second, strong semantic relations between words (like synonymy or meronymy) happens rarely within the same window, so these relations will not be well embedded into vectors.

fastText introduced in Bojanowski et al. (2016) uses internal additional information from the corpus to solve the latter drawback. They train a Skip-gram architecture to predict a word w_c given the central word w_t and all the n-grams $\mathcal{G}_{w_t}$ (subwords of 3 up to 6 letters) of w_t. The objective function becomes :

$$\sum_{t=1}^{C} \sum_{k=-n}^{n} \sum_{w \in \mathcal{G}_{w_t}} \log p(w_{t+k}|w) \qquad (3)$$

Along learning one vector per word, fastText also learns one vector per n-gram. fastText is able to extract more semantic relations between words that share common n-gram(s) (like fish and fishing) which can also help to provide good embeddings for rare words since we can obtain a vector by summing vectors of its n-grams.

In what follows, we report related works that leverage external resources in order to address the two raised issues about the window approach.

2.2 Using External Resources

Even with larger and larger text data available on the Web, extracting and encoding every linguistic relations into word embeddings directly from corpora is a difficult task. One way to add more relations into embeddings is to use external data. Lexical databases like WordNet or sets of synonyms like MyThes thesaurus can be used during learning or in a post-processing step to specialize word embeddings. For example, Yu and Dredze (2014) include prior knowledge about synonyms from WordNet and the Paraphrase Database in a joint model built upon Word2vec. Faruqui et al. (2015) introduce a graph-based retrofitting method where they post-process learned vectors with respect to semantic relationships extracted from additional lexical resources. Kiela et al. (2015) propose to specialize the embeddings either on similarity or relatedness relations in a Skip-gram joint learning approach by adding new contexts from external thesaurus or from a norm association base in the function to optimize. Bian et al. (2014) combine several sources (syllables, POS tags, antonyms/synonyms, Freebase relations) and incorporate them into a CBOW model. These approaches have generally the objective to improve tasks such as document classification, synonym detection or word similarity. They rely on additional resources whose construction is a time-consuming and error-prone task and tend generally to specialize the embeddings to the external corpus used. Moreover, lexical databases contain less information than dictionaries (117k entries in WordNet, 200k in a dictionary) and less accurate content (some different words in WordNet belong to the same synset thus have the same definition).

Another type of external resources are knowledge bases, containing triplets. Each triplet links two entities with a relation, for example Paris – is capital of – France. Several methods (Weston et al., 2013; Wang et al., 2014; Xu et al., 2014) have been proposed to use the information from knowledge base to improve semantic relations in word embeddings, and extract more easily relational facts from text. These approaches are focused on knowledge base dependent task.

3 `Dict2vec`

The definition of a word is a group of words or sentences explaining its meaning. A dictionary is a set of tuples (word, definition) for several words. For example, one may find in a dictionary :

> **car**: A road vehicle, typically with four wheels, powered by an internal combustion engine and able to carry a small number of people.[3]

The presence of words like "vehicle", "road" or "engine" in the definition of "car" illustrates the relevance of using word definitions for obtaining weak supervision allowing us to get semantically related pairs of words.

`Dict2vec` models this information by building strong and weak pairs of words (§3.1), in order to provide both a novel positive sampling objective (§3.2) and a novel controlled negative sampling objective (§3.3). These objectives participate to the global objective function of `Dict2vec` (§3.4).

[2] https://en.wikipedia.org/wiki/Alan_Turing

[3] Definition from Oxford dictionary.

3.1 Strong pairs, weak pairs

In a definition, each word does not have the same semantic relevance. In the definition of "car", the words "internal" or "number" are less relevant than "vehicle". We introduce the concept of strong and weak pairs in order to capture this relevance. If the word w_a is in the definition of the word w_b and w_b is in the definition of w_a, they form a strong pair, as well as the K closest words to w_a (resp. w_b) form a strong pair with w_b (resp. w_a). If the word w_a is in the definition of w_b but w_b is not in the definition of w_a, they form a weak pair.

The word "vehicle" is in the definition of "car" and "car" is in the definition of "vehicle". Hence, (car–vehicle) is a strong pair. The word "road" is in the definition of "car", but "car" is not in the definition of "road". Therefore, (car–road) is a weak pair.

Some weak pairs can be promoted as strong pairs if the two words are among the K closest neighbours of each other. We chose the K closest words according to the cosine distance from a pretrained word embedding and find that using $K = 5$ is a good trade-off between semantic and syntactic extracted information.

3.2 Positive sampling

We introduce the concept of positive sampling based on strong and weak pairs. We move closer vectors of words forming either a strong or a weak pair in addition to moving vectors of words co-occurring within the same window.

Let $\mathcal{S}(w)$ be the set of all words forming a strong pair with the word w and $\mathcal{W}(w)$ be the set of all words forming a weak pair with w. For each target w_t from the corpus, we build $\mathcal{V}_s(w_t)$ a random set of n_s words drawn with replacement from $\mathcal{S}(w_t)$ and $\mathcal{V}_w(w_t)$ a random set of n_w words drawn with replacement from $\mathcal{W}(w_t)$. We compute the cost of positive sampling J_{pos} for each target as follows:

$$\begin{aligned} J_{pos}(w_t) = \ & \beta_s \sum_{w_i \in \mathcal{V}_s(w_t)} \ell(v_t \cdot v_i) \\ & + \beta_w \sum_{w_j \in \mathcal{V}_w(w_t)} \ell(v_t \cdot v_j) \end{aligned} \tag{4}$$

where ℓ is the logistic loss function defined by $\ell : x \mapsto \log(1 + e^{-x})$ and v_t (resp. v_i and v_j) is the vector associated to w_t (resp. w_i and w_j).

The objective is to minimize this cost for all targets, thus moving closer words forming a strong or a weak pair.

The coefficients β_s and β_w, as well as the number of drawn pairs n_s and n_w, tune the importance of strong and weak pairs during the learning phase. We discuss the choice of these hyperparameters in Section 5. When $\beta_s = 0$ and $\beta_w = 0$, our model is the Skip-gram model of Mikolov et al. (2013).

3.3 Controlled negative sampling

Negative sampling consists in considering two random words from the vocabulary $\mathcal{V}$ to be unrelated. For each word w_t from the vocabulary, we generate a set $\mathcal{F}(w_t)$ of k randomly selected words from the vocabulary :

$$\mathcal{F}(w_t) = \{w_i\}^k, w_i \in \mathcal{V} \setminus \{w_t\} \tag{5}$$

The model aims at separating the vectors of words from $\mathcal{F}(w_t)$ and the vector of w_t. More formally, this is equivalent to minimize the cost J_{neg} for each target word w_t as follows:

$$J_{neg}(w_t) = \sum_{w_i \in \mathcal{F}(w_t)} \ell(-v_t \cdot v_i) \tag{6}$$

where the notation ℓ, v_t and v_i are the same as described in previous subsection.

However, there is a non-zero probability that w_i and w_t are related. Therefore, the model will move their vectors further instead of moving them closer. With strong/weak word pairs in Dict2vec, it becomes possible to better ensure that this is less likely to occur: we prevent a negative example to be a word that forms a weak or strong pair with with w_t. The negative sampling objective from Equation 6 becomes :

$$J_{neg}(w_t) = \sum_{\substack{w_i \in \mathcal{F}(w_t) \\ w_i \notin \mathcal{S}(w_t) \\ w_i \notin \mathcal{W}(w_t)}} \ell(-v_t \cdot v_i) \tag{7}$$

In our experiments, we noticed this method discards around 2% of generated negative pairs. The influence on evaluation depends on the nature of the corpus and is discussed at Section 5.4.

3.4 Global objective function

Our objective function is derived from the noise-contrastive estimation which is a more efficient objective function than the log-likelihood in Equation 1 according to Mikolov et al. (2013). We add the positive sampling and the controlled negative sampling described before and compute the cost for each (target,context) pair (w_t, w_c) from the corpus as follows:

$$J(w_t, w_c) = \ell(v_t \cdot v_c) + J_{pos}(w_t) + J_{neg}(w_t) \tag{8}$$

The global objective is obtained by summing every pair's cost over the entire corpus :

$$J = \sum_{t=1}^{C} \sum_{c=-n}^{n} J(w_t, w_{t+c}) \tag{9}$$

4 Experimental setup

4.1 Fetching online definitions

We extract all unique words with more than 5 occurrences from a full Wikipedia dump, representing around 2.2M words. Since there is no dictionary that contains a definition for all existing words (the word w might be in the dictionary D_i but not in D_j), we combine several dictionaries to get a definition for almost all of these words (some words are too rare to have a definition anyway). We use the English version of Cambridge, Oxford, Collins and dictionary.com. For each word, we download the 4 different webpages, and use regex to extract the definitions from the HTML template specific to each website, making the process fully accurate. Our approach does not focus on polysemy, so we concatenate all definitions for each word. Then we concatenate results from all dictionaries, remove stop words and punctuation and lowercase all words. For our illustrative example in Section 3, we obtain :

> **car**: road vehicle engine wheels seats small [...] platform lift.

Among the 2.2M unique words, only 200K does have a definition. We generate strong and weak pairs from the downloaded definitions according to the rule described in subsection 3.1 leading to 417K strong pairs (when the parameter K from 3.1 is set to 5) and 3.9M weak pairs.

4.2 Training settings

We train our model with the generated pairs from subsection 4.1 and the November 2016 English dump from Wikipedia [4]. After removing all XML tags and converting all words to lowercase (with the help of Mahoney's script[5]), we separate the corpus into 3 files containing respectively the first 50M tokens, the first 200M tokens, and the full dump. Our model uses additional knowledge during training. For a fair comparison against other frameworks, we also incorporate this information into the training data and create two versions for each file : one containing only data from Wikipedia (corpus A) and one with data from Wikipedia concatenated with the definitions extracted (corpus B).

We use the same hyperparameters we usually find in the literature for all models. We use 5 negatives samples, 5 epochs, a window size of 5, a vector size of 100 (resp. 200 and 300) for the 50M file (resp. 200M and full dump) and we remove the words with less than 5 occurrences. We follow the same evaluation protocol as Word2vec and fastText to provide the fairest comparison against competitors, so every other hyperparameters (K, β_s, β_w, n_s, n_w) are tuned using a grid search to maximize the weighted average score. For n_s and n_w, we go from 0 to 10 with a step of 1 and find the optimal values to be $n_s = 4$ and $n_w = 5$. For β_s and β_w we go from 0 to 2 with a step of 0.05 and find $\beta_s = 0.8$ and $\beta_w = 0.45$ to be the best values for our model. Table 1 reports training times for the three models (all experiments were run on a E3-1246 v3 processor).

	50M	200M	Full
Word2vec	15m30	86m	2600m
fastText	8m44	66m	1870m
Dict2vec	4m09	26m	642m

Table 1: Training time (in min) of Word2vec, fastText and Dict2vec models for several corpus.

4.3 Word similarity evaluation

We follow the standard method for word similarity evaluation by computing the Spearman's rank correlation coefficient (Spearman, 1904) between human similarity evaluation of pairs of words, and the cosine similarity of the corresponding word vectors. A score close to 1 indicates an embedding close to the human judgement.

We use MC-30 (Miller and Charles, 1991), MEN (Bruni et al., 2014), MTurk-287 (Radinsky et al., 2011), MTurk-771 (Halawi et al., 2012),

[4] https://dumps.wikimedia.org/enwiki/20161101/

[5] http://mattmahoney.net/dc/textdata#appendixa

RG-65 (Rubenstein and Goodenough, 1965), RW (Luong et al., 2013), SimVerb-3500 (Gerz et al., 2016), WordSim-353 (Finkelstein et al., 2001) and YP-130 (Yang and Powers, 2006) classic datasets. We follow the same protocol used by Word2vec and fastText by discarding pairs which contain a word that is not in our embedding. Since all models are trained with the same corpora, the embeddings have the same words, therefore all competitors share the same OOV rates.

We run each experiment 3 times and report in Table 2 the average score to minimize the effect of the neural network random initialization. We compute the average by weighting each score by the number of pairs evaluated in its dataset in the same way as Iacobacci et al. (2016). We multiply each score by $1,000$ to improve readability.

4.4 Text classification evaluation

Our text classification task follows the same setup as the one for fastText in Joulin et al. (2016). We train a neural network composed of a single hidden layer where the input layer corresponds to the bag of words of a document and the output layer is the probability to belong to each label. The weights between the input and the hidden layer are initialized with the generated embeddings and are fixed during training, so that the evaluation score solely depends on the embedding. We update the weights of the neural network classifier with gradient descent. We use the datasets AG-News [6], DBpedia (Auer et al., 2007) and Yelp reviews (polarity and full)[7]. We split each datasets into a training and a test file. We use the same training and test files for all models and report the classification accuracy obtained on the test file.

4.5 Baselines

We train Word2vec[8] and fastText[9] on the same 3 files and their 2 respective versions (A and B) described in 4.2 and use the same hyperparameters also described in 4.2 for all models. We train Word2vec with the Skip-gram model since our method is based on the Skip-gram model. We also train GloVe with their respective hyperparameters described in Pennington et al. (2014), but the results are lower than all other baselines (weighted average on word similarity task is 350 on the 50M file, 389 on the 200M file and 454 on the full dump) so we do no report GloVe's results.

We also retrofit the learned embeddings on corpus A with the Faruqui's method to compare another method using additional resources. The retrofitting introduces external knowledge from the WordNet semantic lexicon (Miller, 1995). We use the **Faruqui's Retrofitting**[10] with the WN_{all} semantic lexicon from WordNet and 10 iterations as advised in the paper of Faruqui et al. (2015). Furthermore, we compare the performance of our method when using WordNet additional resources instead of dictionaries.

5 Results and model analysis

5.1 Semantic similarity

Table 2 (top) reports the Spearman's rank correlation scores obtained with the method described in subsection 4.3. We observe that our model outperforms state-of-the-art approaches for most of the datasets on the 50M and 200M tokens files, and almost all datasets on the full dump (this is significant according to a two-sided Wilcoxon signed-rank test with $\alpha = 0.05$). With the weighted average score, our model improves fastText's performance on raw corpus (column A) by 28.3% on the 50M file, by 17.7% on the 200M and by 12.8% on the full dump. Even when we train fastText with the same additional knowledge as ours (column B), our model improves performance by 2.9% on the 50M file, by 5.1% in the 200M and by 11.9% on the full dump.

We notice the column B (corpus composed of Wikipedia and definitions) has better results than the column A for the 50M ($+24\%$ on average) and the 200M file ($+12\%$ on average). This demonstrates the strong semantic relations one can find in definitions, and that simply incorporating definitions in small training file can boost the performance of the embeddings. Moreover, when the training file is large (full dump), our supervised method with pairs is more efficient, as the boost brought by the concatenation of definitions is insignificant ($+1.5\%$ on average).

We also note that the number of strong and weak pairs drawn must be set according to the size of the training file. For the 50M and 200M tokens files, we train our model with hyperparameters $n_s = 4$ and $n_w = 5$. For the full dump (20

Table 3: Percentage changes of word similarity scores for several datasets after the Faruqui's retrofitting method is applied. We compare each model to their own non-retrofitted version (vs self) and our non-retrofitted version (vs our). A positive percentage indicates the level of improvement of the retrofitting approach, while a negative percentage shows that the compared method is better without retrofitting. As an illustration: the +13.9% at the top left means that retrofitting Word2vec's vectors improves the initial vectors output by 13.9%, while the -7.3% below indicates that our approach without retrofitting is better than the retrofitted Word2vec's vectors.

times larger than the 200M tokens file), the number of windows in the corpus is largely increased, so is the number of (target,context) pairs. Therefore, we need to adjust the influence of strong and weak pairs and decrease n_s and n_w. We set $n_s = 2$, $n_w = 3$ to train on the full dump.

The Faruqui's retrofitting method improves the word similarity scores on all frameworks for all datasets, except on RW and WS353 (Table 3). But even when Word2vec and fastText are retrofitted, their scores are still worse than our non-retrofitted model (every percentage on the *vs our* line are negative). We also notice that our model is compatible with a retrofitting improvement method as our scores are also increased with Faruqui's method.

We also observe that, although our model is superior on each corpus size, our model trained on the 50M tokens file outperforms the other models trained on the full dump (an improvement of 17% compared to the results of fastText, our best competitor, trained on the full dump). This means considering strong and weak pairs is more efficient than increasing the corpus size and that using dictionaries is a good way to improve the quality of the embeddings when the training file is small.

The models based on knowledge bases cited in §2.2 do not provide word similarity scores on all the datasets we used. However, for the reported scores, Dict2vec outperforms these models : Kiela et al. (2015) achieves a correlation of 0.72 on the MEN dataset (vs. 0.756); Xu et al. (2014) achieves 0.683 on the WS353-ALL dataset (vs. 0.758).

5.2 Text classification accuracy

Table 2 (bottom) reports the classification accuracy for the considered datasets. Our model achieves the same performances as Word2vec and fastText on the 50M file and slightly improves results on the 200M file and the full dump. Using supervision with pairs during training does not make our model specific to the word similarity task which shows that our embeddings can also be used in downstream extrinsic tasks.

Note that for this experiment, the embeddings were fixed and not updated during learning (we only learned the classifier parameters) since our objective was rather to evaluate the capability of the embeddings to be used for another task rather than obtaining the best possible models. It is anyway possible to obtain better results by updating the embeddings and the classifier parameters with respect to the supervised information to adapt the embeddings to the classification task at hand as done in Joulin et al. (2016).

5.3 Dictionaries vs. WordNet

		Raw	R_{WN}	R_{dict}
50M	w2v	453	474	**479**
	FT	467	476	**489**
	our	569	582	**582**
200M	w2v	471	488	**494**
	FT	503	504	**524**
	our	569	581	**587**
full	w2v	488	507	**512**
	FT	508	503	**529**
	our	571	583	**592**

Table 4: Weighted average Spearman correlation score of raw vectors and after retrofitting with WordNet pairs (R_{WN}) and dictionary pairs (R_{dict}).

Table 4 reports the Spearman's rank correlation score for vectors obtained after training (Raw column) and the scores after we retrofit those vectors with pairs from WordNet (R_{WN}) and extracted pairs from dictionaries (R_{dict}). Retrofitting with dictionaries outperforms retrofitting with WordNet lexicons, meaning that data from dictionaries are better suited to improve embeddings toward semantic similarities when retrofitting.

	50M	200M	full
No pairs	453	471	488
With WordNet pairs	564	566	559
With dictionary pairs	**569**	**569**	**571**

Table 5: Weighted average Spearman correlation score of Dict2vec vectors when trained without pairs and with WordNet or dictionary pairs.

We also trained Dict2vec with pairs from WordNet as well as no additional pairs during training (in this case, this is the Skip-gram model from Word2vec). Results are reported in Table 5. Training with WordNet pairs increases the scores, showing that the supervision brought by positive sampling is beneficial to the model, but lags behind the training using dictionary pairs demonstrating once again that dictionaries contain more semantic information than WordNet.

5.4 Positive and negative sampling

For the positive sampling, an empirical grid search shows that a $\frac{1}{2}$ ratio between β_s and β_w is a good rule-of-thumb for tuning these hyperparameters. We also notice that when these coefficients are too low ($\beta_s \leq 0.5$ and $\beta_w \leq 0.2$), results get worse because the model does not take into account the information from the strong and weak pairs. On the other side, when they are too high ($\beta_s \geq 1.2$ and $\beta_w \geq 0.6$), the model discards too much the information from the context in favor of the information from the pairs. This behaviour is similar when the number of strong and weak pairs is too low or too high ($n_s, n_w \leq 2$ or $n_s, n_w \geq 5$).

For the negative sampling, we notice that the control brought by the pairs increases the average weighted score by 0.7% compared to the uncontrolled version. We also observe that increasing the number of negative samples does not significantly improve the results except for the RW dataset where using 25 negative samples can boost performances by 10%. Indeed, this dataset is mostly composed of rare words so the embeddings must learn to differentiate unrelated words rather than moving closer related ones.

5.5 Vector size

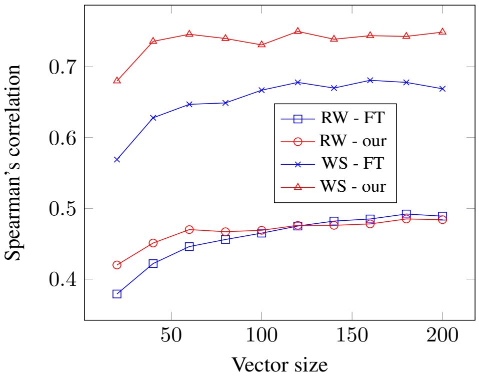

Figure 1: Spearman's rank correlation coefficient for RW-STANFORD (RW) and WS-353-ALL (WS) on the fastText model (FT) and our, with different vector size. Training is done on the corpus A of 50M tokens.

In Fig. 1, we observe that our model is still able to outperform state-of-the-art approaches when we reduce the dimension of the embeddings to 20 or 40. We also notice that increasing the vector size does increase the performance, but only until a dimension around 100, which is the common dimension used when training on the 50M tokens file for related approaches reported here.

6 Conclusion

In this paper, we presented `Dict2vec`, a new approach for learning word embeddings using lexical dictionaries. It is based on a Skip-gram model where the objective function is extended by leveraging word pairs extracted from the definitions weighted differently with respect to the strength of the pairs. Our approach shows better results than state-of-the-art word embeddings methods for the word similarity task, including methods based on a retrofitting from external sources. We also provide the full source code to reproduce the experiments.

Abstract

In this paper, we propose new methods to learn Chinese word representations. Chinese characters are composed of graphical components, which carry rich semantics. It is common for a Chinese learner to comprehend the meaning of a word from these graphical components. As a result, we propose models that enhance word representations by character glyphs. The character glyph features are directly learned from the bitmaps of characters by convolutional auto-encoder(convAE), and the glyph features improve Chinese word representations which are already enhanced by character embeddings. Another contribution in this paper is that we created several evaluation datasets in traditional Chinese and made them public.

1 Introduction

No matter which target language it is, high quality word representations (also known as word "embeddings") are keys to many natural language processing tasks, for example, sentence classification (Kim, 2014), question answering (Zhou et al., 2015), machine translation (Sutskever et al., 2014), etc. Besides, word-level representations are building blocks in producing phrase-level (Cho et al., 2014) and sentence-level (Kiros et al., 2015) representations.

In this paper, we focus on learning Chinese word representations. A Chinese word is composed of characters which contain rich semantics. The meaning of a Chinese word is often related to the meaning of its compositional characters. Therefore, Chinese word embedding can be enhanced by its compositional character embeddings (Chen et al., 2015; Xu et al., 2016). Furthermore, a Chinese character is composed of several graphical components. Characters with the same component share similar semantic or pronunciation. When a Chinese user encounters a previously unseen character, it is instinctive to guess the meaning (and pronunciation) from its graphical components, so understanding the graphical components and associating them with semantics help people learning Chinese. Radicals[1] are the graphical components used to index Chinese characters in a dictionary. By identifying the radical of a character, one obtains a rough meaning of that character, so it is used in learning Chinese word embedding (Yin et al., 2016) and character embedding (Sun et al., 2014; Li et al., 2015). However, other components in addition to radicals may contain potentially useful information in word representation learning.

Our research begins with a question: *Can machines learn Chinese word representations from glyphs of characters?* By exploiting the glyphs of characters as images in word representation learning, all the graphical components in a character are considered, not limited to radicals. In our proposed methods, we render character glyphs to fixed-size grayscale images which are referred to as "character bitmaps", as illustrated in Fig.1. A similar idea was also used in (Liu et al., 2017) to help classifying wikipedia article titles into 12 categories. We use a convAE to extract character features from the bitmap to represent the glyphs. It is also possible to represent the glyph of a character by the graphical components in it. We do not choose this way because there is no unique way to decompose a character, and directly learning representation from bitmaps is more straightforward. Then we use the models parallel to Skip-gram (Mikolov et al., 2013a) or GloVe (Penning-

[1] https://en.wikipedia.org/wiki/Radical_(Chinese_characters)

ton et al., 2014) to learn word representations from the character glyph features. Although we only consider traditional Chinese characters in this paper, and the examples given below are based on the traditional characters, the same ideas and methods can be applied on the simplified characters.

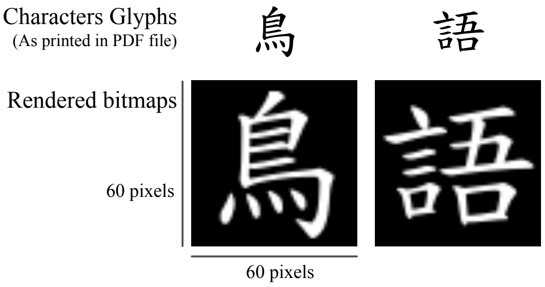

Figure 1: A Chinese character is represented as a fixed-size gray-scale image which is referred to as "character bitmap" in this paper.

2 Background Knowledge and Related Works

To give a clear illustration of our own work, we briefly introduce the representative methods of word representation learning in Section 2.1. In Section 2.2, we will introduce some of the linguistic properties of Chinese, and then introduce the methods that utilize these properties to improve word representations.

2.1 Word Representation Learning

Mainstream research of word representation is built upon the distributional hypothesis, that is, words with similar contexts share similar meanings. Usually a large-scale corpus is used, and word representations are produced from the co-occurrence information of a word and its context. Existing methods of producing word representations could be separated into two families (Levy et al., 2015): count-based family (Turney and Pantel, 2010; Bullinaria and Levy, 2007), and prediction-based family. Word representations can be obtained by training a neural-network-based models (Bengio et al., 2003; Collobert et al., 2011). The representative methods are briefly introduced below.

2.1.1 CBOW and Skipgram

Both continuous bag-of-words (CBOW) model and Skipgram model train with words and contexts in a sliding local context window (Mikolov et al., 2013a). Both of them assign each word w_i with an embedding $\vec{w}_i$. CBOW predicts the word given its context embeddings, while Skipgram predicts contexts given the word embedding. Predicting the occurrence of word/context in CBOW and Skipgram models could be viewed as learning a multi-class classification neural network (the number of classes is the size of vocabulary). In (Mikolov et al., 2013b), the authors introduced several techniques to improve the performance. Negative sampling is introduced to speed up learning, and subsampling frequent words is introduced to randomly discard training examples with frequent words (such as "the", "a", "of"), and has an effect similar to the removal of stop words.

2.1.2 GloVe

Instead of using local context windows, (Pennington et al., 2014) proposed GloVe model. Training GloVe word representations begins with creating a co-occurrence matrix X from a corpus, where each matrix entry X_{ij} represents the counts that word w_j appears in the context of word w_i. In (Pennington et al., 2014), the authors used a harmonic weighting function for co-occurrence count, that is, word-context pairs with distance d contributes $\frac{1}{d}$ to the global co-occurrence count.

Let $\vec{w}_i$ be the word representation of word w_i, and $\tilde{\vec{w}}_j$ be the word representation of word w_j as context, GloVe model minimizes the loss:

$$\sum_{i,j\in \substack{non-zero\\ entries\ of\ X}} f(X_{ij})(\vec{w}_i^T\tilde{\vec{w}}_j+b_i+\tilde{b}_j-log(X_{ij})),$$

where b_i is the bias for word w_i, and $\tilde{b}_j$ is the bias for context w_j. A weighting function $f(X_{ij})$ is introduced because the authors consider rare co-occurrence word-context pairs carry less information than frequent ones, and their contributions to the total loss should be decreased. The weighting function $f(X_{ij})$ is defined as below. It depends on the co-occurrence count, and the authors set parameters $x_{max} = 100$, $\alpha = 0.75$.

$$f(X_{ij}) = \begin{cases} (\frac{X_{ij}}{x_{max}})^{\alpha} & \text{if } X_{ij} < x_{max} \\ 1 & \text{otherwise} \end{cases}$$

In the GloVe model, each word has 2 representations $\vec{w}$ and $\tilde{\vec{w}}$. The authors suggest using $\vec{w} + \tilde{\vec{w}}$ as the word representation, and reported improvements over using $\vec{w}$ only.

2.2 Improving Chinese Word Representation Learning

2.2.1 The Chinese Language

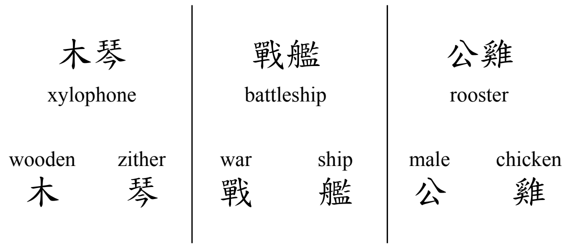

Figure 2: Examples of compositional Chinese words. Still, the reader should keep in mind that NOT all Chinese words are compositional (related to the meanings of its compositional characters).

A Chinese word is composed of a sequence of characters. The meanings of some Chinese words are related to the composition of the meanings of their characters. For example, "戰艦" (battleship), is composed of two characters, "戰" (war) and "艦" (ship). More examples are given in Fig. 2. To improve Chinese word representations with sub-word information, character-enhanced word embedding (CWE) (Chen et al., 2015) in Section 2.2.2 is proposed.

(A) Radicals:		虫	木	氵(水)
(B) Semantics:		anthropods, reptiles	plants, wooden materials	water, liquid
(C) Characters:	(C-1)	蝶 (butterfly)	棉 (cotton)	海 (sea)
	(C-2)	蜂 (bee)	楓 (maple)	溪 (river)
	(C-3)	蚊 (mosquito)	棍 (stick)	湯 (soup)
	(C-4)	蛇 (snake)	梅 (plum)	淚 (tear)
	(C-5)	蟹 (crab)	果 (fruit)	泉 (spring)

Figure 3: Some examples of radicals and the characters containing them. In rows (C-1) to (C-4), the radicals are at the left hand side of the character, while in row (C-5), the radicals are at the bottom, and may have different of shapes.

A Chinese character is composed of several graphical components. Characters with the same component share similar semantic or phonetic properties. In a Chinese dictionary characters with similar coarse semantics are grouped into categories for the ease of searching. The common graphical component which relates to the common semantic is chosen to index the category, known as a radical. Examples are given in Fig. 3. There are three radicals in row (A), and their semantic meanings are in row (B). In each column, there are five characters containing each radical. It is easy to find that the characters having the same radical have meanings related to the radical in some aspect. A radical can be put in different positions in a character. For example, in rows (C-1) to (C-4), the radicals are at the left hand side of a character, but in row (C-5), the radicals are at the bottom. The shape of a radical can be different in different positions. For example, the third radical which represents "water" or "liquid" has different forms when it is at the left hand side or the bottom of a character. Because radicals serve as a strong semantic indicator of a character, multi-granularity embedding (MGE) (Yin et al., 2016) in Section 2.2.3 incorporates radical embeddings in learning word representation.

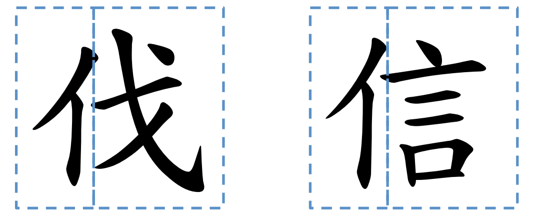

Figure 4: Both characters in the figure have the same radical "亻" (means humans) at the left hand side, but their meanings are the composition of the graphical components at the right hand side and their radical.

Usually the components other than radicals determine the pronunciation of the characters, but in some cases they also influence the meaning of a character. Two examples are given in Fig. 4[2]. Both characters in Fig. 4 have the same radical "亻" (means humans) at the left hand side, but the graphical components at the right hand side also have semantic meanings related to the characters. Considering the left character "伐" (means attack). Its right component "戈" means "weapon", and the meaning of the character "伐" is the composition of the meaning of its two components (a human with a weapon). None of the previous word embedding approach considers all the components of Chinese characters in our best knowledge.

[2] The two example characters here have the same glyphs in the traditional and simplified Chinese characters.

2.2.2 Character-enhanced Word Embedding (CWE)

The main idea of CWE is that word embedding is enhanced by its compositional character embeddings. CWE predicts the word from both word and character embeddings of contexts, as illustrated in Fig. 5 (a). For word w_i, the CWE word embedding $\vec{w}_i^{cwe}$ has the following form:

$$\vec{w}_i^{cwe} = \vec{w}_i + \frac{1}{|C(i)|} \sum_{c_j \in C(i)} \vec{c}_j$$

where $\vec{w}_i$ is the word embedding, $\vec{c}_j$ is the embedding of the j-th character in w_i, and $C(i)$ is the set of compositional characters of word w_i. Mean value of CWE word embeddings of contexts are then used to predict the word w_i.

Sometimes one character has several different meanings, this is known as the ambiguity problem. To deal with this, each character is assigned with a bag of embeddings. During training, one of the embeddings is picked to form the modified word embedding. The authors proposed three methods to decide which embedding is picked: position-based, cluster-based, and non-parametric cluster-based character embeddings.

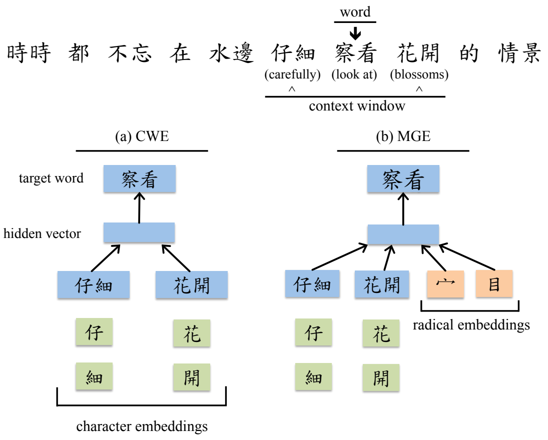

Figure 5: Model comparison of Character-enhanced Word Embedding (CWE) and Multi-granularity Embedding (MGE).

2.2.3 Multi-granularity Embedding (MGE)

Based on CBOW and CWE, (Yin et al., 2016) proposed MGE, which predicts target word with its radical embeddings and modified word embeddings of context in CWE, as shown in Fig.5 (b).

There is no ambiguity of radicals, so each radical is assigned with one embedding $\vec{r}$. We denote $\vec{r}_k$ as the radical embedding of character c_k. MGE predicts the target word w_i with the following hidden vector:

$$\vec{h}_i = \frac{1}{|C(i)|} \sum_{c_k \in C(i)} \vec{r}_k + \frac{1}{|W(i)|} \sum_{w_j \in W(i)} \vec{w}_j^{cwe}$$

, where W(i) is the set of contexts words of w_i, $\vec{w}_j^{cwe}$ is the CWE word embedding of w_j. MGE picks character embeddings with the position-based method in CWE, and picks radical embeddings according to a character-radical index built from a dictionary during training. When non-compositional word is encountered, only the word embedding is used to form $\vec{h}_i$.

3 Model

We first extract glyph features from bitmaps with the convAE in Section 3.1. The glyph features are used to enhance the existing word representation learning models in Section 3.2. In Section 3.3, we try to learn word representations directly from the glyph features.

3.1 Character Bitmap Feature Extraction

A convAE (Masci et al., 2011) is used to reduce the dimensions of rendered character bitmaps and capture high-level features. The architecture of the convAE is shown in Fig. 6. The convAE is composed of 5 convolutional layers in both encoder and decoder. The stride larger than one is used instead of pooling layers. Convolutional and deconvolutional layers on the same level share the same kernel. The input image is a 60×60 8-bit grayscale bitmap, and the encoder extracts 512-dimensional feature. The feature of character c_k from the encoder is refer to as character glyph feature $\vec{g}_k$ in the paper.

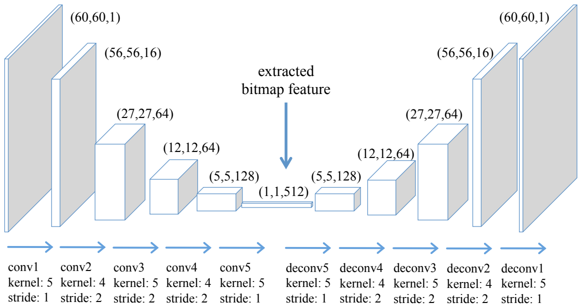

Figure 6: The architecture of convAE.

3.2 Glyph-Enhanced Word Embedding (GWE)

3.2.1 Enhanced by Context Word Glyphs

We modify CWE model based on CBOW in Section 2.2.2 to incorporate context character glyph features (ctxG). This modified word embedding $\vec{w}_i^{ctxG}$ of word w_i has the form:

$$\vec{w}_i^{ctxG} = \vec{w}_i + \frac{1}{|C(i)|} \sum_{c_j \in C(i)} (\vec{c}_j + \vec{g}_j),$$

where $C(i)$ is the compositional characters of w_i and $\vec{g}_j$ is the glyph feature of c_j. The model predicts target word w_i from ctxG word embeddings of contexts, as shown in Fig.7. The parameters in the convAE are pre-trained, thus not jointly learned with embeddings $\vec{w}$ and $\vec{c}$, so character glyph features $\vec{g}$ are fixed during training.

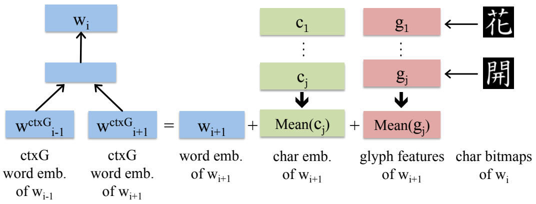

Figure 7: Illustration of exploiting context word glyphs. Mean value of character glyph features in the context is added to the hidden vector that predicts target word.

3.2.2 Enhanced by Target Word Glyphs

Here we propose another variant. In this model, the model structure is the same as in Fig.7. The difference lies in the hidden vector used to predict the target word. Instead of adding mean value of character glyph features of the contexts, it adds mean value of glyph feature of the target word (tarG), as shown in Fig.8. As in Section 3.2.1, convAE is not jointly learned.

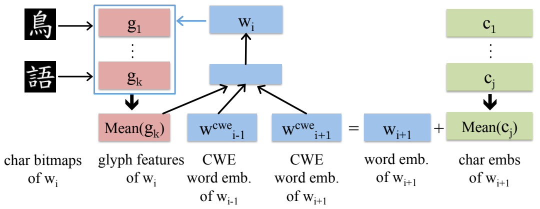

Figure 8: Illustration of exploiting target word glyphs. Mean value of character glyph features of target words help predicting target word itself.

3.3 Directly Learn From Character Glyph Features

3.3.1 RNN-Skipgram

We learn word representation $\vec{w}_i$ directly from the sequence of character glyph features $\{\vec{g}_k, c_k \in C(i)\}$ of word w_i, with the objective of Skipgram. As in Fig.9, a 2-layer Gated Recurrent Units (GRU) (Cho et al., 2014) network followed by 2 fully connected ELU (Clevert et al., 2015) layers produces word representation $\vec{w}_i$ from input sequence $\{\vec{g}_k\}$ of word w_i. $\vec{w}_i$ is then used to predict the contexts of w_i. In the training we use negative sampling and subsampling on frequent words from (Mikolov et al., 2013b).

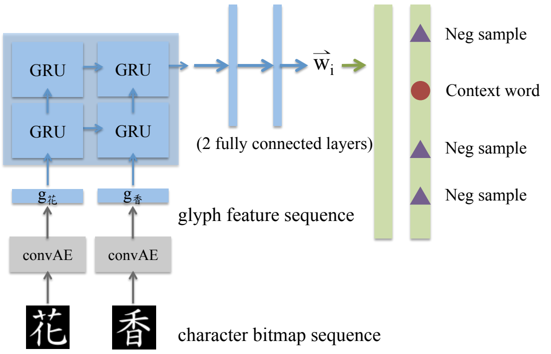

Figure 9: Model architecture of RNN-Skipgram model. Produced word representation $\vec{w}_i$ is used to predict the context of word w_i.

3.3.2 RNN-GloVe

We modify GloVe model to directly learn from character glyph features as in Fig.10. We feed character glyph feature sequence $\{\vec{g}_k, c_k \in C(i)\}$, $\{\vec{g}_{k'}, c_{k'} \in C(j)\}$ of word w_i and context w_j to a shared GRU network. Outputs of GRU are then fed to two different fully connected ELU layers to produce word representations $\vec{w}_i$ and $\vec{\tilde{w}}_j$. The inner product of $\vec{w}_i$ and $\vec{\tilde{w}}_j$ is the prediction of log co-occurrence $log(X_{ij})$. We apply the same loss function with weights in GloVe. We follow (Pennington et al., 2014) and use $\vec{w}_i + \vec{\tilde{w}}_i$ for evaluations of word representation.

4 Experimental Setup

4.1 Preprocessing

We learned word representations with traditional Chinese texts from Central News Agency daily newspapers from 1991 to 2002 (Chinese Giga-

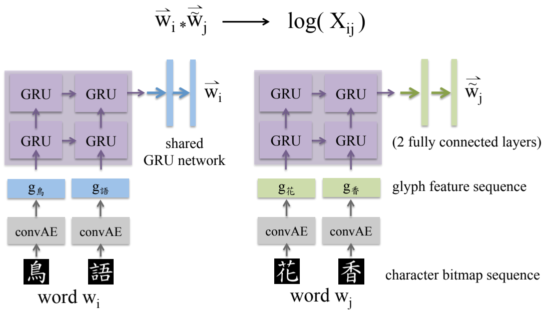

Figure 10: Model architecture of RNN-GloVe. A shared GRU network and 2 different sets of fully connected ELU layers produce $\vec{w}_i$ and $\vec{\tilde{w}}_j$. Inner product of $\vec{w}_i$ and $\vec{\tilde{w}}_j$ is the prediction of log co-occurrence $log(X_{ij})$.

word, LDC2003T09). All foreign words, numerical words, and punctuations were removed. Word segmentation was performed using open source python package `jieba`[3]. In all 316,960,386 segmented words, we extracted 8780 unique characters, and used a true type font (BiauKai) to render each character glyph to a 60×60 8-bit grayscale bitmap. Furthermore, We removed words whose frequency $<=$ 25, leaving 158,565 unique words as the vocabulary set.

4.2 Extracting Visual Features of Character Bitmap

Inspired by (Zeiler et al., 2011), layer-wise training was applied to our convAE. From lower level to higher, the kernel of each layer is trained individually, with other kernels frozen for 100 epochs. Loss function is the Euclidean distance between input and reconstructed bitmap, and we added $l1$ regularization to the activations of convolution layers. We chose Adagrad as the optimizing algorithm, and set batch size $=$ 20 and learning rate $= 0.001$.

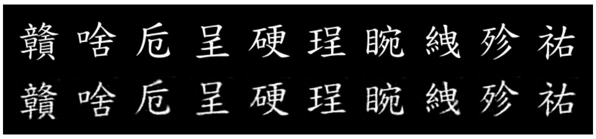

Figure 11: The input bitmaps of convAE and their reconstructions. The input bitmaps are in the upper row, while the reconstructions are in the lower row.

The comparison between the input bitmaps and their reconstructions is shown in Fig 11. The input bitmaps are in the upper row, while the reconstructions are in the lower row. We further visualized the extracted character glyph features with t-SNE (Maaten and Hinton, 2008). Part of the visualization result is shown in Fig. 12. From Fig. 12, we found that the characters with the same components are clustered. The result shows that the features extracted by the convAE are capable of expressing the graphical information in the bitmaps.

4.3 Training Details of Word Representations

We used CWE code[4] to implement both CBOW and Skipgram, along with the CWE. The number of multi-embedding was set to 3. We modified the CWE code to produce GWE representations. For CBOW, Skipgram, CWE, GWE and RNN-Skipgram, we used the following hyperparameters. Context window was set to 5 to both sides of a word. We used 10 negative samples, and threshold t of subsampling was set to 10^{-5}.

Since Yin at al. did not publish their code, we followed their paper and reproduced the MGE model. We created the mapping between characters and radicals from the Unihan database[5]. Each character corresponds to one of the 214 radicals in this dataset, and the same hyperparameters were used in training as above. Note that we did not separate non-compositional words during training as the original CWE and MGE did.

We used the GloVe code[6] to train the baseline GloVe vectors. In construction of co-occurrence matrix for GloVe and RNN-GloVe, we followed the parameter settings of $x_{max} = 100$ and $\alpha = 0.75$ in (Pennington et al., 2014). Context window was 5 words to the both sides of a word, and harmonic weighting was used on co-occurrence counts. For the RNN-GloVe model, we removed entries whose value < 0.5 to speed up training.

RNN-Skipgram and RNN-GloVe generated 200-dimensional word embeddings, while other models generated 512-dimensional word embeddings.

To encourage further research, we published our convAE and embedding models on github[7]. Evaluation datasets were also uploaded, whose details will be explained in Section 5.

5 Evaluation

5.1 Word Similarity

A word similarity test contains multiple word pairs and their human annotated similarity scores. Word representations are considered good if the calculated similarity and human annotated scores have a high rank correlation. We computed the Spearman's correlation between human annotated scores and cosine similarity of word representations.

Since there is little resource for traditional Chinese, we translated WordSim-240 and WordSim-296 datasets provided by (Chen et al., 2015). Note that this translation is non-trivial. Some frequent words are considered out-of-vocabulary (OOV) due to the different usage between the simplified and traditional. For example, “butter” is translated to “黃油” in simplified, but “奶油” in traditional. Besides, we manually translated SimLex-999 (Hill et al., 2016) to traditional Chinese, and used it as the third testing dataset. We also made these datasets public along with our code.

When calculating similarities, word pairs containing OOVs were removed. In Table 1, there are only 237, 284 and 979 word pairs left in WordSim-240, WordSim-296 and SimLex-999, respectively. The results are presented in Table 1. The results of ordinary CBOW and Skipgram are shown in the table. CBOW/Skipgram+CWE represents CWE trained as CBOW or Skipgram. For CWE, we only show the results of position-based character embeddings here because the results of cluster-based character embeddings are worse in the experiments. We found that CWE only consistently improved the performance on SimLex-999 for both CBOW and Skipgram probably because SimLex-999 contains more words that could be understood from their compositional characters. On SimLex-999, we observed that CWE was better with CBOW than Skipgram. We think the reason is that CBOW+CWE predicts the target word with the mean value of all character embeddings in the context, thus has a less noisy feature; however Skipgram+CWE uses character embeddings of an individual word. This noisy feature could cause

Model	WS-240	WS-296	SL-999
CBOW	**0.5203**	0.5550	0.3330
+CWE	0.4914	**0.5553**	0.3471
+CWE+MGE	0.3767	0.2962	0.2762
+CWE+ctxG	0.4982	0.5549	**0.3538**

Skipgram	**0.5922**	0.5876	0.3663
+CWE	0.5916	**0.5936**	0.3668
+CWE+ctxG	0.5886	0.5856	**0.3686**
RNN-Skipgram	0.3414	0.3698	0.2464
RNN-Glove	0.2963	0.1563	0.1010

Table 1: Spearman's correlation between human annotated scores and cosine similarity of word representations on three datasets: WordSim-240, WordSim-296 and SimLex-999. The higher the values, the better the results.

negative effects on predicting the target word. The GWEs were learned based on CWE in two ways. “ctxG” represents using glyph features of context words, while “tarG” represents using glyph features of target words. The glyph features improved CWE on WordSim-240 and SimLex-999, but not WordSim-296.

As for MGE results, we were not able to reproduce the performance in (Yin et al., 2016). We list possible reasons as below: we did not separate non-compositional word during training (character and radical embeddings are not used for these words), and the we created character-radical index from different data source. We conjecture that the first to be the most crucial factor in reproducing MGE.

The results of RNN-Skipgram and RNN-GloVe are also in Table 1. Their results are not comparable with CBOW and Skipgram. From the results, we conclude that it is not easy to produce word representations directly from glyphs. We think the reason is that RNN representations are dependent on each other. Updating model parameters for word w_i would also change the word representation of word w_j. As a result it is much more difficult to train such models.

We further inspect the impact of glyph features by doing significance test[8] between proposed methods and existing ones. The p-values of the tests are given in Table 2. We found only “tarG” method has a p-value less than 0.05 over CWE.

	+CWE+ctxG	+CWE+tarG
CBOW	0.085	0.215
CBOW+CWE	0.190	**0.008**

Table 2: p-values of significance tests between proposed methods and existing ones.

5.2 Word Analogy

An analogy problem has the following form: *“king”:“queen” = “man”:“?”*, and *“woman”* is answer to *“?”*. By answering the question correctly, the model is considered capable of expressing semantic relationships. Furthermore, the analogy relation could be expressed by vector arithmetic of word representations as shown in (Mikolov et al., 2013b). For the above problem, we find word w_i such that $w_i = \arg\max_w \ cos(\vec{w}, \vec{w}_{queen} - \vec{w}_{king} + \vec{w}_{man})$.

Method	Capital	City	Family	J&P
CBOW	**0.8006**	**0.7200**	0.4228	0.3100
+CWE	0.7858	0.5829	0.4743	0.2667

RNN-Skipgram	0.0000	0.0057	0.0368	-
RNN-Glove	0.0281	0.0057	0.0184	-

Table 3: Accuracy of analogy problems for capitals of countries, (China) states/provinces of cities, family relations, and our proposed *job&place* (J&P) dataset. The higher the values, the better the results.

As in the previous subsection, we translated the word analogy dataset in (Chen et al., 2015) to traditional. The dataset contains 3 groups of analogy problems: capitals of countries, (China) states/provinces of cities, and family relations. Considering that most capital and city names do not relate to the meaning of their compositional characters, and that we did not separate non-compositional word in our experiments, we proposed a new analogy dataset composed of jobs and places (*job&place*). Nonetheless, there might be multiple corresponding places for a single job. For instance, A *“doctor”* could be in a *“hospital”* or *“clinic”*. In this *job&place* dataset, we provide a set of places for each job. The model is considered to answer correctly as long as the predicted word is in this set.

We take the mean of all word representations of places ($mean(\vec{w}_{places_1})$) for the first job (job_1), and find the place for another job (job_2) by calculating w_i such that $w_i = \arg\max_w \ cos(\vec{w}, mean(\vec{w}_{places_1}) - \vec{w}_{job_1} + \vec{w}_{job_2})$.

The results are shown in Table 3. we observed CWE only improved accuracy only for the family group. The results are not surprising. The words of family relations are compositional in Chinese, however capital and city names are usually not. We observed that GWE further improved CWE for words in the family group. From Table 3, we found that glyph features are helpful when the characters can enhance word representations. This is very reasonable because glyph features are fruitful representations of characters. If character information does not play a role in learning word representations, character glyphs may not be useful. The same phenomenon is observed in Table 1.

[8] We followed the method described in `https://stats.stackexchange.com/questions/17696/`

In our *job&place*, we still observed that GWE improving CWE, however both CWE and GWE were slightly worse than CBOW. We also observed that Skipgram-based methods became worse than CBOW-based methods, while in all previous evaluation Skipgram-based methods are consistently better.

The results of RNN-Skipgram and RNN-GloVe are still poor. We observe that the word representations learned from RNN can no longer be expressed by vector arithmetic. The reason is still under investigation.

5.3 Case Study

To further probe the effect of glyph features, we show the following word pairs in SimLex-999 whose calculated cosine similarities are higher based on GWE models than CWE. The pairs may not look alike, but their components share related semantics. For example, in “伶俐” (clever), the component “利”(sharp) is compositional to the meaning of “俐”(acute), describing someone with a sharp mind. Other examples show the ability to associate semantics with radicals.

Models	詞 (word) & 字典 (dictionary)	椅子 (chair) & 板凳 (bench)
CBOW	0.2342	0.3469
+CWE	0.2918	0.3640
+CWE+ctx_Glyph	**0.3361**	**0.3903**
+CWE+tar_Glyph	0.2857	0.3746

Models	鳥 (bird) & 火雞 (turkey)	聰明 (smart) & 伶俐 (clever)
CBOW	0.2640	0.2634
+CWE	0.3064	0.2409
+CWE+ctxG	0.3190	0.2710
+CWE+ctxG	**0.3422**	**0.2976**

Table 4: Case study on word pairs in SimLex-999.

We also provide several counter-examples. Below are some word pairs which are not similar, however GWE methods produces higher similarity than CBOW or CWE. Take “山峰” (mountain) and “蜂蜜” (honey) as example. Since they share no common characters, the only thing in common is the component “夆”, and we assume this to be the reason for the higher similarity. Also note that in the pair “無趣” (boring) and “好笑” (funny), the CWE similarity is also higher. We conclude that the character “無” (none) is not strong enough, so the character “趣” (fun) overrides the word “無趣” (boring), thus a higher score was mistakenly assigned.

Models	山峰 (mountain) & 蜂蜜 (honey)	書桌 (desk) & 水果 (fruit)
CBOW	0.0581	0.0495
+CWE	0.0842	0.0719
+CWE+ctxG	0.0736	**0.0942**
+CWE+tarG	**0.1093**	0.0733

Models	無趣 (boring) & 好笑 (funny)	胃 (stomach) & 腰 (waist)
CBOW	0.3645	0.2388
+CWE	0.5351	0.2073
+CWE+ctxG	0.5209	0.2500
+CWE+ctxG	**0.5426**	**0.2643**

Table 5: Counter examples to which GWE methods give higher similarity scores than CBOW or CWE.

6 Conclusions

This work is a pioneer in enhancing Chinese word representations with character glyphs. The character glyph features are directly learned from the bitmaps of characters by convAE. We then proposed 2 methods in learning Chinese word representations: the first is to use character glyph features as enhancement; the other is to directly learn word representation from sequences of glyph features. In experiments, we found the latter totally infeasible. Training word representations with RNN without word and character information is challenging. Nonetheless, the glyph features improved the character-enhanced Chinese word representations, especially on the word analogy task related to family.

The results of exploiting character glyph features in word representation learning was ordinary. Perhaps the co-occurrence information in the corpus plays a bigger role than glyph features. Nonetheless, the idea to treat each Chinese character as image is innovative. As more character-level models(Zheng et al., 2013; Kim, 2014; Zhang et al., 2015) are proposed in the NLP field, we believe glyph features could serve as an enhancement, and we will further examine the effect of glyph features on other tasks, such as word segmentation, POS tagging, dependency parsing, or downstream tasks such as text classification, or document retrieval.

Learning Paraphrastic Sentence Embeddings from Back-Translated Bitext

John Wieting[1] **Jonathan Mallinson**[2] **Kevin Gimpel**[1]
[1]Toyota Technological Institute at Chicago, Chicago, IL, 60637, USA
[2]School of Informatics, University of Edinburgh, Edinburgh, UK
{jwieting,kgimpel}@ttic.edu, j.mallinson@ed.ac.uk

Abstract

We consider the problem of learning general-purpose, paraphrastic sentence embeddings in the setting of Wieting et al. (2016b). We use neural machine translation to generate sentential paraphrases via back-translation of bilingual sentence pairs. We evaluate the paraphrase pairs by their ability to serve as training data for learning paraphrastic sentence embeddings. We find that the data quality is stronger than prior work based on bitext and on par with manually-written English paraphrase pairs, with the advantage that our approach can scale up to generate large training sets for many languages and domains. We experiment with several language pairs and data sources, and develop a variety of data filtering techniques. In the process, we explore how neural machine translation output differs from human-written sentences, finding clear differences in length, the amount of repetition, and the use of rare words.[1]

1 Introduction

Pretrained word embeddings have received a great deal of attention from the research community, but there is much less work on developing pretrained embeddings for *sentences*. Here we target sentence embeddings that are "paraphrastic" in the sense that two sentences with similar meanings are close in the embedding space. Wieting et al. (2016b) developed paraphrastic sentence embeddings that are useful for semantic textual similarity tasks and can also be used as initialization for supervised semantic tasks.

R:	We understand that has already commenced, but there is a long way to go.
T:	This situation has already commenced, but much still needs to be done.
R:	The restaurant is closed on Sundays. No breakfast is available on Sunday mornings.
T:	The restaurant stays closed Sundays so no breakfast is served these days.
R:	Improved central bank policy is another huge factor.
T:	Another crucial factor is the improved policy of the central banks.

Table 1: Illustrative examples of references (R) paired with back-translations (T).

To learn their sentence embeddings, Wieting et al. used the Paraphrase Database (PPDB) (Ganitkevitch et al., 2013). PPDB contains a large set of paraphrastic textual fragments extracted automatically from bilingual text ("bitext"), which is readily available for languages and domains. Versions of PPDB have been released for several languages (Ganitkevitch and Callison-Burch, 2014).

However, more recent work has shown that the fragmental nature of PPDB's pairs can be problematic, especially for recurrent networks (Wieting and Gimpel, 2017). Better performance can be achieved with a smaller set of sentence pairs derived from aligning Simple English and standard English Wikipedia (Coster and Kauchak, 2011). While effective, this type of data is inherently limited in size and scope, and not available for languages other than English.

PPDB is appealing in that it only requires bitext. We would like to retain this property but develop a data resource with sentence pairs rather than phrase pairs. We turn to neural machine translation (NMT) (Sutskever et al., 2014; Bahdanau et al., 2014; Sennrich et al., 2016a), which has matured recently to yield strong performance especially in terms of producing grammatical outputs.

In this paper, we build NMT systems for three

[1] Generated paraphrases and code are available at http://ttic.uchicago.edu/~wieting.

Proceedings of the 2017 Conference on Empirical Methods in Natural Language Processing, pages 274–285
Copenhagen, Denmark, September 7–11, 2017. ©2017 Association for Computational Linguistics

language pairs, then use them to back-translate the non-English side of the training bitext. The resulting data consists of sentence pairs containing an English reference and the output of an X-to-English NMT system. Table 1 shows examples. We use this data for training paraphrastic sentence embeddings, yielding results that are much stronger than when using PPDB and competitive with the Simple English Wikipedia data.

Since bitext is abundant and available for many language pairs and domains,[2] we also develop several methods of filtering the data, including based on sentence length, quality measures, and measures of difference between the reference and its back-translation. We find length to be an effective filtering method, showing that very short length ranges—where the translation is 1 to 10 words—are best for learning.

In studying quality measures for filtering, we train a classifier to predict if a sentence is a reference or a back-translation, then score sentences by the classifier score. This investigation allows us to examine the kinds of phenomena that best distinguish NMT output from references in this controlled setting of translating the bitext training data. NMT output has more repetitions of both words and longer n-grams, and uses fewer rare words than the references.

We release our generated sentence pairs to the research community with the hope that the data can inspire others to develop additional filtering methods, to experiment with richer architectures for sentence embeddings, and to further analyze the differences between neural machine translations and references.

2 Related Work

We describe related work in learning general-purpose sentence embeddings, work in automatically generating or discovering paraphrases, and finally prior work in leveraging neural machine translation for embedding learning.

Paraphrastic sentence embeddings. Our learning and evaluation setting is the same as that considered by Wieting et al. (2016b) and Wieting et al. (2016a), in which the goal is to learn paraphrastic sentence embeddings that can be used for downstream tasks. They trained models on PPDB and evaluated them using a suite of semantic textual similarity (STS) tasks and supervised semantic tasks. Others have begun to consider this setting as well (Arora et al., 2017).

Other work in learning general purpose sentence embeddings has used autoencoders (Socher et al., 2011; Hill et al., 2016), encoder-decoder architectures (Kiros et al., 2015), or other learning frameworks (Le and Mikolov, 2014; Pham et al., 2015). Wieting et al. (2016b) and Hill et al. (2016) provide many empirical comparisons to this prior work. For conciseness, we compare only to the strongest configurations from their results.

Paraphrase generation and discovery. There is a rich history of research in generating or finding naturally-occurring sentential paraphrases (Barzilay and McKeown, 2001; Dolan et al., 2004; Dolan and Brockett, 2005; Quirk et al., 2004; Zhao et al., 2010; Coster and Kauchak, 2011; Xu et al., 2014, 2015).

The most relevant work uses bilingual corpora, e.g., Zhao et al. (2008) and Bannard and Callison-Burch (2005), the latter leading to PPDB. Our goals are highly similar to those of the PPDB project, which has also been produced for many languages (Ganitkevitch and Callison-Burch, 2014) since it only relies on the availability of bilingual text.

Prior work has shown that PPDB can be used for learning embeddings for words and phrases (Faruqui et al., 2015; Wieting et al., 2015). However, when learning sentence embeddings, Wieting and Gimpel (2017) showed that PPDB is not as effective as sentential paraphrases, especially for recurrent networks. These results are intuitive because the phrases in PPDB are short and often cut across constituent boundaries. For sentential paraphrases, Wieting and Gimpel (2017) used a dataset developed for text simplification by Coster and Kauchak (2011). It was created by aligning sentences from Simple English and standard English Wikipedia. We compare our data to both PPDB and this Wikipedia dataset.

Neural machine translation for paraphrastic embedding learning. Sutskever et al. (2014) trained NMT systems and visualized part of the space of the source language encoder for their English→French system. Hill et al. (2016) evaluated the encoders of English-to-X NMT systems as sentence representations, finding them to

[2] For example, CzEng 1.6 (Bojar et al., 2016) contains a billion words across its 8 domains.

perform poorly compared to several other methods based on unlabeled data. Mallinson et al. (2017) adapted trained NMT models to produce sentence similarity scores in semantic evaluations. They used pairs of NMT systems, one to translate an English sentence into multiple foreign translations and the other to then translate back to English. Other work has used neural MT architectures and training settings to obtain better word embeddings (Hill et al., 2014a,b).

Our approach differs in that we only use the NMT system to generate training data for training sentence embeddings, rather than use it as the source of the model. This permits us to decouple decisions made in designing the NMT architecture from decisions about which models we will use for learning sentence embeddings. Thus we can benefit from orthogonal work in designing neural architectures to embed sentences.

3 Neural Machine Translation

We now describe the NMT systems we use for generating data for learning sentence embeddings. In our experiments, we use three encoder-decoder NMT models: Czech→English, French→English, and German→English.

We used Groundhog[3] as the implementation of the NMT systems for all experiments. We generally followed the settings and training procedure from previous work (Bahdanau et al., 2014; Sennrich et al., 2016a). As such, all networks have a hidden layer size of 1000 and an embedding layer size of 620. During training, we used Adadelta (Zeiler, 2012), a minibatch size of 80, and the training set was reshuffled between epochs. We trained a network for approximately 7 days on a single GPU (TITAN X), then the embedding layer was fixed and training continued, as suggested by Jean et al. (2015), for 12 hours. Additionally, the softmax was calculated over a filtered list of candidate translations. Following Jean et al. (2015), during decoding, we restrict the softmax layers' output vocabulary to include: the 10000 most common words, the top 25 unigram translations, and the gold translations' unigrams.

All systems were trained on the available training data from the WMT15 shared translation task (15.7 million, 39.2 million, and 4.2 million sentence pairs for CS→EN, FR→EN, and DE→EN, respectively). The training data included: Europarl v7 (Koehn, 2005), the Common Crawl corpus, the UN corpus (Eisele and Chen, 2010), News Commentary v10, the 10^9 French-English corpus, and CzEng 1.0 (Bojar et al., 2016). A breakdown of the sizes of these corpora can be found in Table 3. The data was pre-processed using standard pre-processing scripts found in Moses (Koehn et al., 2007). Rare words were split into sub-word units, following Sennrich et al. (2016b). BLEU scores on the WMT2015 test set for each NMT system can be seen in Table 3.

	Czech	French	German
Europarl	650,000	2,000,000	2,000,000
Common Crawl	160,000	3,000,000	2,000,000
News Commentary	150,000	200,000	200,000
UN	-	12,000,000	-
10^9 French-English	-	22,000,000	-
CzEng	14,700,000	-	-

Table 2: Dataset sizes (numbers of sentence pairs) for data domains used for training NMT systems.

Language	% BLEU
Czech→English	19.7
French→English	20.1
German→English	28.2

Table 3: BLEU scores on the WMT2015 test set.

To produce paraphrases we use "back-translation", i.e., we use our X→English NMT systems to translate the non-English sentence in each training sentence pair into English. We directly use the bitext on which the models were trained. This could potentially lead to pairs in which the reference and translation match exactly, if the model has learned to memorize the reference translations seen during training. However, in practice, since we have so much bitext to draw from, we can easily find data in which they do not match exactly.

Thus our generated data consists of pairs of English references from the bitext along with the NMT-produced English back-translations. We use beam search with a width of 50 to generate multiple translations for each non-English sentence, each of which is a candidate paraphrase for the English reference.

Example outputs of this process are in Table 1, showing some rich paraphrase phenomena in the data. These examples show non-trivial phrase substitutions ("there is a long way to go" and "much still needs to be done"), sentences being merged and simplified, and sentences being rearranged.

[3] Available at https://github.com/sebastien-j/LV_groundhog.

For examples of erroneous paraphrases that can be generated by this process, see Table 11.

4 Models and Training

Our goal is to compare our paraphrase dataset to other datasets by using each to train sentence embeddings, keeping the models and learning procedure fixed. So we select models and a loss function from prior work (Wieting et al., 2016b; Wieting and Gimpel, 2017).

4.1 Models

We wish to embed a word sequence s into a fixed-length vector. We denote the tth word in s as s_t, and we denote its word embedding by x_t. We focus on two models in this paper. The first model, which we call AVG, simply averages the embeddings x_t of all words in s. The only parameters learned in this model are those in the word embeddings themselves, which are stored in the word embedding matrix W_w. This model was found by Wieting et al. (2016b) to perform very strongly for semantic similarity tasks.

The second model, the GATED RECURRENT AVERAGING NETWORK (GRAN) (Wieting and Gimpel, 2017), combines the benefits of AVG and long short-term memory (LSTM) recurrent neural networks (Hochreiter and Schmidhuber, 1997). It first uses an LSTM to generate a hidden vector, h_t, for each word s_t in s. Then h_t is used to compute a gate that is elementwise-multiplied with x_t, resulting in a new hidden vector a_t for each step t:

$$a_t = x_t \odot \sigma(W_x x_t + W_h h_t + b) \qquad (1)$$

where W_x and W_h are parameter matrices, b is a parameter vector, and σ is the elementwise logistic sigmoid function. After all a_t have been generated for a sentence, they are averaged to produce the embedding for that sentence. The GRAN reduces to AVG if the output of the gate is always 1. This model includes as learnable parameters those of the LSTM, the word embeddings, and the additional parameters in Eq. (1). We use W_c to denote the "compositional" parameters, i.e., all parameters other than the word embeddings.

Our motivation for choosing these two models is that they both work well in this transfer learning setting (Wieting et al., 2016b) and they are architecturally similar with one crucial difference: only the GRAN takes into account word order. This difference plays an important role in the effectiveness of the different filtering methods as explored in Section 5.

4.2 Training

We follow the training procedure of Wieting et al. (2015) and Wieting et al. (2016b). The training data is a set S of paraphrastic pairs $\langle s_1, s_2\rangle$ and we optimize a margin-based loss:

$$\min_{W_c, W_w} \frac{1}{|S|}\Bigg(\sum_{\langle s_1,s_2\rangle \in S} \max(0, \delta - \cos(g(s_1), g(s_2)) \\ + \cos(g(s_1), g(t_1))) + \max(0, \delta - \cos(g(s_1), g(s_2)) \\ + \cos(g(s_2), g(t_2)))\Bigg) + \lambda_c \|W_c\|^2 + \lambda_w \|W_{w_{initial}} - W_w\|^2$$

where g is the model (AVG or GRAN), δ is the margin, λ_c and λ_w are regularization parameters, $W_{w_{initial}}$ is the initial word embedding matrix, and t_1 and t_2 are "negative examples" taken from a mini-batch during optimization. The intuition is that we want the two texts to be more similar to each other $(\cos(g(s_1), g(s_2)))$ than either is to their respective negative examples t_1 and t_2, by a margin of at least δ. To select t_1 and t_2, we choose the most similar sentence in some set (other than those in the given pair). For simplicity we use the mini-batch for this set, i.e., we choose t_1 for a given $\langle s_1, s_2\rangle$ as follows:

$$t_1 = \operatorname*{argmax}_{t:\langle t,\cdot\rangle \in S_b \setminus \{\langle s_1,s_2\rangle\}} \cos(g(s_1), g(t))$$

where $S_b \subseteq S$ is the current mini-batch. That is, we want to choose a negative example t_i that is similar to s_i according to the current model. The downside is that we may occasionally choose a phrase t_i that is actually a true paraphrase of s_i.

5 Experiments

We now investigate how best to use our generated paraphrase data for training universal paraphrastic sentence embeddings. We consider 10 data sources: Common Crawl (CC), Europarl (EP), and News Commentary (News) from all 3 language pairs, as well as the 10^9 French-English data (Giga). We extract 150,000 reference/back-translation pairs from each data source. We use 100,000 of these to mine for training data for our sentence embedding models, and the remaining 50,000 are used as train/validation/test data for the reference classification and language models described below.

5.1 Evaluation

We evaluate the quality of a paraphrase dataset by using the experimental setting of Wieting et al. (2016b). We use the paraphrases as training data to create paraphrastic sentence embeddings, using the cosine of the embeddings as the measure of semantic relatedness, then evaluate the embeddings on the SemEval semantic textual similarity (STS) tasks from 2012 to 2015 (Agirre et al., 2012, 2013, 2014, 2015), the SemEval 2015 Twitter task (Xu et al., 2015), and the SemEval 2014 SICK Semantic Relatedness task (Marelli et al., 2014).

Given two sentences, the aim of the STS tasks is to predict their similarity on a 0-5 scale, where 0 indicates the sentences are on different topics and 5 indicates that they are completely equivalent. As our test set, we report the average Pearson's r over these 22 sentence similarity tasks.[4] As development data, we use the 2016 STS tasks (Agirre et al., 2016), where the tuning criterion is the average Pearson's r over its 5 datasets.

5.2 Experimental Setup

For fair comparison among different datasets and dataset filtering methods described below, we use only 24,000 training examples for nearly all experiments. Different filtering methods produce different amounts of training data, and using 24,000 examples allows us to keep the amount of training data constant across filtering methods. It also allows us to complete these several thousand experiments in a reasonable amount of time. In Section 5.8 below, we discuss experiments that scale up to larger amounts of training data.

We use PARAGRAM-SL999 embeddings (Wieting et al., 2015) to initialize the word embedding matrix (W_w) for both models. For all experiments, we fix the mini-batch size to 100, λ_w to 0, λ_c to 0, and the margin δ to 0.4. We train AVG for 20 epochs, and the GRAN for 3, since it converges much faster. For optimization we use Adam (Kingma and Ba, 2014) with a learning rate of 0.001.

Lang.	Data	GRAN	AVG
SimpWiki		67.2	65.8
PPDB		64.5	65.8
CS	CC	65.5	65.4
	EP	66.5	65.1
	News	67.2	65.1
FR	CC	67.3	66.1
	EP	**67.8**	65.7
	Giga	67.4	65.9
	News	67.0	65.2
DE	CC	66.5	**66.2**
	EP	67.2	65.6
	News	66.5	64.7

Table 4: Test results (average Pearson's $r \times 100$ over 22 STS datasets) using a random selection of 24,000 examples from each data source.

We compare to two data resources used in previous work to learn paraphrastic sentence embeddings. The first is phrase pairs from PPDB, used by Wieting et al. (2016b) and Wieting et al. (2016a). PPDB comes in different sizes (S, M, L, XL, XXL, and XXXL), where each larger size subsumes all smaller ones. The pairs in PPDB are sorted by a confidence measure and so the smaller sets contain higher precision paraphrases. We use PPDB XL in this paper, which consists of fairly high precision paraphrases. The other data source is the aligned Simple English / standard English Wikipedia data developed by Coster and Kauchak (2011) and used for learning paraphrastic sentence embeddings by Wieting and Gimpel (2017). We refer to this data source as "SimpWiki". We refer to our back-translated data as "NMT".

5.3 Dataset Comparison

We first compare datasets, randomly sampling 24,000 sentence pairs from each of PPDB, SimpWiki, and each of our NMT datasets. The only hyperparameter to tune for this experiment is the stopping epoch, which we tune based on our development set. The results are shown in Table 4.

We find that the NMT datasets are all effective as training data, outperforming PPDB in all cases when using the GRAN. There are exceptions when using AVG, for which PPDB is quite strong. This is sensible because AVG is not sensitive to word order, so the fragments in PPDB do not cause problems. However, when using the GRAN, which is sensitive to word order, the NMT data is consistently better than PPDB. It often exceeds the performance of training on the SimpWiki data, which consists entirely of human-written sentences.

5.4 Filtering Methods

Above we showed that the NMT data is better than PPDB when using a GRAN and often as good as SimpWiki. Since we have access to so much more NMT data than SimpWiki (which is limited

[4] Statistical significance testing is nontrivial due to averaging Pearson's r so we leave it to future work.

to fewer than 200k sentence pairs), we next experiment with several approaches for filtering the NMT data. We first consider filtering based on length, described in Section 5.5. We then consider filtering based on several quality measures designed to find more natural and higher-quality translations, described in Section 5.6. Finally, we consider several measures of diversity. By diversity we mean here a measure of the lexical and syntactic difference between the reference and its paraphrase. We describe these experiments in Section 5.7. We note that these filtering methods are not all mutually exclusive and could be combined, though in this paper we experiment with each individually and leave combination to future work.

5.5 Length Filtering

We first consider filtering candidate sentence pairs by length, i.e., the number of tokens in the translation. The tunable parameters are the upper and lower bounds of the translation lengths.

We experiment with a partition of length ranges, showing the results in Table 5. These results are averages across all language pairs and data sources of training data for each length range shown. We find it best to select NMT data where the translations have between 0 and 10 tokens, with performance dropping as sentence length increases. This is true for both the GRAN and Avg models. We do the same filtering for the SimpWiki data, though the trend is not nearly as strong. Therefore this is unlikely due to the nature of the evaluation data, and may be due to machine translation quality dropping as sentence length increases. This trend appears even though the datasets with higher ranges have more tokens of training data, since only the number of training sentence pairs is kept constant across configurations.

We then tune the length range using our development data, considering the following length ranges: [0,10], [0,15], [0,20], [0,30], [0,100], [10,20], [10,30], [10,100], [15,25], [15,30], [15,100], [20,30], [20,100], [30,100]. We tune over ranges as well as language, data source, and stopping epoch, each time training on 24,000 sentence pairs. We report the average test results over all languages and datasets in Table 6. We compare to a baseline that draws a random set of data, showing that length-based filtering leads to gains of nearly half a point on average across our test sets.

		Length Range			
Data	Model	0-10	10-20	20-30	30-100
SimpWiki	GRAN	67.4	67.7	67.1	67.3
	Avg	65.9	65.7	65.6	65.9
NMT	GRAN	66.6	66.5	66.0	64.8
	Avg	65.7	65.6	65.3	65.0

Table 5: Test correlations for our models when trained on sentences with particular length ranges (averaged over languages and data sources for the NMT rows). Results are on STS datasets (Pearson's $r \times 100$).

	NMT		SimpWiki	
Filtering Method	GRAN	Avg	GRAN	Avg
None (Random)	66.9	65.5	67.2	65.8
Length	67.3	66.0	67.4	66.2
Tuned Len. Range	[0,10]	[0,10]	[0,10]	[0,15]

Table 6: Length filtering test results after tuning length ranges on development data (averaged over languages and data sources for the NMT rows). Results are on STS datasets (Pearson's $r \times 100$).

The tuned length ranges are short for both NMT and SimpWiki. The distribution of lengths in the NMT and SimpWiki data is fairly similar. The 10 NMT datasets all have mean translation lengths between 22 and 28 tokens. The data has fairly large standard deviations (11-25 tokens) indicating that there are some very long translations in the data. SimpWiki has a mean length of 24.2 and a standard deviation of 13.1.

5.6 Quality Filtering

We also consider filtering based on several measures of the "quality" of the back-translation:

- **Translation Cost**: We use the cost (negative log likelihood) of the translation from the NMT system, divided by the number of tokens in the translation.
- **Language Model**: We train a separate language model for each language/data pair on 40,000 references that are separate from the 100,000 used for mining data. Due to the small data size, we train a 3-gram language model and use the KenLM toolkit (Heafield, 2011).
- **Reference/Translation Classification**: We train binary classifiers to predict whether a given sentence is a reference or translation (described in Section 5.6.1). We use the probability of being a reference as the score for filtering.

For translation cost, we tune the upper bound of the cost over the range $[0.2, 1]$ using increments

Filtering Method	GRAN	AVG
None (Random)	66.9	65.5
Translation Cost	66.6	65.4
Language Model	66.7	65.5
Reference Classification	67.0	65.5

Table 7: Quality filtering test results after tuning quality hyperparameters on development data (averaged over languages and data sources for the NMT rows). Results are on STS datasets (Pearson's $r \times 100$).

of 0.1. For the language model, we tune an upper bound on the perplexity of the translations among the set $\{25, 50, 75, 100, 150, 200, \infty\}$. For the classifier, we tune the minimum probability of being a reference over the range $[0, 0.9]$ using increments of 0.1.

Table 7 shows average test results over all languages and datasets after tuning hyperparameters on our development data for each. The translation cost and language model are not helpful for filtering, as random selection outperforms them. Both methods are outperformed by the reference classifier, which slightly outperforms random selection when using the stronger GRAN model. We now discuss further how we trained the reference classifier and the data characteristics that it reveals. We did not experiment with quality filtering for SimpWiki since it is human-written text.

5.6.1 Reference/Translation Classification

We experiment with predicting whether a given sentence is a reference or a back-translation, hypothesizing that generated sentences with high probabilities of being references are of higher quality. We train two kinds of binary classifiers, one using an LSTM and the other using word averaging, followed by a softmax layer. We select 40,000 reference/translation pairs for training and 5,000 for each of validation and testing. A single example is a sentence with label 1 if it is a reference translation and 0 if it is a translation.

In training, we consider the entire k-best list as examples of translations, selecting one translation to be the 0-labeled example. We either do this randomly or we score each sentence in the k-best list using our model and select the one with the highest probability of being a reference as the 0-labeled example. We tune this choice as well as an L_2 regularizer on the word embeddings (tuned over $\{10^{-5}, 10^{-6}, 10^{-7}, 10^{-8}, 0\}$). We use PARAGRAM-SL999 embeddings (Wieting et al., 2015) to initialize the word embeddings for both models. Models were trained by minimizing cross entropy for 10 epochs using Adam with learning rate 0.001. We performed this procedure separately for each of the 10 language/data pairs.

Model	Lang.	Data	Test Acc.	+ Acc.	- Acc.

Table 8: Results of reference/translation classification (accuracy×100). The highest score in each column is in boldface. Final two columns show accuracies of positive (reference) and negative classes, respectively.

The results are shown in Table 8. While performance varies greatly across data sources, the LSTM always outperforms the word averaging model. For our translation-reference classification, we note that our results can be further improved. We also trained models on 90,000 examples, essentially doubling the amount of data, and the results improved by about 2% absolute on each dataset on both the validation and testing data.

Analyzing Reference Classification. We inspected the output of our reference classifier and noted a few qualitative trends which we then verified empirically. First, neural MT systems tend to use a smaller vocabulary and exhibit more restricted use of phrases. They correspondingly tend to show more repetition in terms of both words and longer n-grams. This hypothesis can be verified empirically in several ways. We do so by calculating the entropy of the unigrams and trigrams for both the references and the translations from our 150,000 reference-translation pairs.[5] We also calculate the repetition percentage of unigrams and

[5] We randomly selected translations from the beam search.

Lang.	Data	Ent. (uni)	Ent. (tri)	Rep. (uni)	Rep. (tri)

	News	0.40	0.37	-1.02%	-0.24%
All		0.46	0.74	-2.80%	-2.26%

Table 9: Differences in entropy and repetition of unigrams/trigrams in references and translations. Negative values indicate translations have a higher value, so references show consistently higher entropies and lower repetition rates.

trigrams in both the references and translations. This is defined as the percentage of words that are repetitions (i.e., have already appeared in the sentence). For unigrams, we only consider words consisting of at least 3 characters.

The results are shown in Table 9, in which we subtract the translation value from the reference value for each measure. The translated text has lower n-gram entropies and higher rates of repetition. This appears for all datasets, but is strongest for common crawl and French-English 10[9].

We also noticed that translations are less likely to use rare words, instead willing to use a larger sequence of short words to convey the same meaning. We found that translations were sometimes more vague and, unsurprisingly, were more likely to be ungrammatical.

We check whether our classifier is learning these patterns by computing the reference probabilities $P(\mathrm{R})$ of 100,000 randomly sampled translation-reference pairs from each dataset (the same used to train models). We then compute the correlation between our classification score and different metrics: the repetition rate of the sentence, the average inverse-document frequency (IDF) of the sentence,[6] and the translation length.

The results are shown in Table 10. Negative correlations with repetitions indicates that fewer repetitions lead to higher $P(\mathrm{R})$. A positive correlation with average IDF indicates that $P(\mathrm{R})$ rewards the use of rare words. Interestingly, negative correlation with length suggests that the classifier prefers more concise sentences.[7] We show examples of these phenomena in Table 11. The first two examples show the tendency of NMT to repeat words and phrases. The second two show how they tend to use sequences of common words ("put at risk") rather than rare words ("endangering").

Metric	Spearman's ρ
Unigram repetition rate	-35.1
Trigram repetition rate	-18.4
Average IDF	27.8
Length	-34.0

Table 10: Spearman's ρ between our reference classifier probability and various measures.

	Sentence	$P(\mathrm{R})$
R:	Room was comfortable and the staff at the front desk were very helpful.	1.0

R:	The enchantment of your wedding day, captured in images by Flore-Ael Surun.	0.98
T:	The wedding of the wedding, put into images by Flore-Ael A.	<0.01
R:	Mexico and Sweden are longstanding supporters of the CTBT.	1.0
T:	Mexico and Sweden have been supporters of CTBT for a long time now.	0.06
R:	We thought Mr Haider ' s Austria was endangering our freedom.	1.0
T:	We thought that our freedom was put at risk by Austria by Mr Haider.	0.09

Table 11: Illustrative examples of references (R) and back-translations (T), along with probabilities from the reference classifier. See text for details.

5.7 Diversity Filtering

We consider several filtering criteria based on measures that encourage particular amounts of disparity between the reference and its back-translation:

- **n-gram Overlap**: Our n-gram overlap measures are calculated by counting n-grams of a given order in both the reference and translation, then dividing the number of shared n-grams by the total number of n-grams in the reference or translation, whichever has fewer. We use three n-gram overlap scores ($n \in \{1, 2, 3\}$).
- **BLEU Score**: We use a smoothed sentence-level BLEU variant from Nakov et al. (2012) that uses smoothing for all n-gram lengths and also smooths the brevity penalty.

[6] Wikipedia was used to calculate the frequencies of the tokens. All tokens were lowercased.

[7] This is noteworthy because the average sentence length of translations and references is not significantly different.

	NMT		SimpWiki	
Filtering Method	GRAN	AVG	GRAN	AVG
Random	66.9	65.5	67.2	65.8
Unigram Overlap	66.6	66.1	67.8	67.4
Bigram Overlap	67.0	65.5	68.0	67.2
Trigram Overlap	66.9	65.4	67.8	66.6
BLEU Score	67.1	65.3	67.5	66.5

Table 12: Diversity filtering test results after tuning filtering hyperparameters on development data (averaged over languages and data sources for the NMT rows). Results are on STS datasets (Pearson's $r \times 100$).

Data	GRAN	AVG
PPDB	64.6	66.3
SimpWiki (100k/168k)	67.4	**67.7**
CC-CS (24k)	66.8	-
CC-CS (100k)	**68.5**	-
CC-DE (24k)	-	66.6
CC-DE (168k)	-	67.6

Table 13: Test results with more training data. More data helps both AVG and GRAN to match or surpass training on SimpWiki. Both comfortably surpass PPDB. The number of training examples used is in parentheses.

For both methods, the tunable hyperparameters are the upper and lower bounds for the above scores. We tune over the cross product of lower bounds $\{0, 0.1, 0.2, 0.3\}$ and upper bounds $\{0.6, 0.7, 0.8, 0.9, 1.0\}$. Our intuition is that the best data will have some amount of n-gram overlap, but not too much. Too much n-gram overlap will lead to pairs that are not useful for learning.

The results are shown in Table 12, for both models and for both NMT and SimpWiki. We find that the diversity filtering methods lead to consistent improvements when training on SimpWiki. We believe this is because many of the sentence pairs in SimpWiki are near-duplicates and these filtering methods favor data with more differences.

Diversity filtering can also help when selecting NMT data, though the differences are smaller. We do note that unigram overlap is the strongest filtering strategy for AVG. When looking at the threshold tuning, the best lower bounds are often 0 or 0.1 and the best upper bounds are typically 0.6-0.7, indicating that sentence pairs with a high degree of word overlap are not useful for training. We also find that the GRAN benefits more from filtering based on higher-order n-gram overlap than AVG.

5.8 Scaling Up

Unlike the SimpWiki data, which is naturally limited and only available for English, we can scale our approach. Since we use data on which the NMT systems were trained and perform back-translation, we can easily produce large training sets of paraphrastic sentence pairs for many languages and data domains, limited only by the availability of bitext.

To test this, we took the tuned filtering methods and language/data pairs (according to our development dataset only), and trained them on more data. These were CC-CS for GRAN and CC-DE for AVG. We also trained each model on the same number of sentence pairs from SimpWiki.[8] We also compare to PPDB XL, and since PPDB has fewer tokens per example, we use enough PPDB data so that it has at least as many tokens as the SimpWiki data used in the experiment.[9]

Table 13 shows clear improvements when using more training data, providing evidence that our approach can scale to larger datasets. The NMT data surpasses SimpWiki for the GRAN, while the SimpWiki and NMT data perform similarly for AVG. PPDB is outperformed by both data sources for both models. Even when we train on all 52M tokens in PPDB XXL, AVG only reaches 66.5.

6 Conclusion

We showed how back-translation can be used to generate effective training data for paraphrastic sentence embeddings. We explored filtering strategies that improve the generated data; in doing so, we identified characteristics that distinguish NMT output from references. Our hope is that these results can enable learning paraphrastic sentence embeddings with powerful neural architectures across many languages and domains.

Acknowledgments

This research used resources of the Argonne Leadership Computing Facility, which is a DOE Office of Science User Facility supported under Contract DE-AC02-06CH11357. We thank the developers of Theano (Theano Development Team, 2016) and NVIDIA Corporation for donating GPUs used in this research.

[8] Since the CC-CS data was the smallest dataset used to train the CS NMT system (See Table 3), we only used 100,000 pairs for the GRAN experiment. For AVG, we used the full 167,689.

[9] 800,011 pairs for GRAN and 1,341,188 for AVG.

Joint Embeddings of Chinese Words, Characters, and Fine-grained Subcharacter Components

Abstract

Word embeddings have attracted much attention recently. Different from alphabetic writing systems, Chinese characters are often composed of subcharacter components which are also semantically informative. In this work, we propose an approach to jointly embed Chinese words as well as their characters and fine-grained subcharacter components. We use three likelihoods to evaluate whether the context words, characters, and components can predict the current target word, and collected 13,253 subcharacter components to demonstrate the existing approaches of decomposing Chinese characters are not enough. Evaluation on both word similarity and word analogy tasks demonstrates the superior performance of our model.

1 Introduction

Distributed word representation represents a word as a vector in a continuous vector space and can better uncover both the semantic and syntactic information over traditional one-hot representations. It has been successfully applied to many downstream natural language processing (NLP) tasks as input features, such as named entity recognition (Collobert et al., 2011), text classification (Joulin et al., 2016), sentiment analysis (Tang et al., 2014), and question answering (Zhou et al., 2015). Among many embedding methods (Bengio et al., 2003; Mnih and Hinton, 2009), CBOW and Skip-Gram models are very popular due to their simplicity and efficiency, making it feasible to learn good embeddings of words from large scale training corpora (Mikolov et al., 2013b,a).

Despite the success and popularity of word embeddings, most of the existing methods treat each word as the minimum unit, which ignores the morphological information of words. Rare words cannot be well represented when optimizing a cost function related to a rare word and its contexts. To address this issue, some recent studies (Luong et al., 2013; Qiu et al., 2014; Sun et al., 2016a; Wieting et al., 2016) have investigated how to exploit morphemes or character n-grams to learn better embeddings of English words.

Different from other alphabetic writing systems such as English, written Chinese is logosyllabic, i.e., a Chinese character can be a word on its own or part of a polysyllabic word[1]. The characters themselves are often composed of subcharacter components which are also semantically informative. The subword items of Chinese words, including characters and subcharacter components, contain rich semantic information. The characters composing a word can indicate the semantic meaning of the word and the subcharacter components, such as radicals and components themselves being a character, composing a character can indicate the semantic meaning of the character. The components of characters can be roughly divided into two types: semantic component and phonetic component. The semantic component indicates the meaning of a character while the phonetic component indicates the sound of a character. For example, 氵 (water) is the semantic component of characters 湖 (lake) and 海 (sea), 马 (horse) is the phonetic component of characters 妈 (mother) and 骂 (scold) where both 妈 and 骂 are pronounced similar to 马.

Leveraging the subword information such as characters and subcharacter components can enhance Chinese word embeddings with internal morphological semantics. Some methods have been proposed to incorporate the subword infor-

Copenhagen, Denmark, September 7–11, 2017.

mation for Chinese word embeddings. Sun et al. (2014) and Li et al. (2015) proposed methods to enhance Chinese character embeddings with radicals based on C&W model (Collobert and Weston, 2008) and word2vec models (Mikolov et al., 2013a,b) respectively. Chen et al. (2015) used Chinese characters to improve Chinese word embeddings and proposed the CWE model to jointly learn *Chinese word and character* embeddings. Xu et al. (2016) extended the CWE model by exploiting the internal semantic similarity between a word and its characters in a cross-lingual manner. To combine both the *radical-character* and *character-word* compositions, Yin et al. (2016) proposed a multi-granularity embedding (MGE) model based on the CWE model, which represents the context as a combination of surrounding words, surrounding characters, and the radicals of the target word. Particularly, they developed a dictionary of 20,847 characters and 296 radicals.

However, all the above approaches still missed a lot of fine-grained components in Chinese characters. Formally and historically, radicals are character components used to index Chinese characters in dictionaries. Although many of the radicals are also semantic components, a character has only one radical, which cannot fully uncover the semantics and structure of the character. Besides over 200 radicals, there are more than 10,000 components which are also semantically meaningful or phonetically useful. For example, Chinese character 照 (illuminate, reflect, mirror, picture) has one radical 灬 (the corresponding traditional Chinese radical is 火, meaning fire) and three other components, i.e., 日 (sun), 刀 (knife), and 口 (mouth). Shi et al. (2015) proposed using WUBI input method to decompose the Chinese characters into components. However, WUBI input method uses rules to group Chinese characters into meaningless clusters which can fit the alphabet based keyboard. The semantics of the components are not straightforwardly meaningful.

In this work, we present a model to jointly learn the embeddings of Chinese words, characters, and subcharacter components. The learned Chinese word embeddings can leverage the external context co-occurrence information and incorporate rich internal subword semantic information. Experiments on both word similarity and word analogy tasks demonstrate the effectiveness of our model over previous works. The code and data are available at `https://github.com/HKUST-KnowComp/JWE`.

2 Joint Learning Word Embedding

In this section, we introduce our joint learning word embedding model (JWE), which combines words, characters, and subcharacter components information. Our model is based on CBOW model (Mikolov et al., 2013a). JWE uses the average of context word vectors, the average of context character vectors, and the average of context subcharacter vectors to predict the target word, and uses the sum of these three prediction losses as the objective function.

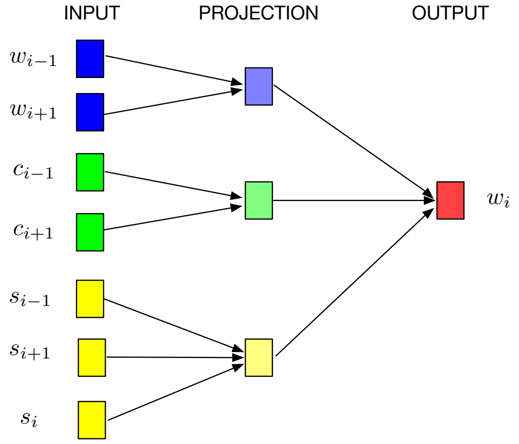

Figure 1: Illustration of JWE. w_i is the target word. w_{i-1} and w_{i+1} are the left word and right word of w_i respectively. c_{i-1} and c_{i+1} represent the characters in the context. s_{i-1} and s_{i+1} represent the subcharacters in the context, s_i represents the subcharacters of the target word w_i.

We denote D as the training corpus, $W = (w_1, w_2, \cdots, w_N)$ as the vocabulary of words, $C = (c_1, c_2, \cdots, c_M)$ as the vocabulary of characters, $S = (s_1, s_2, \cdots, s_K)$ as the vocabulary of subcharacters, and T as the context window size respectively. As illustrated in Figure 1, JWE aims to maximize the sum of log-likelihoods of three predictive conditional probabilities for a target word w_i:

$$L(w_i) = \sum_{k=1}^{3} \log P(w_i | h_{i_k}), \qquad (1)$$

where $h_{i_1}, h_{i_2}, h_{i_3}$ are the composition of context words, context characters, context subcharacters respectively. Let $\boldsymbol{v}_{w_i}, \boldsymbol{v}_{c_i}, \boldsymbol{v}_{s_i}$ be the "input" vectors of word w_i, character c_i, and subcharacter s_i

respectively, $\hat{\boldsymbol{v}}_{w_i}$ be the "output" vectors of word w_i. The conditional probability is defined by the softmax function as follows:

$$p(w_i|h_{i_k}) = \frac{\exp(\boldsymbol{h}_{i_k}^T \hat{\boldsymbol{v}}_{w_i})}{\sum_{j=1}^{N} \exp(\boldsymbol{h}_{i_k}^T \hat{\boldsymbol{v}}_{w_j})}, \quad \text{k} = 1, 2, 3, \tag{2}$$

where $\boldsymbol{h}_{i_1}$ is the average of the "input" vectors of words in the context, i.e.:

$$\boldsymbol{h}_{i_1} = \frac{1}{2T} \sum_{-T \le j \le T, j \ne 0} \boldsymbol{v}_{w_{i+j}}. \tag{3}$$

Similarly, $\boldsymbol{h}_{i_2}$ is the average of characters' "input" vectors in the context, $\boldsymbol{h}_{i_3}$ is the average of subcharacters' "input" vectors in the context or in the target word or all of them. Given a corpus D, JWE maximizes the overall log likelihood:

$$L(D) = \sum_{w_i \in D} L(w_i), \tag{4}$$

where the optimization follows the implementation of negative sampling used in CBOW model (Mikolov et al., 2013a).

This objective function is different from that of MGE (Yin et al., 2016). For a target word w_i, the objective function of MGE is almost equivalent to maximizing $P(w_i|\boldsymbol{h}_{i_1} + \boldsymbol{h}_{i_2} + \boldsymbol{h}_{i_3})$. During the backpropagation, the gradients of $\boldsymbol{h}_{i_1}, \boldsymbol{h}_{i_2}, \boldsymbol{h}_{i_3}$ can be different in our model while they are always same in MGE, so the gradients of the embeddings of words, characters, subcharacter components can be different in our model while they are same in MGE. Thus, the representations of words, characters, and subcharacter components are decoupled and can be better trained in our model. A similar decoupled objective function is used in (Sun et al., 2016a) to learn English word embeddings and phrase embeddings. Our model differs from theirs in that we combine the subwords of both the context words and target word to predict the target word while they use the morphemes of the target English word to predict it.

3 Experiments

We quantitatively evaluate the quality of word embeddings learned by our model on word similarity evaluation and word analogy tasks.

3.1 Experimental Settings

Model	Wordsim-240	Wordsim-295
CBOW	0.5009	0.5985
CWE	0.5133	0.5805
MGE	0.5128	0.5425
JWE+c+p1	0.5437	0.6549
JWE+c+p2	0.5476	0.6676
JWE+c+p3	0.5554	0.6533
JWE+r+p1	0.5478	0.6434
JWE+r+p2	**0.5619**	0.6621
JWE+r+p3	0.5273	0.6461
JWE-n	0.5476	**0.6710**

Table 1: Results on word similarity evaluation. For our JWE model, +c represents the components feature and +r represents the radicals feature; +p indicates which subcharacters are used to predict the target word; +p1 indicates using the surrounding words' subcharacter features; +p2 indicates using the target word's subcharacter features; +p3 indicates using the subcharacter features of both the surrounding words and the target word; -n indicates only using characters without either components or radicals.

Training Corpus. We adopt the Chinese Wikipedia Dump[2] as our training corpus. In preprocessing, pure digits and non Chinese characters are removed. We use THULAC[3] (Sun et al., 2016b) for Chinese word segmentation and POS tagging. We identify all entity names for CWE (Chen et al., 2015) and MGE (Yin et al., 2016) as they do not use the characters information for non-compositional words. Our model (JWE) does not use such a non-compositional word list. We obtained a 1GB training corpus with 153,071,899 tokens and 3,158,225 unique words.

Subcharacter Components. We crawled the components and radicals information of Chinese characters from HTTPCN[4]. We obtained 20,879 characters, 13,253 components and 218 radicals, of which 7,744 characters have more than one components, and 214 characters are equal to their radicals.

Parameter Settings. We compare our method with CBOW (Mikolov et al., 2013b)[5] , CWE (Chen et al., 2015)[6], and MGE (Yin et al., 2016)[7].

[4] http://tool.httpcn.com/zi/

[5] https://code.google.com/p/word2vec/

[6] https://github.com/Leonard-Xu/CWE

[7] We used the source code provided by the author. Our experimental results of baselines are different from that in MGE paper because we used a 1GB corpus while they used a 500MB corpus and we fixed the training iteration while they tried the training iteration in range [5, 200] and chose the best.

For all models, we used the same parameter settings. We fixed the word vector dimension to be 200, the window size to be 5, the training iteration to be 100, the initial learning rate to be 0.025, and the subsampling parameter to be 10^{-4}. Words with frequency less than 5 were ignored during training. We used 10-word negative sampling for optimization.

3.2 Word Similarity

This task evaluates the embedding's ability of uncovering the semantic relatedness of word pairs. We select two different Chinese word similarity datasets, wordsim-240 and wordsim-296 provided by (Chen et al., 2015) for evaluation. There are 240 pairs of Chinese words in wordsim-240 and 296 pairs of Chinese words in wordsim-296. Both datasets contain human-labeled similarity scores for each word pair. There is a word in wordsim-296 that did not appear in the training corpus, so we removed this from the gold-standard to produce wordsim-295. All words in wordsim-240 appeared in the training corpus. The similarity score for a word pair is computed as the cosine similarity of their embeddings generated by the learning model. We compute the Spearman correlation (Myers et al., 2010) between the human-labeled scores and similarity scores computed by embeddings. The evaluation results of our model and baseline methods on wordsim-240 and wordsim-295 are shown in Table 1.

From the results, we can see that JWE substantially outperforms CBOW, CWE, and MGE on the two word similarity datasets. JWE can better leverage the rich morphological information in Chinese words than CWE and MGE. It shows the benefits of decoupling the representation of words, characters, and subcharacter components as opposed to employing concatenation, sum, or average on all of them as the context.

We also observe that JWE with only characters can get competitive results on the word similarity task compared to JWE with characters and subcharacters. The reason may be that characters are enough to provide additional semantic information for computing the similarities of many word pairs in the two datasets. For example, the similarity of 法律 (law, statute) and 律师 (lawyer) in wordsim-295 can be directly inferred from the shared character 律 (law, rule).

3.3 Word Analogy

This task examines the quality of word embedding by its capacity of discovering linguistic regularities between pairs of words. For example, for a tuple like "罗马 (Rome): 意大利 (Italy):: 柏林 (Berlin): 德国 (Germany)", the model can answer correctly if the nearest vector representation to vec(意大利) - vec(罗马) + vec(柏林) is vec(德国) among all words except from 罗马, 意大利, and 柏林. More generally, given an analogy tuple "$a : b :: c : d$," the model answers the analogy question "$a : b :: c$:?" by finding x in the vocabulary such that

$$\arg \max_{x \neq a, x \neq b, x \neq c} cos(\vec{b} - \vec{a} + \vec{c}, \vec{x}).$$

We use accuracy as the evaluation metric. In this task, we use the Chinese word analogy dataset introduced by (Chen et al., 2015), which consists of 1,124 tuples of words and each tuple contains 4 words, coming from three different categories: "Capital" (677 tuples), "State" (175 tuples), and "Family" (272 tuples). Our training corpus covers all the testing words.

Model	Total	Capital	State	Family
CBOW	0.7954	0.8493	0.8857	0.6029
CWE	0.7553	0.8420	0.8743	0.4632
MGE	0.7696	0.8907	0.8857	0.3934
JWE+c+p1	0.7562	0.8272	0.8286	0.5331
JWE+c+p2	0.8407	0.8848	**0.9486**	**0.6618**
JWE+c+p3	**0.8505**	**0.9188**	0.9371	0.6250
JWE+r+p1	0.7553	0.8198	0.8171	0.5551
JWE+r+p2	0.8185	0.8656	0.9143	0.6397
JWE+r+p3	0.8416	0.9010	0.9200	0.6434
JWE-n	0.8229	0.8803	0.9028	0.6286

Table 2: Results on word analogy reasoning. The configurations are the same of the ones used in Table 1.

The results in Table 2 show that JWE outperforms the baselines on all categories' word analogy tasks. Different from the results on the word similarity task, JWE with components consistently performs better than JWE with radicals and JWE without either radicals or components. It demonstrates the necessary of delving deeper into fine-grained components for complex semantic reasoning tasks.

3.4 Case Studies

In addition to evaluating the benefits of incorporating subword information for Chinese word embeddings, it would be interesting to see the relationships of the embeddings of words, characters, and subcharacter components as they are embedded into a same continuous vector space.

照 (photograph)	照片 (photo) 相片 (photo) 拍照 (photograph) 护照 (passport) 照相 (photography)
河 (river)	黄河 (the Yellow River) 河流 (river) 河道 (watercourse) 运河 (canal) 河南 (Henan province)

Table 3: Closest words of characters 照 (photograph) and 河 (river).

Component	疒 (illness)
Closest characters	疗 (cure) 症 (symptom) 痛 (pain) 疮 (sore) 患 (suffer) 痒 (itch) 疳 (infantile malnutrition) 病 (disease) 肿 (swelling)
Closest words	治疗 (cure) 病症 (symptom) 复发 (recurrence) 疼痛 (pain) 症状 (symptom) 腹绞痛 (abdominal pain) 患者 (patients) 癫痫 (epilepsy) 疾病 (disease) 疗法 (therapy)

Table 4: Closest characters and closest words of the component 疒 (illness).

We evaluate the embeddings' abilities of uncovering the semantic relatedness of words, characters, and subcharacter components through case studies. The similarities between them are computed by the cosine similarities of their embeddings. Take two Chinese character 照 (photograph) and 河 (river) as examples, we list their closest words in Table 3. We can see that most of the closest words are semantically related to the corresponding character.

We further take the component 疒 (illness) as an example and list its closest characters and words in Table 4. All of the closest characters and words are semantically related to the component 疒 (illness). Most of them have the component 疒 (illness). 患 (suffer), 肿 (swelling), and 患者 (patients) do not have the component 疒 (illness), but they are also semantically related to 疒 (illness). It shows that JWE does not overuse the component information but leverages both the external context co-occurrence information and internal subword morphological information well.

4 Conclusion and Future Work

In this paper, we propose a model to jointly learn the embeddings of Chinese words, characters, and subcharacter components. Our approach makes full use of subword information to enhance Chinese word embeddings. Experiments show that our model substantially outperforms the baseline methods on Chinese word similarity computation and Chinese word analogy reasoning, and demonstrate the benefits of incorporating fine-grained components compared to just using characters.

There could be several directions to be explored for future work. First, we use the average operation to integrate the subcharacter components as the context to predict the target word. The structure of Chinese characters and the positions of components in the character may be considered to fully leverage the component information of Chinese characters. Second, for any target word, we simply use word context, character context, and subcharacter context to predict it and do not distinguish compositional words and non-compositional words. To solve this problem, attention models may be used to adaptively assign weights to word context, character context, and subcharacter context.

Abstract

We present an unsupervised, language agnostic approach for exploiting morphological regularities present in high dimensional vector spaces. We propose a novel method for generating embeddings of words from their morphological variants using morphological transformation operators. We evaluate this approach on MSR word analogy test set (Mikolov et al., 2013d) with an accuracy of 85% which is 12% higher than the previous best known system.

1 Introduction

Vector representation of words are presently being used to solve a variety of problems like document classification (Sebastiani, 2002), question answering (Tellex et al., 2003) and chunking (Turian et al., 2010).

Word representations capture both syntactic and semantic properties (Mikolov et al., 2013d) of natural language. Soricut and Och (2015) exploited these regularities to generate prefix/suffix based morphological transformation rules in an unsupervised manner. These morphological transformations were represented as vectors in the same embedding space as the vocabulary.

Using Soricut's transformation rules, the major problem is identifying correct rule to apply to a word, i.e. if we have to generate an embedding for "runs", which rule to apply on "run". Experimental results showed that "walk - walks" gives better results than rules like "invent - invents" or "object - objects" in generating word embedding for "runs". In this paper, we try to explore if we can harness this morphological regularity in a much better way, than applying a single rule using vector arithmetic.

Hence, we tried to come up with a global transformation operator, which aligns itself with the source word, to give best possible word embedding for target word. We will have a single transformation operator for each rule, irrespective of the form of root word (like verb or a noun). Our transformation operator is in the form of a matrix, which when applied on a word embedding (cross product of vector representation of word with transformation matrix) gives us a word embedding for target word.

The intuition is not to solve for "invent is to invents as run is to ?" or "object is to objects as run is to ?", but instead we are solving for "walk is to walks, object is to objects, invent is to invents, ... as run is to ?". A transformation operator aims to be a unified transition function for different forms of the same transition.

The idea of projection learning has been applied to a multitude of tasks such as in the learning of cross lingual mappings for translation of English to Spanish (Mikolov et al., 2013b). Our approach has its basis on the same lines but with a different formulation and end goal to learn morphological rules rather than semantic associations and translational constraints (as done by Mikolov).

In summary, the main contributions of this paper is a new method to harness morphological regularities present in high dimensional word embeddings. Using this method, we present state of the art results on MSR word analogy dataset.

This paper is structured as follows. We first discuss the corpus used for training the transformation operators in section 2. In section 3, we discuss how these transformation operators are trained. Later in sections 4, we analyze and discuss the results of our experiments. We finish this paper with future scope of our work in section 5.

2 Datasets

We are using word embeddings trained on Google News corpus (Mikolov et al., 2013c) for our experiments. For the model trained in this paper, we have used the Skip-gram (Mikolov et al., 2013a) algorithm. The dimensionality has been fixed at 300 with a minimum count of 5 along with negative sampling. As training set and for estimating the frequencies of words, we use the Wikipedia data (Shaoul, 2010). The corpus contains about 1 billion tokens.

The MSR dataset (Mikolov et al., 2013d) contains 8000 analogy questions. This data set has been used by us for testing our model. The relations portrayed by these questions are morpho-syntactic, and can be categorized according to parts of speech - adjectives, nouns and verbs. Adjective relations include comparative and superlative (good is to best as smart is to smartest). Noun relations include singular and plural, possessive and non-possessive (dog is to dog's as cat is to cat's). Verb relations are tense modifications (work is to worked as accept is to accepted).

For all the experiments, we have calculated the fraction of answers correctly answered by the system on MSR word analogy dataset.

3 Transformation Matrix

The thresholds mentioned in this section have been determined after empirical fine tuning.

To compute the transformation matrix of a rule, we first extract in an unsupervised way all the word pairs following that transition rule. For example, in case of the rule <null,s>, we find word pairs such as <boy,boys>, <object,objects> and <invent,invents>. In this paper, we used the data structure TRIE for computational optimization. However, we don't want cases which do not follow the general regularity of a rule. One such case may be <hat,hated> which does not follow the general trend of the transformation <null,ed>. For eliminating these cases, we set a threshold of cosine similarity of the word vectors of the two words of the pair at 0.2. Also, the frequency of both these words should be greater than 1000 (so that they are well trained). Since our transformation matrix is derived from all the word pairs following a particular transition rule, we carefully use only those word pairs which are of high frequency. We do so because highly frequent words have better trained word embeddings.

Suppose we get "N" highly frequent word pairs following the same regularity(transition rule). For our experiments, the lower threshold of "N" is set at 50. Dimensions of word embedding of a word in our model is "D". Using first word of our "N" chosen word pairs, we create a matrix "A" of dimensions N*D, where each row is vector representation of a word. Similarly, we create another matrix B, of similar dimensions as A, using second word of our chosen word pairs.

We now propose that a matrix "X" (our transformation matrix) exists such that,

$$
\begin{aligned}
A * X &= B \\
or, X &= A^{-1} * B
\end{aligned}
\tag{1}
$$

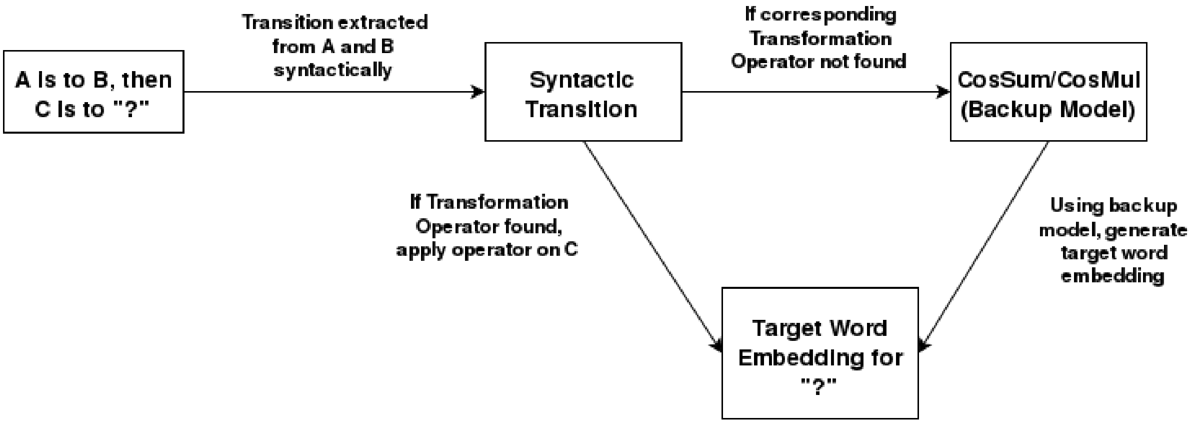
(all instances of A that we encountered were non-singular). Our matrix "X" will be of dimensions "D*D" and when applied to a word embedding (matrix of dimensions 1*D, it gives a matrix of dimensions 1*D as output), it results in the word embedding of the transformed form of the word.

Due to inverse property of a matrix, it accurately remembers the word pairs used for computing. The matrix also appears to align itself with the word embedding of other words (not used for its training) to transform them according to the rule that the matrix follows. Some interesting results are shown in table 1.

Word1	Word2	Word3	Operator	Word4	Cosine
decides	decided	studies	<s , d>	studied	0.89
reach	reaches	go	<null , es>	goes	1.0
ask	asks	reduce	<null , s>	reduces	0.91

Table 1: Some example results of transformation operators.

While testing, we extract the syntactic transition using the first two words of the analogy question. For example, for pairs like <reach, reached>, < walk, walked>, we are able to extract that they follow <null, ed> rule syntactically. But, for <go, went>, we are not able to find any transformation operator after syntactic analysis, and for such cases, we fall back on CosSum/CosMul (Levy et al., 2014) approaches as our backup. Mikolov et al. showed that relations between words are reflected to a large extent in the offsets between their vector embeddings (queen - king = woman - man), and thus the vector of the hidden word b^* will be similar to the vector $b - a + a^*$, suggesting that the



A is to B, then C is to "?"

If Transformation Operator found, apply operator on C
Using backup model, generate target word embedding
Target Word Embedding for "?"

Figure 1: System Workflow

analogy question can be solved by optimizing:

$$\underset{b^* \in V}{arg\ max}\,(sim(b^*, b - a + a^*)) \tag{2}$$

where V is the vocabulary and sim is a similarity measure. Specifically, they used the cosine similarity measure, defined as:

$$cos(u, v) = \frac{u\,.\,v}{||u||\,.\,||v||} \tag{3}$$

resulting in:

$$\underset{b^* \in V}{arg\ max}\,(cos(b^*, b - a + a^*)) \tag{4}$$

Equation 4 has been referred to as CosAdd model.

While experimenting, Omer Levy (Levy et al., 2014) found that for an analogy question “London is to England as Baghdad is to - ?”, using CosAdd model, they got *Mosul* - a large Iraqi city, instead of *Iraq* which is a country, as an answer. They were seeking for Iraq because of its similarity to England (both are countries), similarity to Baghdad (similar geography/culture) and dissimilarity to London (different geography/culture). While Iraq was much more similar to England than Mosul was (because both Iraq and England are countries), the sums were dominated by the geographic and cultural aspect of the analogy.

Hence to achieve better balancing among different aspects of similarity, they proposed a new model, where they moved from additive to multiplicative approach:

$$\underset{b^* \in V}{arg\ max}\,\frac{cos(b^*, b)\,.\,cos(b^*, a^*)}{cos(b^*, a) + \epsilon} \tag{5}$$

$$(\epsilon = 0.001\ to\ prevent\ division\ by\ zero)$$

This was equivalent to taking the logarithm of each term before summation, thus amplifying the differences between small quantities and reducing the differences between larger ones. This model has been referred to as CosMul model.

Even though our transformation operator can handle any sort of transformation, but if we are not able to detect the rule syntactically, we are not able to determine which transformation operator to use, and hence, we fall back on CosSum/CosMul. Like for the above mentioned examples, we will use transformation operator (if existing) for transformations like <reach, reached>, since we can find the rule syntactically, but for <go, went>, we can not, since we can not extract the corresponding rule itself - even if the matrix can handle such transitions.

If a transformation matrix exists for a transition rule, we apply the corresponding transformation matrix on the word embedding of the third word and search the whole vocabulary for the word with an embedding most similar to the transformed embedding (ignoring the third word itself). If the similarity of the resultant word's embedding with our transformed embedding is less than 0.68 (determined empirically) or the transformation matrix itself does not exist, we fall back on the CosSum/CosMul techniques.

Levy et. al. (2015) proposed the systems CosSum and CosMul in which they showed that tuning the hyperparameters has a significant impact on the performance. Hyperparameters are all the modifications and system design choices which are a part of the final algorithm.

Figure 1 gives an overview of how target word embedding is generated using transformation operators and our backup models.

4 Result and Analysis

Model	CosSum	CosSum w/ M	CosMul	CosMul w/ M
SGNS-L	0.69	-	**0.729**	-
Glove-L	0.628	-	0.685	-

Table 4: Example results of transformation operators for irregular transformations.

In table 2, GN denotes the scores of Google-News word embeddings on the test set. SGNS-L and Glove-L (Levy et al., 2015) denote the results of Skip-gram with negative sampling and Glove word embeddings respectively, both trained on large datasets. SG denotes the scores of our word2vec trained model (on 1B tokens). "w/ M" implies that we have used matrix arithmetic (along with CosSum/CosMul as backup) for word analogy answering questions. Our model uses "CosSum" and "CosMul" as backup transformation method in case a transformation operator (matrix) does not exist. We see that the results of GN+Matrix are better than the previously used models.

However, one thing we noticed was that the model trained on Google-News did not contain words with apostrophe sign(s) and 1000 out of 8000 words in MSR word analogy test set contained apostrophe sign(s). Also, we noticed that in SG, the matrix approach was able to answer word analogy queries where words contained apostrophe sign(s), with an accuracy of 93.7% since it is a very common transformation - which resulted in well trained transformation matrix. So, we used SG as a backup for words which were not found in GN. The results of this hybrid model are denoted by GN-SG Hybrid. We see that this model performs considerably better than the existing state of the art system.

Word1	Word2	Word3	Operator	Word4	Cosine
reach	reached	go	<null , ed>	went	0.80
recognize	recognizes	be	<null , s>	is	0.70

Table 5: Example results of transformation operators for complete change of word form.

As we can see in table 3, our approach works really well for analogy questions where target word experiences regular transformation, i.e. the transformation type is simple addition/subtraction of suffix/prefix.

In table 4 and table 5 we observe that transformations are irregular transformations i.e there is slight change in word form while addition/subtraction of suffix/prefix or there is complete change in word form in the target word of our analogy question. This is an interesting observation, because even though our rule extraction (as explained above) is syntactic in nature, our method still learns and can apply transformation rules on words which undergo such irregular/complete transformations.

In operator "<null,s>", we see that our transformation matrix works pretty well irrespective of the form the word. For example, it works for "school-schools" and "reduce-reduces" which are noun and verb word pairs respectively. Our approach works by statistically creating global transformation operators and is agnostic in applying them (i.e. applied on a verb or a noun). Our transformation rules learn from both noun transitions and verb transitions and hence, even though we agree that linguistically there is a difference between noun and verb transitions, our approach performed better than previously existing systems

We also observed that in some cases, cosine similarity score is 1. This is mostly because "stricter-strictest" was used for training transformation matrix of "<r,st>" operator.

Although our cosine scores for irregular/complete transformations are not that high with respect to scores for regular transformations, our system still performs at par or better than previous known systems. It is still able to predict words with high accuracy using its limited training corpora.

These observations can also help us analyze how certain complex transformations (irregular/complete) still behave similar to their regular counterpart computationally, as is apparent from our transformation matrix - which has learnt itself from rules that were extracted via all possible prefix and suffix substitutions from w1 to w2, and thus irregular/complete transformations would not be present in training our transformation matrix (where w1 and w2 belong to our vocabulary V - the size of our corpus).

We conclude that our matrix is able to harness morphological regularities present in word pairs used for training.

5 Future Work

The main application of this approach lies in its ability to generate representations for unseen/unreliable words on the go. If we encounter a word such as "preparedness" for which we do not have a representation or our representation is not reliable, we can identify any reliable form of the word, say "prepared" and apply <null,ness> operator on it, resulting in a representation for "preparedness". In a similar case, we can generate embeddings for words such as "unpreparedness" from "prepared" by sequentially applying <null,ness> and a prefix operator trained in a similar manner - <null,un>. Overall, this results in a much larger vocabulary than of the model initially being used.

We observe that for a transformation matrix to exist, we need enough word pairs (frequent enough to be included) to train a transformation matrix, and to cover majority of the transformation rules. Since many languages face problem of data scarcity, we face problem of "missing" transformation matrix for a transformation rule.

We will also explore if we can generate better word embeddings for words that are not highly frequent (hence less reliable), by applying transformation operators on their morphological variants, which are highly frequent and hence more reliable. For example, if for word pair "<walked,walking>", "walked" was not highly frequent in our corpora, we would not include it in training our transformation matrix for operator "<ed,ing>" because "walked" didn't have a well trained word embedding (being less frequent). But, if we have walk as highly frequent, and a transformation matrix for rule "<null,ed>", we can generate a better word embedding for "walked", and in turn use "<walked,walking>" for training our transformation matrix for rule "<ed,ing>".

In our current approach, for problem "If A is to B, then C is to ?", we do syntactic analysis on "A" and "B" to find out the transformation rule (and hence the transformation matrix) to be applied on "C" to find our "?". Rather than doing syntactic analysis, we will focus on finding out the correct transformation matrix by applying all transformation matrices on "A" and then analyzing output of each matrix. The one which will give closest result to "B" can be safely assumed to be the correct rule (transformation matrix), and hence will be applied on "C" to find "?". We will also analyze this approach's impact in terms of space and time complexities with respect to our current system. This will also enable us to find transformation matrix for word pairs which do not follow a syntactic transformation.

Abstract

We introduce a novel mixed character-word architecture to improve Chinese sentence representations, by utilizing rich semantic information of word internal structures. Our architecture uses two key strategies. The first is a mask gate on characters, learning the relation among characters in a word. The second is a max-pooling operation on words, adaptively finding the optimal mixture of the atomic and compositional word representations. Finally, the proposed architecture is applied to various sentence composition models, which achieves substantial performance gains over baseline models on sentence similarity task.

1 Introduction

To understand the meaning of a sentence is a prerequisite to solve many natural language processing problems. Obviously, this requires a good representation of the meaning of a sentence. Recently, neural network based methods have shown advantage in learning task-specific sentence representations (Kalchbrenner et al., 2014; Tai et al., 2015; Chen et al., 2015a; Cheng and Kartsaklis, 2015) and generic sentence representations (Le and Mikolov, 2014; Hermann and Blunsom, 2014; Kiros et al., 2015; Kenter et al., 2016; Wang et al., 2017). To learn generic sentence representations that perform robustly across tasks as effective as word representations, Wieting et al. (2016b) proposes an architecture based on the supervision from the Paraphrase Database (Ganitkevitch et al., 2013).

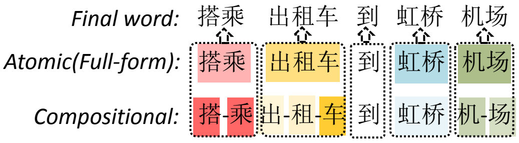

Figure 1: An example sentence that consists of five words as “搭乘(take) 出租车(taxi) 到(to) 虹桥(Hongqiao) 机场(airport)”. Most of these words are compositional, namely word “搭乘” consists of characters “搭(take)” and “乘(ride)”, word “出租车” constitutes characters “出(out)”, “租(rent)” and “车(car)”, and word “机场” is composed of characters “机(machine)” and “场(field)”. The color depth represents (1) contributions of each character to the compositional word meaning, and (2) contributions of the atomic (which ignore inner structures) and compositional word to the final word meaning. The deeper color means more contributions.

Despite the fact that Chinese has unique word internal structures, there is no work focusing on learning generic Chinese sentence representations. In contrast to English, Chinese characters contain rich information and are capable of indicating semantic meanings of words. As illustrated in Figure 1, the internal structures of Chinese words express two characteristics: (1) Each character in a word contribute differently to the compositional word meaning (Wong et al., 2009) such as the word “出租车(taxi)”. The first two characters “出租(rent)” are descriptive modifiers of the last character “车(car)”, and make the last character play the most important role in expressing word meaning. (2) The atomic and compositional representations contribute differently to different types of words (MacGregor and Shtyrov, 2013). For instance, the meaning of “机场(airport)”, a low-frequency word, can be better expressed by the compositional word representation, while the non-transparent word “虹桥(Hongqiao)” is better expressed by the atomic word representation.

Proceedings of the 2017 Conference on Empirical Methods in Natural Language Processing, pages 298–303
Copenhagen, Denmark, September 7–11, 2017. ©2017 Association for Computational Linguistics

The word internal structures have been proven to be useful for Chinese word representations. Chen et al. (2015b) proposes a character-enhanced word representation model by adding the averaged character embeddings to the word embedding. Xu et al. (2016) extends this work by using weighted character embeddings. The weights are cosine similarities between embeddings of a word's English translation and its constituent characters' English translations. However, their work calculates weights based on a bilingual dictionary, which brings lots of mistakes because words in two languages do not mantain one-to-one relationship. Furthermore, they only consider the first characteristic of word internal structures, but ignore the contributions of the atomic and compositional word to the final word meaning. Similar ideas of adaptively utilizing character level informations have also been investigated in English recently (Hashimoto and Tsuruoka, 2016; Rei et al., 2016; Miyamoto and Cho, 2016). It should be noted that these studies are not focus on learning sentence embeddings.

In this paper, we explore word internal structures to learn generic sentence representations, and propose a mixed character-word architecture which can be integrated into various sentence composition models. In the proposed architecture, a mask gate is employed to model the relation among characters in a word, and pooling mechanism is leveraged to model the contributions of the atomic and compositional word embeddings to the final word representations. Experiments on sentence similarity (as well as word similarity) demonstrate the effectiveness of our method. In addition, as there are no publicly available Chinese sentence similarity datasets, we build a dataset to directly test the quality of sentence representations. The code and data will be publicly released.

2 Model Description

The problem of learning compositional sentence representations can be formulated as $g^{comp} = f(x)$, where f is the **composition function** which combines the **word representations** $x = \langle x_1, x_2, ..., x_n \rangle$ into the compositional sentence representation g^{comp}.

2.1 Mixed Character-Word Representation

In our method, the final word representation is a fusion of the atomic and compositional word embeddings. The atomic word representation is calculated by projecting word level inputs into a high-dimensional space by a look up table, while the compositional word representation is computed as a gated composition of character representations:

$$x_i^{comp} = \sum_{j=1}^{m} v_{ij} \cdot c_{ij}, \qquad (1)$$

where c_{ij} is the *j*-th character representation in the *i*-th word. The mask gate $v_{ij} \in \mathbb{R}^d$ controls the contribution of the *j*-th character in the *i*-th word. This is achieved by using a feed-forward neural network operated on the concatenation of a character and a word, under the assumption that the contribution of a character is correlated with both character itself and its relation with the corresponding word:

$$v_{ij} = tanh(W \cdot [c_{ij}; x_i]), \qquad (2)$$

where $W \in \mathbb{R}^{d \times 2d}$ is a trainable parameter. The proposed mask gate is a vector instead of a single value, which introduces more variations to character meaning in the composition process.

Then, the atomic and compositional word representations are mixed with max-pooling:

$$x_i^{final} = \max_{k=1}^{d}(x_{ik}^{atomic}, x_{ik}^{comp}), \qquad (3)$$

the *max* is an element-wise function to capture the most important features (i.e., the highest value in each dimension) in the two word representations.

2.2 Sentence Composition Model

Given word embeddings, we make a systematic comparison of five different composition models for sentence representations as follows:

1. $g = Average(x) = \frac{1}{n}\sum_{i=1}^{n} x_i$
2. $g = Matrix(x) = \frac{1}{n}\sum_{i=1}^{n} f(W_m x_i)$
3. $g = Dan(x) = f(W_d(\frac{1}{n}\sum_{i=1}^{n} x_i) + b)$
4. $g = RNN(x) = f(W_x x_i + W_h h_{i-1} + b)$
5. $g = LSTM(x) = o_t \odot f(c_i)$, where $c_i = f_i \cdot c_{i-1} + i_i \cdot \widetilde{c_i}$ and $\widetilde{c_i} = \sigma(W_{xc} x_i + W_{hc} h_{i-1})$

Average model, as the simplest composition model, represents sentences with averaged word vectors which are updated during training. The

Matrix and Dan models are proposed in Zanzotto et al. (2010) and Iyyer et al. (2015), respectively. By using matrix transformations and nonlinear functions, the two models represent sentence meaning in a more flexible way (Wang and Zong, 2017). We also include RNN and LSTM models, which are widely used in recent years. The parameters $\{i_t, f_t, o_t\} \in \mathbb{R}^d$ denote the input gate, the forget gate and the output gate, respectively. $c_t \in \mathbb{R}^d$ is the short-term memory state to store the history information. $\{W_m, W_d, W_x, W_h, W_{xc}, W_{hc}\} \in \mathbb{R}^{d \times d}$ are trainable parameters. h_{i-1} denotes representations in hidden layers. Sentence representations in RNN and LSTM models are hidden vectors of the last token.

2.3 Objective Function

This paper aims to learn the general-purpose sentence representations based on supervision from Chinese paraphrase pairs. Following the approach of Wieting et al. (2016b), we employ the max-margin objective function to train sentence representations by maximizing the distance between positive examples and negative examples.

3 Experimental Setting and Dataset

3.1 Experimental Setting

We construct four groups of models (G1˜G4) which serve as baselines to test the proposed mixed character-word models (*G5*). Group *G1* includes six baseline models, which have shown impressive performance in English. The first two are averaged word vectors and averaged character vectors. Followed by PV-DM model which uses auxiliary vectors to represent sentences and trains them together with word vectors, and FastSent model which utilizes a encoder-decoder model and encodes sentences as averaged word embeddings. The last two are Char-CNN model which is CNN model with character n-gram filters, and Charagram model which represents sentences with a character n-gram count vector. Group *G2* are the sentence representation models proposed by Wieting et al. (2016b), which utilize only word level information. We also compared our method with word representation models of Chen et al. (2015b) and Xu et al. (2016) in Group *G3* and *G4* respectively, by incorporate them into five sentence composition models in Section 2.2.

In all models, the word and character embeddings are initialized with 300-dimension vectors trained by Skip-gram model (Mikolov et al., 2013) on a corpus with 3 billion Chinese words. All models are implemented with Theano (Bergstra et al., 2010) and Lasagne (Dieleman et al., 2015), and optimized using Adam (Kingma and Ba, 2014). The hyper-parameters[1] are selected by testing different values and evaluating their effects on the development set. In this paper, we run all experiments 5 times and report the mean values.

3.2 Training Dataset

The training dataset is a set of paraphrase pairs in which two sentences in each pair represent the same meanings. Specifically, we extract Chinese paraphrases in machine translation evaluation corpora NIST2003[2] and CWMT2015[3]. Moreover, we select aligned sub-sentence pairs between paraphrases to enlarge the training corpus. Specifically, we first segment the sentences into sub-sentences according to punctuations of *comma, semicolon, colon, question mark, ellipses, and periods*. Then we pair all sub-sentences between a paraphrase and select sub-sentence pairs (s_1, s_2) which satisfy the following two constraints: (1) the number of overlapping words of sub-sentence s_1 and s_2 should meet the condition: $0.9 > len(overlap(s_1, s_2))/min(len(s_1), len(s_2)) > 0.2$, where $len(s)$ denotes the number of words in sentence s; (2) the relative length of sub-sentence should meet the condition: $max(len(s_1), len(s_2))/min(len(s_1), len(s_2)) <= 2$. Finally, we get 30,846 paraphrases (18,187 paraphrases from NIST including 11,413 sub-sentence pairs, and 12,659 paraphrases from CWMT which include 7,912 sub-sentence pairs).

3.3 Testing Dataset

We also build the testing dataset, which are sentence pairs collocated with human similarity ratings. We choose candidate sentences from the People's Daily and Baidu encyclopedia corpora. To assure sentence pairs to be representative of the full variation in semantic similarity, we choose

[1] We use a mini-batch of 25 and tune the initial learning rate over {0.001, 0.005, 0.0001, 0.0005}. For the Dan and the Matrix models, we tune over activation function (tanh or linear or rectified linear unit) and number of layers (1 or 2).

[2] which contains 1,100 English sentences with 4 Chinese translations and can be found at: https://catalog.ldc.upenn.edu/LDC2006T04

[3] which contains 1,859 English sentences with 4 Chinese translations and can be found at: http://www.ai-ia.ac.cn/cwmt2015/evaluation.html

high similarity sentence pairs[4] and then randomly pair the single sentences to construct low similarity sentence pairs. To collect human similarity ratings for sentence pairs, we use online questionnaire[5] and follow the gold standard[6] to guide the rating process of participants. The subjects are paid 7 cents for rating each sentence pair within a range of 0 5 score. In total, we obtain 104 valid questionnaires and every sentence pair is evaluated by average 8 persons. We use the average subjects' ratings for one paraphrase as its final similarity score, and the higher score means that the two sentences have more similar meaning. We then randomly partition the datasets into test and development splits in 9:1.

4 Results and Discussion

We use the Pearson's correlation coefficient to examine relationships between the averaged human ratings and the predicted cosine similarity scores of all models. Moreover, the Wilcoxon's test shows that significant difference ($p < 0.01$) exits between our models with baseline models.

From Table 1, we can see superiority of the proposed mixed character-word models (*G5*), which have significantly improved the performance over both word and character-word based models. This result indicates that it is important to find the appropriate way to fuse character and word level informations. Using mask gate alone and max pooling alone yield an improvement of 1.05 points and 0.83 points respectively, and using both strategies improves the averaged character-word models by 1.52 points. Another observation is that models with character level information (*G3, G4, G5*) perform better than word based models (*G2*), which indicates the great potential of Chinese characters in learning sentence representations. Comparing different composition functions, we can see that two simple models outperform others in all groups: the DAN model and the Matrix model. The simplest Average model achieves competitive results while the most complex LSTM model does not show advantages.

Group	Model	Test
G1: Baselines	Add (character)	0.6737
	Add (word)	0.7518
	PV-DM (Le and Mikolov, 2014)	0.7561

	RNN	**0.8408**
	LSTM	**0.8000**

Table 1: Correlation coefficients of model predictions with subject similarity ratings on Chinese sentence similarity task. The bold data refers to best among models with same composition function.

4.1 Effects of Mask Gate and Max Pooling

The mask gate assigns different weights to characters in a word, hopefully leading to better word representations. To intuitively show effects of the mask gate, we check characters whose l2-norm increase after applying the mask gate approach. We find that characters like "罪(crime)" in "罪状(guilty)", "虎 (tiger)" in "美洲虎 (jaguar)" and "瓜 (melon)" in "黄瓜 (cucumber)" achieve more weights. The above results show that the mask gate approach successfully model the first characteristic of word internal structure (i.e., assigning more weights to key characters). To quantitatively display the results, we extract the word representations calculated by the five composition models in four different groups and evaluate their quality on WordSim-297 dataset[7] using the Pearson correlation method. As shown in Table 2, the mask gate approach significantly improves the quality of word representations.

[4] Here we choose high similarity sentence pairs by using edit distance and human post-processing.

Average	0.4311	0.4584	0.4789	**0.5245**
Dan	0.4470	0.5410	0.5561	**0.5716**
Matrix	0.4496	0.5458	0.5548	**0.5694**
RNN	0.4562	0.5656	0.5550	**0.5674**
LSTM	0.4535	0.5674	0.5627	**0.5734**

Table 2: Correlation coefficients of model predictions with subject similarity ratings on Chinese word similarity task, where *G2* $\sim$ *G5* are the same as in Table 1.

The max-pooling approach is supposed to model different contributions of the atomic and compositional word vectors to the final word vector. To find out what have max-pooling method learned, we use contribution weights by calculating cosine similarities between the final word representation with the atomic and compositional word representations. The results show interesting relationships with word frequency. For high-frequency words, the contribution of compositional word representations are more dominant. While for low-frequency words, both high[8] and low contribution ratios of compositional word representations can be found. When looking into the words with the most lowest ratio, we find a large portion of English abbreviations like *NBA*, *BBC*, *GDP* etc., and a portion of metaphor words like "挂靴(retire, hanging boots)" and "扯皮(wrangle, pull skin)". Both kinds of these words are non-transparent, which indicates that the max-pooling method can successfully model the second characteristic of word internal structure and encode word transparency to some extent.

5 Conclusion and Further work

In this paper, we introduce a novel mixed character-word architecture to improve generic Chinese sentence representations by exploiting the complex internal structures of words. Extensive experiments and analyses have indicated that our models can encode word transparency and learn different semantic contributions across characters. We have also created a dataset to evaluate composition models of Chinese sentences, which could advance the research for related fields.

Future work includes applying the proposed method to other aspects of nominal semantics, such as understanding compound nouns in other languages, and to explore the compositionality of words and compounds.

High-risk learning:
acquiring new word vectors from tiny data

Abstract

Distributional semantics models are known to struggle with small data. It is generally accepted that in order to learn 'a good vector' for a word, a model must have sufficient examples of its usage. This contradicts the fact that humans can guess the meaning of a word from a few occurrences only. In this paper, we show that a neural language model such as Word2Vec only necessitates minor modifications to its standard architecture to learn new terms from tiny data, using background knowledge from a previously learnt semantic space. We test our model on word definitions and on a nonce task involving 2-6 sentences' worth of context, showing a large increase in performance over state-of-the-art models on the definitional task.

1 Introduction

Distributional models (DS: Turney and Pantel (2010); Clark (2012); Erk (2012)), and in particular neural network approaches (Bengio et al., 2003; Collobert et al., 2011; Huang et al., 2012; Mikolov et al., 2013), do not fare well in the absence of large corpora. That is, for a DS model to learn a word vector, it must have seen that word a sufficient number of times. This is in sharp contrast with the human ability to perform *fast mapping*, i.e. the acquisition of a new concept from a single exposure to information (Lake et al., 2011; Trueswell et al., 2013; Lake et al., 2016).

There are at least two reasons for wanting to acquire vectors from very small data. First, some words are simply rare in corpora, but potentially crucial to some applications (consider, for instance, the processing of text containing technical terminology). Second, it seems that fast-mapping should be a prerequisite for any system pretending to cognitive plausibility: an intelligent agent with learning capabilities should be able to make educated guesses about new concepts it encounters.

One way to deal with data sparsity issues when learning word vectors is to use morphological structure as a way to overcome the lack of primary data (Lazaridou et al., 2013; Luong et al., 2013; Kisselew et al., 2015; Padó et al., 2016). Whilst such work has shown promising result, it is only applicable when there is transparent morphology to fall back on. Another strand of research has been started by Lazaridou et al. (2017), who recently showed that by using simple summation over the (previously learnt) contexts of a nonce word, it is possible to obtain good correlation with human judgements in a similarity task. It is important to note that both these strategies assume that rare words are special cases of the distributional semantics apparatus, and thus require separate approaches to model them.

Having different algorithms for modelling the same phenomenon means however that we need some meta-theory to know when to apply one or the other: it is for instance unclear at which frequency a rare word is not rare anymore. Further, methods like summation are naturally self-limiting: they create frustratingly strong baselines but are too simplistic to be extended and improved in any meaningful way. In this paper, our underlying assumption is thus that it would be desirable to build a single, all-purpose architecture to learn word representations from *any* amount of data. The work we present views fast-mapping as a component of an incremental architecture: the rare word case is simply the first part of the concept learning process, *regardless of how many times it will eventually be encountered.*

With the aim of producing such an incremen-

Proceedings of the 2017 Conference on Empirical Methods in Natural Language Processing, pages 304–309
Copenhagen, Denmark, September 7–11, 2017.

tal system, we demonstrate that the general architecture of neural language models like Word2Vec (Mikolov et al., 2013) is actually suited to modelling words from a few occurrences only, providing minor adjustments are made to the model itself and its parameters. Our main conclusion is that the combination of a heightened learning rate and greedy processing results in very reasonable one-shot learning, but that some safeguards must be in place to mitigate the high risks associated with this strategy.

2 Task description

We want to simulate the process by which a competent speaker encounters a new word in known contexts. That is, we assume an existing vocabulary (i.e. a previously trained semantic space) which can help the speaker 'guess' the meaning of the new word. To evaluate this process, we use two datasets, described below.

The definitional nonce dataset We build a novel dataset based on encyclopedic data, simulating the case where the context of the unknown word is supposedly maximally informative.[1] We first record all Wikipedia titles containing one word only (e.g. *Albedo, Insulin*). We then extract the first sentence of the Wikipedia page corresponding to each target title (e.g. *Insulin is a peptide hormone produced by beta cells in the pancreas.*), and tokenise that sentence using the Spacy toolkit.[2] Each occurrence of the target in the sentence is replaced with a slot (___).

From this original dataset, we only retain sentences with enough information (i.e. a length over 10 words), corresponding to targets which are frequent enough in the UkWaC corpus (Baroni et al. (2009), minimum frequency of 200). The frequency threshold allows us to make sure that we have a high-quality gold vector to compare our learnt representation to. We then randomly sample 1000 sentences, manually checking the data to remove instances that are, in fact, not definitional. We split the data into 700 training and 300 test instances.

On this dataset, we simulate first-time exposure to the nonce word by changing the label of the gold standard vector in the background semantic space, and producing a new, randomly initialised vector for the nonce. So for instance, *insulin* becomes *insulin_gold*, and a new random embedding is added to the input matrix for *insulin*. This setup allows us to easily measure the similarity of the newly learnt vector, obtained from one definition, to the vector produced by exposure to the whole Wikipedia. To measure the relative performance of various setups, we calculate the Reciprocal Rank (RR) of the gold vector in the list of all nearest neighbours to the learnt representation. We average RRs over the number of instances in the dataset, thus obtaining a single MRR figure (Mean Reciprocal Rank).

The Chimera dataset Our second dataset is the 'Chimera' dataset of (Lazaridou et al., 2017).[3] This dataset was specifically constructed to simulate a nonce situation where a speaker encounters a word for the first time in naturally-occurring (and not necessarily informative) sentences. Each instance in the data is a nonce, associated with 2-6 sentences showing the word in context. The novel concept is created as a 'chimera', i.e. a mixture of two existing and somewhat related concepts (e.g., a buffalo crossed with an elephant). The sentences associated with the nonce are utterances containing one of the components of the chimera, randomly extracted from a large corpus.

The dataset was annotated by humans in terms of the similarity of the nonce to other, randomly selected concepts. Fig. 1 gives an example of a data point with 2 sentences of context, with the nonce capitalised (*VALTUOR*, a combination of *cucumber* and *celery*). The sentences are followed by the 'probes' of the trial, i.e. the concepts that the nonce must be compared to. Finally, human similarity responses are given for each probe with respect to the nonce. Each chimera was rated by an average of 143 subjects. In our experiments, we simply replace all occurrences of the original nonce with a slot (___) and learn a representation for that slot. For each setting (2, 4 and 6 sentences), we randomly split the 330 instances in the data into 220 for training and 110 for testing.

Following the authors of the dataset, we evaluate by calculating the correlation between system and human judgements. For each trial, we calculate Spearman correlation (ρ) between the similarities given by the system to each nonce-probe pair, and the human responses. The overall result is the average Spearman across all trials.

3 Baseline models

We test two state-of-the art systems: a) Word2Vec (W2V) in its Gensim[4] implementation, allowing for update of a prior semantic space; b) the additive model of Lazaridou et al. (2017), using a background space from W2V.

We note that both models allow for some sort of incrementality. W2V processes input one context at a time (or several, if mini-batches are implemented), performing gradient descent after each new input. The network's weights in the input, which correspond to the created word vectors, can be inspected at any time.[5] As for addition, it also affords the ability to stop and restart training at any time: a typical implementation of this behaviour can be found in distributional semantics models based on random indexing (see e.g. QasemiZadeh et al., 2017). This is in contrast with so-called 'count-based' models calculated by computing a frequency matrix over a fixed corpus, which is then globally modified through a transformation such as Pointwise Mutual Information.

Word2Vec We consider W2V's 'skip-gram' model, which learns word vectors by predicting the context words of a particular target. The W2V architecture includes several important parameters, which we briefly describe below.

In W2V, predicting a word implies the ability to distinguish it from so-called *negative samples*, i.e. other words which are *not* the observed item. The number of negative samples to be considered can be tuned. What counts as a context for a particular target depends on the *window size* around that target. W2V features random resizing of the window, which has been shown to increase the model's performance. Further, each sentence passed to the model undergoes *subsampling*, a random process by which some words are dropped out of the input as a function of their overall frequency. Finally, the *learning rate* α measures how quickly the system learns at each training iteration. Traditionally, α is set low (0.025 for Gensim) in order not to overshoot the system's error minimum.

Gensim has an update function which allows us to save a W2V model and continue learning from new data: this lets us simulate prior acquisition of a background vocabulary and new learning from a nonce's context. As background vocabulary, we use a semantic space trained on a Wikipedia snapshot of $1.6B$ words with Gensim's standard parameters (initial learning rate of 0.025, 5 negative samples, a window of ± 5 words, subsampling $1e^{-3}$, 5 epochs). We use the skip-gram model with a minimum word count of 50 and vector dimensionality 400. This results in a space with $259,376$ word vectors. We verify the quality of this space by calculating correlation with the similarity ratings in the MEN dataset (Bruni et al., 2014). We obtain $\rho = 0.75$, indicating an excellent fit with human judgements.

Additive model Lazaridou et al. (2017) use a simple additive model, which sums the vectors of the context words of the nonce, taking as context the entire sentence where the target occurs. Their model operates on multimodal vectors, built over both text and images. In the present work, however, we use the semantic space described above, built on Wikipedia text only. We do not normalise vectors before summing, as we found that the system's performance was better than with normalisation. We also discard function words when summing, using a stopword list. We found that this step affects results very positively.

The results for our state-of-the-art models are shown in the top sections of Tables 1 and 2. W2V is run with the standard Gensim parameters, under the skip-gram model. It is clear from the results that W2V is unable to learn nonces from definitions ($MRR = 0.00007$). The additive model, on the other hand, performs well: an MRR of 0.03686 means that the median rank of the true vector is 861, out of a challenging

[4] Available at https://github.com/RaRe-Technologies/gensim.

[5] Technically speaking, standard W2V is not fully incremental, as it requires a first pass through the corpus to compute a vocabulary, with associated frequencies. As we show in §5, it however allows for an incremental interpretation, given minor modifications.

$259,376$ neighbours (the size of the vocabulary). On the Chimeras dataset, W2V still performs well under the sum model – although the difference is not as marked and possibly indicates that this dataset is more difficult (which we would expect, as the sentences are not as informative as in the encyclopedia case).

4 Nonce2Vec

Our system, Nonce2Vec (N2V),[6] modifies W2V in the following ways.

Initialisation: since addition gives a good approximation of the nonce word, we initialise our vectors to the sum of all known words in the context sentences (see §3). Note that this is not strictly equivalent to the pure sum model, as subsampling takes care of frequent word deletion in this setup (as opposed to a stopword list). In practice, this means that the initialised vectors are of slightly lesser quality than the ones from the sum model.

Parameter choice: we experiment with higher learning rates coupled with larger window sizes. That is, the model should take the risk of a) overshooting a minimum error; b) greedily considering irrelevant contexts in order to increase its chance to learn anything. We mitigate these risks through *selective training* and appropriate *parameter decay* (see below).

Window resizing: we suppress the random window resizing step when learning the nonce. This is because we need as much data as possible and accordingly need a large window around the target. Resizing would make us run the risk of ending up with a small window of a few words only, which would be uninformative.

Subsampling: With the goal of keeping most of our tiny data, we adopt a subsampling rate that only discards extremely frequent words.

Selective training: we only train the nonce. That is, we only update the weights of the network for the target. This ensures that, despite the high selected learning rate, the previously learnt vectors, associated with the other words in the sentence, will not be radically shifted towards the meaning expressed in that particular sentence.

Whilst the above modifications are appropriate to deal with the first mention of a word, we must ask in what measure they still are applicable when the term is encountered again (see §1). With a view to cater for incrementality, we introduce a notion of **parameter decay** in the system. We hypothesise that the initial high-risk strategy, combining high learning rate and greedy processing of the data, should only be used in the very first training steps. Indeed, this strategy drastically moves the initialised vector to what the system assumes is the right neighbourhood of the semantic space. Once this positioning has taken place, the system should refine its guess rather than wildly moving in the space. We thus suggest that the learning rate itself, but also the subsampling value and window size should be returned to more conventional standards as soon as it is desirable. To achieve this, we apply some exponential decay to the learning rate of the nonce, proportional to the number of times the term has been seen: every time t that we train a pair containing the target word, we set α to $\alpha_0 e^{-\lambda t}$, where α_0 is our initial learning rate. We also decrease the window size and increase subsampling rate on a per-sentence basis (see §5).

	MRR	Median rank
W2V	0.00007	111012
Sum	0.03686	861
N2V	**0.04907**	**623**

Table 1: Results on definitional dataset

	L2 ρ	L4 ρ	L6 ρ
W2V	0.1459	0.2457	0.2498
Sum	**0.3376**	0.3624	**0.4080**
N2V	0.3320	**0.3668**	0.3890

Table 2: Results on chimera dataset

5 Experiments

We first tune N2V's initial parameters on the training part of the definitional dataset. We experiment with a range of values for the learning rate ($[0.5, 0.8, 1, 2, 5, 10, 20]$), window size ($[5, 10, 15, 20]$), the number of negative samples ($[3, 5, 10]$), the number of epochs ($[1, 5]$) and the subsampling rate ($[500, 1000, 10000]$). Here, given the size of the data, the minimum frequency for a word to be considered is 1. The best performance is obtained for a window of 15 words, 3 negative samples, a learning rate of 1, a subsampling rate of 10000, an exponential decay where $\lambda = \frac{1}{70}$, and one single epoch (that is, the system truly implements fast-mapping). When applied to

[6] Code available at `https://github.com/minimalparts/nonce2vec`.

the test set, N2V shows a dramatic improvement in performance over the simple sum model, reaching $MMR = 0.04907$ (median rank 623).

On the training set of the Chimeras, we further tune the per-sentence decrease in window size and increase in subsampling. For the window size, we experiment with a reduction of $[1...6]$ words on either side of the target, not going under a window of ± 3 words. Further, we adjust each word's subsampling rate by a factor in the range $[1.1, 1.2...1.9, 2.0]$. Our results confirm that indeed, an appropriate change in those parameters is required: keeping them constant results in decreasing performance as more sentences are introduced. On the training set, we obtain our best performance (averaged over the 2-, 4- and 6-sentences datasets) for a per-sentence window size decrease of 5 words on either side of the target, and adjusting subsampling by a factor of 1.9. Table 2 shows results on the three corresponding test sets using those parameters. Unfortunately, on this dataset, N2V does not improve on addition.

The difference in performance between the definitional and the Chimeras datasets may be explained in two ways. First, the chimera sentences were randomly selected and thus, are not necessarily hugely informative about the nature of the nonce. Second, the most informative sentences are not necessarily at the beginning of the fragment, so the system heightens its learning rate on the wrong data: the risk does not pay off. This suggests that a truly intelligent system should adjust its parameters in a non-monotonic way, to take into account the quality of the information it is processing. This point seems to be an important general requirement for any architecture that claims incrementality: our results indicate very strongly that a notion of *informativeness* must play a role in the learning decisions of the system. This conclusion is in line with work in other domains, e.g. interactive word learning using dialogue, where performance is linked to the ability of the system to measure its own confidence in particular pieces of knowledge and ask questions with a high information gain (Yu et al., 2016). It also meets with general considerations on language acquisition, which accounts for the ability of young children to learn from limited 'primary linguistic data' by restricting explanatory models to those that provide such efficiency (Clark and Lappin, 2010).

6 Conclusion

We have proposed Nonce2Vec, a Word2Vec-inspired architecture to learn new words from tiny data. It requires a high-risk strategy combining heightened learning rate and greedy processing of the context. The particularly good performance of the system on definitions makes us confident that it is possible to build a unique, unified algorithm for learning word meaning from any amount of data. However, the less impressive performance on naturally-occurring sentences indicates that an ideal system should modulate its learning as a function of the informativeness of a context sentence, that is, take risks 'at the right time'.

As pointed out in the introduction, Nonce2Vec is designed with a view to be an essential component of an incremental concept learning architecture. In order to validate our system as a suitable, generic solution for word learning, we will have to test it on various data sizes, from the type of low- to middle-frequency terms found in e.g. the Rare Words dataset (Luong et al., 2013), to highly frequent words. We would like to systematically evaluate, in particular, how fast the system can gain an understanding of a concept which is fully equivalent to a vector built from big data. We believe that both quality and speed of learning will be strongly influenced by the ability of the algorithm to detect what we called *informative* sentences. Our future work will thus investigate how to capture and measure informativeness.

Acknowledgments

Abstract

In this paper, we propose to learn word embeddings based on the recent fixed-size ordinally forgetting encoding (FOFE) method, which can almost uniquely encode any variable-length sequence into a fixed-size representation. We use FOFE to fully encode the left and right context of each word in a corpus to construct a novel word-context matrix, which is further weighted and factorized using truncated SVD to generate low-dimension word embedding vectors. We have evaluated this alternative method in encoding word-context statistics and show the new FOFE method has a notable effect on the resulting word embeddings. Experimental results on several popular word similarity tasks have demonstrated that the proposed method outperforms many recently popular neural prediction methods as well as the conventional SVD models that use canonical count based techniques to generate word context matrices.

1 Introduction

Low dimensional vectors as word representations are very popular in NLP tasks such as inferring semantic similarity and relatedness. Most of these representations are based on either matrix factorization or context sampling described by (Baroni et al., 2014) as count or predict models. The basis for both models is the distributional hypothesis (Harris, 1954), which states that words that appear in similar contexts have similar meaning. Traditional context representations have been obtained by capturing co-occurrences of words from a fixed-size window relative to the focus word. This representation however does not encompass the entirety of the context surrounding the focus word. Therefore, the distributional hypothesis is not being taken advantage of to the fullest extent. In this work, we seek to capture these contexts through the fixed-size ordinally forgetting encoding (FOFE) method, recently proposed in (Zhang et al., 2015b). In addition to just capturing word co-occurrences, we attempt to use the FOFE to encode the full contexts of each focus word, including the order information of the context sequences. We believe the full encoding of contexts can enhance the resulting word embedding vectors, derived by factoring the corresponding word-context matrix. As argued in (Zhang et al., 2015b), the FOFE method can almost uniquely encode discrete sequences of varying lengths into a fixed-size code, and this encoding method was used to address the challenges of a limited size window when using deep neural networks for language modeling. The resulting algorithm fulfills the needs of keeping long term dependency while being fast. The word order in a sequence is modeled by FOFE using an ordinally-forgetting mechanism which encodes each position of every word in the sequence.

In this paper, we elaborate how to use the FOFE to fully encode context information of each focus word in text corpora, and present a new method to construct the word-context matrix for word embedding, which may be weighted and factorized as in traditional vector space models (Turney and Pantel, 2010). Next, we report our experimental results on several popular word similarity tasks, which demonstrate that the proposed FOFE-based approach leads to significantly better performance in these tasks, comparing with the conventional vector space models as well as the popular neural prediction methods, such as *word2vec*, *GloVe* and more recent *Swivel*. Finally, this paper will conclude with the analysis and prospects of com-

bining this approach with other methods.

2 Related Work

There has been some debate as to what the optimal length of a text should be for measuring word similarity. Word occurrences from a fixed context window of words can be used to represent a context (Lund and Burgess, 1996). The word co-occurrence frequencies are based on fixed windows spanning in both directions from the focus word. This is then used to create a word-context matrix from which row vectors can be used to measure word similarity. A weighting step is usually applied to highlight words with close association in the co-occurrence matrix, and the truncated SVD is used to factorize the weighted matrix to generate low-dimension word vectors. Recently, (Mikolov et al., 2013a) has introduced an alternative way to generate word embeddings using the skipgram model trained with stochastic gradient descent and negative sampling, named as SGNS. SGNS tries to maximize the dot product between $w \cdot c$ where both a word w and a context c are obtained from observed word-context pairs, and meanwhile it also tries to minimize the dot product between $w \cdot c'$ where c' is a negative sample representing some contexts that are not observed in the corpus. More recently, (Levy and Goldberg, 2014) has showed that the objective function of SGNS is essentially seeking to minimize the difference between the models estimate and the log of co-occurrence count. Their finding has shown that the optimal solution is a weighted factorization of a pointwise mutual information matrix shifted by the log of the number of negative samples.

SGNS and GloVe (Pennington et al., 2014) select a fixed window of usually 5 words or less around a focus word to encode its context and the word order information within the window is completely ignored. Other attempts to fully capture the contexts have been successful with the use of recurrent neural networks (RNNs) but these methods are much more expensive to run over large corpora when comparing with the proposed FOFE method in this paper. Some previous approaches to encode order information, such as such as BEAGLE (Jones and Mewhort, 2007) and Random Permutations (Sahlgren et al., 2008), typically require the use of expensive operations such as convolution and permutation to process all n-grams within a context window to memorize order information for a given word. On the contrary, the FOFE methods only use a simple recursion to process a sentence once to memorize both context and order information for all words in the sentence.

3 FOFE based Embedding

To capture the full essence of the distributional hypothesis, we need to fully encode the left and right context of each focus word in the text, and further take into accounts that words closer to the focus word should play a bigger role in representing the context relevant to the focus word than other words locating much farther away. Traditional co-occurrence word-context matrixes fail to address these concerns of context representation.

In this work, we propose to make use of the fixed-size ordinally-forgetting encoding (FOFE) method, proposed in (Zhang et al., 2015b) as a unique encoding method for any variable-length sequence of discrete words.

Given a vocabulary of size K, FOFE uses 1-of-K one-hot representation to represent each word. To encode any variable-length sequence of words, FOFE generates the code using a simple recursive formula from the first word (w_1) to the last one (w_T) of the sequence: (assume $z_0 = 0$)

$$z_t = \alpha \cdot z_{t-1} + e_t \; (1 \leq t \leq T) \qquad (1)$$

where z_t denotes the FOFE code for the partial sequence up to word w_t, α is a constant forgetting factor, and e_t denotes the one-hot vector representation of word w_t. In this case, the code z_T may be viewed as a fixed-size representation of any sequence of $\{w_1, w_2, \cdots, w_T\}$. For example, assume we have three symbols in vocabulary, e.g., *A*, *B*, *C*, whose 1-of-K codes are $[1, 0, 0]$, $[0, 1, 0]$ and $[0, 0, 1]$ respectively. When calculating from left to right, the FOFE code for the sequence $\{ABC\}$ is $[\alpha^2, \alpha, 1]$, and that of $\{ABCBC\}$ is $[\alpha^4, \alpha + \alpha^3, 1 + \alpha^2]$.

The uniqueness of the FOFE code is made evident if the original sequence can be unequivocally recovered from the given FOFE code. According to (Zhang et al., 2015b), FOFE codes have some nice theoretical properties to ensure the uniqueness, as exemplified by the following two theorems [1]:

Theorem 1 *If the forgetting factor* α *satisfies* $0 < \alpha \leq 0.5$, FOFE *is unique for any* K *and* T.

[1] See (Zhang et al., 2015a) for the proof of these two theorems.

Theorem 2 *For* $0.5 < \alpha < 1$*, given any finite values of* K *and* T*,* FOFE *is almost unique everywhere for* $\alpha \in (0.5, 1.0)$*, except only a finite set of countable choices of* α*.*

Finally, for alpha values less than or equal to 0.5 and greater than 0, the FOFE is unique for any sequence. For alpha values greater than 0.5, the chance of collision is extremely low and the FOFE is unique in almost all cases. Too find more about the theoretical correctness of FOFE, please refer to (Zhang et al., 2015b). In other words, the FOFE codes can almost uniquely encode any sequences, serving as a fixed-size but theoretically lossless representation for any variable-length sequences.

In this work, we propose to use FOFE to encode the full context where each focus word appears in text. As shown in Figure 1, the left context of a focus word, i.e., *bank*, may be viewed as a sequence and encoded as a FOFE code L from the left to right while its right context is encoded as another FOFE code R from right to left. When a proper forgetter factor α is chosen, the two FOFE codes can almost fully represent the context of the focus word. If the focus word appears multiple times in text, a pair of FOFE codes $[L, R]$ is generated for each occurrence. Next, a mean vector is calculated for each word from all of its occurrences in text. Finally, as shown in Figure 1, we may line up these mean vectors (one word per row) to form a new word-context matrix, called the FOFE matrix here.

4 PMI-based Weighting and SVD-based Matrix Factorization

We further weight the above FOFE matrix using the standard positive pointwise mutual information (PMI) (Church and Hanks, 1990) which has been shown to be of benefit for regular word-context matrices (Pantel and Lin, 2002). PMI is used as a measure of association between a word and a context. PMI tries to compute the association probabilities based on co-occurrence frequencies. Positive pointwise mutual information is a commonly adopted approach where all negative values in the PMI matrix are replaced with zero. The PMI-based weighting function is critical here since it helps to highlight the more surprising events in original word-context matrix.

There are significant benefits in working with low-dimensional dense vectors, as noted by (Deerwester et al., 1990) with the use of truncated singular value decomposition (SVD). Here, we also use truncated SVD to factorize the above weighted FOFE matrix as the product of three dense matrices U, Σ, V^T, where U and V^T have orthonormal columns and Σ is a diagonal matrix consisting of singular values. If we select Σ to be of rank d, its diagonal values represent the top d singular values, and U_d can be used to represent all word embeddings with d dimensions where each row represents a word vector.

5 Experiments

We conducted experiments on several popular word similarity data sets and compare our FOFE method with other existing word embedding models in these tasks. In this work, we opt to use five data sets: *WordSim353* (Finkelstein et al., 2001), *MEN* (Bruni et al., 2012), *Mechanical Turk* (Radinsky et al., 2011), *Rare Words* (Luong et al., 2013) and *SimLex-999* (Hill et al., 2015). The word similarity performance is evaluated based on the Spearman rank correlation coefficient obtained by comparing cosine distance between word vectors and human assigned similarity scores.

For our training data, we use the standard *enwiki9* corpus which contains 130 million words. The pre-processing stage includes discarding extremely long sentences, tokenizing, lowercasing and splitting each sentence as a context. Our vocabulary size is chosen to be 80,000 for the most frequent words in the corpus. All words not in the vocabulary are replaced with the token <*unk*>. In this work, we use a python-based library, called *scipy* [2], to perform truncated SVD to factorize all word-context matrices.

5.1 Experimental Setup

Our first baseline is the conventional vector space model (VSM) (Turney and Pantel, 2010), relying on the PMI-weighted co-occurrence matrix with dimensionality reduction performed using truncated SVD. The dimension of word vectors is chosen to be 300 and this number is kept the same for all models examined in this paper. Our main goal is to outperform VSM as the model proposed in this paper also uses SVD based matrix factorization. This allows for appropriate comparisons between the different word encoding methods.

Figure 1: i) encoding left and right contexts of each focus word with FOFE and ii) forming the FOFE word-context matrix.

For the purpose of completeness, the other non-SVD based embedding models, mainly the more recent neural prediction methods, are also compared in our experiments. As a result, we build the second baseline using the skip-gram model provided by the `word2vec` software package (Mikolov et al., 2013a), denoted as SGNS. The word embeddings are generated using the recommended hyper-parameters from (Levy et al., 2015). Their findings show a larger number of negative samples is preferable and increments on the window size have minimal improvements on word similarity tasks. In our experiments the number of negative samples is set to 5 and the window size is set to 5. In addition, we set the subsampling rate to 10^{-4} and run 3 iterations for training. In adition to SGNS, we also obtained results for CBOW, GloVe (Pennington et al., 2014) and Swivel (Shazeer et al., 2016) models using similar recommended settings. While the window size has a fixed limit in the baseline models, our model does not have a window size parameter as the entire sentence is fully captured as well as distinctions between left and right contexts when generating the FOFE codes. The impact of closer context words is further highlighted by the use of the forgetting factor which is unique to the FOFE based word embedding.

Finally, we use the FOFE codes to construct the word-context matrix and generate word embedding as described in sections 3 and 4. Throughout our experiments, we have chosen to use a constant forgetting factor $\alpha = 0.7$. There is no significant difference in word similarity scores after experimenting with different α values between $[0.6, 0.9]$ when generating FOFE codes.

We have applied the same hyperparameters to both VSM and FOFE methods and fine-tune them based on the recommended settings provided in (Levy et al., 2015). Although it has been previously reported that context distribution smoothing (Mikolov et al., 2013b) can provide a net positive effect, it did not yield significant gains in our experiments. On the other hand, the eigenvalue

Table 1: The best achieved performance of various word embedding models on all five examined word similarity tasks.

Method	WordSim353	MEN	Mech Turk	Rare Words	SimLex-999
VSM+SVD	0.7109	0.7130	0.6258	0.4813	**0.3866**
CBOW	0.6763	0.6768	0.6621	0.4280	0.3549
GloVe	0.5873	0.6350	0.5831	0.3934	0.2883
SGNS	0.7028	0.6689	0.6187	0.4360	0.3709
Swivel	0.7303	0.7246	**0.7024**	0.4430	0.3323
FOFE+SVD	**0.7580**	**0.7637**	0.6525	**0.5002**	**0.3866**

weighting parameter tuning (Caron, 2001) proved to be incredibly effective for some datasets but ineffectual in others. The net benefit however is palpable and we include it for both VSM and FOFE methods.

5.2 Results and Discussion

The best results of all word embedding models are summarized in Table 1 for all five examined data sets, which include the the traditional count based VSM with SVD alongside SGNS using `word2vec` and our proposed FOFE word embeddings. The most discernible piece of information from the table is that the FOFE method significantly outperforms the traditional count based VSM method on most of these word similarity tasks. The results in Table 1 show that substantial gains are obtained by FOFE in *WordSim353*, *MEN* and *Rare Words* data sets. The *MEN* dataset shows a 7% relative improvement over the conventional VSM.

Among all of these five data sets, the proposed FOFE word embedding significantly outperforms VSM in four tasks while yielding similar performance as VSM in the last data set, i.e. *SimLex-999*. FOFE also outperforms all the other models except Swivel in the *Mech Turk* dataset. It is important to note that this paper does not state that SVD is obligatory to obtain the best model. The FOFE method can be complemented with other models such as Swivel in place of count based encoding methods. It is also theoretically guaranteed that the original sentence is perfectly recoverable from this FOFE code. This theoretical guarantee is clearly missing in previous methods to encode word order information, such as both BEAGLE and Random Permutations. It is evident that overall the FOFE encoding method does achieve significant gains in performance in these word similarity tests over the traditional VSM method that applies the same factorization method. This is substantial as (Levy et al., 2015) demonstrates that larger window sizes when using SVD does not payoff and the optimal context window is 2. We establish that we can indeed encode more information into our embedding with the FOFE codes.

In summary, our experimental results show great promise in using the FOFE encoding to represent word contexts for traditional matrix factorization methods. As for future work, the FOFE encoding method may be combined with other popular algorithms, such as Swivel, to replace the co-occurrence statistics based on a fixed window size.

6 Conclusion

The ability to capture the full context without restriction can play a crucial factor in generating superior word embeddings that excel in NLP tasks. The fixed-size ordinally forgetting encoding (FOFE) has the ability to seize large contexts while discriminating contexts that are farther away as being less significant. Conventional embeddings are derived from ambiguous co-occurrence statistics that fail to adequately discriminate contexts words even within the fixed-size window. The FOFE encoding technique trumps other approaches in its ability to procure the state of the art results in several word similarity tasks when combined with prominent factorization practices.

Abstract

Many Natural Language Processing (NLP) models rely on distributed vector representations of words. Because the process of training word vectors can require large amounts of data and computation, NLP researchers and practitioners often utilize pre-trained embeddings downloaded from the Web. However, finding the best embeddings for a given task is difficult, and can be computationally prohibitive. We present a framework, called VecShare, that makes it easy to share and retrieve word embeddings on the Web. The framework leverages a public data-sharing infrastructure to host embedding sets, and provides automated mechanisms for retrieving the embeddings most similar to a given corpus. We perform an experimental evaluation of VecShare's similarity strategies, and show that they are effective at efficiently retrieving embeddings that boost accuracy in a document classification task. Finally, we provide an open-source Python library for using the VecShare framework.[1]

1 Introduction

Word embeddings capture syntactic and semantic properties of words, and are a key component of many modern NLP models (Turian et al., 2010). However, high-quality embeddings can be expensive to train. As a result, rather than training their own embeddings, NLP researchers and practitioners often download pre-trained embeddings from the Web, e.g. (Limsopatham and Collier, 2016; Cheng et al., 2016).

However, existing methods for sharing embeddings on the Web are suboptimal. Current practice primarily consists of contributors posting embedding sets to their own Web sites. No central embedding repository exists, and it is difficult for users to know which embedding sets are available. Furthermore, determining the utility of an embedding set for a particular NLP task entails significant time and computational costs, as users must manually download and evaluate multiple complete embedding sets. Methods exist for automatically scoring an embedding set, but these are limited to specific tasks and lack integration with existing code bases (Faruqui and Dyer, 2014).

Our goal in this paper is to introduce a framework that makes sharing word embeddings easier for NLP researchers and practitioners. It should be simple and fast to post, browse, and retrieve embeddings from a public data store. Additionally, integration with existing NLP codebases should be more seamless: software libraries should automatically identify and download the particular embeddings that are likely to be relevant to a user's corpus.

This paper presents VecShare, a framework for sharing word embeddings. As its data store, it uses an existing public data-sharing platform, which provides searching and browsing capability. To solve the critical challenge of helping users quickly find relevant embeddings, we introduce embedding *indexers*. The indexers compute and share compact representations, called *signatures*, for each embedding set. Users employ a software library that downloads the signatures and compares them against the user's corpus. Using the signatures, the library efficiently evaluates the utility of each shared embedding set and determines which sets are most likely to be relevant. The library can then automatically download the relevant embeddings and make them available

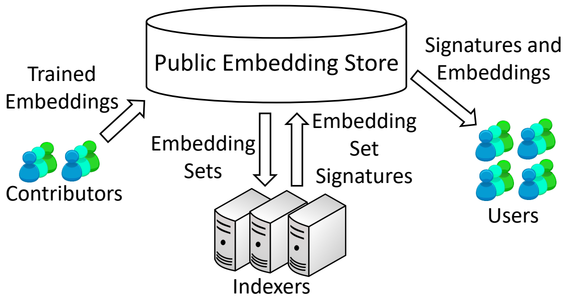

Figure 1: The VecShare Framework.

within the user's code. Finally, VecShare is an open source framework: new embeddings, indexers, and signature methods can be independently added at any time.

We perform experiments evaluating different signature methods in selecting embeddings for document classification tasks, and demonstrate that an ensemble signature based on simple features (e.g. vocabulary overlap with the user's corpus, or similarities between a sample of embedding pairs) can select helpful embeddings. We release a Python library for NLP researchers and practitioners that can query the embedding library, and automatically select and download relevant embeddings for a given corpus.

2 The VecShare Framework

The VecShare framework is illustrated in Figure 1. Contributors upload embedding sets to a *Public Embedding Store*, hosted on a public data-sharing platform. *Indexers* periodically poll the embedding store, detecting and indexing newly uploaded embedding sets. For each embedding set, indexers store a *signature* that compactly represents the content of the embedding set. The indexer uses these signatures to return relevant embedding sets to users. A *user* can then retrieve embeddings for their particular corpus from the data store, using a software library built for this purpose.

The current VecShare implementation uses the public data sharing website data.world as its embedding store.[2] We chose data.world for its ease of use and robustness, but any publicly-available data share that allows search by tags and programmatic access is sufficient to house VecShare. Below, we describe the details of the framework.

2.1 Contributors

A contributor who has computed a set of word embeddings adds the embeddings to VecShare by uploading the data to the share, following a simple standard format with $n + 1$ fields where the first field is a word, and the remaining fields give the n-dimensional embedding of the word. The contributor tags the data set with a designated tag so that indexers can automatically identify that the data set is an indexable word embedding set. For embedding sets to be applicable to certain kinds of signatures, contributors can also elect to upload additional metadata with their embeddings (in our initial implementation, metadata includes a frequency ranking of terms in the corpus, and the total number of tokens used to construct the embeddings).

2.2 Indexers and Signatures

Indexers periodically poll the embedding store, looking for new embedding sets uploaded by contributors. For each embedding set, the indexer computes and stores a signature designed to capture characteristics of the embeddings. To estimate the relevance of each embedding set for the user's task, these signatures are later compared to corresponding signatures created from the user's corpus. Thus, each signature method has an associated *similarity measure*, which takes in a pair of signatures (one from a VecShare embedding set, and the other from the user's corpus) and outputs a numeric similarity score for the pair.

We explore two primary signature methods in this paper. The first, *VocabRk*, consists of (up to) the T_v most frequent words in the embedding corpus, excluding a set of stop words. The similarity method is the negative average rank of the signature words within the user's frequency-ordered vocabulary. Words not in the user's corpus are assigned a rank of T. Thus, the most similar embedding set under the *VocabRk* signature is thus the one with the lowest average rank.

The *VocabRk* signature method relies only on vocabulary overlap, and entirely ignores the embeddings themselves. We also experiment with a second signature method that does utilize the embeddings. The *SimCorr* signature for a set of embeddings E consists of the embeddings for the T_s most frequent words in E's corpus (again excluding stop words). To estimate the similarity between the user's corpus C and the embeddings E,

[2] http://data.world/

the *SimCorr* method first computes a set of embeddings on the user's corpus. For all words found in both E's signature and in the user's corpus, *SimCorr* computes all pairwise cosine similarities between pairs of E embeddings, and pairs of C embeddings. The Pearson correlation coefficient between the E-based cosine similarities and the C-based ones is taken as the *SimCorr* similarity measure. Thus, two embedding sets that estimate similarity of terms in a similar manner will be deemed similar according the *SimCorr* measure, even if the vector values of the embeddings differ substantially between the two sets.

The indexers make their signatures available to users by simply sharing a signature data set on the public data store, which is read by the VecShare software library. Like the other components of VecShare, the indexers of the framework are extensible – new indexers, signature and similarity measures can be created at any time.

2.3 Libraries

Users access the VecShare framework using a code library. Embeddings can be requested by name if the user desires a particular embedding (e.g. "300 dimensional Google News word2vec embeddings"), or the user can query an indexer to find embedding sets most likely to be useful for the user's task. Importantly, the software library performs embedding selection locally on the user's machine, using signature similarity methods described previously. The user's corpus does not need to be uploaded or shared.

Once the target embedding set has been identified, the library downloads the target embeddings for the particular words in the user's vocabulary. Thus, if the user's vocabulary is much smaller than that of the embedding set, this download can be much more compact than the full embedding set.

A contribution of this paper is the release of a Python library for the framework, which implements the *VocabRk* similarity computation. With this library, leveraging the framework to select and retrieve the top-ranked embeddings for a given corpus requires just one line of code.

3 Experiments

We now evaluate the effectiveness of the signature methods described in the previous section at identifying high-quality embedding sets for a given corpus, for the task of text classification. We also quantify the improvement in efficiency when using VecShare rather than following the current practice of downloading and testing multiple embedding sets.

In our experiments, we set the parameters $T_v = 5,000$ and $T_s = 1,000$, and we discard the top 100 most frequent words as stopwords. When training embeddings on the user's corpus, we use word2vec.

3.1 Experimental Methodology

We perform experiments in two settings: first with *large-corpus embeddings*, where we use word2vec and GloVe embedding sets trained on billions of tokens. The large-corpus embeddings are representative of state-of-the-art models, but are trained over very broad-topic corpora (billions of tokens of newswire, Web or social media text). To better measure whether VecShare can harness more specific, targeted embedding sets, we also evaluate over *small-corpus* embeddings.

For the large-corpus embeddings, we utilize three sets of GloVe embeddings (Pennington et al., 2014): **wik+**, 100-dimensional embeddings trained on six billion tokens of Wikipedia and the Gigaword corpus; **web**, 300-dimensional embeddings trained on 42 billion tokens of the Common Crawl Web dataset; and **twtr**, 100-dimensional embeddings trained on 27 billion tokens of Twitter posts. We also utilize **gnws**, 300-dimensional word2vec embeddings trained on three billion tokens of Google News data.[3]

For the small corpus embeddings, we created a topically diverse collection of subsets of the New York Times corpus (Sandhaus, 2008), across seven categories (agriculture, arts, books, economics, government, movies, and weather). We then trained word2vec embeddings on each subset, to create seven distinct similarly-sized, small corpus embedding sets.

For our experiments, we utilize the embeddings as features for document classification within a convolutional neural network (Chollet, 2017). We evaluate on four document classification tasks: Reuters-21578 newswire topic classification (Lewis, 1997), subjectivity classification (Pang and Lee, 2004), IMDB movie review classification (Maas et al., 2011), and the 20news classification task.[4]

Table 2: Experimental results using small-corpus embeddings. The *VocabRk* and *SimCorr* methods outperform the baselines, and the *All* method performs best in terms of both correlation ρ and text classification accuracy.

In addition to the *VocabRk* and *SimCorr* methods described in the previous section, we also evaluate against two simple baselines: *Random*, which selects an embedding set at random, and *MaxTkn*, which adopts a "bigger is better" strategy, always selecting the embedding set trained over the largest text corpus.

Finally, as discussed below our experimental results reveal that the different signature methods have distinct strengths. Thus, we also evaluate *All*, a simple ensemble of the *VocabRk, SimCorr*, and *MaxTkn* methods. *All* simply takes an even average of the rankings output by its three constituent signature methods. The *All* method selects the single embedding set with the lowest average ranking, breaking ties in favor of the *VocabRk* method.

3.2 Results

Our results are shown in Tables 1 and 2. For each classification task and each method, "Sel." indicates the embedding set that the method selects (that is, the one the method ranks most similar to the text classification data set). We report two measures of the quality of a signature method: ρ, the Pearson correlation between the similarity scores assigned by the method and the set's accuracy on the classification task; and "Acc.," the accuracy of the embeddings selected by the method.

The results show that for the small-corpus embeddings, the *VocabRk* and *SimCorr* signature methods perform well, beating the random baseline overall. By contrast, for the large-corpus embeddings, the *MaxTkn* method performs the best of the individual methods (primarily due to its strong performance on the idiosyncratic 20news data set). The *All* ensemble method achieves performance nearly as high as the best possible embedding selection (represented as the *Oracle* method in the tables).

An alternative to using pre-trained embeddings is to train embeddings on the evaluation corpus itself. We found that this approach achieved an average accuracy of 0.746 across our four data sets, lower than our results using the *All* method. Utilizing the pre-trained embeddings, especially those computed over large corpora, provides a significant boost in text classification accuracy.

3.3 Efficiency Experiment

We also evaluated the relative gain in time and space efficiency that VecShare provides over the current practice of manually evaluating each embedding set and selecting the embedding that performs best. The efficiency experiment was performed on a single machine with a 2.3 GHz quad-core CPU and 8GB of main memory, using a test framework containing 11 embedding sets.

Embedding selection was performed using both the *VocabRk* signature method on VecShare and the conventional method of selecting embeddings, which trains models for each embedding set and then evaluates those models on the test corpus. The conventional approach required an average of 177 minutes to train, evaluate, and select an embedding set for each test corpus. Whereas, the *VocabRk* signature method on the VecShare framework required an average of 38 seconds to select an embedding for each test corpus, an average speedup of 280x. Additionally, VecShare substantially reduces space cost: the total size of the signatures in the experiments is 4-5 orders of magnitude smaller than the full embedding sets.

4 Conclusions and Future Work

We presented VecShare, a framework for sharing word vector representations. The VecShare framework uses signatures to help researchers and practitioners quickly identify helpful embeddings for their task. We released a Python library that allows practitioners to access the framework. We also performed experiments quantifying the accuracy and efficiency of VecShare's embedding selection approach on text classification. Further experiments on additional data sets and NLP tasks are necessary.

In future work, we wish to explore embedding signatures that leverage richer knowledge of the practitioner's corpus and task. Finally, we hope to extend VecShare's embedding selection methods to consider syntheses of multiple distinct embedding sets, tailored to the practitioner's task and corpus.

Word Re-Embedding via Manifold Dimensionality Retention

Souleiman Hasan and **Edward Curry**

National University of Ireland, Galway
{souleiman.hasan, edward.curry}@lero.ie

Abstract

Word embeddings seek to recover a Euclidean metric space by mapping words into vectors, starting from words co-occurrences in a corpus. Word embeddings may underestimate the similarity between nearby words, and overestimate it between distant words in the Euclidean metric space. In this paper, we re-embed pre-trained word embeddings with a stage of manifold learning which retains dimensionality. We show that this approach is theoretically founded in the metric recovery paradigm, and empirically show that it can improve on state-of-the-art embeddings in word similarity tasks $0.5 - 5.0\%$ points depending on the original space.

1 Introduction

Concepts have been hypothesized in the cognitive psychometric literature as points in a Euclidean metric space, with empirical support from human judgement experiments (Rumelhart and Abrahamson, 1973; Sternberg and Gardner, 1983). Word embeddings, such as GloVe (Pennington et al., 2014a) and Word2Vec (Mikolov et al., 2013), harvest observed features of the latent Euclidean space such as words co-occurrence counts in a corpus and turn words into dense vectors of a few hundred dimensions. Word embeddings have proved useful in downstream NLP tasks such as Part of Speech Tagging (Collobert, 2011), Named Entity Recognition (Turian et al., 2010), and Machine Translation (Devlin et al., 2014). However, the potential of word embeddings and further improvements remain a research question.

When comparing word pairs similarities obtained from word embeddings, to word pairs similarities obtained from human judgement, it is observed that word embeddings slightly underestimate the similarity between similar words, and overestimate the similarity between distant words. For example, in the WS353 (Finkelstein et al., 2001) word similarity ground truth:

$$\begin{aligned} sim(\text{“}shore\text{”}, \text{“}woodland\text{”}) &= 3.08 \\ < sim(\text{“}physics\text{”}, \text{“}proton\text{”}) &= 8.12 \end{aligned}$$

However, the use of GloVe 42B 300d embedding with cosine similarity (see Section 4) yields the opposite order:

$$\begin{aligned} sim(\text{“}shore\text{”}, \text{“}woodland\text{”}) &= 0.36 \\ > sim(\text{“}physics\text{”}, \text{“}proton\text{”}) &= 0.33 \end{aligned}$$

Re-embedding the space using a manifold learning stage can rectify this. Manifold learning works by estimating the distance between nearby words using direct similarity assignment in a local neighbourhood, while distance between faraway words is approximated by multiple neighbourhoods based on the manifold shape. This observation forms the basis for the rest of this paper.

For instance, using Locally Linear Embedding (LLE) (Roweis and Saul, 2000) on top of GloVe, as described in this paper, can recover the right pairs order yielding:

$$\begin{aligned} sim(\text{“}shore\text{”}, \text{“}woodland\text{”}) &= 0.08 \\ < sim(\text{“}physics\text{”}, \text{“}proton\text{”}) &= 0.25 \end{aligned}$$

Hashimoto et al. (Hashimoto et al., 2016) put word embeddings under a paradigm which seeks to recover the underlying Euclidean metric semantic space. In this paradigm, word embeddings land into a space where a Euclidean metric can be used. They show that co-occurrence counts are the results of random walk sequences in the metric space, corresponding to sentences in a corpus.

Hashimoto et al. link this to manifold learning which also seeks to recover a Euclidean space

but starting from local neighbourhoods of objects, such as images or words. Global distances are built by adding up small local neighbourhoods. The authors show that word embedding algorithms can be used to solve manifold learning by generating random walks, aka sentences, on the manifold neighbourhood graph, and then embedding them.

In this work we follow a methodology which adheres to this paradigm and adopt a different angle, as per Figure 1. We start from an off-the-shelf word embedding, then we take a sample of it and feed it into manifold learning which leverages local word neighbourhoods formed in the original embedding space, learns the manifold, and embeds it into a new Euclidean space. The resulting re-embedding space is a recovery of a Euclidean metric space that is empirically better than the original word embedding when tested on word similarity tasks.

These results show that word embeddings can be improved in estimating the latent metric. Such an approach can provide new opportunities to improve our understanding of embedding methods, their properties, and limits. It also allows us to reuse and re-embed off-the-shelf pre-trained embeddings, saving time on training, while aiming at improved results in downstream NLP tasks, and other data processing tasks (Hasan and Curry, 2014; Hasan, 2017; Freitas and Curry, 2014).

Section 2 discusses the related literature to this work. Section 3 details the proposed approach. Sections 4 and 5 discuss the experiments and results. The paper concludes with Section 6.

2 Related Work

The relationship to related work is depicted in Figure 1. Word embeddings are unsupervised methods based on word co-occurrence counts which can be directly observed in a corpus. Mikolov et al. presents a neural network-based architecture which learns a word representation by learning to predict its context words (Mikolov et al., 2013). Pennington et al. proposed GloVe, which directly leverages nonzero word-word co-occurrences in a global manner (Pennington et al., 2014a).

The idea of embedding objects from a high dimensional space, e.g. images, into a smaller dimensional space constitute the area of manifold learning. For instance, Roweis and Saul present the Locally Linear Embedding (LLE) algorithm and show that pixel-based distance between images is meaningful only at a local neighbourhood scale (Roweis and Saul, 2000). Reconstructions can capture the underlying manifold of the data, and can embed the high dimensional objects, into a lower dimensional Euclidean space while preserving neighbourhoods. Other methods exist such as Isomap (Balasubramanian and Schwartz, 2002) and t-SNE (Maaten and Hinton, 2008).

Hashimoto et al. show that word embeddings and manifold learning are both methods to recover a Euclidean metric using co-occurrence counts and high dimensional features respectively (Hashimoto et al., 2016). They show that word embeddings can be used to solve manifold learning when starting from a high dimensional space. In this paper we start from a trained word embedding space, and learn a manifold from it to improve results. We do not use manifold learning to reduce dimensionality, but to transform between two equally-dimensional coordinate systems.

Other related work comes from word embedding post-processing. Labutov and Lipson use a supervised model to re-embed words for a target task (Labutov and Lipson, 2013). Lee et al. filter out abnormal dimensions from a GloVe space according to their histograms and show a slight improvement in performance (Lee et al., 2016). Mu at al. perform similar post-processing through the removal of the mean vector and vectors re-projection (Mu et al., 2017). We see manifold learning as a generic, unsupervised, nonlinear, and theoretically-founded model for post-processing that can cover linear post-processing such as PCA and normalization of vectors.

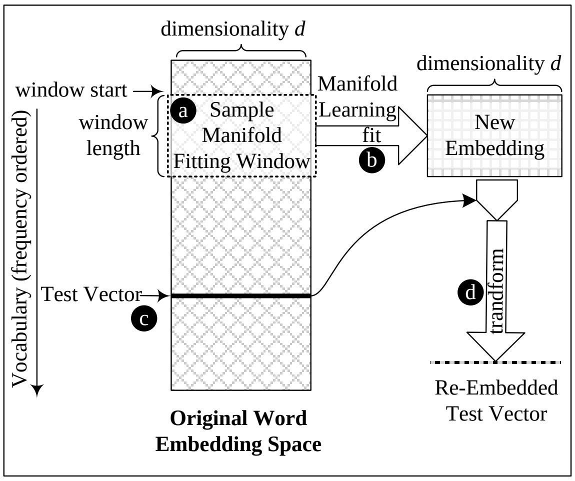

Figure 2: Re-Embedding via Manifold Learning.

3 Approach

Figure 2 illustrates our re-embedding method. We start from an original embedding space with vectors ordered by words frequencies. In step (a), we pick a sample window of vectors from this space to be used for learning the manifold. In step (b), we fit the manifold learning model to the selected sample using an algorithm such as LLE. We retain the dimensionality at this stage. In step (c), an arbitrary test vector can be selected from the original space. In step (d), the resulting fitted model serves as a transformation which can be used to transform the test vector into a vector which lives in the new re-embedding space, and used in downstream tasks.

In step (a), a sample subset of the words is used based on word frequency rank. The rational is that word embedding attempts to recover a metric space and frequent words co-occurrences can represent a better sampling of the underlying space due to their frequent usage, rather than being handled equally with other points, thus can better recover the manifold shape. Experimenting with subsets from all the vocabulary or non-frequent words, may yield no improvement. Additionally, manifold learning on all points is computationally expensive. The sampling used here follows a sliding sample window to study the effect of its start position and size. Various ways to choose a sample, e.g. random sampling, can be followed, but word frequency should remain a factor in where the sample is taken from.

In step (b), the sample is used to fit a manifold. For LLE (Saul and Roweis, 2000), that is done through learning the weights which can reconstruct each word vector from the sample X through its K-nearest neighbours in the sample, by minimizing the error function:

$$\mathcal{E}(W) = \sum_i \left| \vec{X}_i - \sum_j W_{ij}\vec{X}_j \right|^2 \qquad (1)$$

such that $W_{ij} = 0$ if $\vec{X}_j$ is not in the K-nearest neighbours of $\vec{X}_i$. The weights are then used to construct a new embedding Y of the sample X via a neighbourhood-preserving mapping through minimizing the cost function:

$$\Phi(Y) = \sum_i \left| \vec{Y}_i - \sum_j W_{ij}\vec{Y}_j \right|^2 \qquad (2)$$

In steps (c) and (d), to transform an arbitrary vector $\vec{x}$, the weights are first constructed from only the K-nearest neighbours of $\vec{x}$ in the sample X, by minimizing the function:

$$\mathcal{E}(W^x) = \left| \vec{x} - \sum_j W^x_j \vec{X}_j \right|^2 \qquad (3)$$

such that $W^x_j = 0$ if $\vec{X}_j$ is not in the K-nearest neighbours of $\vec{x}$. The weights are then used along with the new embedding Y to transform $\vec{x}$ into $\vec{y}$ which lives in the new embedding space through the equation:

$$\vec{y} = \sum_j W^x_j \vec{Y}_j \qquad (4)$$

where $\vec{Y}_j$ is the transform, from step (b), of $\vec{X}_j$ that is in the K-nearest neighbours of $\vec{x}$.

4 Experiments

Original Embedding Spaces. The original word embeddings used are pre-trained GloVe models: Wikipedia 2014 + Gigaword 5 (6B tokens, 400K vocab, 50d, 100d, 200d, & 300d vectors), and Common Crawl (42B tokens, 1.9M vocab, 300d vectors) (Pennington et al., 2014b). The vectors are ordered by the frequency of their corresponding words, so the vector representing the word 'the' comes first in the space.

Task. We use similarity tasks WS353 (Finkelstein et al., 2001) and RG65 (Rubenstein and Goodenough, 1965).

Space	Task	GloVe	Re-Embedding
6B 50d	WS353	**61.2**	56.6
6B 50d	RG65	**60.2**	53.0
6B 100d	WS353	**64.5**	64.3
6B 100d	RG65	65.3	**67.3**
6B 200d	WS353	68.5	**69.7**
6B 200d	RG65	75.5	**76.0**
6B 300d	WS353	65.8	**70.3**
6B 300d	RG65	75.5	**80.5**
42B 300d	WS353	75.2	**78.4**
42B 300d	RG65	80.0	**83.4**

Table 1: Average performance on similarity tasks. (Window start $\in [5000, 15000]$, Number of LLE local neighbours =1000, Window length = 1001, Manifold dimensionality = Space dimensionality.)

Baseline. We use the performance by the original word embeddings on the tasks. For each original space, we normalize features using their minimum and maximum values to $[-1, +1]$, and then normalize vectors to unit norms. For each pair of words in the similarity task, we get the normalized vectors and measure the cosine similarity. We finally compute the Spearman Rank Correlation with human judgements.

Approach. For a given original embedding, we normalize vectors to unit norms, then we conduct Manifold (Mfd) Re-Embedding using LLE as explained in Section 3. For each similarity task, we transform the vectors of test words into the re-embedding space before computing the cosine similarity, and the final Spearman score. We vary relevant parameters and see what effect they have on the performance, so we can understand the effectiveness of the approach and its limits.

5 Results and Discussion

Average Performance. Table 1 shows that the re-embedding method outperforms the baseline in most cases with improvements from 0.5% to 5.0%. These results are achieved for effective manifold training windows which start anywhere between 5000 and 15000. The table also shows that improvements are over spaces with underlying bigger corpora and vectors, i.e. good quality vectors which facilitate the embedding.

Manifold Dimensionality Retention. Figure 3 shows that for a given window, the re-embedding performs better when the dimensionality of the learned manifold is chosen to be closer to the original space dimensionality. In other words, dimensional reduction on the original space will bare a cost in performance.

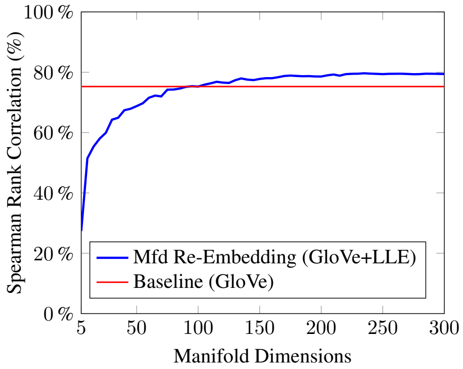

Figure 3: Accuracy on WS353 similarity task as a function of manifold dimensionality. (Space is GloVe 42B 300d. Window start = 7000, LLE local neighbours =1000, Window length = 1001.)

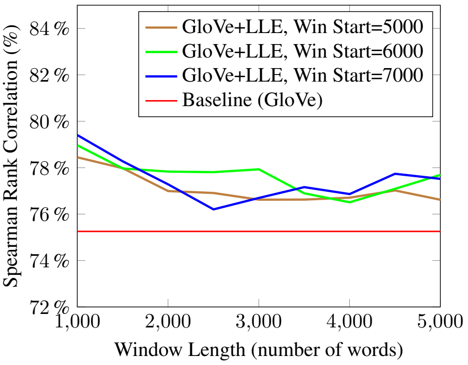

Figure 4: Accuracy on WS353 as a function of window length. (GloVe 42B 300d, LLE local neighbours =1000. Manifold dimensions =300.)

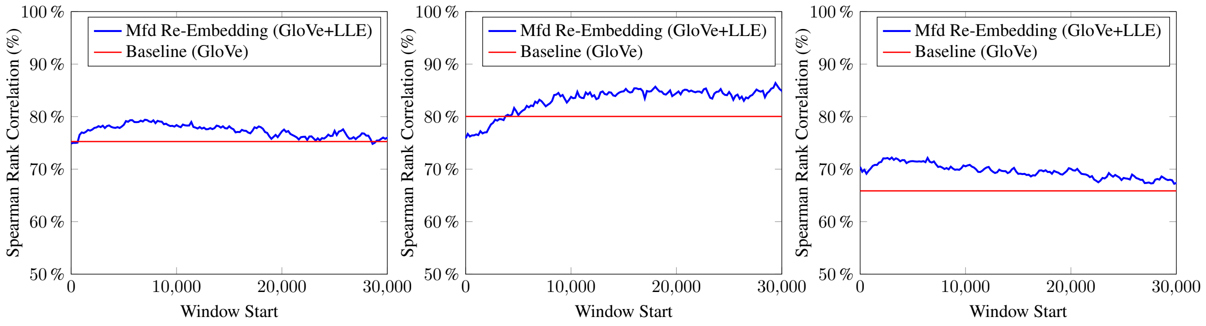
Manifold learning typically starts from a high-dimensional raw space, such as pixels, and aims to reduce the dimensionality. In our method we start from a word embedding which is already a good embedding of the raw word co-occurrences. So, dimensionality shall be retained, as suggested by Figure 3, or otherwise information can be lost during eigenvectors computation and selection in the manifold learning.

Effect of Window Length. Figure 4 shows that the best window length to choose is as close as possible to the number of local neighbours used by the manifold learning. Performance drops slightly with higher values of window length, but becomes stable after an initial drop.

Effect of Window Start. Figure 5 shows that the performance is first modest when the manifold is trained on the most frequent word vectors (i.e. stop words), but then picks up and outperforms the baseline for most cases. Performance drops grad-



(a) 42B 300d, WS353

(b) 42B 300d, RG65

(c) 6B 300d, WS353

Figure 5: Accuracy on similarity tasks as a function of window start. (a) Original space GloVe 42B 300d, with WS353. (b) 42B 300d, with RG65. (c) 6B 300d, with WS353. (LLE local neighbours =1000, Window length = 1001, Manifold dimensionality = 300.)

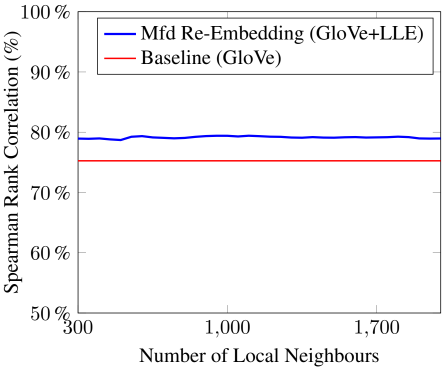


Figure 6: Accuracy on WS353 as a function of the number of manifold local neighbours. (42B 300d, Window start = 7000, Manifold dimensionality = 300, Window length = local neighbours+1.

ually as the manifold is trained on relatively less frequent word vectors.

Effect of the Number of Local Neighbours. Figure 6 shows that the performance is generally stable with variation in the number of local neighbours that the manifold is learned upon. Generally lower numbers of local neighbours mean faster manifold learning.

Discussion. The above results show that word re-embedding based on manifold learning can help the original space recover the Euclidean metric, and thus improves performance on word similarity tasks. The ability of re-embedding to achieve improved results depends on the quality of the vectors in the original space. It also depends on the choice of the window used to learn the manifold. The window start is the most influential variable, and it should be chosen just after the stop words in the original space. The choice of other parameters is relatively easier: the length of the window should be close or equal to the number of local neighbours, which in turn can be chosen from a wide range with no significant difference. The dimensionality of the original embedding space should be retained and used for learning the manifold to guarantee the best re-embedding.

6 Conclusions and Future Work

In this paper we presented a new method to re-embed words from off-the-shelf embeddings based on manifold learning. We showed that such an approach is theoretically founded in the metric recovery paradigm and can empirically improve the performance of state-of-the-art embeddings in word similarity tasks. In future work we intend to extend the experiments to include other original pre-trained embeddings, and other algorithms for manifold learning. We also intend to extend the experiments to other NLP tasks in addition to word similarity such as word analogies.

Abstract

This paper proposes to address the word sense ambiguity issue in an unsupervised manner, where word sense representations are learned along a word sense selection mechanism given contexts. Prior work focused on designing a single model to deliver both mechanisms, and thus suffered from either coarse-grained representation learning or inefficient sense selection. The proposed modular approach, *MUSE*, implements flexible modules to optimize distinct mechanisms, achieving the first purely sense-level representation learning system with linear-time sense selection. We leverage reinforcement learning to enable joint training on the proposed modules, and introduce various exploration techniques on sense selection for better robustness. The experiments on benchmark data show that the proposed approach achieves the state-of-the-art performance on synonym selection as well as on contextual word similarities in terms of MaxSimC.

1 Introduction

Recently, deep learning methodologies have dominated several research areas in natural language processing (NLP), such as machine translation, language understanding, and dialogue systems. However, most of applications usually utilize word-level embeddings to obtain semantics. Considering that natural language is highly ambiguous, the standard word embeddings may suffer from polysemy issues. Neelakantan et al. (2014) pointed out that, due to triangle inequality in vector space, if one word has two different senses but is restricted to *one embedding*, the sum of the distances between the word and its synonym in each sense would upper-bound the distance between the respective synonyms, which may be mutually irrelevant, in embedding space[1]. Due to the theoretical inability to account for polysemy using a single embedding representation per word, multi-sense word representations are proposed to address the ambiguity issue using multiple embedding representations for different senses in a word (Reisinger and Mooney, 2010; Huang et al., 2012).

This paper focuses on unsupervised learning from the unannotated corpus. There are two key mechanisms for a multi-sense word representation system in such scenario: 1) a sense selection (decoding) mechanism infers the most probable sense for a word given its context and 2) a sense representation mechanism learns to embed word senses in a continuous space.

Under this framework, prior work focused on designing a single model to deliver both mechanisms (Neelakantan et al., 2014; Li and Jurafsky, 2015; Qiu et al., 2016). However, the previously proposed models introduce side-effects: 1) mixing word-level and sense-level tokens achieves efficient sense selection but introduces ambiguous word-level tokens during the representation learning process (Neelakantan et al., 2014; Li and Jurafsky, 2015), and 2) pure sense-level tokens prevent ambiguity from word-level tokens but require exponential time complexity when decoding a sense sequence (Qiu et al., 2016).

Unlike the prior work, this paper proposes *MUSE*[2]—a novel modularization framework incorporating sense selection and representation learning models, which implements flexible modules to optimize distinct mechanisms. Specifically,

[1] $d(\text{rock}, \text{stone}) + d(\text{rock}, \text{shake}) \geq d(\text{stone}, \text{shake})$

[2] The trained models and code are available at https://github.com/MiuLab/MUSE.

Proceedings of the 2017 Conference on Empirical Methods in Natural Language Processing, pages 327–337
Copenhagen, Denmark, September 7–11, 2017. ©2017 Association for Computational Linguistics

MUSE enables linear time sense identity decoding with a *sense selection module* and purely sense-level representation learning with a *sense representation module*.

With the modular design, we propose a novel joint learning algorithm on the modules by connecting to a reinforcement learning scenario, which achieves the following advantages. First, the decision making process under reinforcement learning better captures the sense selection mechanism than probabilistic and clustering methods. Second, our reinforcement learning algorithm realizes the first single objective function for modular unsupervised sense representation systems. Finally, we introduce various exploration techniques under reinforcement learning on sense selection to enhance robustness.

In summary, our contributions are five-fold:

- *MUSE* is the first system that maintains purely sense-level representation learning with linear-time sense decoding.
- We are among the first to leverage reinforcement learning to model the sense selection process in sense representations system.
- We are among the first to propose a single objective for modularized unsupervised sense embedding learning.
- We introduce a sense exploration mechanism for the sense selection module to achieve better flexibility and robustness.
- Our experimental results show the state-of-the-art performance for synonym selection and contextual word similarities in terms of MaxSimC.

2 Related Work

There are three dominant types of approaches for learning multi-sense word representations in the literature: 1) clustering methods, 2) probabilistic modeling methods, and 3) lexical ontology based methods. Our reinforcement learning based approach can be loosely connected to clustering methods and probabilistic modeling methods.

Reisinger and Mooney (2010) first proposed multi-sense word representations on the vector space based on clustering techniques. With the power of deep learning, some work exploited neural networks to learn embeddings with sense selection based on clustering (Huang et al., 2012; Neelakantan et al., 2014). Chen et al. (2014) replaced the clustering procedure with a word sense disambiguation model using WordNet (Miller, 1995). Kågebäck et al. (2015) and Vu and Parker (2016) further leveraged a weighting mechanism and interactive process in the clustering procedure. Moreover, Guo et al. (2014) leveraged bilingual resources for clustering. However, most of the above approaches separated the clustering procedure and the representation learning procedure without a joint objective, which may suffer from the error propagation issue. Instead, the proposed approach, MUSE, enables joint training on sense selection and representation learning.

Instead of clustering, probabilistic modeling methods have been applied for learning multi-sense embeddings in order to make the sense selection more flexible, where Tian et al. (2014) and Jauhar et al. (2015) conducted probabilistic modeling with EM training. Li and Jurafsky (2015) exploited Chinese Restaurant Process to infer the sense identity. Furthermore, Bartunov et al. (2016) developed a non-parametric Bayesian extension on the skip-gram model (Mikolov et al., 2013b). Despite reasonable modeling on sense selection, all above methods mixed word-level and sense-level tokens during representation learning—unable to conduct representation learning in the pure sense level due to the complicated computation in their EM algorithms.

Recently, Qiu et al. (2016) proposed an EM algorithm to learn purely sense-level representations, where the computational cost is high when decoding the sense identity sequence, because it takes exponential time to search all sense combination within a context window. Our modular design addresses such drawback, where the sense selection module decodes a sense sequence with linear-time complexity, while the sense representation module remains representation learning in the pure sense level.

Unlike a lot of relevant work that requires additional resources such as the lexical ontology (Pilehvar and Collier, 2016; Rothe and Schütze, 2015; Jauhar et al., 2015; Chen et al., 2015; Iacobacci et al., 2015) or bilingual data (Guo et al., 2014; Ettinger et al., 2016; Šuster et al., 2016), which may be unavailable in some language, our model can be trained using only an unlabeled corpus. Also, some prior work proposed to learn topical embeddings and word embeddings jointly in order to consider the contexts (Liu et al., 2015a,b), whereas this paper focuses on learning multi-sense

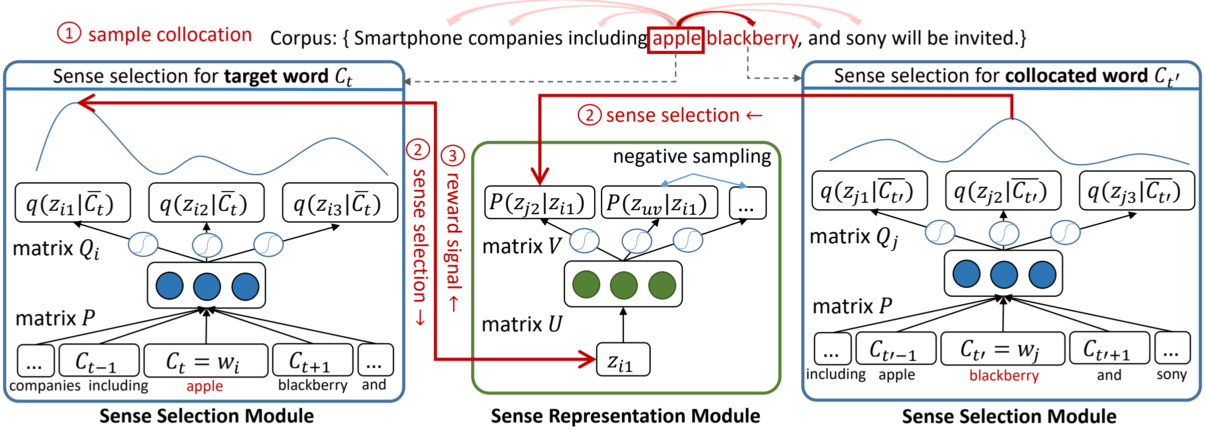

Figure 1: The *MUSE* architecture with a 3-step learning algorithm: 1) collocation sampling, 2) sense selection for sense representation learning, and 3) optimizing sense selection with a reward signal from sense representation. Reward signal is only passed to the target word to stabilize model training due to directional architecture in the sense representation module.

word embeddings.

3 Proposed Approach: MUSE

This work proposes a framework to modularize two key mechanisms for multi-sense word representations: a *sense selection module* and a *sense representation module*. The sense selection module decides which sense to use given a text context, whereas the sense representation module learns meaningful representations based on its statistical characteristics. Unlike prior work that must suffer from either inefficient sense selection (Qiu et al., 2016) or coarse-grained representation learning (Neelakantan et al., 2014; Li and Jurafsky, 2015; Bartunov et al., 2016), the proposed modularized framework is capable of performing efficient sense selection and learning representations in pure sense level simultaneously.

To learn sense-level representations, a sense selection model should be first established for sense identity decoding. On the other hand, the sense embeddings should guide the sense selection model when decoding a sense identity sequence. Therefore, these two modules should be tangled. This indicates that a naive two-stage algorithm or two separate learning algorithms proposed by prior work are not optimal.

By connecting the proposed formulation with reinforcement learning literature, we design a novel joint training algorithm. Besides, taking advantage of the form of reinforcement learning, we are among the first to investigate various exploration techniques in sense selection for unsupervised sense embedding learning.

3.1 Model Architecture

Our model architecture is illustrated in Figure 1, where there are two modules in optimization.

3.1.1 Sense Selection Module

Formally speaking, given a corpus C, vocabulary W, and the t-th word $C_t = w_i \in W$, we would like to find the most probable sense $z_{ik} \in Z_i$, where Z_i is the set of senses in word w_i. Assuming that a word sense is determined by the local context, we exploit a local context $\bar{C}_t = \{C_{t-m}, \cdots, C_{t+m}\}$ for sense selection according to the Markov assumption, where m is the size of a context window. Then we can either formulate a probabilistic policy $\pi(z_{ik} \mid \bar{C}_t)$ about sense selection or estimate the *individual* likelihood $q(z_{ik} \mid \bar{C}_t)$ for each sense identity.

To ensure efficiency, here we exploit a linear neural architecture that takes word-level input tokens and outputs sense-level identities. The architecture is similar to continuous bag-of-words (CBOW) (Mikolov et al., 2013a). Specifically, given a *word* embedding matrix P, the local context can be modeled as the summation of word embeddings from its context $\bar{C}_t$. The output can be formulated with a 3-mode tensor Q, whose dimensions denote words, senses, and latent variables. Then we can model $\pi(z_{ik} \mid \bar{C}_t)$ or $q(z_{ik} \mid \bar{C}_t)$ correspondingly. Here we model $\pi(\cdot)$ as a *categorical* distribution using a softmax layer:

$$\pi(z_{ik} \mid \bar{C}_t) = \frac{\exp(Q_{ik}^T \sum_{j \in \bar{C}_t} P_j)}{\sum_{k' \in Z_i} \exp(Q_{ik'}^T \sum_{j \in \bar{C}_t} P_j)}. \tag{1}$$

On the other hand, the likelihood of selecting *distinct* sense identities, $q(z_{ik} \mid \bar{C}_t)$, is modeled as a *Bernoulli* distribution with a sigmoid function $\sigma(\cdot)$:

$$q(z_{ik} \mid \bar{C}_t) = \sigma(Q_{ik}^T \sum_{j \in \bar{C}_t} P_j). \tag{2}$$

Different modeling approaches require different learning methods, especially for the unsupervised setting. We leave the corresponding learning algorithms in § 3.2. Finally, with a built sense selection module, we can apply any selection algorithm such as a greedy selection strategy to infer the sense identity z_{ik} given a word w_i with its context C_t.

We note that modularized model enables efficient sense selection by leveraging word-level tokens, while remaining purely sense-level tokens in the representation module. Specifically, if n denotes $\max_k |Z_k|$, decoding L words takes $O(nL)$ senses to be searched due to independent sense selection. The prior work using a single model with purely sense-level tokens (Qiu et al., 2016) requires exponential time to calculate the collocation energy for every possible combination of sense identities within a context window, $O(n^{2m})$, for a *single target sense*. Further, Qiu et al. (2016) took an additional sequence decoding step with quadratic time complexity $O(n^{4m}L)$, based on an exponential number n^{2m} in the base unit. It demonstrates the achievement about sense inference efficiency in our proposed model.

3.1.2 Sense Representation Module

The semantic representation learning is typically formulated as a maximum likelihood estimation (MLE) problem for collocation likelihood. In this paper, we use the skip-gram formulation (Mikolov et al., 2013b) considering that it requires less training time, where only two sense identities are required for stochastic training. Other popular candidates, like GloVe (Pennington et al., 2014) and CBOW (Mikolov et al., 2013a), require more sense identities to be selected as input and thus not suitable for our scenario. For example, GloVe (Pennington et al., 2014) takes computationally expensive collocation *counting* statistics for each token in a corpus as input, which requires sense selection for every occurrence of the target word across the whole corpus for a single optimization step.

To learn the representations, we first create input sense representation matrix U and collocation estimation matrix V as the learning targets. Given a target word w_i and collocated word w_j with corresponding local contexts, we map them to their sense identities as z_{ik} and z_{jl} by the sense selection module, and maximize the sense collocation log likelihood $\log \mathcal{L}(\cdot)$. A natural choice of the likelihood function is formulated as a categorical distribution over all possible collocated senses given the target sense z_{ik}:

$$\max_{U,V} \ \log \mathcal{L}(z_{jl} \mid z_{ik}) = \log \frac{\exp(U_{z_{ik}}^T V_{z_{jl}})}{\sum_{z_{uv}} \exp(U_{z_{ik}}^T V_{z_{uv}})}. \tag{3}$$

Instead of enumerating all possible collocated senses which is computationally expensive, we use the skip-gram objective (4) (Mikolov et al., 2013b) to approximate (3) as shown in the green block of Figure 1.

$$\max_{U,V} \ \log \bar{\mathcal{L}}(z_{jl} \mid z_{ik}) = \log \sigma(U_{z_{ik}}^T V_{z_{jl}}) \tag{4}$$
$$+ \sum_{v=1}^{M} \mathbb{E}_{z_{uv} \sim p_{neg}(z)} [\log \sigma(-U_{z_{ik}}^T V_{z_{uv}})],$$

where $p_{neg}(z)$ is the distribution over all senses for negative samples. In our experiment with $|Z_i|$ senses for word w_i, we use $(1/|Z_i|)$ word-level unigram as sense-level unigram for efficiency and the 3/4-th power trick in Mikolov et al. (2013b).

We note that our modular framework can easily maintain purely sense-level tokens with an arbitrary representation learning model. In contrast, most related work using probabilistic modeling (Tian et al., 2014; Jauhar et al., 2015; Li and Jurafsky, 2015; Bartunov et al., 2016) binded sense representations with the sense selection mechanism, so efficient sense selection by leveraging word-level tokens can be achieved only at the cost of mixing word-level and sense-level tokens in their representation learning process.

3.2 Learning

Without the supervised signal for the proposed modules, it is desirable to connect two modules in a way where they can improve each other by their own estimations. First, a trivial way is to forward the prediction of the sense selection module to the representation module. Then we cast the estimated collocation likelihood as a reward signal for the selected sense for effective learning.

To realize the above procedure, we cast the learning problem a one-step Markov decision process (MDP) (Sutton and Barto, 1998), where the state, action, and reward correspond to context $\bar{C}_t$, sense z_{ik}, and collocation log likelihood $\log \bar{\mathcal{L}}(\cdot)$, respectively. Based on different modeling methods ((1) or (2)) in the sense selection module, we connect the model to respective reinforcement learning algorithms to solve the MDP. Specifically, we refer (1) to policy distribution and refer (2) to Q-value estimation in the reinforcement learning literature.

The proposed MDP framework embodies several nuances of sense selection. First, the decision of a word sense is Markov: taking the whole corpus into consideration is not more helpful than a handful of necessary local contexts. Second, the decision making in MDP exploits a hard decision for selecting sense identity, which captures the sense selection process more naturally than a joint probability distribution among senses (Qiu et al., 2016). Finally, we exploit the reward mechanism in MDP to enable joint training: the estimation of sense representation is treated as a reward signal to guide sense selection. In contrast, the decision making under clustering (Huang et al., 2012; Neelakantan et al., 2014) considers the similarity within clusters instead of the outcome of a decision using a reward signal as MDP.

3.2.1 Policy Gradient Method

Because (1) fits a valid probability distribution, an intuitive optimization target is the expectation of resulting collocation likelihood among each sense. In addition, as the skip-gram formulation in (4) is unidirectional ($\bar{\mathcal{L}}(z_{ik} \mid z_{jl}) \neq \bar{\mathcal{L}}(z_{jl} \mid z_{ik})$), we perform one-side optimization for the target sense z_{ik} to stabilize model training[3]. That is, for the target word w_i and the collocated word w_j given respective contexts $\bar{C}_t$ and $\bar{C}_{t'}$ $(0 < |t - t'| \leq m)$, we first draw a sense z_{jl} for w_j from the policy $\pi(\cdot \mid \bar{C}_{t'})$ and optimize the expected collocation likelihood for the target sense z_{ik} as follows,

$$\max_{P,Q} \; \mathbb{E}_{z_{ik} \sim \pi(\cdot \mid \bar{C}_t)} [\log \bar{\mathcal{L}}(z_{jl} \mid z_{ik})]. \quad (5)$$

Note that (4) can be merged into (5) as a single objective. The objective is differentiable and supports stochastic optimization (Lei et al., 2016), which uses a stochastic sample z_{ik} for optimization.

However, there are two possible disadvantages in this formulation. First, because the policy assumes the probability distribution in (1), optimizing the selected sense must affect the estimation of the other senses. Second, if applying stochastic gradient ascent to optimizing (5), it would always lower the probability estimation for the selected sense z_{ik} even if the model accurately selects the right sense. The detailed proof is in Appendix A.

3.2.2 Value-Based Method

To address the above issues, we apply the Q-learning algorithm (Mnih et al., 2013). Instead of maintaining a probabilistic policy for sense selection, Q-learning estimates the Q-value (resulting collocation log likelihood) for each sense candidate directly and independently. Thus, the estimation of unselected senses may not be influenced by the selected one. Note that in one-step MDP, the reward is equivalent to the Q-value, so we will use reward and Q-value interchangeably, hereinafter, based on the context.

We further follow the convention of recent neural reinforcement learning by reducing the reward range to aid model training (Mnih et al., 2013). Specifically, we replace the *log likelihood* $\log \bar{\mathcal{L}}(\cdot) \in (-\inf, 0]$ with the *likelihood* $\bar{\mathcal{L}}(\cdot) \in [0, 1]$ as the reward function. Due to the monotonic operation in $\log()$, the relative ordering of the reward remains the same.

Furthermore, we exploit the probabilistic nature of likelihood for Q-learning. To elaborate, as Q-learning is used to approximate the Q-value for each action in typical reinforcement learning, most literature adopted square loss to characterize the discrepancy between the target and estimated Q-values (Mnih et al., 2013). In our setting where the Q-value/reward is a likelihood function, our model exploits cross-entropy loss to better capture the characteristics of probability distribution.

Given that the collocation likelihood in (4) is an *approximation* to the original categorical distribution with a softmax function shown in (3) (Mikolov et al., 2013b), we revise the formulation by omitting the negative sampling term. The resulting formulation $\hat{\mathcal{L}}(\cdot)$ is a Bernoulli distribution indicating whether z_{jl} collocates or not given z_{ik}:

$$\hat{\mathcal{L}}(z_{jl} \mid z_{ik}) = \sigma(U_{z_{ik}}^T V_{z_{jl}}). \quad (6)$$

[3] We observe about 4% performance drop by optimizing input selection z_{ik} and output selection z_{jl} simultaneously.

There are three advantages about using $\hat{\mathcal{L}}(\cdot)$ instead of approximated $\bar{\mathcal{L}}(\cdot)$ and original $\mathcal{L}(\cdot)$. First, regarding the variance of estimation, $\hat{\mathcal{L}}(\cdot)$ better captures $\mathcal{L}(\cdot)$ than $\bar{\mathcal{L}}(\cdot)$ because $\bar{\mathcal{L}}(\cdot)$ involves sampling:

$$Var(\bar{\mathcal{L}}(\cdot)) \geq Var(\hat{\mathcal{L}}(\cdot)) = Var(\mathcal{L}(\cdot)) = 0. \quad (7)$$

Second, regarding the relative ordering of estimation, for any two collocated senses z_{jl} and $z_{jl'}$ with a target sense z_{ik}, the following equivalence holds:

$$\begin{aligned} & \mathcal{L}(z_{jl} \mid z_{ik}) < \mathcal{L}(z_{jl'} \mid z_{ik}) \\ \Leftrightarrow \quad & \bar{\mathcal{L}}(z_{jl} \mid z_{ik}) < \bar{\mathcal{L}}(z_{jl'} \mid z_{ik}) \\ \Leftrightarrow \quad & \hat{\mathcal{L}}(z_{jl} \mid z_{ik}) < \hat{\mathcal{L}}(z_{jl'} \mid z_{ik}) \end{aligned} \quad (8)$$

Third, for collocation computation, $\mathcal{L}(\cdot)$ requires all sense identities and $\bar{\mathcal{L}}(\cdot)$ requires $(M+1)$ sense identities, whereas $\hat{\mathcal{L}}(\cdot)$ only requires 1 sense identity. In sum, the proposed $\hat{\mathcal{L}}(\cdot)$ approximates $\mathcal{L}(\cdot)$ with no variance, no "bias" (in terms of relative ordering), and significantly less computation.

Finally, because both target distribution $\hat{\mathcal{L}}(\cdot)$ and estimated distribution $q(\cdot)$ in (2) are Bernoulli distributions, we follow the last section to conduct one-side optimization by fixing a collocated sense z_{jl} and optimize the selected sense z_{ik} with cross entropy as

$$\min_{P,Q} \; H(\hat{\mathcal{L}}(z_{ik} \mid z_{jl}), q(z_{ik} \mid \bar{C}_t)). \quad (9)$$

3.2.3 Joint Training

To jointly train sense selection and sense representation modules, we first select a pair of the collocated senses, z_{ik} and z_{jl}, based on the sense selection module with any selecting strategy (e.g. greedy), and then optimize the sense representation module and the sense selection module using the above derivations. Algorithm 1 describes the proposed MUSE model training procedure.

As modular frameworks, the major distinction between our modular framework and two-stage clustering-representation learning framework (Neelakantan et al., 2014; Vu and Parker, 2016) is that we establish a reward signal from the sense representation to the sense selection module to enable immediate and joint optimization.

3.3 Sense Selection Strategy

Given a fitness estimation for each sense, exploiting the greedy sense is the most popular strategy for clustering algorithms (Neelakantan et al., 2014; Kågebäck et al., 2015) and hard-EM algorithms (Qiu et al., 2016; Jauhar et al., 2015) in literature. However, there are two incentives to conduct exploration. First, in the early training stage when the fitness is not well estimated, it is desirable to explore underestimated senses. Second, due to high ambiguity in natural language, sometimes multiple senses in a word would fit in the same context. The dilemma between exploring sub-optimal choices and exploiting the optimal choice is called exploration-exploitation trade-off in reinforcement learning (Sutton and Barto, 1998).

Algorithm 1: Learning Algorithm

```
for $w_i = C_t \in C$ do
    sample $w_j = C_{t'} (0 < |t' - t| \leq m)$;
    $z_{ik} =$ select$(C_t, w_i)$;
    $z_{jl} =$ select$(C_{t'}, w_j)$;
    optimize $U, V$ by (4) for the sense
      representation module;
    optimize $P, Q$ by (5) or (9) for the sense
      selection module;
```

We introduce exploration mechanisms for sense selection for both policy gradient and Q-learning. For policy gradient, we sample the policy distribution to approximate the expectation in (5). Because of the flexible formulation of Q-learning, the following classic exploration mechanisms are applied to sense selection:

- *Greedy*: selects the sense with the largest Q-value (no exploration).
- ϵ-*Greedy*: selects a random sense with ϵ probability, and adopts the greedy strategy otherwise (Mnih et al., 2013).
- *Boltzmann*: samples the sense based on the Boltzmann distribution modeled by Q-value. We directly use (1) as the Boltzmann distribution for simplicity.

We note that Q-learning with Boltzmann sampling yields the same sampling process as policy gradient but different optimization objectives. To our best knowledge, we are among the first to explore several exploration strategies for unsupervised sense embedding learning.

In the following sections, MUSE-Policy denotes the proposed MUSE model with policy learning and MUSE-Greedy denotes the model using corresponding sense selection strategy for Q-learning.

4 Experiments

We evaluate our proposed MUSE model in both quantitative and qualitative experiments.

4.1 Experimental Setup

Our model is trained on the April 2010 Wikipedia dump (Shaoul and Westbury, 2010), which contains approximately 1 billion tokens. For fair comparison, we adopt the same vocabulary set as Huang et al. (2012) and Neelakantan et al. (2014). For preprocessing, we convert all words to their lower cases, apply the Stanford tokenizer and the Stanford sentence tokenizer (Manning et al., 2014), and remove all sentences with less than 10 tokens. The number of senses per word in Q is set to 3 as the prior work (Neelakantan et al., 2014).

In the experiments, the context window size is set to 5 ($|\bar{C}_t| = 11$). Subsampling technique introduced by `word2vec` (Mikolov et al., 2013b) is applied to accelerate the training process. The learning rate is set to 0.025. The embedding dimension is 300. We initialize Q and V as zeros, and P and U from uniform distribution $[-\sqrt{1/100}, \sqrt{1/100}]$ such that each embedding has unit length in expectation (Lei et al., 2015). Our model uses 25 negative senses for negative sampling in (4). We use $\epsilon = 5\%$ for ϵ-Greedy sense selection strategy

In optimization, we conduct mini-batch training with 2048 batch size using the following procedure: 1) select senses in the batch; 2) optimize U, V using stochastic training within the batch for efficiency; 3) optimize P, Q using mini-batch training for robustness.

4.2 Experiment 1: Contextual Word Similarity

To evaluate the quality of the learned sense embeddings, we compute the similarity score between each word pair given their respective local contexts and compare with the human-judged score using Stanford's Contextual Word Similarities (SCWS) dataset (Huang et al., 2012). Specifically, given a list of word pairs with corresponding contexts, $S = \{(w_i, \bar{C}_t, w_j, \bar{C}_{t'})\}$, we calculate the Spearman's rank correlation ρ between human-judged similarity and model similarity estimations[4]. Two major contextual similarity estimations are introduced by Reisinger and Mooney (2010): AvgSimC and MaxSimC. AvgSimC is a *soft* measurement that addresses the contextual information with a probability estimation:

Method	MaxSimC	AvgSimC
Huang et al. (2012)	26.1	65.7
Neelakantan et al. (2014)	60.1	**69.3**
Tian et al. (2014)	63.6	65.4
Li and Jurafsky (2015)	66.6	66.8
Bartunov et al. (2016)	53.8	61.2
Qiu et al. (2016)	64.9	66.1
MUSE-Policy	66.1	67.4
MUSE-Greedy	66.3	68.3
MUSE-ϵ-Greedy	67.4†	68.6
MUSE-Boltzmann	**67.9**†	68.7

Table 1: Spearman's rank correlation ρ x100 on the SCWS dataset. † denotes superior performance to all unsupervised competitors.

$$\text{AvgSimC}(w_i, \bar{C}_t, w_j, \bar{C}_{t'}) = \sum_{k=1}^{|Z_i|}\sum_{l=1}^{|Z_j|} \pi(z_{ik}|\bar{C}_t)\pi(z_{jl}|\bar{C}_{t'})d(z_{ik}, z_{jl}),$$

where $d(z_{ik}, z_{jl})$ refers to the cosine similarity between $U_{z_{ik}}$ and $U_{z_{jl}}$. AvgSimC weights the similarity measurement of each sense pair z_{ik} and z_{jl} by their probability estimations. On the other hand, MaxSimC is a *hard* measurement that only considers the most probable senses:

$$\begin{aligned}\text{MaxSimC}(w_i, \bar{C}_t, w_j, \bar{C}_{t'}) &= d(z_{ik}, z_{jl}),\\ z_{ik} &= \arg\max_{z_{ik'}} \pi(z_{ik'}|\bar{C}_t),\\ z_{jl} &= \arg\max_{z_{jl'}} \pi(z_{jl'}|\bar{C}_{t'}).\end{aligned}$$

The baselines for comparison include classic clustering methods (Huang et al., 2012; Neelakantan et al., 2014), EM algorithms (Tian et al., 2014; Qiu et al., 2016; Bartunov et al., 2016), and Chinese Restaurant Process (Li and Jurafsky, 2015)[5], where all approaches are trained on the same corpus except Qiu et al. (2016) used more recent Wikipedia dumps. The embedding sizes of all baselines are 300, except 50 in Huang et al. (2012). For every competitor with multiple settings, we report the best performance in each similarity measurement setting and show in Table 1.

[4] For example, human-judged similarity between "... east **bank** of the Des Moines River ..." and "... basis of all **money** laundering ..." is 2.5 out of 10.0 in SCWS dataset (Huang et al., 2012).

[5] We run Li and Jurafsky (2015)'s released code on our corpus for fair comparison.

Retro-SG	56.25	65.09	73.33

Table 2: Accuracy on synonym selection. † denotes superior performance to all unsupervised competitors.

Our MUSE model achieves the state-of-the-art performance on MaxSimC, demonstrating superior quality on independent sense embeddings. On the other hand, MUSE achieves comparable performance with the best competitor in terms of AvgSimC (68.7 vs. 69.3), while MUSE outperforms the same competitor significantly in terms of MaxSimC (67.9 vs. 60.1). The results demonstrate not only the high quality of sense representations but also accurate sense selection.

From the application perspective, MaxSimC refers to a typical scenario using single embedding per word, while AvgSimC employs multiple sense vectors simultaneously per word, which not only brings computational overhead but changes existing neural architecture for NLP. Hence, we argue that MaxSimC better characterize practical usage of a sense representation system than AvgSimC.

Among various learning methods for MUSE, policy gradient performs worst, echoing our argument in § 3.2.1. On the other hand, the superior performance of Boltzmann sampling and ϵ-Greedy over Greedy selection demonstrates the effectiveness of exploration.

Finally, replacing $\bar{\mathcal{L}}(\cdot)$ with $\hat{\mathcal{L}}(\cdot)$ as the reward signal yields 2.3 times speedup for MUSE-ϵ-Greedy and 1.3 times speedup for MUSE-Boltzmann to reach 67.0 in MaxSimC, which demonstrates the efficacy of proposed approximation $\hat{\mathcal{L}}(\cdot)$ over typical $\bar{\mathcal{L}}(\cdot)$ in terms of convergence.

4.3 Experiment 2: Synonym Selection

We further evaluate our model on synonym selection using multi-sense word representations (Jauhar et al., 2015). Three standard synonym selection datasets, ESL-50 (Turney, 2001), RD-300 (Jarmasz and Szpakowicz, 2004), and TOEFL-80 (Landauer and Dumais, 1997), are performed. In the datasets, each question consists of a question word w_Q and four answer candidates $\{w_A, w_B, w_C, w_D\}$, and the goal is to select the most semantically synonymous choice among the four candidates. For example, in the TOEFL-80 dataset, a question shows {(Q) enormously, (A) appropriately, (B) uniquely, (C) tremendously, (D) decidedly}, and the answer is (C). For multi-sense representations system, it selects the synonym of the question word w_Q using the maximum sense-level cosine similarity as a proxy of the semantic similarity (Jauhar et al., 2015).

Our model is compared with the following baselines: 1) conventional word embeddings: global context vectors (Huang et al., 2012) and skip-gram (Mikolov et al., 2013b); 2) applying supervised word sense disambiguation using the IMS system and then applying skip-gram on disambiguated corpus (IMS+SG) (Zhong and Ng, 2010); 3) unsupervised sense embeddings: EM algorithm (Jauhar et al., 2015), multi-sense skip-gram (MSSG) (Neelakantan et al., 2014), Chinese restaurant process (CRP) (Li and Jurafsky, 2015), and the MUSE models; 4) supervised sense embeddings with WordNet (Miller, 1995): retrofitting global context vectors (Retro-GC) and retrofitting skip-gram (Retro-SG) (Jauhar et al., 2015).

Among unsupervised sense embedding approaches, CRP and MSSG refer to the baselines with highest MaxSimC and AvgSimC in Table 1 respectively. Here we report the setting for baselines based on the best average performance in this task. We also show the performance of supervised sense embeddings as an upperbound of unsupervised methods due to the usage of additional supervised information from WordNet.

The results are shown in Table 2, where our MUSE-ϵ-Greedy and MUSE-Boltzmann significantly outperform all unsupervised sense embeddings methods, echoing the superior quality of our

sense vectors in last section. MUSE-Boltzmann also outperforms the supervised sense embeddings except 1 setting without any supervised signal during training. Finally, the MUSE methods with proper exploration outperform all unsupervised baselines consistently, demonstrating the importance of exploration.

4.4 Qualitative Analysis

We further conduct qualitative analysis to check the semantic meanings of different senses learned by MUSE with k-nearest neighbors (k-NN) using sense representations. In addition, we provide contexts in the training corpus where the sense will be selected to validate the sense selection module. Table 3 shows the results. The learned sense embeddings of the words “tie”, “blackberry”, and “head” clearly correspond to correct senses under different contexts.

Since we address an unsupervised setting that learns sense embeddings from unannotated corpus, the discovered senses highly depend on the training corpus. From our manual inspection, it is common for our model to discover only two senses in a word, like “tie” and “blackberry”. However, we maintain our effort in developing unsupervised sense embeddings learning methods in this work, and the number of discovered sense is not a focus.

5 Conclusion

This paper proposes a novel modularized framework for unsupervised sense representation learning, which supports not only the flexible design of modular tasks but also joint optimization among modules. The proposed model is the first work that implements purely sense-level representation learning with linear-time sense selection, and achieves the state-of-the-art performance on benchmark contextual word similarity and synonym selection tasks. In the future, we plan to investigate reinforcement learning methods to incorporate multi-sense word representations for downstream NLP tasks.

A Doubly Stochastic Gradient

To derive doubly stochastic gradient for equation (5), we first denote (5) as $J(\Theta)$ with $\Theta = \{P, Q\}$ and resolve the expectation form as:

$$\begin{aligned} J(\theta) &= \mathbb{E}_{z_{ik} \sim \pi(\cdot|\bar{C}_t)}[\log \bar{\mathcal{L}}(z_{jl} \mid z_{ik})] \\ &= \sum_k \pi(z_{ik} \mid \bar{C}_t) \log \bar{\mathcal{L}}(z_{jl}|z_{ik}). \end{aligned}$$

Denote $\Theta = \{P, Q\}$ as the parameter set for policy π. The gradient with respect to Θ should be:

$$\frac{\partial J(\theta)}{\partial \Theta} = \frac{\partial}{\partial \Theta} \sum_k \pi(z_{ik} \mid \bar{C}_t) \log \bar{\mathcal{L}}(z_{jl}|z_{ik})$$

$$= \sum_k \log \bar{\mathcal{L}}(z_{jl}|z_{ik}) \frac{\partial \pi(z_{ik} \mid \bar{C}_t)}{\partial \Theta}$$

$$= \sum_k \log \bar{\mathcal{L}}(z_{jl}|z_{ik}) (\frac{\partial \log \pi(z_{ik} \mid \bar{C}_t)}{\partial \Theta})(\pi(z_{ik} \mid \bar{C}_t))$$

$$= \mathbb{E}_{z_{ik} \sim \pi(\cdot|\bar{C}_t)}[\log \bar{\mathcal{L}}(z_{jl} \mid z_{ik}) \frac{\partial \log \pi(z_{ik} \mid \bar{C}_t)}{\partial \Theta}]$$

Accordingly, if we conduct typical stochastic gradient ascent training on $J(\Theta)$ with respect to Θ from samples z_{ik} with a learning rate η, the update formula will be:

$$\Theta = \Theta + \eta \log \bar{\mathcal{L}}(z_{jl} \mid z_{ik}) \frac{\partial \log \pi(z_{ik} \mid \bar{C}_t)}{\partial \Theta}.$$

However, the collocation log likelihood should always be non-positive: $\log \bar{\mathcal{L}}(z_{jl} \mid z_{ik}) \leq 0$. Therefore, as long as the collocation log likelihood $\log \bar{\mathcal{L}}(z_{jl} \mid z_{ik})$ is negative, the update formula is to minimize the likelihood of choosing z_{ik}, despite the fact that z_{ik} may be good choices. On the other hand, if the log likelihood reaches 0, according to (4), it indicates:

$$\begin{aligned} &\log \bar{\mathcal{L}}(z_{jl} \mid z_{ik}) = 0 \Rightarrow \quad \bar{\mathcal{L}}(z_{jl} \mid z_{ik}) = 1 \\ \Rightarrow \quad & U_{z_{ik}}^T V_{z_{jl}} \to \infty, \ U_{z_{ik}}^T V_{z_{uv}} \to \infty, \ \forall z_{uv}, \end{aligned}$$

which leads to computational overflow from an infinity value.

Reporting Score Distributions Makes a Difference: Performance Study of LSTM-networks for Sequence Tagging

Abstract

In this paper we show that reporting a single performance score is insufficient to compare non-deterministic approaches. We demonstrate for common sequence tagging tasks that the seed value for the random number generator can result in *statistically significant* ($p < 10^{-4}$) differences for state-of-the-art systems. For two recent systems for NER, we observe an absolute difference of one percentage point F_1-score depending on the selected seed value, making these systems perceived either as *state-of-the-art* or *mediocre*. Instead of publishing and reporting single performance scores, we propose to compare score distributions based on multiple executions. Based on the evaluation of 50.000 LSTM-networks for five sequence tagging tasks, we present network architectures that produce both superior performance as well as are more stable with respect to the remaining hyperparameters. The full experimental results are published in (Reimers and Gurevych, 2017).[1] The implementation of our network is publicly available.[2]

1 Introduction

Large efforts are spent in our community on developing new *state-of-the-art* approaches. To document that those approaches are better, they are applied to unseen data and the obtained performance score is compared to previous approaches. In order to make results comparable, a provided split between train, development and test data is often used, for example from a former shared task.

In recent years, deep neural networks were shown to achieve state-of-the-art performance for a wide range of NLP tasks, including many sequence tagging tasks (Ma and Hovy, 2016), dependency parsing (Andor et al., 2016), and machine translation (Wu et al., 2016). The training process for neural networks is highly non-deterministic as it usually depends on a random weight initialization, a random shuffling of the training data for each epoch, and repeatedly applying random dropout masks. The error function of a neural network is a highly non-convex function of the parameters with the potential for many distinct local minima (LeCun et al., 1998; Erhan et al., 2010). Depending on the seed value for the pseudo-random number generator, the network will converge to a different local minimum.

Our experiments show that these different local minima have vastly different characteristics on unseen data. For the recent NER system by Ma and Hovy (2016) we observed that, depending on the random seed value, the performance on unseen data varies between 89.99% and 91.00% F_1-score. The difference between the best and worst performance is statistically significant ($p < 10^{-4}$) using a randomization test[3]. In conclusion, whether this newly developed approach is perceived as *state-of-the-art* or as *mediocre*, largely depends on which random seed value is selected. This issue is not limited to this specific approach, but potentially applies to all approaches with non-deterministic training processes.

This large dependence on the random seed value creates several challenges when evaluating new approaches:

[2] https://github.com/UKPLab/emnlp2017-bilstm-cnn-crf

[3] 1 Million iterations. p-value adapted using the Bonferroni correction to take the 86 tested seed values into account.

Proceedings of the 2017 Conference on Empirical Methods in Natural Language Processing, pages 338–348
Copenhagen, Denmark, September 7–11, 2017.

- Observing a (statistically significant) improvement through a new non-deterministic approach might not be the result of a superior approach, but the result of having a more favorable sequence of random numbers.

- Promising approaches might be rejected too early, as they fail to deliver an outperformance simply due to a less favorable sequence of random numbers.

- Reproducing results is difficult.

To study the impact of the random seed value on the performance we will focus on five linguistic sequence tagging tasks: POS-tagging, Chunking, Named Entity Recognition, Entity Recognition[4], and Event Detection. Further we will focus on Long-Short-Term-Memory (LSTM) Networks (Hochreiter and Schmidhuber, 1997b), as those demonstrated state-of-the-art performance for a wide variety of sequence tagging tasks (Ma and Hovy, 2016; Lample et al., 2016; Søgaard and Goldberg, 2016).

Fixing the random seed value would solve the issue with the reproducibility, however, there is no justification for choosing one seed value over another seed value. Hence, instead of reporting and comparing a single performance, we show that comparing score distributions can lead to new insights into the functioning of algorithms.

Our main contributions are:

1. Showing the implications of non-deterministic approaches on the evaluation of approaches and the requirement to compare score distributions instead of single performance scores.

2. Comparison of two recent, state-of-the-art systems for NER and showing that reporting a single performance score can be misleading.

3. In-depth analysis of different LSTM-architectures for five sequence tagging tasks with respect to: superior performance, stability of results, and importance of tuning parameters.

2 Background

Validating and reproducing results is an important activity in science to manifest the correctness of previous conclusions and to gain new insights into the presented approaches. Fokkens et al. (2013) show that reproducing results is not always straightforward, as factors like preprocessing (e.g. tokenization), experimental setup (e.g. splitting data), the version of components, the exact implementation of features, and the treatment of ties can have a major impact on the achieved performance and sometimes on the drawn conclusions.

For approaches with non-deterministic training procedures, like neural networks, reproducing exact results becomes even more difficult, as randomness can play a major role in the outcome of experiments. The error function of a neural network is a highly non-convex function of the parameters with the potential for many distinct local minima (LeCun et al., 1998; Erhan et al., 2010). The sequence of random numbers plays a major role to which minima the network converges during the training process. However, not all minima generalize equally well to unseen data. Erhan et al. (2010) showed for the MNIST handwritten digit recognition task that different random seeds result in largely varying performances. They noted further that with increasing depth of the neural network, the probability of finding poor local minima increases.

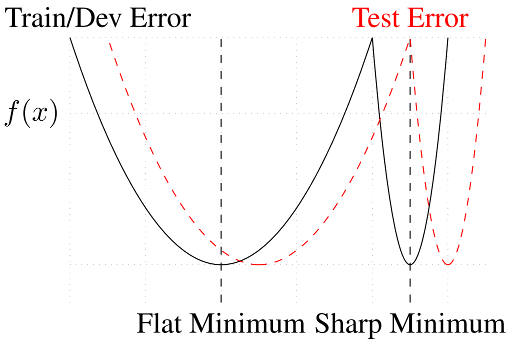

Figure 1: A conceptual sketch of flat and sharp minima from Keskar et al. (2016). The Y-axis indicates values of the error function and the X-axis the weight-space.

As (informally) defined by Hochreiter and Schmidhuber (1997a), a minimum can be flat, where the error function remains approximately constant for a large connected region in weight-space, or it can be sharp, where the error function increases rapidly in

[4] Entity Recognition labels all tokens that refer to an entity in a sentence, also generic phrases like *U.S. president*.

a small neighborhood of the minimum. A conceptual sketch is given in Figure 1. The error functions for training and testing are typically not perfectly synced, i.e. the local minima on the train or development set are not the local minima for the held-out test set. A sharp minimum usually depicts poorer generalization capabilities, as a slight variation results in a rapid increase of the error function. On the other hand, flat minima generalize better on new data (Keskar et al., 2016). Keskar et al. observe for the MNIST, TIMIT, and CIFAR dataset, that the generalization gap is not due to *over-fitting* or *over-training*, but due to different generalization capabilities of the local minima the networks converge to.

A priori it is unknown to which type of local minimum a neural network will converge. Some methods like the weight initialization (Erhan et al., 2010; Glorot and Bengio, 2010) or small-batch training (Keskar et al., 2016) help to avoid bad (e.g. sharp) minima. Nonetheless, the non-deterministic behavior of approaches must be considered when they are evaluated.

3 Impact of Randomness in the Evaluation of Neural Networks

Two recent, state-of-the-art systems for NER are proposed by Ma and Hovy (2016)[5] and by Lample et al. (2016)[6]. Lample et al. report an F_1-score of 90.94% and Ma and Hovy report an F_1-score of 91.21%. Ma and Hovy draw the conclusion that their system achieves a significant improvement over the system by Lample et al.

We re-ran both implementations multiple times, each time only changing the seed value of the random number generator. We ran the Ma and Hovy system 86 times and the Lample et al. system, due to its high computational requirement, for 41 times. The score distribution is depicted as a violin plot in Figure 2. Using a Kolmogorov-Smirnov significance test (Massey, 1951), we observe a statistically significant difference between these two distributions ($p < 0.01$). The plot reveals that the quartiles for the Lample et al. system are above those of the Ma and Hovy system. Further it reveals a smaller standard deviation σ of the F_1-scores for the Lample et al. system. Using a Brown-Forsythe test, the standard deviations are different with $p < 0.05$. Table 1 shows the minimum, the maximum, and the median performance for the test performances.

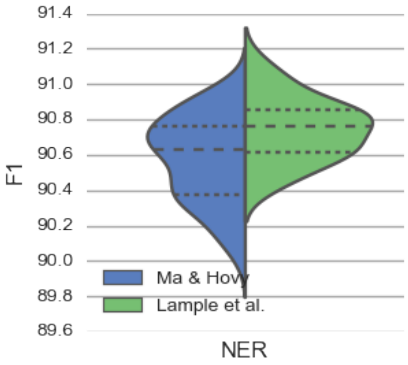

Figure 2: Distribution of scores for re-running the system by Ma and Hovy (left) and Lample et al. (right) multiple times with different seed values. Dashed lines indicate quartiles.

Based on this observation, we draw the conclusion that the system by Lample et al. outperforms the system by Ma and Hovy, as their implementation achieves a higher score distribution and shows a lower standard deviation.

In a usual setup, approaches would be compared on a development set and the run with the highest development score would be used for unseen data, i.e. be used to report the test performance. For the Lample et al. system we observe a Spearman's rank correlation between the development and the test score of $\rho = 0.229$. This indicates a weak correlation and that the performance on the development set is not a reliable indicator. Using the run with the best development score (94.44%) would yield a test performance of mere 90.31%. Using the second best run on development set (94.28%), would yield state-of-the-art performance with 91.00%. This difference is statistically significant ($p < 0.002$). In conclusion, a development set will not necessarily solve the issue with bad local minima.

The main difference between these two approaches is in the generation of character-based representations: Ma and Hovy uses a Convolutional Neural Network (CNN) (LeCun et al., 1989), while Lample et al. uses an LSTM-network. As our experiments in section 6.4 show, both approaches perform comparably if all other parameters were kept the same. Further, we could only observe a

System	Reported F_1	# Seed values	Min. F_1	Median F_1	Max. F_1	σ
Ma and Hovy	91.21%	86	89.99%	90.64%	91.00%	0.00241
Lample et al.	90.94%	41	90.19%	90.81%	91.14%	0.00176

Table 1: The system by Ma and Hovy (2016) and Lample et al. (2016) were run multiple times with different seed values.

Task	Dataset	# Configs	Median Difference	95th percentile	Max. Difference
POS	Penn Treebank	269	0.17%	0.78%	1.55%
Chunking	CoNLL 2000	385	0.17%	0.50%	0.81%
NER	CoNLL 2003	406	0.38%	1.08%	2.59%
Entities	ACE 2005	405	0.72%	2.10%	8.23%
Events	TempEval 3	365	0.43%	1.23%	1.73%

Table 2: The table depicts the median, the 95th percentile and the maximum difference between networks with the same hyperparameters but different random seed values.

statistically significant improvement for the tasks POS, Chunking and Event Detection. For NER and Entity Recognition, the difference was statistically not significant given the number of tested hyperparameters.

In the next step, we evaluated the impact of the random seed value for the five sequence tagging tasks described in section 4. We sampled randomly 1830 different configurations, for example different numbers of recurrent units, and ran the network twice, each time with a different seed value. The results are depicted in Table 2.

The largest difference was observed for the ACE 2005 Entities dataset: Using one seed value, the network achieved an F_1 performance of 82.5% while using another seed value, the network achieved a performance of only 74.3%. Even though this is a rare extreme case, the median difference between different weight initializations is still large. For example for the CoNLL 2003 NER dataset, the median difference is at 0.38% and the 95th percentile is at 1.08%.

In conclusion, if the fact of different local minima is not taken care of and single performance scores are compared, there is a high chance of drawing false conclusions and either rejecting promising approaches or selecting weaker approaches due to a more or less favorable sequence of random numbers.

4 Experimental Setup

In order to find LSTM-network architectures that perform robustly on different tasks, we selected five classical NLP tasks as benchmark tasks: Part-of-Speech tagging (*POS*), Chunking, Named Entity Recognition (*NER*), Entity Recognition (*Entities*) and Event Detection (*Events*).

For Part-of-Speech tagging, we use the benchmark setup described by Toutanova et al. (2003). Using the full training set for POS tagging would hinder our ability to detect design choices that are consistently better than others. The error rate for this dataset is approximately 3% (Marcus et al., 1993), making all improvements above 97% accuracy likely the result of chance. A 97.24% accuracy was achieved by Toutanova et al. (2003). Hence, we reduced the training set size from over 38.000 sentences to the first 500 sentences. This decreased the accuracy to about 95%.

For Chunking, we use the CoNLL 2000 shared task setup. For Named Entity Recognition (NER), we use the CoNLL 2003 setup. The ACE 2005 entity recognition task annotated not only named entities, but all words referring to an entity, e.g. the phrase *U.S. president*. We use the same data split as Li et al. (2013). For the Event Detection task, we use the TempEval3 Task B setup. There, the smallest extent of text, usually a single word, that expresses the occurrence of an event, is annotated.

For the POS-task, we report accuracy and for the other tasks we report the F_1-score.

4.1 Model

We use a BiLSTM-network for sequence tagging as described in (Huang et al., 2015; Ma and Hovy, 2016; Lample et al., 2016). To be able to evaluate a large number of different network configurations, we optimized our implementation for efficiency, reducing by a factor of 6 the time required per epoch compared to Ma and Hovy (2016).

4.2 Evaluated Parameters

We evaluate the following design choices and hyperparameters:

Pre-trained Word Embeddings. We evaluate the Google News embeddings (*G. News*)[7] from Mikolov et al. (2013), the Bag of Words (*Le. BoW*) as well as the dependency based embeddings (*Le. Dep.*)[8] by Levy and Goldberg (2014), three different GloVe embeddings[9] from Pennington et al. (2014) trained either on Wikipedia 2014 + Gigaword 5 (*GloVe1* with 100 dimensions and *GloVe2* with 300 dimensions) or on Common Crawl (*GloVe3*), and the Komninos and Manandhar (2016) embeddings (*Komn.*)[10]. We also evaluate the approach of Bojanowski et al. (2016) (*FastText*), which trains embeddings for n-grams with length 3 to 6. The embedding for a word is defined as the sum of the embeddings of the n-grams.

Character Representation. We evaluate the approaches of Ma and Hovy (2016) using Convolutional Neural Networks (CNN) as well as the approach of Lample et al. (2016) using LSTM-networks to derive character-based representations.

Optimizer. Besides Stochastic Gradient Descent (*SGD*), we evaluate *Adagrad* (Duchi et al., 2011), *Adadelta* (Zeiler, 2012), *RMSProp* (Hinton, 2012), *Adam* (Kingma and Ba, 2014), and *Nadam* (Dozat, 2015), an Adam variant that incorporates Nesterov momentum (Nesterov, 1983) as optimizers.

Gradient Clipping and Normalization. Two common strategies to deal with the exploding gradient problem are *gradient clipping* (Mikolov, 2012) and *gradient normalization* (Pascanu et al., 2013). Gradient clipping involves clipping the gradient's components element-wise if it exceeds a defined threshold. Gradient normalization has a better theoretical justification and rescales the gradient whenever the norm goes over a threshold.

Tagging schemes. We evaluate the *BIO* and *IOBES* schemes for tagging segments.

Dropout. We compare *no dropout*, *naive dropout*, and *variational dropout* (Gal and Ghahramani, 2016). Naive dropout applies a new dropout mask at every time step of the LSTM-layers. Variational dropout applies the same dropout mask for all time steps in the same sentence. Further, it applies dropout to the recurrent units. We evaluate the dropout rates $\{0.05, 0.1, 0.25, 0.5\}$.

Classifier. We evaluate a Softmax classifier as well as a CRF classifier as the last layer of the network.

Number of LSTM-layers. We evaluated *1*, *2*, and *3* stacked BiLSTM-layers.

Number of recurrent units. For each LSTM-layer, we selected independently a number of recurrent units from the set $\{25, 50, 75, 100, 125\}$.

Mini-batch sizes. We evaluate the mini-batch sizes 1, 8, 16, 32, and 64.

5 Robust Model Evaluation

We have shown in section 3 that re-running non-deterministic approaches multiple times and comparing score distributions is essential to draw correct conclusions. However, to truly understand the capabilities of an approach, it is interesting to test the approach with different sets of hyperparameters for the complete network.

Training and tuning a neural network can be time consuming, sometimes taking multiple days to train a single instance of a network. A priori it is hard to know which hyperparameters will yield the best performance and the selection of the parameters often makes the difference between *mediocre* and *state-of-the-art* performance (Hutter et al., 2014). If an approach yields good performance only for a narrow set of parameters, it might be difficult to adapt the approach to new tasks, new domains

[7] https://code.google.com/archive/p/word2vec/

[8] https://levyomer.wordpress.com/2014/04/25/dependency-based-word-embeddings/

[9] http://nlp.stanford.edu/projects/glove/

[10] https://www.cs.york.ac.uk/nlp/extvec/

or new languages, as a large range of possible parameters must be evaluated, each time requiring a significant amount of training time. Hence it is desirable, that the approach yields stable results for a wide range of parameters.

In order to find approaches that result in high performance and are robust against the remaining parameters, we decided to randomly sample several hundred network configurations from the set described in section 4.2. For each sampled configuration, we compare different options, e.g. different options for the last layer of the network. For example, we sampled in total 975 configurations and each configuration was trained with a Softmax classifier as well as with a CRF classifier, totaling to 1950 trained networks.

Dataset	# Configs	Softmax	CRF
POS $\Delta Acc.$	111	18.9% -0.20%	**81.1%**
Chunking ΔF_1	229	4.8% -0.38%	**95.2%**
NER ΔF_1	232	9.5% -0.66%	**90.5%**
Entities ΔF_1	210	13.3% -0.84%	**86.7%**
Events ΔF_1	202	**61.9%**	38.1% -0.15%
Average		21.7%	**78.3%**

Table 3: Percentages of configurations where Softmax or CRF classifiers demonstrated a higher test performance.

Our results are presented in Table 3. The table shows that for the NER task 232 configurations were sampled randomly and for 210 of the 232 configurations (90.5%), the CRF setup achieved a better test performance than the setup with a Softmax classifier. To measure the difference between these two options, we compute the median of the absolute differences: Let S_i be the test performance (F_1-measure) for the Softmax setup for configuration i and C_i the test performance for the CRF setup. We then compute $\Delta F_1 = \text{median}(S_1 - C_1, S_2 - C_2, \ldots, S_{232} - C_{232})$. For the NER task, the median difference was $\Delta F_1 = -0.66\%$, i.e. the setup with a Softmax classifier achieved on average an F_1-score of 0.66 percentage points below that of the CRF setup.

We also evaluated the standard deviation of the F_1-scores to detect approaches that are less dependent on the remaining hyperparameters and the random number generator. The standard deviation σ for the CRF-classifier is with 0.0060 significantly lower ($p < 10^{-3}$ using Brown-Forsythe test) than for the Softmax classifier with $\sigma = 0.0082$.

6 Results

This section highlights our main insights in the evaluation of different design choices for BiLSTM architectures. We limit the number of results we present for reasons of brevity. Detailed information can be found in (Reimers and Gurevych, 2017).[11]

6.1 Classifier

Table 3 shows a comparison between using a Softmax classifier as a last layer and using a CRF classifier. The BiLSTM-CRF architecture by Huang et al. (2015) achieves a better performance on 4 out of 5 tasks. For the NER task it further achieves a 27% lower standard deviation (statistically significant with $p < 10^{-3}$), indicating that it is less sensitive to the remaining configuration of the network.

The CRF classifier only fails for the Event Detection task. This task has nearly no dependency between tags, as often only a single token is annotated as an event trigger in a sentence.

We studied the differences between these two classifiers in terms of number of LSTM-layers. As Figure 3 shows, a Softmax classifier profits from a deep LSTM-network with multiple stacked layers. On the other hand, if a CRF classifier is used, the effect of additional LSTM-layers is much smaller.

6.2 Optimizer

We evaluated six optimizers with the suggested default configuration from their respective papers. We observed that SGD is quite sensitive towards the selection of the learning rate and it failed in many instances to converge. For the optimizers SGD, Adagrad and Adadelta we observed a large standard deviation in terms of test performance,

[11] https://public.ukp.informatik.tu-darmstadt.de/reimers/Optimal_Hyperparameters_for_Deep_LSTM-Networks.pdf

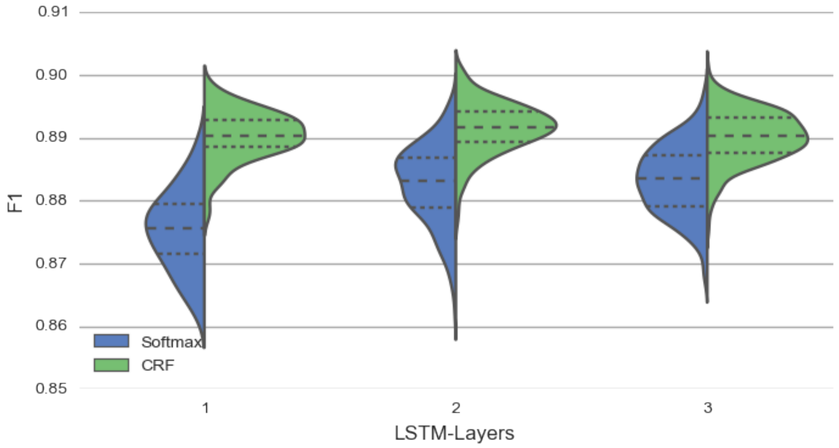

Figure 3: Difference between Softmax and CRF classifier for different number of BiLSTM-layers for the CoNLL 2003 NER dataset.

which was for the NER task at 0.1328 for SGD, 0.0139 for Adagrad, and 0.0138 for Adadelta. The optimizers RMSProp, Adam, and Nadam on the other hand produced much more stable results. Not only were the medians for these three optimizers higher, but also the standard deviation was with 0.0096, 0.0091, and 0.0092 roughly 35% smaller in comparison to Adagrad. A large standard deviation indicates that the optimizer is sensitive to the hyperparameters as well as to the random initialization and bears the risk that the optimizer produces subpar results.

The best result was achieved by Nadam. For 453 out of 882 configurations (51.4%), it yielded the highest performance out of the six tested optimizers. For the NER task, it produced on average a 0.82 percentage points better performance than Adagrad.

Besides test performance, the convergence speed is important in order to reduce training time. Here, Nadam had the best convergence speed. For the NER dataset, Nadam converged on average after 9 epochs, whereas SGD required 42 epochs.

6.3 Word Embeddings

The pre-trained word embeddings had a large impact on the performance as shown in Table 4. The embeddings by Komninos and Manandhar (2016) resulted in the best performance for the POS, the Entities and the Events task. For the Chunking task, the dependency-based embeddings of Levy and Goldberg (2014) are slightly ahead of the Komninos embeddings, the significance level is at $p = 0.025$. For NER, the GloVe embeddings trained on common crawl perform on par with the Komninos embeddings ($p = 0.391$).

We observe that the underlying word embeddings have a large impact on the performance for all tasks. Well suited word embeddings are especially critical for datasets with small training sets. For the POS task we observe a median difference of 4.97% between the Komninos embeddings and the GloVe2 embeddings.

Note we only evaluated the pre-trained embeddings provided by different authors, but not the underlying algorithms to generate these embeddings. The quality of word embeddings depends on many factors, including the size, the quality, and the preprocessing of the data corpus. As the corpora are not comparable, our results do not allow concluding that one approach is superior for generating word embeddings.

6.4 Character Representation

We evaluate the approaches of Ma and Hovy (2016) using Convolutional Neural Networks (CNN) as well as the approach of Lample et al. (2016) using LSTM-networks to derive character-based representations.

Table 5 shows that character-based representations yield a statistically significant difference only for the POS, the Chunking, and the Events task. For NER and Entity Recognition, the difference to not using a character-based representation is not significant ($p > 0.01$).

Dataset	Le. Dep.	Le. BoW	GloVe1	GloVe2	GloVe3	Komn.	G. News	FastText
POS $\Delta Acc.$	6.5% -0.39%	0.0% -2.52%	0.0% -4.14%	0.0% -4.97%	0.0% -2.60%	**93.5%**	0.0% -1.95%	0.0% -2.28%
Chunking ΔF_1	**60.8%**	0.0% -0.52%	0.0% -1.09%	0.0% -1.50%	0.0% -0.93%	37.1% -0.10%	2.1% -0.48%	0.0% -0.75%
NER ΔF_1	4.5% -0.85%	0.0% -1.17%	22.7% -0.15%	0.0% -0.73%	**43.6%**	27.3% -0.08%	1.8% -0.75%	0.0% -0.89%
Entities ΔF_1	4.2% -0.92%	7.6% -0.89%	0.8% -1.50%	0.0% -2.24%	6.7% -0.80%	**57.1%**	21.8% -0.33%	1.7% -1.13%
Events ΔF_1	12.9% -0.55%	4.8% -0.78%	0.0% -2.77%	0.0% -3.55%	0.0% -2.55%	**71.8%**	9.7% -0.67%	0.8% -1.36%
Average	17.8%	2.5%	4.7%	0.0%	10.1%	**57.4%**	7.1%	0.5%

Table 4: Randomly sampled configurations were evaluated with 8 possible word embeddings. 108 configurations were sampled for POS, 97 for Chunking, 110 for NER, 119 for Entities, and 124 for Events.

The difference between the CNN approach by Ma and Hovy (2016) and the LSTM approach by Lample et al. (2016) to derive a character-based representations is statistically insignificant for all tasks. This is quite surprising, as both approaches have fundamentally different properties: The CNN approach from Ma and Hovy (2016) takes only trigrams into account. It is also position independent, i.e. the network will not be able to distinguish between trigrams at the beginning, in the middle, or at the end of a word, which can be crucial information for some tasks. The BiLSTM approach from Lample et al. (2016) takes all characters of the word into account. Further, it is position aware, i.e. it can distinguish between characters at the start and at the end of the word. Intuitively, one would think that the LSTM approach by Lample et al. would be superior.

Task	No	CNN	LSTM
POS $\Delta Acc.$	4.9% -0.90%	**58.2%**	36.9% -0.05%
Chunking ΔF_1	13.3% -0.20%	43.2% -0.00%	**43.6%**
NER ΔF_1	27.2% -0.11%	**36.4%**	36.4% -0.01%
Entities ΔF_1	26.8% -0.07%	36.0% 0.00%	**37.3%**
Events ΔF_1	20.5% -0.44%	35.6% -0.04%	**43.8%**
Average	18.5%	**41.9%**	39.6%

Table 5: Comparison of not using character-based representations and using CNNs (Ma and Hovy, 2016) or LSTMs (Lample et al., 2016) to derive character-based representations. 225 configurations were sampled for POS, 241 for Chunking, 217 for NER, 228 for Entities, and 219 for Events.

6.5 Gradient Clipping and Normalization

For *gradient clipping* (Mikolov, 2012) we couldn't observe any improvement for the thresholds of 1, 3, 5, and 10 for any of the five tasks.

Gradient normalization has a better theoretical justification (Pascanu et al., 2013) and we can confirm with our experiments that it performs better. Not normalizing the gradient was the best option only for 5.6% of the 492 evaluated configurations (under null-hypothesis we would expect 20%). Which threshold to choose, as long as it is not too small or too large, is of lower importance. In most cases, a threshold of 1 was the best option (30.5% of the cases).

We observed a large performance increase compared to not normalizing the gradient. The median increase was between 0.29 percentage points F_1-score for the Chunking task and 0.82 percentage points for the POS task.

6.6 Dropout

Dropout is a popular method to deal with overfitting for neural networks (Srivastava et al., 2014). We could observe that *variational dropout* (Gal and Ghahramani, 2016) clearly outperforms *naive dropout* and not using dropout. It was the best option in 83.5% of the 479 evaluated configurations. The median performance increase in comparison to not using dropout was between 0.31 percentage points for the POS-task and 1.98 for the Entities task. We also observed a large improvement in comparison to naive dropout between 0.19 percentage points for the POS task and 1.32 percentage points for the Entities task. Variational dropout showed the smallest standard deviation, indicating that it is less dependent on the remaining hyperparameters and the random number sequence.

We further evaluated whether variational dropout should be applied to the output units of the LSTM-network, to the recurrent units, or to both. We observed that applying dropout to both dimensions gave in most cases (62.6%) the best results. The median performance increase was between 0.05 percentage points and 0.82 percentage points.

6.7 Further Evaluated Parameters

The tagging schemes `BIO` and `IOBES` performed on par for 4 out of 5 tasks. For the Entities task, the `BIO` scheme significantly outperformed the `IOBES` scheme for 88.7% of the tested configurations. The median difference was $\Delta F_1 = -1.01\%$.

For the evaluated tasks, 2 stacked LSTM-layers achieved the best performance. For the POS-tagging task, 1 and 2 layers performed on par. For flat networks with a single LSTM-layer, around 150 recurrent units yielded the best performance. For networks with 2 or 3 layers, around 100 recurrent units per network yielded the best performance. However, the impact of the number of recurrent units was extremely small.

For tasks with small training sets, smaller mini-batch sizes of 1 up to 16 appears to be a good choice. For larger training sets sizes of 8 - 32 appears to be a good choice. Mini-batch sizes of 64 usually performed worst.

7 Conclusion

In this paper, we demonstrated that the sequence of random numbers has a *statistically significant* impact on the test performance and that wrong conclusions can be made if performance scores based on single runs are compared. We demonstrated this for the two recent state-of-the-art NER systems by Ma and Hovy (2016) and Lample et al. (2016). Based on the published performance scores, Ma and Hovy draw the conclusion of a significant improvement over the approach of Lample et al. Re-executing the provided implementations with different seed values however showed that the implementation of Lample et al. results in a superior score distribution generalizing better to unseen data.

Comparing score distributions reduces the risk of rejecting promising approaches or falsely accepting weaker approaches. Further it can lead to new insights on the properties of an approach. We demonstrated this for ten design choices and hyperparameters of LSTM-networks for five tasks.

By studying the standard deviation of scores, we estimated the dependence on hyperparameters and on the random seed value for different approaches. We showed that SGD, Adagrad and Adadelta have a higher dependence than RMSProp, Adam or Nadam. We have shown that variational dropout also reduces the dependence on the hyperparameters and on the random seed value. As future work, we will investigate if those methods are either less dependent on the hyperparameters or are less dependent on the random seed value, e.g. if they avoid converging to bad local minima.

By testing a large number of configurations, we showed that some choices consistently lead to superior performance and are less dependent on the remaining configuration of the network. Thus, there is a good chance that these configurations require less tuning when applied to new tasks or domains.

Abstract

We introduce a novel neural easy-first decoder that learns to solve sequence tagging tasks in a flexible order. In contrast to previous easy-first decoders, our models are end-to-end differentiable. The decoder iteratively updates a "sketch" of the predictions over the sequence. At its core is an attention mechanism that controls which parts of the input are strategically the best to process next. We present a new constrained softmax transformation that ensures the same cumulative attention to every word, and show how to efficiently evaluate and backpropagate over it. Our models compare favourably to BILSTM taggers on three sequence tagging tasks.

1 Introduction

In the last years, neural models have led to major advances in several structured NLP problems, including sequence tagging (Plank et al., 2016; Lample et al., 2016), sequence-to-sequence prediction (Sutskever et al., 2014), and sequence-to-tree (Dyer et al., 2015). Part of the success comes from clever architectures such as (bidirectional) long-short term memories (BILSTMs; Hochreiter and Schmidhuber (1997); Graves et al. (2005)) and attention mechanisms (Bahdanau et al., 2015), which are able to select the pieces of context relevant for prediction.

A noticeable aspect about many of the systems above is that they typically decode from left to right, greedily or with a narrow beam. While this is computationally convenient and reminiscent of the way humans process spoken language, the combination of unidirectional decoding and greediness leads to error propagation and suboptimal classification performance. This can partly be mitigated by globally normalized models (Andor et al., 2016) and imitation learning (Daumé et al., 2009; Ross et al., 2011; Bengio et al., 2015), however these techniques still have a left-to-right bias.

Easy-first decoders (Tsuruoka and Tsujii, 2005; Goldberg and Elhadad, 2010, §2) are an interesting alternative: instead of a fixed decoding order, these methods schedule their own actions by prefering "easier" decisions over more difficult ones. A disadvantage is that these models are harder to learn, due to the factorial number of orderings leading to correct predictions. Usually, gradients are *not* backpropagated over this combinatorial latent space (Kiperwasser and Goldberg, 2016a), or a separate model is used to determine the easiest next move (Clark and Manning, 2016).

In this paper, we develop novel, **fully differentiable, neural easy-first sequence taggers** (§3). Instead of taking discrete actions, our decoders use an attention mechanism to decide (in a soft manner) which word to focus on for the next tagging decision. Our models are able to learn their own sense of "easiness": the words receiving focus may not be the ones the model is most confident about, but the best to avoid error propagation in the long run. To make sure that all words receive the same cumulative attention, we further contribute with a new **constrained softmax transformation** (§4). This transformation extends the softmax by permitting upper bound constraints on the amount of probability a word can receive. We show how to evaluate this transformation and backpropagate its gradients.

We run experiments in three sequence tagging tasks: multilingual part-of-speech (POS) tagging, named entity recognition (NER), and word-level quality estimation (§5). We complement our findings with a visual analysis of the attention distribu-

Algorithm 1 Easy-First Sequence Tagging

```
Input: input sequence $x_{1:L}$
Output: tagged sequence $\widehat{y}_{1:L}$
1: initialize $\mathcal{B} = \mathcal{S} = \varnothing$
2: while $\mathcal{B} \neq \{1, \dots, L\}$ do
3:     for each non-covered position $i \notin \mathcal{B}$ do
4:         compute scores $f(i, y_i; x_{1:L}, \mathcal{S}),\ \forall y_i$
5:     end for
6:     $(j, \widehat{y}_j) = \mathsf{argmax}_{i,y_i}\ f(i, y_i; x_{1:L}, \mathcal{S})$
7:     $\mathcal{S} \leftarrow \mathcal{S} \cup \{(j, \widehat{y}_j)\}, \mathcal{B} \leftarrow \mathcal{B} \cup \{j\}$
8: end while
```

tions produced by the decoder, to help understand what tagging decisions the model finds the easiest.

2 Easy-First Decoders

The idea behind easy-first decoding is to perform "easier" and less risky decisions before committing to more difficult ones (Tsuruoka and Tsujii, 2005; Goldberg and Elhadad, 2010; Ma et al., 2013). Alg. 1 shows the overall procedure for a sequence tagging problem (the idea carries out to other structured problems). Let $x_{1:L}$ be an input sequence (e.g. words in a sentence) and $y_{1:L}$ be the corresponding tag sequence (e.g. their POS tags). The algorithm assigns tags one position i at the time, maintaining a set $\mathcal{B}$ of **covered positions**. It also maintains a set $\mathcal{S}$ of pairs $(i, \widehat{y}_i)$, storing the tags that have already been predicted at those positions. We can regard this set as a **sketch** of the output sequence, built incrementally while the algorithm is executed. At each time step, the model computes a score $f(i, y_i; x_{1:L}, \mathcal{S})$ for each position $i \notin \mathcal{B}$ and each candidate tag y_i, taking into account the current "sketch" $\mathcal{S}$, which provides useful contextual information. The "easiest" position and the corresponding tag are then jointly obtained by maximizing this score (line 6). The algorithm terminates when all positions are covered.

Previous work has trained easy-first systems with variants of the perceptron algorithm (Goldberg and Elhadad, 2010; Ma et al., 2013) or with a gradient-based method (Kiperwasser and Goldberg, 2016a)—but without backpropagating information about the best ordering chosen by the algorithm (only tag mistakes). In fact, doing so directly would be hard, since the space of possible orderings is combinatorial—the argmax in line 6 is not continuous, let alone differentiable. In the next section, we introduce a fully differentiable easy-first system that sidesteps this problem by working with a "continuous" space of actions.

Attention Mechanism
Sketch Generator
Input/Sketch Representation
From the AP comes this story

Figure 1: A neural easy-first system applied to a POS tagging problem. Given the current input/sketch representation, an attention mechanism decides where to focus (see bar plot) and is used to generate the next sketch. Right: A sequence of sketches $(\mathbf{S}^n)_{n=1}^N$ generated along the way.

3 Neural Easy-First Sequence Taggers

Let $\Delta^{L-1} := \{\boldsymbol{\alpha} \in \mathbb{R}^L \,|\, \mathbf{1}^\top \boldsymbol{\alpha} = 1, \boldsymbol{\alpha} \geq \mathbf{0}\}$ be the probability simplex. Our **neural easy-first decoders** depart from Alg. 1 in the following key points:

- Instead of picking the position with the largest score at each step (line 6 in Alg. 1), we compute a (continuous) attention distribution $\boldsymbol{\alpha} \in \Delta^{L-1}$ over word positions.
- Instead of a set of covered positions $\mathcal{B}$, we maintain a (continuous) **cumulative attention vector $\boldsymbol{\beta}$** $\in \mathbb{R}^L$ (ideally in $[0,1]^L$) over the L positions in the sequence.
- The sketch set $\mathcal{S}$ is replaced by a **sketch matrix $\mathbf{S}$** $\in \mathbb{R}^{D_s \times L}$, whose columns are D_s-dimensional vector representations of the output labels to be predicted.

The high-level procedure is shown in Figure 1. We describe two models that implement this procedure: a **single-state model** and a **full-state model**. They differ in the way they update the sketch matrix: the single-state model applies a rank-one update, while the full-state model does a full update.

3.1 Single-State Model (NEF-S)

Let $\mathsf{concat}(\boldsymbol{x}_1, \dots, \boldsymbol{x}_K) \in \mathbb{R}^{\sum_{k=1}^K D_k}$ be the concatenation of the vectors $\boldsymbol{x}_k \in \mathbb{R}^{D_k}$. We use the shorthand $\mathsf{affine}(\boldsymbol{x}) := \mathbf{W}\boldsymbol{x} + \boldsymbol{b}$ to denote an affine transformation of $\boldsymbol{x}$, where $\mathbf{W}$ is a weight matrix and $\boldsymbol{b}$ is a bias vector.

Alg. 2 shows the overall procedure. We start by encoding the input sequence $x_{1:L}$ as a matrix

Algorithm 2 Neural Easy-First Sequence Tagging

```
Input: input sequence $x_{1:L}$, sketch steps $N$
Output: tagged sequence $\widehat{y}_{1:L}$
 1: initialize $\boldsymbol{\beta}^0 = \mathbf{0}$ and $\boldsymbol{s}_i^0 = \mathbf{0}$, $\forall i \in [L]$
 2: encode sequence as $[\boldsymbol{h}_1, \ldots, \boldsymbol{h}_L]$
 3: for $n = 1, 2, \ldots, N$ do
 4:     for each position $i \in [L]$ do
 5:         compute $\boldsymbol{c}_i^n$ and $z_i^n$ (Eqs. 1–2)
 6:     end for
 7:     compute attention $\boldsymbol{\alpha}^n = \rho(\boldsymbol{z}^n; \boldsymbol{\beta}^{n-1})$
 8:     for each position $i \in [L]$ do
 9:         refine sketch $\boldsymbol{s}_i^n$ from $\alpha_i^n$ and $\boldsymbol{c}_i^n$, via Eq. 4 (single-state) or Eq. 7 (full-state)
10:     end for
11:     $\boldsymbol{\beta}^n = \boldsymbol{\beta}^{n-1} + \boldsymbol{\alpha}^n$
12: end for
13: for each position $i \in [L]$ do
14:     $\boldsymbol{p}_i = \mathsf{softmax}(\mathsf{affine}(\mathsf{concat}(\boldsymbol{h}_i, \boldsymbol{s}_i^N)))$
15:     predict $\widehat{y}_i = \mathsf{argmax}_{y_i}\, p_i(y_i)$
16: end for
```

$\mathbf{H} = [\boldsymbol{h}_1, \ldots, \boldsymbol{h}_L] \in \mathbb{R}^{D_h \times L}$ (line 2). Our model is completely agnostic about this encoding step. In our experiments, we compute $\mathbf{H}$ by composing a lookup embedding layer with a BILSTM (Hochreiter and Schmidhuber, 1997; Graves et al., 2005), as this strategy was successful in similar structured prediction tasks. However, other choices are possible, for example using convolutional layers.

As stated above, our algorithm maintains a cumulative attention vector $\boldsymbol{\beta} \in \mathbb{R}^L$ and a sketch matrix $\mathbf{S} \in \mathbb{R}^{D_s \times L}$, both with all entries initialized to zero. It then performs N sketching steps, which progressively refine this sketch matrix, producing versions $\mathbf{S}^1, \ldots, \mathbf{S}^N$. At the nth step, the following operations are performed:

Input-Sketch Contextual Representation. For each word $i \in [L]$, we compute a state $\boldsymbol{c}_i^n$ summarizing the surrounding local information about other words and sketches. We use a simple vector concatenation over a w-wide context window:

$$\boldsymbol{c}_i^n = \mathsf{concat}(\boldsymbol{h}_{i-w}, \ldots, \boldsymbol{h}_{i+w}, \boldsymbol{s}_{i-w}^{n-1}, \ldots, \boldsymbol{s}_{i+w}^{n-1}), \tag{1}$$

where we denote by $\boldsymbol{s}_j^{n-1}$ the jth column of $\mathbf{S}^{n-1}$. The intuition is that the current sketches provide valuable information about the neighboring words' predictions that can influence the prediction for the ith word. In the vanilla easy-first algorithm, this was assumed in the score computation (line 4 of Alg. 1).

Attention Mechanism. We then use an attention mechanism to decide what is the "best" word to focus on next. This is done in a similar way as the feedforward attention proposed by Bahdanau et al. (2015). We first compute a score for each word $i \in [L]$ based on its contextual representation,

$$z_i^n = \boldsymbol{v}^\top \mathsf{tanh}(\mathsf{affine}(\boldsymbol{c}_i^n)), \tag{2}$$

where $\boldsymbol{v} \in \mathbb{R}^{D_z}$ is a model parameter. Then, we aggregate these scores in a vector $\boldsymbol{z}^n \in \mathbb{R}^L$ and apply a transformation ρ to map them to a probability distribution $\boldsymbol{\alpha}^n \in \Delta^{L-1}$ (optionally taking into account the past cumulative attention $\boldsymbol{\beta}^{n-1}$):

$$\boldsymbol{\alpha}^n = \rho(\boldsymbol{z}^n; \boldsymbol{\beta}^{n-1}). \tag{3}$$

The "standard" choice for ρ is the softmax transformation. However, in this work, we consider other possible transformations (to be described in §4). After this, the cumulative attention is updated via $\boldsymbol{\beta}^n = \boldsymbol{\beta}^{n-1} + \boldsymbol{\alpha}^n$.

Sketch Generation. Now that we have a distribution $\boldsymbol{\alpha}^n \in \Delta^{L-1}$ over word positions, it remains to generate a sketch for those words. We first compute a **single-state** vector representation of the entire sentence $\bar{\boldsymbol{c}}^n = \sum_{i=1}^L \alpha_i^n \boldsymbol{c}_i^n$ as the weighted average of the word states defined in Eq. 1. Then, we update each column of the sketch matrix as:[1]

$$\boldsymbol{s}_i^n = \boldsymbol{s}_i^{n-1} + \alpha_i^n \cdot \mathsf{tanh}(\mathsf{affine}(\bar{\boldsymbol{c}}^n)), \;\; \forall i \in [L]. \tag{4}$$

The intuition for this update is the following: in the extreme case where the attention distribution is peaked on a single word (say, the kth word, $\boldsymbol{\alpha}^n = \boldsymbol{e}_k$), we obtain $\bar{\boldsymbol{c}}^n = \boldsymbol{c}_k^n$ and the sketch update only affects that word, i.e.,

$$\boldsymbol{s}_i^n = \begin{cases} \boldsymbol{s}_i^{n-1} + \mathsf{tanh}(\mathsf{affine}(\boldsymbol{c}_k^n)) & \text{if } i = k \\ \boldsymbol{s}_i^{n-1} & \text{if } i \neq k. \end{cases} \tag{5}$$

This is similar to the sketch update in the original easy-first algorithm (line 7 in Alg. 1).

The three operations above are repeated N times (or "sketch steps"). The standard choice is $N = L$ (one step per word), which mimics the vanilla easy-first algorithm. However, it is possible to have fewer steps (or more, if we want the decoder to be able to "self-correct"). After completing the N sketch steps, we obtain the final sketch matrix $\mathbf{S}^N = [\boldsymbol{s}_1^N, \ldots, \boldsymbol{s}_L^N]$. Then, we compute a tag probability for every word as follows:[2]

$$\boldsymbol{p}_i = \mathsf{softmax}(\mathsf{affine}(\mathsf{concat}(\boldsymbol{h}_i, \boldsymbol{s}_i^N))). \tag{6}$$

[1] Note that this is a rank-one update, as it can be written in matrix notation as $\mathbf{S}^n = \mathbf{S}^{n-1} + \mathsf{tanh}(\mathsf{affine}(\bar{\boldsymbol{c}}^n)) \cdot \boldsymbol{\alpha}^{n\top}$.

[2] We found the concatenation with $\boldsymbol{h}_i$ in Eq. 6 beneficial to transfer input information directly to the output layer, avoiding the need of flowing this information through the sketches.

In §5, we compare this to a BILSTM tagger, which predicts according to $\boldsymbol{p}_i = \mathsf{softmax}(\mathsf{affine}(\boldsymbol{h}_i))$.

3.2 Full-State Model (NEF-F)

The full-state model differs from the single-state model in §3.1 by computing a full matrix for every sketch step, instead of a single vector. Namely, instead of Eq. 4, it does the following sketch update for every word $i \in [L]$:

$$\boldsymbol{s}_i^n = \boldsymbol{s}_i^{n-1} + \alpha_i^n \cdot \mathsf{tanh}(\mathsf{affine}(\boldsymbol{c}_i^n)). \quad (7)$$

Note that the only difference is in replacing the single vector $\bar{\boldsymbol{c}}^n$ by the word-specific vector $\boldsymbol{c}_i^n$. As a result, this is no longer a rank-one update of the sketch matrix, but a full update. In the extreme case where the attention is peaked on a single word, the sketch update reduces to the same form as in the single-state model (Eq. 5). However, the full-state model is generally more flexible and allows processing words in parallel, since it allows different sketch updates for multiple words receiving attention, instead of trying to force those words to receive the same update. We will see in the experiments (§5) that this flexibility can be important in practice.

3.3 Computational Complexity

For both models, assuming that the $\rho(\boldsymbol{z}; \boldsymbol{\beta})$ transformation in Eq. 3 takes $O(L)$ time to compute, the total runtime of Alg. 2 is $O((N+K)L)$ (where K is the number of tags), which becomes $O(L^2)$ if $K \leq N = L$. This is so because the input-sketch representation, the attention mechanism, and the sketch generation step all have $O(L)$ complexity, and the final softmax layer requires $O(KL)$ operations. This is the same runtime of the vanilla easy-first algorithm, though the latter can be reduced to $O(KL\log L)$ with caching and a heap, if the scores in line 4 depend only on local sketches (Goldberg and Elhadad, 2010). By comparison, a standard BILSTM tagger has runtime $O(KL)$.

4 Constrained Softmax Attention

An important part of our models is their attention component (line 7 in Alg. 2). To keep the "easy-first" intuition, we would like the transformation ρ in Eq. 3 to have a couple of properties:

1. **Sparsity:** being able to generate sparse distributions $\boldsymbol{\alpha}^n$ (ideally, peaked on a single word).
2. **Evenness:** over iterations, spreading attention evenly over the words. Ideally, the cumulative attention should satisfy $\boldsymbol{\beta}^n \in [0,1]^L$ for every $n \in [N]$ and $\boldsymbol{\beta}^N = \mathbf{1}$.

The standard choice for attention mechanisms is the **softmax** transformation, $\boldsymbol{\alpha}^n = \mathsf{softmax}(\boldsymbol{z}^n)$. However, the softmax does not satisfy either of the properties above. For the first requirement, we could incorporate a "temperature" parameter in the softmax to push for more peaked distributions. However, this does not guarantee sparsity (only "hard attention" in the limit) and we found it numerically unstable when plugged in Alg. 2. For the second one, we could add a penalty before the softmax transformation, $\boldsymbol{\alpha}^n = \mathsf{softmax}(\boldsymbol{z}^n - \lambda\boldsymbol{\beta}^{n-1})$, where $\lambda \geq 0$ is a tunable hyperparameter. This strategy was found effective to prevent a word to receive too much attention, but it made the model less accurate.

An alternative is the **sparsemax** transformation (Martins and Astudillo, 2016):

$$\mathsf{sparsemax}(\boldsymbol{z}) = \underset{\boldsymbol{\alpha} \in \Delta^{L-1}}{\mathsf{argmin}} \|\boldsymbol{\alpha} - \boldsymbol{z}\|^2. \quad (8)$$

The sparsemax maintains most of the appealing properties of the softmax (efficiency to evaluate and backpropagate), and it is able to generate truly sparse distributions. However, it still does not satisfy the "evenness" property.

Instead, we propose a novel **constrained softmax** transformation that satisfies both requirements. It resembles the standard softmax, but it allows imposing hard constraints on the maximal probability assigned to each word. Let us start by writing the (standard) softmax in the following variational form (**?**):

$$\begin{aligned} \mathsf{softmax}(\boldsymbol{z}) &= \underset{\boldsymbol{\alpha} \in \Delta^{L-1}}{\mathsf{argmin}}\ \mathbf{KL}(\boldsymbol{\alpha} \| \mathsf{softmax}(\boldsymbol{z})) \\ &= \underset{\boldsymbol{\alpha} \in \Delta^{L-1}}{\mathsf{argmin}}\ -\mathbf{H}(\boldsymbol{\alpha}) - \boldsymbol{z}^\top \boldsymbol{\alpha}, \quad (9) \end{aligned}$$

where **KL** and **H** denote the Kullback-Leibler divergence and the entropy, respectively. Based on this observation, we define the constrained softmax transformation as follows:

$$\begin{aligned} \mathsf{csoftmax}(\boldsymbol{z}; \boldsymbol{u}) &= \underset{\boldsymbol{\alpha} \in \Delta^{L-1}}{\mathsf{argmin}}\ -\mathbf{H}(\boldsymbol{\alpha}) - \boldsymbol{z}^\top \boldsymbol{\alpha} \\ &\qquad \text{s.t.} \quad \boldsymbol{\alpha} \leq \boldsymbol{u}, \quad (10) \end{aligned}$$

where $\boldsymbol{u} \in \mathbb{R}^L$ is a vector of upper bounds. Note that, if $\boldsymbol{u} \geq \mathbf{1}$, all constraints are loose and this

Algorithm 3 Constrained Softmax Forward

```
Input: $\boldsymbol{z}, \boldsymbol{u}$
Output: $\boldsymbol{\alpha} = \mathsf{csoftmax}(\boldsymbol{z}; \boldsymbol{u})$
initialize $s := 0, \mathcal{A} := [L], Z := \sum_{i=1}^{K} \mathsf{exp}(z_i)$
sort $q_{i_1} \geq \ldots \geq q_{i_L}$, where $q_i = \mathsf{exp}(z_i)/u_i, \forall i \in [L]$
for $k = 1$ to $L$ do
    $\alpha_{i_k} := \mathsf{exp}(z_{i_k})(1-s)/Z$
    if $\alpha_{i_k} > u_{i_k}$ then
        $Z := Z - \mathsf{exp}(z_{i_k})$
        $\alpha_{i_k} := u_{i_k}, \quad s := s + u_{i_k}, \quad \mathcal{A} := \mathcal{A} \setminus \{i_k\}$
    end if
end for
```

reduces to the standard softmax; on the contrary, if $\boldsymbol{u} \in \Delta^{L-1}$, they are tight and we must have $\boldsymbol{\alpha} = \boldsymbol{u}$ due to the normalization constraint. Thus, we propose the following for Eq. 3:

$$\boldsymbol{\alpha}^n = \mathsf{csoftmax}(\boldsymbol{z}^n; \mathbf{1} - \boldsymbol{\beta}^{n-1}). \tag{11}$$

The constraints guarantee $\boldsymbol{\beta}^n = \boldsymbol{\beta}^{n-1} + \boldsymbol{\alpha}^n \leq \mathbf{1}$. Since $\mathbf{1}^\top \boldsymbol{\beta}^N = \sum_{n=1}^{N} \mathbf{1}^\top \boldsymbol{\alpha}^n = N$, they also ensure that $\boldsymbol{\beta}^N = \mathbf{1}$, hence the "evenness" property is fully satisfied. Intuitively, each word gets a credit of one unit of attention that is consumed during the execution of the algorithm. When this credit expires, all subsequent attention weights for that word will be zero.

The next proposition shows how to evaluate the constrained softmax and compute its gradients.

Proposition 1 *Let* $\boldsymbol{\alpha} = \mathsf{csoftmax}(\boldsymbol{z}; \boldsymbol{u})$*, and define the set* $\mathcal{A} = \{i \in [L] \mid \alpha_i < u_i\}$ *of the constraints in Eq. 10 that are met strictly. Then:*

- **Forward propagation.** *The solution of Eq. 10 can be written in closed form as* $\alpha_i = \min\{\mathsf{exp}(z_i)/Z, u_i\}$*, where* $Z = \frac{\sum_{i \in \mathcal{A}} \mathsf{exp}(z_i)}{1 - \sum_{i \notin \mathcal{A}} u_i}$.
- **Gradient backpropagation.** *Let* $L(\boldsymbol{\theta})$ *be a loss function,* $\mathrm{d}\boldsymbol{\alpha} = \nabla_{\boldsymbol{\alpha}} L(\boldsymbol{\theta})$ *be the output gradient, and* $\mathrm{d}\boldsymbol{z} = \nabla_{\boldsymbol{z}} L(\boldsymbol{\theta})$ *and* $\mathrm{d}\boldsymbol{u} = \nabla_{\boldsymbol{u}} L(\boldsymbol{\theta})$ *be the input gradients. Then, we have:*

$$\mathrm{d}z_i = \mathbb{1}(i \in \mathcal{A})\alpha_i(\mathrm{d}\alpha_i - m) \tag{12}$$

$$\mathrm{d}u_i = \mathbb{1}(i \notin \mathcal{A})(\mathrm{d}\alpha_i - m), \tag{13}$$

where $m = (\sum_{i \in \mathcal{A}} \alpha_i \, \mathrm{d}\alpha_i)/(1 - \sum_{i \notin \mathcal{A}} u_i)$.

Proof: See App. A (supplementary material). ■

Algs. 3–4 turn the results in Prop. 1 into concrete procedures for evaluating csoftmax and for backpropagating its gradient. Their runtimes are respectively $O(L \log L)$ and $O(L)$.

Algorithm 4 Constrained Softmax Backprop

```
Input: $\boldsymbol{z}, \boldsymbol{u}, \mathrm{d}\boldsymbol{\alpha}$ (and cached $\boldsymbol{\alpha}, \mathcal{A}, s$ from Alg. 3)
Output: $\mathrm{d}\boldsymbol{z}, \mathrm{d}\boldsymbol{u}$
$m := \sum_{i \in \mathcal{A}} \alpha_i \, \mathrm{d}\alpha_i/(1-s)$
for $i \in [L]$ do
    if $i \in \mathcal{A}$ then
        $\mathrm{d}z_i := \alpha_i(\mathrm{d}\alpha_i - m), \quad \mathrm{d}u_i := 0$
    else
        $\mathrm{d}z_i := 0, \quad \mathrm{d}u_i := \mathrm{d}\alpha_i - m$
    end if
end for
```

5 Experiments

We evaluate our neural easy-first models in three sequence tagging tasks: POS tagging, NER, and word quality estimation.

5.1 Part-of-Speech Tagging

We ran POS tagging experiments in 12 languages from the Universal Dependencies project v1.4 (Nivre et al., 2016), using the standard splits. The datasets contain 17 universal tags.[3]

We implemented Alg. 2 in DyNet (Neubig et al., 2017), which we extended with the constrained softmax operator (Algs. 3–4).[4] We used 64-dimensional word embeddings, initialized with pre-trained Polyglot vectors (Al-Rfou et al., 2013). Apart from the words, we embedded prefix and suffix character n-grams with $n \leq 4$. We set the affix embedding size to 50 and summed all these embeddings; in the end, we obtained a 164-dimensional representation for each word (words, prefixes, and suffixes). We then fed these embeddings into a BILSTM (with 50 hidden units in each direction) to obtain the encoder states $[\boldsymbol{h}_1, \ldots, \boldsymbol{h}_L] \in \mathbb{R}^{100 \times L}$. The other hyperparameters were set as follows: we used a context size $w = 2$, set the pre-attention size D_z and the sketch size D_s to 50, and applied dropout with a probability of 0.2 after the embedding and BILSTM layers and before the final softmax output layer.[5] We ran 20 epochs of Adagrad to minimize the cross-entropy loss, with a stepsize of 0.1, and gradient

[3] Our choice of languages covers 8 families: Romance (French, Portuguese, Spanish), Germanic (English, German), Slavic (Czech, Russian), Semitic (Arabic), Indo-Iranian (Hindi), Austronesian (Indonesian), Sino-Tibetan (Chinese), and Japonic (Japanese). For all languages, we used the datasets that have the canonical language name, except for Russian, where we used the (much larger) SynTagRus corpus. We prefered large datasets over small ones, to reduce the impact of overfitting in our analysis.

[4] The code is available at `https://github.com/Unbabel/neural-easy-first`.

[5] These hyperparameters were tuned in the English development set, and kept fixed across languages.

Table 1: POS tagging accuracies. The average in the rightmost column is over the words of each treebank. †Note that Gillick et al. (2016) and Plank et al. (2016) are not strictly comparable, since they use older versions of the treebanks (UD1.1 and UD1.2, respectively).

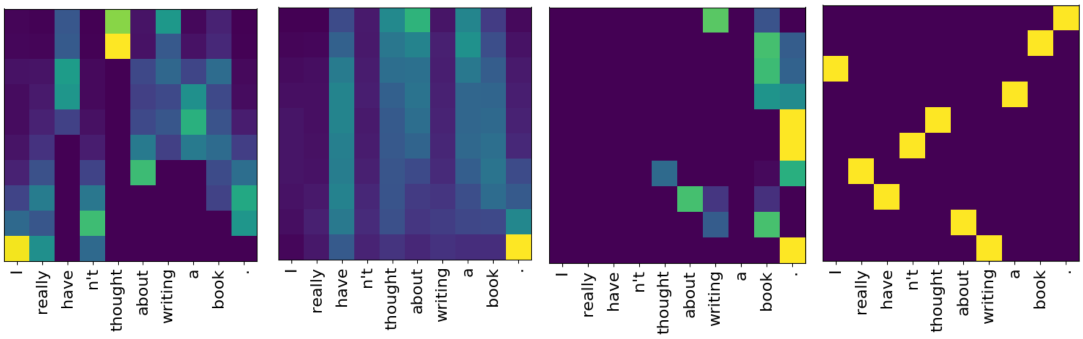

Figure 2: Attention visualization for English POS tagging. From the left: constrained softmax, softmax, sparsemax, vanilla. Rows correspond to attention vectors (high values in yellow, low ones in dark blue).

clipping of 5 (DyNet's default). We excluded from the training set sentences longer than 50 words.

Table 1 compares several variants of our neural easy-first system—the single-state model (NEF-S), the full-state model (NEF-F), and the latter with softmax, sparsemax, and csoftmax attention. We used as many sketch steps as the number of words, $N = L$. As baselines, we used:

- A feature-based linear model (TurboTagger, Martins et al. (2013)).
- A BILSTM tagger identical to our system, but without sketch steps ($N = 0$).
- A vanilla easy-first tagger (Alg. 1), using the argument of the softmax in Eq. 6 as the scoring function. This uses the same sketch representations as the neural easy-first systems, but replaces the attention mechanism by "hard" attention placed on the highest scored word.

For comparison, we also show the accuracies reported by Gillick et al. (2016) for their byte-to-span system (trained separately on each language) and by Plank et al. (2016) for their state-of-the-art multi-task BILSTM tagger (these results are not fully comparable though, due to different treebank versions).

Among the neural easy-first systems, we observe that NEF-F with csoftmax attention generally outperforms the others, but the differences are very slight (excluding the sparsemax attention system, which performed substancially worse). This system wins over the linear system for all languages but Spanish, and over the BILSTM baseline for 9 out of 12 languages (loses in Arabic and German, and ties in Japanese). Note, however, that the differences are small (95.47% against 95.39%, averaged across treebanks). We conjecture that this is due to the fact that the BILSTM already captures most of the relevant context in its encoder. Our NEF-F system with csoftmax also wins over the vanilla easy-first system for 10 out of 12 languages (arguably due to its ability to backpropagate the gradients through the soft attention mechanism), but the difference in the average score is again small (95.47% against 95.42%).

Figure 2 depicts some patterns learned by the NEF-F model with various attention types. With the csoftmax, the model learns to move left and right, and the main verb *"thought"* is the most prominent candidate for the easiest decision. In fact, in 57% of the test sentences, the model focuses first on a verb. The "raindrop" appearance of the plot is due to the evenness property of csoftmax, which causes the attention over a word to increase gradually until the cumulative attention is exhausted. This constrasts with the softmax attention (less diverse and non-sparse) and the sparsemax (sparse, but not even). We show for comparison the (hard) decisions made by the vanilla easy-first decoder.

5.2 Named Entity Recognition

Next, we applied our model to NER. We used the official datasets from the CoNLL 2002-3 shared tasks (Sang, 2002; Sang and De Meulder, 2003), which tag names, locations, and organizations using a BIO scheme, and cover four languages (Dutch, English, German, and Spanish). We made two experiments: one using the exact same BILSTM and NEF models with a standard softmax output layer, as in §5.1 (which does not guarantee valid segmentations), and another one replacing the output softmax layer by a sequential CRF layer, which requires learning $O(K^2)$ additional parameters for pairs of consecutive tags (Huang et al., 2015; Lample et al., 2016). We used the same hyperparameters as in the POS tagging experiments, except the dropout probability, which was set to 0.3 (tuned on the validation set). For English, we used pre-trained 300-dimensional GloVe-840B embeddings (Pennington et al., 2014); for Spanish and German, we used the 64-dimensional word embeddings from Lample et al. (2016); for Dutch we used the aforementioned Polyglot vectors. All embeddings are fine-tuned during training. Since many words are not entities, and those receive a default "outside" tag, we expect that fewer sketch steps are necessary to achieve top performance.

Table 2 shows the results, which confirm this hypothesis. We compare the same BILSTM baseline to our NEF-S and NEF-F models with csoftmax attention (with and without the CRF output layer), varying the maximum number of sketch steps. We also compare against the byte-to-span model of Gillick et al. (2016) and the state-of-the-art character-based LSTM-CRF system of Lample et al. (2016).[6] We can see that, for all languages, the NEF-CRF-F model with 5 steps is consistently better than the BILSTM-CRF and, with the exception of English, the NEF-CRF-S model. The same holds for the BILSTM and NEF-F models without the CRF output layer. With the exception of German, increasing the number of steps did not make a big difference.

	Dut.	Eng.	Ger.	Spa.
Gillick et al. (2016)	78.08	84.57	72.08	81.83

Table 2: F_1 scores for NER, computed by the CoNLL 2002 evaluation script.

Figure 3 shows the attention distributions over the sketch steps for an English sentence, for full-state models trained with $N \in \{5, L\}$. The model with L sketch steps learned that it is easiest to focus on the beginning of a named entity, and then to move to the right to identify the full span. The model with only 5 sketch steps learns to go straight to the point, placing most attention on the entity words and ignoring most of the O-tokens.

5.3 Word-Level Quality Estimation

Finally, we evaluate our model's performance on word-level translation quality estimation. The goal is to evaluate a translation system's quality without access to reference translations (Blatz et al., 2004; Specia et al., 2013). Given a sentence pair (a source sentence and its machine translated sentence in a target language), a word-level system classifies each target word as OK or BAD. We used the official English-German dataset from the WMT16 shared task (Bojar et al., 2016).

This task differs from the previous ones in which its input is a sentence pair and not a single

[6] The current state of the art on these datasets (Gillick et al., 2016; Lample et al., 2016; Ma and Hovy, 2016) is achieved by more sophisticated systems with more parameters, mixing character and word-based models, sharing a model across languages, or combining CRFs with convolutional and recurrent layers. We used simpler models in our experiments since our goal is to assess how much the neural easy-first systems can bring in addition to a BILSTM system, rather than building a state-of-the-art system.

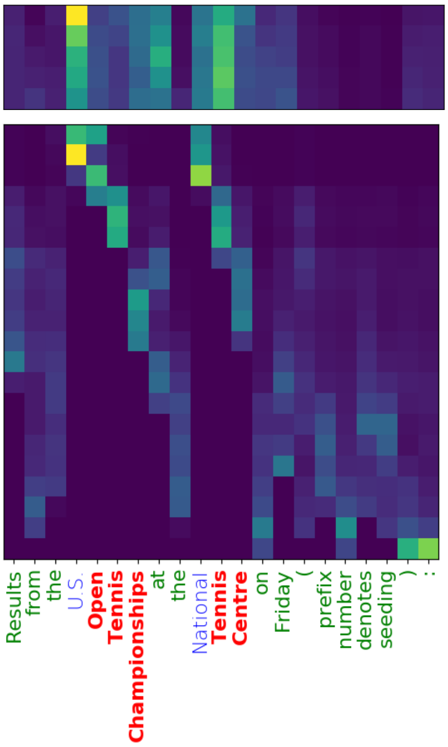

Figure 3: Attention visualization for English NER, for 5 (top) and L (bottom) sketch steps. Words tagged as B-* are marked in light blue, those with I-* tags, in bold red, and with O-* tags, in green.

sentence. We replaced the affix embeddings by the concatenation of the 64-dimensional embeddings of the target words with those of the aligned source words (we used the alignments provided in the shared task), yielding 128-dimensional representations. We used the same hyperparameters as in the POS tagging task, except the dropout probability, set to 0.1. We followed prior work (Kreutzer et al., 2015) and upweighted the BAD words in the loss function to make the model more pessimistic; we used a weight of 5 (tuned in the validation set).

BILSTM	NEF-S		NEF-F	
	$N = 5$	$N = L$	$N = 5$	$N = L$
39.71	40.91	40.99	**41.18**	40.84

Table 3: F_1-MULT scores (product of F_1 for OK and BAD words) for word-level quality estimation, computed by the official shared task script.

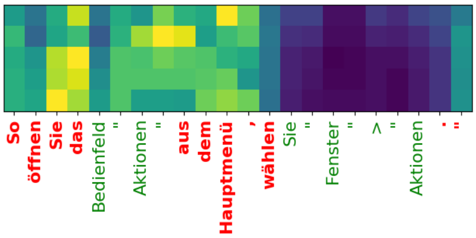

Figure 4: Example for word-level quality estimation. The source sentence is *"To open the Actions panel, from the main menu, choose Window > Actions."* BAD words are red (bold font), OK words are green.

Table 3 shows the results. We see that all our NEF-S and NEF-F models outperform the BILSTM, and that the NEF-F model with 5 sketch steps achieved the best results.[7] Figure 4 illustrates the attention over the target words for 5 sketches. We observe that the attention focuses early in the areas predicted BAD and moves left and right within these areas, not wasting attention on the OK part of the sentence. This block-wise focus makes sense for quality estimation, since often complete phrases are BAD.

5.4 Ablation Study

To better understand our proposed model, we carried out an ablation study for NER on the English dataset. The following alternate configurations were tried and compared against the NEF-CRF-F model with csoftmax attention and 5 sketch steps:

- A NEF-CRF-F model for which the final concatenation in Eq. 6 was removed, being replaced by $\boldsymbol{p}_i = \mathsf{softmax}(\mathsf{affine}(\boldsymbol{s}_i^N))$. The goal was to see if the sketches retain enough information about the input to make a final prediction without requiring the states $\boldsymbol{h}_i$.
- A model for which the attention mechanism applied at each sketch step was replaced by a uniform distribution over the input words.
- A vanilla easy-first system (Alg. 1). Since this system can only focus on one word at the time (unlike the models with soft attention), we tried both $N = 5$ and $N = L$ sketch steps.
- A left-to-right and right-to-left model, which replaces the attention mechanism by one of these two prescribed orders.

Table 4 shows the results. As expected, the neural easy-first system was the best performing one, although the difference with respect to the ablated

[7] Our best system would rank third in the shared task, out of 13 submissions. The winner system, which achieved 49.52 F_1-MULT, was considerably more complex than ours, using an ensemble of three neural networks with a linear system (Martins et al., 2016).

NEF-CRF-F, $N = 5$	**88.01**
NEF-CRF-F w/out concat, $N = 5$	87.47
Uniform Attention, $N = 5$	87.46
Vanilla EF + CRF, $N = 5$	87.17
Vanilla EF + CRF, $N = L$	87.46
Left-to-right + CRF, $N = L$	87.57
Right-to-left + CRF, $N = L$	87.53

Table 4: Ablation experiments. Reported are F_1 scores for NER in the English test set.

systems is relatively small. Removing the concatenation in Eq. 6 is harmful, which suggests that there is information about the input not retained in the sketches. The uniform attention performs surprisingly well, and so do the left-to-right and right-to-left models, but they are still about half a point behind. The vanilla easy-first system has the worst performance with $N = 5$. This is due to the fact that the vanilla model is uncapable of processing words "in parallel" in the same sketch step, a disadvantage with respect to the neural easy-first models, which have this capability due to their soft attention mechanisms (see the top image in Fig. 3).

6 Related Work

Vanilla easy-first decoders have been used in POS tagging (Tsuruoka and Tsujii, 2005; Ma et al., 2013), dependency parsing (Goldberg and Elhadad, 2010), and coreference resolution (Stoyanov and Eisner, 2012), being related to cyclic dependency networks and guided learning (Toutanova et al., 2003; Shen et al., 2007). More recent works compute scores with a neural network (Socher et al., 2011; Clark and Manning, 2016; Kiperwasser and Goldberg, 2016a), but they still operate in a discrete space to pick the easiest actions (the non-differentiable argmax in line 6 of Alg. 1). Generalizing this idea to "continuous" operations is at the very core of our paper, allowing gradients to be fully backpropagated. In a different context, building differentiable computation structures has also been addressed by Graves et al. (2014); Grefenstette et al. (2015).

An important contribution of our paper is the constrained softmax transformation. Others have proposed alternatives to softmax attention, including the sparsemax (Martins and Astudillo, 2016) and multi-focal attention (Globerson et al., 2016). The latter computes a KL projection onto a budget polytope to focus on multiple words. Our constrained softmax also corresponds to a KL projection, but (i) it involves box constraints instead of a budget, (ii) it is normalized to 1, and (iii) we also backpropagate the gradient over the constraint variables. It also achieves sparsity (see the "raindrop" plots in Figures 2–4), and is suitable for sequentially computing attention distributions when diversity is desired (e.g. soft 1-to-1 alignments). Recently, Chorowski and Jaitly (2016) developed an heuristic with a threshold on the total attention as a "coverage criterion" (see their Eq. 11), however their heuristic is non-differentiable.

Our sketch generation step is similar in spirit to the "deep recurrent attentive writer" (DRAW, Gregor et al. (2015)) which generates images by iteratively refining sketches with a recurrent neural network (RNN). However, our goal is very different: instead of generating images, we generate vectors that lead to a final sequence tagging prediction.

Finally, the visualization provided in Figures 2–4 brings up the question how to understand and rationalize predictions by neural network systems, addressed by Lei et al. (2016). Their model, however, uses a form of stochastic attention and it does not perform any iterative refinement like ours.

7 Conclusions

We introduced novel fully-differentiable easy-first taggers that learn to make predictions over sequences in an order that is adapted to the task at hand. The decoder iteratively updates a sketch of the predictions by interacting with an attention mechanism. To spread attention evenly through all words, we introduced a new constrained softmax transformation, along with an algorithm to backpropagate its gradients. Our neural-easy first decoder consistently outperformed a BILSTM on a range of sequence tagging tasks.

A natural direction for future work is to go beyond sequence tagging (which we regard as a simple first step) toward other NLP structured prediction problems, such as sequence-to-sequence prediction. This requires replacing the sketch matrix in Alg. 2 by a dynamic memory structure.

A Proof of Proposition 1

We provide here a detailed proof of Proposition 1.

A.1 Forward Propagation

The optimization problem is

$$\mathsf{csoftmax}(\boldsymbol{z}, \boldsymbol{u}) = \mathsf{argmin} \quad -H(\boldsymbol{\alpha}) - \boldsymbol{z}^\top \boldsymbol{\alpha} \\ \text{s.t.} \quad \begin{cases} \mathbf{1}^\top \boldsymbol{\alpha} = 1 \\ \mathbf{0} \leq \boldsymbol{\alpha} \leq \boldsymbol{u}. \end{cases}$$

The Lagrangian function is:

$$\begin{aligned} \mathcal{L}(\boldsymbol{\alpha}, \lambda, \boldsymbol{\mu}, \boldsymbol{\nu}) &= -H(\boldsymbol{\alpha}) - \boldsymbol{z}^\top \boldsymbol{\alpha} + \lambda(\mathbf{1}^\top \boldsymbol{\alpha} - 1) \\ &\quad -\boldsymbol{\mu}^\top \boldsymbol{\alpha} + \boldsymbol{\nu}^\top (\boldsymbol{\alpha} - \boldsymbol{u}). \end{aligned} \tag{14}$$

To obtain the solution, we invoke the Karush-Kuhn-Tucker conditions. From the stationarity condition, we have $\mathbf{0} = \log(\boldsymbol{\alpha}) + \mathbf{1} - \boldsymbol{z} + \lambda\mathbf{1} - \boldsymbol{\mu} + \boldsymbol{\nu}$, which due to the primal feasibility condition implies that the solution is of the form:

$$\boldsymbol{\alpha} = \exp(\boldsymbol{z} + \boldsymbol{\mu} - \boldsymbol{\nu})/Z, \tag{15}$$

where Z is a normalization constant. From the complementarity slackness condition, we have that $0 < \alpha_i < u_i$ implies that $\mu_i = \nu_i = 0$ and therefore $\alpha_i = \exp(z_i)/Z$. On the other hand, $\nu_i > 0$ implies $\alpha_i = u_i$. Hence the solution can be written as $\alpha_i = \min\{\exp(z_i)/Z, u_i\}$, where Z is determined such that the distribution normalizes:

$$Z = \frac{\sum_{i \in \mathcal{A}} \exp(z_i)}{1 - \sum_{i \notin \mathcal{A}} u_i}, \tag{16}$$

with $\mathcal{A} = \{i \in [L] \mid \alpha_i < u_i\}$.

A.2 Gradient Backpropagation

We now turn to the problem of backpropagating the gradients through the constrained softmax transformation. For that, we need to compute its Jacobian matrix, i.e., the derivatives $\frac{\partial \alpha_i}{\partial z_j}$ and $\frac{\partial \alpha_i}{\partial u_j}$ for $i, j \in [L]$. Let us first express $\boldsymbol{\alpha}$ as

$$\alpha_i = \begin{cases} \frac{\exp(z_i)(1-s)}{\sum_{j \in \mathcal{A}} \exp(z_j)}, & i \in \mathcal{A} \\ u_i, & i \notin \mathcal{A}, \end{cases} \tag{17}$$

where $s = \sum_{j \notin \mathcal{A}} u_j$. Note that we have $\partial s / \partial z_j = 0, \ \forall j$, and $\partial s / \partial u_j = \mathbb{1}(j \notin \mathcal{A})$. To compute the entries of the Jacobian matrix, we need to consider several cases.

Case 1: $\boxed{i \in \mathcal{A}.}$ In this case, the evaluation of Eq. 17 goes through the first branch. Let us first compute the derivative with respect to u_j. Two things can happen: if $j \in \mathcal{A}$, then s does not depend on u_j, hence $\frac{\partial \alpha_i}{\partial u_j} = 0$. Else, if $j \notin \mathcal{A}$, we have

$$\frac{\partial \alpha_i}{\partial u_j} = \frac{-\exp(z_i) \frac{\partial s}{\partial u_j}}{\sum_{k \in \mathcal{A}} \exp(z_k)} = -\alpha_i/(1-s).$$

Now let us compute the derivative with respect to z_j. Three things can happen: if $j \in \mathcal{A}$ and $i \neq j$, we have

$$\begin{aligned} \frac{\partial \alpha_i}{\partial z_j} &= \frac{-\exp(z_i)\exp(z_j)(1-s)}{\left(\sum_{k \in \mathcal{A}} \exp(z_k)\right)^2} \\ &= -\alpha_i \alpha_j/(1-s). \end{aligned} \tag{18}$$

If $j \in \mathcal{A}$ and $i = j$, we have

$$\begin{aligned}\frac{\partial \alpha_i}{\partial z_i} &= (1-s) \times \\ & \quad \frac{\mathsf{exp}(z_i) \sum_{k \in \mathcal{A}} \mathsf{exp}(z_k) - \mathsf{exp}(z_i)^2}{\left(\sum_{k \in \mathcal{A}} \mathsf{exp}(z_k)\right)^2} \\ &= \alpha_i - \alpha_i^2/(1-s). \end{aligned} \tag{19}$$

Finally, if $j \notin \mathcal{A}$, we have $\frac{\partial \alpha_i}{\partial z_j} = 0$.

Case 2: $\boxed{i \notin \mathcal{A}.}$ In this case, the evaluation of Eq. 17 goes through the second branch, which means that $\frac{\partial \alpha_i}{\partial z_j} = 0$, always. Let us now compute the derivative with respect to u_j. This derivative is always zero unless $i = j$, in which case $\frac{\partial \alpha_i}{\partial u_j} = 1$.

To sum up, we have:

$$\frac{\partial \alpha_i}{\partial z_j} = \begin{cases} \mathbb{1}(i=j)\alpha_i - \frac{\alpha_i \alpha_j}{1-s}, & \text{if } i, j \in \mathcal{A} \\ 0, & \text{otherwise,} \end{cases} \tag{20}$$

and

$$\frac{\partial \alpha_i}{\partial u_j} = \begin{cases} -\frac{\alpha_i}{1-s}, & \text{if } i \in \mathcal{A}, j \notin \mathcal{A} \\ 1, & \text{if } i, j \notin \mathcal{A}, i = j \\ 0, & \text{otherwise.} \end{cases} \tag{21}$$

Therefore, we obtain:

$$\begin{aligned} \mathrm{d}z_j &= \sum_i \frac{\partial \alpha_i}{\partial z_j} \mathrm{d}\alpha_i \\ &= \mathbb{1}(j \in \mathcal{A}) \left(\alpha_j \mathrm{d}\alpha_j - \frac{\alpha_j \sum_{i \in \mathcal{A}} \alpha_i \mathrm{d}\alpha_i}{1-s} \right) \\ &= \mathbb{1}(j \in \mathcal{A}) \alpha_j (\mathrm{d}\alpha_j - m), \end{aligned} \tag{22}$$

and

$$\begin{aligned} \mathrm{d}u_j &= \sum_i \frac{\partial \alpha_i}{\partial u_j} \mathrm{d}\alpha_i \\ &= \mathbb{1}(j \notin \mathcal{A}) \left(\mathrm{d}\alpha_j - \frac{\sum_{i \in \mathcal{A}} \alpha_i \mathrm{d}\alpha_i}{1-s} \right) \\ &= \mathbb{1}(j \notin \mathcal{A}) (\mathrm{d}\alpha_j - m), \end{aligned} \tag{23}$$

where $m = \frac{\sum_{i \in \mathcal{A}} \alpha_i \mathrm{d}\alpha_i}{1-s}$.

Incremental Skip-gram Model with Negative Sampling

Nobuhiro Kaji and **Hayato Kobayashi**
Yahoo Japan Corporation
{nkaji,hakobaya}@yahoo-corp.jp

Abstract

This paper explores an incremental training strategy for the skip-gram model with negative sampling (SGNS) from both empirical and theoretical perspectives. Existing methods of neural word embeddings, including SGNS, are multi-pass algorithms and thus cannot perform incremental model update. To address this problem, we present a simple incremental extension of SGNS and provide a thorough theoretical analysis to demonstrate its validity. Empirical experiments demonstrated the correctness of the theoretical analysis as well as the practical usefulness of the incremental algorithm.

1 Introduction

Existing methods of neural word embeddings are typically designed to go through the entire training data multiple times. For example, negative sampling (Mikolov et al., 2013b) needs to pre-compute the noise distribution from the entire training data before performing Stochastic Gradient Descent (SGD). It thus needs to go through the training data at least twice. Similarly, hierarchical soft-max (Mikolov et al., 2013b) has to determine the tree structure and GloVe (Pennington et al., 2014) has to count co-occurrence frequencies before performing SGD.

The fact that those existing methods are multi-pass algorithms means that they cannot perform incremental model update when additional training data is provided. Instead, they have to re-train the model on the old and new training data from scratch.

However, the re-training is obviously inefficient since it has to process the entire training data received thus far whenever new training data is provided. This is especially problematic when the amount of the new training data is relatively smaller than the old one. One such situation is that the embedding model is updated on a small amount of training data that includes newly emerged words for instantly adding them to the vocabulary set. Another situation is that the word embeddings are learned from ever-evolving data such as news articles and microblogs (Peng et al., 2017) and the embedding model is periodically updated on newly generated data (*e.g.*, once in a week or month).

This paper investigates an incremental training method of word embeddings with a focus on the skip-gram model with negative sampling (SGNS) (Mikolov et al., 2013b) for its popularity. We present a simple incremental extension of SGNS, referred to as *incremental SGNS*, and provide a thorough theoretical analysis to demonstrate its validity. Our analysis reveals that, under a mild assumption, the optimal solution of incremental SGNS agrees with the original SGNS when the training data size is infinitely large. See Section 4 for the formal and strict statement. Additionally, we present techniques for the efficient implementation of incremental SGNS.

Three experiments were conducted to assess the correctness of the theoretical analysis as well as the practical usefulness of incremental SGNS. The first experiment empirically investigates the validity of the theoretical analysis result. The second experiment compares the word embeddings learned by incremental SGNS and the original SGNS across five benchmark datasets, and demonstrates that those word embeddings are of comparable quality. The last experiment explores the training time of incremental SGNS, demonstrating that it is able to save much training time by avoiding expensive re-training when additional training data is provided.

2 SGNS Overview

As a preliminary, this section provides a brief overview of SGNS.

Given a word sequence, $w_1, w_2, \ldots, w_n$, for training, the skip-gram model seeks to minimize the following objective to learn word embeddings:

$$\mathcal{L}_{\text{SG}} = -\frac{1}{n} \sum_{i=1}^{n} \sum_{\substack{|j| \leq c \\ j \neq 0}} \log p(w_{i+j} \mid w_i),$$

where w_i is a target word and w_{i+j} is a context word within a window of size c. $p(w_{i+j} \mid w_i)$ represents the probability that w_{i+j} appears within the neighbor of w_i, and is defined as

$$p(w_{i+j} \mid w_i) = \frac{\exp(\mathbf{t}_{w_i} \cdot \mathbf{c}_{w_{i+j}})}{\sum_{w \in \mathcal{W}} \exp(\mathbf{t}_{w_i} \cdot \mathbf{c}_w)}, \qquad (1)$$

where $\mathbf{t}_w$ and $\mathbf{c}_w$ are w's embeddings when it behaves as a target and context, respectively. $\mathcal{W}$ represents the vocabulary set.

Since it is too expensive to optimize the above objective, Mikolov et al. (2013b) proposed negative sampling to speed up skip-gram training. This approximates Eq. (1) using sigmoid functions and k randomly-sampled words, called *negative samples*. The resulting objective is given as

$$\mathcal{L}_{\text{SGNS}} = -\frac{1}{n} \sum_{i=1}^{n} \sum_{\substack{|j| \leq c \\ j \neq 0}} \psi^{+}_{w_i, w_{i+j}} + k \mathbb{E}_{v \sim q(v)} [\psi^{-}_{w_i, v}],$$

where $\psi^{+}_{w,v} = \log \sigma(\mathbf{t}_w \cdot \mathbf{c}_v)$, $\psi^{-}_{w,v} = \log \sigma(-\mathbf{t}_w \cdot \mathbf{c}_v)$, and $\sigma(x)$ is the sigmoid function. The negative sample v is drawn from a smoothed unigram probability distribution referred to as *noise distribution*: $q(v) \propto f(v)^{\alpha}$, where $f(v)$ represents the frequency of a word v in the training data and α is a smoothing parameter ($0 < \alpha \leq 1$).

The objective is optimized by SGD. Given a target-context word pair (w_i and w_{i+j}) and k negative samples ($v_1, v_2, \ldots, v_k$) drawn from the noise distribution, the gradient of $-\psi^{+}_{w_i, w_{i+j}} - k \mathbb{E}_{v \sim q(v)} [\psi^{-}_{w_i, v}] \approx -\psi^{+}_{w_i, w_{i+j}} - \sum_{k'=1}^{k} \psi^{-}_{w_i, v_{k'}}$ is computed. Then, the gradient descent is performed to update $\mathbf{t}_{w_i}$, $\mathbf{c}_{w_{i+j}}$, and $\mathbf{c}_{v_1}, \ldots, \mathbf{c}_{v_k}$.

SGNS training needs to go over the entire training data to pre-compute the noise distribution $q(v)$ before performing SGD. This makes it difficult to perform incremental model update when additional training data is provided.

3 Incremental SGNS

This section explores incremental training of SGNS. The incremental training algorithm (Section 3.1), its efficient implementation (Section 3.2), and the computational complexity (Section 3.3) are discussed in turn.

3.1 Algorithm

Algorithm 1 presents *incremental SGNS*, which goes through the training data in a single-pass to update word embeddings incrementally. Unlike the original SGNS, it does not pre-compute the noise distribution. Instead, it reads the training data word by word[1] to incrementally update the word frequency distribution and the noise distribution while performing SGD. Hereafter, the original SGNS (*c.f.*, Section 2) is referred to as *batch SGNS* to emphasize that the noise distribution is computed in a batch fashion.

The learning rate for SGD is adjusted by using AdaGrad (Duchi et al., 2011). Although the linear decay function has widely been used for training batch SGNS (Mikolov, 2013), adaptive methods such as AdaGrad are more suitable for the incremental training since the amount of training data is unknown in advance or can increase unboundedly.

It is straightforward to extend the incremental SGNS to the mini-batch setting by reading a subset of the training data (or mini-batch), rather than a single word, at a time to update the noise distribution and perform SGD (Algorithm 2). Although this paper primarily focuses on the incremental SGNS, the mini-batch algorithm is also important in practical terms because it is easier to be multithreaded.

Alternatives to Algorithms 2 might be possible. Other possible approaches include computing the noise distribution separately on each subset of the training data, fixing the noise distribution after computing it from the first (possibly large) subset, and so on. We exclude such alternatives from our investigation because it is considered difficult to provide them with theoretical justification.

3.2 Efficient implementation

Although the incremental SGNS is conceptually simple, implementation issues are involved.

[1] In practice, Algorithm 1 buffers a sequence of words $w_{i-c}, \ldots, w_{i+c}$ (rather than a single word w_i) at each step, as it requires an access to the context words w_{i+j} in line 7. This is not a practical problem because the window size c is usually small and independent from the training data size n.

Algorithm 1 Incremental SGNS

```
$f(w) \leftarrow 0$ for all $w \in \mathcal{W}$
for $i = 1, \ldots, n$ do
    $f(w_i) \leftarrow f(w_i) + 1$
    $q(w) \leftarrow \frac{f(w)^\alpha}{\sum_{w' \in \mathcal{W}} f(w')^\alpha}$ for all $w \in \mathcal{W}$
    for $j = -c, \ldots, -1, 1, \ldots, c$ do
        draw $k$ negative samples from $q(w)$: $v_1, \ldots, v_k$
        use SGD to update $\mathbf{t}_{w_i}$, $\mathbf{c}_{w_{i+j}}$, and $\mathbf{c}_{v_1}, \ldots, \mathbf{c}_{v_k}$
    end for
end for
```

Algorithm 2 Mini-batch SGNS

```
for each subset $\mathcal{D}$ of the training data do
    update the noise distribution using $\mathcal{D}$
    perform SGD over $\mathcal{D}$
end for
```

3.2.1 Dynamic vocabulary

One problem that arises when training incremental SGNS is how to maintain the vocabulary set. Since new words emerge endlessly in the training data, the vocabulary set can grow unboundedly and exhaust a memory.

We address this problem by dynamically changing the vocabulary set. The Misra-Gries algorithm (Misra and Gries, 1982) is used to approximately keep track of top-m frequent words during training, and those words are used as the dynamic vocabulary set. This method allows the maximum vocabulary size to be explicitly limited to m, while being able to dynamically change the vocabulary set.

3.2.2 Adaptive unigram table

Another problem is how to generate negative samples efficiently. Since k negative samples per target-context pair have to be generated by the noise distribution, the sampling speed has a significant effect on the overall training efficiency.

Let us first examine how negative samples are generated in batch SGNS. In a popular implementation (Mikolov, 2013), a word array (referred to as a *unigram table*) is constructed such that the number of a word w in it is proportional to $q(w)$. See Table 1 for an example. Using the unigram table, negative samples can be efficiently generated by sampling the table elements uniformly at random. It takes only $O(1)$ time to generate one negative sample.

w	a	b	c
$q(w)$	0.5	0.3	0.2

$T = (a, a, a, a, a, b, b, b, c, c)$

Table 1: Example noise distribution $q(w)$ for the vocabulary set $\mathcal{W} = \{a, b, c\}$ (left) and the corresponding unigram table T of size 10 (right).

Algorithm 3 Adaptive unigram table.

```
1:  $f(w) \leftarrow 0$ for all $w \in \mathcal{W}$
2:  $z \leftarrow 0$
3:  for $i = 1, \ldots, n$ do
4:      $f(w_i) \leftarrow f(w_i) + 1$
5:      $F \leftarrow f(w_i)^\alpha - (f(w_i) - 1)^\alpha$
6:      $z \leftarrow z + F$
7:      if $|T| < \tau$ then
8:          add $F$ copies of $w_i$ to $T$
9:      else
10:         for $j = 1, \ldots, \tau$ do
11:             $T[j] \leftarrow w_i$ with probability $\frac{F}{z}$
12:         end for
13:     end if
14: end for
```

The above method assumes that the noise distribution is fixed and thus cannot be used directly for the incremental training. One simple solution is to reconstruct the unigram table whenever new training data is provided. However, such a method is not effective for the incremental SGNS, because the unigram table reconstruction requires $\mathcal{O}(|\mathcal{W}|)$ time.[2]

We propose a reservoir-based algorithm for efficiently updating the unigram table (Vitter, 1985; Efraimidis, 2015) (Algorithm 3). The algorithm incrementally update the unigram table T while limiting its maximum size to τ. In case $|T| < \tau$, it can be easily confirmed that the number of a word w in T is $f(w)^\alpha (\propto q(w))$. In case $|T| = \tau$, since $z = \sum_{w \in \mathcal{W}} f(w)^\alpha$ is equal to the normalization factor of the noise distribution, it can be proven by induction that, for all j, $T[j]$ is a word w with probability $q(w)$. See (Vitter, 1985; Efraimidis, 2015) for reference.

Note on implementation In line 8, F copies of w_i are added to T. When F is not an integer, the copies are generated so that their expected number becomes F. Specifically, $\lceil F \rceil$ copies are added to T with probability $F - \lfloor F \rfloor$, and $\lfloor F \rfloor$ copies are added otherwise.

The loop from line 10 to 12 becomes expensive if implemented straightforwardly because the maximum table size τ is typically set large (*e.g.*, $\tau = 10^8$ in `word2vec` (Mikolov, 2013)). For acceleration, instead of checking all elements in the unigram table, randomly chosen $\frac{\tau F}{z}$ elements are substituted with w_i. Note that $\frac{\tau F}{z}$ is the expected

[2] This overhead is amortized in mini-batch SGNS if the mini-batch size is sufficiently large. Our discussion here is dedicated to efficiently perform the incremental training irrespective of the mini-batch size.

number of table elements to be substituted in the original algorithm. This approximation achieves great speed-up because we usually have $F \ll z$. In fact, it can be proven that it takes $O(1)$ time when $\alpha = 1.0$. See Appendix[3] A for more discussions.

3.3 Computational complexity

Both incremental and batch SGNS have the same space complexity, which is independent of the training data size n. Both require $\mathcal{O}(|\mathcal{W}|)$ space to store the word embeddings and the word frequency counts, and $\mathcal{O}(|T|)$ space to store the unigram table.

The two algorithms also have the same time complexity. Both require $\mathcal{O}(n)$ training time when the training data size is n. Although incremental SGNS requires extra time for updating the dynamic vocabulary and adaptive unigram table, these costs are practically negligible, as will be demonstrated in Section 5.3.

4 Theoretical Analysis

Although the extension from batch to incremental SGNS is simple and intuitive, it is not readily clear whether incremental SGNS can learn word embeddings as well as the batch counterpart. To answer this question, in this section we examine incremental SGNS from a theoretical point of view.

The analysis begins by examining the difference between the objectives optimized by batch and incremental SGNS (Section 4.1). Then, probabilistic properties of their difference are investigated to demonstrate the relationship between batch and incremental SGNS (Sections 4.2 and 4.3). We shortly touch the mini-batch SGNS at the end of this section (Section 4.4).

4.1 Objective difference

As discussed in Section 2, batch SGNS optimizes the following objective:

$$\mathcal{L}_{\mathrm{B}}(\theta) = -\frac{1}{n}\sum_{i=1}^{n}\sum_{\substack{|j|\le c\\ j\neq 0}} \psi^{+}_{w_i,w_{i+j}} + k\mathbb{E}_{v\sim q_n(v)}[\psi^{-}_{w_i,v}],$$

where $\theta = (\mathbf{t}_1, \mathbf{t}_2, \ldots, \mathbf{t}_{|\mathcal{W}|}, \mathbf{c}_1, \mathbf{c}_2, \ldots, \mathbf{c}_{|\mathcal{W}|})$ collectively represents the model parameters[4] (*i.e.*, word embeddings) and $q_n(v)$ represents the noise distribution. Note that the noise distribution is represented in a different notation than Section 2 to make its dependence on the whole training data explicit. The function $q_i(v)$ is defined as $q_i(v) = \frac{f_i(v)^{\alpha}}{\sum_{v'\in\mathcal{W}} f_i(v')^{\alpha}}$, where $f_i(v)$ represents the word frequency in the first i words of the training data.

In contrast, incremental SGNS computes the gradient of $-\psi^{+}_{w_i,w_{i+j}} - k\mathbb{E}_{v\sim q_i(v)}[\psi^{-}_{w_i,v}]$ at each step to perform gradient descent. Note that the noise distribution does not depend on n but rather on i. Because it can be seen as a sample approximation of the gradient of

$$\mathcal{L}_{\mathrm{I}}(\theta) = -\frac{1}{n}\sum_{i=1}^{n}\sum_{\substack{|j|\le c\\ j\neq 0}} \psi^{+}_{w_i,w_{i+j}} + k\mathbb{E}_{v\sim q_i(v)}[\psi^{-}_{w_i,v}],$$

incremental SGNS can be interpreted as optimizing $\mathcal{L}_{\mathrm{I}}(\theta)$ with SGD.

Since the expectation terms in the objectives can be rewritten as $\mathbb{E}_{v\sim q_i(v)}[\psi^{-}_{w_i,v}] = \sum_{v\in\mathcal{W}} q_i(v)\psi^{-}_{w_i,v}$, the difference between the two objectives can be given as

$$\begin{aligned}
\Delta\mathcal{L}(\theta) &= \mathcal{L}_{\mathrm{B}}(\theta) - \mathcal{L}_{\mathrm{I}}(\theta)\\
&= \frac{1}{n}\sum_{i=1}^{n}\sum_{\substack{|j|\le c\\ j\neq 0}} k \sum_{v\in\mathcal{W}} (q_i(v) - q_n(v))\psi^{-}_{w_i,v}\\
&= \frac{2ck}{n}\sum_{i=1}^{n}\sum_{v\in\mathcal{W}} (q_i(v) - q_n(v))\psi^{-}_{w_i,v}\\
&= \frac{2ck}{n}\sum_{w,v\in\mathcal{W}}\sum_{i=1}^{n} \delta_{w_i,w}(q_i(v) - q_n(v))\psi^{-}_{w,v}
\end{aligned}$$

where $\delta_{w,v} = \delta(w = v)$ is the delta function.

4.2 Unsmoothed case

Let us begin by examining the objective difference $\Delta\mathcal{L}(\theta)$ in the unsmoothed case, $\alpha = 1.0$.

The technical difficulty in analyzing $\Delta\mathcal{L}(\theta)$ is that it is dependent on the word order in the training data. To address this difficulty, we assume that the words in the training data are generated from some stationary distribution. This assumption allows us to investigate the property of $\Delta\mathcal{L}(\theta)$ from a probabilistic perspective. Regarding the validity of this assumption, we want to note that this assumption is already taken by the original SGNS: the probability that the target and context words co-occur is assumed to be independent of their position in the training data.

[3] The appendices are in the supplementary material.

[4] We treat words as integers and thus $\mathcal{W} = \{1, 2, \ldots |\mathcal{W}|\}$.

We below introduce some definitions and notations as the preparation of the analysis.

Definition 1. Let $\mathrm{X}_{i,w}$ be a random variable that represents $\delta_{w_i,w}$. It takes 1 when the i-th word in the training data is $w \in \mathcal{W}$ and 0 otherwise.

Remind that we assume that the words in the training data are generated from a stationary distribution. This assumption means that the expectation and (co)variance of $\mathrm{X}_{i,w}$ do not depend on the index i. Hereafter, they are respectively denoted as $\mathbb{E}[\mathrm{X}_{i,w}] = \mu_w$ and $\mathbb{V}[\mathrm{X}_{i,w}, \mathrm{X}_{j,v}] = \rho_{w,v}$.

Definition 2. Let $\mathrm{Y}_{i,w}$ be a random variable that represents $q_i(w)$ when $\alpha = 1.0$. It is given as $\mathrm{Y}_{i,w} = \frac{1}{i}\sum_{i'=1}^{i} \mathrm{X}_{i',w}$.

4.2.1 Convergence of the first and second order moments of $\Delta\mathcal{L}(\theta)$

It can be shown that the first order moment of $\Delta\mathcal{L}(\theta)$ has an analytical form.

Theorem 1. *The first order moment of $\Delta\mathcal{L}(\theta)$ is given as*

$$\mathbb{E}[\Delta\mathcal{L}(\theta)] = \frac{2ck(H_n - 1)}{n} \sum_{w,v\in\mathcal{W}} \rho_{w,v}\psi^-_{w,v},$$

where H_n is the n-th harmonic number.

Sketch of proof. Notice that $\mathbb{E}[\Delta\mathcal{L}(\theta)]$ can be written as

$$\frac{2ck}{n} \sum_{w,v\in\mathcal{W}} \sum_{i=1}^{n} \big(\mathbb{E}[\mathrm{X}_{i,w}\mathrm{Y}_{i,v}] - \mathbb{E}[\mathrm{X}_{i,w}\mathrm{Y}_{n,v}]\big)\psi^-_{w,v}.$$

Because we have, for any i and j such that $i \leq j$,

$$\mathbb{E}[\mathrm{X}_{i,w}\mathrm{Y}_{j,v}] = \sum_{j'=1}^{j} \mathbb{E}[\mathrm{X}_{i,w}\frac{\mathrm{X}_{j',v}}{j}] = \mu_w\mu_v + \frac{\rho_{w,v}}{j},$$

plugging this into $\mathbb{E}[\Delta\mathcal{L}(\theta)]$ proves the theorem. See Appendix B.1 for the complete proof. □

Theorem 1 readily gives the convergence property of the first order moment of $\Delta\mathcal{L}(\theta)$:

Theorem 2. *The first-order moment of $\Delta\mathcal{L}(\theta)$ decreases in the order of $\mathcal{O}(\frac{\log(n)}{n})$:*

$$\mathbb{E}[\Delta\mathcal{L}(\theta)] = \mathcal{O}\bigg(\frac{\log(n)}{n}\bigg),$$

and thus converges to zero in the limit of infinity:

$$\lim_{n\to\infty} \mathbb{E}[\Delta\mathcal{L}(\theta)] = 0.$$

Proof. We have $H_n = \mathcal{O}(\log(n))$ from the upper integral bound, and thus Theorem 1 gives the proof. □

A similar result to Theorem 2 can be obtained for the second order moment of $\Delta\mathcal{L}(\theta)$ as well.

Theorem 3. *The second-order moment of $\Delta\mathcal{L}(\theta)$ decreases in the order of $\mathcal{O}(\frac{\log(n)}{n})$:*

$$\mathbb{E}[\Delta\mathcal{L}(\theta)^2] = \mathcal{O}\bigg(\frac{\log(n)}{n}\bigg),$$

and thus converges to zero in the limit of infinity:

$$\lim_{n\to\infty} \mathbb{E}[\Delta\mathcal{L}(\theta)^2] = 0.$$

Proof. Omitted. See Appendix B.2. □

4.2.2 Main result

The above theorems reveal the relationship between the optimal solutions of the two objectives, as stated in the next lemma.

Lemma 4. *Let θ^* and $\hat{\theta}$ be the optimal solutions of $\mathcal{L}_B(\theta)$ and $\mathcal{L}_I(\theta)$, respectively: $\theta^* = \arg\min_\theta \mathcal{L}_B(\theta)$ and $\hat{\theta} = \arg\min_\theta \mathcal{L}_I(\theta)$. Then,*

$$\lim_{n\to\infty} \mathbb{E}[\mathcal{L}_B(\hat{\theta}) - \mathcal{L}_B(\theta^*)] = 0, \tag{2}$$

$$\lim_{n\to\infty} \mathbb{V}[\mathcal{L}_B(\hat{\theta}) - \mathcal{L}_B(\theta^*)] = 0. \tag{3}$$

Proof. The proof is made by the squeeze theorem. Let $l = \mathcal{L}_\mathrm{B}(\hat{\theta}) - \mathcal{L}_\mathrm{B}(\theta^*)$. The optimality of θ^* gives $0 \leq l$. Also, the optimality of $\hat{\theta}$ gives

$$\begin{aligned} l &= \mathcal{L}_\mathrm{B}(\hat{\theta}) - \mathcal{L}_\mathrm{I}(\theta^*) + \mathcal{L}_\mathrm{I}(\theta^*) - \mathcal{L}_\mathrm{B}(\theta^*) \\ &\leq \mathcal{L}_\mathrm{B}(\hat{\theta}) - \mathcal{L}_\mathrm{I}(\hat{\theta}) + \mathcal{L}_\mathrm{I}(\theta^*) - \mathcal{L}_\mathrm{B}(\theta^*) \\ &= \Delta\mathcal{L}(\hat{\theta}) - \Delta\mathcal{L}(\theta^*). \end{aligned}$$

We thus have $0 \leq \mathbb{E}[l] \leq \mathbb{E}[\Delta\mathcal{L}(\hat{\theta}) - \Delta\mathcal{L}(\theta^*)]$. Since Theorem 2 implies that the right hand side converges to zero when $n \to \infty$, the squeeze theorem gives Eq. (2). Next, we have

$$\begin{aligned} \mathbb{V}[l] = \mathbb{E}[l^2] - \mathbb{E}[l]^2 &\leq \mathbb{E}[l^2] \\ &\leq \mathbb{E}[(\Delta\mathcal{L}(\hat{\theta}) - \Delta\mathcal{L}(\theta^*))^2] \\ &\leq \mathbb{E}[(\Delta\mathcal{L}(\hat{\theta}) - \Delta\mathcal{L}(\theta^*))^2] \\ &\quad + \mathbb{E}[(\Delta\mathcal{L}(\hat{\theta}) + \Delta\mathcal{L}(\theta^*))^2] \\ &= 2\mathbb{E}[\Delta\mathcal{L}(\hat{\theta})^2] + 2\mathbb{E}[\Delta\mathcal{L}(\theta^*)^2]. \end{aligned} \tag{4}$$

Theorem 3 suggests that Eq. (4) converges to zero when $n \to \infty$. Also, the non-negativity of the variance gives $0 \leq \mathbb{V}[l]$. Therefore, the squeeze theorem gives Eq. (3). □

We are now ready to provide the main result of the analysis. The next theorem shows the convergence of $\mathcal{L}_{\mathrm{B}}(\hat{\theta})$.

Theorem 5. *$\mathcal{L}_B(\hat{\theta})$ converges in probability to $\mathcal{L}_B(\theta^*)$:*

$$\forall \epsilon > 0, \lim_{n\to\infty} \Pr\Big[|\mathcal{L}_B(\hat{\theta}) - \mathcal{L}_B(\theta^*)| \geq \epsilon\Big] = 0.$$

Sketch of proof. Let again $l = \mathcal{L}_{\mathrm{B}}(\hat{\theta}) - \mathcal{L}_{\mathrm{B}}(\theta^*)$. Chebyshev's inequality gives, for any $\epsilon_1 > 0$,

$$\lim_{n\to\infty} \frac{\mathbb{V}[l]}{\epsilon_1^2} \geq \lim_{n\to\infty} \Pr\Big[|l - \mathbb{E}[l]| \geq \epsilon_1\Big].$$

Remember that Eq. (2) means that for any $\epsilon_2 > 0$, there exists n' such that if $n' \leq n$ then $|\mathbb{E}[l]| < \epsilon_2$. Therefore, we have

$$\lim_{n\to\infty} \frac{\mathbb{V}[l]}{\epsilon_1^2} \geq \lim_{n\to\infty} \Pr\Big[|l| \geq \epsilon_1 + \epsilon_2\Big] \geq 0.$$

The arbitrary property of ϵ_1 and ϵ_2 allows $\epsilon_1 + \epsilon_2$ to be rewritten as ϵ. Also, Eq. (3) implies that $\lim_{n\to\infty} \frac{\mathbb{V}[l]}{\epsilon_1^2} = 0$. This completes the proof. See Appendix B.3 for the detailed proof. □

Informally, this theorem can be interpreted as suggesting that the optimal solutions of batch and incremental SGNS agree when n is infinitely large.

4.3 Smoothed case

We next examine the smoothed case ($0 < \alpha < 1$). In this case, the noise distribution can be represented by using the ones in the unsmoothed case:

$$q_i(w) = \frac{f_i(w)^\alpha}{\sum_{w' \in \mathcal{W}} f_i(w')^\alpha} = \frac{\left(\frac{f_i(w)}{F_i}\right)^\alpha}{\sum_{w' \in \mathcal{W}} \left(\frac{f_i(w')}{F_i}\right)^\alpha}$$

where $F_i = \sum_{w' \in \mathcal{W}} f_i(w')$ and $\frac{f_i(w)}{F_i}$ corresponds to the unsmoothed noise distribution.

Definition 3. Let $\mathrm{Z}_{i,w}$ be a random variable that represents $q_i(w)$ in the smoothed case. Then, it can be written by using $\mathrm{Y}_{i,w}$:

$$\mathrm{Z}_{i,w} = g_w(\mathrm{Y}_{i,1}, \mathrm{Y}_{i,2}, \ldots, \mathrm{Y}_{i,|\mathcal{W}|})$$

where $g_w(x_1, x_2, \ldots, x_{|\mathcal{W}|}) = \frac{x_w^\alpha}{\sum_{w' \in \mathcal{W}} x_{w'}^\alpha}$.

Because $\mathrm{Z}_{i,w}$ is no longer a linear combination of $\mathrm{X}_{i,w}$, it becomes difficult to derive similar proofs to the unsmoothed case. To address this difficulty, $\mathrm{Z}_{i,w}$ is approximated by the first-order Taylor expansion around

$$\mathbb{E}[(\mathrm{Y}_{i,1}, \mathrm{Y}_{i,2}, \ldots, \mathrm{Y}_{i,|\mathcal{W}|})] = (\mu_1, \mu_2, \ldots, \mu_{|\mathcal{W}|}).$$

The first-order Taylor approximation gives

$$\mathrm{Z}_{i,w} \approx g_w(\mu) + \sum_{v \in \mathcal{W}} M_{w,v}(\mathrm{Y}_{i,v} - g_v(\mu))$$

where $\mu = (\mu_1, \mu_2, \ldots, \mu_{|\mathcal{W}|})$ and $M_{w,v} = \frac{\partial g_w(x)}{\partial x_v}|_{x=\mu}$. Consequently, it can be shown that the first and second order moments of $\Delta\mathcal{L}(\theta)$ have the order of $\mathcal{O}(\frac{\log(n)}{n})$ in the smoothed case as well. See Appendix C for the details.

4.4 Mini-batch SGNS

The same analysis result can also be obtained for the mini-batch SGNS. We can prove Theorems 2 and 3 in the mini-batch case as well (see Appendix D for the proof). The other part of the analysis remains the same.

5 Experiments

Three experiments were conducted to investigate the correctness of the theoretical analysis (Section 5.1) and the practical usefulness of incremental SGNS (Sections 5.2 and 5.3). Details of the experimental settings that do not fit into the paper are presented in Appendix E.

5.1 Validation of theorems

An empirical experiment was conducted to validate the result of the theoretical analysis. Since it is difficult to assess the main result in Section 4.2.2 directly, the theorems in Sections 4.2.1, from which the main result is readily derived, were investigated. Specifically, the first and second order moments of $\Delta\mathcal{L}(\theta)$ were computed on datasets of increasing sizes to empirically investigate the convergence property.

Datasets of various sizes were constructed from the English Gigaword corpus (Napoles et al., 2012). The datasets made up of n words were constructed by randomly sampling sentences from the Gigaword corpus. The value of n was varied over $\{10^3, 10^4, 10^5, 10^6, 10^7\}$. $10,000$ different datasets were created for each size n to compute the first and second order moments.

Figure 1 (top left) shows log-log plots of the first order moments of $\Delta\mathcal{L}(\theta)$ computed on the different sized datasets when $\alpha = 1.0$. The crosses

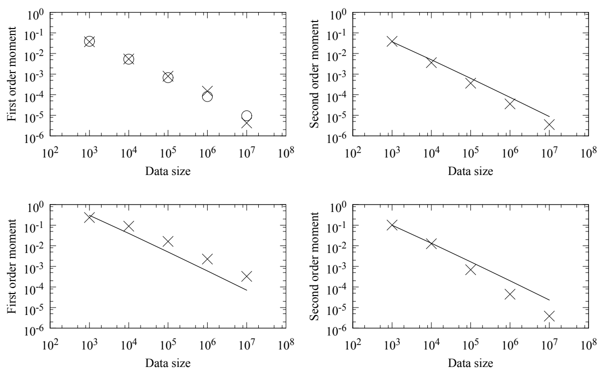

Figure 1: Log-log plots of the first and second order moments of $\Delta\mathcal{L}(\theta)$ on the different sized datasets when $\alpha = 1.0$ (top left and top right) and $\alpha = 0.75$ (bottom left and bottom right).

and circles represent the empirical values and theoretical values obtained by Theorem 1, respectively. Figure 1 (top right) similarly illustrates the second order moments of $\Delta\mathcal{L}(\theta)$. Since Theorem 3 suggests that the second order moment decreases in the order of $\mathcal{O}(\frac{\log(n)}{n})$, the graph $y \propto \frac{\log(x)}{x}$ is also shown. The graph was fitted to the empirical data by minimizing the squared error.

The top left figure demonstrates that the empirical values of the first order moments fit the theoretical result very well, providing a strong empirical evidence for the correctness of Theorem 1. In addition, the two figures show that the first and second order moments decrease almost in the order of $\mathcal{O}(\frac{\log(n)}{n})$, converging to zero as the data size increases. This result validates Theorems 2 and 3.

Figures 1 (bottom left) and (bottom right) show similar results when $\alpha = 0.75$. Since we do not have theoretical estimates of the first order moment when $\alpha \neq 1.0$, the graphs $y \propto \frac{\log(n)}{n}$ are shown in both figures. From these, we can again observe that the first and second order moments decrease almost in the order of $\mathcal{O}(\frac{\log(n)}{n})$. This indicates the validity of the investigation in Section 4.3. The relatively larger deviations from the graphs $y \propto \frac{\log(n)}{n}$, compared with the top right figure, are considered to be attributed to the first-order Taylor approximation.

5.2 Quality of word embeddings

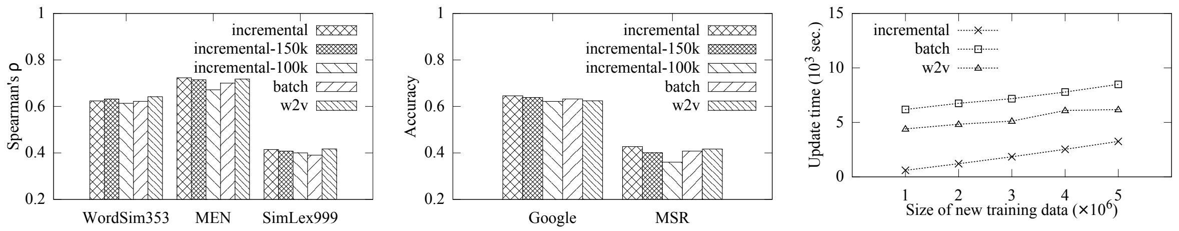
The next experiment investigates the quality of the word embeddings learned by incremental SGNS through comparison with the batch counterparts.

The Gigaword corpus was used for the training. For the comparison, both our own implementation of batch SGNS as well as WORD2VEC (Mikolov et al., 2013c) were used (denoted as **batch** and **w2v**). The training configurations of the three methods were set the same as much as possible, although it is impossible to do so perfectly. For example, incremental SGNS (denoted as **incremental**) utilized the dynamic vocabulary (*c.f.*, Section 3.2.1) and thus we set the maximum vocabulary size m to control the vocabulary size. On the other hand, we set a frequency threshold to determine the vocabulary size of **w2v**. We set $m = 240$k for **incremental**, while setting the frequency threshold to 100 for **w2v**. This yields vocabulary sets of comparable sizes: $220,389$ and $246,134$.

The learned word embeddings were assessed on five benchmark datasets commonly used in the literature (Levy et al., 2015): WordSim353 (Agirre et al., 2009), MEN (Bruni et al., 2013), SimLex-999 (Hill et al., 2015), the MSR analogy dataset (Mikolov et al., 2013c), the Google analogy dataset (Mikolov et al., 2013a). The former three are for a semantic similarity task, and the remaining two are for a word analogy task. As evaluation measures, Spearman's ρ and prediction accuracy were used in the two tasks, respectively.

Figures 2 (a) and (b) represent the results on the similarity datasets and the analogy datasets. We see that the three methods (**incremental**, **batch**, and **w2v**) perform equally well on all of the datasets. This indicates that incremental SGNS can learn as good word embeddings as the batch counterparts, while being able to perform incremental model update. Although **incremental** performs slightly better than the batch methods in some datasets, the difference seems to be a product of chance.

The figures also show the results of incremental SGNS when the maximum vocabulary size m was reduced to 150k and 100k (**incremental-150k** and **incremental-100k**). The resulting vocabulary sizes were $135,447$ and $86,993$, respectively. We see that **incremental-150k** and **incremental-100k** perform comparatively well with **incremental**, although relatively large performance drops are observed in some datasets (MEN and MSR). This demonstrates that the Misra-Gries algorithm can effectively control the vocabulary size.



(a) (b) (c)

Figure 2: (a): Spearman's ρ on the word similarity datasets. (b): Accuracy on the analogy datasets. (c): Update time when new training data is provided.

5.3 Update time

The last experiment investigates how much time incremental SGNS can save by avoiding re-training when updating the word embeddings.

In this experiment, **incremental** was first trained on the initial training data of size[5] n_1 and then updated on the new training data of size n_2 to measure the update time. For comparison, **batch** and **w2v** were re-trained on the combination of the initial and new training data. We fixed $n_1 = 10^7$ and varied n_2 over $\{1\times10^6, 2\times10^6, \ldots, 5\times10^6\}$. The experiment was conducted on Intel® Xeon® 2GHz CPU. The update time was averaged over five trials.

Figure 2 (c) compares the update time of the three methods across various values of n_2. We see that **incremental** significantly reduces the update time. It achieves 10 and 7.3 times speed-up compared with **batch** and **w2v** (when $n_2 = 10^6$). This represents the advantage of the incremental algorithm, as well as the time efficiency of the dynamic vocabulary and adaptive unigram table. We note that **batch** is slower than **w2v** because it uses AdaGrad, which maintains different learning rates for different dimensions of the parameter, while **w2v** uses the same learning rate for all dimensions.

6 Related Work

Word representations based on distributional semantics have been common (Turney and Pantel, 2010; Baroni and Lenci, 2010). The distributional methods typically begin by constructing a word-context matrix and then applying dimension reduction techniques such as SVD to obtain high-quality word meaning representations. Although some studies investigated incremental updating of the word-context matrix (Yin et al., 2015; Goyal and Daume III, 2011), they did not explore the reduced representations. On the other hand, neural word embeddings have recently gained much popularity as an alternative. However, most previous studies have not explored incremental strategies (Mikolov et al., 2013a,b; Pennington et al., 2014).

Peng et al. (2017) proposed an incremental learning method of hierarchical soft-max. Because hierarchical soft-max and negative sampling have different advantages (Peng et al., 2017), the incremental SGNS and their method are complementary to each other. Also, their updating method needs to scan not only new but also old training data, and thus is not an incremental algorithm in a strict sense. As a consequence, it potentially incurs the same time complexity as the re-training. Another consequence is that their method has to retain the old training data and thus wastes space, while incremental SGNS can discard old training examples after processing them.

Very recently, May et al. (2017) also proposed an incremental algorithm for SGNS. However, their work differs from ours in that their algorithm is not designed to use smoothed noise distribution (*i.e.*, the smoothing parameter α is assumed fixed as $\alpha = 1.0$ in their method), which is a key to learn high-quality word embeddings. Another difference is that they did not provide theoretical justification for their algorithm.

There are publicly available implementations for training SGNS, one of the most popular being WORD2VEC (Mikolov, 2013). However, it does not support an incremental training method. GENSIM (Řehůřek and Sojka, 2010) also offers SGNS training. Although GENSIM allows the incremental updating of SGNS models, it is done in an ad-hoc manner. In GENSIM, the vocabulary set as well as the unigram table are fixed once trained, meaning that new words cannot be added. Also,

[5] The number of sentences here.

they do not provide any theoretical accounts for the validity of their training method. Finally, we want to note that most of the existing implementations can be easily extended to support the incremental (or mini-batch) SGNS by simply keep updating the noise distribution.

7 Conclusion and Future Work

This paper proposed incremental SGNS and provided thorough theoretical analysis to demonstrate its validity. We also conducted experiments to empirically demonstrate its effectiveness. Although the incremental model update is often required in practical machine learning applications, only a little attention has been paid to learning word embeddings incrementally. We consider that incremental SGNS successfully addresses this situation and serves as an useful tool for practitioners.

The success of this work suggests several research directions to be explored in the future. One possibility is to explore extending other embedding methods such as GloVe (Pennington et al., 2014) to incremental algorithms. Such studies would further extend the potential of word embedding methods.

Abstract

Domain similarity measures can be used to gauge adaptability and select suitable data for transfer learning, but existing approaches define ad hoc measures that are deemed suitable for respective tasks. Inspired by work on curriculum learning, we propose to *learn* data selection measures using Bayesian Optimization and evaluate them across models, domains and tasks. Our learned measures outperform existing domain similarity measures significantly on three tasks: sentiment analysis, part-of-speech tagging, and parsing. We show the importance of complementing similarity with diversity, and that learned measures are—to some degree—transferable across models, domains, and even tasks.

1 Introduction

Natural Language Processing (NLP) models suffer considerably when applied in the wild. The distribution of the test data is typically very different from the data used during training, causing a model's performance to deteriorate substantially. Domain adaptation is a prominent approach to transfer learning that can help to bridge this gap; many approaches were suggested so far (Blitzer et al., 2007; Daumé III, 2007; Jiang and Zhai, 2007; Ma et al., 2014; Schnabel and Schütze, 2014). However, most work focused on one-to-one scenarios. Only recently research considered using multiple sources. Such studies are rare and typically rely on specific model transfer approaches (Mansour, 2009; Wu and Huang, 2016).

Inspired by work on curriculum learning (Bengio et al., 2009; Tsvetkov et al., 2016), we instead propose—to the best of our knowledge—the first model-agnostic *data selection* approach to transfer learning. Contrary to curriculum learning that aims at speeding up learning (see §6), we aim at *learning to select* the most relevant data from multiple sources using data metrics. While several measures have been proposed in the past (Moore and Lewis, 2010; Axelrod et al., 2011; Van Asch and Daelemans, 2010; Plank and van Noord, 2011; Remus, 2012), prior work is limited in studying metrics mostly in isolation, using only the notion of similarity (Ben-David et al., 2007) and focusing on a single task (see §6). Our hypothesis is that different tasks or even different domains demand different notions of similarity. In this paper we go beyond prior work by i) studying a range of similarity metrics, including diversity; and ii) testing the robustness of the learned weights across models (e.g., whether a more complex model can be approximated with a simpler surrogate), domains and tasks (to delimit the transferability of the learned weights).

The contributions of this work are threefold. First, we present the first model-independent approach to *learn* a data selection measure for transfer learning. It outperforms baselines across three tasks and multiple domains and is competitive with state-of-the-art domain adaptation approaches. Second, prior work on transfer learning mostly focused on similarity. We demonstrate empirically that diversity is as important as—and complements—domain similarity for transfer learning. Finally, we show—for the first time—to what degree learned measures *transfer* across models, domains and tasks.

2 Background: Transfer learning

Transfer learning generally involves the concepts of a domain and a task (Pan and Yang, 2010). A domain $\mathcal{D}$ consists of a feature space $\mathcal{X}$ and a marginal probability distribution $P(X)$ over $\mathcal{X}$,

Proceedings of the 2017 Conference on Empirical Methods in Natural Language Processing, pages 372–382
Copenhagen, Denmark, September 7–11, 2017. ©2017 Association for Computational Linguistics

where $X = \{x_1, \cdots, x_n\} \in \mathcal{X}$. For document classification with a bag-of-words, $\mathcal{X}$ is the space of all document vectors, x_i is the i-th document vector, and X is a sample of documents.

Given a domain $\mathcal{D} = \{\mathcal{X}, P(X)\}$, a task $\mathcal{T}$ consists of a label space $\mathcal{Y}$ and a conditional probability distribution $P(Y|X)$ that is typically learned from training data consisting of pairs $\{x_i, y_i\}$, where $x_i \in X$ and $y_i \in Y$.

Finally, given a source domain $\mathcal{D}_S$, a corresponding source task $\mathcal{T}_S$, as well as a target domain $\mathcal{D}_T$ and a target task $\mathcal{T}_T$, transfer learning seeks to facilitate the learning of the target conditional probability distribution $P(Y_T|X_T)$ in $\mathcal{D}_T$ with the information gained from $\mathcal{D}_S$ and $\mathcal{T}_S$ where $\mathcal{D}_S \neq \mathcal{D}_T$ or $\mathcal{T}_S \neq \mathcal{T}_T$. We will focus on the scenario where $\mathcal{D}_S \neq \mathcal{D}_T$ assuming that $\mathcal{T}_S = \mathcal{T}_T$, commonly referred to as domain adaptation. We investigate transfer across tasks in §5.3.

Existing research in domain adaptation has generally focused on the scenario of one-to-one adaptation: Given a set of source domains A and a set of target domains B, a model is evaluated based on its ability to adapt between all pairs (a, b) in the Cartesian product $A \times B$ where $a \in A$ and $b \in B$ (Remus, 2012). However, adaptation between two dissimilar domains is often undesirable, as it may lead to negative transfer (Rosenstein et al., 2005). Only recently, many-to-one adaptation (Mansour, 2009; Wu and Huang, 2016) has received some attention, as it replicates the realistic scenario of multiple source domains where performance on the target domain is the foremost objective.

3 Data selection model

In order to select training data for adaptation for a task $\mathcal{T}$, existing approaches rank the available n training examples $X = \{x_1, x_2, \cdots, x_n\}$ of k source domains $D = \{\mathcal{D}_1, \mathcal{D}_2, \cdots, \mathcal{D}_k\}$ according to a domain similarity measure $\mathcal{S}$ and choose the top m samples for training their algorithm. While this has been shown to work empirically (Moore and Lewis, 2010; Axelrod et al., 2011; Plank and van Noord, 2011; Van Asch and Daelemans, 2010; Remus, 2012), using a pre-existing metric leaves us unable to adapt to the characteristics of our task $\mathcal{T}$ and target domain $\mathcal{D}_T$ and foregoes additional knowledge that may be gleaned from the interaction of different metrics. For this reason, we propose to *learn* the following linear domain similarity measure $\mathcal{S}$ as a linear combination of feature values:

$$\mathcal{S} = \phi(X) \cdot w^\intercal \tag{1}$$

where $\phi(X) \in \mathbb{R}^{n \times l}$ are the similarity and diversity features further described in §3.2 for each training example, with l being the number of features, while $w \in \mathbb{R}^l$ are the weights learned by Bayesian Optimization.

We aim to learn weights w in order to optimize the objective function J of the respective task $\mathcal{T}$ on a small number of validation examples of the corresponding target domain $\mathcal{D}_T$.

3.1 Bayesian Optimization for data selection

As the learned measure $\mathcal{S}$ should be agnostic of the particular objective function J, we cannot use gradient-based methods for optimization. Similar to Tsvetkov et al. (2016), we use Bayesian Optimization (Brochu et al., 2010), which has emerged as an efficient framework to optimize any function. For instance, it has repeatedly found better settings of neural network hyperparameters than domain experts (Snoek et al., 2012).

Given a black-box function $f : \mathbb{X} \rightarrow \mathbb{R}$, Bayesian Optimization aims to find an input $\hat{x} \in \arg\min_{x \in \mathbb{X}} f(x)$ that globally minimizes f. For this, it requires a prior $p(f)$ over the function and an acquisition function $a_{p(f)} : \mathbb{X} \rightarrow \mathbb{R}$ that calculates the *utility* of any evaluation at any x.

Bayesian Optimization then proceeds iteratively. At iteration t, 1) it finds the most promising input $x_t \in \arg\max a_p(x)$ through numerical optimization; 2) it then evaluates the surrogate function $y_t \sim f(x_t) + \mathcal{N}(0, \sigma^2)$ on this input and adds the resulting data point (x_t, y_t) to the set of observations $\mathcal{O}_{t-1} = (x_j, y_j)_{j=1 \dots t-1}$; 3) finally, it updates the prior $p(f|\mathcal{O}_t)$ and the acquisition function $a_{p(f|\mathcal{O}_t)}$.

For data selection, the black-box function f looks as follows: 1) It takes as input a set of weights w that should be evaluated; 2) the training examples of all source domains are then scored and sorted according to Equation 1; 3) the model for the respective task $\mathcal{T}$ is trained on the top n samples; 4) the model is evaluated on the validation set according to the evaluation measure J and the value of J is returned.

Gaussian Processes (GP) are a popular choice for $p(f)$ due to their descriptive power (Rasmussen, 2006). We use GP with Monte Carlo acquistion and Expected Improvement (EI)

(Močkus, 1974) as acquisition function as this combination has been shown to outperform comparable approaches (Snoek et al., 2012).[1]

3.2 Features

Existing work on data selection for domain adaptation selects data based on its *similarity* to the target domain. Several measures have been proposed in the literature (Van Asch and Daelemans, 2010; Plank and van Noord, 2011; Remus, 2012), but were so far only used in isolation.

Only selecting training instances with respect to the target domain also fails to account for instances that are richer and better suited for knowledge acquisition. For this reason, we consider—to our knowledge for the first time—whether intrinsic qualities of the training data accounting for *diversity* are of use for domain adaptation in NLP.

Similarity We use a range of similarity metrics. Some metrics might be better suited for some tasks, while different measures might capture complementary information. We thus use the following measures as features for learning a more effective domain similarity metric.

We define similarity features over probability distributions in accordance with existing literature (Plank and van Noord, 2011). Let P be the representation of a source training example, while Q is the corresponding target domain representation. Let further $M = \frac{1}{2}(P + Q)$, i.e. the average distribution between P and Q and let $D_{KL}(P||Q) = \sum_{i=1}^{n} p_i \log \frac{p_i}{q_i}$, i.e., the KL divergence between the two domains. We do not use D_{KL} as a feature as it is undefined for distributions where some event $q_i \in Q$ has probability 0, which is common for term distributions. Our features are:

- Jensen-Shannon divergence (Lin, 1991): $\frac{1}{2}[D_{KL}(P||M) + D_{KL}(Q||M)]$. Jensen-Shannon divergence is a smoothed, symmetric variant of D_{KL} that has been successfully used for domain adaptation (Plank and van Noord, 2011; Remus, 2012).
- Rényi divergence (Rényi, 1961): $\frac{1}{\alpha-1} \log(\sum_{i=1}^{n} \frac{p_i^{\alpha}}{q_i^{\alpha-1}})$. Rényi divergence reduces to D_{KL} if $\alpha = 1$. We set $\alpha = 0.99$ following Van Asch and Daelemans (2010).
- Bhattacharyya distance (Bhattacharya, 1943): $\ln(\sum_i \sqrt{P_i Q_i})$
- Cosine similarity (Lee, 2001): $\frac{P \cdot Q}{\|P\| \, \|Q\|}$. We can treat the distributions alternatively as vectors and consider geometrically motivated distance functions such as cosine similarity as well as the following.
- Euclidean distance (Lee, 2001): $\sqrt{\sum_i (P_i - Q_i)^2}$.
- Variational dist. (Lee, 2001): $\sum_i |P_i - Q_i|$.

We consider three different representations for calculating the above domain similarity measures:

- Term distributions (Plank and van Noord, 2011): $t \in \mathbb{R}^{|V|}$ where t_i is the probability of the i-th word in the vocabulary V.
- Topic distributions (Plank and van Noord, 2011): $t \in \mathbb{R}^n$ where t_i is the probability of the i-th topic as determined by an LDA model (Blei et al., 2003) trained on the data and n is the number of topics.
- Word embeddings (Mikolov et al., 2013): $\frac{1}{n} \sum_i v_{w_i} \sqrt{\frac{a}{p(w_i)}}$ where n is the number of words with embeddings in the document, v_{w_i} is the pre-trained embedding of the i-th word, $p(w_i)$ its probability, and a is a smoothing factor used to discount frequent probabilities. A similar weighted sum has recently been shown to outperform supervised approaches for other tasks (Arora et al., 2017). As embeddings may be negative, we use them only with the latter three geometric features above.

Diversity For each training example, we calculate its diversity based on the words in the example. Let p_i and p_j be probabilities of the word types t_i and t_j in the training data and $\cos(v_{t_i}, v_{t_j})$ the cosine similarity between their word embeddings. We employ measures that have been used in the past for measuring diversity (Tsvetkov et al., 2016):

- Number of word types: $\#types$.
- Type-token ratio: $\frac{\#types}{\#tokens}$.
- Entropy (Shannon, 1948): $-\sum_i p_i \ln(p_i)$.
- Simpson's index (Simpson, 1949): $-\sum_i p_i^2$.
- Rényi entropy (Rényi, 1961): $\frac{1}{\alpha-1} \log(\sum_i p_i^{\alpha})$
- Quadratic entropy (Rao, 1982): $\sum_{i,j} \cos(v_{t_i}, v_{t_j}) p_i p_j$.

[1] We also experimented with FABOLAS (Klein et al., 2017), but found its ability to adjust the training set size during optimization to be inconclusive for our relatively small training sets.

4 Experiments

4.1 Tasks, datasets, and models

We evaluate our approach on three tasks: sentiment analysis, part-of speech (POS) tagging, and dependency parsing. We use the n examples with the highest score as determined by the learned data selection measure for training our models.[2] We show statistics for all datasets in Table 1.

Sentiment Analysis For sentiment analysis, we evaluate on the Amazon reviews dataset (Blitzer et al., 2006). We use tf-idf-weighted unigram and bigram features and a linear SVM classifier (Blitzer et al., 2007). We set the vocabulary size to 10,000 and the number of training examples $n = 1600$ to conform with existing approaches (Bollegala et al., 2011) and stratify the training set.

POS tagging For POS tagging and parsing, we evaluate on the coarse-grained POS data (12 universal POS) of the SANCL 2012 shared task (Petrov and McDonald, 2012). Each domain—except for WSJ—contains around 2000-5000 labeled sentences and more than 100,000 unlabeled sentences. In the case of WSJ, we use its dev and test data as labeled samples and treat the remaining sections as unlabeled. We set $n = 2000$ for POS tagging and parsing to retain enough examples for the most-similar-domain baseline.

To evaluate the impact of model choice, we compare two models: a Structured Perceptron (in-house implementation with commonly used features pertaining to tags, words, case, prefixes, as well as prefixes and suffixes) trained for 5 iterations with a learning rate of 0.2; and a state-of-the-art Bi-LSTM tagger (Plank et al., 2016) with word and character embeddings as input. We perform early stopping on the validation set with patience of 2 and use otherwise default hyperparameters[3] as provided by the authors.

Parsing For parsing, we evaluate the state-of-the-art Bi-LSTM parser by Kiperwasser and Goldberg (2016) with default hyperparameters.[4] We use the same domains as used for POS tagging, i.e., the dependency parsing data with gold POS as made available in the SANCL 2012 shared task.[5]

Table 1: Number of labeled and unlabeled sentences for each domain in the Amazon Reviews dataset (Blitzer et al., 2006) (above) and the SANCL 2012 dataset (Petrov and McDonald, 2012) for POS tagging and parsing (below).

4.2 Training details

In practice, as feature values occupy different ranges, we have found it helpful to apply z-normalisation similar to Tsvetkov et al. (2016). We moreover constrain the weights w to $[-1, 1]$.

For each dataset, we treat each domain as target domain and all other domains as source domains. Similar to Bousmalis et al. (2016), we chose to use a small number (100) target domain examples as validation set. We optimize each similarity measure using Bayesian Optimization with 300 iterations according to the objective measure J of each task (accuracy for sentiment analysis and POS tagging; LAS for parsing) with respect to the validation set of the corresponding target domain.

Unlabeled data is used in addition to calculate the representation of the target domain and to calculate the source domain representation for the most similar domain baseline. We train an LDA model (Blei et al., 2003) with 50 topics and 10 iterations for topic distribution-based representations and use GloVe embeddings (Pennington et al., 2014) trained on 42B tokens of Common Crawl data[6] for word embedding-based representations.

For sentiment analysis, we conduct 10 runs of each feature set for every domain and report mean and variance. For POS tagging and parsing, we observe that variance is low and perform one run while retaining random seeds for reproducibility.

Table 2: Accuracy scores for data selection for sentiment analysis domain adaptation on the Amazon reviews dataset (Blitzer et al., 2006). Best: bold; second-best: underlined.

4.3 Baselines and features

We compare the learned measures to three baselines: i) a random baseline that randomly selects n training samples from all source domains (*random*); ii) the top n examples selected using Jensen-Shannon divergence (*JS – examples*), which outperformed other measures in previous work (Plank and van Noord, 2011; Remus, 2012); iii) n examples randomly selected from the most similar source domain determined by Jensen-Shannon divergence (*JS – domain*). We additionally compare against training on all available source data (6,000 examples for sentiment analysis; 14,700-17,569 examples for POS tagging and parsing depending on the target domain).

We optimize data selection using Bayesian Optimization with every feature set: similarity features respectively based on i) word embeddings, ii) term distributions, and iii) topic distributions; and iv) diversity features. In addition, we investigate how well different representations help each other by using similarity features with the two best-performing representations, term distributions and topic distributions. Finally, we explore whether diversity and similarity-based features complement each other by in turn using each similarity-based feature set together with diversity features.

5 Results

Sentiment analysis We show results for sentiment analysis in Table 2. First of all, the baselines show that the sentiment review domains are clearly delimited. Adapting between two similar domains such as Book and DVD is more productive than adaptation between dissimilar domains, e.g. Books and Electronics, as shown in previous work (Blitzer et al., 2007). This explains the strong performance of the most-similar-domain baseline. In contrast, selecting individual examples based on a domain similarity measure performs only as good as chance. Thus, when domains are more clear-cut, selecting from the closest domain is a stronger baseline than selecting from the entire pool of source data.

If we learn a data selection measure using Bayesian Optimization, we are able to outperform the baselines with almost all feature sets. Performance gains are considerable for all domains with individual feature sets (term similarity, word embeddings similarity, diversity and topic similarity), except for Books were improvements for some single feature sets are smaller. Term distributions and topic distributions are the best-performing representations for calculating similarity, with term distributions performing slightly better across all domains. Combining term distribution-based and topic distribution-based features only provides marginal gains over the individual feature sets, demonstrating that most of the information is contained in the similarity features rather than the representations.

Diversity features perform comparatively to the best similarity features and outperform them on two domains. Furthermore, the combination of diversity and similarity features yields another sizable gain of around 1 percentage point for almost all domains over the best similarity features, which shows that diversity and similarity features capture complementary information. Term distribution and topic distribution-based similarity features in

conjunction with diversity features finally yield the best performance, outperforming the baselines by 2-6 points in absolute accuracy.

Finally, we compare data selection to training on all available source data (in this setup, 6,000 instances). The result complements the findings of the most-similar baseline: as domains are dissimilar, training on all available sources is detrimental.

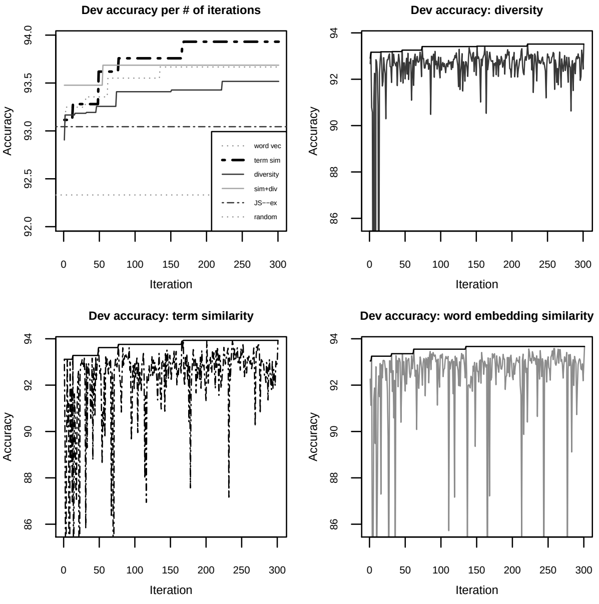

Figure 1: Dev accuracy curves of Bayes Optimization for POS tagging on the Reviews domain. Best dev acc for different feature sets (top-left). Best dev acc vs. exploration (top-right, bottom).

POS tagging Results for POS tagging are given in Table 3. Using Bayesian Optimization, we are able to outperform the baselines with almost all feature sets, except for a few cases (e.g., diversity and word embeddings similarity, topic and term distributions). Overall term distribution-based similarity emerges as the most powerful individual feature. Combining it with diversity does not prove as beneficial as in the sentiment analysis case, however, often yields the second-best results.

Notice that for POS tagging/parsing, in contrast to sentiment analysis, the most-similar domain baseline is not effective, it often performs only as good as chance, or even hurts. In contrast, the baseline that selects instances (*JS – examples*) rather than a domain performs better. This makes sense as in SA topically closer domains express sentiment in more similar ways, while for POS tagging having more varied training instances is intuitively more beneficial. In fact, when inspecting the domain distribution of our approach, we find that the best SA model chooses more instances from the closest domain, while for POS tagging instances are more balanced across domains. This suggests that the Web treebank domains are less clear-cut. In fact, training a model on all sources, which is considerably more and varied data (in this setup, 14-17.5k training instances) is beneficial. This is in line with findings in machine translation (Mirkin and Besacier, 2014), which show that similarity-based selection works best if domains are very different. Results are thus less pronounced for POS tagging, and we leave experimenting with larger n for future work.

To gain some insight into the optimization procedure, Figure 1 shows the development accuracy for the Structured Perceptron for an example domain. The top-right and bottom graphs show the hypothesis space exploration of Bayesian Optimization for different single feature sets, while the

	Target domains

Table 4: Accuracy scores for cross-model transfer of learned data selection weights for part-of-speech tagging from Structured Perceptron (P$_{proxy}$) to Bi-LSTM tagger (B) (Plank et al., 2016) on the SANCL 2012 shared task dataset (Petrov and McDonald, 2012). Data selection weights are learned using model $\mathcal{M}_S$; Bi-LSTM tagger (B) is then trained using the learned weights. Better than baselines: underlined.

top-left graph displays the overall best dev accuracy for different features. We observe again that term similarity is among the best feature sets and results in a larger explored space (more variance), in contrast to the diversity features whose development accuracy increases less and results in an overall less explored space. Exploration plots for other features/models looks similar.

Parsing The results for parsing are given in Table 3. Diversity features are stronger than for POS tagging and outperform the baselines for all except the Reviews domain. Similarly to POS tagging, term distribution-based similarity as well as its combination with diversity features yield the best results across most domains.

5.1 Transfer across models

In addition, we are interested how well the metric learned for one target domain transfers to other settings. We first investigate its ability to transfer to another model. In practice, a metric can be learned using a model that is cheap to evaluate and serves as proxy for a state-of-the-art model, in a way similar to uptraining (Petrov et al., 2010). For this, we employ the data selection features learned using the Structured Perceptron model for POS tagging and use them to select data for the Bi-LSTM tagger. The results in Table 4 indicate that cross-model transfer is indeed possible, with most transferred feature sets achieving similar results or even outperforming features learned with the Bi-LSTM. In particular, transferred diversity significantly outperforms its in-model equivalent. This is encouraging, as it allows to learn a data selection metric using less complex models.

5.2 Transfer across domains

We explore whether data selection parameters learned for one target domain transfer to other target domains. For each domain, we use the weights with the highest performance on the validation set and use them for data selection with the remaining domains as target domains. We conduct 10 runs for the best-performing feature sets for sentiment analysis and report the average accuracy scores in Table 5 (for POS tagging, see Table 6).

		Target domains

SDAMS	-	78.29	79.13	84.06	86.29

Table 5: Accuracy scores for cross-domain transfer of learned data selection weights on Amazon reviews (Blitzer et al., 2006). $\mathcal{D}_S$: target domain used for learning metric $\mathcal{S}$. B: Book. D: DVD. E: Electronics. K: Kitchen. Sim: term distribution-based similarity. Div: diversity. Best per feature set: bold. In-domain results: gray. SDAMS (Wu and Huang, 2016) listed as comparison.

The transfer of the weights learned with Bayesian Optimization is quite robust in most cases. Feature sets like Similarity or Diversity trained on Books outperform the strong JS – $\mathcal{D}$ baseline in all 6 cases, for Electronics and Kitchen in 4/6 cases (off-diagonals for box 2 and 3 in Table 5). In some cases, the transferred weights even outperform the data selection metric learned for the respective domain, such as on D->E with sim and sim+div features and by almost 2 pp on E->D.

Same features as in Table 5. In-task results: gray. Better than base: underlined.

Transferred similarity+diversity features mostly achieve higher performance than other feature sets, but the higher number of parameters runs the risk of overfitting to the domain as can be observed with two instances of negative transfer with sim+div features.

As a reference, we also list the performance of the state-of-the-art multi-domain adaptation approach (Wu and Huang, 2016), which shows that task-independent data selection is in fact competitive with a task-specific, heuristic state-of-the-art domain adaptation approach. In fact our *transferred* similarity+diversity feature (E->D) outperforms the state-of-the-art (Wu and Huang, 2016) on DVD. This is encouraging as previous work (Remus, 2012) has shown that data selection and domain adaptation can be complementary.

5.3 Transfer across tasks

We finally investigate whether data selection is task-specific or whether a metric learned on one task can be transferred to another one. For each feature set, we use the learned weights for each domain in the source task (for sentiment analysis, we use the best weights on the validation set; for POS tagging, we use the Structured Perceptron model) and run experiments with them for all domains in the target task.[7] We report the averaged accuracy scores for transfer across all tasks in Table 7.

Transfer is productive between related tasks, i.e. POS tagging and parsing results are similar to those obtained with data selection learned for the particular task. We observe large drops in performance for transfer between unrelated tasks, such

[7] E.g., for SA->POS, for each feature set, we obtain one set of weights for each of 4 SA domains, which we use to select data for the 6 POS domains, yielding $4 \cdot 6 = 24$ results.

as sentiment analysis and POS tagging, which is expected since these are very different tasks. Between related tasks, the combination of similarity and diversity features achieves the most robust transfer and outperforms the baselines in both cases. This suggests that even in the absence of target task data, we only require data of a related task to learn a successful data selection measure.

6 Related work

Most prior work on data selection for transfer learning focuses on phrase-based machine translation. Typically language models are leveraged via perplexity or cross-entropy scoring to select target data (Moore and Lewis, 2010; Axelrod et al., 2011; Duh et al., 2013; Mirkin and Besacier, 2014). A recent study investigates data selection for neural machine translation (van der Wees et al., 2017). Perplexity was also used to select training data for dependency parsing (Søgaard, 2011), but has been found to be less suitable for tasks such as sentiment analysis (Ruder et al., 2017). In general, there are fewer studies on data selection for other tasks, e.g., constituent parsing (McClosky et al., 2010), dependency parsing (Plank and van Noord, 2011; Søgaard, 2011) and sentiment analysis (Remus, 2012). Work on predicting task accuracy is related, but can be seen as complementary (Ravi et al., 2008; Van Asch and Daelemans, 2010).

Many domain similarity metrics have been proposed. Blitzer et al. (2007) show that proxy $\mathcal{A}$ distance can be used to measure the adaptability between two domains in order to determine examples for annotation. Van Asch and Daelemans (2010) find that Rényi divergence outperforms other metrics in predicting POS tagging accuracy, while Plank and van Noord (2011) observe that topic distribution-based representations with Jensen-Shannon divergence perform best for data selection for parsing. Remus (2012) apply Jensen-Shannon divergence to select training examples for sentiment analysis. Finally, Wu and Huang (2016) propose a similarity metric based on a sentiment graph. We test previously explored similarity metrics and complement them with diversity.

Very recently interest emerged in *curriculum learning* (Bengio et al., 2009). It is inspired by human active learning by providing easier examples at initial learning stages (e.g., by curriculum strategies such as growing vocabulary size). Curriculum learning employs a range of data metrics, but aims at altering the order in which the entire training data is selected, rather than *selecting* data. In contrast to us, curriculum learning is mostly aimed at speeding up the learning, while we focus on learning metrics for transfer learning. Other related work in this direction include using Reinforcement Learning to learn what data to select during neural network training (Fan et al., 2017).

There is a long history of research in adaptive data selection, with early approaches grounded in information theory using a Bayesian learning framework (MacKay, 1992). It has also been studied extensively as active learning (El-Gamal, 1991). Curriculum learning is related to active learning (Settles, 2012), whose view is different: active learning aims at finding the most difficult instances to label, examples typically close to the decision boundary. Confidence-based measures are prominent, but as such are less widely applicable than our model-agnostic approach.

The approach most similar to ours is by Tsvetkov et al. (2016) who use Bayesian Optimization to learn a curriculum for training word embeddings. Rather than ordering data (in their case, paragraphs), we use Bayesian Optimization for learning to *select* relevant training instances that are useful for transfer learning in order to prevent negative transfer (Rosenstein et al., 2005). To the best of our knowledge there is no prior work that uses this strategy for transfer learning.

7 Conclusion

We propose to use Bayesian Optimization to learn data selection measures for transfer learning. Our results outperform existing domain similarity metrics on three tasks (sentiment analysis, POS tagging and parsing), and are competitive with a state-of-the-art domain adaptation approach. More importantly, we present the first study on the transferability of such measures, showing promising results to port them across models, domains and related tasks.

Unsupervised Pretraining for Sequence to Sequence Learning

Prajit Ramachandran and **Peter J. Liu** and **Quoc V. Le**

Abstract

This work presents a general unsupervised learning method to improve the accuracy of sequence to sequence (seq2seq) models. In our method, the weights of the encoder and decoder of a seq2seq model are initialized with the pretrained weights of two language models and then fine-tuned with labeled data. We apply this method to challenging benchmarks in machine translation and abstractive summarization and find that it significantly improves the subsequent supervised models. Our main result is that pretraining improves the generalization of seq2seq models. We achieve state-of-the-art results on the WMT English→German task, surpassing a range of methods using both phrase-based machine translation and neural machine translation. Our method achieves a significant improvement of 1.3 BLEU from the previous best models on both WMT'14 and WMT'15 English→German. We also conduct human evaluations on abstractive summarization and find that our method outperforms a purely supervised learning baseline in a statistically significant manner.

1 Introduction

Sequence to sequence (*seq2seq*) models (Sutskever et al., 2014; Cho et al., 2014; Kalchbrenner and Blunsom, 2013; Allen, 1987; Ñeco and Forcada, 1997) are extremely effective on a variety of tasks that require a mapping between a variable-length input sequence to a variable-length output sequence. The main weakness of sequence to sequence models, and deep networks in general, lies in the fact that they can easily overfit when the amount of supervised training data is small.

In this work, we propose a simple and effective technique for using unsupervised pretraining to improve seq2seq models. Our proposal is to initialize both encoder and decoder networks with pretrained weights of two language models. These pretrained weights are then fine-tuned with the labeled corpus. During the fine-tuning phase, we jointly train the seq2seq objective with the language modeling objectives to prevent overfitting.

We benchmark this method on machine translation for English→German and abstractive summarization on CNN and Daily Mail articles. Our main result is that a seq2seq model, with pretraining, exceeds the strongest possible baseline in both neural machine translation and phrase-based machine translation. Our model obtains an improvement of 1.3 BLEU from the previous best models on both WMT'14 and WMT'15 English→German. On human evaluations for abstractive summarization, we find that our model outperforms a purely supervised baseline, both in terms of correctness and in avoiding unwanted repetition.

We also perform ablation studies to understand the behaviors of the pretraining method. Our study confirms that among many other possible choices of using a language model in seq2seq with attention, the above proposal works best. Our study also shows that, for translation, the main gains come from the improved generalization due to the pretrained features. For summarization, pretraining the encoder gives large improvements, suggesting that the gains come from the improved optimization of the encoder that has been unrolled for hundreds of timesteps. On both tasks, our proposed method always improves generalization on the test sets.

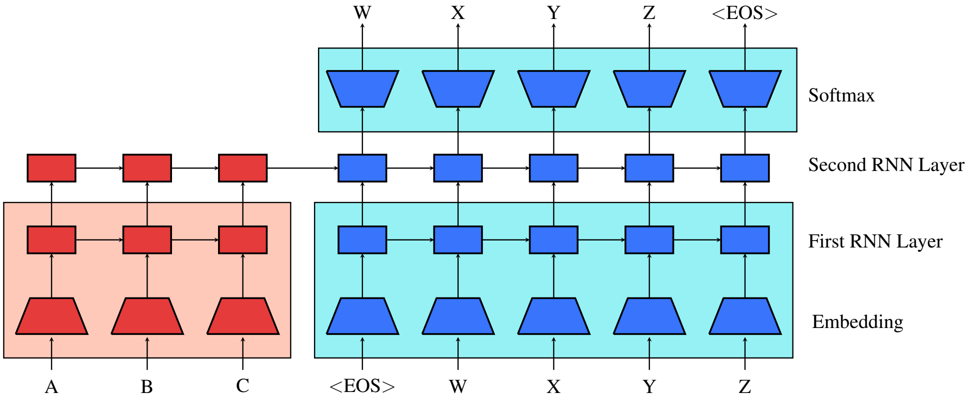

Figure 1: Pretrained sequence to sequence model. The red parameters are the encoder and the blue parameters are the decoder. All parameters in a shaded box are pretrained, either from the source side (light red) or target side (light blue) language model. Otherwise, they are randomly initialized.

2 Methods

In the following section, we will describe our basic unsupervised pretraining procedure for sequence to sequence learning and how to modify sequence to sequence learning to effectively make use of the pretrained weights. We then show several extensions to improve the basic model.

2.1 Basic Procedure

Given an input sequence $x_1, x_2, ..., x_m$ and an output sequence $y_n, y_{n-1}, ..., y_1$, the objective of sequence to sequence learning is to maximize the likelihood $p(y_n, y_{n-1}, ..., y_1 | x_1, x_2, ..., x_m)$. Common sequence to sequence learning methods decompose this objective as $p(y_n, y_{n-1}, ..., y_1 | x_1, x_2, ..., x_m) = \prod_{t=1}^{n} p(y_t | y_{t-1}, ..., y_1; x_1, x_2, ..., x_m)$.

In sequence to sequence learning, an RNN encoder is used to represent $x_1, ..., x_m$ as a hidden vector, which is given to an RNN decoder to produce the output sequence. Our method is based on the observation that without the encoder, the decoder essentially acts like a language model on y's. Similarly, the encoder with an additional output layer also acts like a language model. Thus it is natural to use trained languages models to initialize the encoder and decoder.

Therefore, the basic procedure of our approach is to pretrain both the seq2seq encoder and decoder networks with language models, which can be trained on large amounts of unlabeled text data. This can be seen in Figure 1, where the parameters in the shaded boxes are pretrained. In the following we will describe the method in detail using machine translation as an example application.

First, two monolingual datasets are collected, one for the source side language, and one for the target side language. A language model (*LM*) is trained on each dataset independently, giving an LM trained on the source side corpus and an LM trained on the target side corpus.

After two language models are trained, a multi-layer seq2seq model M is constructed. The embedding and first LSTM layers of the encoder and decoder are initialized with the pretrained weights. To be even more efficient, the softmax of the decoder is initialized with the softmax of the pretrained target side LM.

2.2 Monolingual language modeling losses

After the seq2seq model M is initialized with the two LMs, it is fine-tuned with a labeled dataset. However, this procedure may lead to *catastrophic forgetting*, where the model's performance on the language modeling tasks falls dramatically after fine-tuning (Goodfellow et al., 2013). This may hamper the model's ability to generalize, especially when trained on small labeled datasets.

To ensure that the model does not overfit the labeled data, we regularize the parameters that were pretrained by continuing to train with the monolingual language modeling losses. The seq2seq and language modeling losses are weighted equally.

In our ablation study, we find that this technique is complementary to pretraining and is important in achieving high performance.

2.3 Other improvements to the model

Pretraining and the monolingual language modeling losses provide the vast majority of improvements to the model. However in early experimentation, we found minor but consistent improvements with two additional techniques: a) residual connections and b) multi-layer attention (see Figure 2).

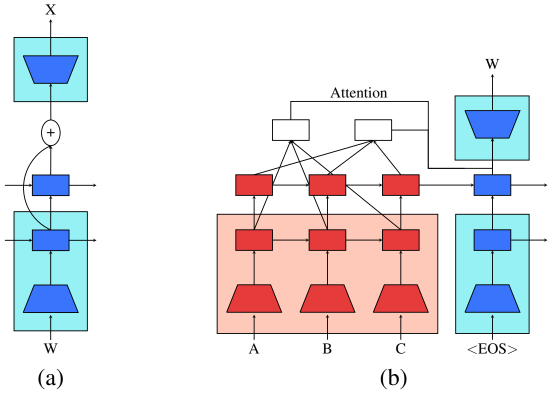

Figure 2: Two small improvements to the baseline model: (a) residual connection, and (b) multi-layer attention.

Residual connections: As described, the input vector to the decoder softmax layer is a random vector because the high level (non-first) layers of the LSTM are randomly initialized. This introduces random gradients to the pretrained parameters. To avoid this, we use a residual connection from the output of the first LSTM layer directly to the input of the softmax (see Figure 2-a).

Multi-layer attention: In all our models, we use an attention mechanism (Bahdanau et al., 2015), where the model attends over both top and first layer (see Figure 2-b). More concretely, given a query vector q_t from the decoder, encoder states from the first layer $h_1^1, \ldots, h_T^1$, and encoder states from the last layer $h_1^L, \ldots, h_T^L$, we compute the attention context vector c_t as follows:

$$\alpha_i = \frac{\exp(q_t \cdot h_i^N)}{\sum_{j=1}^T \exp(q_t \cdot h_j^N)} \qquad c_t^1 = \sum_{i=1}^T \alpha_i h_i^1$$

$$c_t^N = \sum_{i=1}^T \alpha_i h_i^N \qquad c_t = [c_t^1; c_t^N]$$

3 Experiments

In the following section, we apply our approach to two important tasks in seq2seq learning: machine translation and abstractive summarization. On each task, we compare against the previous best systems. We also perform ablation experiments to understand the behavior of each component of our method.

3.1 Machine Translation

Dataset and Evaluation: For machine translation, we evaluate our method on the WMT English→German task (Bojar et al., 2015). We used the WMT 14 training dataset, which is slightly smaller than the WMT 15 dataset. Because the dataset has some noisy examples, we used a language detection system to filter the training examples. Sentences pairs where either the source was not English or the target was not German were thrown away. This resulted in around 4 million training examples. Following Sennrich et al. (2015a), we use subword units (Sennrich et al., 2015b) with 89500 merge operations, giving a vocabulary size around 90000. The validation set is the concatenated newstest2012 and newstest2013, and our test sets are newstest2014 and newstest2015. Evaluation on the validation set was with case-sensitive BLEU (Papineni et al., 2002) on tokenized text using `multi-bleu.perl`. Evaluation on the test sets was with case-sensitive BLEU on detokenized text using `mteval-v13a.pl`. The monolingual training datasets are the News Crawl English and German corpora, each of which has more than a billion tokens.

Experimental settings: The language models were trained in the same fashion as (Jozefowicz et al., 2016) We used a 1 layer 4096 dimensional LSTM with the hidden state projected down to 1024 units (Sak et al., 2014) and trained for one week on 32 Tesla K40 GPUs. Our seq2seq model was a 3 layer model, where the second and third layers each have 1000 hidden units. The monolingual objectives, residual connection, and the modified attention were all used. We used the Adam optimizer (Kingma and Ba, 2015) and train with asynchronous SGD on 16 GPUs for speed. We used a learning rate of 5e-5 which is multiplied by 0.8 every 50K steps after an initial 400K steps, gradient clipping with norm 5.0 (Pascanu et al., 2013), and dropout of 0.2 on non-recurrent connections (Zaremba et al., 2014). We used early stopping on validation set perplexity. A beam size of 10 was used for decoding. Our ensemble is con-

structed with the 5 best performing models on the validation set, which are trained with different hyperparameters.

Results: Table 1 shows the results of our method in comparison with other baselines. Our method achieves a new state-of-the-art for single model performance on both newstest2014 and newstest2015, significantly outperforming the competitive semi-supervised *backtranslation* technique (Sennrich et al., 2015a). Equally impressive is the fact that our best single model outperforms the previous state of the art ensemble of 4 models. Our ensemble of 5 models matches or exceeds the previous best ensemble of 12 models.

Ablation study: In order to better understand the effects of pretraining, we conducted an ablation study by modifying the pretraining scheme. We were primarily interested in varying the pretraining scheme and the monolingual language modeling objectives because these two techniques produce the largest gains in the model. Figure 3 shows the drop in validation BLEU of various ablations compared with the full model. The *full model* uses LMs trained with monolingual data to initialize the encoder and decoder, in addition to the language modeling objective. In the following, we interpret the findings of the study. Note that some findings are specific to the translation task.

Given the results from the ablation study, we can make the following observations:

- Only pretraining the decoder is better than only pretraining the encoder: Only pretraining the encoder leads to a 1.6 BLEU point drop while only pretraining the decoder leads to a 1.0 BLEU point drop.

- Pretrain as much as possible because the benefits compound: given the drops of no pretraining at all (-2.0) and only pretraining the encoder (-1.6), the additive estimate of the drop of only pretraining the decoder side is $-2.0 - (-1.6) = -0.4$; however the actual drop is -1.0 which is a much larger drop than the additive estimate.

- Pretraining the softmax is important: Pretraining only the embeddings and first LSTM layer gives a large drop of 1.6 BLEU points.

- The language modeling objective is a strong regularizer: The drop in BLEU points of pretraining the entire model and not using the LM objective is as bad as using the LM objective without pretraining.

- Pretraining on a lot of unlabeled data is essential for learning to extract powerful features: If the model is initialized with LMs that are pretrained on the source part and target part of the *parallel* corpus, the drop in performance is as large as not pretraining at all. However, performance remains strong when pretrained on the large, non-news Wikipedia corpus.

To understand the contributions of unsupervised pretraining vs. supervised training, we track the performance of pretraining as a function of dataset size. For this, we trained a a model with and without pretraining on random subsets of the English→German corpus. Both models use the additional LM objective. The results are summarized in Figure 4. When a 100% of the labeled data is used, the gap between the pretrained and no pretrain model is 2.0 BLEU points. However, that gap grows when less data is available. When trained on 20% of the labeled data, the gap becomes 3.8 BLEU points. This demonstrates that the pretrained models degrade less as the labeled dataset becomes smaller.

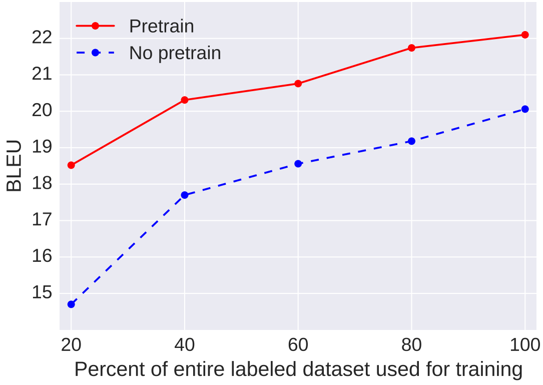

Figure 4: Validation performance of pretraining vs. no pretraining when trained on a subset of the entire labeled dataset for English→German translation.

3.2 Abstractive Summarization

Dataset and Evaluation: For a low-resource abstractive summarization task, we use the CNN/Daily Mail corpus from (Hermann et al., 2015). Following Nallapati et al. (2016), we modify the data collection scripts to restore the bullet point summaries. The task is to predict the bullet point summaries from a news article. The dataset has fewer than 300K document-summary pairs. To compare against Nallapati et al. (2016), we used the anonymized corpus. However, for our ablation study, we used the non-anonymized corpus.[1] We evaluate our system using full length ROUGE (Lin, 2004). For the anonymized corpus in particular, we considered each highlight as a separate sentence following Nallapati et al. (2016). In this setting, we used the English Gigaword corpus (Napoles et al., 2012) as our larger, unlabeled "monolingual" corpus, although all data used in this task is in English.

Experimental settings: We use subword units (Sennrich et al., 2015b) with 31500 merges, resulting in a vocabulary size of about 32000. We use up to the first 600 tokens of the document and

[1] We encourage future researchers to use the non-anonymized version because it is a more realistic summarization setting with a larger vocabulary. Our numbers on the non-anonymized test set are 35.56 ROUGE-1, 14.60 ROUGE-2, and 25.08 ROUGE-L. We did not consider highlights as separate sentences.

System	*ROUGE-1*	*ROUGE-2*	*ROUGE-L*
Seq2seq + pretrained embeddings (Nallapati et al., 2016)	32.49	11.84	29.47
+ temporal attention (Nallapati et al., 2016)	**35.46**	**13.30**	**32.65**
Pretrained seq2seq	32.56	11.89	29.44

Table 2: Results on the anonymized CNN/Daily Mail dataset.

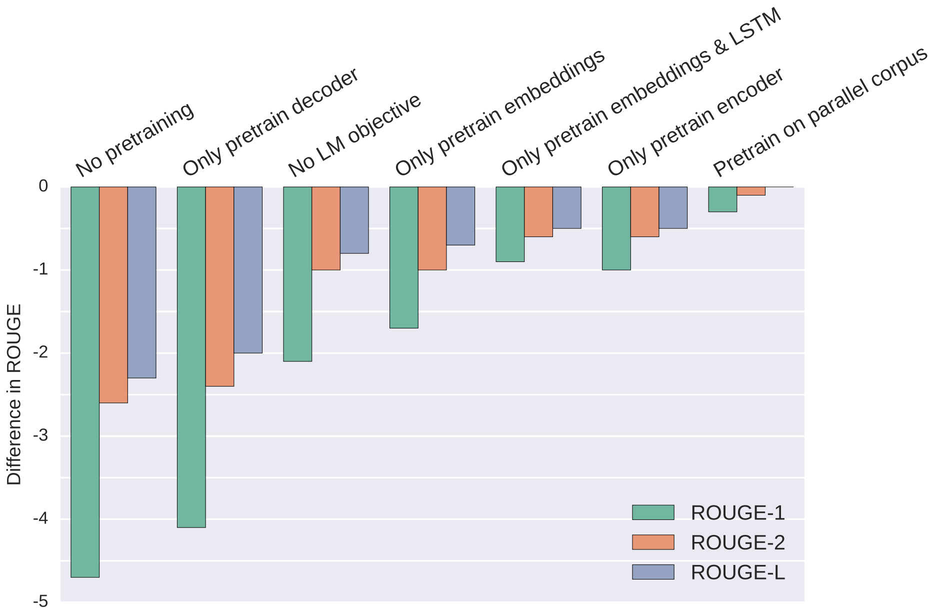

Figure 5: Summarization ablation study measuring the difference in validation ROUGE between various ablations and the full model. More negative is worse. The full model uses LMs trained with unlabeled data to initialize the encoder and decoder, plus the language modeling objective.

predict the entire summary. Only one language model is trained and it is used to initialize both the encoder and decoder, since the source and target languages are the same. However, the encoder and decoder are not tied. The LM is a one-layer LSTM of size 1024 trained in a similar fashion to Jozefowicz et al. (2016). For the seq2seq model, we use the same settings as the machine translation experiments. The only differences are that we use a 2 layer model with the second layer having 1024 hidden units, and that the learning rate is multiplied by 0.8 every 30K steps after an initial 100K steps.

Results: Table 2 summarizes our results on the anonymized version of the corpus. Our pretrained model is only able to match the previous baseline seq2seq of Nallapati et al. (2016). Interestingly, they use pretrained word2vec (Mikolov et al., 2013) vectors to initialize their word embeddings. As we show in our ablation study, just pretraining the embeddings itself gives a large improvement. Furthermore, our model is a unidirectional LSTM while they use a bidirectional LSTM. They also use a longer context of 800 tokens, whereas we used a context of 600 tokens due to GPU memory issues.

Ablation study: We performed an ablation study similar to the one performed on the machine translation model. The results are reported in Figure 5. Here we report the drops on ROUGE-1, ROUGE-2, and ROUGE-L on the non-anonymized validation set.

Given the results from our ablation study, we can make the following observations:

- Pretraining appears to improve optimization: in contrast with the machine translation model, it is more beneficial to only pretrain the encoder than only the decoder of the summarization model. One interpretation is that pretraining enables the gradient to flow much further back in time than randomly initialized weights. This may also explain why pretraining on the parallel corpus is no worse than pretraining on a larger monolingual corpus.

- The language modeling objective is a strong regularizer: A model without the LM objective has a significant drop in ROUGE scores.

Human evaluation: As ROUGE may not be able to capture the quality of summarization, we also performed a small qualitative study to understand the human impression of the summaries produced by different models. We took 200 random documents and compared the performance of a pretrained and non-pretrained system. The document, gold summary, and the two system outputs were presented to a human evaluator who was asked to rate each system output on a scale of 1-5 with 5 being the best score. The system outputs were presented in random order and the evaluator did not know the identity of either output. The evaluator noted if there were repetitive phrases or sentences in either system outputs. Unwanted repetition was also noticed by Nallapati et al. (2016).

Table 3 and 4 show the results of the study. In both cases, the pretrained system outperforms the system without pretraining in a statistically significant manner. The better optimization enabled by pretraining improves the generated summaries and decreases unwanted repetition in the output.

NP > *P*	*NP* = *P*	*NP* < *P*
29	88	83

Table 3: The count of how often the no pretrain system (*NP*) achieves a higher, equal, and lower score than the pretrained system (*P*) in the side-by-side study where the human evaluator gave each system a score from 1-5. The sign statistical test gives a p-value of < 0.0001 for rejecting the null hypothesis that there is no difference in the score obtained by either system.

		No pretrain	
		No repeats	Repeats
Pretrain	No repeats	67	65
	Repeats	24	44

Table 4: The count of how often the pretrain and no pretrain systems contain repeated phrases or sentences in their outputs in the side-by-side study. McNemar's test gives a p-value of < 0.0001 for rejecting the null hypothesis that the two systems repeat the same proportion of times. The pretrained system clearly repeats less than the system without pretraining.

4 Related Work

Unsupervised pretraining has been intensively studied in the past years, most notably is the work by Dahl et al. (2012) who found that pretraining with deep belief networks improved feedforward acoustic models. More recent acoustic models have found pretraining unnecessary (Xiong et al., 2016; Zhang et al., 2016; Chan et al., 2015), probably because the reconstruction objective of deep belief networks is too easy. In contrast, we find that pretraining language models by next step prediction significantly improves seq2seq on challenging real world datasets.

Despite its appeal, unsupervised learning has not been widely used to improve supervised training. Dai and Le (2015); Radford et al. (2017) are amongst the rare studies which showed the benefits of pretraining in a semi-supervised learning setting. Their methods are similar to ours except that they did not have a decoder network and thus could not apply to seq2seq learning. Similarly, Zhang and Zong (2016) found it useful to add an additional task of sentence reordering of source-side monolingual data for neural machine translation. Various forms of transfer or multitask learning with seq2seq framework also have the flavors of our algorithm (Zoph et al., 2016; Luong et al., 2015; Firat et al., 2016).

Perhaps most closely related to our method is the work by Gulcehre et al. (2015), who combined a language model with an already trained seq2seq model by fine-tuning additional deep output layers. Empirically, their method produces small improvements over the supervised baseline. We suspect that their method does not produce significant gains because (i) the models are trained independently of each other and are not fine-tuned (ii) the LM is combined with the seq2seq model after the last layer, wasting the benefit of the low level LM features, and (iii) only using the LM on the decoder side. Venugopalan et al. (2016) addressed (i) but still experienced minor improvements. Using pretrained GloVe embedding vectors (Pennington et al., 2014) had more impact.

Related to our approach in principle is the work by Chen et al. (2016) who proposed a two-term, theoretically motivated unsupervised objective for unpaired input-output samples. Though they did not apply their method to seq2seq learning, their framework can be modified to do so. In that case, the first term pushes the output to be highly probable under some scoring model, and the second term ensures that the output depends on the input. In the seq2seq setting, we interpret the first term as a pretrained language model scoring the output sequence. In our work, we fold the pretrained language model into the decoder. We believe that using the pretrained language model only for scoring is less efficient that using all the pretrained weights. Our use of labeled examples satisfies the second term. These connections provide a theoretical grounding for our work.

In our experiments, we benchmark our method on machine translation, where other unsupervised methods are shown to give promising results (Sennrich et al., 2015a; Cheng et al., 2016). In backtranslation (Sennrich et al., 2015a), the trained model is used to decode unlabeled data to yield extra labeled data. One can argue that this method may not have a natural analogue to other tasks such as summarization. We note that their technique is complementary to ours, and may lead to additional gains in machine translation. The method of using autoencoders in Cheng et al. (2016) is promising, though it can be argued that autoencoding is an easy objective and language modeling may force the unsupervised models to learn better features.

5 Conclusion

We presented a novel unsupervised pretraining method to improve sequence to sequence learning. The method can aid in both generalization and optimization. Our scheme involves pretraining two language models in the source and target domain, and initializing the embeddings, first LSTM layers, and softmax of a sequence to sequence model with the weights of the language models. Using our method, we achieved state-of-the-art machine translation results on both WMT'14 and WMT'15 English to German. A key advantage of this technique is that it is flexible and can be applied to a large variety of tasks.

Efficient Attention using a Fixed-Size Memory Representation

Abstract

The standard content-based attention mechanism typically used in sequence-to-sequence models is computationally expensive as it requires the comparison of large encoder and decoder states at each time step. In this work, we propose an alternative attention mechanism based on a fixed size memory representation that is more efficient. Our technique predicts a compact set of K attention contexts during encoding and lets the decoder compute an efficient lookup that does not need to consult the memory. We show that our approach performs on-par with the standard attention mechanism while yielding inference speedups of 20% for real-world translation tasks and more for tasks with longer sequences. By visualizing attention scores we demonstrate that our models learn distinct, meaningful alignments.

1 Introduction

Sequence-to-sequence models (Sutskever et al., 2014; Cho et al., 2014) have achieved state of the art results across a wide variety of tasks, including Neural Machine Translation (NMT) (Bahdanau et al., 2014; Wu et al., 2016), text summarization (Rush et al., 2015; Nallapati et al., 2016), speech recognition (Chan et al., 2015; Chorowski and Jaitly, 2016), image captioning (Xu et al., 2015), and conversational modeling (Vinyals and Le, 2015; Li et al., 2015).

The most popular approaches are based on an encoder-decoder architecture consisting of two recurrent neural networks (RNNs) and an attention mechanism that aligns target to source tokens (Bahdanau et al., 2014; Luong et al., 2015). The typical attention mechanism used in these architectures computes a new attention context at each decoding step based on the current state of the decoder. Intuitively, this corresponds to looking at the source sequence after the output of every single target token.

Inspired by how humans process sentences, we believe it may be unnecessary to look back at the entire original source sequence at each step.[1] We thus propose an alternative attention mechanism (section 3) that leads to smaller computational time complexity. Our method predicts K attention context vectors while reading the source, and learns to use a weighted average of these vectors at each step of decoding. Thus, we avoid looking back at the source sequence once it has been encoded. We show (section 4) that this speeds up inference while performing on-par with the standard mechanism on both toy and real-world WMT translation datasets. We also show that our mechanism leads to larger speedups as sequences get longer. Finally, by visualizing the attention scores (section 5), we verify that the proposed technique learns meaningful alignments, and that different attention context vectors specialize on different parts of the source.

2 Background

2.1 Sequence-to-Sequence Model with Attention

Our models are based on an encoder-decoder architecture with attention mechanism (Bahdanau et al., 2014; Luong et al., 2015). An encoder function takes as input a sequence of source tokens $\mathbf{x} = (x_1,...,x_m)$ and produces a sequence of states $\mathbf{s} = (s_1,...,s_m)$ .The decoder is an RNN that predicts the probability of a target sequence $\mathbf{y} = (y_1,...,y_T \,|\, \mathbf{s})$. The probability of each target token $y_i \in \{1,...,|V|\}$ is predicted based on the recurrent state in the decoder RNN, h_i, the previous words, $y_{<i}$, and a context vector c_i. The context vector c_i, also referred to as the attention vector, is calculated as a weighted average of the source states.

[1] Eye-tracking and keystroke logging data from human translators show that translators generally do not reread previously translated source text words when producing target text (Carl et al., 2011).

Proceedings of the 2017 Conference on Empirical Methods in Natural Language Processing, pages 392–400
Copenhagen, Denmark, September 7–11, 2017.

$$c_i = \sum_j \alpha_{ij} s_j \tag{1}$$

$$\alpha_i = \text{softmax}(f_{att}(h_i, \mathbf{s})) \tag{2}$$

Here, $f_{att}(h_i, \mathbf{s})$ is an attention function that calculates an unnormalized alignment score between the encoder state s_j and the decoder state h_i. Variants of f_{att} used in Bahdanau et al. (2014) and Luong et al. (2015) are:

$$f_{att}(h_i, s_j) = \begin{cases} v_a^T \tanh(W_a[h_i, s_j]), & \textit{Bahdanau} \\ h_i^T W_a s_j & \textit{Luong} \end{cases}$$

where W_a and v_a are model parameters learned to predict alignment. Let $|S|$ and $|T|$ denote the lengths of the source and target sequences respectively and D denoate the state size of the encoder and decoder RNN. Such content-based attention mechanisms result in inference times of $O(D^2|S||T|)$[2], as each context vector depends on the current decoder state h_i and all encoder states, and requires an $O(D^2)$ matrix multiplication.

The decoder outputs a distribution over a vocabulary of fixed-size $|V|$:

$$P(y_i | y_{<i}, \mathbf{x}) = \text{softmax}(W[s_i; c_i] + b) \tag{3}$$

The model is trained end-to-end by minimizing the negative log likelihood of the target words using stochastic gradient descent.

3 Memory-Based Attention Model

Our proposed model is shown in Figure 1. During encoding, we compute an attention matrix $C \in \mathbb{R}^{K \times D}$, where K is the number of attention vectors and a hyperparameter of our method, and D is the dimensionality of the top-most encoder state. This matrix is computed by predicting a score vector $\alpha_t \in \mathbb{R}^K$ at each encoding time step t. C is then a linear combination of the encoder states, weighted by α_t:

$$C_k = \sum_{t=0}^{|S|} \alpha_{tk} s_t \tag{4}$$

$$\alpha_t = \text{softmax}(W_\alpha s_t), \tag{5}$$

where W_α is a parameter matrix in $\mathbb{R}^{K \times D}$.

The computational time complexity for this operation is $O(KD|S|)$. One can think of C as compact fixed-length memory that the decoder will perform attention over. In contrast, standard approaches use a variable-length set of encoder states for attention. At each decoding step, we similarly predict K scores $\beta \in \mathbb{R}^K$. The final attention context c is a linear combination of the rows in C weighted by the scores. Intuitively, each decoder step predicts how important each of the K attention vectors is.

$$c = \sum_{i=0}^{K} \beta_i C_i \tag{6}$$

$$\beta = \text{softmax}(W_\beta h) \tag{7}$$

Here, h is the current state of the decoder, and W_β is a learned parameter matrix. Note that we do not access the encoder states at each decoder step. We simply take a linear combination of the attention matrix C pre-computed during encoding - a much cheaper operation that is independent of the length of the source sequence. The time complexity of this computation is $O(KD|T|)$ as multiplication with the K attention matrices needs to happen at each decoding step.

Summing $O(KD|S|)$ from encoding and $O(KD|T|)$ from decoding, we have a total linear computational complexity of $O(KD(|S| + |T|)$. As D is typically very large, 512 or 1024 units in most applications, we expect our model to be faster than the standard attention mechanism running in $O(D^2|S||T|)$. For long sequences (as in summarization, where —S— is large), we also expect our model to be faster than the cheaper dot-based attention mechanism, which needs $O(D|S||T|)$ computation time and requires encoder and decoder states sizes to match.

We also experimented with using a sigmoid function instead of the softmax to score the encoder and decoder attention scores, resulting in 4 possible combinations. We call this choice the *scoring function*. A softmax scoring function calculates normalized scores, while the sigmoid scoring function results in unnormalized scores that can be understood as gates.

3.1 Model Interpretations

Our memory-based attention model can be understood intuitively in two ways. We can interpret it as ”predicting” the set of attention contexts produced by a standard attention mechanism during encoding. To see this, assume we set $K \approx |T|$. In this case, we predict all $|T|$ attention contexts during the encoding stage and learn to choose the right one during decoding. This is cheaper than computing contexts one-by-one based on the decoder and encoder content. In fact, we could enforce this objective by first training

[2] An exception is the dot-attention from Luong et al. (2015), which is $O(D|S||T|)$, which we discuss further in Section 3.

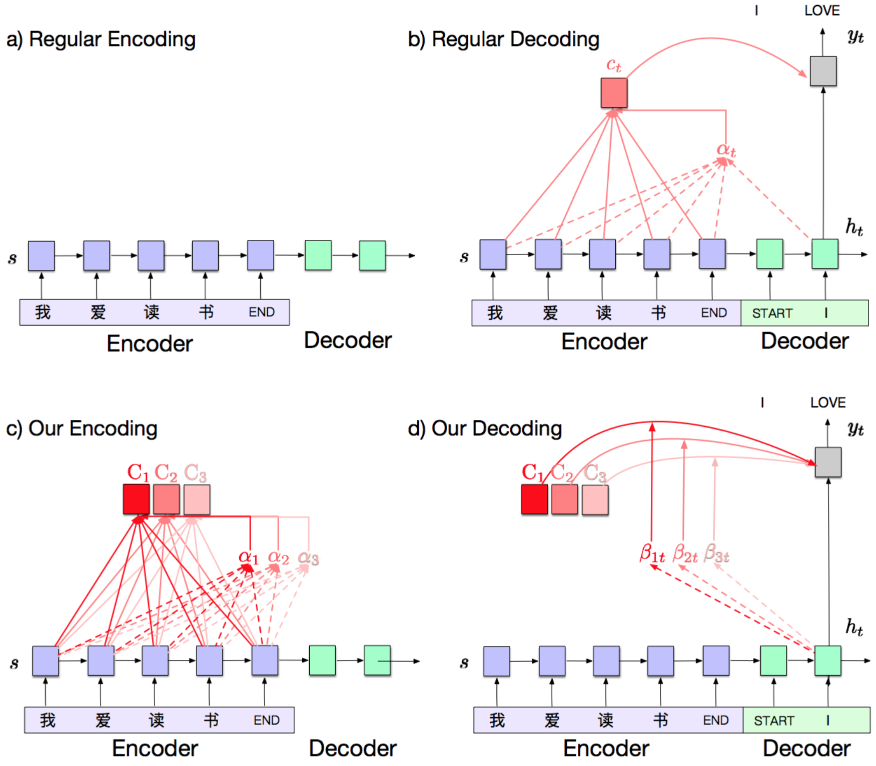

Figure 1: Memory Attention model architecture. K attention vectors are predicted during encoding, and a linear combination is chosen during decoding. In our example, $K = 3$.

a regular attention model and adding a regularization term to force the memory matrix C to be close to the $T \times D$ vectors computed by the standard attention. We leave it to future work to explore such an objective.

Alternatively, we can interpret our mechanism as first predicting a compact $K \times D$ memory matrix, a representation of the source sequence, and then performing *location-based* attention on the memory by picking which row of the matrix to attend to. Standard location-based attention mechanism, by contrast, predicts a location in the source sequence to focus on (Luong et al., 2015; Xu et al., 2015).

3.2 Position Encodings (PE)

In the above formulation, the predictions of attention contexts are symmetric. That is, C_i is not forced to be different from $C_{j \neq i}$. While we would hope for the model to learn to generate distinct attention contexts, we now present an extension that pushes the model into this direction. We add *position encodings* to the score matrix that forces the first few context vector $C_1, C_2, ...$ to focus on the beginning of the sequence and the last few vectors $..., C_{K-1}, C_K$ to focus on the end (thereby encouraging in-between vectors to focus on the middle).

Explicitly, we multiply the score vector α with position encodings $l_s \in \mathbb{R}^K$:

$$C^{PE} = \sum_{s=0}^{|S|} \alpha^{PE} h_s \tag{8}$$

$$\alpha_s^{PE} = \text{softmax}(W_\alpha h_s \circ l_s) \tag{9}$$

To obtain l_s we first calculate a constant matrix L where we define each element as

$$L_{ks} = (1 - k/K)(1 - s/\mathcal{S}) + \frac{k}{K}\frac{s}{\mathcal{S}}, \tag{10}$$

adapting a formula from (Sukhbaatar et al., 2015). Here, $k \in \{1, 2, ..., K\}$ is the context vector index and $\mathcal{S}$ is the maximum sequence length across all source sequences. The manifold is shown graphically in Figure 2. We can see that earlier encoder states are upweighted in the first context vectors, and later states are upweighted in later vectors. The symmetry of the manifold and its stationary point having value 0.5 both follow from Eq. 10. The elements of the matrix that fall beyond the sequence lengths are then masked out and the remaining elements are renormalized across the timestep dimension. This results in the jagged array of position encodings $\{l_{ks}\}$.

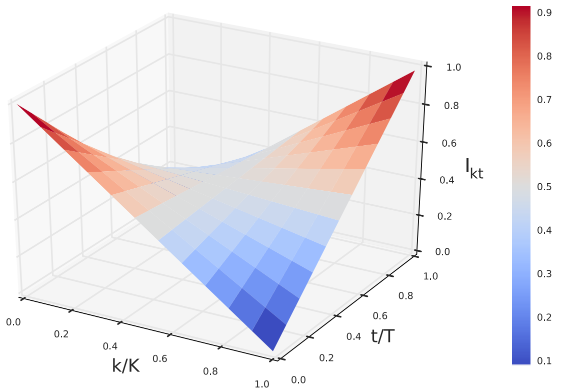

Figure 2: Surface for the position encodings.

4 Experiments

4.1 Toy Copying Experiment

Due to the reduction of computational time complexity we expect our method to yield performance gains especially for longer sequences and tasks where the source can be compactly represented in a fixed-size memory matrix. To investigate the trade-off between speed and performance, we compare our technique to standard models with and without attention on a Sequence Copy Task of varying length like in Graves et al. (2014). We generated 4 training datasets of 100,000 examples and a validation dataset of 1,000 examples. The vocabulary size was 20. For each dataset, the sequences had lengths randomly chosen between 0 to L, for $L \in \{10,50,100,200\}$ unique to each dataset.

4.1.1 Training Setup

All models are implemented using TensorFlow based on the seq2seq implementation of Britz et al. (2017)[3] and trained on a single machine with a Nvidia K40m GPU. We use a 2-layer 256-unit, a bidirectional LSTM (Hochreiter and Schmidhuber, 1997) encoder, a 2-layer 256-unit LSTM decoder, and 256-dimensional embeddings. For the attention baseline, we use the standard parametrized attention (Bahdanau et al., 2014). Dropout of 0.2 (0.8 keep probability) is applied to the input of each cell and we optimize using Adam (Kingma and Ba, 2014) at a learning rate of 0.0001 and batch size 128. We train for at most 200,000 steps (see Figure 3 for sample learning curves). BLEU scores are calculated on tokenized data using the *multi-bleu.perl* script in Moses.[4] We decode using beam search with a beam size of 10 (Wiseman and Rush, 2016).

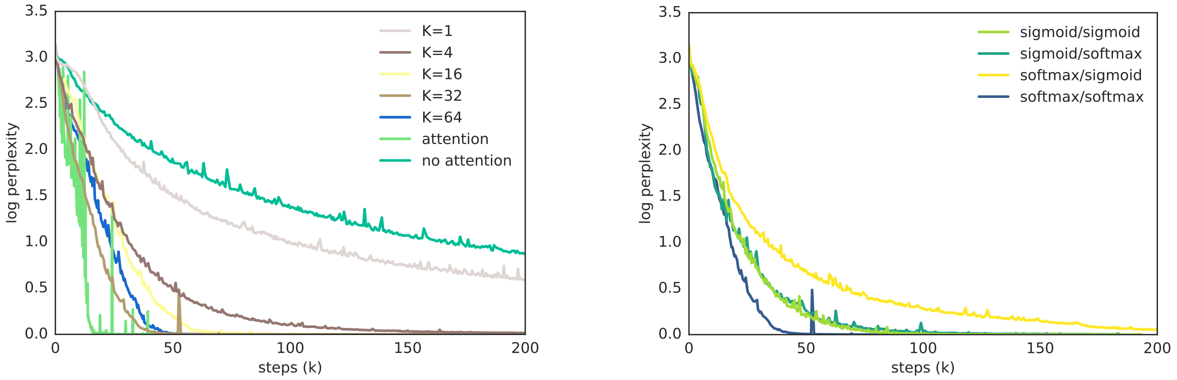
Table 1: BLEU scores and computation times with varying K and sequence length compared to baseline models with and without attention.

4.1.2 Results

Table 1 shows the BLEU scores of our model on different sequence lengths while varying K. This is a study of the trade-off between computational time and representational power. A large K allows us to compute complex source representations, while a K of 1 limits the source representation to a single vector. We can see that performance consistently increases with K up to a point that depends on the data length, with longer sequences requiring more complex representations. The results with and without position encodings are almost identical on the toy data. Our technique learns to fit the data as well as the standard attention mechanism despite having less representational power. Both beat the non-attention baseline by a significant margin.

[3] http://github.com/google/seq2seq

[4] http://github.com/moses-smt/mosesdecoder



(a) Comparison of varying K for copying sequences of length 200 on evaluation data, showing that large K leads to faster convergence and small K performs similarly to the non-attentional baseline.

(b) Comparison of sigmoid and softmax functions for choosing the encoder and decoder attention scores on evaluation data, showing that choice of gating/normalization matters.

Figure 3: Training Curves for the Toy Copy task

That we are able to represent the source sequence with a fixed size matrix with fewer than $|S|$ rows suggests that traditional attention mechanisms may be representing the source with redundancies and wasting computational resources. This makes intuitive sense for the toy task, which should require a relatively simple representation.

The last column shows that our technique significantly speeds up the inference process. The gap in inference speed increases as sequences become longer. We measured inference time on the full validation set of 1,000 examples, not including data loading or model construction times.

Figure 3a shows the learning curves for sequence length 200. We see that $K=1$ is unable to fit the data distribution, while $K \in \{32,64\}$ fits the data almost as quickly as the attention-based model. Figure 3b shows the effect of varying the encoder and decoder scoring functions between softmax and sigmoid. All combinations manage to fit the data, but some converge faster than others. In section 5 we show that distinct alignments are learned by different function combinations.

4.2 Machine Translation

Next, we explore if the memory-based attention mechanism is able to fit complex real-world datasets. For this purpose we use 4 large machine translation datasets of WMT'17[5] on the following language pairs: English-Czech (en-cs, 52M examples), English-German (en-de, 5.9M examples), English-Finish (en-fi, 2.6M examples), and English-Turkish (en-tr, 207,373 examples). We used the newly available preprocessed datasets for the WMT'17 task.[6] Note that our scores may not be directly comparable to other work that performs their own data pre-processing. We learn shared vocabularies of 16,000 subword units using the BPE algorithm (Sennrich et al., 2016). We use newstest2015 as a validation set, and report BLEU on newstest2016.

4.2.1 Training Setup

We use a similar setup to the Toy Copy task, but use 512 RNN and embedding units, train using 8 distributed workers with 1 GPU each, and train for at most 1M steps. We save checkpoints every 30 minutes during training, and choose the best based on the validation BLEU score.

4.2.2 Results

Table 2 compares our approach with and without position encodings, and with varying values for hyperparameter K, to baseline models with regular attention mechanism. Learning curves are shown in Figure 4. We see that our memory attention model with sufficiently high K performs on-par with, or slightly better, than the attention-based baseline model despite its simpler nature. Across the board, models with $K = 64$ performed better than corresponding models with $K=32$, suggesting that using a larger number of attention vectors can capture a richer understanding of source sequences. Position encodings also seem to consistently improve model performance.

Table 3 shows that our model results in faster decoding time even on a complex dataset with a large

Table 2: BLEU scores on WMT'17 translation datasets from the memory attention models and regular attention baselines. We picked the best out of the four scoring function combinations on the validation set. Note that en-tr does not have an official test set. Best test scores on each dataset are highlighted.

Model	**Decoding Time (s)**
$K=32$	26.85
$K=64$	27.13
Attention	33.28

Table 3: Decoding time, averaged across 10 runs, for the en-de validation set (2169 examples) with average sequence length of 35. Results are similar for both PE and non-PE models.

vocabulary of 16k. We measured decoding time over the full validation set, not including time used for model setup and data loading, averaged across 10 runs. The average sequence length for examples in this data was 35, and we expect more significant speedups for tasks with longer sequences, as suggested by our experiments on toy data. Note that in our NMT examples/experiments, $K \approx T$, but we obtain computational savings from the fact that $K \ll D$. We may be able to set $K \ll T$, as in toy copying, and still get very good performance in other tasks. For instance, in summarization the source is complex but the representation of the source required to perform the task is "simple" (i.e. all that is needed to generate the abstract).

Figure 5 shows the effect of using sigmoid and softmax function in the encoders and decoders. We found that softmax/softmax consistently performs badly, while all other combinations perform about equally well. We report results for the best combination only (as chosen on the validation set), but we found this choice to only make a minor difference.

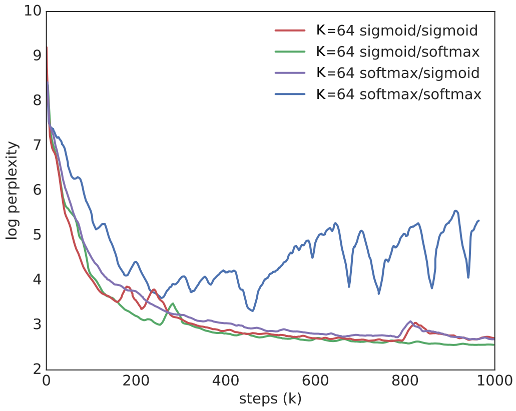

Figure 5: Comparing training curves for en-fi for different encoder/decoder scoring functions for our models at $K = 64$.

5 Visualizing Attention

A useful property of the standard attention mechanism is that it produces meaningful alignment between source and target sequences. Often, the attention mechanism learns to progressively focus on the next source token as it decodes the target. These visualizations can be an important tool in debugging and evaluating seq2seq models and are often used for unknown token replacement.

This raises the question of whether or not our proposed memory attention mechanism also learns to generate meaningful alignments. Due to limiting the number of attention contexts to a number that is generally less than the sequence length, it is not immediately obvious what each context would learn to focus on. Our hope was that the model would learn to focus on multiple alignments at the same time, within the same attention vector. For example, if the source sequence is of length 40 and we have $K = 10$ attention contexts, we would hope that C_1 roughly focuses on tokens 1 to 4, C_2 on tokens 5 to 8, and so on. Figures 6 and 7 show that this is indeed the case. To generate this visualization we multiply the attention scores α and β from the encoder and decoder. Figure 8 shows a sample translation task visualization.

Figure 6 suggests that our model learns distinct ways to use its memory depending on the encoder and decoder functions. Interestingly, using softmax normalization results in attention maps typical of those derived from using standard attention, i.e. a relatively linear mapping between source and target tokens. Meanwhile, using sigmoid gating results in what seems to be a distributed representation of the source sequences across encoder time steps, with multiple contiguous attention contexts being accessed at each decoding step.

6 Related Work

Our contributions build on previous work in making seq2seq models more computationally efficient. Luong et al. (2015) introduce various attention mechanisms that are computationally simpler and perform as well or better than the original one presented in Bahdanau et al. (2014). However, these typically still require $O(D^2)$ computation complexity, or lack the flexibility to look at the full source sequence. Efficient location-based attention (Xu et al., 2015) has also been explored in the image recognition domain.

Wu et al. (2016) presents several enhancements to the standard seq2seq architecture that allow more efficient computation on GPUs, such as only attending on the bottom layer. Kalchbrenner et al. (2016) propose a linear time architecture based on stacked convolutional neural networks. Gehring et al. (2016) also propose the use of convolutional encoders to speed up NMT. de Brébisson and Vincent (2016) propose a linear attention mechanism based on covariance matrices applied to information retrieval. Raffel et al. (2017) enable online linear time attention calculation by enforcing that the alignment between input and output sequence elements be monotonic. Previously, monotonic attention was proposed for morphological inflection generation by Aharoni and Goldberg (2016).

7 Conclusion

In this work, we propose a novel memory-based attention mechanism that results in a linear computational time of $O(KD(|S| + |T|))$ during decoding in seq2seq models. Through a series of experiments, we demonstrate that our technique leads to consistent inference speedups as sequences get longer, and can fit complex data distributions such as those found in Neural Machine Translation. We show that our attention mechanism learns meaningful alignments despite being constrained to a fixed representation after encoding. We encourage future work that explores the optimal values of K for various language tasks and examines whether or not it is possible to predict K based on the task at hand. We also encourage evaluating our models on other tasks that must deal with long sequences but have compact representations, such as summarization and question-answering, and further exploration of their effect on memory and training speed.

Rotated Word Vector Representations and their Interpretability

Sungjoon Park and **JinYeong Bak** and **Alice Oh**
Department of Computing, KAIST, Republic of Korea
{sungjoon.park, jy.bak}@kaist.ac.kr, alice.oh@kaist.edu

Abstract

Vector representation of words improves performance in various NLP tasks, but the high-dimensional word vectors are very difficult to interpret. We apply several rotation algorithms to the vector representation of words to improve the interpretability. Unlike previous approaches that induce sparsity, the rotated vectors are interpretable while preserving the expressive performance of the original vectors. Furthermore, any pre-built word vector representation can be rotated for improved interpretability. We apply rotation to skip-grams and glove and compare the expressive power and interpretability with the original vectors and the sparse overcomplete vectors. The results show that the rotated vectors outperform the original and the sparse overcomplete vectors for interpretability and expressiveness tasks.

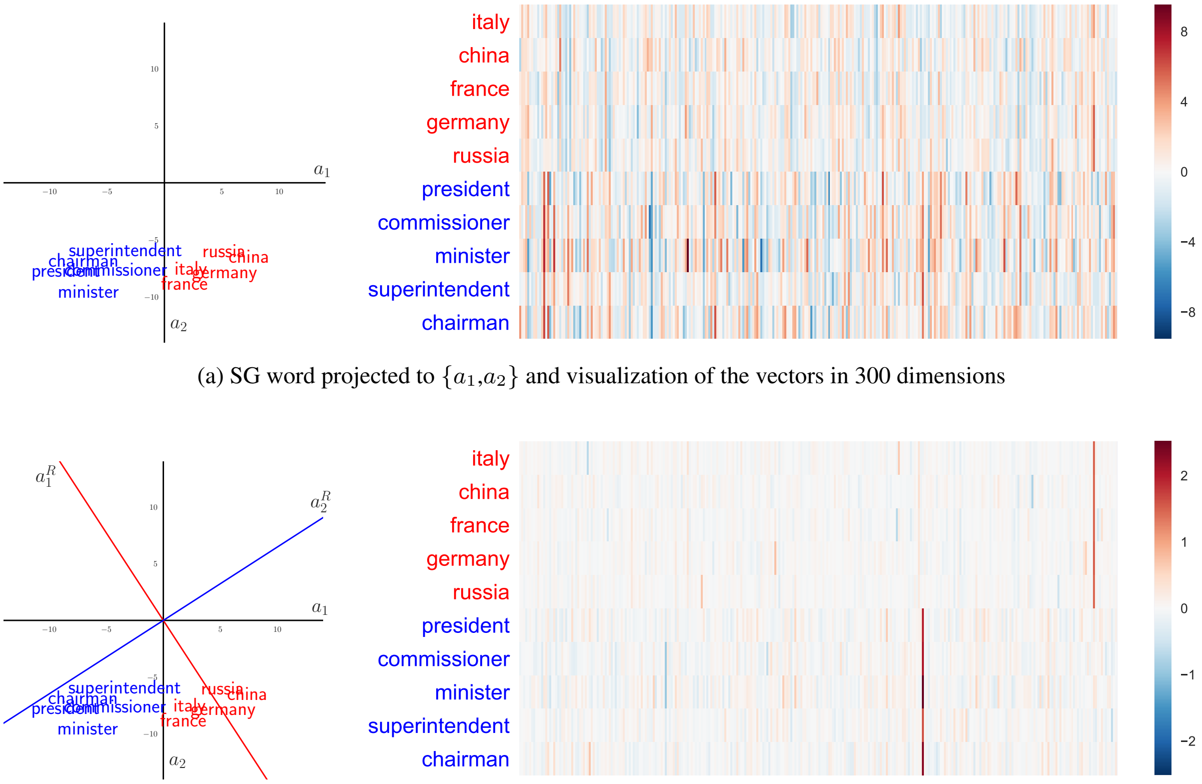
1 Introduction

Vector representations of words contain rich semantic and syntactic information and thus improve the performance of numerous natural language processing tasks. The vectors also play a basic role as an embedding layer in deep learning models for NLP, affecting the expressive performance of the model (Iyyer et al., 2014; Tai et al., 2015; Yang et al., 2016). However, the many dimensions comprising the vector representation are not amenable to interpretation.

Previous research on vector representation of words has proposed improving interpretability while keeping the expressive performance by inducing sparsity in word vector dimensions (Murphy et al., 2012; Fyshe et al., 2014). Recent research has proposed to build sparse vector representations from a large corpus and added the non-negativity constraint using improved projected gradient (Luo et al., 2015), while (Sun et al., 2016) learns l1-regularised vectors. But, these models cannot be learned over pre-trained word vectors based on skip-gram (Mikolov et al., 2013) or glove (Pennington et al., 2014) which are widely used. Faruqui et al. proposes an alternative approach to stand-alone models by forming sparse representations based on the pre-trained models. To do this, they use overcomplete vectors, which are much higher in dimensionality than the original vectors.

Unlike these sparsity-inducing approaches, we construct an interpretable word vector representation by using the pre-trained word vectors as input and using a basis rotation algorithm from the Exploratory Factor Analysis (EFA) literature used in developing psychological scales (Osborne and Costello, 2009). Like the word vector representation, every single item in the scale is represented as a numeric vector in the latent factor space. The set of item vectors are represented in a factor loading matrix, and the matrix is rotated such that the factors (i.e., dimensions) become interpretable. The rotation achieves a *Simple Structure* (Thurstone, 1947) through minimizing the row and the column complexity of the matrix (Crawford and Ferguson, 1970). We elaborate on this process in the next section. As in EFA, we rotate the word vector representation matrix to obtain dimension-wise interpretability while retaining the number of dimensions the same. For example, Figure 1 shows the rotated skip-gram vectors for two groups of words. These words are top five words of two dimensions from rotated Word2Vec.

Our main contribution is applying the matrix rotation algorithm from psychometric analysis to word vector representation models to improve the interpretability of the vector. This approach gives an answer to the question why and how word vec-



(a) SG word projected to $\{a_1,a_2\}$ and visualization of the vectors in 300 dimensions

(b) Rotated word vectors in $\{a_1^R,a_2^R\}$ and visualization of the vectors in 300 dimensions

Figure 1: Overview of rotating word vectors dimensions. We plot (a) unrotated and (b) rotated skip-gram word vectors in 2-D projected embedding space using PCA (left), and visualization of the vectors in original 300 dimensional space (right). Colors of words indicates the meaning of countries (Red) and positions (Blue). As in (b), after the dimensions are rotated, interpretability for each dimensions is improved having meaning of countries and positions.

tor representations work well by revealing a hidden structure of the original word vectors. That is, it is meaningful to transform the hard-to-interpret dimensions of the pre-built word vectors, which are widely used, to more interpretable vectors. We also show that the rotated vectors retain their effectiveness with respect to downstream tasks without re-building the vector representations.

Our method can be applied to any type of word vectors as a post-processing method such that it does not require a large corpus to be trained. In addition, it does not require additional number of dimensions so it does not increase the complexity of the model. Furthermore, we explore the characteristics of the rotated word vectors.

2 Factor Rotation

We take the rotation algorithm from the exploratory factor analysis (EFA) conducted to verify the construct validity of the psychological scale in development. For example, when validating a scale measuring respondents' latent factors, such as "Engineering problem solving" and "Interest in engineering", items should be similar within a factor, and distinguished between factors. As shown in Table 1, EFA projects every item into the latent factor space as an unrotated factor loading matrix. However, since it is unclear what the factor means, factor rotation is applied to the matrix that produces the rotated factor loading matrix which enhances the interpretability of the dimensions (Osborne, 2015).

2.1 Rotating Factors

The rotation algorithm transforms factor loading matrix to the *simple structure* which is much easier to interpret (Thurstone, 1947). It involves post-multiplication of a $p \times m$ input matrix A by an $m \times m$ square matrix T, to compute the rotated matrix Λ,

$$\Lambda = AT \tag{1}$$

Latent Factors	Items	Unrotated Factor Matrix		Rotated Factor Matrix	
		Factor 1	Factor 2	Factor 1	Factor 2
Engineering Problem Solving	How well did you feel prepared for:				
	(1) Defining what the problem really is	.759	-.389	**.830**	.153
	(2) Thinking up potential solutions to the problem	.784	-.392	**.861**	.157
	(3) Detailing how to implement the solution to the problem	.798	-.416	**.888**	.146
Interest in Engineering	(1) I find many topics in engineering to be interesting	.630	.521	.194	**.793**
	(2) Solving engineering problems is interesting to me	.660	.630	.149	**.901**
	(3) Engineering fascinates me	.669	.627	.158	**.906**

Table 1: An example of the factor rotation process to verify the construct validity of the psychological scale and its intended latent factor (left) in development. Items and loadings are from (Osborne, 2015).

which minimizes the cost function $f(\Lambda)$, also known as the rotation criterion. The function minimizes the *complexity* of the matrix, to make the rotated matrix have a few large values in a row or a column.

Minimizing the complexity allows non-binary values in the vector, and thus a more complex solution that the perfect simple structure. This is a more realistic solution since a solution with binary vectors may be misleading in representing the factor of interest (Yates, 1988; Browne, 2001). More details are described in the next subsection.

The intuition behind this approach is that inducing interpretability by factor rotation reforms the word embedding matrix to have a *simple structure* by linear transformation. It encourages each word vector (row) and dimension (column) to have a few large values, leading to more interpretable dimensions as shown in Fig 1.

2.2 Crawford-Ferguson Rotation Family

The rotation criterion introduced in Crawford and Ferguson is a family of complexity functions as follows:

$$\begin{aligned} f(\Lambda) = (1-\kappa)\ \Sigma_{i=1}^{p}\Sigma_{j=1}^{m}\Sigma_{l\neq j,l=1}^{m}\lambda_{ij}^{2}\lambda_{il}^{2} \\ +\ \kappa\ \Sigma_{j=1}^{m}\Sigma_{i=1}^{p}\Sigma_{l\neq i,l=1}^{m}\lambda_{ij}^{2}\lambda_{lj}^{2} \end{aligned} \tag{2}$$

where λ_{ij} is an element of Λ. The first term represents the row (item) complexity, and the second term represents the column (factor) complexity. The ratio between the two is adjusted by the parameter κ ($0 \leq k \leq 1$). The criterion is a generalized version of the widely used criteria, the orthomax family (Harman, 1960) which includes quartimax (Carroll, 1953; Ferguson, 1954; Neuhaus and Wrigley, 1954), varimax (Kaiser, 1958), and direct quartimin (Carroll, 1960). It effectively reflects the simple structure as well (Browne, 2001). In this work, we apply the following representative κ values in Table 2 (Sass and Schmitt, 2010).

	Quartimax	Varimax	Parsimax	FacParsim
κ	0	$\frac{1}{p}$	$\frac{m-1}{p+m-2}$	1

Table 2: Representative κ values used. As (Sass and Schmitt, 2010), we use 4 criterion referred to as CF-Quartimax, CF-Varimax, CF-Parsimax, CF-FacParsim. We omit 'CF-' for simplicity and do not separate the name of the kappa condition whether it is orthogonal or oblique. FacParsim stands for factor parsimony.

In addition, the constraints for the rotation matrix T can be applied in general. We can categorize the rotation as orthogonal and oblique based on the constraint. Orthogonal rotation assumes the correlation between the rotated dimensions is zero. Hence, the matrix should be an orthogonal matrix that with $m(m-1)/2$ constraints, satisfies:

$$T'T = I \tag{3}$$

Oblique rotations allow the correlation between dimension to be non-zero, resulting in m constraints satisfying:

$$diag(T^{-1}T^{-1'}) = I \tag{4}$$

The solution for the input matrix is computed by using the gradient projection algorithm (Jennrich, 2001, 2002). The algorithm minimizes equation 2 while satisfying the constraints of the rotation matrix.

3 Experimental Settings

We choose the Wikipedia English articles[1] to train the word vector models. The corpus contains 5.3M articles, 83M sentences and 1,676M tokens. For

[1] https://dumps.wikimedia.org/enwiki/20170120/

preprocessing, we leave only the alphanumeric tokens and apply lowercase to all words. Then we remove the words with frequency less than 50, and the size of the remaining vocabulary is 306,491.

We train skip-gram[2] (Mikolov et al., 2013) and glove[3] (Pennington et al., 2014) based on the corpus by using existing implementations. We set the window size to 5 for both skip-gram and glove. We set the number of negative samples to 5 and the number of dimensions to 300. We use the default values for the other hyperparameters. The size of the resulting word vector matrix is (306,491, 300).

We compare our model with two baseline models: sparse overcomplete vector representations (SOV) and the non-negative version of the SOV. We set the hyperparameters of these models as $\lambda = .5$, $\tau = 10^{-5}$, $K = 3000$ for SG, and $\lambda = 1.0$, $\tau = 10^{-5}$, $K = 3000$ for Glove (Faruqui et al., 2015). We excluded methods as baselines that construct interpretable word vectors using huge training corpora because our method works with pre-trained vectors.

We apply four rotation algorithms for each orthogonal and oblique rotation, listed in Table 2. Since we have two original word vector representations, we have 16 (4 x 2 x 2) rotated vectors in total. We implement the algorithm through TensorFlow (Abadi et al., 2016), and it is publicly available on GitHub[4].

4 Interpretability

In this section, we show how the rotation of word vectors results in improved dimension-wise interpretability using the word intrusion task. (Murphy et al., 2012; Faruqui et al., 2015; Sun et al., 2016).

4.1 Word Intrusion

Word intrusion task seeks to measure the semantic coherence of a set of words. For example, consider a set of words consists of ('daughter', 'wife', 'sister', 'mother', 'son') and add an 'intruder' word ('bigram') to the set. Since the words except intruder has similar meanings to each other, we can easily pick out the intruder to conclude that the five words are sharing coherent meanings.

We apply this task to measure interpretability of every word vector dimensions. If we choose the words with the highest embedding values for each of the dimensions (top words for that dimension) and add an random (intruder) word and see whether the intruder can be easily identified, then we can conclude the dimension is semantically coherent. In this way, we can measure the extent of interpretability of a dimension in vector representations by this task. Note that we pick top words for a dimension by looking only for the value of that dimension, ignoring values in the other dimensions.

Specifically, we first choose the top five words in each dimension, and then we choose an intruder word based on two criteria: 1) it is in the lower half of that dimension, and 2) it is in the top 10% in some other dimension. Also, we follow the settings of the measure ($k = 5$, top 10%) from previous works. We see similar results when we run experiments with larger k. (Murphy et al., 2012; Sun et al., 2016)

In the standard word intrusion task, human evaluators pick out the intruder words, and the results report the accuracy of the evaluators (Chang et al., 2009). But this approach would be impractical to use for all experimental conditions with 300 dimensions and the baselines, so we use the following distance ratio (DR) metric as an alternative approach in (Sun et al., 2016) with slight modifications. Another advantage of our metric is that it can be used to quantify the distance between the intruder and the non-intruder words. We define the overall metric as the average of the ratio between D^a_{inter} and D^a_{intra} over d dimensions as

$$DR_{overall} = \frac{1}{d} \frac{\Sigma^d_{a=1} D^a_{inter}}{\Sigma^d_{a=1} D^a_{intra}} \qquad (5)$$

where D^a_{intra} is the average distance of every pair among the top k words in dimension a

$$D^a_{intra} = \frac{\Sigma_{w_i} \Sigma_{w_j} dist(w_i, w_j)}{k(k-1)}, \qquad (6)$$

and D^a_{inter} is the average distance between the intruder word and each of the top k words in dimension a

$$D^a_{inter} = \frac{\Sigma_{w_i} dist(w_i, w_{intruder})}{k}. \qquad (7)$$

We define $dist(w_j, w_k)$ as the cosine distance between w_j and w_k. We set $k = 5$ and repeat this three times for each dimension a and use the average to compute $DR_{overall}$.

FacParsim (oblique)	1.145	1.081

Table 3: Overall distance ratio ($DR_{overall}$) of the original, sparse overcomplete vectors, and the rotated (orthogonal and oblique) vector representations. Rotated vectors show improved interpretability over SOV and the original.

4.2 Results

Table 3 shows the results of word intrusion in terms of the distance ratio metric. Overall, the results of the rotated vector representations show improvements over SOV and the original word vector representations. For skip-grams, orthogonal parsimax shows the best result while for Glove, orthogonal varimax outperforms the others. Among oblique rotation, varimax and quartimax show better performance than factor parsimony.

In general, interpretability varies with different values of κ. It increases when κ is close to zero and decreases when κ is close to one, putting more weight on the column complexity. Also, orthogonal rotation shows better performance than oblique rotation when κ is controlled.

4.3 Qualitative Examples

We present the top words of five dimensions for skip-gram and rotated skip-gram (parsimax-orthogonal) in Table 4. The dimensions shown are randomly selected for both conditions.

Overall, the top words in each dimension of skip-gram do not clearly show a common topic among them. Only a few dimensions out of 300 are interpretable, such as the second row in the table which is related to numbers. The overall distance ratio of the original vectors is slightly higher than one.

For the rotated word vectors, the top words show clear semantic coherence. The first row shows words about social network services, the second row is about biology, the third row is about geographical locations in the US, and the fourth is about paintings. As the last row shows, some of these dimensions represent syntactic features.

Table 4: 5 top words for the original and the rotated skip-gram word representations. The rotated vectors show common semantic or syntactic coherence while the original vectors do not.

5 Expressive Performance

We evaluate the expressive power of word vector representations on the following tasks and report Spearman's correlation coefficient for the first task, and accuracy for the other tasks. Table 5 shows the results.

5.1 Evaluation

We briefly describe the seven benchmark tasks: word similarity and semantic/syntactic analogy, and four classification tasks. For the classification tasks, we average the word vectors in each training sentence or phrase to use them as features. SVM and random forest classifier are trained to predict the target values, and hyperparameters are tuned on the validation set.

Word Similarity (Simil.) SimLex-999 (Hill et al., 2016) presented to evaluate the similarity of word pairs, rather than relatedness. We compute the cosine similarity between the given word pairs, and report the Spearman's correlation coefficient as a measure of consistency between the similarity and human ratings.

Semantic and Syntactic Analogies (Analg. sem, syn). The second and third tasks are word analogy tasks proposed by (Mikolov et al., 2013). The semantic task includes 8,869 questions (sem) and the syntactic task includes 10,675 questions (syn).

Sentiment Analysis (Sent.) The first classification task is sentiment classification on the movie reviews (Socher et al., 2013). This dataset contains

	# dims	Simil.	Analg. (sem)	Analg. (syn)	Sent.	Ques.	Topics (Sp.)	NP brckt.

Table 5: Evaluation results of the original skip-gram, sparse overcomplete vectors (SOV), and the rotated (orthogonal and oblique) word vectors on various tasks. The left three columns show tasks based on cosine similarity, and the right four columns show classification tasks using average word vectors as features. Overall, the rotated word vectors show higher or comparable performance to that of the SOV and the original. We observe a similar pattern in Glove as well.

6,920, 872, 1,821 sentences for training, development, and test, respectively. The goal of this task is to predict positive or negative sentiment of the reviews.

Question Classification (Ques.) Next, we use TREC dataset to classify categories of the questions (Faruqui et al., 2015). We divide the dataset into 4,952, 500, 500 for training, development, and test. The dataset has six types of questions including about person, location, etc.

Topic Classification (Topics: Sp.) Next, we obtain the 20 newsgroup dataset to classify Sports (baseball vs. hockey) topics (Yogatama and Smith, 2014; Faruqui et al., 2015). The dataset consists of 958, 239, 796 for training, development, and test.

NP bracketing (NP brckt.) The final task is classifying noun phrases in terms of bracketing (Lazaridou et al., 2013; Faruqui et al., 2015). Each phrase consists of three words, and the task is to predict the correct bracketing to match the similar words. We compute the average of NPs and perform ten-fold cross-validation over 2,227 phrases. The classifiers are trained and the hyperparameters are tuned for every fold.

5.2 Results

Word Similarity and Analogies We observe improved performance of oblique rotation of word vectors compared to the original and the SOV in word similarity and semantic analogy tasks. In the syntactic analogy, orthogonal rotation shows the same performance as the original. Note that the orthogonal rotations preserve the cosine-based expressive performances because the cosine similarity between any two vectors does not change after the orthogonal rotation.

Classification Tasks The SOV models show slightly higher performance except the question classification task. However, we can observe the rotated word vectors have improved performance over the original vectors. We observe a similar pattern in Glove as well. In conclusion, the rotated representations preserve the expressive power of the original word vectors, and it is quite close to that of the sparse representation with 10 times larger dimensionality.

6 Understanding Rotated Word Vectors

In this section, we perform several experiments to understand the characteristics of the rotated word vector representations.

6.1 Directionality

One conventional approach to make the word vectors to be more interpretable is by forcing the representation to have non-negative values (Faruqui et al., 2015; Luo et al., 2015). However, the dimensions in the rotated vectors are not non-negative, spread in both directions. Hence, we investigate the relationship between the directionality (positive / negative) and interpretability.

	(A)	(B)	(C)	(D)	(E)	(F)	(G)
	Desc	Asc	Cor	Cor	Cor	Cor	DR
	(Hi)	(Lo)	(Hi, Lo)	(abs, DR)	(abs, intra)	(abs, inter)	(abs)

Table 6: Overall distance ratio based on the top words extracted from the values in word vectors sorted by descending order (Hi) and ascending order (Lo). Cor(Hi, Lo) is correlation between two distance ratios based on both directions. Next three columns present correlation between the absolute word vector values of the top words and distance ratios. The last columns shows selective distance ratio measure. The results implies generally both direction is interpretable, one direction is more interpretable than the other within a dimension, and larger absolute value in a dimension means higher interpretability. (* $p < .05$, ** $p < .01$, *** $p < .001$)

Overall Interpretability of both directions The first two columns (A) and (B) in table 6 show the overall distance ratio computed over the top words extracted by descending order and ascending order, respectively. In other words, (A) refers to the top words having the highest positive values in each dimension, while (B) uses the lowest negative values. Note that we used descending order in word intrusion task in the previous section.

Interestingly, the overall distance ratios in both directions are comparable to each other. On average, both sides of a dimension are more interpretable than the unrotated vector representations except the oblique factor parsimony rotation.

Interpretability of both directions within a dimension Next, we compare the interpretability of both directions within a dimension. We first define the distance ratio of an individual dimension a as follows:

$$DR^a = \frac{D^a_{inter}}{D^a_{intra}} \tag{8}$$

We compute the ratio by using top words extracted from positive and negative directions for every dimension, and compute Spearman's correlation of the distance ratio pairs. Table 6 column (C) shows the results. All of the rotation conditions except the oblique factor parsimony shows significant ($p < .05$) negative correlation, meaning that both directions are hard to be highly interpretable within a dimension simultaneously.

Dir.	Topwords
+	depends, depend, rely, focused, focuses
-	on, upon, onto, again, until
+	years, month, weeks, days, decades
-	many, several, ago, numerous, various
+	that, which, when, where, but
-	consists, includes, provides, contains, serves
+	criticizes, excelled, tended, much, criticized
-	october, july, april, september, june
+	were, hoc, recently, their, had
-	largest, oldest, longest, biggest, tallest

Table 7: Examples of top words in both directions. The words are extracted from a part of the orthogonal parsimax rotated skip-gram word vectors.

Case Study We present the top words in both directions for some dimensions of orthogonal parsimax rotated word vectors. As shown in table 7, some dimensions show a relationship between the opposite directions that they consist of consecutively used words, such as ”rely on”, ”depends upon”, ”which includes”, ”that contains”, ”many years”, ”weeks ago”. However, other dimensions show that one direction is relatively more interpretable than the other direction.

6.2 Selecting the Direction

Next, it is natural to question whether the larger absolute value in word vectors means higher interpretability, regardless of its directionality. We verify the relation between them by investigating the size of the absolute value in a dimension and the individual distance ratios.

Relation to distance ratio Table 6 column (D) presents Spearman's correlation between individual distance ratio and the mean absolute vector value of top words for that dimension. The fifth column (E) also shows the correlation between the intra-distance among the top words and the mean absolute value, and the sixth column (F) is the relationship of the inter-distance among the top words and the intruder and the mean absolute value.

Correlation coefficients show that the larger mean absolute value means higher interpretability for that dimension. In detail, there exists tendencies that larger mean absolute value of dimension reduces the intra-distances among the top words while increasing the inter-distances among the top words and the intruder.

Overall, we summarize our findings as follows: 1) generally both directions are somewhat interpretable, 2) one direction is usually more interpretable than the other within a dimension, and 3) a larger absolute value in a dimension means higher interpretability of the dimension.

Selective Distance Ratio We can select a more interpretable direction for each dimension through inspecting the mean absolute value of the top words in both directions. If we choose a direction that has a larger mean absolute value among the top words, each dimension should be easier to interpret.

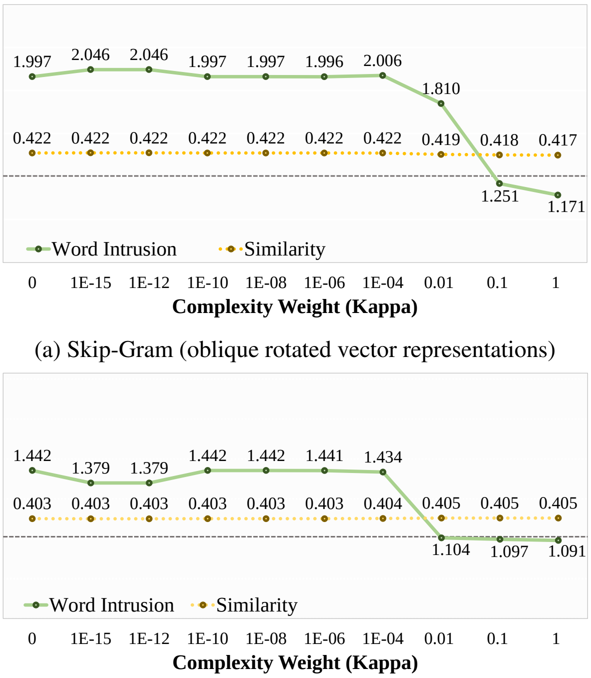
Table 6 column (G) presents this distance ratio computed on the rotated vectors, resulting in increased distance ratio values. We name this ratio as the overall selective distance ratio. This measure could be effectively used when vector representation is interpretable in both directions.

6.3 Effect of κ

We explore the effect on performance of the ratio between the row and the column complexity of the rotation criteria. As shown in section 4, choosing an appropriate κ is important for interpretability.

We set the κ value from zero to one and the numbers divided on a log scale. We run the word similarity task and the word intrusion to evaluate the performance. We present Spearman's correlation and the selective overall distance ratio.

Figure 2 shows that the performance of the similarity task tends not to change regardless of κ, however, the selective distance ratio starts to decrease when $\kappa > .01$. Considering the ratio between the number of rows and columns of the word vector matrix, giving too much weight to the column complexity results in degraded interpretability.



(a) Skip-Gram (oblique rotated vector representations)

(b) Glove (oblique rotated vector representations)

Figure 2: Spearman's correlation of the word similarity and the selective distance ratio of word intrusion changes over κs, computed over oblique rotated (a) skip-gram and (b) glove vectors. Dashed line is original performance for each task. Word similarity does not change regardless of κs, while the distance ratio falls when κ is larger than 1e-4.

In our experiments, κ values of the quartimax, varimax, and parsimax rotation are computed as 0, 3e-06, 1e-04 respectively. Based on the results, our selection of kappas have shown interpretability improvement effectively, compared to factor parsimony ($\kappa = 1$). We observe these tendencies in orthogonal rotations as well.

6.4 Effect of the Number of Dimensions

To investigate the effect of the number of dimensions to interpretability of dimensions, we also measure the overall distance ratio ($DR_{overall}$) on 50, 100 and 200 dimensions of unrotated skip-gram and parsimax (orthogonal) and varimax (oblique) rotated word vectors.

Figure 3 shows the results. For all settings, the rotated vectors orthogonal (parsimax) and oblique (varimax) show higher $DR_{overall}$ score than the original skip-gram vectors.

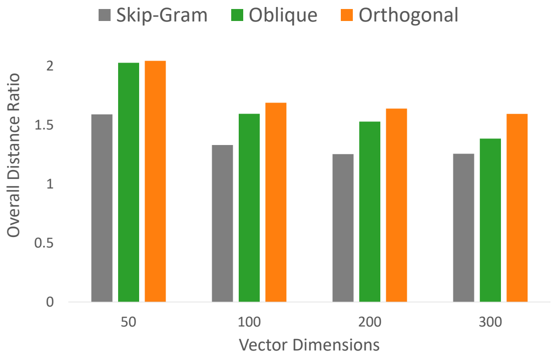


Figure 3: Overall distance ratio ($DR_{overall}$) over word vector dimensions. The rotated vectors (parsimax-orthogonal and varimax-oblique) show higher $DR_{overall}$ score than the original skip-gram vectors.

7 Related Work

Since distributed representations play an important role in various NLP tasks, they are applied to semantics (Herbelot and Vecchi, 2015; Qiu et al., 2015; Woodsend and Lapata, 2015), with incorporating external information to them (Tian et al., 2016; Nguyen et al., 2016). In addition, finding interpretable regularities from the representations is often conducted through non-negative and sparse coding (Murphy et al., 2012; Faruqui et al., 2015; Luo et al., 2015; Kober et al., 2016), and regularization (Sun et al., 2016). Instead, our approach is using rotation, showing better results in terms of interpretability.

Meanwhile, various rotation methods are proposed such as CF-family (Crawford and Ferguson, 1970), Infomax (McKeon, 1968), Minimum Entropy (Jennrich, 2006), Geomin (Yates, 1988), procrustues (Hurley and Cattell, 1962), and promax rotation criteria. (Hendrickson and White, 1964). Incorporating prior knowledge about rotated matrix is possible through target rotations (Harman, 1960; Browne, 1972a,b) are proposed as well. There are various ways to rotated dimensions, we select a CF-family that covers frequently used rotation methods in practice.

8 Conclusion and Discussions

In this paper, we applied the rotation algorithm to improve interpretability of distributed representation of words. We applied quartimax, varimax, parsimax and factor parsimony rotation by using the Crawford-Ferguson rotation criteria, then we constructed the rotated word vector representations. We evaluated the expressive performance and interpretability for the rotated word vectors by word similarity, analogy, classification, and word intrusion task. The results show that the rotated word vector representations are highly interpretable with preserving expressive performance.

In addition, we explored the characteristics of the rotated word vectors: we observed 1) increased interpretability in both directions and 2) the positive relation between absolute value of the dimension and interpretability. Based on these observations, we proposed the selective distance ratio to measure and maximize the interpretability when the vector representation has interpretable meaning in both directions. We expect that the rotation algorithm can be easily applied to other word vector representations.

Our results imply that a rotated word vector can be used to understand what the word vectors are comprised of. Since a lexicon can be decomposed into morphemes, a word can have multiple meaning as a polysemy, contain information of syntactic structure in its meaning (Carpenter et al., 1995; MacDonald et al., 1994; Trueswell et al., 1994), or it can be divided into a variety of sub-components. Hence, we can investigate the lexical semantics of words by exploring the dimensions for which a word has higher values.

In addition, there are practical implications of interpreting the dimensions as well. Based on the meanings, we can remove irrelevant dimensions for a specific task of interest, in order to secure more efficient storage of the vectors and decrease the complexity of downstream NLP models. We will examine the issues in future work.

We plan to explore following issues. First, we apply target rotation (Harman, 1960; Browne, 1972a,b) to incorporate prior knowledge when constructing the rotated word vector representations. Second, we will investigate the interpretability of hidden structures of neural networks for NLP tasks such as (Yang et al., 2016; Li et al., 2016), when the rotated word vectors are used as an embedding layer.

A causal framework for explaining the predictions of black-box sequence-to-sequence models

David Alvarez-Melis and **Tommi S. Jaakkola**
CSAIL, MIT
{davidam, tommi}@csail.mit.edu

Abstract

We interpret the predictions of any black-box structured input-structured output model around a specific input-output pair. Our method returns an "explanation" consisting of groups of input-output tokens that are causally related. These dependencies are inferred by querying the black-box model with perturbed inputs, generating a graph over tokens from the responses, and solving a partitioning problem to select the most relevant components. We focus the general approach on sequence-to-sequence problems, adopting a variational autoencoder to yield meaningful input perturbations. We test our method across several NLP sequence generation tasks.

1 Introduction

Interpretability is often the first casualty when adopting complex predictors. This is particularly true for structured prediction methods at the core of many natural language processing tasks such as machine translation (MT). For example, deep learning models for NLP involve a large number of parameters and complex architectures, making them practically black-box systems. While such systems achieve state-of-the-art results in MT (Bahdanau et al., 2014), summarization (Rush et al., 2015) and speech recognition (Chan et al., 2015), they remain largely uninterpretable, although attention mechanisms (Bahdanau et al., 2014) can shed some light on how they operate.

Stronger forms of interpretability could offer several advantages, from trust in model predictions, error analysis, to model refinement. For example, critical medical decisions are increasingly being assisted by complex predictions that should lend themselves to easy verification by human experts. Without understanding how inputs get mapped to the outputs, it is also challenging to diagnose the source of potential errors. A slightly less obvious application concerns model improvement (Ribeiro et al., 2016) where interpretability can be used to detect biases in the methods.

Interpretability has been approached primarily from two main angles: *model interpretability*, i.e., making the architecture itself interpretable, and *prediction interpretability*, i.e., explaining particular predictions of the model (cf. (Lei et al., 2016)). Requiring the model itself to be transparent is often too restrictive and challenging to achieve. Indeed, prediction interpretability can be more easily sought *a posteriori* for black-box systems including neural networks.

In this work, we propose a novel approach to prediction interpretability with only oracle access to the model generating the prediction. Following (Ribeiro et al., 2016), we turn the local behavior of the model around the given input into an interpretable representation of its operation. In contrast to previous approaches, we consider structured prediction where both inputs and outputs are combinatorial objects, and our explanation consists of a summary of operation rather than a simpler prediction method.

Our method returns an "explanation" consisting of sets of input and output tokens that are causally related under the black-box model. Causal dependencies arise from analyzing perturbed versions of inputs that are passed through the black-

Proceedings of the 2017 Conference on Empirical Methods in Natural Language Processing, pages 412–421
Copenhagen, Denmark, September 7–11, 2017. ©2017 Association for Computational Linguistics

box model. Although such perturbations might be available in limited cases, we generate them automatically. For sentences, we adopt a variational autoencoder to produce semantically related sentence variations. The resulting inferred causal dependencies (interval estimates) form a dense bipartite graph over tokens from which explanations can be derived as robust min-cut k-partitions.

We demonstrate quantitatively that our method can recover known dependencies. As a starting point, we show that a grapheme-to-phoneme dictionary can be largely recovered if given to the method as a black-box model. We then show that the explanations provided by our method closely resemble the attention scores used by a neural machine translation system. Moreover, we illustrate how our summaries can be used to gain insights and detect biases in translation systems. Our main contributions are:

- We propose a general framework for explaining structured black-box models
- For sequential data, we propose a variational autoencoder for controlled generation of input perturbations required for causal analysis
- We evaluate the explanations produced by our framework on various sequence-to-sequence prediction tasks, showing they can recover known associations and provide insights into the workings of complex systems.

2 Related Work

There is a wide body of work spanning various fields centered around the notion of "interpretability". This term, however, is underdetermined, so the goals, methods and formalisms of these approaches are often non-overlapping (Lipton, 2016). In the context of machine learning, perhaps the most visible line of work on interpretability focuses on medical applications (Caruana et al., 2015), where trust can be a decisive factor on whether a model is used or not. With the ever-growing success and popularity of deep learning methods for image processing, recent work has addressed interpretability in this setting, usually requiring access to the method's activations and gradients (Selvaraju et al., 2016), or directly modeling how influence propagates (Bach et al., 2015). For a broad overview of interpretability in machine learning, we refer the reader to the recent survey by Doshi-Velez and Kim (2017).

Most similar to this work are the approaches of Lei et al. (2016) and Ribeiro et al. (2016). The former proposes a model that justifies its predictions in terms of fragments of the input. This approach formulates explanation generation as part of the learning problem, and, as most previous work, only deals with the case where predictions are scalar or categorical. On the other hand, Ribeiro et al. (2016) propose a framework for explaining the predictions of black-box classifiers by means of locally-faithful interpretable models. They focus on sparse linear models as explanations, and rely on local perturbations of the instance to explain. Their model assumes the input directly admits a fixed size interpretable representation in euclidean space, so their framework operates directly on this vector-valued representation.

Our method differs from—and can be thought of as generalizing—these approaches in two fundamental aspects. First, our framework considers both inputs and outputs to be structured objects thus extending beyond the classification setting. This requires rethinking the notion of explanation to adapt it to variable-size combinatorial objects. Second, while our approach shares the locality and model-agnostic view of Ribeiro et al. (2016), generating perturbed versions of structured objects is a challenging task by itself. We propose a solution to this problem in the case of sequence-to-sequence learning.

3 Interpreting structured prediction

Explaining predictions in the structured input-structured output setting poses various challenges. As opposed to scalar or categorical prediction, structured predictions vary in size and complexity. Thus, one must decide not only how to explain the prediction, but also what parts of it to explain. Intuitively, the "size" of an explanation should grow with the size of the input and output. A good explanation would ideally also decompose into *cognitive chunks* (Doshi-Velez and Kim, 2017): basic units of explanation which are a priori bounded in size. Thus, we seek a framework that naturally decomposes an explanation into (potentially several) *explaining components*, each of which justifies, from the perspective of the black-box model, parts of the output relative to the parts of the input.

Formally, suppose we have a black-box model $F : \mathcal{X} \to \mathcal{Y}$ that maps a structured input $\mathbf{x} \in \mathcal{X}$ to a structured output $\mathbf{y} \in \mathcal{Y}$. We make no assumptions on the spaces $\mathcal{X}, \mathcal{Y}$, except that their elements admit a feature-set representation $\mathbf{x} = \{x_1, x_2, \dots, x_n\}$, $\mathbf{y} = \{y_1, y_2, \dots, y_m\}$. Thus, $\mathbf{x}$ and $\mathbf{y}$ can be sequences, graphs or images. We refer to the elements x_i and y_j as units or "tokens" due to our motivating application of sentences, though everything in this work holds for other combinatorial objects.

For a given input output pair $(\mathbf{x}, \mathbf{y})$, we are interested in obtaining an *explanation* of $\mathbf{y}$ in terms of $\mathbf{x}$. Following (Ribeiro et al., 2016), we seek explanations via *interpretable representations* that are both i) *locally faithful*, in the sense that they approximate how the model behaves in the vicinity of $\mathbf{x}$, and ii) *model agnostic*, that is, that do not require any knowledge of F. For example, we would like to identify whether token x_i is a likely cause for the occurrence of y_j in the output when the input context is $\mathbf{x}$. Our assumption is that we can summarize the behavior of F around $\mathbf{x}$ in terms of a weighted bipartite graph $G = (V_x \cup V_y, E)$, where the nodes V_x and V_y correspond to the elements in $\mathbf{x}$ and $\mathbf{y}$, respectively, and the weight of each edge E_{ij} corresponds to the influence of the occurrence of token x_i on the appearance of y_j. The bipartite graph representation suggests naturally that the explanation be given in terms of explaining components. We can formalize these components as subgraphs $G^k = (V_x^k \cup V_y^k, E^k)$, where the elements in V_x^k are likely causes for the elements in V_y^k. Thus, we define an explanation of $\mathbf{y}$ as a collection of such components: $E_{x \to y} = \{G^1, \dots, G^k\}$.

Our approach formalizes this framework through a pipeline (sketched in Figure 1) consisting of three main components, described in detail in the following section: a perturbation model for exercising F locally, a causal inference model for inferring associations between inputs and predictions, and a selection step for partitioning and selecting the most relevant sets of associations. We refer to this framework as a *structured-output causal rationalizer* (SocRat).

A note on alignment models When the inputs and outputs are sequences such as sentences, one might envision using an alignment model, such as those used in MT, to provide an explanation. This differs from our approach in several respects. Specifically, we focus on explaining the behavior of the "black box" mapping F only locally, around the current input context, not globally. Any global alignment model would require access to substantial parallel data to train and would have varying coverage of the local context around the specific example of interest. Any global model would likely also suffer from misspecification in relation to F. A more related approach to ours would be an alignment model trained locally based on the same perturbed sentences and associated outputs that we generate.

4 Building blocks

4.1 Perturbation Model

The first step in our approach consists of obtaining *perturbed* versions of the input: semantically similar to the original but with potential changes in elements and their order. This is a major challenge with any structured inputs. We propose to do this using a variational autoencoder (VAE) (Kingma and Welling, 2014; Rezende et al., 2014). VAEs have been successfully used with fixed dimensional inputs such as images (Rezende and Mohamed, 2015; Sønderby et al., 2016) and recently also adapted to generating sentences from continuous representations (Bowman et al., 2016). The goal is to introduce the perturbation in the continuous latent representation rather than directly on the structured inputs.

A VAE is composed of a probabilistic encoder $\textsc{Enc} : \mathcal{X} \to \mathbb{R}^d$ and a decoder $\textsc{Dec} : \mathbb{R}^d \to \mathcal{X}$. The encoder defines a distribution over latent codes $q(\mathbf{z}|\mathbf{x})$, typically by means of a two-step procedure that first maps $\mathbf{x} \mapsto (\boldsymbol{\mu}, \boldsymbol{\sigma})$ and then samples $\mathbf{z}$ from a gaussian distribution with these parameters. We can leverage this stochasticity to obtain perturbed versions of the input

by sampling repeatedly from this distribution, and then mapping these back to the original space using the decoder. The training regime for the VAE ensures approximately that a small perturbation of the hidden representation maintains similar semantic content while introducing small changes in the decoded surface form. We emphasize that the approach would likely fail with an ordinary autoencoder where small changes in the latent representation can result in large changes in the decoded output. In practice, we ensure diversity of perturbations by scaling the variance term $\boldsymbol{\sigma}$ and sampling points $\tilde{\mathbf{z}}$ and different resolutions. We provide further details of this procedure in the supplement. Naturally, we can train this perturbation model in advance on (unlabeled) data from the input domain $\mathcal{X}$, and then use it as a subroutine in our method. After this process is complete, we have N pairs of perturbed input-output pairs: $\{(\tilde{\mathbf{x}}_i, \tilde{\mathbf{y}}_i)\}_{i=1}^N$ which exercise the mapping F around semantically similar inputs.

4.2 Causal model

The second step consists of using the perturbed input-output pairs $\{(\tilde{\mathbf{x}}_i, \tilde{\mathbf{y}}_i)\}_{i=1}^N$ to infer causal dependencies between the original input and output tokens. A naive approach would consider 2x2 contingency tables representing presence/absence of input/output tokens together with a test statistic for assessing their dependence. Instead, we incorporate *all* input tokens simultaneously to predict the occurrence of a single output token via logistic regression. The quality of these dependency estimators will depend on the frequency with which each input and output token occurs in the perturbations. Thus, we are interested in obtaining uncertainty estimates for these predictions, which can be naturally done with a Bayesian approach to logistic regression. Let $\phi_{\mathbf{x}}(\tilde{\mathbf{x}}) \in \{0,1\}^{|\mathbf{x}|}$ be a binary vector encoding the presence of the original tokens $x_1, \ldots, x_n$ from $\mathbf{x}$ in the perturbed version $\tilde{\mathbf{x}}$. For each target token $y_j \in \mathbf{y}$, we estimate a model:

$$P(y_j \in \tilde{\mathbf{y}} \mid \tilde{\mathbf{x}}) = \sigma(\boldsymbol{\theta}_j^T \phi_{\mathbf{x}}(\tilde{\mathbf{x}})) \qquad (1)$$

where $\sigma(z) = (1 + \exp(-z))^{-1}$. We use a Gaussian approximation for the logarithm of the logistic function together with the prior $p(\boldsymbol{\theta}) = \mathcal{N}(\boldsymbol{\theta}_0, \mathbf{H}_0^{-1})$ (Murphy, 2012). Since in our case all tokens are guaranteed to occur at least once (we include the original example pair as part of the set), we use $\boldsymbol{\theta}_0 = \alpha\mathbf{1}, \mathbf{H}_0 = \beta\mathbf{I}$, with $\alpha, \beta > 0$. Upon completion of this step, we have dependency coefficients between all original input and output tokens $\{\theta_{ij}\}$, along with their uncertainty estimates.

4.3 Explanation Selection

The last step in our interpretability framework consists of selecting a set explanations for $(\mathbf{x}, \mathbf{y})$. The steps so far yield a dense bipartite graph between the input and output tokens. Unless $|\mathbf{x}|$ and $|\mathbf{y}|$ are small, this graph itself may not be sufficiently interpretable. We are interested in selecting *relevant* components of this dependency graph, i.e., partition the vertex set of $\mathcal{G}$ into disjoint subsets so as to minimize the weight of omitted edges (i.e. the k-cut value of the partition).

Graph partitioning is a well studied NP-complete problem (Garey et al., 1976). The usual setting assumes deterministic edge weights, but in our case we are interested in incorporating the uncertainty of the dependency estimates—resulting from their finite sample estimation—into the partitioning problem. For this, we rely on the approach of Fan et al. (2012) designed for interval estimates of edge weights. At a high level, this is a robust optimization formulation which seeks to minimize worst case cut values, and can be cast as a Mixed Integer Programming (MIP) problem. Specifically, for a bipartite graph $G = (U, V, E)$

Algorithm 1 Structured-output causal rationalizer

```
procedure SOCRAT($\mathbf{x}, \mathbf{y}, F$)
    $(\boldsymbol{\mu}, \boldsymbol{\sigma}) \leftarrow$ ENCODE($\mathbf{x}$)            } Perturbation

        $\tilde{\mathbf{z}}_i \leftarrow$ SAMPLE($\boldsymbol{\mu}, \boldsymbol{\sigma}$)
        $\tilde{\mathbf{x}}_i \leftarrow$ DECODE($\tilde{\mathbf{z}}_i$)
        $\tilde{\mathbf{y}}_i \leftarrow F(\tilde{\mathbf{x}}_i)$
    end for
    $G \leftarrow$ CAUSAL($\mathbf{x}, \mathbf{y}, \{\tilde{\mathbf{x}}_i, \tilde{\mathbf{y}}_i\}_{i=1}^N$)
    $E_{x \mapsto y} \leftarrow$ BIPARTITION($G$)
    $E_{x \mapsto y} \leftarrow$ SORT($E_{x \mapsto y}$)          ▷ By cut capacity
    return $E_{x \mapsto y}$
end procedure
```

with edge weights given as uncertainty intervals $\theta_{ij} \pm \hat{\theta}_{ij}$, the partitioning problem is given by

$$\min_{(x^u_{ik}, x^v_{jk}, y_{ij}) \in Y} \sum_{i=1}^{n} \sum_{j=1}^{m} \theta_{ij} y_{ij} + \max_{\substack{S: S \subseteq V, |S| \leq \Gamma \\ (i_t, j_t) \in V \setminus S}} \sum_{(i,j) \in S} \hat{\theta}_{ij} y_{ij} + (\Gamma - \lfloor \Gamma \rfloor) \hat{\theta}_{i_t, j_t} y_{i_t, j_t} \tag{2}$$

where x^u_{ik}, x^v_{jk} are binary variables indicating subset belonging for elements of U and V respectively, y_{ij} are binary auxiliary variables indicating whether i and j are in different partitions, and Y is a set of constraints that ensure the K-partition is valid. Γ is a parameter in $[0, |V|]$ which adjusts the robustness of the partition (the number of deviations from the mean edge values). See the supplement for further explanation of this objective.

If $|\mathbf{x}|$ and $|\mathbf{y}|$ are small, the number of clusters K will also be small, so we can simply return all the partitions (i.e. the *explanation chunks*) $E^k_{x \to y} := (V^k_x \cup V^k_y)$. However, when K is large, one might wish to entertain only the κ most relevant explanations. The graph partitioning framework provides us with a natural way to score the importance of each chunk. Intuitively, subgraphs that have few high-valued edges connecting them to other parts of the graph (i.e. low *cut-capacity*) can be thought of as *self-contained* explanations, and thus more relevant for interpretability. We can therefore define the importance score an atom as:

$$\text{importance}(E^k_{x \to y}) := - \sum_{(i,j) \in X_k} \theta_{ij} \tag{3}$$

where X_k is the cut-set implied by $E^k_{x \to y}$:

$$X_k = \{(i,j) \in E \mid i \in E^k_{x \to y}, \ j \in V \setminus E^k_{x \to y}\}$$

The full interpretability method is succinctly expressed in Algorithm 1.

5 Experimental Framework

5.1 Training and optimization

For the experiments involving sentence inputs, we train in advance the VAE described in Section 4.1. We use symmetric encoder-decoders consisting of recurrent neural networks with an intermediate variational layer. In our case, however, we use L stacked RNN's on both sides, and a stacked variational layer. Training variational autoencoders for text is notoriously hard. In addition to dropout and KLD annealing (Bowman et al., 2016), we found that slowly scaling the variance sampled from the normal distribution from 0 to 1 made training much more stable.

For the partitioning step we compare the robust formulation described above with two classical approaches to bipartite graph partitioning which do not take uncertainty into account: the coclustering method of Dhillon (2001) and the biclustering method of Kluger et al. (2003). For these two, we use off-the-shelf implementations,[1] while we solve the MIP problem version of (2) with the optimization library `gurobi`.[2]

5.2 Recovering simple mappings

Before using our interpretability framework in real tasks where quantitative evaluation of explanations is challenging, we test it in a simplified setting where the "black-box" is simple and fully known. A reasonable minimum expectation on our method is that it should be able to infer many of these simple dependencies. For this purpose, we use the CMU Dictionary of word pronunciations,[3] which is based on the ARPAbet symbol set and consists of about 130K word-to-phoneme pairs. Phonemes are expressed as tokens of 1 to 3 characters. An example entry in this dictionary is the pair *vowels* ↦ `V AW1 AH0 L Z`. Though the mapping is simple, it is not one-to-one (a group of characters can correspond to a single phoneme) nor deterministic (the same character can map to different phonemes depending on the context). Thus, it provides a reasonable testbed

for our method. The setting is as follows: given an input-output pair from the `cmudict` "black-box", we use our method to infer dependencies between characters in the input and phonemes in the output. Since locality in this context is morphological instead of semantic, we produce perturbations selecting n words randomly from the intersection of the `cmudict` vocabulary and the set of words with edit distance at most 2 from the original word.

To evaluate the inferred dependencies, we randomly selected 100 key-value pairs from the dictionary and manually labeled them with character-to-phoneme alignments. Even though our framework is not geared to produce pairwise alignments, it should nevertheless be able to recover them to a certain extent. To provide a point of reference, we compare against a (strong) baseline that is tailored to such a task: a state-of-the-art unsupervised word alignment method based on Monte Carlo inference (Tiedemann and Östling, 2016). The results in Figure 2 show that the version of our method that uses the uncertainty clustering performs remarkably close to the alignment system, with an alignment error rate only ten points above an oracle version of this system that was trained on the *full* arpabet dictionary (dashed line). The raw and partitioned explanations provided by our method for an example input-output pair are shown in Table 1, where the edge widths correspond to the estimated strength of dependency. Throughout this work we display the nodes in the same lexical order of the inputs/outputs to facilitate reading, even if that makes the explanation chunks less visibly discernible. Instead, we sometimes provide an additional (sorted) heatplot of dependency values to show these partitions.

5.3 Machine Translation

In our second set of experiments we evaluate our explanation model in a relevant and popular sequence-to-sequence task: machine translation. As black-boxes, we use three different methods for translating English into German: (i) Azure's Machine Translation system, (ii) a Neural MT model, and (iii) a human (native speaker of German). We provide details on all three systems in the supplement. We translate the same English sentences with all three methods, and explain their predictions using SOCRAT. To be able to generate sentences with similar language and structure as those used to train the two automatic systems, we use the monolingual English side of the WMT14 dataset to train the variational autoencoder described in Section 4.1. For every explanation instance, we sample $S = 100$ perturbations and use the black-boxes to translate them. In all cases, we use the same default SOCRAT configurations, including the robust partitioning method.

In Figure 3, we show the explanations provided by our method for the predictions of each of the three systems on the input sentence *"Students said they looked forward to his class"*. Although the three black-boxes all provided different translations, the explanations show a mostly consistent clustering around the two phrases in the sentence, and in all three cases the cluster with the highest cut value (i.e. the most relevant explanative chunk) is the one containing the subject. Interestingly, the

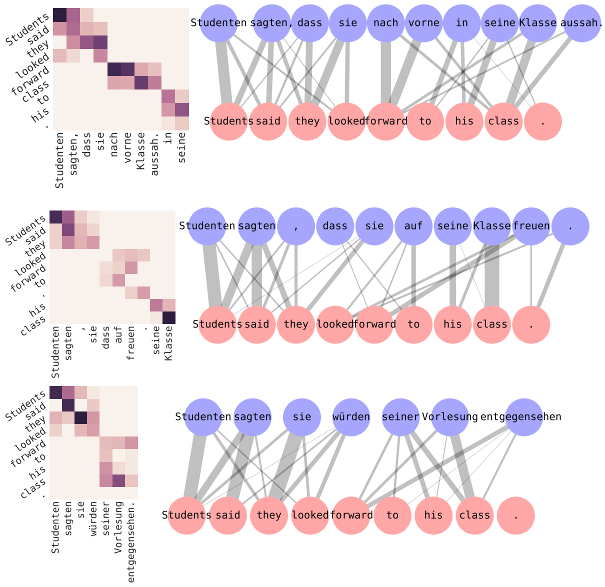

Figure 3: Explanations for the predictions of three Black-Box translators: Azure (top), NMT (middle) and human (bottom). Note that the rows and columns of the heatmaps are permuted to show explanation *chunks* (clusters).

dependency coefficients are overall higher for the human than for the other systems, suggesting more coherence in the translations (potentially because the human translated sentences in context, while the two automatic systems carry over no information from one example to the next).

The NMT system, as opposed to the other two, is not truly a black-box. We can *open the box* to get a glimpse on the true dependencies on the inputs used by the system at prediction time (the attention weights) and compare them to the explanation graph. The attention matrix, however, is dense and not normalized over target tokens, so it is not directly comparable to our dependency scores. Nevertheless, we can partition it with the coclustering method described in Section 4.3 to enforce group structure and make it easier to compare. Figure 4 shows the attention matrix and the explanation for an example sentence of the test set. Their overall cluster structure agrees, though our method shows conservatism with respect to the dependencies of the function words (*to*, *for*). Interestingly, our method is able to figure out that the <unk> token was likely produced by the word "appeals", as shown by the explanation graph.

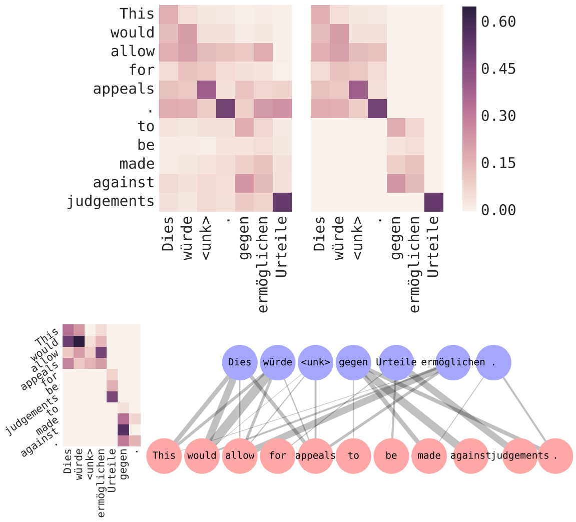

Figure 4: **Top**: Original and clustered attention matrix of the NMT system for a given translation. **Bottom**: Dependency estimates and explanation graph generated by SocRat with with $S = 100$.

It must be emphasized that although we display attention scores in various experiments in this work, we do so only for qualitative evaluation purposes. Our model-agnostic framework can be used on top of models that do not use attention mechanisms or for which this information is hard to extract. Even in cases where it is available, the explanation provided by SocRat might be complementary or even preferable to attention scores because: (a) being normalized on both directions (as opposed to only over source tokens) and partitioned, it is often more interpretable than a dense attention matrix, and (b) it can be retrieved *chunk*-by-*chunk* in decreasing order of relevance, which is especially important when explaining large inputs and/or outputs.

5.4 A (mediocre) dialogue system

So far we have used our method to explain (mostly) correct predictions of meaningful models. But we can use it to gain insights into the workings of flawed black-box systems too. To test this, we train a simple dialogue system on the OpenSubtitle corpus (Tiedemann, 2009), consisting of ∼14M two-step movie dialogues. As before, we use a sequence-to-sequence model with attention, but now we constrain the quality of the model, using only two layers, hidden state dimension of 1000 and no hyper-parameter tuning.

Input	Prediction
What do you mean it doesn't matter?	*I don't know*
Perhaps have we met before?	*I don't think so*
Can I get you two a cocktail?	*No, thanks.*

Table 2: "Good" dialogue system predictions.

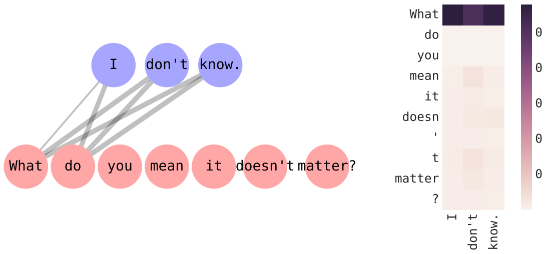

Figure 5: Explanation with $S = 50$ (left) and attention (right) for the first prediction in Table 2.

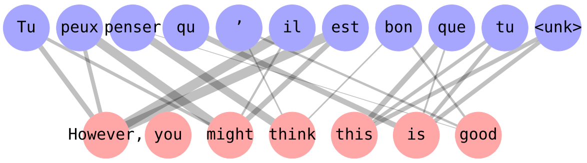

Figure 6: Explanation with $S = 50$ for the prediction of the biased translator.

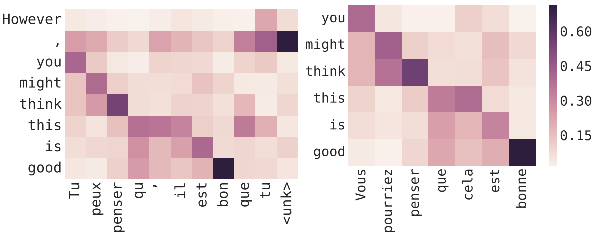

Figure 7: Attention scores on similar sentences by the biased translator.

Although most of the predictions of this model are short and repetitive (*Yes*/*No*/<unk> answers), some of them are seemingly meaningful, and might—if observed in isolation—lead one to believe the system is much better than it actually is. For example, the predictions in Table 2 suggest a complex use of the input to generate the output. To better understand this model, we rationalize its predictions using SocRat. The explanation graph for one such "good" prediction, shown in Figure 5, suggests that there is little influence of anything except the tokens *What* and *you* on the output. Thus, our method suggests that this model is using only partial information of the input and has probably memorized the connection between question words and responses. This is confirmed upon inspecting the model's attention scores for this prediction (same figure, right pane).

5.5 Bias detection in parallel corpora

Natural language processing methods that derive semantics from large corpora have been shown to incorporate biases present in the data, such as archaic stereotypes of male/female occupations (Caliskan et al., 2017) and sexist adjective associations (Bolukbasi et al., 2016). Thus, there is interest in methods that can detect and address those biases. For our last set of experiments, we use our approach to diagnose and explain biased translations of MT systems, first on a simplistic but *verifiable* synthetic setting, where we inject a pre-specified spurious association into an otherwise normal parallel training corpus, and then on an industrial-quality black-box system.

We simulate a biased corpus as follows. Starting from the WMT14 English-French dataset, we identify French sentences written in the informal register (e.g. containing the singular second person *tu*) and prepend their English translation with the word *However*. We obtain about 6K examples this way, after which we add an additional 1M examples that do not contain the word *however* on the English side. The purpose of this is to attempt to induce a (false) association between this adverb and the informal register in French. We then train a sequence-to-sequence model on this polluted data, and we use it to translate adversarially-chosen sentences containing the contaminating token. For example, given the input sentence "*However, you might think this is good*", the method predicts the translation "*Tu peux penser qu ' il est bon que tu <unk>*", which, albeit far from perfect, seems reasonable. However, using SocRat to explain this prediction (cf. Figure 6) raises a red flag: there is an inexplicable strong dependency between the function word *however* and tokens in the output associated with the informal register (*tu*, *peux*), and a lack of dependency between the second *tu* and the source-side pronoun *you*. The model's attention for this prediction (shown in Figure 7, left) confirms that it has picked up this spurious association. Indeed, translating the English sentence now without the prepended adverb

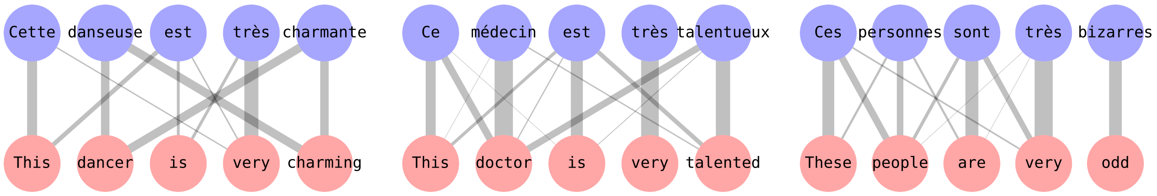

Figure 8: Explanations for biased translations of similar gender-neutral English sentences into French generated with Azure's MT service. The first two require gender declination in the target (French) language, while the third one, in plural, does not. The dependencies in the first two shed light on the cause of the biased selection of gender in the output sentence.

results in a switch to the formal register, as shown in the second plot in Figure 7.

Although somewhat contrived, this synthetic setting works as a litmus test to show that our method is able to detect *known* artificial biases from a model's predictions. We now move to a real setting, where we investigate biases in the predictions of an industrial-quality translation system. We use Azure's MT service to translate into French various simple sentences that lack gender specification in English, but which require gender-declined words in the output. We choose sentences containing occupations and adjectives previously shown to exhibit gender biases in linguistic corpora (Bolukbasi et al., 2016). After observing the choice of gender in the translation, we use SoCRat to explain the output.

In line with previous results, we observe that this translation model exhibits a concerning preference for the masculine grammatical gender in sentences containing occupations such as *doctor, professor* or adjectives such as *smart, talented*, while choosing the feminine gender for *charming, compassionate* subjects who are *dancers* or *nurses*. The explanation graphs for two such examples, shown in Figure 8 (left and center), suggest strong associations between the gender-neutral but stereotype-prone source tokens (*nurse, doctor, charming*) and the gender-carrying target tokens (i.e. the feminine-declined *cette, danseuse, charmante* in the first sentence and the masculine *ce, médecin, talenteux* in the second). While it is not unusual to observe interactions between multiple source and target tokens, the strength of dependence in some of these pairs (*charming*→*danseuse*, *doctor*→*ce*) is unexplained from a grammatical point of view. For comparison, the third example—a sentence in the plural form that does not involve choice of grammatical gender in French—shows comparatively much weaker associations across words in different parts of the sentence.

6 Discussion

Our model-agnostic framework for prediction interpretability with structured data can produce reasonable, coherent, and often insightful explanations. The results on the machine translation task demonstrate how such a method yields a partial view into the inner workings of a black-box system. Lastly, the results of the last two experiments also suggest potential for improving existing systems, by questioning seemingly correct predictions and explaining those that are not.

The method admits several possible modifications. Although we focused on sequence-to-sequence tasks, SocRat generalizes to other settings where inputs and outputs can be expressed as sets of features. An interesting application would be to infer dependencies between textual and image features in image-to-text prediction (e.g. image captioning). Also, we used a VAE-based sampling for object perturbations but other approaches are possible depending on the nature of the domain or data.

Abstract

Advances in neural variational inference have facilitated the learning of powerful directed graphical models with continuous latent variables, such as variational autoencoders. The hope is that such models will learn to represent rich, multi-modal latent factors in real-world data, such as natural language text. However, current models often assume simplistic priors on the latent variables — such as the uni-modal Gaussian distribution — which are incapable of representing complex latent factors efficiently. To overcome this restriction, we propose the simple, but highly flexible, piecewise constant distribution. This distribution has the capacity to represent an exponential number of modes of a latent target distribution, while remaining mathematically tractable. Our results demonstrate that incorporating this new latent distribution into different models yields substantial improvements in natural language processing tasks such as document modeling and natural language generation for dialogue.

1 Introduction

The development of the variational autoencoder framework (Kingma and Welling, 2014; Rezende et al., 2014) has paved the way for learning large-scale, directed latent variable models. This has led to significant progress in a diverse set of machine learning applications, ranging from computer vision (Gregor et al., 2015; Larsen et al., 2016) to natural language processing tasks (Mnih and Gregor, 2014; Miao et al., 2016; Bowman et al., 2015; Serban et al., 2017b). It is hoped that this framework will enable the learning of generative processes of real-world data — including text, audio and images — by disentangling and representing the underlying latent factors in the data. However, latent factors in real-world data are often highly complex. For example, topics in newswire text and responses in conversational dialogue often posses latent factors that follow non-linear (non-smooth), multi-modal distributions (i.e. distributions with multiple local maxima).

Nevertheless, the majority of current models assume a simple prior in the form of a multivariate Gaussian distribution in order to maintain mathematical and computational tractability. This is often a highly restrictive and unrealistic assumption to impose on the structure of the latent variables. First, it imposes a strong uni-modal structure on the latent variable space; latent variable samples from the generating model (prior distribution) all cluster around a single mean. Second, it forces the latent variables to follow a perfectly symmetric distribution with constant kurtosis; this makes it difficult to represent asymmetric or rarely occurring factors. Such constraints on the latent variables increase pressure on the down-stream generative model, which in turn is forced to carefully partition the probability mass for each latent factor throughout its intermediate layers. For complex, multi-modal distributions — such as the distribution over topics in a text corpus, or natural language responses in a dialogue system — the uni-modal Gaussian prior inhibits the model's ability to extract and represent important latent structure in the data. In order to learn more expressive latent variable models, we therefore need more flexible, yet tractable, priors.

In this paper, we introduce a simple, flexible

Proceedings of the 2017 Conference on Empirical Methods in Natural Language Processing, pages 422–432
Copenhagen, Denmark, September 7–11, 2017.

prior distribution based on the piecewise constant distribution. We derive an analytical, tractable form that is applicable to the variational autoencoder framework and propose a differentiable parametrization for it. We then evaluate the effectiveness of the distribution when utilized both as a prior and as approximate posterior across variational architectures in two natural language processing tasks: document modeling and natural language generation for dialogue. We show that the piecewise constant distribution is able to capture elements of a target distribution that cannot be captured by simpler priors — such as the uni-modal Gaussian. We demonstrate state-of-the-art results on three document modeling tasks, and show improvements on a dialogue natural language generation. Finally, we illustrate qualitatively how the piecewise constant distribution represents multi-modal latent structure in the data.

2 Related Work

The idea of using an artificial neural network to approximate an inference model dates back to the early work of Hinton and colleagues (Hinton and Zemel, 1994; Hinton et al., 1995; Dayan and Hinton, 1996). Researchers later proposed Markov chain Monte Carlo methods (MCMC) (Neal, 1992), which do not scale well and mix slowly, as well as variational approaches which require a tractable, factored distribution to approximate the true posterior distribution (Jordan et al., 1999). Others have since proposed using feed-forward inference models to initialize the mean-field inference algorithm for training Boltzmann architectures (Salakhutdinov and Larochelle, 2010; Ororbia II et al., 2015). Recently, the variational autoencoder framework (VAE) was proposed by Kingma and Welling (2014) and Rezende et al. (2014), closely related to the method proposed by Mnih and Gregor (2014). This framework allows the joint training of an inference network and a directed generative model, maximizing a variational lower-bound on the data log-likelihood and facilitating exact sampling of the variational posterior. Our work extends this framework.

With respect to document modeling, neural architectures have been shown to outperform well-established topic models such as Latent Dirichlet Allocation (LDA) (Hofmann, 1999; Blei et al., 2003). Researchers have successfully proposed several models involving discrete latent variables (Salakhutdinov and Hinton, 2009; Hinton and Salakhutdinov, 2009; Srivastava et al., 2013; Larochelle and Lauly, 2012; Uria et al., 2014; Lauly et al., 2016; Bornschein and Bengio, 2015; Mnih and Gregor, 2014). The success of such discrete latent variable models — which are able to partition probability mass into separate regions — serves as one of our main motivations for investigating models with more flexible continuous latent variables for document modeling. More recently, Miao et al. (2016) proposed to use continuous latent variables for document modeling.

Researchers have also investigated latent variable models for dialogue modeling and dialogue natural language generation (Bangalore et al., 2008; Crook et al., 2009; Zhai and Williams, 2014). The success of discrete latent variable models in this task also motivates our investigation of more flexible continuous latent variables. Closely related to our proposed approach is the Variational Hierarchical Recurrent Encoder-Decoder (*VHRED*, described below) (Serban et al., 2017b), a neural architecture with latent multivariate Gaussian variables.

Researchers have explored more flexible distributions for the latent variables in VAEs, such as autoregressive distributions, hierarchical probabilistic models and approximations based on MCMC sampling (Rezende et al., 2014; Rezende and Mohamed, 2015; Kingma et al., 2016; Ranganath et al., 2016; Maaløe et al., 2016; Salimans et al., 2015; Burda et al., 2016; Chen et al., 2017; Ruiz et al., 2016). These are all complimentary to our approach; it is possible to combine them with the piecewise constant latent variables. In parallel to our work, multiple research groups have also proposed VAEs with discrete latent variables (Maddison et al., 2017; Jang et al., 2017; Rolfe, 2017; Johnson et al., 2016). This is a promising line of research, however these approaches often require approximations which may be inaccurate when applied to larger scale tasks, such as document modeling or natural language generation. Finally, discrete latent variables may be inappropriate for certain natural language processing tasks.

3 Neural Variational Models

We start by introducing the neural variational learning framework. We focus on modeling discrete output variables (e.g. words) in the context of natural language processing applications. However, the framework can easily be adapted to handle continuous output variables.

3.1 Neural Variational Learning

Let $w_1, \ldots, w_N$ be a sequence of N tokens (words) conditioned on a continuous latent variable z. Further, let c be an additional observed variable which conditions both z and $w_1, \ldots, w_N$. Then, the distribution over words is:

$$P_\theta(w_1, \ldots, w_N|c) = \int \prod_{n=1}^{N} P_\theta(w_n|w_{<n}, z, c) P_\theta(z|c) dz,$$

where θ are the model parameters. The model first generates the higher-level, continuous latent variable z conditioned on c. Given z and c, it then generates the word sequence $w_1, \ldots, w_N$. For unsupervised modeling of documents, the c is excluded and the words are assumed to be independent of each other, when conditioned on z:

$$P_\theta(w_1, \ldots, w_N) = \int \prod_{n=1}^{N} P_\theta(w_n|z) P_\theta(z) dz.$$

Model parameters can be learned using the variational lower-bound (Kingma and Welling, 2014):

$$\begin{aligned} &\log P_\theta(w_1, \ldots, w_N|c) \\ &\quad \geq \quad \mathrm{E}_{z \sim Q_\psi(z|w_1,\ldots,w_N,c)}[\log P_\theta(w_n|w_{<n}, z, c)] \\ &\qquad - \mathrm{KL}\left[Q_\psi(z|w_1, \ldots, w_N, c) || P_\theta(z|c)\right], \qquad (1) \end{aligned}$$

where we note that $Q_\psi(z|w_1, \ldots, w_N, c)$ is the approximation to the intractable, true posterior $P_\theta(z|w_1, \ldots, w_N, c)$. Q is called the *encoder*, or sometimes the *recognition model* or *inference model*, and it is parametrized by ψ. The distribution $P_\theta(z|c)$ is the prior model for z, where the only available information is c. The VAE framework further employs the re-parametrization trick, which allows one to move the derivative of the lower-bound inside the expectation. To accomplish this, z is parametrized as a transformation of a fixed, parameter-free random distribution $z = f_\theta(\epsilon)$, where ϵ is drawn from a random distribution. Here, f is a transformation of ϵ, parametrized by θ, such that $f_\theta(\epsilon) \sim P_\theta(z|c)$. For example, ϵ might be drawn from a standard Gaussian distribution and f might be defined as $f_\theta(\epsilon) = \mu + \sigma\epsilon$, where μ and σ are in the parameter set θ. In this case, z is able to represent any Gaussian with mean μ and variance σ^2.

Model parameters are learned by maximizing the variational lower-bound in eq. (1) using gradient descent, where the expectation is computed using samples from the approximate posterior.

The majority of work on VAEs propose to parametrize z as multivariate Gaussian distributions. However, this unrealistic assumption may critically hurt the expressiveness of the latent variable model. See Appendix A for a detailed discussion. This motivates the proposed piecewise constant latent variable distribution.

3.2 Piecewise Constant Distribution

We propose to learn latent variables by parametrizing z using a piecewise constant probability density function (PDF). This should allow z to represent complex aspects of the data distribution in latent variable space, such as non-smooth regions of probability mass and multiple modes.

Let $n \in \mathbb{N}$ be the number of piecewise constant components. We assume z is drawn from PDF:

$$P(z) = \frac{1}{K} \sum_{i=1}^{n} 1_{\left(\frac{i-1}{n} \leq z \leq \frac{i}{n}\right)} a_i, \qquad (2)$$

where $1_{(x)}$ is the indicator function, which is one when x is true and otherwise zero. The distribution parameters are $a_i > 0$, for $i = 1, \ldots, n$. The normalization constant is:

$$K = \sum_{i=1}^{n} K_i, \text{ where } K_0 = 0, K_i = \frac{a_i}{n}, \text{ for } i = 1, \ldots, n.$$

It is straightforward to show that a piecewise constant distribution with more than $n > 2$ pieces is capable of representing a bi-modal distribution. When $n > 2$, a vector z of piecewise constant variables can represent a probability density with $2^{|z|}$ modes. Figure 1 illustrates how these variables help model complex, multi-modal distributions.

In order to compute the variational bound, we need to draw samples from the piecewise constant distribution using its inverse cumulative distribution function (CDF). Further, we need to compute the KL divergence between the prior and posterior. The inverse CDF and KL divergence quantities are both derived in Appendix B. During training we must compute derivatives of the variational bound in eq. (1). These expressions involve derivatives of indicator functions, which have derivatives zero everywhere except for the changing points where the derivative is undefined. However, the probability of sampling the value exactly at its changing

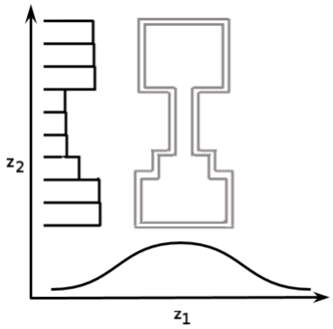

Figure 1: Joint density plot of a pair of Gaussian and piecewise constant variables. The horizontal axis corresponds to z_1, which is a univariate Gaussian variable. The vertical axis corresponds to z_2, which is a piecewise constant variable.

point is effectively zero. Thus, we fix these derivatives to zero. Similar approximations are used in training networks with rectified linear units.

4 Latent Variable Parametrizations

In this section, we develop the parametrization of both the Gaussian variable and our proposed piecewise constant latent variable.

Let x be the current output sequence, which the model must generate (e.g. $w_1, \ldots, w_N$). Let c be the observed conditioning information. If the task contains additional conditioning information this will be embedded by c. For example, for dialogue natural language generation c represents an embedding of the dialogue history, while for document modeling $c = \emptyset$.

4.1 Gaussian Parametrization

Let μ^{prior} and $\sigma^{2,\text{prior}}$ be the prior mean and variance, and let μ^{post} and $\sigma^{2,\text{post}}$ be the approximate posterior mean and variance. For Gaussian latent variables, the prior distribution mean and variances are encoded using linear transformations of a hidden state. In particular, the prior distribution covariance is encoded as a diagonal covariance matrix using a softplus function:

$$\begin{aligned}\mu^{\text{prior}} &= H_\mu^{\text{prior}}\text{Enc}(c) + b_\mu^{\text{prior}},\\ \sigma^{2,\text{prior}} &= \text{diag}(\log(1 + \exp(H_\sigma^{\text{prior}}\text{Enc}(c) + b_\sigma^{\text{prior}}))),\end{aligned}$$

where $\text{Enc}(c)$ is an embedding of the conditioning information c (e.g. for dialogue natural language generation this might, for example, be produced by an LSTM encoder applied to the dialogue history), which is shared across all latent variable dimensions. The matrices $H_\mu^{\text{prior}}, H_\sigma^{\text{prior}}$ and vectors $b_\mu^{\text{prior}}, b_\sigma^{\text{prior}}$ are learnable parameters. For the posterior distribution, previous work has shown it is better to parametrize the posterior distribution as a linear interpolation of the prior distribution mean and variance and a new estimate of the mean and variance based on the observation x (Fraccaro et al., 2016). The interpolation is controlled by a gating mechanism, allowing the model to turn on/off latent dimensions:

$$\begin{aligned}\mu^{\text{post}} =& (1 - \alpha_\mu)\mu^{\text{prior}} + \alpha_\mu \left(H_\mu^{\text{post}}\text{Enc}(c, x) + b_\mu^{\text{post}}\right),\\ \sigma^{2,\text{post}} =& (1 - \alpha_\sigma)\sigma^{2,\text{prior}}\\ &+ \alpha_\sigma \text{diag}(\log(1 + \exp(H_\sigma^{\text{post}}\text{Enc}(c, x) + b_\sigma^{\text{post}}))),\end{aligned}$$

where $\text{Enc}(c, x)$ is an embedding of both c and x. The matrices $H_\mu^{\text{post}}, H_\sigma^{\text{post}}$ and the vectors $b_\mu^{\text{post}}, b_\sigma^{\text{post}}, \alpha_\mu, \alpha_\sigma$ are parameters to be learned. The interpolation mechanism is controlled by α_μ and α_σ, which are initialized to zero (i.e. initialized such that the posterior is equal to the prior).

4.2 Piecewise Constant Parametrization

We parametrize the piecewise prior parameters using an exponential function applied to a linear transformation of the conditioning information:

$$a_i^{\text{prior}} = \exp(H_{a,i}^{\text{prior}}\text{Enc}(c) + b_{a,i}^{\text{prior}}), \quad i = 1, \ldots, n,$$

where matrix H_a^{prior} and vector b_a^{prior} are learnable. As before, we define the posterior parameters as a function of both c and x:

$$a_i^{\text{post}} = \exp(H_{a,i}^{\text{post}}\text{Enc}(c, x) + b_{a,i}^{\text{post}}), \quad i = 1, \ldots, n,$$

where H_a^{post} and b_a^{post} are parameters.

5 Variational Text Modeling

We now introduce two classes of VAEs. The models are extended by incorporating the Gaussian and piecewise latent variable parametrizations.

5.1 Document Model

The neural variational document model (*NVDM*) model has previously been proposed for document modeling (Mnih and Gregor, 2014; Miao et al., 2016), where the latent variables are Gaussian. Since the original *NVDM* uses Gaussian latent variables, we will refer to it as *G-NVDM*. We propose two novel models building on *G-NVDM*. The first model we propose uses piecewise constant latent variables instead of Gaussian latent variables.

We refer to this model as *P-NVDM*. The second model we propose uses a combination of Gaussian and piecewise constant latent variables. The models sample the Gaussian and piecewise constant latent variables independently and then concatenates them together into one vector. We refer to this model as *H-NVDM*.

Let V be the vocabulary of document words. Let W represent a document matrix, where row w_i is the 1-of-$|V|$ binary encoding of the i'th word in the document. Each model has an encoder component $Enc(W)$, which compresses a document vector into a continuous distributed representation upon which the approximate posterior is built. For document modeling, word order information is not taken into account and no additional conditioning information is available. Therefore, each model uses a bag-of-words encoder, defined as a multi-layer perceptron (MLP) $Enc(c = \emptyset, x) = Enc(x)$. Based on preliminary experiments, we choose the encoder to be a two-layered MLP with parametrized rectified linear activation functions (we omit these parameters for simplicity). For the approximate posterior, each model has the parameter matrix W_a^{post} and vector b_a^{post} for the piecewise latent variables, and the parameter matrices $W_\mu^{\text{post}}, W_\sigma^{\text{post}}$ and vectors $b_\mu^{\text{post}}, b_\sigma^{\text{post}}$ for the Gaussian means and variances. For the prior, each model has parameter vector b_a^{prior} for the piecewise latent variables, and vectors $b_\mu^{\text{prior}}, b_\sigma^{\text{prior}}$ for the Gaussian means and variances. We initialize the bias parameters to zero in order to start with centered Gaussian and piecewise constant priors. The encoder will adapt these priors as learning progresses, using the gating mechanism to turn on/off latent dimensions.

Let z be the vector of latent variables sampled according to the approximate posterior distribution. Given z, the decoder $Dec(w, z)$ outputs a distribution over words in the document:

$$Dec(w, z) = \frac{\exp\left(-w^{\mathrm{T}} R z + b_w\right)}{\sum_{w'} \exp\left(-w^{\mathrm{T}} R z + b_{w'}\right)},$$

where R is a parameter matrix and b is a parameter vector corresponding to the bias for each word to be learned. This output probability distribution is combined with the KL divergences to compute the lower-bound in eq. (1). See Appendix C.

Our baseline model *G-NVDM* is an improvement over the original *NVDM* proposed by Mnih and Gregor (2014) and Miao et al. (2016). We learn the prior mean and variance, while these were fixed to a standard Gaussian in previous work. This increases the flexibility of the model and makes optimization easier. In addition, we use a gating mechanism for the approximate posterior of the Gaussian variables. This gating mechanism allows the model to turn off latent variable (i.e. fix the approximate posterior to equal the prior for specific latent variables) when computing the final posterior parameters. Furthermore, Miao et al. (2016) alternated between optimizing the approximate posterior parameters and the generative model parameters, while we optimize all parameters simultaneously.

5.2 Dialogue Model

The variational hierarchical recurrent encoder-decoder (*VHRED*) model has previously been proposed for dialogue modeling and natural language generation (Serban et al., 2017b, 2016a). The model decomposes dialogues using a two-level hierarchy: sequences of utterances (e.g. sentences), and sub-sequences of tokens (e.g. words). Let $\mathbf{w}_n$ be the n'th utterance in a dialogue with N utterances. Let $w_{n,m}$ be the m'th word in the n'th utterance from vocabulary V given as a 1-of-$|V|$ binary encoding. Let M_n be the number of words in the n'th utterance. For each utterance $n = 1, \dots, N$, the model generates a latent variable z_n. Conditioned on this latent variable, the model then generates the next utterance:

$$P_\theta(\mathbf{w}_1, z_1, \dots, \mathbf{w}_N, z_N) = \prod_{n=1}^{N} P_\theta(z_n | \mathbf{w}_{<n}) \times \prod_{m=1}^{M_n} P_\theta(w_{n,m} | w_{n,<m}, \mathbf{w}_{<n}, z_n),$$

where θ are the model parameters. *VHRED* consists of three RNN modules: an *encoder* RNN, a *context* RNN and a *decoder* RNN. The *encoder* RNN computes an embedding for each utterance. This embedding is fed into the *context* RNN, which computes a hidden state summarizing the dialogue context before utterance n: h_{n-1}^{con}. This state represents the additional conditioning information, which is used to compute the prior distribution over z_n:

$$P_\theta(z_n \mid \mathbf{w}_{<n}) = f_\theta^{\text{prior}}(z_n; h_{n-1}^{con}),$$

where f^{prior} is a PDF parametrized by both θ and h_{n-1}^{con}. A sample is drawn from this distribution: $z_n \sim P_\theta(z_n | \mathbf{w}_{<n})$. This sample is given as input

to the *decoder* RNN, which then computes the output probabilities of the words in the next utterance. The model is trained by maximizing the variational lower-bound, which factorizes into independent terms for each sub-sequence (utterance):

$$\begin{aligned}
&\log P_\theta(\mathbf{w}_1, \ldots, \mathbf{w}_N) \\
&\geq \sum_{n=1}^{N} - \mathrm{KL}\left[Q_\psi(z_n \mid \mathbf{w}_1, \ldots, \mathbf{w}_n) || P_\theta(z_n \mid \mathbf{w}_{<n})\right] \\
&\qquad + \mathbb{E}_{Q_\psi(z_n \mid \mathbf{w}_1, \ldots, \mathbf{w}_n)}\left[\log P_\theta(\mathbf{w}_n \mid z_n, \mathbf{w}_{<n})\right],
\end{aligned}$$

where distribution Q_ψ is the approximate posterior distribution with parameters ψ, computed similarly as the prior distribution but further conditioned on the *encoder* RNN hidden state of the next utterance.

The original *VHRED* model (Serban et al., 2017b) used Gaussian latent variables. We refer to this model as *G-VHRED*. The first model we propose uses piecewise constant latent variables instead of Gaussian latent variables. We refer to this model as *P-VHRED*. The second model we propose takes advantage of the representation power of both Gaussian and piecewise constant latent variables. This model samples both a Gaussian latent variable z_n^{gaussian} and a piecewise latent variable $z_n^{\text{piecewise}}$ independently conditioned on the *context* RNN hidden state:

$$\begin{aligned}
P_\theta(z_n^{\text{gaussian}} \mid \mathbf{w}_{<n}) &= f_\theta^{\text{prior, gaussian}}(z_n^{\text{gaussian}}; h_{n-1}^{con}), \\
P_\theta(z_n^{\text{piecewise}} \mid \mathbf{w}_{<n}) &= f_\theta^{\text{prior, piecewise}}(z_n^{\text{piecewise}}; h_{n-1}^{con}),
\end{aligned}$$

where $f^{\text{prior, gaussian}}$ and $f^{\text{prior, piecewise}}$ are PDFs parametrized by independent subsets of parameters θ. We refer to this model as *H-VHRED*.

6 Experiments

We evaluate the proposed models on two types of natural language processing tasks: document modeling and dialogue natural language generation. All models are trained with back-propagation using the variational lower-bound on the log-likelihood or the exact log-likelihood. We use the first-order gradient descent optimizer Adam (Kingma and Ba, 2015) with gradient clipping (Pascanu et al., 2012)[1]

6.1 Document Modeling

Tasks We use three different datasets for document modeling experiments. First, we use the 20 News-Groups (20-NG) dataset (Hinton and Salakhutdinov, 2009). Second, we use the Reuters corpus (RCV1-V2), using a version that contained a selected 5,000 term vocabulary. As in previous work (Hinton and Salakhutdinov, 2009; Larochelle and Lauly, 2012), we transform the original word frequencies using the equation $\log(1 + \text{TF})$, where TF is the original word frequency. Third, to test our document models on text from a non-English language, we use the Brazilian Portuguese CADE12 dataset (Cardoso-Cachopo, 2007). For all datasets, we track the validation bound on a subset of 100 vectors randomly drawn from each training corpus.

Training All models were trained using minibatches with 100 examples each. A learning rate of 0.002 was used. Model selection and early stopping were conducted using the validation lower-bound, estimated using five stochastic samples per validation example. Inference networks used 100 units in each hidden layer for 20-NG and CADE, and 100 for RCV1. We experimented with both 50 and 100 latent random variables for each class of models, and found that 50 latent variables performed best on the validation set. For *H-NVDM* we vary the number of components used in the PDF, investigating the effect that 3 and 5 pieces had on the final quality of the model. The number

Table 2: Word query similarity test on 20 News-Groups: for the query 'space", we retrieve the top 10 nearest words in word embedding space based on Euclidean distance. *H-NVDM-5* associates multiple meanings to the query, while *G-NVDM* only associates the most frequent meaning.

of hidden units was chosen via preliminary experimentation with smaller models. On 20-NG, we use the same set-up as (Hinton and Salakhutdinov, 2009) and therefore report the perplexities of a topic model (*LDA*, (Hinton and Salakhutdinov, 2009)), the document neural auto-regressive estimator (*docNADE*, (Larochelle and Lauly, 2012)), and a neural variational document model with a fixed standard Gaussian prior (*NVDM*, lowest reported perplexity, (Miao et al., 2016)).

Results In Table 1, we report the test document perplexity: $\exp(-\frac{1}{D}\sum_n \frac{1}{L_n} \log P_\theta(x_n)$. We use the variational lower-bound as an approximation based on 10 samples, as was done in (Mnih and Gregor, 2014). First, we note that the best baseline model (i.e. the *NVDM*) is more competitive when both the prior and posterior models are learnt together (i.e. the *G-NVDM*), as opposed to the fixed prior of (Miao et al., 2016). Next, we observe that integrating our proposed piecewise variables yields even better results in our document modeling experiments, substantially improving over the baselines. More importantly, in the 20-NG and Reuters datasets, increasing the number of pieces from 3 to 5 further reduces perplexity. Thus, we have achieved a new state-of-the-art perplexity on 20 News-Groups task and — to the best of our knowledge – better perplexities on the CADE12 and RCV1 tasks compared to using a state-of-the-art model like the *G-NVDM*. We also evaluated the converged models using an non-parametric inference procedure, where a separate approximate posterior is learned for each test example in order to tighten the variational lower-bound. *H-NVDM* also performed best in this evaluation across all three datasets, which confirms that the performance improvement is due to the piecewise components. See appendix for details.

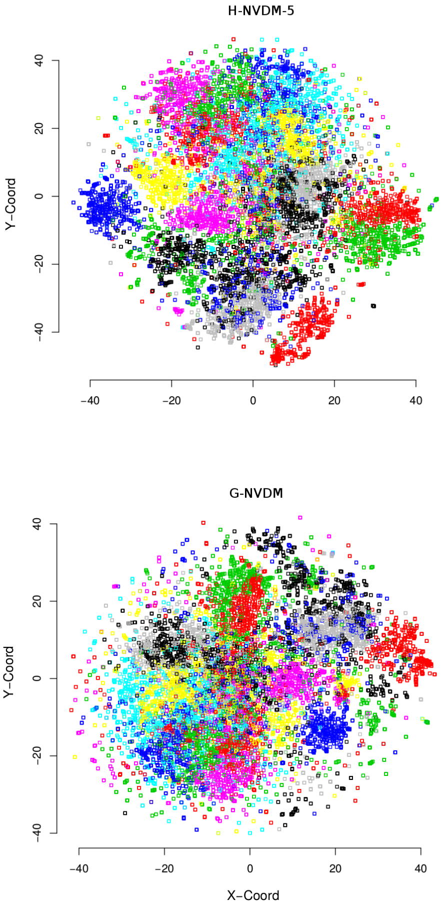

Figure 2: Latent variable approximate posterior means t-SNE visualization on 20-NG for *G-NVDM* and *H-NVDM-5*. Colors correspond to the topic labels assigned to each document.

In Table 2, we examine the top ten highest ranked words given the query term "space", using the decoder parameter matrix. The piecewise variables appear to have a significant effect on what is uncovered by the model.In the case of "space", the hybrid with 5 pieces seems to value two senses of the word–one related to "outer space" (e.g., "sun", "world", etc.) and another related to the dimensions of depth, height, and width within which things may exist and move (e.g., "area", "form", "scale", etc.). On the other hand, *G-NVDM* appears to only capture the "outer space" sense of

Model	Activity	Entity

P-VHRED	5	2.49
H-VHRED	8.41	**3.72**

Table 3: Ubuntu evaluation using F1 metrics w.r.t. activities and entities. *G-VHRED*, *P-VHRED* and *H-VHRED* all outperform the baseline *HRED*. *G-VHRED* performs best w.r.t. activities and *H-VHRED* performs best w.r.t. entities.

the word. More examples are in the appendix.

Finally, we visualized the means of the approximate posterior latent variables on 20-NG through a t-SNE projection. As shown in Figure 2, both *G-NVDM* and *H-NVDM-5* learn representations which disentangle the topic clusters on 20-NG. However, *G-NVDM* appears to have more dispersed clusters and more outliers (i.e. data points in the periphery) compared to *H-NVDM-5*. Although it is difficult to draw conclusions based on these plots, these findings could potentially be explained by the Gaussian latent variables fitting the latent factors poorly.

6.2 Dialogue Modeling

Task We evaluate *VHRED* on a natural language generation task, where the goal is to generate responses in a dialogue. This is a difficult problem, which has been extensively studied in the recent literature (Ritter et al., 2011; Lowe et al., 2015; Sordoni et al., 2015; Li et al., 2016; Serban et al., 2016a,b). Dialogue response generation has recently gained a significant amount of attention from industry, with high-profile projects such as Google SmartReply (Kannan et al., 2016) and Microsoft Xiaoice (Markoff and Mozur, 2015). Even more recently, Amazon has announced the Alexa Prize Challenge for the research community with the goal of developing a natural and engaging chatbot system (Farber, 2016).

We evaluate on the technical support response generation task for the Ubuntu operating system. We use the well-known Ubuntu Dialogue Corpus (Lowe et al., 2015, 2017), which consists of about 1/2 million natural language dialogues extracted from the #Ubuntu Internet Relayed Chat (IRC) channel. The technical problems discussed span a wide range of software-related and hardware-related issues. Given a dialogue history — such as a conversation between a user and a technical support assistant — the model must generate the next appropriate response in the dialogue. For example, when it is the turn of the technical support assistant, the model must generate an appropriate response helping the user resolve their problem.

We evaluate the models using the activity- and entity-based metrics designed specifically for the Ubuntu domain (Serban et al., 2017a). These metrics compare the *activities* and *entities* in the model generated responses with those of the reference responses; activities are verbs referring to high-level actions (e.g. *download*, *install*, *unzip*) and entities are nouns referring to technical objects (e.g. *Firefox*, *GNOME*). The more activities and entities a model response overlaps with the reference response (e.g. expert response) the more likely the response will lead to a solution.

Training The models were trained to maximize the log-likelihood of training examples using a learning rate of 0.0002 and mini-batches of size 80. We use a variant of truncated backpropagation. We terminate the training procedure for each model using early stopping, estimated using one stochastic sample per validation example. We evaluate the models by generating dialogue responses: conditioned on a dialogue context, we fix the model latent variables to their median values and then generate the response using a beam search with size 5. We select model hyperparameters based on the validation set using the F1 activity metric, as described earlier.

It is often difficult to train generative models for language with stochastic latent variables (Bowman et al., 2015; Serban et al., 2017b). For the latent variable models, we therefore experiment with reweighing the KL divergence terms in the variational lower-bound with values 0.25, 0.50, 0.75 and 1.0. In addition to this, we linearly increase the KL divergence weights starting from zero to their final value over the first 75000 training batches. Finally, we weaken the *decoder* RNN by randomly replacing words inputted to the decoder RNN with the unknown token with 25% probability. These steps are important for effectively training the models, and the latter two have been used in previous work by Bowman et al. (2015) and Serban et al. (2017b).

HRED (Baseline): We compare to the *HRED* model (Serban et al., 2016a): a sequence-to-sequence model, shown to outperform other established models on this task, such as the LSTM RNN language model (Serban et al., 2017a). The *HRED* model's *encoder* RNN uses a bidirectional GRU RNN encoder, where the forward and backward RNNs each have 1000 hidden units. The context RNN is a GRU encoder with 1000 hidden units, and the decoder RNN is an LSTM decoder with 2000 hidden units.[2] The encoder and context RNNs both use layer normalization (Ba et al., 2016).[3] We also experiment with an additional rectified linear layer applied on the inputs to the decoder RNN. As with other hyper-parameters, we choose whether to include this additional layer based on the validation set performance. *HRED*, as well as all other models, use a word embedding dimensionality of size 400.

G-HRED: We compare to *G-VHRED*, which is *VHRED* with Gaussian latent variables (Serban et al., 2017b). *G-VHRED* uses the same hyper-parameters for the encoder, context and decoder RNNs as the HRED model. The model has 100 Gaussian latent variables per utterance.

P-HRED: The first model we propose is *P-VHRED*, which is *VHRED* model with piecewise constant latent variables. We use $n = 3$ number of pieces for each latent variable. *P-VHRED* also uses the same hyper parameters for the encoder, context and decoder RNNs as the *HRED* model. Similar to *G-VHRED*, *P-VHRED* has 100 piecewise constant latent variables per utterance.

H-HRED: The second model we propose is *H-VHRED*, which has 100 piecewise constant (with $n = 3$ pieces per variable) and 100 Gaussian latent variables per utterance. *H-VHRED* also uses the same hyper-parameters for the encoder, context and decoder RNNs as *HRED*.

Results: The results are given in Table 3. All latent variable models outperform *HRED* w.r.t. both activities and entities. This strongly suggests that the high-level concepts represented by the latent variables help generate meaningful, goal-directed responses. Furthermore, each type of latent variable appears to help with a different aspects of the generation task. *G-VHRED* performs best w.r.t. activities (e.g. *download*, *install* and so on), which occur frequently in the dataset. This suggests that the Gaussian latent variables learn useful latent representations for frequent actions. On the other hand, *H-VHRED* performs best w.r.t. entities (e.g. *Firefox*, *GNOME*), which are often much rarer and mutually exclusive in the dataset. This suggests that the combination of Gaussian and piecewise latent variables help learn useful representations for entities, which could not be learned by Gaussian latent variables alone. We further conducted a qualitative analysis of the model responses, which supports these conclusions. See Appendix G.[4]

7 Conclusions

In this paper, we have sought to learn rich and flexible multi-modal representations of latent variables for complex natural language processing tasks. We have proposed the piecewise constant distribution for the variational autoencoder framework. We have derived closed-form expressions for the necessary quantities required for in the autoencoder framework, and proposed an efficient, differentiable implementation of it. We have incorporated the proposed piecewise constant distribution into two model classes — *NVDM* and *VHRED* — and evaluated the proposed models on document modeling and dialogue modeling tasks. We have achieved state-of-the-art results on three document modeling tasks, and have demonstrated substantial improvements on a dialogue modeling task. Overall, the results highlight the benefits of incorporating the flexible, multi-modal piecewise constant distribution into variational autoencoders. Future work should explore other natural language processing tasks, where the data is likely to arise from complex, multi-modal latent factors.

The authors thank Hugo Larochelle for sharing the NewsGroup 20 dataset. The authors thank Laurent Charlin, Sungjin Ahn, and Ryan Lowe for constructive feedback. This research was enabled in part by support provided by Calcul Qubec (`www.calculquebec.ca`) and Compute Canada (`www.computecanada.ca`).

[2] Since training lasted between 1-3 weeks for each model, we had to fix the number of hidden units during preliminary experiments on the training and validation datasets.

[3] We did not apply layer normalization to the decoder RNN, because several of our colleagues have found that this may hurt the performance of generative language models.

[4] Results on a Twitter dataset are given in the appendix.

Learning the Structure of Variable-Order CRFs: a Finite-State Perspective

Thomas Lavergne and **François Yvon**

Campus Universitaire, F-91 403 Orsay, France
{lavergne,yvon}@limsi.fr

Abstract

The computational complexity of linear-chain Conditional Random Fields (CRFs) makes it difficult to deal with very large label sets and long range dependencies. Such situations are not rare and arise when dealing with morphologically rich languages or joint labelling tasks. We extend here recent proposals to consider variable order CRFs. Using an effective finite-state representation of variable-length dependencies, we propose new ways to perform feature selection at large scale and report experimental results where we outperform strong baselines on a tagging task.

1 Introduction

Conditional Random Fields (CRFs) (Lafferty et al., 2001; Sutton and McCallum, 2006) are a method of choice for many sequence labelling tasks such as Part of Speech (PoS) tagging, Text Chunking, or Named Entity Recognition. Linear-chain CRFs are easy to train by solving a convex optimization problem, can accomodate rich feature patterns, and enjoy polynomial exact inference procedures. They also deliver state-of-the-art performance for many tasks, sometimes surpassing seq2seq neural models (Schnober et al., 2016).

A major issue with CRFs is the complexity of training and inference procedures, which are quadratic in the number of possible output labels for first order models and grow exponentially when higher order dependencies are considered. This is problematic for tasks such as precise PoS tagging for Morphologically Rich Languages (MRLs), where the number of morphosyntactic labels is in the thousands (Hajič, 2000; Müller et al., 2013). Large label sets also naturally arise when *joint labelling tasks* (eg. simultaneous PoS tagging and text chunking) are considered, For such tasks, processing first-order models is demanding, and full size higher-order models are out of the question. Attempts to overcome this difficulty are based on a greedy approach which starts with first-order dependencies between labels and iteratively increases the scope of dependency patterns under the constraint that a high-order dependency is selected only if it extends an existing lower order feature (Müller et al., 2013). As a result, feature selection may only choose only few higher-order features, motivating the need for an effective variable-order CRF (voCRF) training procedure (Ye et al., 2009).[1] The latest implementation of this idea (Vieira et al., 2016) relies on (structured) sparsity promoting regularization (Martins et al., 2011) and on finite-state techniques, handling high-order features at a small extra cost (see § 2). In this approach, the sparse set of label dependency patterns is represented in a finite-state automaton, which arises as the result of the feature selection process.

In this paper, we somehow reverse the perspective and consider VoCRF training mostly as an automaton inference problem. This leads us to consider alternative techniques for learning the finite-state machine representing the dependency structure of sparse VoCRFs (see § 3). Two lines of enquiries are explored: (a) to take into account the internal structure of large tag sets in order to learn better and/or leaner feature sets; (b) to detect unconditional structural dependencies in label sequences in order to speed-up the discovery of useful features. These ideas are implemented in 6 feature selection strategies, allowing us to explore a large set of dependency structures. Relying on lazy finite-state operations, we train VoCRFs up to order 5, and achieve PoS tagging performance that

[1] This is reminiscent of *variable order HMMs*, introduced eg. in (Schütze and Singer, 1994; Ron et al., 1996).

Proceedings of the 2017 Conference on Empirical Methods in Natural Language Processing, pages 433–439
Copenhagen, Denmark, September 7–11, 2017.

surpass strong baselines for two MRLs (see § 4).

2 Variable order CRFs

In this section, we recall the basics of CRFs and VoCRFs and introduce some notations.

2.1 Basics

First-order CRFs use the following model:

$$p_\theta(\mathbf{y}|\mathbf{x}) = Z_\theta(\mathbf{x})^{-1} \exp(\theta^T F(\mathbf{x}, \mathbf{y})) \quad (1)$$

where $\mathbf{x} = (x_1, \ldots, x_T)$ and $\mathbf{y} = (y_1, \ldots, y_T)$ are the input (in $\mathcal{X}^T$) and output (in $\mathcal{Y}^T$) sequences and $Z_\theta(\mathbf{x})$ is a normalizer. Each component $F_j(\mathbf{x}, \mathbf{y})$ of the global feature vector decomposes as a sum of local features $\sum_{t=1}^{T} f_j(y_{t-1}, y_t, x_t)$ and is associated to parameter θ_j. Local features typically use binary tests and take the form:

$$f_{u,g}(y_{t-1}, y_t, x, t) = \mathbb{I}(y_t = u \wedge g(x,t))$$
$$f_{uv,g}(y_{t-1}, y_t, x, t) = \mathbb{I}(y_{t-1} y_t = uv \wedge g(x,t))$$

where $\mathbb{I}()$ is an indicator function and $g()$ tests a local property of $\mathbf{x}$ around x_t. In this setting, the number of parameters is $|\mathcal{Y}|^2 \times |\mathcal{X}|_{\text{train}}$, where $|A|$ is the cardinality of A and $|\mathcal{X}|_{\text{train}}$ is the number of values of $g(x,t)$ observed in the training set. Even in moderate size applications, the parameter set can be very large and contain dozen of millions of features, due to the introduction of sequential dependencies in the model.

Given N i.i.d. sequences $\{\mathbf{x}^{(i)}, \mathbf{y}^{(i)}\}_{i=1}^{N}$, estimation is based on the minimization of the negated conditional log-likelihood $l(\theta)$. Optimizing this objective requires to compute its gradient and to repeatedly evaluate the conditional expectation of the feature vector. This can be done using a forward-backward algorithm having a complexity that grows quadratically with $|\mathcal{Y}|$. $l(\theta)$ is usually complemented with a regularization term so as to avoid overfitting and stabilize the optimization. Common regularizers use the ℓ_1- or the ℓ_2-norm of the parameter vector, the former having the benefit to promote sparsity, thereby performing automatic feature selection (Tibshirani, 1996).

2.2 Variable order CRFs (VoCRFs)

When the label set is large, many pairs of labels never occur in the training data and the sparsity of label ngrams quickly increases with the order p of the model. In the *variable order CRF* model, it is assumed that only a small number of ngrams (out of $|\mathcal{Y}|^p$) are associated with a non-zero parameter value. Denoting $\mathcal{W}$ the set of such ngrams and $w \in \mathcal{W}$, a generic feature function is then $f_{w,g}(w, x, t) = \mathbb{I}(y_{t-s} \ldots y_t = w \wedge g(x,t))$.

Algorithm 1: Building $A[\mathcal{W}]$

```
$\mathcal{W}$ : list of patterns, $A[\mathcal{W}]$ initially empty
$\mathcal{U}$ = Pref($\mathcal{W}$)
foreach $w \in \mathcal{W}$ do
    TrieInsert($w, A[\mathcal{W}]$)
// Add missing transitions
foreach $u = vy \in \mathcal{U}$ do
    new FailureTrans($u$, LgSuff($v$,$\mathcal{U}$))
```

In (order-p) VoCRFs, the computational cost of training and inference is proportional to the size of a finite-state automaton $A[\mathcal{W}]$ encoding the patterns in $\mathcal{W}$,[2] which can be much less than $|\mathcal{Y}|^p$. Our procedure for building $A[\mathcal{W}]$ is sketched in Algorithm 1, where `TrieInsert` inserts a string in a trie, `Pref`$(\mathcal{W})$ computes the set of prefixes of the strings in $\mathcal{W}$,[3] `LgSuff`$(v,\mathcal{U})$ returns the longest suffix of v in $\mathcal{U}$, and `FailureTrans` is a special ε-transition used only when no labelled transition exists (Allauzen et al., 2003).[4] Each state (or pattern prefix) v in $A[\mathcal{W}]$ is associated with a set of feature functions $\{f_{u,g}, \forall u \in$ `Suff`$(v), g\}$.[5] The forward step of the gradient computation maintains one value $\alpha(v,t)$ per state and time step, which is recursively accumulated over all paths ending in v at time t.

The next question is to identify $\mathcal{W}$. The simplest method keeps all the ngrams viewed in training, additionally filtering rare patterns (Cuong et al., 2014). However, frequency based feature selection does not take interactions into account and is not the best solution. Ideally, one would like to train a complete order-p model with a sparsity promoting penalty, a technique that only works for small label sets.[6] The greedy algorithm of

[2] More precisely, Vieira et al. (2016) consider $\overline{\mathcal{W}}$, the closure of $\mathcal{W}$ under suffix and last character substitution, which factors as $\overline{\mathcal{W}} = \mathcal{H} \times \mathcal{Y}$. The complexity of training depends on the size of the finite-state automaton representing $\overline{\mathcal{W}}$.

[3] A trie has one state for each prefix.

[4] This was also suggested by Cotterell and Eisner (2015) as a way to build a more compact pattern automaton.

[5] Upon reaching a state v, we need to access the features that fire for that pattern, and also for all its suffixes. Each state thus stores a set of pattern; each pattern is associated with a set of tests on the observation (cf. 2.1).

[6] Recall that the size of parameter set is exponential wrt. the model order.

Schmidt and Murphy (2010); Vieira et al. (2016) is more scalable: it starts with all unigram patterns and iteratively grows $\mathcal{W}$ by extending the ngrams that have been selected in the simpler model. At each round of training, feature selection is performed using a ℓ_1 penalty and identifies the patterns that will be further augmented.

3 Learning patterns

We introduce now several alternatives for learning $\mathcal{W}$. Our motivation for doing so is twofold: (a) to take the internal structure of large label sets into account; (b) to identify more abstract patterns in label sequences, possibly containing gaps or iterations, which could yield smaller $A[\mathcal{W}]$. As discussed below, both motivations can be combined.

3.1 Greedy ℓ_1

The greedy strategy iteratively grows patterns up to order p. Considering all possible unigram and bigram patterns, we train a sparse model to select a first set of useful bigrams. In subsequent iterations, each pattern w selected at order k is extended in all possible ways to specify the pattern set at order $k + 1$, which will be filtered during the next training round. This approach is close, yet simpler, than the group lasso approach of Vieira et al. (2016) and experimentally yields slightly smaller pattern sets (see Table 2). This is because we do not enforce closure under last-character replacement: once pattern w is pruned, longer patterns ending in w are never considered.[7]

3.2 Component-wise training

Large tag sets often occur in joint tasks, where multiple levels of information are encoded in one compound tag. For instance, the fine grain labels in the Tiger corpus (Brants et al., 2002) combine PoS and morphological information in tags such as `NN.Dat.Sg.Fem` for a feminine singular dative noun. In the sequel, we refer to each piece of information as a tag *component*. We assume that all tags contain the same components, using a "non-applicable" value whenever needed. Using features that test arbitrary combinations of tag components would make feature selection much more difficult, as the number of possible patterns grows combinatorially with the number of components. We keep things simple by allowing features to only evaluate one single component at a time: this allows us to identify dependencies of different orders for each component.

Assuming that each tag y contains K components $y = [z_1, z_2 \dots, z_K]$, with $z_k \in \mathcal{Y}_k$, $\mathcal{W}$ is then computed as in § 3.1, except that we now consider one distinct set of patterns $\mathcal{W}_k$ for each component k. At each training round, each set $\mathcal{W}_k$ is extended and pruned independently from the others. Note that all these automata are trained simultaneously using a common set of features. This process results in K automata, which are intersected on the fly[8] using "lazy" composition. In our experiments, we also consider the case where we additionally combine the automaton representing complete tag sequences: this has the beneficial effect to restrict the combinations of subtags to values that actually exist in the data.

3.3 Pruned language models

Another approach for computing $\mathcal{W}$ assumes that useful dependencies between tags can be identified using an auxiliary language model (LM) trained *without paying any attention to observation sequences*. A pattern w will then be deemed useful for the labelling task only if w is a useful history in a LM of tag sequences. This strategy was implemented by first training a compact p-gram LM with entropy pruning[9] (Stolcke, 1998) and including all the surviving histories in $\mathcal{W}$. In a second step, we train the complete CRF as usual, with all observation features and ℓ_1 penalty to further prune the parameter set.

Table 1: Corpus description

3.4 Maximum entropy language models

Another technique, which combines the two previous ideas, relies on Maximum Entropy LMs

[7] cf. the discussion in (Vieira et al., 2016, § 4).

[8] Formally, each $A[\mathcal{W}_k]$ has transitions labelled with elements of $\mathcal{Y}_k$; lazy intersection operates on "generalized" transitions, where each label z is replaced with $[?, \dots, z, \dots, ?]$, where ? matches any symbol. $A[\mathcal{W}]$ is the intersection $\bigcap_k A[\mathcal{W}_k]$ and is labelled with completely specified tags.

[9] Starting with a full back-off n-gram language model, this approach discards n-grams if their removal causes a sufficiently small drop in cross-entropy. We used the implementation of Stolcke (2002).

(MELMs) (Rosenfeld, 1996). MELMs decompose the probabililty of a sequence $y_1 \dots y_T$ using the chain rule, where each term $p_\lambda(y_t|y_{<t})$ is a locally normalized exponential model including all possible ngram features up to order p:

$$p(y_t|y_{<t}; \lambda) = Z(\lambda)^{-1} \exp \lambda^T G(y_1 \dots y_t)$$

In contrast to globally normalized models, the complexity of training remains linear wrt. $|\mathcal{Y}|$, irrespective of p. It it also straightforward both to (a) use a ℓ_1 penalty to perform feature selection; (b) include features that only test specific components of a complex tag. For an order p model, our feature functions evaluate all n-grams (for $n \leq p$) of complete tags or of one specific component:

$$\begin{aligned} G_w(y_1, \dots, y_t) =& \mathbb{I}(y_{t-n+1} \dots y_t = w) \\ G_u(y_1, \dots, y_t) =& \mathbb{I}(z_{k,t-n+1} \dots z_{k,t} = u) \end{aligned}$$

Once a first round of feature selection has been performed,[10] we compute $A[\mathcal{W}]$ as explained above. The last step of training reintroduces the observations and estimates the CRF paramaters. A variant of this approach adds extra *gappy* features to the n-gram features. Gappy features at order p test whether some label u occurs in the remote past anywhere between position $t - p + 1$[11] and $t - n$. They take the following form:

$$\begin{aligned} G_{w,u}(y_1, \dots, y_t) =& \mathbb{I}(y_{t-n+1} \dots y_t = w \wedge \\ & u \in \{y_{t-p+1} \dots y_{t-n}\}), \end{aligned}$$

and likewise for features testing components.

4 Experiments

4.1 Training protocol

The following protocol is used throughout: (a) identify $\mathcal{W}$ (§3) - note that this may imply to tune a regularization parameter; (b) train a full model (including tests on the observations for each pattern in $\mathcal{W}$) using ℓ_1 regularization and a very small ℓ_2 term to stabilize convergence. The best regularization in (a) and (b) is selected on development data and targets either perplexity (for LMs) or label accuracy (for CRFs).

4.2 Datasets and Features

Experiments are run on two MRLs: for Czech, we use the CoNLL 2009 data set (Hajič et al., 2009) and for German, the Tiger Treebank with the split of Fraser et al. (2013)). Both datasets include rich morphological attributes (cf. Table 1).

All the patterns in $\mathcal{W}$ are combined with *lexical* features testing the current word x_t, its prefixes and suffixes of length 1 to 4, its capitalization and the presence of digit or punctuation symbols. Additional contextual features also test words in a local window around position t. These tests greatly increase the feature count and are not provided for all label patterns: for unigram patterns, we test the presence of all unigrams and bigrams of words in a window of 5 words; for bigrams patterns we only test for all unigrams in a window of 3 words. Contextual features are not used for larger patterns.

4.3 Results

We consider several baselines: Maxent and MEMM models, neither of which considers label dependencies in training, a linear chain CRF[12] and our own implementation of the group lasso of Vieira et al. (2016). For the latter, we contrast two setups: one where each pattern in $\mathcal{W}$ gives rise to one single feature, and one where it is conjoined with tests on the observation.[13] All scores in Table 2 are label accuracies on unseen test data.

As expected, Maxent and MEMM are outperformed by almost all variants of CRFs, and their scores are only reported for completeness. `Group lasso` results demonstrate the effectiveness of using contextual information with high order features: the gain is ≈ 0.7 points for both languages and all values of p. `Greedy` ℓ_1 achieves accuracy results similar to `group lasso`, suggesting that ℓ_1 penalty alone is effective to select high-order features. It also yields slighly smaller models and very comparable training time across the board: indeed, greedy parameter selection strategies imply multiple rounds of training which are overall quite costly, due to the size of the full label set. Testing individual subtags (§ 3.2) results in a slight improvement (≈+0.3) in accuracy over `Greedy` ℓ_1. When using an additional automata for the full tag, we get a larger gain of ≈ 0.6 points for Czech, slightly less for German: including a model for complete tags also prevents to gener-

[10] As the LM building step only look at labels, we tune the regularization to optimize the perplexity of the LM on a development set.

[11] We use $p = 6$ in our experiments.

Table 2: Experimental results. Each cell reports accuracy, number of states in $A[\mathcal{W}]$ and total training time. Group lasso is our reimplementation of Vieira et al. (2016) (+Ctx = +context features) ; Greedy ℓ_1 is described in section 3.1, Component-wise is the decomposition approach of § 3.2, PrunedLM and MELM (+Gaps) were described in § 3.3 and § 3.4.

ate invalid combinations of subtags. These models represent different tradeoffs between accuracy and training time: the 4-gram `Component-wise` experiment only took 14 hrs to complete on German data and outperforms the corresponding `Greedy` ℓ_1 setup while containing approximately 100 times less features. `Component-wise+Full` is more comparable in size and training time to `Greedy` ℓ_1, but yields a larger improvement in performance. The last sets of experiments with LMs yields even better operating points, as the first stage of pattern selection is performed with a cheap model. They are our best trade-off to date, yielding the best performance for all values of p.

5 Conclusion

In this work, we have explored ways to take advantage of the flexibility offered by implementations of VoCRFs based on finite-state techniques. We have proposed strategies to include tests on subparts of complex tags, as well as to select useful label patterns with auxiliary unconditional LMs. Experiments with two MRLs with large tagsets yielded consistent improvements (≈ +0.8 points) over strong baselines. They offer new perspectives to perform feature selection in high order CRFs. In our future work, we intend to also explore how to complement ℓ_1 penalties with terms penalizing more explicitely the processing time; we also wish to study how these ideas can be used in combination with neural models.

Abstract

We make distributed stochastic gradient descent faster by exchanging sparse updates instead of dense updates. Gradient updates are positively skewed as most updates are near zero, so we map the 99% smallest updates (by absolute value) to zero then exchange sparse matrices. This method can be combined with quantization to further improve the compression. We explore different configurations and apply them to neural machine translation and MNIST image classification tasks. Most configurations work on MNIST, whereas different configurations reduce convergence rate on the more complex translation task. Our experiments show that we can achieve up to 49% speed up on MNIST and 22% on NMT without damaging the final accuracy or BLEU.

1 Introduction

Distributed computing is essential to train large neural networks on large data sets (Raina et al., 2009). We focus on data parallelism: nodes jointly optimize the same model on different parts of the training data, exchanging gradients and parameters over the network. This network communication is costly, so prior work developed two ways to approximately compress network traffic: 1-bit quantization (Seide et al., 2014) and sending sparse matrices by dropping small updates (Strom, 2015; Dryden et al., 2016). These methods were developed and tested on speech recognition and toy MNIST systems. In porting these approximations to neural machine translation (NMT) (Ñeco and Forcada, 1996; Bahdanau et al., 2014), we find that translation is less tolerant to quantization.

Throughout this paper, we compare neural machine translation behavior with a toy MNIST system, chosen because prior work used a similar system (Dryden et al., 2016). NMT parameters are dominated by three large embedding matrices: source language input, target language input, and target language output. These matrices deal with vocabulary words, only a small fraction of which are seen in a mini-batch, so we expect skewed gradients. In contrast, MNIST systems exercise every parameter in every mini-batch. Additionally, NMT systems consist of multiple parameters with different scales and sizes, compared to MNIST's 3-layers network with uniform size. More formally, gradient updates have positive skewness coefficient (Zwillinger and Kokoska, 1999): most are close to zero but a few are large.

2 Related Work

An orthogonal line of work optimizes the SGD algorithm and communication pattern. Zinkevich et al. (2010) proposed an asynchronous architecture where each node can push and pull the model independently to avoid waiting for the slower node. Chilimbi et al. (2014) and Recht et al. (2011) suggest updating the model without a lock, allowing race conditions. Additionally, Dean et al. (2012) run multiple minibatches before exchanging updates, reducing the communication cost. Our work is a more continuous version, in which the most important updates are sent between minibatches. Zhang et al. (2015) downweight gradients based on stale parameters.

Approximate gradient compression is not a new idea. 1-Bit SGD (Seide et al., 2014), and later Quantization SGD (Alistarh et al., 2016), work by converting the gradient update into a 1-bit matrix, thus reducing data communication significantly. Strom (2015) proposed threshold quantiza-

Proceedings of the 2017 Conference on Empirical Methods in Natural Language Processing, pages 440–445
Copenhagen, Denmark, September 7–11, 2017. ©2017 Association for Computational Linguistics

tion, which only sends gradient updates that larger than a predefined constant threshold. However, the optimal threshold is not easy to choose and, moreover, it can change over time during optimization. Dryden et al. (2016) set the threshold so as to keep a constant number of gradients each iteration.

3 Distributed SGD

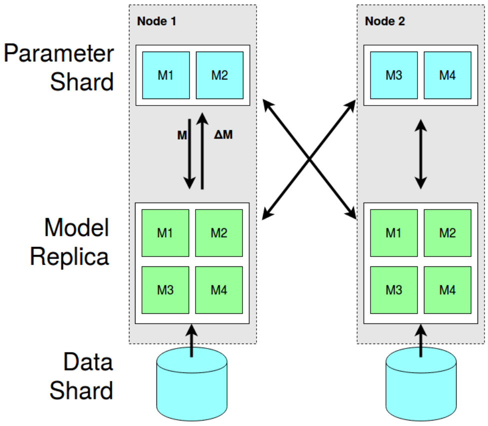

Figure 1: Distributed SGD architecture with parameter sharding.

We used distributed SGD with parameter sharding (Dean et al., 2012), shown in Figure 1. Each of the N workers is both a client and a server. Servers are responsible for $1/N$th of the parameters.

Clients have a copy of all parameters, which they use to compute gradients. These gradients are split into N pieces and pushed to the appropriate servers. Similarly, each client pulls parameters from all servers. Each node converses with all N nodes regarding $1/N$th of the parameters, so bandwidth per node is constant.

4 Sparse Gradient Exchange

We sparsify gradient updates by removing the R% smallest gradients by absolute value, dubbing this Gradient Dropping. This approach is slightly different from Dryden et al. (2016) as we used a single threshold based on absolute value, instead of dropping the positive and negative gradients separately. This is simpler to execute and works just as well.

Small gradients can accumulate over time and we find that zeroing them damages convergence. Following Seide et al. (2014), we remember residuals (in our case dropped values) locally and add them to the next gradient, before dropping again.

Algorithm 1 Gradient dropping algorithm given gradient ∇ and dropping rate R.

```
function GRADDROP($\nabla$, $R$)
    $\nabla + = residuals$
    Select $threshold$: R% of $|\nabla|$ is smaller
    $dropped \leftarrow 0$
    $dropped[i] \leftarrow \nabla[i] \forall i : |\nabla[i]| > threshold$
    $residuals \leftarrow \nabla - dropped$
    return $sparse(dropped)$
end function
```

Gradient Dropping is shown in Algorithm 1. This function is applied to all data transmissions, including parameter pulls encoded as deltas from the last version pulled by the client. To compute these deltas, we store the last pulled copy server-side. Synchronous SGD has one copy. Asynchronous SGD has a copy per client, but the server is responsible for $1/N$th of the parameters for N clients so memory is constant.

Selection to obtain the threshold is expensive (Alabi et al., 2012). However, this can be approximated. We sample 0.1% of the gradient and obtain the threshold by running selection on the samples.

Parameters and their gradients may not be on comparable scales across different parts of the neural network. We can select a threshold locally to each matrix of parameters or globally for all parameters. In the experiments, we find that layer normalization (Lei Ba et al., 2016) makes a global threshold work, so by default we use layer normalization with one global threshold. Without layer normalization, a global threshold degrades convergence for NMT. Prior work used global thresholds and sometimes column-wise quantization.

5 Experiment

We experiment with an image classification task based on MNIST dataset (LeCun et al., 1998) and Romanian→English neural machine translation system.

For our image classification experiment, we build a fully connected neural network with three 4069-neuron hidden layers. We use AdaGrad with an initial learning rate of 0.005. The mini-batch size of 40 is used. This setup is identical to Dryden et al. (2016).

Our NMT experiment is based on Sennrich et al. (2016), which won first place in the 2016 Workshop on Machine Translation. It is based on an attentional encoder-decoder LSTM with

Drop Ratio	words/sec (NMT)	images/sec (MNIST)
0%	13100	2489
90%	14443	3174
99%	14740	3726
99.9%	14786	3921

Table 1: Training speed with various drop ratios.

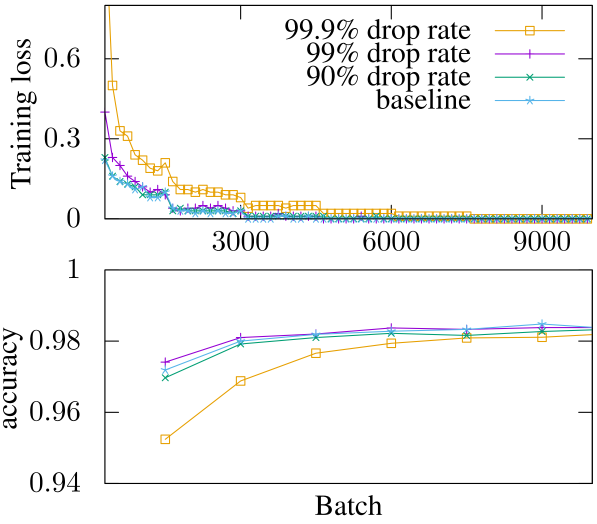

Figure 2: MNIST: Training loss and accuracy for different dropping ratios.

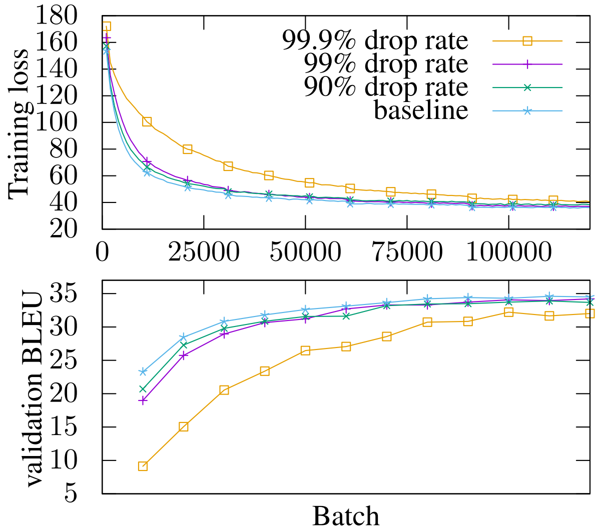

Figure 3: NMT: Training loss and validation BLEU for different dropping ratios.

119M parameters. The default batch size is 80. We save and validate every 10000 steps. We pick 4 saved models with the highest validation BLEU and average them into the final model. AmuNMT (Junczys-Dowmunt et al., 2016) is used for decoding with a beam size of 12. Our test system has PCI Express 3.0 x16 for each of 4 NVIDIA Pascal Titan Xs. All experiments used asynchronous SGD, though our method applies to synchronous SGD as well.

5.1 Drop Ratio

To find an appropriate dropping ratio $R\%$, we tried 90%, 99%, and 99.9% then measured performance in terms of loss and classification accuracy or translation quality approximated by BLEU (Papineni et al., 2002) for image classification and NMT task respectively.

Figure 3 shows that the model still learns after dropping 99.9% of the gradients, albeit with a worse BLEU score. However, dropping 99% of the gradient has little impact on convergence or BLEU, despite exchanging 50x less data with offset-value encoding. The x-axis in both plots is batches, showing that we are not relying on speed improvement to compensate for convergence.

Dryden et al. (2016) used a fixed dropping ratio of 98.4% without testing other options. Switching to 99% corresponds to more than a 1.5x reduction in network bandwidth.

For MNIST, gradient dropping oddly improves accuracy in early batches. The same is not seen for NMT, so we caution against interpreting slight gains on MNIST as regularization.

5.2 Local vs Global Threshold

Parameters may not be on a comparable scale so, as discussed in Section 4, we experiment with local thresholds for each matrix or a global threshold for all gradients. We also investigate the effect of layer normalization. We use a drop ratio of 99% as suggested previously. Based on the results and due to the complicated interaction with sharding, we did not implement locally thresholded pulling, so only locally thresholded pushing is shown.

The results show that layer normalization has no visible impact on MNIST. On the other side, our NMT system performed poorly as, without layer normalization, parameters are on various scales and global thresholding underperforms. Furthermore, our NMT system has more parameter categories compared to MNIST's 3-layer network.

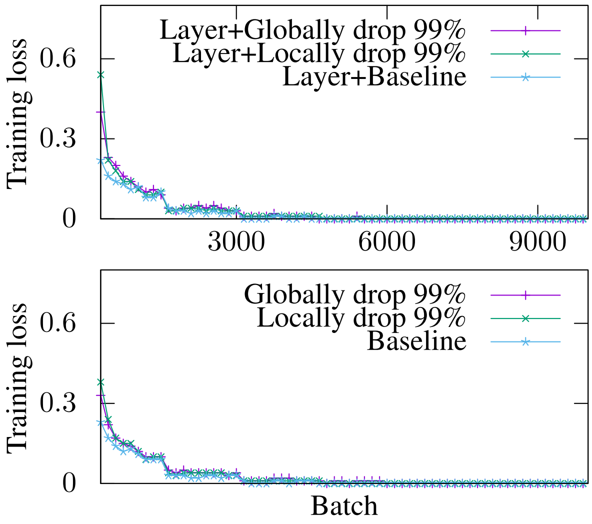

Figure 4: MNIST: Comparison of local and global thresholds with and without layer normalization.

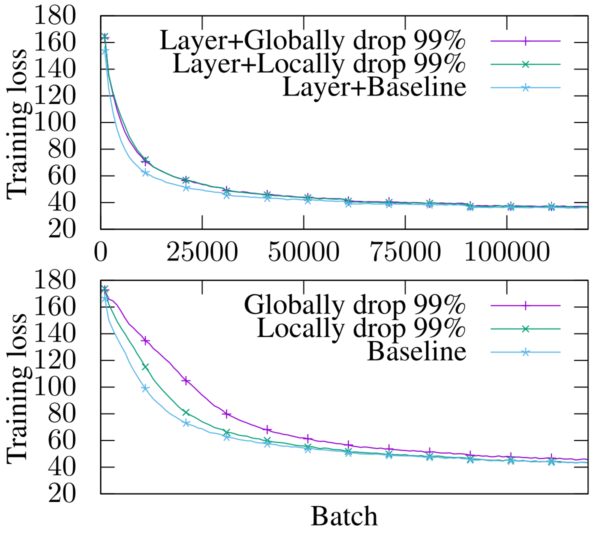

Figure 5: NMT: Comparison of local and global thresholds with and without layer normalization.

5.3 Convergence Rate

While dropping gradients greatly reduces the communication cost, it is shown in Table 1 that overall speed improvement is not significant for our NMT experiment. For our NMT experiment with 4 Titan Xs, communication time is only around 13% of the total training time. Dropping 99% of the gradient leads to 11% speed improvement. Additionally, we added an extra experiment of NMT with batch-size of 32 to give more communication cost ratio. In this scenario, communication is 17% of the total training time and we see a 22% average speed improvement. For MNIST, communication is 41% of the total training time and we see a 49% average speed improvement. Computation got faster by reducing multitasking.

We investigate the convergence rate: the combination of loss and speed. For MNIST, we train the model for 20 epochs as mentioned in Dryden et al. (2016). For NMT, we tested this with batch sizes of 80 and 32 and trained for 13.5 hours.

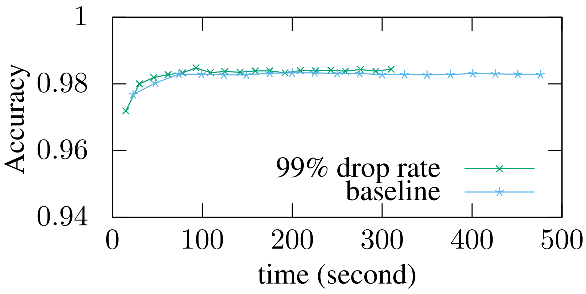

Figure 6: MNIST classification accuracy over time.

As shown in Figure 6, our baseline MNIST experiment reached 99.28% final accuracy, and reached 99.42% final accuracy with a 99% drop rate. It also shown that it has better convergence rate in general with gradient dropping.

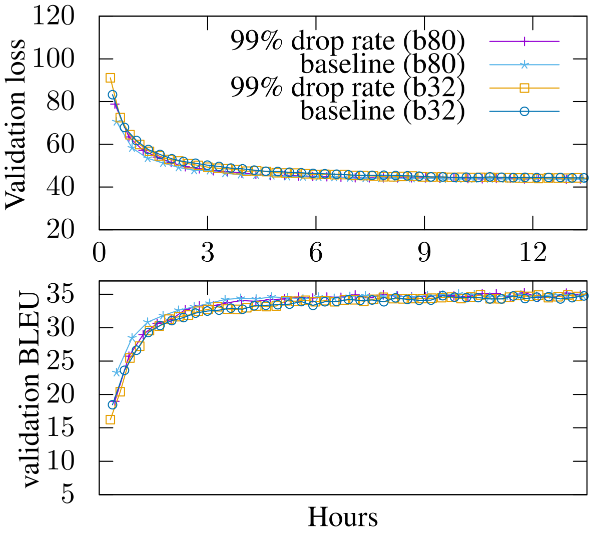

Figure 7: NMT validation BLEU and loss over time.

Our NMT experiment result is shown in Table 2. Final BLEU scores are essentially unchanged.

Experiment	Final %BLEU	Time to reach 33% BLEU
batch-size 80		
+ baseline	34.51	2.6 hours
+ 99% grad-drop	34.40	2.7 hours
batch-size 32		
+ baseline	34.16	4.2 hours
+ 99% grad-drop	34.08	3.2 hours

Table 2: Summary of BLEU score obtained.

Our algorithm converges 23% faster than the baseline when the batch size is 32, and nearly the same with a batch size of 80. This in a setting with fast communication: 15.75 GB/s theoretical over PCI express 3.0 x16.

5.4 1-Bit Quantization

We can obtain further compression by applying 1-bit quantization after gradient dropping. Strom (2015) quantized simply by mapping all surviving values to the dropping threshold, effectively the minimum surviving absolute value. Dryden et al. (2016) took the averages of values being quantized, as is more standard. They also quantized at the column level, rather than choosing centers globally. We tested 1-bit quantization with 3 different configurations: threshold, column-wise average, and global average. The quantization is applied after gradient dropping with a 99% drop rate, layer normalization, and a global threshold.

Figure 8 shows that 1-bit quantization slows down the convergence rate for NMT. This differs from prior work (Seide et al., 2014; Dryden et al., 2016) which reported no impact from 1-bit quantization. Yet, we agree with their experiments: all tested types of quantization work on MNIST. This emphasizes the need for task variety in experiments.

NMT has more skew in its top 1% gradients, so it makes sense that 1-bit quantization causes more loss. 2-bit quantization is sufficient.

6 Conclusion and Future Work

Gradient updates are positively skewed: most are close to zero. This can be exploited by keeping 99% of gradient updates locally, reducing communication size to 50x smaller with a coordinate-value encoding.

Prior work suggested that 1-bit quantization can be applied to further compress the communication.

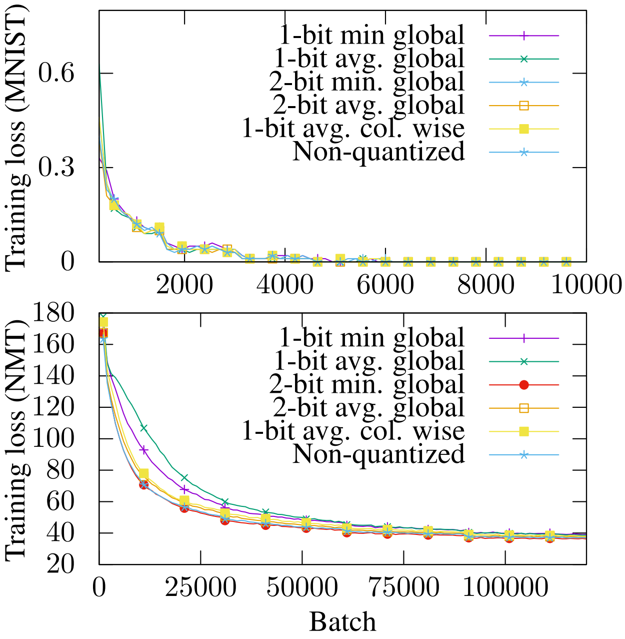

Figure 8: Training loss for different quantization methods.

However, we found out that this is not true for NMT. We attribute this to skew in the embedding layers. However, 2-bit quantization is likely to be sufficient, separating large movers from small changes. Additionally, our NMT system consists of many parameters with different scales, thus layer normalization or using local threshold per-parameter is necessary. On the hand side, MNIST seems to work with any configurations we tried.

Our experiment with 4 Titan Xs shows that on average only 17% of the time is spent communicating (with batch size 32) and we achieve 22% speed up. Our future work is to test this approach on systems with expensive communication cost, such as multi-node environments.

Abstract

Online topic modeling, i.e., topic modeling with stochastic variational inference, is a powerful and efficient technique for analyzing large datasets, and ADAGRAD is a widely-used technique for tuning learning rates during online gradient optimization. However, these two techniques do not work well together. We show that this is because ADAGRAD uses accumulation of previous gradients as the learning rates' denominators. For online topic modeling, the magnitude of gradients is very large. It causes learning rates to shrink very quickly, so the parameters cannot fully converge until the training ends.

Probabilistic topic models (Blei, 2012) are popular algorithms for uncovering hidden thematic structure in text. They have been widely used to help people understand and navigate document collections (Blei et al., 2003), multilingual collections (Hu et al., 2014), images (Chong et al., 2009), networks (Chang and Blei, 2009; Yang et al., 2016), etc. Probabilistic topic modeling usually requires computing a posterior distribution over thousands or millions of latent variables, which is often intractable. Variational inference (Blei et al., 2016, VI) approximates posterior distributions. Stochastic variational inference (Hoffman et al., 2013, SVI) is its natural online extension and enables the analysis of large datasets.

Online topic models (Hoffman et al., 2010; Bryant and Sudderth, 2012; Paisley et al., 2015) optimize the global parameters of interest using stochastic gradient ascent. At each iteration, they sample data points to estimate the gradient. In practice, the sample has only a small percentage of the vocabulary. The resulting sparse gradients hurt performance. ADAGRAD (Duchi et al., 2011) is designed for high dimensional online optimization problems and adjusts learning rates for each dimension, favoring rare features. This makes ADAGRAD well-suited for tasks with sparse gradients such as distributed deep networks (Dean et al., 2012), forward-backward splitting (Duchi and Singer, 2009), and regularized dual averaging methods (Xiao, 2010).

Thus, it may seem reasonable to apply ADAGRAD to optimize online topic models. However, ADAGRAD is not suitable for online topic models (Section 1). This is because to get a topic model, the training algorithm must break the symmetry between parameters of words that are highly related to the topic and words that are not related to the topic. Before the algorithm converges, the magnitude of gradients of the parameters are very large. Since ADAGRAD uses the accumulation of previous gradients as learning rates' denominators, the learning rates shrink very quickly. Thus, the algorithm cannot break the symmetry quickly. We provide solutions for this problem. Two alternative learning rate methods, i.e., ADADELTA (Zeiler, 2012) and ADAM (Kingma and Ba, 2014), can address this incompatibility with online topic models. When the dataset is small enough, e.g., a corpus with only hundreds of documents, ADAGRAD can still work.

1 Buridan's Optimizer

Latent Dirichlet allocation (Blei et al., 2003, LDA) is perhaps the most well known topic model. In this section, we analyze problems with ADAGRAD for online LDA (Hoffman et al., 2010), and provide some solutions. Our analysis is easy to generalize to other online topic models, e.g., online Hierarchical Dirichlet Process (Wang et al., 2011, HDP).

Copenhagen, Denmark, September 7–11, 2017. ©2017 Association for Computational Linguistics

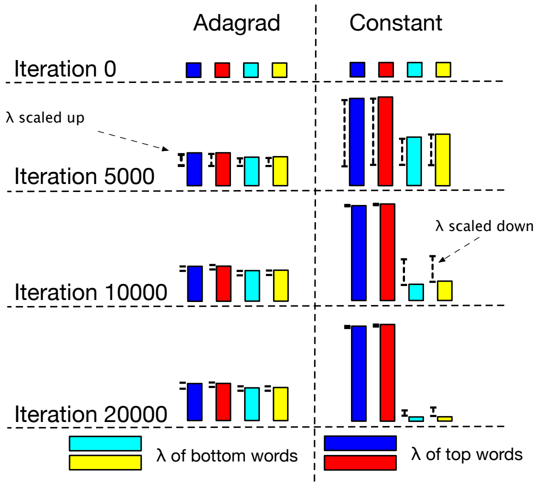

Figure 1: Illustration of ADAGRAD's problem. Initially, the topic does not favor particular words over others, so the training algorithm incorrectly increases the parameters of bottom words. Then, ADAGRAD learning rates decrease too quickly, leaving the tie between top and bottom unbroken. Thus, the algorithm fails to form appropriate topics. A constant rate easily breaks the tie. When the tie is broken, the algorithm decreases the parameters of bottom words and increases the parameters of top words until convergence.

1.1 Online LDA

To train LDA, we want to compute the posterior

$$p(\beta,\theta,z\,|\,w,\alpha,\eta) \propto \prod_{k=1}^{K} p(\beta_k\,|\,\eta)\cdot \prod_{d=1}^{D} p(\theta_d\,|\,\alpha) \prod_{n=1}^{N_d} p(z_{dn}\,|\,\theta_d)p(w_{dn}\,|\,\beta_{z_{dn}}),$$

where β_k is the topic-word distribution for the k^{th} of K topics, θ_d is the document-topic distribution for the d^{th} of D document, z_{dn} is the topic assignment for the n^{th} of N_d words in in the d^{th} document, w_{dn} is the word type of the n^{th} word in the d^{th} document, with α and η the Dirichlet priors over the document-topic and topic-word distributions.

However, this is intractable. Stochastic variational inference (SVI) is a popular approach for approximation. It first posits a mean field variational distribution

$$q(\beta,\theta,z\,|\,\lambda,\gamma,\phi) = \prod_{k=1}^{K} q(\beta_k\,|\,\lambda_k)\cdot \prod_{d=1}^{D} q(\theta_d\,|\,\gamma_d) \prod_{n=1}^{N_d} q(z_{dn}\,|\,\phi_{dn}),$$

where γ (Dirichlet) and ϕ (multinomial) are local parameters and λ (Dirichlet) is a global parameter. SVI then optimizes the variational parameters to minimize the KL divergence between the variational distribution and the true posterior.

At iteration t, SVI samples a document d from the corpus and updates the local parameters:

$$\phi^d_{vk} \propto \exp\left\{\Psi\left(\gamma_{dk}\right) + \Psi\left(\lambda^{(t)}_{kv}\right) - \Psi\left(\sum_i \lambda^{(t)}_{ki}\right)\right\}, \tag{1}$$

$$\gamma^{(t)}_k = \alpha + \sum_v n_v \phi^d_{vk}, \tag{2}$$

where n_v is the number of words v in d, and $\Psi\left(.\right)$ is the digamma function. After finding ϕ^d and γ^d, SVI optimizes the global parameters using stochastic gradient ascent,

$$\begin{aligned}\lambda^{(t+1)}_{kv} &= (1-\rho^{(t)}_{kv})\lambda^{(t)}_{kv} + \rho^{(t)}_{kv}(\eta + D\phi^d_{vk}n_{dv})\\ &= (1-\rho^{(t)}_{kv})\lambda^{(t)}_{kv} + \rho^{(t)}_{kv}\hat{\lambda}^{(t)}_{kv}\\ &= \lambda^{(t)}_{kv} + \rho^{(t)}_{kv}g^{(t)}_{kv},\end{aligned} \tag{3}$$

where $\rho^{(t)}$ is the learning rate, $\hat{\lambda}^{(t)}_{kv} = \eta + D\phi^d_{vk}n_{dv}$ is the intermediate parameter and $g^{(t)}_{kv} = -\lambda^{(t)}_{kv} + \hat{\lambda}^{(t)}_{kv}$ is the gradient.

1.2 ADAGRAD for Online LDA

In general, $\rho^{(t)}_{kv} = \kappa^{(t)}$, for all $v \in 1,..,V$ and $k \in 1,...,K$, where $\kappa^{(t)}$ can be a decreasing rate (Hoffman et al., 2013), a small constant (Collobert et al., 2011) or an adaptive rate (Ranganath et al., 2013). These three methods are all global learning rate methods, which cannot adaptively adjust learning rate for each dimension of the parameter, or address the problems caused by sparse gradients.

ADAGRAD is a popular learning rate method designed for online optimization problems with high dimension and sparse gradients. Thus, it seems reasonable to apply ADAGRAD to update learning rates for online topic models. When using ADAGRAD (Duchi et al., 2011) with online LDA, the update rule for the each learning rate is

$$\rho^{(t)}_{kv} = \frac{\rho_0}{\sqrt{\epsilon + \sum_{i=0}^{t}\left(g^{(i)}_{kv}\right)^2}}, \tag{4}$$

where ρ_0 is a constant, and a very small ϵ guarantees that the learning rates are non-zero.

1.3 ADAGRAD's Indecision

A philosophical thought experiment provides us with the story of Buridan's ass (Bayle, 1826): situated between two piles of equally tasty hay, the poor animal starved to death. ADAGRAD faces a similar problem in breaking the symmetries of common variational inference initializations. For convenience, we unfold an example with a single document at each iteration. Our analysis generalizes to mini-batches.

Initially, the topics $\beta_{1:K}$ do not favor particular words over others as inference cannot know *a priori* which words will have high probability in a particular topic. The algorithm must break ties between parameters of the top and bottom words in a topic. Unfortunately, the momentum of ADAGRAD fails for topic models. We now explain why this is.

ADAGRAD looks to the gradient for clues about what features will be important. This is because before the equilibrium is broken, the values of different λ_{kv} are close, so Equation 1 will be approximately seen as $\phi_{vk}^{d} \propto \exp\{\Psi(\gamma_{dk})\}$, which implicates that λ has very small influence on the optimization of ϕ. If some topics are prevalent in the sampled document d, large probability will be assigned to the corresponding $\phi_{\cdot k}$, meaning that all words in document d are treated as top words. The initial clues are at best random and at words counter productive.

However, ADAGRAD uses these cues to prefer some dimensions over others. Let λ^* be the optimum; the topic ADAGRAD should find at convergence: $\lambda_{kv}^* \approx \mathbb{E}\left[\hat{\lambda}_{kv}^{(t)}\right]$. By definition, once the algorithm converges, λ_{kv}^* for top words will have very large values while λ_{kv}^* for bottom words will be small. After using noisy momentum terms, it must overcome initial faulty signals.

We now show the lower and upper bounds of $\mathbb{E}\left[\hat{\lambda}_{kv}^{(t)}\right]$ to show how big of an uphill battle ADAGRAD faces. Expanding the update rule,

$$\begin{aligned}\mathbb{E}\left[\hat{\lambda}_{kv}^{(t)}\right] &= \mathbb{E}\left[\eta + D\phi_{vk}^{d} n_{dv}\right] \\ &= \eta + D\bar{n}_v \mathbb{E}\left[\phi_{vk}\right],\end{aligned}$$

where $\bar{n}_v = \sum_{i=1}^{D} n_{iv}/D$, and ϕ_{vk} is the probability that word v is assigned to topic k. For a bottom word, $\phi_{vk} \to 0$. For a top word, $\phi_{vk} \geq 1/K$. After convergence, for a bottom word $\mathbb{E}\left[\phi_{vk}\right] \approx \eta$. For a top word, $1/K \leq \mathbb{E}\left[\phi_{vk}\right] \leq 1$. Thus, the lower and upper bounds of $\mathbb{E}\left[\hat{\lambda}_{kv}^{(t)}\right]$ are

$$\eta + (1/K)D\bar{n}_v \leq \mathbb{E}\left[\hat{\lambda}_{kv}^{(t)}\right] \leq \eta + D\bar{n}_v.$$

For a large datasets, $D\bar{n}_v$ should be large. Thus for top words, λ_{kv}^* will converge to a large value: quite a large hill to climb.

How quickly the algorithm climbs the hill is inversely proportional to the gradient size. We next show that the magnitude of gradients of top words are very large before the algorithm converges. Let g^* be the gradient after convergence. We show the bounds of $|g_{kv}|$, where $|.|$ is the absolute value, in the following:

$$\begin{aligned}|\,g_{kv}^*\,| &= |-\lambda_{kv}^* + \eta + D\phi_{vk}^{d} n_{dv}\,| \\ &\approx |-\eta - D\bar{n}_v E[\phi_{vk}] + \eta + D\phi_{vk}^{d} n_{dv}\,| \\ &\approx \mathbb{E}\left[\phi_{vk}\right] * D\,|\,n_{dv} - \bar{n}_v\,|\,.\end{aligned}$$

Thus,

$$(D/K)\,|\,n_{dv} - \bar{n}_v\,| \leq |\,g_{kv}^*\,| \leq D\,|\,n_{dv} - \bar{n}_v\,|\,.$$

Only when $n_{dv} = \bar{n}_v$, does $|\,g_{kv}^{(t)}\,| = 0$. Otherwise, due to the large D, $|\,g_{kv}^*\,|$ will be large. However, in practice, n_{dv} varies largely from document to document, which leads to large values of $|\,g_{kv}^*\,|$. Based on the gradient's property, when λ_{kv} is far away from the optimum, $|\,g_{kv}^{(t)}\,| \geq |\,g_{kv}^*\,|$. Thus, the values of $|\,g_{kv}^{(t)}\,|$ for the top words are very large before convergence.

ADAGRAD uses the accumulations of previous gradients as learning rates' denominators. Because of these large gradients in the first several iterations, learning rates soon decrease to small values; even if a topic has gathered a few words, ADAGRAD lacks the momentum to move other words into the topic. These small learning rates slows the updates of λ.

In sum, the initial gradient signals confuse the algorithm, the gradients are large enough to impede progress later, and large datasets imply a very large hill the algorithm must climb. Since the update progresses slowly, online LDA needs more iterations to break the equilibrium. Because the gradients of all words are still very large, the learning rates decrease quickly, which makes the update progress slower. When the update progresses more slowly, online LDA needs more iterations to break the tie. This cycle repeats, until some learning rates decrease to zero and learning effectively stops. Thus, the algorithm will never break the tie or infer good topics. Figure 1 illustrates the problem of online LDA with ADAGRAD.

1.4 Alternative Solutions

ADADELTA (Zeiler, 2012) and ADAM (Kingma and Ba, 2014) are extensions to ADAGRAD. ADADELTA does not have guaranteed convergence on convex optimization problems. Even though ADAM has a theoretical bound on its convergence rate, it is controlled by and sensitive to several learning rate parameters. For good performance with ADAM, manual adjustment is necessary. In addition, since ADADELTA computes the moving average of updates, and ADAM needs to compute the bias-corrected gradient estimate, they require more intricate implementations. Consequently, these two methods are not as popular as ADAGRAD for beginners. However, for SVI latent variable models, they can address the problems with ADAGRAD.

ADADELTA updates the learning rates with the following rule:

$$\rho_{kv}^{(t)} = \frac{\sqrt{\mathbb{E}\left[(\lambda_{kv}^{(t)} - \lambda_{kv}^{(t-1)})\right] + \varepsilon}}{\sqrt{\mathbb{E}\left[g_{kv}^{(t)}\right] + \varepsilon}}, \qquad (5)$$

where $\mathbb{E}\left[x^{(t)}\right] = \rho_0 \mathbb{E}\left[x^{(t-1)}\right] + (1-\rho_0)(x^{(t)})^2$, ρ_0 is a decay constant, and ε is for numerical stability.

ADAM's update rule is determined based on estimates of first and second moments of the gradients:

$$\begin{aligned} m_{kv}^{(t)} &= b_m m_{kv}^{(t-1)} + (1-b_m) g_{kv}^{(t)}, \\ u_{kv}^{(t)} &= b_u u_{kv}^{(t-1)} + (1-b_u)(g_{kv}^{(t)})^2, \\ \hat{m}_{kv}^{(t)} &= \frac{m_{kv}^{(t)}}{1-b_m^t}, \hat{u}_{kv}^{(t)} = \frac{u_{kv}^{(t)}}{1-b_u^t}, \\ \lambda_{kv}^{(t+1)} &= \lambda_{kv}^{(t)} + \rho_0 \hat{m}_{kv}^{(t)} / (\sqrt{\hat{u}_{kv}^{(t)}} + \varepsilon), \quad (6) \end{aligned}$$

where ρ_0 is a constant, b controls the decay rate.

Both ADADELTA and ADAM use the moving average of gradients as the denominator of learning rates. The learning rates will not monotonically decrease, but vary in a certain range. This property prevents online topic models from being trapped and breaks the tie between top words and bottom topic words. ADAM in particular uses bias-corrected estimate of gradient $\hat{m}_{kv}$, rather than the original stochastic gradient g_{kv} to guide direction for the optimization and therefore achieves better results.

In addition, the magnitude of gradients is proportional to the dataset's size. Thus, when the dataset is small enough, ADAGRAD will still work.

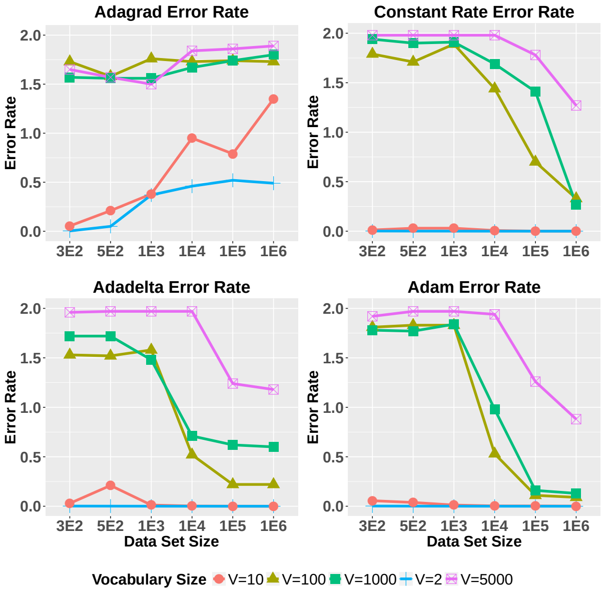

Figure 2: Experimental results on synthetic data sets. We vary the vocabulary size V, and the number of documents D. ADADELTA, ADAM and constant rate perform better with more data, while ADAGRAD only does well with small values of D.

2 Empirical Study

We study three datasets: **synthetic data**, **Wikipedia** and **SMS spam corpus**.[1] We use the generative process of LDA to generate synthetic data. We vary the vocabulary size $V \in \{2, 10, 100, 1000, 5000\}$, and the number of documents $D \in \{300, 500, 10^3, 10^4, 10^5, 10^6\}$. The **Wikipedia** dataset consists of 1M articles collected from Wikipedia.[2] The vocabulary is the same as (Hoffman et al., 2010). The SMS corpus is a small corpus containing 1084 documents.

2.1 Metrics and Settings

Error rate: For experiments on synthetic data set, we use error rate

$$\text{Error}(\hat{\beta}) = \frac{1}{K} \sum\nolimits_{k=1}^{K} \min_i ||\hat{\beta}_i - \beta_k||_1 \qquad (7)$$

to measure the difference between the estimated $\hat{\beta}$ and the known β. The min greedily matches each $\hat{\beta}_k$ to its best fit. While an uncommon metric for unsupervised algorithms, on the synthetic data we have the true β.

[1] http://www.esp.uem.es/jmgomez/smsspamcorpus/
[2] http://www.wikipedia.org

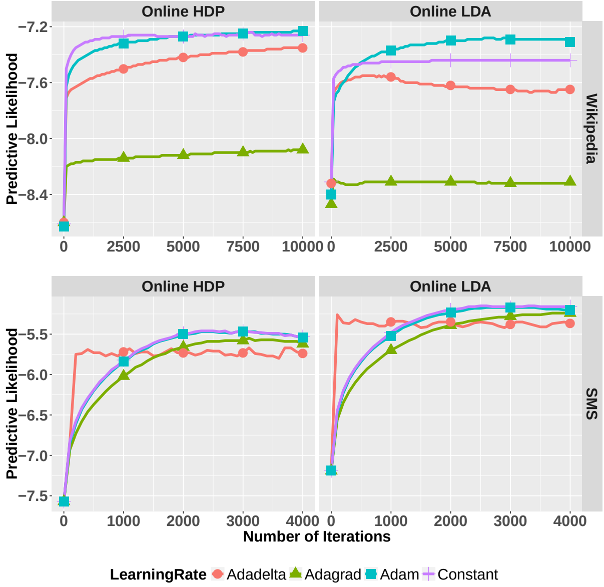

Figure 3: Experimental results on real corpora. Larger predictive likelihood is better. On Wikipedia, ADAGRAD has does worse than other methods. On SMS corpus, ADAGRAD is competitive.

Predictive likelihood: For experiments on real data sets, we use per-word likelihood (Hoffman et al., 2013) to evaluate the model quality. We randomly hold out 10K documents and 100 documents on Wikipedia and SMS respectively.

Settings: In the experiments on synthetic data, we use online LDA (Hoffman et al., 2010), since the data is generated by LDA. In the experiments on real datasets, we use online LDA and online HDP (Wang et al., 2011). In the experiments on Wikipedia, we set the number of topics $K = 100$ and the mini-batch size $M = 100$. In the experiments on SMS corpus, we set $K = 10$ and $M = 20$. For ADAM, we use the default setting of b, and set $\rho_0 = 10$ and $\epsilon = 1000$. For ADADELTA, we set $\epsilon = 1000$. For ADAGRAD, we set $\rho_0 = \epsilon = 1$. These are best settings for these three methods. The best constant rate is 10^{-3}.

2.2 Experimental Results

Figure 2 illustrates the experimental results on synthetic datasets. ADAGRAD only works well with small datasets. When the number of documents increases, ADAGRAD performance degrades. Conversely, other methods can handle more documents.

Figure 3 illustrates experimental results on real corpora. ADAGRAD gets competitive results to the other algorithms on the small SMS corpus. However on very large Wikipedia corpus, ADAGRAD fails to infer good topics, and its predictive ability is worse than the other methods. While ADADELTA and ADAM work well on Wikipedia, ADAM is the clear winner between the two.

3 Conclusion

ADAGRAD is a simple and popular technique for online learning, but is not compatible with traditional initializations and objective functions for online topic models. We show that practitioners are best off using simpler online learning techniques or ADADELTA and ADAM, which are two variants of ADAGRAD, which use the moving average of gradients as denominator. These two methods avoid ADAGRAD's problem. In particular, ADAM performs much better for prediction.

We would like to build a deeper understanding of which aspects of an unsupervised objective, near-uniform initialization, and non-identifiability contribute to these issues and to discover other learning problems that may share these issues.

Recurrent Attention Network on Memory for Aspect Sentiment Analysis

Abstract

We propose a novel framework based on neural networks to identify the sentiment of opinion targets in a comment/review. Our framework adopts multiple-attention mechanism to capture sentiment features separated by a long distance, so that it is more robust against irrelevant information. The results of multiple attentions are non-linearly combined with a recurrent neural network, which strengthens the expressive power of our model for handling more complications. The weighted-memory mechanism not only helps us avoid the labor-intensive feature engineering work, but also provides a tailor-made memory for different opinion targets of a sentence. We examine the merit of our model on four datasets: two are from SemEval2014, i.e. reviews of restaurants and laptops; a twitter dataset, for testing its performance on social media data; and a Chinese news comment dataset, for testing its language sensitivity. The experimental results show that our model consistently outperforms the state-of-the-art methods on different types of data.

1 Introduction

The goal of aspect sentiment analysis is to identify the sentiment polarity (i.e., negative, neutral, or positive) of a specific opinion target expressed in a comment/review by a reviewer. For example, in “I bought a mobile phone, its camera is wonderful but the battery life is short”, there are three opinion targets, “camera”, “battery life”, and “mobile phone”. The reviewer has a positive sentiment on the “camera”, a negative sentiment on the “battery life”, and a mixed sentiment on the “mobile phone”. Sentence-oriented sentiment analysis methods (Socher et al., 2011; Appel et al., 2016) are not capable to capture such fine-grained sentiments on opinion targets.

In order to identify the sentiment of an individual opinion target, one critical task is to model appropriate context features for the target in its original sentence. In simple cases, the sentiment of a target is identifiable with a syntactically nearby opinion word, e.g. “wonderful” for “camera”. However, there are many cases in which opinion words are enclosed in more complicated contexts. E.g., “Its camera is not wonderful enough” might express a neutral sentiment on “camera”, but not negative. Such complications usually hinder conventional approaches to aspect sentiment analysis.

To model the sentiment of the above phrase-like word sequence (i.e. “not wonderful enough”), LSTM-based methods are proposed, such as target dependent LSTM (TD-LSTM) (Tang et al., 2015). TD-LSTM might suffer from the problem that after it captures a sentiment feature far from the target, it needs to propagate the feature word by word to the target, in which case it's likely to lose this feature, such as the feature “cost-effective” for “the phone” in “My overall feeling is that the phone, after using it for three months and considering its price, is really cost-effective”.[1] Attention mechanism, which has been successfully used in machine translation (Bahdanau et al., 2014), can enforce a model to pay more attention to the important part of a sentence. There are already some works using attention in sentiment analysis to exploit this advantage (Wang et al., 2016; Tang et al., 2016). Another observation is that some types of

[*] Corresponding author.

[1] Although LSTM could keep information for a long distance by preventing the vanishing gradient problem, it usually requires a large training corpus to capture the flexible usage of parenthesis.

Copenhagen, Denmark, September 7–11, 2017. ©2017 Association for Computational Linguistics

sentence structures are particularly challenging for target sentiment analysis. For example, in "Except Patrick, all other actors don't play well", the word "except" and the phrase "don't play well" produce a positive sentiment on "Patrick". It's hard to synthesize these features just by LSTM, since their positions are dispersed. Single attention based methods (e.g. (Wang et al., 2016)) are also not capable to overcome such difficulty, because attending multiple words with one attention may hide the characteristic of each attended word.

In this paper, we propose a novel framework to solve the above problems in target sentiment analysis. Specifically, our framework first adopts a bidirectional LSTM (BLSTM) to produce the memory (i.e. the states of time steps generated by LSTM) from the input, as bidirectional recurrent neural networks (RNNs) were found effective for a similar purpose in machine translation (Bahdanau et al., 2014). The memory slices are then weighted according to their relative positions to the target, so that different targets from the same sentence have their own tailor-made memories. After that, we pay multiple attentions on the position-weighted memory and nonlinearly combine the attention results with a recurrent network, i.e. GRUs. Finally, we apply softmax on the output of the GRU network to predict the sentiment on the target.

Our framework introduces a novel way of applying multiple-attention mechanism to synthesize important features in difficult sentence structures. It's sort of analogous to the cognition procedure of a person, who might first notice part of the important information at the beginning, then notices more as she reads through, and finally combines the information from multiple attentions to draw a conclusion. For the above sentence, our model may attend the word "except" first, and then attends the phrase "don't play well", finally combines them to generate a positive feature for "Patrick". Tang et al. (2016) also adopted the idea of multiple attentions, but they used the result of a previous attention to help the next attention attend more accurate information. Their vector fed to softmax for classification is only from the final attention, which is essentially a linear combination of input embeddings (they did not have a memory component). Thus, the above limitation of single attention based methods also holds for (Tang et al., 2016). In contrast, our model combines the results of multiple attentions with a GRU network, which has different behaviors inherited from RNNs, such as forgetting, maintaining, and non-linearly transforming, and thus allows a better prediction accuracy.

We evaluate our approach on four datasets: the first two come from SemEval 2014 (Pontiki et al., 2014), containing reviews of restaurant domain and laptop domain; the third one is a collection of tweets, collected by (Dong et al., 2014); to examine whether our framework is language-insensitive (since languages show differences in quite a few aspects in expressing sentiments), we prepared a dataset of Chinese news comments with people mentions as opinion targets. The experimental results show that our model performs well for different types of data, and consistently outperforms the state-of-the-art methods.

2 Related Work

The task of aspect sentiment classification belongs to entity-level sentiment analysis. Conventional representative methods for this task include rule-based methods (Ding et al., 2008) and statistic-based methods (Jiang et al., 2011; Zhao et al., 2010). Ganapathibhotla and Liu (2008) extracted 2-tuples of (opinion target, opinion word) from comments and then identified the sentiment of opinion targets. Deng and Wiebe (2015) adopted Probabilistic Soft Logic to handle the task. There are also statistic-based approaches which employ SVM (Jiang et al., 2011) or MaxEnt-LDA (Zhao et al., 2010). These methods need either laborious feature engineering work or massive extra-linguistic resources.

Neural Networks (NNs) have the capability of fusing original features to generate new representations through multiple hidden layers. Recursive NN (Rec-NN) can conduct semantic compositions on tree structures, which has been used for syntactic analysis (Socher et al., 2010) and sentence sentiment analysis (Socher et al., 2013). (Dong et al., 2014; Nguyen and Shirai, 2015) adopted Rec-NN for aspect sentiment classification, by converting the opinion target as the tree root and propagating the sentiment of targets depending on the context and syntactic relationships between them. However, Rec-NN needs dependency parsing which is likely ineffective on nonstandard texts such as news comments and tweets. (Chen et al., 2016) employed Convolution NNs to identify the senti-

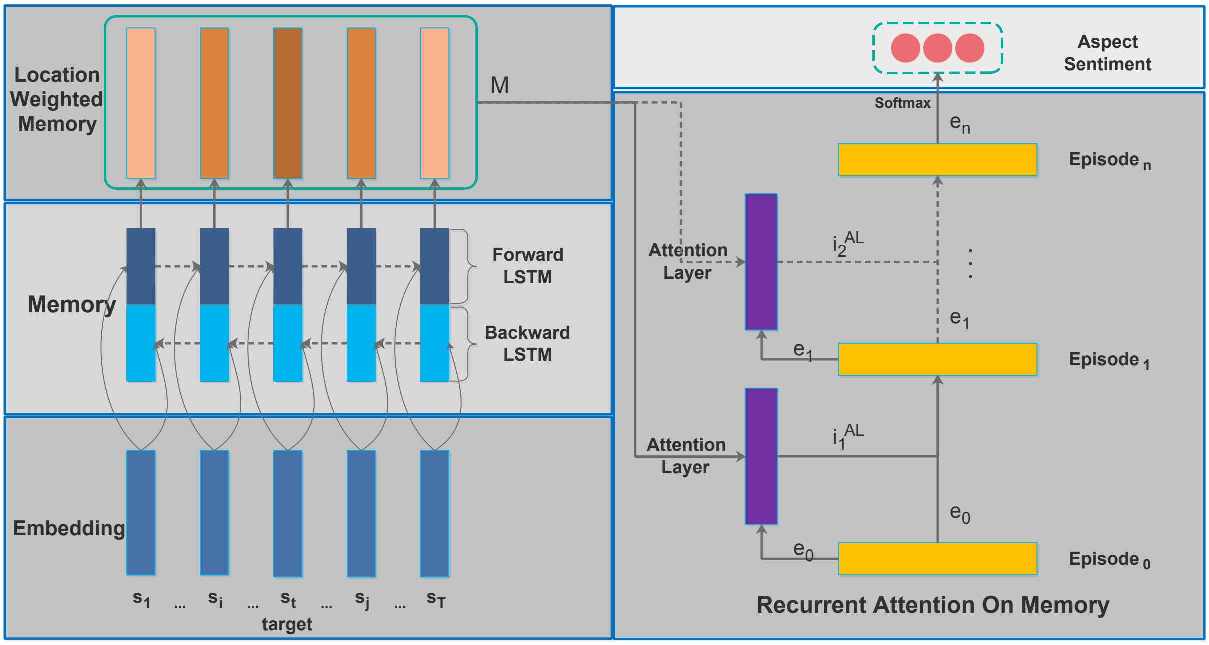

Figure 1: Model architecture. The dotted lines on the right indicate a layer may or may not be added.

ment of a clause which is then used to infer the sentiment of the target. The method has an assumption that an opinion word and its target lie in the same clause. TD-LSTM (Tang et al., 2015) utilizes LSTM to model the context information of a target by placing the target in the middle and propagating the state word by word from the beginning and the tail to the target respectively to capture the information before and after it. Nevertheless, TD-LSTM might not work well when the opinion word is far from the target, because the captured feature is likely to be lost ((Cho et al., 2014) reported similar problems of LSTM-based models in machine translation).

(Graves et al., 2014) introduced the concept of memory for NNs and proposed a differentiable process to read and write memory, which is called Neural Turing Machine (NTM). Attention mechanism, which has been used successfully in many areas (Bahdanau et al., 2014; Rush et al., 2015), can be treated as a simplified version of NTM because the size of memory is unlimited and we only need to read from it. Single attention or multiple attentions were applied in aspect sentiment classification in some previous works (Wang et al., 2016; Tang et al., 2016). One difference between our method and (Tang et al., 2016) is that we introduce a memory module between the attention module and the input module, thus our method can synthesize features of word sequences such as sentiment phrases (e.g. “not wonderful enough”). More importantly, we combine the results of attentions in a nonlinear way. (Wang et al., 2016) only uses one attention, while our model uses multiple attentions. The effectiveness of multiple attentions was also investigated in QA task (Kumar et al., 2015), which shows that multiple attentions allow a model to attend different parts of the input during each pass. (Kumar et al., 2015) assigns attention scores to memory slices independently and their attention process is more complex, while we produce a normalized attention distribution to attend information from the memory.

3 Our Model

The architecture of our model is shown in Figure 1, which consists of five modules: input module, memory module, position-weighted memory module, recurrent attention module, and output module. Suppose the input sentence is $\mathbf{s} = \{s_1, \ldots, s_{\tau-1}, s_\tau, s_{\tau+1}, \ldots, s_T\}$, the goal of our model is to predict the sentiment polarity of the target s_τ. For simplicity, we notate a target as one word here, where necessary, we will elaborate how to handle phrase-form targets, e.g. “battery life”.

3.1 Input Embedding

Let $\mathbb{L} \in \mathbb{R}^{d \times |V|}$ be an embedding lookup table generated by an unsupervised method such as GloVe (Pennington et al., 2014) or CBOW

(Mikolov et al., 2013), where d is the dimension of word vectors and $|V|$ is the vocabulary size. The input module retrieves the word vectors from $\mathbb{L}$ for an input sequence and gets a list of vectors $\{v_1, \ldots, v_t, \ldots, v_T\}$ where $v_t \in \mathbb{R}^d$. $\mathbb{L}$ may or may not be tuned in the training of our framework. If it is not tuned, the model can utilize the words' similarity revealed in the original embedding space. If it is tuned, we expect the model would capture some intrinsic information that is useful for the sentiment analysis task.

3.2 BLSTM for Memory Building

MemNet (Tang et al., 2016) simply used the sequence of word vectors as memory, which cannot synthesize phrase-like features in the original sentence. It is straightforward to achieve the goal with the models of RNN family. In this paper, we use Deep Bidirectional LSTM (DBLSTM) to build the memory which records all information to be read in the subsequent modules.

At each time step t, the forward LSTM not only outputs the hidden state $\overrightarrow{h}_t^l$ at its layer l ($\overrightarrow{h}_t^0 = v_t$) but also maintains a memory $\overrightarrow{c}_t^l$ inside its hidden cell. The update process at time t is as follows:

$$i = \sigma(\overrightarrow{W}_i \overrightarrow{h}_t^{l-1} + \overrightarrow{U}_i \overrightarrow{h}_{t-1}^l) \tag{1}$$

$$f = \sigma(\overrightarrow{W}_f \overrightarrow{h}_t^{l-1} + \overrightarrow{U}_f \overrightarrow{h}_{t-1}^l) \tag{2}$$

$$o = \sigma(\overrightarrow{W}_o \overrightarrow{h}_t^{l-1} + \overrightarrow{U}_o \overrightarrow{h}_{t-1}^l) \tag{3}$$

$$g = \tanh(\overrightarrow{W}_g \overrightarrow{h}_t^{l-1} + \overrightarrow{U}_g \overrightarrow{h}_{t-1}^l) \tag{4}$$

$$\overrightarrow{c}_t^l = f \odot \overrightarrow{c}_{t-1}^l + i \odot g \tag{5}$$

$$\overrightarrow{h}_t^l = o \odot \tanh(\overrightarrow{c}_t^l) \tag{6}$$

where σ and $\tanh$ are sigmoid and hyperbolic tangent functions, $\overrightarrow{W}_i, \overrightarrow{W}_f, \overrightarrow{W}_o, \overrightarrow{W}_g \in \mathbb{R}^{\overrightarrow{d}_l \times \overrightarrow{d}_{l-1}}$, $\overrightarrow{U}_i, \overrightarrow{U}_f, \overrightarrow{U}_o, \overrightarrow{U}_g \in \mathbb{R}^{\overrightarrow{d}_l \times \overrightarrow{d}_l}$, and $\overrightarrow{d}_l$ is the number of hidden cells at the layer l of the forward LSTM. The gates $i, f, o \in \mathbb{R}^{\overrightarrow{d}_l}$ simulate binary switches that control whether to update the information from the current input, whether to forget the information in the memory cells, and whether to reveal the information in memory cells to the output, respectively. The backward LSTM does the same thing, except that its input sequence is reversed. If there are L layers stacked in the BLSTM, the final memory generated in this module is $M^* = \{m_1^*, \ldots, m_t^*, \ldots, m_T^*\}$, where $m_t^* = (\overrightarrow{h}_t^L, \overleftarrow{h}_t^L) \in \mathbb{R}^{\overrightarrow{d}_L + \overleftarrow{d}_L}$. In our framework, we use 2 layers of BLSTM to build the memory, as it generally performs well in NLP tasks (Karpathy et al., 2015).

3.3 Position-Weighted Memory

The memory generated in the above module is the same for multiple targets in one comment, which is not flexible enough for predicting respective sentiments of these targets. To ease this problem, we adopt an intuitive method to edit the memory to produce a tailor-made input memory for each target. Specifically, the closer to the target a word is, the higher its memory slide is weighted. We define the distance as the number of words between the word and the target. One might want to use the length of the path from the specific word to the target in the dependency tree as the distance, which is a worthwhile option to try in the future work, given the condition that dependency parsing on the input text is effective enough. Precisely, the weight for the word at position t is calculated as:

$$w_t = 1 - \frac{|t - \tau|}{t_{max}} \tag{7}$$

where t_{max} is truncation length of the input. We also calculate $u_t = \frac{t-\tau}{t_{max}}$ to memorize the relative offset between each word and the target. If the target is a phrase, the distance (i.e. $t - \tau$) is calculated with its left or right boundary index according to which side w_t locates. The final position-weighted memory of a target is $M = \{m_1, \ldots, m_t, \ldots, m_T\}$ where $m_t = (w_t \cdot m_t^*, u_t) \in \mathbb{R}^{\overrightarrow{d}_L + \overleftarrow{d}_L + 1}$. The weighted memory is designed to up-weight nearer sentiment words, and the recurrent attention module, discussed below, attends long-distance sentiment words. Thus, they work together to expect a better prediction accuracy.

3.4 Recurrent Attention on Memory

To accurately predict the sentiment of a target, it is essential to: (1) correctly distill the related information from its position-weighted memory; and (2) appropriately manufacture such information as the input of sentiment classification. We employ multiple attentions to fulfil the first aspect, and a recurrent network for the second which non-linearly combines the attention results with GRUs (since GRUs have less number of parameters). For example, "except" and "don't play well" in "Except Patrick, all other actors don't play well" are attended by different attentions, and combined to produce a positive sentiment on "Patrick".

Particularly, we employ a GRU to update the episode e after each attention. Let e_{t-1} denote the episode at the previous time and i_t^{AL} is the current information attended from the memory M, and the process of updating e_t is as follows:

$$r = \sigma(W_r i_t^{AL} + U_r e_{t-1}) \tag{8}$$

$$z = \sigma(W_z i_t^{AL} + U_z e_{t-1}) \tag{9}$$

$$\tilde{e}_t = \tanh(W_x i_t^{AL} + W_g(r \odot e_{t-1})) \tag{10}$$

$$e_t = (1-z) \odot e_{t-1} + z \odot \tilde{e}_t \tag{11}$$

where $W_r, W_z \in \mathbb{R}^{H\times(\overrightarrow{d}_L+\overleftarrow{d}_L+1)}$, $U_r, U_z \in \mathbb{R}^{H\times H}$, $W_g \in \mathbb{R}^{H\times(\overrightarrow{d}_L+\overleftarrow{d}_L+1)}$, $W_x \in \mathbb{R}^{H\times H}$, and H is the hidden size of GRU. As we can see from Equations (10) and (11), the state of episode e_t is the interpolation of e_{t-1} and the candidate hidden vector $\tilde{e}_t$. A vector of 0's is used as e_0.

For calculating the attended information i_t^{AL} at t, the input of an attention layer (AL for short) includes the memory slices $m_j (1 \leq j \leq T)$ and the previous episode e_{t-1}. We first calculate the attention score of each memory slice as follows:

$$g_j^t = W_t^{AL}(m_j, e_{t-1}[, v_\tau]) + b_t^{AL}, \tag{12}$$

where $[, v_\tau]$ indicates when the attention result relies on particular aspects such as those of products, we also add the target vector v_τ because different product aspects have different preference on opinion words; when the target is a person, there is no need to do so. If the target is a phrase, v_τ takes the average of word embeddings. We utilize the previous episode for the current attention, since it can guide the model to attend different useful information. (Tang et al., 2016) also adopts multiple attentions, but they don't combine the results of different attentions.

Then we calculate the normalized attention score of each memory slice as:

$$\alpha_j^t = \frac{\exp(g_j^t)}{\sum_k \exp(g_k^t)}. \tag{13}$$

Finally, the inputs to a GRU (i.e. Eqs. 8 to 11) at time t are the episode e_{t-1} at time $t-1$ and the content i_t^{AL}, which is read from the memory as:

$$i_t^{AL} = \sum_{j=1}^{T} \alpha_j^t m_j. \tag{14}$$

3.5 Output and Model Training

After N-time attentions on the memory, the final episode e_N serves as the feature and is fed into a softmax layer to predict the target sentiment.

The model is trained by minimizing the cross entropy plus an L_2 regularization term:

$$\mathcal{L} = \sum_{(x,y)\in D} \sum_{c\in C} y^c \log f^c(x;\theta) + \lambda \parallel \theta \parallel^2 \tag{15}$$

where C is the sentiment category set, D is the collection of training data, $y \in \mathbb{R}^{|C|}$ is a one-hot vector where the element for the true sentiment is 1, $f(x;\theta)$ is the predicted sentiment distribution of the model, λ is the weight of L_2 regularization term. We also adopt dropout and early stopping to ease overfitting.

4 Experiments

4.1 Experimental Setting

We conduct experiments on four datasets, as shown in Table 1. The first two are from SemEval 2014 (Pontiki et al., 2014), containing reviews of restaurant and laptop domains, which are widely used in previous works. The third one is a collection of tweets, collected by (Dong et al., 2014). The last one is prepared by us for testing the language sensitivity of our model, which contains Chinese news comments and has politicians and entertainers as opinion targets. We purposely add more negation, contrastive, and question comments to make it more challenging. Each comment is annotated by at least two annotators, and only if they agree with each other, the comment will be added into our dataset. Moreover, we replace each opinion target (i.e. word/phrase of pronoun or person name) with a placeholder, as did in (Dong et al., 2014). For the first two datasets, we removed a few examples having the "conflict label", e.g., "Certainly not the best sushi in New York, however, it is always fresh" (Pontiki et al., 2014).

We use 300-dimension word vectors pre-trained by GloVe (Pennington et al., 2014) (whose vocabulary size is 1.9M[2]) for our experiments on the English datasets, as previous works did (Tang et al., 2016). Some works employed domain-specific training corpus to learn embeddings for better performance, such as TD-LSTM (Tang et al., 2015) on the tweet dataset. In contrast, we prefer to use

[2] http://nlp.stanford.edu/projects/glove/

Dataset		Negative	Neutral	Positive

	Testing	838	1,054	732

Table 1: Details of the experimental datasets.

the general embeddings from (Pennington et al., 2014) for all datasets, so that the experimental results can better reveal the model's capability and the figures are directly comparable across different papers. The embeddings for Chinese experiments are trained with a corpus of 1.4 billion tokens with CBOW[3].

4.2 Compared Methods

We compare our proposed framework of Recurrent Attention on Memory (**RAM**) with the following methods:

- Average Context: There are two versions of this method. The first one, named **AC-S**, averages the word vectors before the target and the word vectors after the target separately. The second one, named **AC**, averages the word vectors of the full context.
- SVM (Kiritchenko et al., 2014): The traditional state-of-the-art method using SVMs on surface features, lexicon features and parsing features, which is the best team in SemEval 2014.
- Rec-NN (Dong et al., 2014): It firstly uses rules to transform the dependency tree and put the opinion target at the root, and then performs semantic composition with Recursive NNs for sentiment prediction.
- TD-LSTM (Tang et al., 2015): It uses a forward LSTM and a backward LSTM to abstract the information before and after the target. Finally, it takes the hidden states of LSTM at last time step to represent the context for prediction. We reproduce its results on the tweet dataset with our embeddings, and also run it for the other three datasets.
- TD-LSTM-A: We developed TD-LSTM to make it have one attention on the outputs of forward and backward LSTMs, respectively.
- MemNet (Tang et al., 2016): It applies attention multiple times on the word embeddings, and the last attention's output is fed to softmax for prediction, without combining the results of different attentions. We produce its results on all four datasets with the code released by the authors.[4]

For each method, the maximum number of training iterations is 100, and the model with the minimum training error is utilized for testing. We will discuss different settings of RAM later.

4.3 Main Results

The first evaluation metric is Accuracy, which is used in (Tang et al., 2016). Because the datasets have unbalanced classes as shown in Table 1, Macro-averaged F-measure is also reported, as did in (Dong et al., 2014; Tang et al., 2015). As shown by the results in Table 2, our RAM consistently outperforms all compared methods on these four datasets. AC and AC-S perform poorly, because averaging context is equivalent to paying identical attention to each word which would hide the true sentiment word. Rec-NN is better than TD-LSTM but not as good as our method. The advantage of Rec-NN is that it utilizes the result of dependency parsing which might shorten the distance between the opinion target and the related opinion word. However, dependency parsing is not guaranteed to work well on irregular texts such as tweets, which may still result in long path between the opinion word and its target, so that the opinion features would also be lost while being propagated. TD-LSTM performs less competitive than our method on all the datasets, particularly on the tweet dataset, because in this dataset sentiment words are usually far from person names,

for which case the multiple-attention mechanism is designed to work. TD-LSTM-A also performs worse than our method, because its two attentions, i.e. one for the text before the target and the other for the after, cannot tackle some cases where more than one features being attended are at the same side of the target.

Our method steadily performs better than MemNet on all four datasets, particularly on the News comment dataset, its improvement is more than 10%. MemNet adopts multiple attentions in order to improve the attention results, given the assumption that the result of an attention at a later hop should be better than that at the beginning. MemNet doesn't combine the results of multiple attentions, and the vector fed to softmax is the result of the last attention, which is essentially the linear combination of word embeddings. As we described before, attending too many words in one time may hide the characteristic of each word, moreover, the sentiment transition usually combines features in a nonlinear way. Our model overcomes this shortcoming with a GRU network to combine the results of multiple attentions. The feature-based SVM, which needs labor-intensive feature engineering works and a mass of extra linguistic resources, doesn't display its advantage, because the features for aspect sentiment analysis cannot be extracted as easily as for sentence or document level sentiment analysis.

4.4 Effects of Attention Layers

One major setting that affects the performance of our model is the number of attention layers. We evaluate our framework with 1 to 5 attention layers, and the results are given in Table 3, where NAL means using N attentions. In general, our model with 2 or 3 attention layers works better, but the advantage is not always there for different datasets. For example, for the Restaurant dataset, our model with 4 attention layers performs the best. Using 1 attention is always not as good as using more, which shows that one-time attention might not be sufficient to capture the sentiment features in complicated cases. One the other hand, the performance is not monotonically increasing with respect to the number of attentions. RAM-4AL is generally not as good as RAM-3AL, it is because as the model's complexity increases, the model becomes more difficult to train and less generalizable.

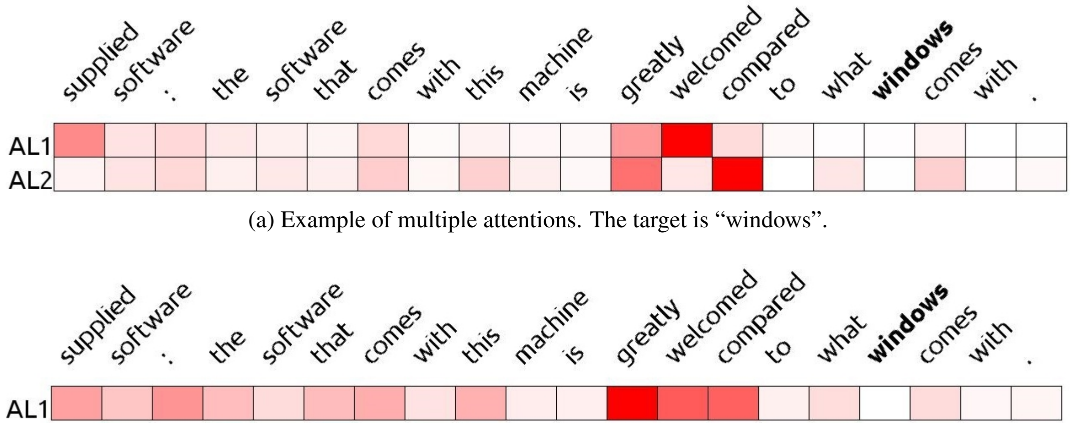
4.5 Effects of Embedding Tuning

The compared embedding tuning strategies are:

- RAM-3AL-T-R: It does not pre-train word embeddings, but initializes embeddings randomly and then tunes them in the supervised

Embedding	Laptop	Restaurant	Tweet	Comment
RAM-3AL-T-R	0.5806	0.7129	0.6272	0.6749
RAM-3AL-T	0.6854	0.7522	0.6402	0.7283
RAM-3AL-NT	**0.7449**	**0.8023**	**0.6936**	**0.7389**

Table 4: The impact of different embedding tuning strategies.



(a) Example of multiple attentions. The target is "windows".

(b) Example of single attention. The target is "windows".

Figure 2: Comparison of single attention and multiple attentions. Attention score by Eq. 13 is used as the color-coding.

training stage.

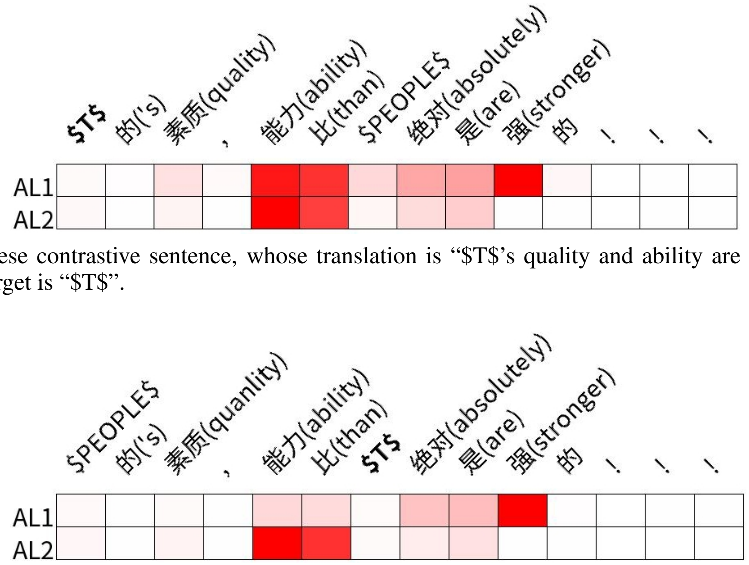
- RAM-3AL-T: Using the pre-trained embeddings initially, and they are also tuned in the training.
- RAM-3AL-NT: The pre-trained embeddings are not tuned in the training.

From Table 4, we can see that RAM-3AL-T-R performs very poorly, especially when the size of training data is smaller. The reason could be threefold: (1) The amount of labelled samples in the four experimental datasets is too small to tune reliable embeddings from scratch for the in-vocabulary words (i.e. existing in the training data); (2) A lot of out-of-vocabulary (OOV) words, i.e. absent from the training data, but exist in the testing data; (3) It increases the risk of overfitting after adding the embedding parameters to the solution space (it requires the embeddings not only to fit model parameters, but also to capture the similarity among words). During training, we indeed observed that the training error converges too fast in RAM-3AL-T-R. RAM-3AL-T can utilize the embedding similarity among words at the beginning of training, but fine tuning will destroy this similarity during training. On the other hand, the initial embeddings of OOV words in the testing data are not tuned, so that their similarity with vocabulary words are also destroyed. In addition, RAM-3AL-T also suffers from the risk of overfitting. RAM-3AL-NT performs the best on all four datasets, and we also observe that the training error converges gradually while the model parameters are being updated with the error signal from the output layer.

4.6 Case Study

We pick some testing examples from the datasets and visualize their attention results. To make the visualized results comprehensible, we remove the BLSTM memory module to make the attention module directly work on the word embeddings, thus we can check whether the attention results conform with our intuition. The visualization results are shown in Figures 2 and 3.

Figures 2a and 2b present the differences between using two attentions and using one attention, which show that multiple attentions are useful to attend correct features. As shown in Figure 2a, in order to identify the sentiment of "windows", the model firstly notices "welcomed" and secondly notices "compared" before the aspect target "windows". Finally it combines them with the GRU network, and generates a negative sentiment because the compared item (i.e. "windows") after a positive sentiment word (i.e. "welcomed") is less preferred. While the attention result of the model



(a) Example of a Chinese contrastive sentence, whose translation is "T's quality and ability are absolutely stronger than $PEOPLE$!!!". The target is "T".

(b) The sentence from 3a with a different target, i.e. "$PEOPLE$'s quality and ability are absolutely stronger than T!!!".

Figure 3: Example of multiple opinion targets. Attention score by Eq. 13 is used as the color-coding.

with only one attention, as shown in Figure 2a, is a sort of uniform distribution and mingles too many word vectors in a linear way, which would ruin the characteristic of each word.

Figures 3a and 3b present a case that there are more than one opinion targets in a comment, which cannot be analyzed with sentence-level sentiment analysis methods properly. Specifically, it's a comparative sentence in which the reviewer has a positive sentiment on the first commented person, but a negative sentiment on the second person, and our model predicts both of them correctly. Although all useful information (e.g. "than" and "stronger") is attended in both cases, the attention procedures of them show some interesting differences. They mainly attend important information after the target T in the first attention layer AL1. After that, Figure 3b attends more information before T in AL2. Since the same words in Figures 3a and 3b have different memory slices due to position weighting and augmented offset feature, as described in Section 3.3, our model predicts opposite sentiments on the two persons. For example in Figure 3b, the model first attends a positive word "stronger" and then attends "than" before the target, so it reverses the sentiment and finally predicts a negative sentiment.

5 Conclusions and Future Work

In this paper, we proposed a framework to identify the sentiment of opinion targets. The model first runs through the input to generate a memory, in the process of which it can synthesize the word sequence features. And then, the model pays multiple attentions on the memory to pick up important information to predict the final sentiment, by combining the features from different attentions non-linearly. We demonstrated the efficacy of our model on four datasets, and the results show that it can outperform the state-of-the-art methods.

Although multiple-attention mechanism has the potential to synthesize features in complicated sentences, enforcing the model to pay a fix number of attentions to the memory is unnatural and even sort of unreasonable for some cases. Therefore, we need a mechanism to stop the attention process automatically if no more useful information can be read from the memory. We may also try other memory weighting strategies to distinguish multiple targets in one comment more clearly.

Abstract

Attention models are proposed in sentiment analysis because some words are more important than others. However, most existing methods either use local context based text information or user preference information. In this work, we propose a novel attention model trained by cognition grounded eye-tracking data. A reading prediction model is first built using eye-tracking data as dependent data and other features in the context as independent data. The predicted reading time is then used to build a cognition based attention (CBA) layer for neural sentiment analysis. As a comprehensive model, We can capture attentions of words in sentences as well as sentences in documents. Different attention mechanisms can also be incorporated to capture other aspects of attentions. Evaluations show the CBA based method outperforms the state-of-the-art local context based attention methods significantly. This brings insight to how cognition grounded data can be brought into NLP tasks.

1 Introduction

Sentiment analysis is critical for many applications such as sentimental product recommendation (Dong et al., 2013), public opinion detection (Pang et al., 2008), and human-machine interaction (Clavel and Callejas, 2016), etc.Sentiment analysis has been well-explored (Pang et al., 2002; Vanzo et al., 2014; Tang et al., 2015a; Chen et al., 2016; Maas et al., 2011).Recently, deep learning based methods have further elevated the performance of sentiment analysis without the need for labor intensive feature engineering.

Attention models are incorporated into sentiment analysis because not all words are created equal. Some words are more important than others in conveying the message in a sentence. Similarly, some sentences are more important than others in a document. Although the overall reading time as a cognitive process may reflect the syntax and discourse complexity, reading time of individual words is also an indicator of their semantic importance in text (Roseman, 2001; Demberg and Keller, 2008). Previous attention models are built using information embedded in text including users, products and text in local context for sentiment classification (Tang et al., 2015b; Yang et al., 2016; Chen et al., 2016; Gui et al., 2016). However, attention models using local context based text through distributional similarity lack theoretical foundation to reflect the cognitive basis. But, the key in sentiment analysis lies in its cognitive basis. Thus, we envision that cognition grounded data obtained in text reading should be helpful in building an attention model.

In this paper, we propose a novel cognition based attention(CBA) model for sentiment analysis learned from cognition grounded eye-tracking data. Eye-tracking is the process of measuring either the point of gaze or the motion of an eye relative to the head[1]. In psycho-linguistics experiments, Barrett(2016) shows that readers are less likely to fixate on close-class words that are predictable from context. Readers also fixate longer on words which play significant semantic roles (Demberg and Keller, 2008) in addition to infrequent words, ambiguous words, and morphological complex words (Rayner, 1998). Since reading time can be learned from an eye-tracking dataset, predicted reading time of words in its context can be used as indicators of attention weights.

Proceedings of the 2017 Conference on Empirical Methods in Natural Language Processing, pages 462–471
Copenhagen, Denmark, September 7–11, 2017.

We first build a regression model to map syntax, and context features of a word to its reading time based on eye-tracking data. We then apply the model to sentiment analysis text to obtain the estimated reading time of words at the sentence level. The estimated reading time can then be used as the attention weights in its context to build the attention layer in a neural network based sentiment analysis model. Evaluation on the four sentiment analysis benchmark datasets (IMDB, Yelp 13, Yelp 14 and IMDB2) show that our proposed model can significantly improve the performance compared to the state-of-the-art attention methods.
