To sum up, we have two major contributions: (1) We propose a novel cognition grounded attention model to improve the state-of-the-art neural network based sentiment analysis models by learning attention information from eye-tracking data. This is one of the first attempts to use cognition grounded data in sentiment analysis. The CBA model not only can capture attention of words at the sentence level, it can also be aggregated to work at the document level. (2) Evaluation on several real-world datasets in sentiment analysis shows that our method outperforms other state-of-the-art methods significantly. This work validates the effectiveness of cognition grounded data in building attention models.

2 Related works

The basic task in sentiment analysis can be formulated as a classification problem. Class labels can either be binary (positive/negative) or polarity either as intensity by continuous values or as ratings in certain range such as 0 to 5 or 1 to 10, etc..

In recent years, deep learning based methods have greatly improved the performance of sentiment analysis. Commonly used models include Convolutional Neural Networks (Socher et al., 2011), Recursive Neural Network (Socher et al., 2013), and Recurrent Neural Networks (Irsoy and Cardie, 2014). RNN naturally benefits sentiment classification because of its ability to capture sequential information in text. However, standard RNN suffers from the gradient vanishing problem (Bengio et al., 1994) where gradients may grow or decay exponentially over long sequences. To address this problem, Long-Short Term Memory model (LSTM) is introduced by adding a gated mechanism to keep long term memory. Each LSTM layer is generally followed by mean pooling and then feed into the next layer. Experiments in datasets which contain long documents and sentences demonstrate that the LSTM model outperforms the traditional RNN (Tang et al., 2015a,c).

Not all words contribute equally to the semantics of a sentence (Hahn and Keller, 2016). Attention based neural networks are proposed to highlight their difference in contribution (Yang et al., 2016). In document level sentiment classification, both sentence level attention and document level attention are proposed. In the sentence level attention layer, an attention mechanism identifies words that are important. Those informative words are aggregated as attention weights to form sentence embedding representation. This method is generally called local context attention method. Similarly, some sentences can also be highlighted to indicate their importance in a document.

Apart from local context attention, user/product attentions are also included in deep learning based methods either in a separate network (Gui et al., 2016) or a unified network (Tang et al., 2015c; Gui et al., 2016). Some feature engineering method to some specific datasets can also achieve very good result(Sadeghian and Sharafat, 2015). However, they are not suited for other genre of text as user-product information are not generally available.

Attention models can be built not only from local text or user/product information but also from cognitive grounded data, especially eye-tracking data (Rayner, 1998; Allopenna et al., 1998). Joshi (2014) proposes a novel metric called Sentiment Annotation Complexity for measuring sentiment annotation complexity based on eye-tracking data. Mishra (2014) presents a cognitive study of sentiment detection from the perspective of AI where readers are tested as sentiment readers. Mishra (Mishra et al., 2016b) recently proposes a model in sentiment analysis and sarcasm detection by using eye-tracking data as a feature in addition to text features using Naive-Bayes and SVM classifiers.

In other NLP tasks, Joshi (2013) shows that Word-Sense-Disambiguation can make use of simultaneous eye-tracking. Eye-tracking data are also used to measure the difficulty in translation annotation (Mishra et al., 2013). Barrett (2016) finds that gaze patterns during reading are strongly influenced by the role a word plays in terms of syntax, semantic, and discourse.

Among different available eye-tracking datasets, the Dundee corpus, GECO (the Ghent

Eye-Tracking Corpus), and Mishra et al. (Mishra et al., 2016b) are considered high-quality resources (Kennedy, 2003; Cop et al., 2016; Mishra et al., 2016b). The Dundee corpus contains eye movement data from English and French newspapers (Kennedy, 2003). Measurements were taken while 10 participants read 20 newspaper articles. GECO is an English-Dutch bilingual corpus with eye-tracking data from 17 participants collected from reading the complete novel *The Mysterious Affair at Styles*. The corpus has 4,934 sentences, 774,015 tokens, and 9,876 words. The Mishra(Mishra et al., 2016a) dataset contains 994 text snippets with 383 positive and 611 negative examples from newspaper clippings, sampled from seven native speakers.

To predict reading time using eye-tracking data, Tomanek et al. (2010) proposes a regression model using linguistic features related to syntax and semantics for calibration. Hahn (2016) proposes a novel approach to model both skipping and reading using unsupervised method which combines neural attention with auto-encoding trained on raw text using reinforcement learning.

3 Our proposed CBA model

The basic idea of our method is to add a CBA model into a neural-network based LSTM sentiment classifier. Let D be a collection of documents. A document d_k, $d_k \in D$, has m number of sentences $S_1, S_2, ...S_j, ..., S_m$. A sentence S_j is formed by a sequence of words $S_j = w_1^j w_2^j ... w_{l_j}^j$, where l_j is the length of S_j. The features of a word $w_i \in D$ form a feature vector $\vec{v}^{w_i} = [{F_1}^{w_i}, {F_2}^{w_i} .... {F_n}^{w_i}]$ where n is the feature space size. The purpose of document level sentiment classification is to project a document d_k into the target space of L class labels. Similarly, at the sentence level, the purpose is to project a sentence S_j into the target class space.

To build the CBA model, we need to first build a reading time prediction model for words within each sentence. Reading time is predicted based on word features and text features calibrated by eye-tracking data. Note that reading time from an eye-tracking dataset cannot be used directly because the text of any eye-tracking dataset is too small for sufficient coverage. Consequently, our method has four tasks: (1) to predict the reading time of words using eye-tracking data and $\vec{v}_{w_i}$ as features; (2) to build attention models based on predicted reading time at sentence level and document level; (3) to integrate attentions from other attention models; and (4) to add the attention model into the LSTM based sentiment classifier.

3.1 Modeling of reading time

To learn the reading time of words in a sentence, our method is based on regression analysis using eye-tracking data as dependent variables and context information in $\vec{v}_{w \in S_j}$ as independent variables. In the eye-tracking process, a number of different time measures such as *first fixation duration*, *gaze duration*, and *total reading time*. In this work, we only use *the total reading time*.

Since a document set is always available for sentiment analysis, we use features extracted from these documents to train the regression model. We select features based on the works from Demberg(2008) and Tomanek (2010) to include word features such as word length and POS tags as well as context level syntax and semantic features such as the total number of dominated nodes in a dependency parsing three, the maximum dependency distance, semantic category etc..

Given a word w in a sentence S_j, $w \in S_j$, and its feature vector $\vec{v}_{w \in S_j} = [F_1^w, F_2^w, ..., F_n^w]$ where n is the dimension size in feature space, the regression model on eye-tracking data is a mapping function g between reading time $t_{w \in S_j}$ and $\vec{v}_{w \in S_j}$ as defined below:

$$t_{w \in S_j} = g(\alpha_1 F_1^w + \alpha_2 F_2^w + ... + \alpha_n F_n^w + b), \tag{1}$$

where $t_{w \in S_j}$ is the predicted reading time for w, α_i is the weight of feature F_i^w, and b is a constant. Note that the set of $\alpha_i (i = 1...n)$ forms the weight vector $\vec{\alpha}_w$ for $t_{w \in S_j}$. When $\vec{v}_{w \in S_j}$ takes scalar values, g can be an identity function and thus this model becomes a typical linear regression model. When $t_{w \in S_j}$ takes discrete values, g can be a logistic function and this model becomes a typical logistic regression model.

we set g to be the identity function. The objective function then becomes:

$$\min_{\vec{\alpha}} \sum_{a_i \in \vec{\alpha}}^{n} ||t_{w \in S_j} - y_{w \in S_j}||_2^2 + \lambda R(\vec{\alpha}), \tag{2}$$

where $y_{w \in S_j}$ is the true eye-tracking values of reading time, $R(\vec{\alpha})$ is the regularization of $\vec{\alpha}$, and λ is the regularization weight. When $\lambda = 0$, the model degrades to a linear regression function. In this work, we evaluate the use of both the linear regression model and the Ridge regression model.

3.2 Building the attention based model

Once we have predicted reading time for words used in sentences, the attention model can be built with two components. The first component works at the sentence level to give different words different emphasis in a sentence. The second component works at the document level to give different sentences different emphasis in a document.

For a sentence $S_j = w_1 w_2 ... w_i ... w_{l_j}$ with length l_j, each word w_i in S_j has a corresponding reading time t_{w_i}. Let t_{S_j} denote the total reading time of S_j. Then,

$$t_{S_j} = \sum_{i=1, w_i \in S_j}^{l_j} t_{w_i}. \tag{3}$$

For sentence level attention, the CBA weight for w_i in S_j, denoted as $A_{S_j:w_i}$, can be defined as:

$$A_{S_j:w_i} = \frac{t_{w_i}}{t_{S_j}}. \tag{4}$$

This sentence level attention model defined above gives more weights to words that have longer reading time relative to the total reading time of the sentence.

Let a document d_k, $d_k \in D$, be formed by a set of sentences $S_j = w_1 w_2 ... w_i ... w_{l_j}$. Now the CBA weight for a sentence S_j in d_k is defined as:

$$A_{d_k:S_j} = \frac{t_{s_j}}{\sum_{i=1}^{m} t_{S_i}}. \tag{5}$$

This aggregated document level attention model gives more weights to the sentences that have longer reading time relative to the total reading time of the document. Let $\vec{A}_{d_k}$ denote the document level attention weight vector. The size of $\vec{A}_{d_k}$ should be m, the number of sentences in d_k.

Let $\vec{S}_j$ denote the embedding of S_j in N dimensional space, where $S_j \in d_k$. Then, the set of sentence representations for d_k should be a matrix of size $m \times N$, denoted by $\hat{S}_{d_k}$. After the inclusion of the attention model, $\hat{S}_{d_k}$ should be:

$$\hat{S}_{d_k} = \vec{A}_{d_k} \vec{S}_j^T. \tag{6}$$

Let $\vec{d}_k$ denote the document embedding of d_k. Since $\vec{d}_k$ is an N dimensional vector, $\vec{d}_k$ can now be defined by the adjusted attention model as

$$(\vec{d}_k)_i = \sum_{j=1}^{m} (\hat{S}_{d_k})_{i,j}. \tag{7}$$

3.3 Incorporation of other attention models

Since document embedding representation allows the combined use of multiple attention mechanisms, it is to our advantage to incorporate different attention mechanisms which may help to capture different aspects of attentions. Generally speaking, different attention mechanisms can be incorporated either serially or in parallel.

In principle, any number of attention models can be included. As an an example to illustrate the capability of our proposed method, we choose one state-of-the-art local attention model(shorthanded as LA). The model is a semantic-based local attention model proposed by Yang (2016) and also used by Chen (2016). For inclusion serially, the attention weight is formulated as follows:

$$A^s{}_{S_j}{:}w_i = LA_{S_j:w_i} * A_{S_j:w_i}, \tag{8}$$

where $LA_{s_j:w_i}$ the sentence level attention model by the local attention model. To incorporate LA in parallel mode, the attention weight can be formulated by:

$$A^p{}_{S_j}{:}w_i = LA_{S_j}{:}w_i + A_{S_j}{:}w_i. \tag{9}$$

Similar methods can be used at document level.

3.4 General sentiment analysis model

We take the neural network based LSTM sentiment classifier (Gers, 2001) to be applied in both the sentence level and the document level because of its excellent performance on long sentences (Tang et al., 2015a). The basic LSTM model has five internal vectors for a node i including an input gate $\vec{i_i}$, a forget gate $\vec{f_i}$, an output gate $\vec{o_i}$, a candidate memory cell $\vec{c_i'}$, and a memory cell $\vec{c_i}$, and $\vec{i_i}\vec{f_i}$ and $\vec{o_i}$ are used to indicate which values will be updated, forget or for keeping in the LSTM model. $\vec{c_i'}$ and $\vec{c_i}$ are used to keep the candidate features and the actual accepted features, respectively.

At the sentence level, each word w_i in a sentence S_j is represented by its word embedding $\vec{w_i}$ in the N dimensional space. The LSTM cell state $\vec{c_i}$ and the hidden state $\vec{h}_{S_j:w_i}$ can be updated in two steps. In the first step, the previous hidden state $\vec{h}_{S_j:w_{i-1}}$ uses a hyperbolic function to form $\vec{c_i'}$ as defined below.

$$\vec{c_i'} = tanh(\hat{W}_c * [\vec{h}_{S_j:w_{i-1}} * \vec{w_i}] + \hat{b}), \qquad (10)$$

where $\hat{W}_c$ is a parameter matrix, $\vec{h}_{S_j:w_{i-1}}$ is the previous hidden state and $\vec{w_i}$ is the word vector. $\hat{b}$ is the regularization parameter matrix. In the second step, $\vec{c_i}$ is updated by $\vec{c_i'}$ and its previous state $\vec{c}_{i-1}$ to form $\vec{c_i}$ according to the below formula:

$$\vec{c_i} = \vec{f_i} \odot \vec{c}_{i-1} + \vec{i_i} \odot \vec{c_i'}. \qquad (11)$$

The hidden state of w_i can be obtained by

$$\vec{h}_{S_j:w_i} = \vec{o_i} tanh(\vec{f_i} \odot \vec{c_i}). \qquad (12)$$

The forget gate $\vec{f_i}$ is designed to keep the long term memory. A series of hidden states $\vec{h_1}\vec{h_2}...\vec{h_i}$ can serve as input to the attention layer to obtain sentence representation $\vec{S_j}$. In the document level, similar method is used to get the sentence matrix $\hat{S}$ in the document level LSTM layer to obtain the final document representation $\vec{d_k}$.

In our work, the final document representation $\vec{d_k}$ encodes both the sentence level information and the document level information. In the LSTM model, we use a hidden layer to project the final document vector $\vec{d_k^f}$ through a hyperbolic function.

$$\vec{d_k^f} = tanh(\hat{W}_h \vec{d_k} + \hat{b}_h), \qquad (13)$$

where $\hat{W}_h$ is the hidden layer weight matrix and $\hat{b}_h$ is the regularization matrix.

Finally, sentiment prediction for any label $l \epsilon L$ obtained by the softmax function defined below:

$$P(y = l|\vec{d_k^f}) = \frac{e^{\vec{d_k^f}^T \vec{W_l}}}{\sum_{l=1}^{L} e^{\vec{d_k^f}^T \vec{W_l}}} \qquad (14)$$

where $\vec{W_l}$ is the softmax weight for each label.

4 Performance evaluation

Our proposed CBA for sentiment classification is evaluated on four document sets: The first three datasets IMDB, Yelp 13, and Yelp14 which are review texts including user/product information developed by Tang (2015a). The last dataset IMDB2 is a plain text by Maas (2011). All four datasets are tokenized through the Stanford NLP tool (Manning et al., 2014).

Table 1 list the statistics of the datasets including number of classes, number of documents, and average length of sentence. We split train/development/test set in the rate of 8:1:1. The best configuration of the development dataset is used in the test set to obtain the final result.

Data	#class	#doc	#user	#pro	#len*[2]
IMDB	10	84,919	1,310	1,635	24.56
Yelp14	5	231,163	4,818	4,194	17.25
Yelp13	5	78,966	1,631	1,631	17.37
IMDB2	2	50,000	N/A	N/A	20.10

Table 1: Statistics of three benchmark datasets

Two commonly used performance evaluation metrics are used. The first one is accuracy and the second one is rooted mean square error (RMSE)[3]. Let GR_i be the golden sentiment ratings, PR_i be the predicted sentiment rating, and T be the number of documents where $GR_i = PR_i$. Accuracy is then defined by

$$Accuracy = \frac{T}{N}, \qquad (15)$$

and RMSE is defined by

$$RMSE = \sqrt{\sum_{i=1}^{N}(GR_i - PR_i)^2 * \frac{1}{N}}. \qquad (16)$$

We train the skip-gram word embedding (Mikolov et al., 2013) on each dataset separately to initialize the word vectors. All embedding sizes on the model are set to 200, a commonly used size.

Three sets of experiments are conducted. The first is on the selection of the regression model for reading time prediction. The second set of experiments compares our proposed CBA with another sentiment analysis method which use text only. The third set of experiments evaluates the effectiveness of combining different attention models.

4.1 Reading time prediction

The training for the regression model for reading time prediction using eye-tracking data requires the learning from text and context features as discussed in Section 3.1. We compare our regression model with more complex deep learning based regression models in each of the three eye-tracking datasets.[4]

[3] Normally accuracy is a problematic measure in highly unbalanced data sets. But in In IMDB, the largest class only takes less than 20% of all instances out of classes. The most imbalanced data are Yelp 13 whose largest class is 41% among 5 classes and second largest is about 30%. IMDB has a 50/50 split for 2-classes.

[4] Mishra et.al (Mishra et al., 2016a) only provides fixation time. So, fixation time is used when training by this set of eye-tracking data.

We take the first 90% of sentences as training data and the rest 10% as test data. The configuration that performs the best is selected and predicated on the document sentiment analysis dataset to obtain estimated reading time. Ideally, an eye-tracking corpus built from on-line reviews is more suitable for our experiments. But, we can only work with what is available.

In addition to the linear regression model(LL) and the Ridge regression model(RR), we also choose the Recurrent Neural Network (RNN) model and the Long Short Time Memory (LSTM) model for regression learning. For both models, there are two versions. The basic version inputs the extracted feature sets as word representation, labeled as RNN-1 and LSTM-1, respective. The second version takes word embedding (Pennington et al., 2014) as the initial word representation input, labeled as RNN-2 and LSTM-2, respectively. The RMSE results are listed in Table 2.

	GECO	DUNDEE	Mishra
LR	72.47	73.52	87.25
RR	69.47	70.52	84.22
RNN-1	75.47	83.52	96.23
LSTM-1	79.47	84.52	114.25
RNN-2	79.57	86.47	101.25
LSTM-2	83.88	95.88	122.27

Table 2: RMSE for reading time prediction(Unit:Milliseconds)

Note that Ridge Regression(RR) has the best performance on all the three datasets because regularization in RR reduces over-fitting problem.In three eye tracking datasets, the RR can achieve coefficient of determination[5] of 0.32, 0.30 and 0.27 in three eye tracking datasets. The features, their types and the corresponding coefficients in RR are shown in Table 3.

The more complicated deep learning models suffer from serious over-fitting problem. And the result of Deep learning model with word embedding initialization partly supports the fact that the reading time are more depend on the micro level syntax and semantic feature for the word, such as number of letters in word and complexity score of the word instead of the deep level context features.

4.2 Comparison of different sentiment classification methods

Because the features used in our model are all text based, we compare CBA with two groups of baseline methods which also only use review text for learning. Group 1 methods include commonly known linguistic and context features for SVM classifiers. Group 2 includes recent sentiment classification algorithms which are top performers using review text for training including one method that uses local attention model. Below is the list of Group1 methods.

Feature_Name	Type	Cofficient
Number of letters	Num	22.441
Start with capital letter	Bool	1.910
Capital letters only	Bool	161.580
Have alphanumeric letters	Bool	6.020
Is punctuation	Bool	-8.930
Is abbreviation	Bool	10.551
Is entity-critical word	Bool	7.612
Number of dominated nodes	Num	0.980
Max dependency distance	Num	1.982
Inverse document frequency	Num	-9.291
Number of senses in wordnet	Num	7.494
Complexity score	Num	57.240
Constant	Num	239.910

Table 3: Major features used by the Ridge Regression Model

- **Majority** — A simple majority based classifier based on sentence labels.
- **Trigram** — A SVM classifier using unigrams/bigrams/trigram as features.
- **Text feature** — A SVM classifier using word level and context level features, such as n-gram and sentiment lexicons.
- **AvgWordvec** — A SVM classifier that takes the average of word embeddings in Word2Vec as document embedding.

Here is a list of Group 2 methods:

- **SSWE** (Tang et al., 2014) — A SVM classifier using sentiment specific word embedding.
- **RNTN+RNN** (Socher et al., 2013) — A Recursive Neural Tensor Network(RNTN) to represent sentences and trained using RNN.
- **Paragraph vector** (Le and Mikolov, 2014) — A SVM classifier using document embedding as features.
- **LSTM+LA** (Chen et al., 2016) — State-of-the-art LSTM using local context as attention mechanism in both sentence level and document level.

CBA based models	LSTM+CBA^M	0.447	1.495	0.610	0.746	0.613	0.768
	LSTM+CBA^D	0.468	1.419	0.623	0.706	0.628	0.702
	LSTM+CBA^G	**0.489**	**1.365**	**0.638**	**0.697**	**0.641**	**0.678**

Table 4: Evaluation on sentiment classification using review text for training

- **CLSTM** (Xu et al., 2016) — Cached LSTM to capture the overall semantic information in long text. The two variations include regular **CLSTM** and bi-directional **B-CLSTM**.

- **LSTM+UPA** (Chen et al., 2016) — State-of-the-art LSTM including LA as well as user/product as attention mechanism at both sentence level and document level.

Our proposed CBA model has several variations as explained below.

- **LSTM+CBA** — The LSTM classifier using only CBA model at sentence level and document level. Based on the three eye-tracking datasets(GECO, DUNDEE and Mishra's) for reading time prediction, we label the same model by different training data as **LSTM+CBA**^{G},**LSTM+CBA**^{D} and **LSTM+CBA**^{M}.

- **LSTM+CBA+LA**^{G} — The LSTM based classifier using both the CBA model and the local text context based attention model(LA) (Chen et al., 2016). Since combining method can either be serial or in parallel, there are actually two corresponding variations: LSTM+CBA+LA$_s^G$ and LSTM+CBA+LA$_p^G$.

- **LSTM+CBA+UPA**^{G} — The same framework to **LSTM+CBA+LA**^{G} with additional user/product attention. The two corresponding variations are LSTM+CBA+UPA$_s^G$ and LSTM+CBA+UPA$_p^G$.

Table 4 shows the performance of the three groups using review text without user/product information on only the first three datasets methods in Group 1 and Group 2 do not have evaluations on IMDB2. Among all the reference methods that do not use any attention mechanism including all methods in Group 1 and Group 2(except LSTM+LA), LSTM is the best performer. LSTM+LA (2016), which is the state-of-the-art method, uses local attention mechanism to improve performance significantly. Among our CBA based variations, using the GECO dataset gives the best result outperforming LSTM+LA in all three datasets. LSTM+CBA^G has significant improvement over LSTM+LA with p values of $p < 0.016$ on IMDB, $p < 0.0019$ on Yelp 13, and $p < 0.00023$ on Yelp 14. LSTM+CBA^G has the best result compared to the other two variations because GECO has larger participant size. Its text genre is also closer to the review datasets for sentiment analysis.

In the third set of experiment, we compare our LSTM+CBA model with the combination of other attention models including the LA model and the UPA model as shown in Table 5. In the second set of experiment, since the GECO dataset gives the best performance, Table 5 shows the performance of LSTM+CBA using only the GECO dataset including LSTM+CBA^G, LSTM+CBA+LA$_s^G$, LSTM+CBA+LA$_p^G$, LSTM+CBA+UPA$_s^G$,and LSTM+CBA+UPA$_p^G$. Note that UPA is build based on user/product information. So it works

	IMDB		Yelp13		Yelp14		IMDB2	
	ACC	RMSE	ACC	RMSE	ACC	RMSE	ACC	RMSE
LSTM+LA	0.487	1.381	0.631	0.706	0.631	0.715	0.885	0.337

Table 5: Evaluation on sentiment classification on using dual attention

only if user/product information is available. Such data is provided in the first three sets of data.

Table 5 shows that among all three single attention models, UPA outperforms both LA and CBA in the first three datasets. This is easier to understand as UPA already included LA and it has more explicit information from users and products for its attention model compared to CBA which needs to learn hidden attention information. The combined method of CBA with UPA can still further improve performance. When CBA+UPA are combined in parallel, it has the best performance for both Yelp13 and Yelp14 (with p value of 0.027 and 0.032 respectively compare to LSTM+UPA). In the IMDB dataset, however, UPA has the best performance. This may be because user/product information is more effective in movie review IMDB dataset which is more subjective.

However, the UPA model works only if user and product information is available. Thus for IMDB2 where user/product information is not available, only CBA and LA models work and the combined use of CBA+LA gives the best performance.

4.3 Case study

A random sentence sample *'The Shelton hotel is lucky to receive 2stars from me considering ...'* is taken from the Yelp13 dataset to demonstrate the difference in the two attention mechanisms, i.e. local text(LA), and cognition-based(CBA). Figure 1 shows visually the difference in attention weights of the two models.

The attention weights of words in the LA model does not change much. CBA, on the other hand, gives higher weights to the sentiment linked word *2stars* and the verb *receive*. This two words do play significant roles as an indirect object and a main verb, respectively. This case shows that CBA does a better job in capturing micro level information in the sentence level. This support the experimental results in Table 4 and Table 5.

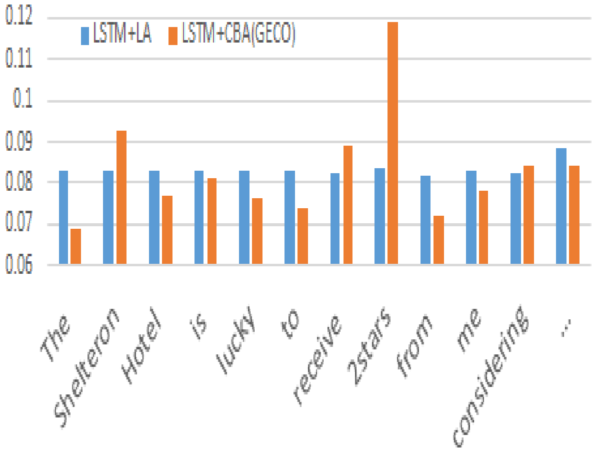

Figure 1: Case Study on attention weights

5 Conclusion and future works

In this paper, we propose a novel cognition based attention model to improve the state-of-the-art neural sentiment analysis model through cognition grounded eye-tracking data. A simple and effective regression model is used to predict reading time using both eye-tracking data and local text features. The predicted reading time is then used to build an attention layer in neural sentiment analysis models. The attention model considers both reading time and other syntactic and context features. It works in both the sentence level and the document level sentiment analysis.

Evaluation on benchmarking datasets validates the effectiveness of our method in sentiment analysis as our method clearly outperforms other state-of-the-art methods that use local context information to build their attention models. Our CBA mechanism can also be combined with other attention mechanisms to provide room for further improvement. Future work includes using other eye-tracking information such as saccade and fixation. The incorporation of other information such as user-product information can also be explored.

Author-aware Aspect Topic Sentiment Model to Retrieve Supporting Opinions from Reviews

Lahari Poddar, Wynne Hsu, Mong Li Lee
School of Computing

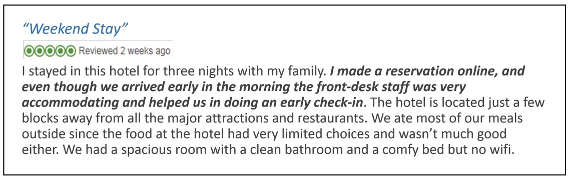
{lahari, whsu, leeml}@comp.nus.edu.sg

Abstract

User generated content about products and services in the form of reviews are often diverse and even contradictory. This makes it difficult for users to know if an opinion in a review is prevalent or biased. We study the problem of searching for supporting opinions in the context of reviews. We propose a framework called SURF, that first identifies opinions expressed in a review, and then finds similar opinions from other reviews. We design a novel probabilistic graphical model that captures opinions as a combination of aspect, topic and sentiment dimensions, takes into account the preferences of individual authors, as well as the quality of the entity under review, and encodes the flow of thoughts in a review by constraining the aspect distribution dynamically among successive review segments. We derive a similarity measure that considers both lexical and semantic similarity to find supporting opinions. Experiments on TripAdvisor hotel reviews and Yelp restaurant reviews show that our model outperforms existing methods for modeling opinions, and the proposed framework is effective in finding supporting opinions.

1 Introduction

In order to make an informed decision when booking a hotel online, a user will often read through its reviews looking for specific feedbacks. For example, if he or she plans to do an early check-in and comes across a review that mentions a hassle-free early check-in as shown in Figure 1, it will be helpful to know whether other guests had similar experiences. If a review complains about bed bugs or noise from construction nearby, then it is important to know if that was an occasional problem based on a single user's experience or happens frequently. However, it is impossible for an individual to go through the large volume of reviews to verify whether an opinion is prevalent.



"Weekend Stay"

●●●●● Reviewed 2 weeks ago

I stayed in this hotel for three nights with my family. ***I made a reservation online, and even though we arrived early in the morning the front-desk staff was very accommodating and helped us in doing an early check-in***. The hotel is located just a few blocks away from all the major attractions and restaurants. We ate most of our meals outside since the food at the hotel had very limited choices and wasn't much good either. We had a spacious room with a clean bathroom and a comfy bed but no wifi.

Figure 1: A sample hotel review

In this work, we study the problem of finding supporting sentences from reviews that corroborate the opinions expressed in a target review sentence. This is useful as it enables users to easily look for appropriate comments on the specific issues they are interested in.

A review is a collection of sentences where each sentence may have multiple segments separated by punctuations or conjunctions. Each segment expresses an opinion that can be represented as a combination of aspect, topic and sentiment. An aspect refers to the overall theme of a segment, a topic is the specific subject or issue discussed and the sentiment for each topic can be neutral, positive or negative. Table 1 shows the segments and the possible latent aspect, topics and sentiment for a sentence of the review in Figure 1.

Review Sentence	Segments	Aspect	Topic	Sentiment
We had a big room with clean bathroom and a comfy bed, but no wifi	We had a big room with clean bathroom	room	room	positive
			bathroom	positive
	a comfy bed	room	bed	positive
	no wifi	amenities	wifi	negative

Table 1: Opinion structure for a review sentence

Given an opinion (in a target segment), we say that a review supports the opinion, if it contains some segment whose aspect, topic and sentiment are similar to those in the target segment. Finding such supporting reviews is a challenge since

Proceedings of the 2017 Conference on Empirical Methods in Natural Language Processing, pages 472–481
Copenhagen, Denmark, September 7–11, 2017. ©2017 Association for Computational Linguistics

reviews are typically short unstructured text and discuss a wide range of topics on various aspects with differing sentiments and vocabulary used.

Topic modeling have been widely used to reduce the effect of huge vocabulary by grouping words in topics. However, the fundamental assumption of topic models is the independence of topics even in the same document. This fails to capture the natural coherence present in reviews, which rarely consist of isolated, unrelated sentences, but are composed of collocated, structured and coherent groups of sentences (Hovy, 1993). We observe that an author's train of thoughts when writing a review is often linear, i.e., he or she will finish discussing one aspect before moving on to the next. In Figure 1, we see that the user first commented on *Service* (*"front-desk staff was very accommodating"*), then the *Location* aspect, followed by the comment on *Food*, and finally moved on to *Room*. This shows that aspects discussed in a review are not chosen from a simple *independent mixture*, but rather, words in close proximity tend to discuss the same aspect and within a review the aspects discussed in the current segment will affect the possible aspects for the successive segments.

We explicitly model this by constraining aspect transition between segments using a review specific Markov chain. Each segment is assumed to discuss a single aspect and possible aspects for a segment are made dependent on the aspects of the previous segments. By tracking aspects of previous segments we are able to ensure constrained aspect sampling for accurate modeling of a review structure. This non-iterative nature of discourse has not been considered by existing works.

For opinion modeling, capturing the sentiment expressed for an aspect is important. Recent works (Kim et al., 2013; Jo and Oh, 2011; Moghaddam and Ester, 2011; Wang et al., 2010; Titov and McDonald, 2008a,b) have developed models to capture aspect and sentiment. However, they do not consider the preferences of authors, or the inherent quality of the entity for the aspect. In a hotel review, the sentiment expressed for *service* depends on both the service standard of the hotel (evident from the sentiment distribution of *service* of all reviews for the hotel) and the expectation of the author for *service* (evident from the sentiment distribution of the author on *service* across all hotels) (Poddar et al., 2017). We take this into account by making the sentiment distribution of a review dependent on both entity and author.

We propose an Author-aware Aspect Topic Sentiment model (Author-ATS) to capture the diverse opinions, taking into account user preferences and thought patterns. The model considers a word to be generated from a hierarchy of aspect, topic and sentiment and encodes the coherent structural property of a review by dynamically constraining aspect distributions. We also develop a non-parametric version of Author-ATS based on Dirichlet Process called Author-ATS (DP).

We develop a SUpporting Review Framework (SURF) that utilizes the Author-ATS model to compute the lexical and semantic similarity of an opinion in a target segment to those in the review corpus, and returns the top-k supporting reviews. Experiments on real world review datasets show the effectiveness of Author-ATS in modeling opinions compared to existing topic models. Furthermore, SURF outperforms keyword-based approaches and word embedding based similarity measures in finding supporting opinions. To the best of our knowledge, this is the first work to find supporting reviews for an opinion expressed in user generated contents.

2 Related Work

There has been substantial research to mine online reviews using topic models (Paul and Girju, 2010; Trabelsi and Zaiane, 2014; Lin and He, 2009; Jo and Oh, 2011; Mukherjee and Liu, 2012; Chen et al., 2013). The Topic Aspect Model (TAM) (Paul and Girju, 2010) jointly discovers aspects and topics from documents. The aspect and topic are independent and each aspect affects all topics in similar manner. However, in reviews, the topics discussed are often closely related to an aspect. JTV (Trabelsi and Zaiane, 2014) encodes topic-viewpoint dependency, but assumes that a document contains only one aspect. JST (Lin and He, 2009) assumes that there is a single sentiment polarity for a review and the topics are chosen conditioned on that, while ASUM in (Jo and Oh, 2011) assumes that all words in a sentence are associated with the same topic and sentiment. In contrast, our proposed model handles the more realistic scenario where sentiments may vary depending on the topics discussed in a review.

For incorporating author information, the User-Sentiment topic model (Zhao et al., 2012) considers the topic-sentiment distribution only from the author perspective and ignores the characteristics of the entity. Supervised topic model (Li et al., 2014) uses explicit ratings to infer sentiments. PDA-LDA (Zhang and Wang, 2015) associates its Dirichlet prior distribution with user and item topic factors. The work in (Yang et al., 2015) models aspects and sentiments based on the demography of authors. However, such demographic information are not always available and it cannot model the bias or preference of an individual.

Additionally, most topic models are concerned about the discourse at word level, and ignore the document structure. HTMM (Gruber et al., 2007) models topic coherence by considering topic transition between sentences. HTSM (Rahman and Wang, 2016) extends HTMM by capturing sentiment shifts along with topic coherence. Both models do not capture the non-repetitive discourse of reviews. Progressive topical dependency model (Du et al., 2010, 2015) captures the sequential nature of ideas among segments, especially in movies or books. However, unlike books, the sequence of topics in reviews is not significant. Rather, once a topic has been discussed in a review, it is unlikely to be mentioned again in a later segment. From this perspective, it is similar to labeled LDA (Ramage et al., 2009) where topic distribution of a document is constrained. However, unlike labeled LDA, the possible aspects of a segment are dynamically constrained depending on previously sampled aspects.

3 Author-ATS Model

Author-ATS models an opinion as hierarchical dependent mixtures, where words are generated from a three-level hierarchical structure of aspects, topics and sentiments. We assume there are A distinct aspects for a domain, for each aspect there are Z topics and for each aspect-topic pair S possible sentiments. We treat a segment as the basic semantic unit, discussing a particular aspect. A review r is a collection of D_r segments where each segment is a document d, consisting of N_d words. We now describe the assumptions and detailed construction of the proposed model.

3.1 Constrained Aspect Generation

We explicitly model the behavior that after an author has finished discussing an aspect and has moved on to the next, he or she is unlikely to return to it again. We assume that each document d discusses a single aspect a_d. The aspect distribution σ_r is drawn from a Dirichlet with parameter α. In order to model the linear writing style of authors, we constrain the possible aspects that can be sampled from σ_r. Whenever an author starts writing a segment, he or she can choose to either (a) talk about an aspect not yet discussed, or (b) continue with the aspect of the previous segment. This is captured by imposing the constraint that the aspect of the j^{th} document is dependent on the aspects of the $(j-1)^{th}, (j-2)^{th}, \cdots, 1^{st}$ documents of the same review.

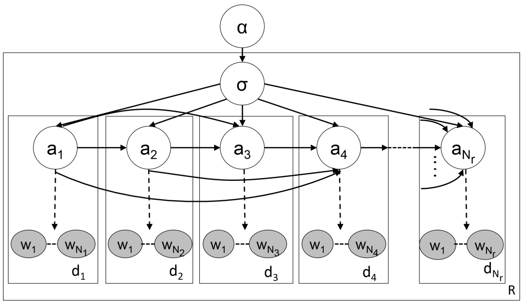


Figure 2: Constrained aspect generation in Author-ATS. Aspects in review form a Markov chain.

With this we relax the *independent mixture* assumption of the standard LDA model for aspects and form a review-specific Markov chain (see Figure 2). Such a higher order Markov chain would normally incur intractable computational complexity due to the exponential size of transition probability matrix. However, in our case, the transition probability can be determined by overall aspect distribution of the review, σ_r and a list of possible aspects for the segment. Since we assume a non-repetitive nature of discourse, the number of possible aspects for a segment is monotonically decreasing for successive segments. This special property enables us to devise a dynamic programming strategy to solve the problem with linear complexity.

Each document is associated with a binary aspect vector Λ. We restrict the sampled aspect of a document to be drawn from only the aspects that are turned on, in Λ of that document. For a document d, $\Lambda_d =< l_1, \cdots, l_A >$ where each $l_a \in \{0, 1\}$ and A is the total number of aspects. Traditionally, for a document d, an aspect a_d is sampled from a multinomial distribution σ_r. Here, we restrict the possible sampled aspects to the list Λ_d. A value of 1 for the entry l_a indicates that the aspect a can be sampled, while 0 indicates that the aspect should not be sampled.

We generate Λ_d by tossing a Bernoulli coin for each aspect a with prior probability Φ_a for value 0. We set Φ_a as the sampling probability for aspects which have been sampled for a previous document. This ensures that an aspect which has been discussed before has lesser probability of coming up again. We set $\Phi_a = 0$ for aspects not sampled in the past, and for the aspect of (immediately) preceding segment. This models aspect coherency in a review document where an author either chooses to discuss a new aspect or continues to talk about the current one.

We define the list of possible aspects for the document d to be $\lambda_d = \{a \mid \Lambda_d[a] = 1\}$. We sample an aspect a_d from σ_r with the constraint that $a_d \in \lambda_d$ i.e. an aspect can be sampled for a document only if it is turned on in the binary aspect vector for the document and thereby exists in the list of possible aspects for the document. Thus, the aspect transition probability among documents becomes dependent on σ_r and the vector λ_d. Unlike regular topic models, Author-ATS is no longer invariant to reshuffling of words and is able to model linear aspect coherency in a review.

3.2 Author-Entity dependent Sentiment Distribution

We account for the dual role of entity and author in a review, by observing that the sentiments expressed are influenced by both the quality of the entity being reviewed and the preferences of the author. We use two Dirichlet distributions to derive sentiment, namely, entity-dependent distribution (ξ) and author-dependent distribution (χ). For each aspect-topic combination, ξ is drawn from a Dirichlet distribution with prior γ^1 and χ is drawn from a Dirichlet distribution with prior γ^0.

Since online reviews describe experiences of people, some words tend to appear frequently (e.g.: 'hotel','trip' or 'mobile', 'phone' for hotel and mobile reviews respectively). We call them *domain stopwords* as they are not specific to any aspect. We use a binary switching variable y_i to determine the type for the i^{th} word. If $y_i = 0$, then the word is aspect neutral (domain stopword); and if $y_i = 1$, it is aspect dependent.

The generative process of the model is as follows:

- Draw a multinomial word distribution ϕ_0 for domain stopwords and ϕ_1 for each aspect, topic and sentiment words from Dir (ω).
- For each author u, draw a multinomial sentiment mixture χ for each aspect and topic from Dir(γ^0)
- For each entity e, draw a multinomial sentiment mixture ξ for each aspect and topic from Dir (γ^1)
- For each review r:
    1. Draw multinomial aspect mixture σ from Dir(α)
    2. For each document $d \in r$:
        (a) Draw Λ_d from Bernoulli (Φ)
        (b) Draw a type mixture ψ from Beta (δ_0, δ_1)
        (c) Sample an aspect a_d from σ s.t. $a_d \in \lambda_d$
        (d) For sampled aspect a_d, draw a topic mixture θ from Dir (β)
        (e) For each word position i where $0 \leq i \leq N_d$
            i. Sample a type y_i from ψ
            ii. Sample a topic z_i from θ
            iii. Sample a sentiment s_i from χ and ξ
            iv. Sample a word w_i from $\begin{cases} \phi_0 & \text{if } y_i = 0, \\ \phi_1 & \text{if } y_i = 1 \end{cases}$

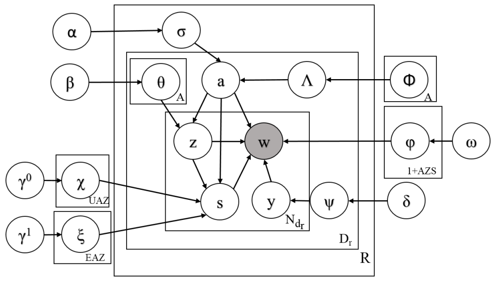

Figure 3: Graphical representation of Author-ATS

Note that for the first document of a review, we set λ_0 to the set of all possible aspects, such that there is no constraint when sampling for the first segment of a review. Figure 3 shows the plate notation for Author-ATS model.

3.3 Bayesian Inference

We employ collapsed Gibbs sampling for inference. Markov chain introduced for aspect coherency makes the aspects non-exchangeable, hence sampling an aspect for a segment will also affect all subsequent segments. Since the exact sampling for this would be computationally expensive, we propose the following approximate posterior considering only the previous segments, which has been shown to work well in similar cases previously (Mimno et al., 2011).

We sample an aspect (a_d) for each document based on the posterior probability of the type, topic and sentiment assignment of each word in the document and the aspects sampled for preceding documents in the review.

$$\begin{aligned} P(a_d|a_{\vec{-d}},\vec{y}_{-d},\vec{z}_{-d},\vec{s}_{-d},\vec{w}) &\propto P(a_d|a_{1:\vec{d}-1}) \\ &\prod_{z=1}^{Z}\prod_{s=1}^{S}\frac{\sum_{w=1}^{W}B(n_w^{a_d,z,s}+\omega)}{\sum_{w=1}^{W}B(n_w^{a_d,z,s,-d}+\omega)} \end{aligned} \tag{1}$$

$$P(a_d|a_{1:\vec{d}-1}) \propto \begin{cases} \frac{n_{a_d}^{r,-d}+\alpha}{\sum_{a\in\lambda_d} n_a^{r,-d}+|\lambda_d|*\alpha} & \text{if } a_d \in \lambda_d \\ 0 & \text{otherwise} \end{cases} \tag{2}$$

where $B(\vec{x})$ is the multidimensional extension of the Beta function. The notation $n_a^{b,-c}$ refers to the number of times a has been assigned to b excluding current occurrence c, e.g. $n_{a_d}^{r,-d}$ denotes the number of documents in review r that has been assigned aspect a_d excluding current document d.

The target aspect a_d is dependent on the aspects sampled for the 1^{st} to $(d-1)^{th}$ documents of the review, denoted by $a_{1:\vec{d}-1}$. We restrict the target aspect a_d to belong to the set defined by Λ_d of the document d to achieve coherence among aspects respecting the nature of discourse observed in review writing styles. This constrained aspect sampling differentiates Author-ATS from existing topic modeling works on review text by explicitly modeling the topic coherence of opinionated text.

After sampling the aspect for the document, we jointly sample the latent type, topic and sentiment for each word within the document. The posterior for the i^{th} word of document d (written by author u for entity e) is given as:

$$P(y_i, z_i, s_i | a_d, \vec{w}, \vec{y}_{-i}, \vec{z}_{-i}, \vec{s}_{-i}) \propto P(y_i|d) * P(z_i|a_d, d)$$
$$* P(s_i|a_d, z_i, u, e, d) * P(w_i|y_i, a_d, z_i, s_i,) \qquad (3)$$

$$\propto \frac{n_{y_i}^{d,-i} + \delta_{y_i}}{\sum_{y=0}^{1}(n_y^{d,-i} + \delta_y)} * \frac{n_{z_i}^{d,a_d,-i} + \beta}{\sum_{z=1}^{Z} n_z^{d,a_d,-i} + Z\beta} *$$
$$\Big(q_1 \frac{n_{s_i}^{u,a_d,z_i,-i} + \gamma^0}{\sum_{s=1}^{S} n_s^{u,a_d,z_i,-i} + S\gamma^0} + q_2 \frac{n_{s_i}^{e,a_d,z_i,-i} + \gamma^1}{\sum_{s=1}^{S} n_s^{e,a_d,z_i,-i} + S\gamma^1}\Big)$$
$$* \frac{n_{w_i}^{\zeta,-i} + \omega}{\sum_{w=1}^{W} n_w^{\zeta,-i} + W\omega} \qquad (4)$$

$$y_i = 0 \Rightarrow \zeta = y_i$$
$$y_i = 1 \Rightarrow \zeta = a_d, z_i, s_i$$

For sampling sentiment, instead of using a single Dirichlet density we use a Dirichlet mixture as the prior (Sjölander et al., 1996; Smucker et al., 2005). It is a weighted combination of two individual Dirichlet densities χ and ξ. Mixture coefficients q_1, q_2 are set to 0.5, giving equal weights to both author and entity. This ensures that the chosen sentiment reflects both the entity's quality for that topic as well as the author's preferences.

3.4 Non-parametric Author-ATS (DP) Model

While the number of aspects for a domain are limited, the number of topics for each aspect may vary significantly and can be difficult to estimate. For restaurants, the topics for *ambiance* are fewer (e.g. music, crowd etc.) compared to *food*. This motivates us to propose a non-parametric version of the Author-ATS model where the number of topics can be automatically discovered.

In this non-parametric version, topic inference is done through Chinese Restaurant Process (CRP), a popular variant of Dirichlet Process (DP). In a Chinese restaurant with infinite number of tables, each with infinite capacity, CRP determines if a customer chooses to sit at an occupied table (with a probability proportional to the number of customers already sitting at the table), or an unoccupied one. Following the idea of CRP, each observed aspect dependent word can either be assigned to an existing topic or to a new topic. The conditional distributions for the Gibbs sampler are omitted due to space constraints.

4 SURF Framework

Given a target sentence in a review SURF computes its similarity with other review sentences using the distributions learned by Author-ATS and returns a list of supporting reviews.

A sentence supports another sentence if they are either lexically or semantically similar. Two sentences are **lexically similar** if they share keywords that are important for an aspect. Whereas two sentences can be **semantically similar** if they share the same sentiment for an aspect and topic even though they use different words. For example, *"The hotel was quite close to space needle"* and *"Major attractions are just walking distance from the hotel"* have high semantic similarity as they both talk about the same aspect 'location' on the topic 'attractions' with a positive sentiment.

We treat each review sentence as a vector and lexical similarity ($lexical\_sim$) is computed as cosine-similarity between the two vectors. The i^{th} entry of a vector signifies importance of the corresponding word to its assigned aspect computed using the *tf-idf* weighting scheme. We define the tf-idf of a word w w.r.t. an aspect a as:

$$tf(w,a) = \sum_{d=1}^{D} P(w|d,a)$$

$$P(w|d,a) = \begin{cases} P(w) & \text{if } w \text{ assigned to } a \text{ in } d \\ 0 & \text{otherwise} \end{cases}$$

$$idf(w, \mathbf{A}) = log \frac{A}{1 + |a \in \mathbf{A} : \exists d \in \mathbf{D}, P(w|d,a) > 0|}$$

$P(w)$ is the generation probability obtained from Author-ATS model. Since words are important with respect to an aspect, unlike traditional tf-idf, these values are computed across reviews on the whole corpus. Words frequently used for describing an aspect often tend to converge across reviews, even though written by different users.

Two sentences are considered semantically similar if they share the same sentiment for an aspect. Let C be the set of words in a sentence. Aspect-topic probability of a sentence is defined as the ratio of generation probability of words generated from the aspect-topic pair a, z to the summation of generation probabilities of all the words.

$$P(C|a,z) = \frac{\sum_{w \in C} P(w|w \text{ has aspect } a \text{ and topic } z)}{\sum_{w \in C} P(w)}$$

We define sim_0 to measure the similarities between two sentences (C_1 and C_2) having the same aspect, topic and sentiment, and sim_1 to measure the similarities of two sentences with the same aspect and sentiment but discussing different topics.

$$sim_0(C_1, C_2, a) = \sum_{z=1}^{Z} P(C_1|a,z)P(C_2|a,z)$$
$$sim_1(C_1, C_2, a) = \sum_{z_1, z_2 \in [1 \cdots Z] z_1 \neq z_2} P(C_1|a,z_1)P(C_2|a,z_2)$$

The semantic similarity between two sentences is:

$$\begin{aligned} semantic\_sim(C_1, C_2, a) = {} & sim_0(C_1, C_2, a) \\ & + \delta sim_1(C_1, C_2, a) \end{aligned}$$

where δ is a damping factor with value less than 1.

Lexical-semantic similarity (LSS) of two sentences with same sentiment for an aspect is measured as a weighted combination of their $lexical\_sim$ and $semantic\_sim$ as defined above.

Ranking of Reviews. Given a review sentence, we employ kNN search to find the k most similar sentences for each of its aspects according to LSS measure. Since a target sentence C may contain multiple aspects, we determine the importance of an aspect a to C as follows:

$$Imp(C,a) = \frac{\sum_{w \in C} P(w|w \text{ has aspect } a)}{\sum_{w \in C} P(w)}$$

For each aspect a with $Imp(C,a) > 0$, we return the top $k * Imp(C,a)$ sentences from the review corpus. Proportionately allocating supporting sentences from each aspect in the top-k results diversifies the result set and ensures that a user is able to find information about whichever aspect of the target sentence she wished to verify.

5 Experiments

Dataset	# entity	# author	# review	# sentence	# vocab
TripAdvisor	12,773	781,403	1,621,956	20,244,293	980,323
Yelp	578	16,981	25,459	232,107	56,200

Table 2: Statistics of datasets used

We perform two sets of experiments to evaluate our proposed framework. We first compare Author-ATS with state-of-the-art topic models using perplexity on test data. Then we evaluate the performance of SURF, for the task of retrieving supporting opinions using human annotation, against keyword based search engine Lucene and a competent word embedding model Word2Vec. We use two real world datasets: (a) hotel reviews from TripAdvisor (Wang et al., 2010), and (b) restaurant reviews from yelp.com. Table 2 shows the statistics of the two datasets.

We pre-process both datasets by removing domain independent stopwords[1]. We retain some negation stopwords (e.g.: *not, can't, didn't*) and join them with the next word (so that 'not good' is treated as a single unit) to help discover sentiment properly. We use common punctuations like '.', '?', '!' to split into sentences. To further split a sentence into segments we use punctuations used to separate clauses like ',', ';' and conjunctions like 'and', 'however', 'but' as separators. We use a domain independent subjectivity lexicon[2] to initialize sentiment distributions. Since aspect words may consist of highly co-occurring words (e.g. 'front-desk', 'walking distance') we use Pointwise Mutual Information (PMI) (Manning and Schütze, 1999) to find such collocations. Bigrams with PMI greater than a threshold (we use 0.05 in our experiments) are treated as a single word.

To make the discovered aspects understandable and intuitive, we provide a few seed words to the models. The seeds are only used during initialization and subsequent iterations of Gibbs sampling are not dependent on them. Table 3 lists the aspect seed words used for both domains.

Aspects	Seed Words
Value for Money	value, rate, price
Room	room, bed, bathroom, clean
Location	location, walk, minute
Service	staff, reservation, front-desk
Food	restaurant, breakfast, buffet
Amenities	pool, parking, internet, wifi

(a) TripAdvisor Dataset

Aspects	Seed Words
Value for Money	value, rate, portions, price
Service	ambience, wifi, music, service
Food	steak, rice, burger, cocktail

(b) Yelp Dataset

Table 3: Sample Aspect Seed Words

[2] http://mpqa.cs.pitt.edu/lexicons/subj_lexicon

5.1 Evaluation of Author-ATS Model

In this set of experiments, we examine the ability of Author-ATS to capture the opinions in reviews.

Perplexity is derived from the likelihood of unseen test data and is a standard measure for evaluating topic models. The lower the perplexity, the less confused the model is on seeing new data, implying a better generalization power. We compare with the following state-of-the-art opinion models:

LDA (Blei et al., 2003) : A topic model where words are generated from a latent topic dimension.

TAM (Paul and Girju, 2010): A topic model for opinion mining where words are generated from a two-level hierarchy of aspect and topic.

JTV (Trabelsi and Zaiane, 2014): A topic model especially for contentious documents where each word has a topic and a viewpoint.

We also implement a baseline model **ATS** based on three-level Aspect-Topic-Sentiment hierarchy. We use this model to show the performance gain by just considering a hierarchical dependency between these dimensions while capturing an opinion. For Author-ATS and ATS, we use 6 aspects, 5 topics for each aspect and 3 sentiments. For fair comparison, we keep the total number of dimensions as close as possible across models. We partition our dataset into train (80%) and test (20%) sets and report five fold cross validation results.

Table 4 shows that ATS outperforms other models in both datasets due to its hierarchical modeling of words. Author-ATS further improves the performance by considering author and entity characteristics as well as the thought patterns of the authors. We note that the performance of the non-parametric model is comparable with Author-ATS, making it easier to use the model for any new domain without having much prior knowledge.

Model	**TripAdvisor**	**Yelp**
LDA	5070	5737
TAM	2980	3468
JTV	3430	4370
ATS	2385	3337
Author-ATS	**2212**	**2784**
Author-ATS(DP)	2300	2829

Table 4: Perplexity values for different models.

Table 5 shows the top words extracted by Author-ATS as domain stopwords. Although these words do not convey any aspect information, they are domain dependent and are not found in a general stopword dictionary.

From Table 6, we observe that the majority of the words are correctly clustered in aspects, and further into specific topics. For example, the first topic for aspect *Room* is about in-room experience ('bed','king-size','view'), whereas the second topic seems to be about bathroom ('shower', 'towels', 'tub'). We also observe that the model is able to obtain contextual sentiment terms which are aspect-topic coherent. For example, words such as 'noise', 'night', 'hear' could be assigned negative sentiment labels for topic 0 of *Room* due to the context in which they are used, e.g., when describing a room, these words probably indicate a noisy room bothering their sleep at night.

Dataset	Domain Stopwords
TripAdvisor	hotel, nice, stay, trip, times, day, place, back
Yelp	good, place, food, time, order, bit, make

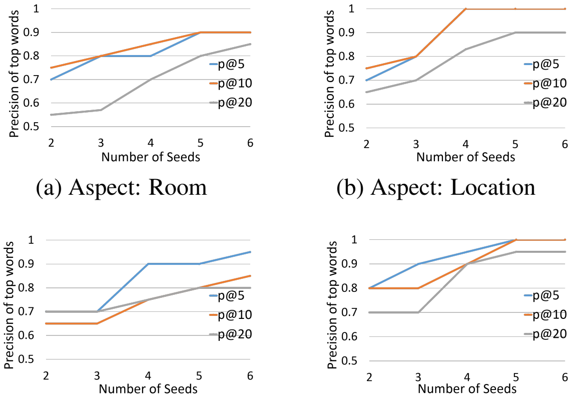
Table 5: Domain stopwords from Author-ATS.

Aspect: **Room**		
Topic 0		
Positive	Negative	Neutral
bed	noise	room
comfortable	night	floor
spacious	sleep	view
king-size	window	size
clean	hear	modern
Topic 1		
Positive	Negative	Neutral
bathroom	small	room
large	door	bathroom
tub	barely	shower
shower	tiny	water
shampoo	kitchen	towels

Aspect: **Service**		
Topic 0		
Positive	Negative	Neutral
staff	night	staff
extremely	greet	call
welcoming	problem	front-desk
care	asked	service
friendly	manager	shuttle
Topic 1		
Positive	Negative	Neutral
card	called	check-in
reservation	upgrade	day
airport	manager	arrived
polite	rude	directions
excellent	questions	time

Table 6: Top words for aspect-topic-sentiments found by Author-ATS for TripAdvisor dataset.

Impact of Seed Words We vary the number of seed words for an aspect and examine its effect on the aspect discovery. We use $p@n$, the fraction of correctly discovered aspect words among the top n words, to evaluate the quality of the results.



(a) Aspect: Room

(b) Aspect: Location

(c) Aspect: Service

(d) Aspect: Food

Figure 4: Impact of varying number of seeds.

The average precision of top-n words for different aspects is obtained by taking the average over all combinations $\binom{6}{m}$ of seed words where m is the number of selected seed words, $2 \leq m \leq 6$. Figure 4 shows the results. We observe that the average precision increases with the number of seeds, and stabilizes when $m \geq 4$. This demonstrates that providing a handful of seed words can go a long way for discovering intended, explainable domain specific aspects.

5.2 Evaluation of SURF

We now evaluate Author-ATS model and LSS measure on retrieving sentences that are *relevant* to a target sentence. A sentence is considered relevant if it expresses similar opinions as the target sentence. A sentence with multiple aspects is relevant if it expresses at least one of the opinions in the target sentence. Precision of the top-k answers are manually determined by three annotators and conflicts are resolved by majority voting.

Recall that LSS considers both lexical and semantic similarity. The computation of semantic similarity requires the aspect-topic-sentiment distribution which is only available in the baseline ATS and Author-ATS models. We define a similarity measure called CJSD that can be used by the various topic models to facilitate comparison. CJSD measures the lexical similarity of two sentences as the cosine similarity of their tf-idf vectors, while the semantic similarity is measured by the similarity of their topic distributions using Jensen-Shannon Divergence(JSD) as follows:

$$CJSD(s_1, s_2) = \lambda\, cosine\_sim(s_1, s_2) + (1-\lambda)\, JSD(s_1, s_2)$$

We randomly select 5 hotels from TripAdvisor and 5 restaurants from Yelp datasets. For each hotel/restaurant, we randomly pick 10 target sentences and retrieve their supporting sentences.The topic distributions of these sentences are obtained using LDA, TAM, JTV, and the proposed models ATS and Author-ATS.

Table 7 shows the average precision for top 5, 10 and 20 results retrieved using various topic models with similarity measure CJSD. We see that Author-ATS model always outperforms other topic models for the task of retrieving supporting sentences. This is consistent with the perplexity results of the models obtained previously.

Table 8 shows the average precision using variants of the proposed model with LSS. Clearly, using LSS always yields a better precision compared to using CJSD, with the best performer being the Author-ATS with LSS combination. SURF framework utilizes this combination for retrieving top-k supporting reviews.

	TripAdvisor			Yelp		
	p@5	p@10	p@20	p@5	p@10	p@20
LDA	0.56	0.48	0.45	0.43	0.42	0.42
TAM	0.58	0.53	0.52	0.49	0.47	0.47
JTV	0.51	0.47	0.53	0.41	0.41	0.43
ATS	0.62	0.60	0.55	0.60	0.57	0.44
Author-ATS	**0.68**	**0.62**	**0.61**	**0.60**	**0.58**	**0.56**

Table 7: Average precision using CJSD

	TripAdvisor			Yelp		
	p@5	p@10	p@20	p@5	p@10	p@20
ATS	0.69	0.62	0.58	0.62	0.59	0.58
Author-ATS	**0.74**	**0.66**	**0.60**	**0.68**	**0.64**	**0.62**
Author-ATS (DP)	0.64	0.63	0.57	0.62	0.56	0.54

Table 8: Average precision using LSS

Next, we compare SURF with the following:

Lucene: A popular keyword based ranking method. We used its default combination of vector space model and boolean model for retrieval.

Word2Vec: (Mikolov et al., 2013) A state-of-the-art algorithm for word embeddings using neural network. Supporting sentences are ranked with Word Mover's distance using the word embeddings. We train on TripAdvisor dataset using CBOW algorithm with context window set to 5 as recommended by the authors. We do not train Word2Vec on the Yelp dataset as it is too small. We set the vector dimension to 500 based on grid search. We also compare with Word2Vec model pre-trained on the large GoogleNews dataset[3].

Table 9 shows the average precision for the top 5, 10 and 20 results retrieved using Lucene, Word2Vec and SURF. Word2Vec performs better when trained on review data, compared to the model trained on general news data. This confirms that domain knowledge is important. It is evident from the results that SURF significantly outperforms existing approaches for opinion search.

	p@5	p@10	p@20
Lucene	0.67	0.58	0.52
Word2Vec (GoggleNews)	0.62	0.48	0.39
Word2Vec (TripAdvisor)	0.70	0.61	0.51
SURF	**0.74**	**0.66**	**0.60**

(a) TripAdvisor

	p@5	p@10	p@20

Word2Vec (GoogleNews)	0.52	0.47	0.37
SURF	**0.68**	**0.64**	**0.62**

(b) Yelp

Table 9: Comparison with Lucene and Word2Vec

For evaluating the coherence of retrieved set of supporting reviews for an aspect, we look at their corresponding user given aspect ratings. For each aspect of each review sentence, we retrieve its top-k supporting sentences. Then we compute the

[3] https://code.google.com/archive/p/word2vec/

Target Sentence: bedroom had the most comfortable mattress, feather soft pillows as well as firmer ones, they thought of keeping every guest comfortable		
Supporting Sentences by **SURF**	Supporting Sentences by **Lucene**	Supporting Sentences by **Word2Vec**
Aspect : **Room** **Statement**: bill clinton suite was huge with two baths, a wonderful jacuzzi and a comfortable bed	bed was very comfortable, as were the large pillows	The room had a microwave, coffemaker, hairdryer, bottled water replenished each day **(x)**
Aspect : **Room** **Statement**: the beds are the most comfortable of any hotel I have stayed in	we were recommending it for our out of town wedding guests, and wanted to make sure they were comfortable **(x)**	It really is a shame because the bed and pillows were super comfortable and we could have had a great night sleep on both nights
Aspect : **Room** **Statement**: the beds were comfortable and they had good selection of towels	who would have imagined that somebody actually thought about where a guest would watch tv **(x)**	They took regular sized hotel rooms and divided them into a sitting room with a bedroom with a door, keeping the bathroom to divide the two areas **(x)**

(a) Target Sentence with Single Aspect

Target Sentence: the check in was quick, with friendly polite service, and the room was very big with a very comfortable king size bed		
Supporting Sentences by **SURF**	Supporting Sentences by **Lucene**	Supporting Sentences by **Word2Vec**
Aspect : **Room** **Statement**: bed was extremely comfortable, I'm hard to please in the department because I sleep on a sleep number bed at home	the room was a great size; bed was very comfortable	The first room assigned was very small and dingy with one king sized bed that just fit **(x)**
Aspect : **Room** **Statement**: room size was large and bed was comfortable	king size bed was comfy	bathroom was well furnished with soap, shampoo/ conditioner, very large, soft towels - perfect **(x)**
Aspect : **Service** **Statement**: service is very friendly	our room faced denny park **(x)**	the room was large and the bed very comfortable and our room faced the street and it was very quiet

(b) Target Sentence with Multiple Aspects

Table 10: Sample Supporting Sentences Retrieved by SURF, Lucene and Word2Vec. Aspects shown for SURF are discovered by Author-ATS model.

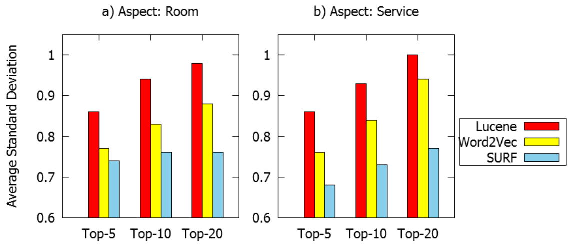

Figure 5: Average standard deviations of aspect ratings for supporting reviews. Smaller deviation implies greater coherence.

standard deviation of the ratings for that aspect in the retrieved supporting reviews. We aggregate the standard deviation values for each aspect over all the reviews and look at the average value. Figure 5 shows results for two aspects from the TripAdvisor dataset. Other aspects also had similar trends.

We rank the retrieved results based on their similarity to the target sentence. Naturally, the longer the retrieved list, the larger is the average standard deviation. We see that SURF has a smaller average standard deviation compared to Word2Vec and Lucene. The gap between the performance of SURF and the other methods also widens as the size of the retrieved results increases. This demonstrates SURF's superiority in retrieving reviews with similar opinions.

Table 10 shows samples of supporting sentences extracted by the different methods. We observe that the sentences retrieved by SURF are semantically similar although the words may be quite different from the target sentence. In contrast, Lucene may retrieve irrelevant sentences matching a keyword used in a totally different context. Word2Vec considers words used in proximity of one another (e.g. *bed, pillow* with *microwave, coffemaker* etc.) to be similar which clearly does not always imply conformity of opinions.

Furthermore, the retrieved results of SURF are categorized according to their aspects making them easy to interpret. Particularly if a target sentence has multiple aspects, then SURF will retrieve results for each aspect. For example, for the second target sentence shown in Table 10, the results contain supporting statements for both *room* and *service*. If a user then wishes to view more results for one of those aspects it will be possible for SURF to fetch more results only for that aspect.

6 Conclusion

We studied the problem of finding supporting sentences to help a user get an idea of consensus about an entity. To this end, we developed a hierarchical topic model to jointly infer aspect-topic-sentiment, and a fine-grained similarity measure. Author-ATS model encodes the coherent writing style of a review by constraining the aspect distributions dynamically. It considers the sentiment distribution of a review to have influence of both the author and the entity. Experimental results on two datasets indicate that the proposed approach is promising compared to existing techniques. With growing amount of user generated content on the web, and more people relying on them to make decisions, we believe that the ability to verify opinions will become increasingly important.

Magnets for Sarcasm:
Making Sarcasm Detection Timely, Contextual and Very Personal

Aniruddha Ghosh
University College Dublin, Ireland.
Aniruddha.Ghosh@ucdconnect.ie

Tony Veale
University College Dublin, Ireland.
Tony.Veale@ucd.ie

Abstract

Sarcasm is a pervasive phenomenon in social media, permitting the concise communication of meaning, affect *and* attitude. Concision requires wit to produce and wit to understand, which demands from each party knowledge of norms, context and a speaker's mindset. Insight into a speaker's psychological profile at the time of production is a valuable source of context for sarcasm detection. Using a neural architecture, we show significant gains in detection accuracy when knowledge of the speaker's mood at the time of production can be inferred. Our focus is on sarcasm detection on Twitter, and show that the mood exhibited by a speaker over tweets leading up to a new post is as useful a cue for sarcasm as the topical context of the post itself. The work opens the door to an empirical exploration not just of sarcasm in text but of the sarcastic state of mind.

1 Introduction

Oscar Wilde memorably described sarcasm as "the lowest form of wit but the highest form of intelligence." Though sarcasm lacks the sophistication of irony, and does little to conceal the speaker's disdain for a target, it is a figurative device that requires as much intelligence from its consumers as its producers. The concision with which sarcasm and irony allow speakers to conflate propositional content and affective stance makes it a pervasive mode of communication in the 140-character *tweets* of Twitter. By combining an overtly positive attitude with a meaning that is more deserving of scorn, sarcasm allows speakers to communicate disappointment about a state of affairs that bites (or etymologically "cuts the flesh") of an addressee. It conveys the feeling the speaker would wish to experience ("I love it when ...") with the state of affairs that up-ends this feeling ("... my friends forget my birthday"). It often combines politeness with mockery to disguise the appearance of hostility while heightening its effect on a listener (Brown and Levinson, 1978; Dews and Winner, 1995). It establishes a wry environment (Dews and Winner, 1999) that has its roots in social norms *and* the speaker's state of mind.

Psychological theories of irony, such as *echoic reminder theory* (Kreuz and Glucksberg, 1989) and *implicit display theory* (Utsumi, 2000b) have yet to fully translate into text-analytic methods. Neuropsychology researchers who have sought patterns of brain activity to identify the neural correlates of sarcasm note that an understanding of sarcasm is highly dependent not just on the context of an utterance but on the state-of-mind and personality of the speaker, as well as on facial expressions and prosody (Shamay-Tsoory et al., 2005). Without the latter markers, purely textual detection must depend largely on the content and context of an utterance, though speaker personality and state-of-mind can also be approximated via text-analytic means. Probabilistic classification models that exploit textual cues – such as the juxtaposition of positive sentiment and negative situations (Riloff et al., 2013), discriminative words and punctuation marks (Davidov et al., 2010), and emoticon usage (González-Ibánez et al., 2011) – have achieved good performance across domains, yet these models typically suffer from an absence of psychological insight into a speaker and topical insight into the context of utterance production. Kreuz and Link (2002) argue that the likelihood of sarcasm is proportional to the amount of knowledge shared by speaker and audience, which includes knowledge of the world *and* knowledge of the speaker and audience. Personality is defined

Proceedings of the 2017 Conference on Empirical Methods in Natural Language Processing, pages 482–491
Copenhagen, Denmark, September 7–11, 2017. ©2017 Association for Computational Linguistics

by Olver and Mooradian (2003) as the "enduring characteristics of the individual" though *mood* – which is changeable – is perhaps just as useful if sampled in a timely fashion. The difference between personality and mood can be likened to that between climate and weather. Tausczik & Pennebaker (2010) have developed a Twitter-based mood analysis web service at *AnalyzeWords.com* which uses a variety of psycholinguistic criteria and the LIWC (*Linguistic Inquiry and Word Count*) resource[1] to quantify the recent mood – i.e. the *recent weather* – of a user along 11 dimensions ranging from Arrogance/Remoteness to Anger and Analyticity. To exploit the stable personality of an online user, Celli et al. (2016) sought a correlation between *Big Five* personality traits (Costa and McCrae, 2008) and the LIWC-quantifiable dimensions found in re-tweets amongst Twitter users. (Rajadesingan et al., 2015) have also shown how relevant aspects of personality can be acquired from a speaker's past tweets. Since personality and mood can each influence the detection process, they underpin our first research question: To what extent can the quantifiable dimensions of either lead to a better understanding of sarcasm? Reliable detection depends as much on the context of an utterance – which provides the motivation for sarcasm – as its content. Consider e.g.:

Speaker Utterance: @MSNBC of course all of those jobs will be in China
In reply to *@realDonaldTrump*: I will be the greatest jobs-producing president that God ever created.

The speaker's sarcastic intent cannot be grasped without knowledge of the larger context. This issue provides our second research question: How can we usefully incorporate utterance context into a neural network model of sarcasm detection? Sarcasm is ubiquitous but always in flux, relying on a changing swirl of socially relevant viewpoints. The following tweet is sarcastic by virtue of its echoic mockery of a widely ventilated opinion:

Time to get my Sunday dose of #fakenews from the failing @nytimes.

This begs the third research question that we explore in the following sections: How can we train our sarcasm detection model to exploit evolving social norms and public opinions?

2 Related Work and Ideas

Sarcasm has been extensively researched by linguists and psychologists (Gibbs and Clark, 1992; Gibbs and Colston, 2007; Kreuz and Glucksberg, 1989; Utsumi, 2000a), yet due to the limited availability of stimuli, sarcasm detection in text has relied chiefly on the recognition of stock patterns and lexical cues. Sarcasm often highlights failed expectations by engaging in a pragmatic pretense that is designed to be seen through (Campbell and Katz, 2012), so cues such as interjections, intensifiers, punctuation and markers of non-veridicality and hyperbole play a crucial role in recognizing sarcastic intent. Likewise, stock plaudits such as "yay!" or "great!" are common in sarcastic product reviews (Tsur et al., 2010), while hashtags such as *#sarcasm*, as compressed vehicles for user intent, are often used to self-annotate sarcastic texts (Davidov et al., 2010). Liebrecht et al. (2013) used topic-specific information and n-grams as discriminative features, while (Lukin and Walker, 2013) showed that phrases such as "no way", "Oh really?" and "not so much" serve to flag a sarcastic intent when used with specific linguistic patterns.

Capelli et al. (1990); Woodland and Voyer (2011) suggest that contextual awareness is a necessary precursor to identifying sarcasm. Sarcasm is a response to a motivating context that appears to force a rueful incongruity between a text and its context. Exploiting the *principle of inferability* (see Kreuz (1996)), Bamman and Smith (2015) modeled shared common knowledge by extracting features from context, the author, and the audience. Khattri et al. (2015) identified sarcasm by seeking a strong contrast in affect toward named entities in current vs. historical tweets, while Rajadesingan et al. (2015) also exploited a contrast in statistically-derived author traits across current and historical tweets. Zhang et al. (2016) use similar sources of contextual information to show the effectiveness of a neural network over more traditional approaches involving manually-selected, discrete features, claiming that automatic feature induction can uncover more subtle markers of sarcasm. Amir et al. (2016) argue that sarcasm detection hinges on speaker modeling, and exploited *user embedding* to quantify incongruity between utterances and the behavioral traits of their authors. These methods measure the disparity between an utterance and expectations arising from knowledge of context or speaker or both together.

[1] https://liwc.wpengine.com/

We build on this double-grounding for sarcasm to improve detection in a neural network model of sarcasm and thereby address our first two research questions. We model the speaker *at the time of utterance production* using mood indicators derived from the most recent prior tweets, and model context using features derived from the proximate cause of the new utterance, the tweet to which an utterance is a response. For our third research question, we present a novel feedback-based annotation scheme that engages authors of training/test tweets in a process of explicit annotation, feeding new examples back into the model. Section 3 outlines the kind and source of features exploited in the model. Section 4 outlines our methods of data collection and annotation. Section 5 presents the neural network model, while section 6 & 7 present our experimental set-up and analysis of results. Finally, section 8 offers some closing remarks.

3 Psychological dimensions and Sarcasm

We cannot perceive a user's state-of-mind directly on Twitter, but we might infer one's current disposition from an analysis of recent tweets, as linguistic expressions tend to be congruent with an author's state-of-mind (Campbell and Katz, 2012). An informative if *low-res* psychological portrait is sketched by web services such as *AnalyzeWords* (Tausczik and Pennebaker, 2010), which analyzes the most recent 1000-words or so of a Twitter user using LIWC to score the user on 11-dimensions: *Upbeat, Worried, Angry, Depressed, Plugged in, Personable, Arrogant, Spacy, Analytic, Sensory* and *In-the-moment*. Sarcasm is often perceptible in the incongruity between utterance and context (Joshi et al., 2015) but it can also be conveyed by an incongruity between text and recent mood.

To understand the relationship between these 11 dimensions (each scored 0..100) and a propensity for sarcasm, we performed a k-Nearest Neighbors (KNN) clustering of the Twitter users that provide the tweets of our sarcastic data set. The *AnalyzeWords* snapshot of each user was taken at the time of that user's tweet in the dataset. A value of 30 for k was chosen empirically to ensure a decent size for the clusters. By calculating Spearman correlations between each group and the 11 *AnalyzeWords* dimensions, we estimated the affinity for sarcasm of different dimensions. Unsurprisingly, we observed that clusters showing a high correlation with negative dimensions, such as *Angry*, also tend to use positive expressions such as 'funny" and 'wow" to mark sarcasm. Here is an example:

@realDonaldTrump They can all fit in your head? Wow! Have you seen someone about this?

Unless one knows that @*realDonaldTrump* often elicits anger, or that the author scored 83 (of 100) for *Angry*, this tweet might seem quite positive. Valence shifters such as "not" might also suggest literal positivity if not for the implicit anger of the author. At the time of the following tweet *AnalyzeWords* scored its author as *Angry=98*.

@realdonaldtrump funny the founder of the birther movement is saying that he's not racist #trumpbirther

Polarizing figures such as @*realDonaldTrump* are magnets for sarcasm on Twitter. By identifying these magnets, we can better detect the sarcasm of a tweet that offers plaudits for negative qualities. We use *AnalyzeWords* to obtain the popular affective feelings for common addressees by averaging the affective dimensions of the users that tweet at them. The top 5 magnets for sarcasm in our data-set of 18K sarcastic tweets are @*hillaryClinton, @realDonaldTrump, @bernieSanders, @AP* and @*megynKelly*. Of these, @*hillaryClinton* is the biggest target for *Angry* tweets while @*megynKelly* is the biggest target for *Analytic* tweets.

Addresses in the political domain score high for both angry tweets and analytic tweets: people analyze the news *and* shoot the messenger. We see much less analyticity – a tendency to use complex expressions linked with logical connectives – in tweets about popular entertainers. To mock such targets, users tend to use affective words that contrast with overall public opinion. The magnet with the highest mean *Angry* score for the tweets that target him is @*realDonaldTrump*, yet 63% of the affective words in the tweets that target him in the data-set are positive. Knowing that @*realDonaldTrump* is a magnet for anger can help a sarcasm detector overcome this positive bias.

4 Dataset Construction

Tweets with sarcastic intent are often misclassified due to a lack of shared context or knowledge between speaker and annotator. Opposing social beliefs and a dearth of topical or personal knowledge can lead to serious misjudgments. Relevant tweet sets can be harvested by searching sarcasm specific hashtags (e.g. #sarcasm). This approach overlooks tweets that are not explicitly tagged as sarcastic by their authors. Thus we have devised a feedback-based system that contacts tweet authors directly *after-the fact* to ask for their authoritative self-annotations for a potentially sarcastic tweet.

4.1 Data collection

To collect annotations from authors for *their own* tweets, we used a Twitterbot named *@onlinesarcasm* to exploit the "retweet with comment" function in Twitter. The bot chooses randomly from tweets that are addressed to any of 700 top Twitter users (as listed by *TwitterCounter.com*), as we expect high-profile figures to be magnets for sarcasm from others. The bot retweets a chosen tweet (s_i) to its author, appending a yes/no question (q_i) as a comment to elicit a reply.

At the time of retweeting (s_i), the 11 *AnalyzeWords.com* dimensions (aw_i) of the tweet's author (u_i) are saved, along with the context tweet (s_j) by author (u_j) that provoked (s_i). Authors respond to the bot by favoriting/retweeting the bot's request or via a reply (re_i) containing #Yes or #No. Author responses often contain more than a simple #Yes or #No response, and so, after observing a series of responses the following linguistic rules were used to extract the training annotations:

- If the number of *retweets* (r_i) or *likes* (l_i) for q_i is non-zero or re_i contains #Yes, then s_i is deemed positive for sarcasm.
- If re_i contains #No or an explicit mention of 'not sarcastic' or 'no sarcasm' or 'truth', then s_i is deemed negative for sarcasm.

We discarded any s_i lacking a context tweet s_j. Using author feedback, a data set of 40K tweets was collected, comprising 18K tweets acknowledged as sarcastic and 22K deemed non-sarcastic. For another test set, we collected 1200 tweets: 550 tweets acknowledged as sarcastic by their authors and 650 acknowledged to be non-sarcastic.

4.2 External datasets

In addition to our own training and test sets, whose annotations come directly from tweet authors, we also used 5 Twitter datasets where tweet information, fetched by tweet identifier, contains identifier of context tweet (Ptáček et al., 2014; Bamman and Smith, 2015; Rajadesingan et al., 2015; Cliche, 2014), from which motivating contexts can be discerned for each. (This contextual requirement prevents us from considering even more of the available sarcasm datasets.) For the context tweets s_j for each s_i in these sets we collected the most recent linked tweets of s_i. To obtain the 11 *AnalyzeWords.com* dimensions for tweet authors, we collect the 50 tweets of u_i posted just prior to s_i, and use the LIWC to estimate the 11 dimensions (Anger, Arrogance, etc.) from those tweets. As *AnalyzeWords.com* does not provide retrospective analyses, and as its code is not public, we reverse-engineered a substitute using the LIWC by following the creators' guidelines in (Tausczik and Pennebaker, 2010). For subsequent evaluations, the 5 external datasets were split into 3 parts each: 80% for training, 10% for development/tuning, and 10% for testing.

5 The Neural Network Model

Ghosh and Veale (2016) described an Artificial Neural Network (ANN) model built around layers of CNNs (Convolutional Neural Networks) and LSTMs (Long Short Term Memory) for sarcasm detection to efficiently capture contrasting text signals of sarcasm within a tweet. We build here on this model as shown in Fig.1, adding input features for the psychological profile of the author and the context of the tweet to those for the tweet itself. The LSTM layer (Hochreiter and Schmidhuber, 1997) captures dependencies amongst non-adjacent contrasting signals for sarcasm within each s_i. We extend this architecture to include a context tweet s_j for each s_i, but instead of concatenating s_j and s_i at the input layer, we stitch them together after the LSTM layer. The text input layer is initialized with embeddings from Google's *Word2Vec* model (Mikolov et al., 2013) with a dimension setting of 300. To further integrate features reflecting the state of mind of the speaker at utterance-time, the values aw_i ($i = 1...11$) for each s_i are concatenated with the feature vector of s_j & s_i in the merge layer. We use a bi-directional LSTM (BLSTM) and forego a *maxpooling* layer to increase throughput to the BLSTM. We prevent overfitting using a dropout layer with a dropout rate of 0.25 after the BLSTM layers. The concatenation layer combines the feature maps of the source and context tweets (s_i & s_j) along with a vector of $\mathrm{aw}_{1...11}$ for the author u_i. The concatenation yields a merge layer of size $\Re^{f(2(|s|m+1)+l)}$ where f, s, m and l are, respectively, the number of BLSTM units, the length of the input se-

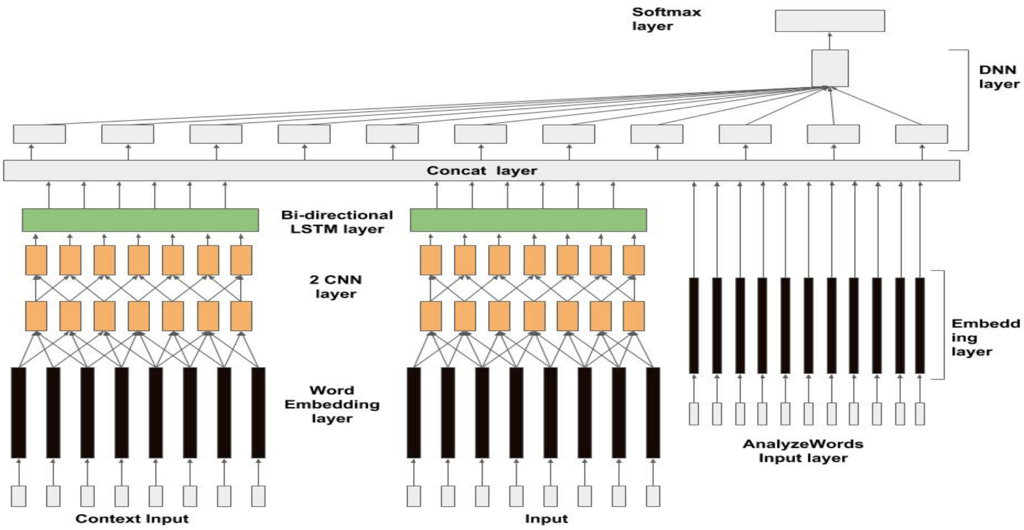

Figure 1: A Neural Architecture for Detecting Sarcasm in Contextualized Utterances

quence, the width of the CNN filter and the length of aw. Notice that the features for a tweet s_i and its immediate context s_j – which we consider the proximate cause of the sarcasm (if any) in s_i – are concatenated only after they have passed through separate sets of CNN and LSTM layers (CNN1 + BLSTM1 and CNN2 + BLSTM2). It is important to keep a tweet and its context separate for as long as possible, as the model is designed to recognize an inherent incongruity between each. This incongruity becomes diffuse if the inputs are combined too soon. EAW is the embedding layer for the 11 *AnalyzeWords* dimensions; it combines the vectors of s_j, s_i and aw, and passes the concatenated features to a Deep Neural Network (DNN) to discriminate both classes (sarcasm vs. non-sarcasm). The code[2] is developed using Keras[3].

6 Evaluation and Experimental Setup

Success with a neural architecture requires apt input features and an equally apt selection of hyper-parameters. After performing a grid search over hyper-parameters, the best configuration of the CNN, LSTM and DNN layers places 1280 hidden memory units into each layer and uses a CNN filter width of 3. A simple baseline will use only the textual content of a tweet s_i without a context s_j or an affective profile aw of the author u_i. To appreciate the contribution of different input sources of information we trained the network on different combinations of these sources.

6.1 Addressee information

If s_i is addressed to u_j, this information can provide additional insights into s_i's tone. In the TTIA *(Target Tweet Including Addressee)* setting the name of the addressee (but not an estimation of the public opinion of the addressee, as so few addresses are actually famous) is added to the baseline along with s_i. If the addressee is a magnet for sarcasm, aspects of this magnetism should still impress themselves on the network during training.

6.2 Contextual Information

In a variant of the baseline called CT *(Context Tweet)*, the features of the tweet s_j to which the target s_i is a response are also added as inputs to the model, to be stitched together with the features of s_i at the concatenation layer. Changes in performance with and without CT will allow us to estimate the value of context in sarcasm detection.

6.3 Author Profile Information

The 11-dimensional *AnalyzeWords* snapshot aw for author u_i at the time s_i is posted offers valuable insights into the intent of u_i. In the PD *(Psychological Dimensions)* configuration, the 11 affective dimensions aw_i are added to the model. They pass through an embeddings layer to be combined with utterance (and possibly context) features at the concatenation layer. To determine the relative contribution of each dimension aw_i to detection competence, we trained the model in two extra modes. In the first, we fed the model with false values for each aw_i, varying values from 0 to

[2] https://github.com/AniSkywalker/SarcasmDetection

[3] https://keras.io/

100, to observe the effects on accuracy when e.g. *Angry* is over- or under-estimated for u_i. In the second extra mode, we excised each aw_i, one at a time in different training runs, to quantify its lack on the model.

6.4 Automatic adaptation

Online sarcasm is often used to comment on the vagaries of politics and current affairs. As topicality is of the essence, we expect a model that regularly acquires new author-annotated training data to bootstrap itself will adapt better to the times and yield better results. To estimate the benefits of bootstrapping we tested the model on an evolving version of the data-set that acquired new training data each week for a month in August 2016.

7 Results & Analysis

Table 3 shows the recall (R), precision (P) and f-score (F1) for our model, called *Sarcasm Magnet*, with alternate configurations on different datasets. The configuration for each setup is given in the second row (e.g. the addition of context tweets requires the use of two LSTMs and two CNNs). Setup TTEA is the baseline which uses only the text of a target tweet; it excludes addressee handles, context tweets (CT) and the psychological dimensions (PD) of authors. Setup TTIA adds addressee handles to the baseline to give our model a small boost, mostly in recall. Setup TTEA+CT adds context tweets to the baseline, yielding a significant boost since a good deal of sarcasm is conversational in nature. In this setup the most significant improvement in recall was observed with the Bamman dataset (Bamman and Smith, 2015). In setup TTIA+CT, which uses context *and* addressee handles, no significant improvement over TTEA+CT is observed, except for precision on Bamman's dataset. In setup TTEA+PD, the affective profile of each author at tweet-time is added to the baseline to yield a significant boost in performance almost as large as that for TTIA+CT. Setup TTIA+CT+PD includes all available information sources (addressee, content, and psychological profile). This column reports (in parentheses) the performance on each dataset by the dataset creator's own system, which is either publicly available or re-implemented from their paper. The results show that *Sarcasm Magnet* beats the state of the art for these data-sets.

Table 1 shows the effect on the model's performance in the absence of specific aw_i values. A boost in recall and a drop in precision shows the bias of the model shifting towards sarcasm when the space of non-sarcastic tweets overlaps with that of sarcastic tweets in the absence of an aw_i that confirms literal intent. So political tweets may be mis-classified as sarcasm in the absence of values for *Angry*, *Depressed*, and *Worried*, suggesting that sarcastic authors often seem less angry, depressed or worried. A drop in precision and recall when *Arrogant/Remote*, *Analytic*, *Plugged in* and *In-the-moment* dimensions are absent suggests sarcastic people to be more socially active and aware, and smarter but more arrogant.

Dimension omitted	**Precision**	**Recall**	**F-score**
None omitted	0.9	0.89	0.9
Sensory	0.85	0.93	0.89
Plugged In	0.84	0.84	0.84
Depressed	0.78	0.96	0.86
Angry	0.81	0.95	0.87
Spacy/Valley girl	0.78	0.97	0.87
Worried	0.79	0.97	0.87
Arrogant/Distant	0.84	0.85	0.84
Analytic	0.86	0.83	0.84
In-the-moment	0.84	0.86	0.85
Upbeat	0.86	0.91	0.88
Personable	0.87	0.88	0.88

Table 1: Performance of the model when a specific dimension aw_i is omitted from training.

7.1 A Tale of Two Contexts

The CT and PD additions each bring significant improvements in F-score, yet when added jointly they bring no significant increases over either used individually. For each is a form of context drawn from different sources that reflects different intuitions but which ultimately offers much the same insights. The impact of the 11 aw dimensions is lower on the 5 external datasets than for the new feedback-based dataset, no doubt because the *AnalyzeWords.com* snapshot of authors in the latter could be taken directly at tweet-time, whilst for the former it was retrospectively approximated using our own jerry-rigged version based on the LIWC. If the official web service were to allow retrospective analyses of Twitter users at specific times we are confident the improvements on the external datasets would mirror those on our own dataset. For now it is interesting to note the effectiveness of the *AnalyzeWords.com* service at affectively profiling Twitter users at specific times, which is to say, at specific contexts in their Twitter time-lines.The service boils down the most recent tweets (approx. 1000 words in total) to 11 dimensions that are more than simple functions of the lexical scores in the LIWC. Rather, it analyzes the selected text as a coherent product of a coherent mind-set, to measure a local propensity for hostility, optimism, depression, emotional detachment and preference for reason. To use our earlier analogy, *AnalyzeWords.com* forecasts the psychological weather around an author, not the user's stable climate. Though we may often speak of a "sarcastic personality" as a stable aspect of some speakers, most users of sarcasm will not fall into this category. As such, insight into the recent mind-set of an author is more valuable to a detector than knowledge of one's personality overall.

7.2 Rolling With The Punches

Our feedback-annotated dataset was collected during a fertile period for sarcasm online: the heights of the 2016 US presidential campaign. The main body of the new dataset was collected and annotated (as described earlier) in the early summer of 2016. During the month of August we acquired additional annotated training data in four weekly tranches, to incrementally retrain the model to an evolving political and social context. As shown in Table 2, each weekly tranche of extra training data yielded increased dividends in terms of F-score and precision or recall when evaluating the model on the same test set (of 1,200 tweets, 550 sarcastic and 650 non-sarcastic). The new annotated data harvested in the final week of August yielded the biggest dividends, especially in Recall, perhaps in a reflection of the growing bitterness of the campaign and of frantic campaigning in (and online commentary about) the pivotal *swing states*. As the candidates were revealing more of themselves to voters, the voters were revealing more of themselves to our model. Specifically, in week 1, 4719 sarcastic and 5361 non-sarcastic tweets were added for training; in week 2, an additional 3179 and 6901 were added; in week 3, 3571 and 6509; and in a week 4 reversal, 6504 and 3574 tweets.

Week	Precision	Recall	F-score
Week 1	0.751	0.752	0.752
week 2	0.790	0.752	0.771
Week 3	0.798	0.775	0.786
Week 4	0.839	0.869	0.85

Table 2: Bootstrapping gains (August, 2016)

8 Conclusions & Future work

Context is vital to the understanding of the fruits of any figurative device, whether metaphor, irony or sarcasm. We have explored two sources of contextual information in this work: the linguistic context of the utterance itself – which we take to be another utterance that is the proximate cause of the text under consideration – and the psychological context of the utterance's author – which we take to be the mind-set that is apparent in the author's most recent writings on Twitter. Each source of context is ultimately grounded in a text and understood in text-analytic terms. It is perhaps not so surprising then that each kind of context yields similarly large improvements to a neural model of sarcasm detection when added in isolation, but no large improvements over either alone when both are combined in a single model.

This work makes three principle contributions to the computational analysis of sarcasm. First, as outlined above, it shows how different kinds of context – from the linguistic to the psychological – can be usefully incorporated to yield improved detection. Second, it shows how accurate annotation of training data can be automated on Twitter by going directly to the source of each training text, to obtain a definitive answer as to its figurative status. So the resulting neural model does not learn to approximate the reasoning of independent human annotators but the mind-set and intent of the authors themselves. Thirdly, and perhaps most usefully for future work by others, this feedback-based dataset will be made available for use by other researchers and in other evaluations. Importantly, this dataset is not merely a collection of yes/no annotated texts, even if the *yes*es and *no*s come from authoritative sources. For each text in the dataset, we can provide the linguistic context to which it is a response, and furthermore, we can provide a psychological snapshot of the author *at the time* the tweet was posted on Twitter. In the end we believe this is the most valuable contribution of the work, as it will allow others to incorporate an understanding of personality and mind-set into their own models of that most personal and moody of figurative devices, sarcasm.

Identifying Humor in Reviews using Background Text Sources

Alex Morales and **ChengXiang Zhai**

Abstract

We study the problem of automatically identifying humorous text from a new kind of text data, i.e., online reviews. We propose a generative language model, based on the theory of incongruity, to model humorous text, which allows us to leverage background text sources, such as Wikipedia entry descriptions, and enables construction of multiple features for identifying humorous reviews. Evaluation of these features using supervised learning for classifying reviews into humorous and non-humorous reviews shows that the features constructed based on the proposed generative model are much more effective than the major features proposed in the existing literature, allowing us to achieve almost 86% accuracy. These humorous review predictions can also supply good indicators for identifying helpful reviews.

1 Introduction

The growth of online feedback systems, such as online reviews in which users can write about their preferences and opinions, has allowed for creativity in the written communication of user ideas. As such, these feedback systems have become ubiquitous, and it's not difficult to imagine a future with smart systems reacting to user's behaviour in a human-like manner (Nijholt, 2014). An essential component for personal communication is the expression of humor. Although many people have studied the theory of humor, it still remains loosely defined (Ritchie, 2009), this leads to difficulties in modelling humor. While the task for identifying humor in text has been previously studied, most approaches have focused on shorter text such as Twitter data (Mihalcea and Strapparava, 2006; Reyes et al., 2012, 2010) (see Section 6 for a more complete review of related work). In this paper, we study the problem of automatically identifying humorous text from a new kind of text data, i.e., online reviews. In order to quantitatively test whether the review is humorous, we devise a novel approach, using the theory of incongruity, to model the reviewer's humorous intent when writing the review. The theory of incongruity states that we laugh because there is something incongruous (Attardo, 1994), in other words, there is a change from our expectation.

Specifically, we propose a general generative language model to model the generation of humorous text. The proposed model is a mixture model with multinomial distributions as component models (i.e., models of topics), similar to Probabilistic Latent Semantic Analysis (Hofmann, 1999). However, the main difference is that the component word distributions (i.e., component language models) are all assumed to be known in our model, and they are designed to model the two types of language used in a humorous text, including 1) the *general background model* estimated using all the reviews, and 2) the reference language models of all the *topical aspects* covered in the review that capture the typical words used when each of the covered aspects is discussed. Thus the model only has the parameters indicating the relative coverage of these component language models. The idea here is to use these parameters to assess how well a review can be explained by collectively by the reference language models corresponding to all the topical aspects covered in the review, which are estimated using an external text source (e.g., Wikipedia).

We construct multiple features based on the generative model and evaluate them using supervised learning for classifying reviews into humorous and non-humorous reviews. Experiment re-

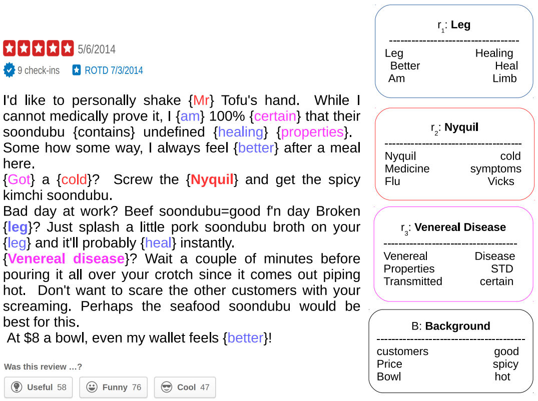
sults on a Yelp[1] review data set show that the features constructed based on the proposed generative model are much more effective than the major features proposed in the existing literature, allowing us to achieve almost 86% accuracy. We also experimented with using the results of humorous review prediction to further predict helpful reviews, and the results show that humorous review prediction can supply good indicators for identifying helpful reviews for consumers.

2 Referential Humor and Incongruity

In this section we describe some observations in our data that have motivated our approach to solving the problem. In particular, we show that humorous reviews tend to reference aspects which deviate from what is expected. That is, in funny reviews, the authors tend to use referential humor, in which specific concepts or entities are referenced to produce comedic effects, which we call *aspects*. Here we define *referential humor* to be a humorous piece of text which references aspects outside of the typical context, in our case restaurant reviews. For the rest of the paper we use humorous and funny interchangeably.

Our study uses review data from Yelp. Yelp has become a popular resource for identifying high quality restaurants. A Yelp user is able to submit reviews rating the overall experience of the restaurants. The reviews submitted to Yelp tend to have similar context, in particular they mention several aspects rating the quality of the restaurant such as food, price, service and so on. This information is expected from the reviewer in their review, however it is not always the case since there is no requirement for writing the review. Yelp users are able to vote for a review in several criterion, such as funny, cool, and useful. This gives the users an incentive for not only creating informative reviews but possibly entertaining reviews.

In Figure 1, we show a humorous review, randomly sampled by using our classifier with a high probability of being funny, where the reviewer asserts that the food has extreme medicinal properties. The reviewer refers to "Nyquil" a common cold medicine to express the food's incredible ability to cure ailments. This appears almost surprising since it would not normally be mentioned in restaurants reviews. To identify the intended humor, we can use the references the reviewer makes, e.g. Nyquil, as clues to what she is emphasising, e.g. the savory soondubu, by making such comparisons, e.g. the heavenly taste and amazing price. Yelp users seem to consider funny reviews which tended to deviate from what was expected into things which would seem out of place.



I'd like to personally shake {Mr} Tofu's hand. While I cannot medically prove it, I {am} 100% {certain} that their soondubu {contains} undefined {healing} {properties}. Some how some way, I always feel {better} after a meal here.
{Got} a {cold}? Screw the {**Nyquil**} and get the spicy kimchi soondubu.
Bad day at work? Beef soondubu=good f'n day Broken {**leg**}? Just splash a little pork soondubu broth on your {leg} and it'll probably {heal} instantly.
{**Venereal disease**}? Wait a couple of minutes before pouring it all over your crotch since it comes out piping hot. Don't want to scare the other customers with your screaming. Perhaps the seafood soondubu would be best for this.
At $8 a bowl, even my wallet feels {better}!

Figure 1: A funny review (left), with $K_d = 3$, aspect topics (right) contain words in their corresponding language model, probabilities removed for clarity, the colored (bracketed) word correspond to a different aspect assignment.

3 Language Models as a Proxy for Incongruity

Motivated by the observations discussed in the previous section (i.e., reviewers tend to reference some entities which seem unexpected in the context of the topic of the review), we propose a generative language model based on the theory of incongruity to model the generation of potentially humorous reviews. Following previous work on humor, we use the definition of incongruity in humor as "what people find unexpected" (Mihalcea and Strapparava, 2006), where "unexpected" concepts are those concepts which people do not consider to be the norm in some domain, later we formalize unexpectedness using our model.

We now describe the proposed model in more detail. Suppose we observe the following references to K_d topical aspects $A_d = \{r_1, r_2, ..., r_{K_d}\}$ in a review $R_d = [w_1, w_2, ..., w_{N_d}]$, where each r_i corresponds to an aspect reference (i.e. NyQuil in our running example), and $w_i \in V$, where V is the vocabulary set. The model generates a word, for some review, at a time, which talks about a specific aspect or is related to the language used in Yelp more broadly; we call the latter the background language model. Thus a word is generated from a mixture model, and its probability is an interpola-

[1] www.yelp.com

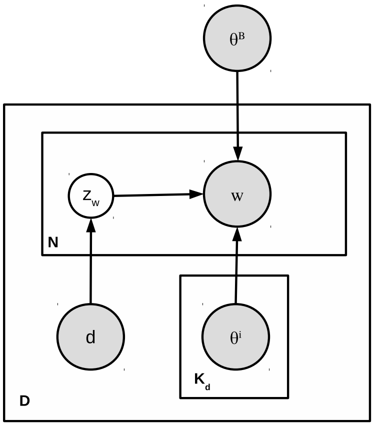


Figure 2: Generation model for reviews, where the dth review has K_d aspects in the review. The shaded nodes here are the observed data and the light node z are the latent variables corresponding to aspect assignments.

tion of the background language and the language of the references as shown in Figure 2.

These aspects provide some context to the underling meaning of a review; the reviewers use these aspects for creative writing when describing their dining experience. These aspects allow us to use external information as the context, thus we develop measures for incongruity addressing the juxtaposition of the aspect's context and the review. The review construction process is represented in a generative model, see Figure 2, where the shaded nodes represent our observations, we have observed the words as well as the referenced aspects which the reviewer has mentioned in their review. The light nodes are the labels for the aspect which has generated the corresponding word. Since the background language model, denoted by θ^B, is review independent, we can simplify the generative model by copying the background language model for each review, thus we can focus on the parameter estimation for each review in parallel.

A key component to the success of our features is the mesh of background text from external sources, or *background text sources*, and the reviews. In our example, Figure 1, Nyquil is a critical component for understanding the humor. However it is difficult to understand some references a reviewer makes without any prior knowledge. To do so, we incorporate external background knowledge in the form of language models for the referenced aspect present in the reviews. If the reviewer has made K_d references to different aspects A_d in review R_d, then for each r_i there is a corresponding language model $\theta_w^{r_i} = P(w|\theta^{r_i})$ over the vocabulary $w \in V$. For simplicity, we describe the model for each document, and use the notation θ_w^i and θ^i for the corresponding language model of r_i.

3.1 Incorporating Background Text Sources

As described before, some features we will use to describe incongruity correspond to the weights of the mixture model used to generate the words in the review, which take into account the language of the references she will make or allude, as shown in Figure 2. The probability that an author will generate a word w, for the dth review given corresponding aspects $\Theta = \{\theta^B, \theta^1, ..., \theta^{K_d}\}$, is

$$P(w, d, \Theta) = \sum_{z=0}^{K_d} P(w, z, d, \Theta) =$$

$$\sum_{z=0}^{K_d} P(w|z, \Theta)P(z|d) = \lambda\theta_w^B + (1-\lambda)\sum_{i=1}^{K_d} \pi_i\theta_w^i$$

Note K_d indicates the different aspects the reviewer will mention in a review, R_d, and hence it can vary between reviews. $\theta_w^B = P(w|z = 0, \Theta)$ is the probability that the word will appear when writing a review (e.g. background language model) and θ_w^i can be interpreted as word distributions over aspect i. Here $\lambda = P(z = 0|d)$ is the weight for the background language model and $\pi_i = \dfrac{P(z = i|d)}{1 - P(z = 0|d)}$ denotes the relative weights of the referenced aspect's language models used in the review. We denote our parameters for review R_d as $\Lambda_{R_d} = \{\pi_1, ..., \pi_{K_d}, \lambda\}$. Note that the parameter set varies depending on how many references the review makes. In order to estimate $P(w|\theta^i)$, we first need to find the aspects that the user is mentioning in their reviews. In general aspects can be defined as any topics explicitly defined in external background text data; in our experiments we define aspects as Wikipedia entities. In subsection 5.1, we describe one way of obtaining these aspects, but first we describe the estimation methodology.

3.2 Parameter Estimation

To estimate our parameters Λ_{R_d}, we would like to maximize the likelihood of $P(R_d)$, which is the same as maximizing the log-likelihood of $P(R_d)$.

That is

$$\begin{aligned}\hat{\Lambda} &= \text{argmax}_{\Lambda} \log P(R_d|\Lambda) \\ &= \text{argmax}_{\Lambda} \sum_{w\in V} c(w, R_d) \log \left(P(w, d, \Theta)\right)\end{aligned}$$

Here $c(w, R_d)$ represents the number of occurrences of the word w in R_d. In order to maximize the log-likelihood we use the EM algorithm (Dempster et al., 1977), to compute the update rules for the parameters λ and $\pi_1, ...\pi_{K_d}$. For the E-Step, at the $n+1$th iteration we have

$$P(z_w = 0) = \frac{\theta_w^B \lambda^{(n)}}{\left(\sum_{l=1}^{K_d} \theta_w^l \pi_l^{(n)}\right)(1-\lambda^{(n)}) + \theta_w^B \lambda^{(n)}}$$

$$P(z_w = j) = \frac{\theta_w^j \pi_j^{(n)}}{\sum_{l=1}^{K_d} \theta_w^l \pi_l^{(n)}}$$

Where z_w is a hidden variable indicating whether we have selected any of the aspect language models, or the background language model, when generating the word w. The update rules for the M-Step are as follows:

$$\lambda^{(n)} = \frac{\sum_{w\in V} c(w, R_d) P(z_w = 0)}{n}, \pi_j^{(n)} = \frac{\sum_{w\in V} c(w, R_d) P(z_w = j)(1 - P(z_w = 0))}{\sum_{l=1}^{K_d} \sum_{w\in V} c(w, R_d) P(z_w = l)(1 - P(z_w = 0))}$$

We ran EM until the parameters converged or a small threshold was reached. Note there is some similarity to other topic modelling approaches like PLSA (Hofmann, 1999). PLSA is a way to soft cluster the documents into several topics, in doing so a word distribution for each topic is learned. In our work we make the assumption that the "topics" are fixed, namely they are the aspects which the reviewer mentions in their review. Note that, we can similarly derive update rules for an different topic model such as LDA (Blei et al., 2003), however prior work, (Lu et al., 2011), shows that LDA does not show superior performance over PLSA empirically for a number of tasks.

4 Features construction

Since we are interested in studying discriminative features for humorous and non-humorous reviews, we set up a classification problem to classify a review into either humorous or non-humorous. In classification problems the data plays a critical role; here the labels are obtained from the funny votes in our Yelp dataset, and we describe how we created the ground-truth in Section 5. Here in this section, we discuss the new features we can construct based on the proposed language model and estimated parameter values.

4.1 Incongruity features

A natural feature in our incongruity model is the estimated background weight, λ, since it indicates how much emphasis the reviewer puts in their review to describe the referenced aspects, we denote this feature by **A1**. Another feature is based on the relative weights for the referenced aspect's language models. There tends to be more 'surprise' in a review when the reviewer talks about multiple aspects equally, this is because the more topics the reviewer writes about the more intricate the review becomes. We use the entropy of the weights $H(R_d) = -\sum_{i=1}^{K_d} \pi_i \log \pi_i$ as another incongruity score and label this feature as **A2**.

4.2 Unexpectedness features

Humor often relies on introducing concepts which seem out of place to produce a comedic effect. Thus we want to measure this divergence from the references and the language expected in the reviews. Hence a natural measure is the KL-divergence measure the distance between the background language model and the aspect language models. We use the largest deviation, $\max_i\{D_{KL}(\theta^i||\theta^B)\}$ as feature **D2**. For this feature we tried different combinations such as a weighted average, but both features seemed to perform equally so we only describe one of them.

By considering the context of the references in the reviews we can distinguish which statements should be considered as humorous, thus we also use the relative weight for each aspect to measure unexpectedness. Formally we have $U_j = \pi_j D_{KL}(\theta^j||\theta^B)$, lastly we will denote $\max_i\{U_i\}$ these set of features as **U2**.

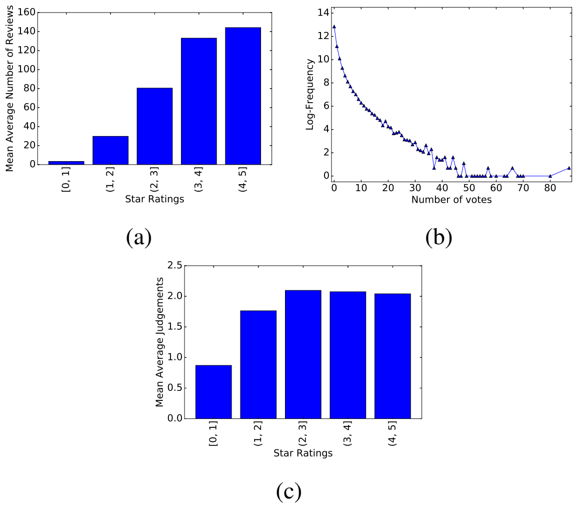
4.3 Baseline features from previous work

For completeness, we also include a description of all the baseline features used in our experiments; they represent the state of the art in defining features for this task. These features described below do not use any external text sources (leveraging external text sources is a novel aspect of our work), and they are more contextual and syntactical based features. We describe some of the most promising features, which have previously shown to be useful in identifying humor in text.

Context features: Due to the popular success of context features by Mihalcea and Pulman (2007) we tried the following features content related features: **C1**: the uni-grams in the review.[2] **C2**: length of the review. **C3**: average word length. **C4**: the ratio of uppercase and lowercase characters to other characters in the review text.

Alliteration: Inspired by the success that Mihalcea and Strapparava (2006) had using the presence and absence of alliteration in jokes, we developed a similar feature for identifying funny reviews. We used CMU's pronunciation dictionary [3] to extract the pronunciation to identify alliteration chains, and rhyme chains in sentences. A chain is a consecutive set of words which have similar pronunciation, for example if the words words "scenery" and "greenery" are consecutive they would form a rhyme chain. Similarly, "vini, vidi, visa" also forms another chain this time an alliteration chain. We used the review's total number of alliteration chains and rhyme chains and denote it by **E1**. Note that there could be different lengths of chains, we experimented with some variations but they performed roughly the same, for simplicity we did not describe them here.

Ambiguity: Ambiguity in word interpretation has also been found to be useful in finding jokes. The reasoning is that if a word has multiple interpretation it is possible that the author intended another interpretation of the word instead of the more common one. We restricted the words in the reviews to only nouns and used Wordnet [4] to extract the synsets for these words. Then we counted the average number of synsets for each of these words, finally we took the mean score for all the words in the reviews. We call these features lexical ambiguity and denote it by **E2**.



(a) (b)

(c)

Figure 3: (a) Mean average number of reviews for restaurants falling in five different star rating ranges. (b) Log occurrences of funny votes per review. (c) Mean average voting judgements for restaurants in different star ratings.

5 Experimental Results

For our experiments we obtained the reviews from the Yelp Dataset Challenge[5], this dataset contains over 1.6 million reviews from 10 different cities. We also crawled reviews from Yelp in the Los Angeles area which is not included in the Yelp Dataset Challenge. This dataset was particularly interesting since the readers are able to vote whether a review is considered *cool*, *funny*, and/or *helpful*. It also allows the flexibility for the reviewers to write longer pieces of text to express their overall rating of a restaurant.

5.1 Identifying Aspects in Reviews

We use recent advancements in Wikification, which aims to connect important entities and concepts in text to Wikipedia, it is also known as disambiguation to Wikipedia. In particular we use the work of Ratinov et al. (2011), in order to obtain the Wikipedia pages of the entities in the reviews, we call these *aspects* of the review. Using the Wikipedia description of the aspects we can compute the language models for each aspect. Using *mitlm*, the MIT language modeling toolkit by Hsu and Glass (2008), we apply Modified Kneser-Ney smoothing to obtain the language models from the Wikipedia pages obtained from review's aspects.

5.2 Preliminaries and Groundtruth Construction

In Figure 3 we give an account of data statistics based on a random sample of 500,000 reviews, focusing on the funny voting judgements and the star rating distributions. In Figure 3a, we notice that on average the highly rated restaurants tend to have more reviews. Since users would

[2] We also considered content-based features derived from PLSA topic weights, however the unigram features outperform these features, thus we exclude them for lack of space.

prefer to dine in a restaurant expecting to get a better overall experience, they create a feedback on the reviews for those highly rated restaurants. This "rich-get-richer" effect has been also been recently observed in other social networks (Su et al., 2016) and a more detailed analysis is out of scope of this paper. We observe that most of the reviews receive a low number of funny votes in Figure 3b, with $\mu = 0.55$, where μ is the average funny rating. Computing the restaurant's average funny votes, then taking the mean by the star ratings for each category range, see Figure 3c, which seems to be consistently increasing across the different star ratings. Note that this also includes the restaurants with zero funny votes, by excluding these we found that the ratings were more consistently stable on about 2.1 votes. Thus regardless of restaurant rating, the funny reviews distribution are stable on average. Considering the prevalence of noise in the voting process, we also analysed those reviews with more than one funny vote ($\mu = 3.90$), and with more than two votes ($\mu = 5.54$).

To construct our ground-truth data, we took all of the reviews at least five funny votes, which indicates the review was collectively funny, and considered those as humorous reviews, we considered all the reviews with zero funny votes as non-humorous reviews. We obtained 17,769 humorous reviews and 856,202 non-humorous, from which we sampled 12,000 reviews from each category, and another 5,000 reviews was left for a development dataset, to obtain a corpus with 34,000 reviews total. In total we collected 2,747 wikipedia pages with an average of about 247 sentences per page. In our work we focused on identifying distinguishing features and relative improvement in a balanced dataset and while the true distribution may be skewed, we leave the unbalance distribution study for future work.

Finally we use five-fold cross validation to evaluate all the methods. Due to the success of linear classifiers in text classification tasks we were interested in studying the Perceptron and Adaboost algorithms, we also used a Naive Bayes classifier which has been shown to perform relatively well in humor recognition tasks (Mihalcea and Strapparava, 2006). We used the Learning Based Java (LBJava) toolkit by Rizzolo and Roth (2010) for the implementation of all the classifiers and used their recommended parameter settings. For the Averaged Perceptron implementation, we used a learning rate of 0.05 and thickness of 5. In Adaboost, we choose BinaryMIRA as our weak learner to do our boosting on. We also considered SparseWinnow and SparseConfidenceWeighted to be our weak learner as well, but the boosting performance for those two learners is marginal on the development set.[6] All experiments were run on an Intel Core i5-4200U CPU with 1.60GHz running Ubuntu.

5.3 Predicting Funny Reviews

We report the results of the features in Table 1. First we can compare the accuracies of the individual features. For the content related features we see that the best features is **C1**, which is consistent to what others have found in humor recognition research (Mihalcea and Pulman, 2007). The other content related features are based on some popular features for detecting useful reviews, however we notice that in the humor context it is not very effective. The performance of the contextual features could indicate that humor is not specific to a particular context and thus comparing different context between humorous and non-humorous text will not always work.

For the alliteration and ambiguity features which were reported to be very useful in short text, such as one-liners and on Twitter, are not as useful in detecting humours reviews. The reason is pretty clear since when writing a funny review, the reviewer does not worry about the limitation of text and thus their humor does not rush to a punch-line. Instead the reviewer is able to write a longer more creative piece, adhering to less structure. The features based on incongruity and unexpectedness, do really well in distinguishing the funny and non-funny reviews. For incongruity the best feature is **A2**, achieving about the same accuracy as unexpectedness features of about 83% accuracy.

The best feature was **D2** achieving an accuracy of around 84% accuracy. The features seem to be consistent over all of our classifiers. This indicates that incorporating background text sources to identify humor in reviews is crucial, and our features we can indirectly capture some common knowledge, e.g. prior knowledge. In particular it provides evidence that humor in online reviews can be better categorized as referential humor (Ritchie, 2009) rather then shorter jokes. The results also suggest that we can use these features to help predict the style of humorous text.

Exploring this would be an interesting venue for future work. When we combine our features for the classification task and find that the best combination is the incongruity features with the divergence features. We do not report the results for features **E1, E2** and other context features, **C2, C3, C4**, since their performance when combined with other features did not add to the accuracy of the more discriminant feature. The divergence feature **D2** plays a big role in the accuracy performance. This is in line with our hypothesis that the more uncommon language used the more it is possible to be for a humorous purpose.

It is interesting to see that AdaBoost performed the best out of all three classifiers achieving about 86% accuracy, especially when more features were added, the classifier was able to use this information for improvement. While Naive Bayes and the Perceptron algorithm did not make such improvement achieving about 85% accuracy.

5.4 Ranking Funny Reviews

From the data we noticed that funny reviews tend to be voted highly useful,in particular we noticed a correlation coefficient of 0.77. Although it would have been easy to use the useful votes as a feature to determine whether the review is funny/not funny, these scores are only available after people have been exposed to these reviews. To test how well the features worked when identifying helpful reviews, in a more realistic setting, we formulated a retrieval problem. Given a set of reviews, $\mathcal{D} = \{R_1, R_2, ..., R_m\}$ and relevant scores based on usefulness, $U = \{u_1, u_2, ..., u_m\}$, is it possible to develop a scoring function such that we rank the useful reviews higher? For this task we used the classification output of Naive Bayes, $P(\text{funny}|R_i)$ where i is the current example under consideration, for our scoring function and trained with the best performing features in the original dataset. We used a with-held dataset crawled from restaurants in Yelp in the Los Angeles area containing about 1,360 reviews with 260 reviews labelled as helpful and the other reviews labelled as not helpful. To obtain the ground truth we used the useful votes in Yelp similar to how we constructed the funny labels, using a threshold of 5 votes minimum to be considered helpful. This experiment reveals two things about our features for detecting humorous reviews. First we see that the preci-

[6] Since our main goal is to understand the effectiveness of various features we did not further tune these parameters since they are presumably orthogonal to the question we study.

K	Precision @ K
1	1.00
10	0.50
25	0.48
50	0.44
100	0.45
200	0.54

sion is around 50%, see Table 2, this is more than two times better than random guess which is about 19% and second that our features can be used to filter out some useful reviews.

6 Related Work

Although there has been much work in the theory of humor by many linguists, philosophers and mathematicians (Paulos, 2008), the definition of humor is still a debated topic of research (Attardo, 1994). There have been many applications from computational humor research; for instance, creating embodied agents using humor, such as chat bots, which could allow for more engaging interactions and can impact many domains in education (Binsted et al., 2006). Existing work on computational humor research can typically be divided into humor recognition and humor generation.

In humor generation, some systems have successfully generated jokes and puns by exploiting some lexical structure in the pun/joke (Lessard and Levison, 1992; Manurung et al., 2008; McKay, 2002). The HAHAcronym project was able to take user inputs and output humorous acronyms and it achieves comical effects by exploiting incongruity (Stock and Strapparava, 2002). Work in automatic generation of humor is limited to particular domains, usually only generating short funny texts.

One of the earliest work on humor recognition in text data is the work of Mihalcea and Strapparave (2006), trying to identify *one-liners*, short sentences with a humorous effect. They frame the problems as a classification problem and develop surface features (alliteration, antonym, and adult slang) as well as context related features. They ultimately proposed that additional knowledge such as, irony, ambiguity, incongruity, and common sense knowledge among other things would be beneficial in humor recognition, but they do not further pursue these avenues. Although they are able to distinguish between humorous and non-humorous one liners, in longer of texts such as reviews it is not so clear that these features suffice. Instead we make use of the creative writing structure of the reviewers by looking at the referenced entities in their reviews.

Although verbal irony can be humorous, and an active topic of research (Wallace, 2013), it is often defined as the "opposite to what the speaker means", and combining features for identifying both humor and irony has been studied (see, e.g., Reyes et al. (2012)). In the work by Reyes et al. (2012), the authors defined the unexpectedness feature as semantic relatedness of concepts in Wordnet and assuming that the less the semantic relatedness of concepts the funnier the text. In our work we use a similar definition but applying it to the "topical" relatedness of the referenced aspects and the background language model. The authors demonstrate that irony and humor share some similar characteristics and thus we can potentially use similar features to discriminate them. There has been some early work in identifying humor features in web comments (Reyes et al., 2010), in these comments the users are able to create humor through dialogue thus making the problem more complex. More recently there was a workshop in SemEval-2017 [7], which focus is on identifying humorous tweets which are related, typically as a punchline, to a particular hashtag.

Kiddon and Brun (2011) aimed to understand "That's what she said" (TWSS) jokes, which they classify as double entendres. They frame the problem as metaphor identification and notice that the source nouns are euphemisms for sexually explicit nouns. They also make use of the common structure of the TWSS jokes to the erotic domains to improve 12% in precision over word-based features. In our work we try to explicitly model the incongruity of the reviewer, by doing so we are able to distinguish the separate language used by the user when introducing humorous concepts. Recently there has been work in consumer research, to identify the prevalence of humor in social media (McGraw et al., 2015). The main focus was to examine the benign violation theory, which "suggest that things are humorous when people perceive something as wrong yet okay". One of their finding suggests that humor is more prevalent in complaints than in praise, thus motivating

[7] http://alt.qcri.org/semeval2017/task6/

the usage of automatic humor identification methods for restaurants regardless of its popularity.

While there is a breadth of work in identifying helpful reviews and opinion spam in reviews (Jindal and Liu, 2008) as well as deceptive opinion spam (Ott et al., 2011), and synthetic opinion spam (Sun et al., 2013); we show that humour can also be used to identify helpful reviews.

7 Conclusion

We have studied humorous text identification in a novel setting involving online reviews. This task has not been studied in the previous work and is different than detecting humorous jokes or one-liners, this allows for creative and expressive writing since the reviewer is not limited in text. In this problem we cannot directly apply the ideas that others have developed in order to identify the humorous reviews. Instead features that are based on the theory of incongruity are shown to outperform previous features and are effective in the classification task. Our model introduces a novel and way to incorporate external text sources for humor identification task, and which can be applied to any natural language provided there is a reference database, i.e. news articles or Wikipedia pages, in that language. We also show that the features developed can also be used to identify helpful reviews. This is very useful in the online review setting since there tends to be a cumulative advantage, that is the "rich get richer" effect which limits the exposure that the users get to other helpful reviews. Thus identifying these types of review early can potentially diversify the types of reviews that the users read.

Although we used a background language model on the entire corpus to capture a sense of expectation, there could be other ways to do this. For example, we could develop neural network embeddings to capture the entities descriptions in the reviews. Another direction would be to use topic models and see whether reviewers are more inclined to compare different types of references when talking about certain aspects of restaurants or other products. A different approach to identifying helpful reviews would be to create entertaining and informative summaries.

Sentiment Lexicon Construction with Representation Learning Based on Hierarchical Sentiment Supervision

Leyi Wang and **Rui Xia**[*]

Abstract

Sentiment lexicon is an important tool for identifying the sentiment polarity of words and texts. How to automatically construct sentiment lexicons has become a research topic in the field of sentiment analysis and opinion mining. Recently there were some attempts to employ representation learning algorithms to construct a sentiment lexicon with sentiment-aware word embedding. However, these methods were normally trained under document-level sentiment supervision. In this paper, we develop a neural architecture to train a sentiment-aware word embedding by integrating the sentiment supervision at both document and word levels, to enhance the quality of word embedding as well as the sentiment lexicon. Experiments on the SemEval 2013-2016 datasets indicate that the sentiment lexicon generated by our approach achieves the state-of-the-art performance in both supervised and unsupervised sentiment classification, in comparison with several strong sentiment lexicon construction methods.

1 Introduction

Sentiment lexicon is a set of words (or phrases) each of which is assigned with a sentiment polarity score. Sentiment lexicon plays an important role in many practical sentiment analysis and opinion mining tasks. There were some manually annotated universal sentiment lexicons such as General Inquireer (GI) and HowNet. However, due to the ubiquitous domain diversity and absence of domain prior knowledge, the automatic construction technique for domain-specific sentiment lexicons has become a challenging research topic in the field of sentiment analysis and opinion mining (Wang and Xia, 2016).

The early work employed unsupervised learning for sentiment lexicon construction. They normally labelled a set of seed words at first, and then learned the polarity of each candidate word, based on either word conjunction relations (e.g., constellation and transition in texts) (Hatzivassiloglou and McKeown, 1997), or the word co-occurrence information (such as pointwise mutual information, PMI) (Turney, 2002), between the candidate word and the seed words. However, the unsupervised manner showed limited effect in sentiment prediction, and the performance greatly depends on the quality of the seed words.

To fully exploit the sentiment labeling information in texts, a series of supervised learning methods was further proposed to learn the sentiment lexicons. For example, Mohammad et al. (2013) proposed to construct sentiment lexicons by calculating PMI between the word and the distantly supervised sentiment labels (such as emoticons) in tweets and the word's sentiment orientation (SO). The resulting lexicons obtained the best results in SemEval 2013. More advanced representation learning models were also utilized, with the aim to construct the sentiment lexicons with efficient word embeddings (Tang et al., 2014a; Hamilton et al., 2016; Vo and Zhang, 2016). The traditional representation learning framework such as Word2Vec only captures the syntactic information in the texts, but ignores the sentiment relations between words. Therefore, some researchers attempted to add sentiment supervision into the network structure, in order to train a sentiment-aware word embedding. For example, Tang et al. (2014a) exploited a dedicated neural architecture to integrate document-level sentiment supervision and the syntactic knowledge for representation

Copenhagen, Denmark, September 7–11, 2017. ©2017 Association for Computational Linguistics

learning. The sentiment-aware word embedding is then used to construct a sentiment lexicon. Vo and Zhang (2016) proposed to learn a two-dimensional sentiment representation based on a simple neural network. The sentiment lexicons generated by their approach obtained better performance to predict the tweet sentiment labels, in comparison with the PMI-based method (Mohammad et al., 2013).

Although these supervised learning methods can to some extent exploit the sentiment labeling information in the texts and can learn a sentiment-aware word embedding, the manner of using document-level sentiment supervision suffers from some complex linguistic phenomena such as negation, transition and comparative degree, and hence unable to capture the fine-grained sentiment information in the text. For example, in the following tweet

> *"Four more fake people added me. Is this why people don't like Twitter? :(",*

the document-level sentiment label is negative, but there is a positive word *"like"* in the text. In representation learning, the embeddings of words are summed up to represent the document, and the word *"like"* will be falsely associated with the negative sentiment label. Such linguistic phenomena occur frequently in review texts, and makes sentiment-aware word representation learning less effective.

To address this problem, in this paper, we propose a new representation learning framework called HSSWE, to learn sentiment-aware word embeddings based on hierarchical sentiment supervision. In HSSWE, the learning algorithm is supervised under both document-level sentiment labels and word-level sentiment annotations (e.g., labeling *"like"* as a positive word). By leveraging the sentiment supervision at both document and word level, our approach can avoid the sentiment learning flaws caused by coarse-grained document-level supervision by incorporating fine-grained word-level supervision, and improve the quality of sentiment-aware word embedding. Finally, following Tang et al. (2014a), a simple classifier was constructed to obtain the domain-specific sentiment lexicon by using word embeddings as inputs.

The main contributions of this work are as follows:

1. To the best of our knowledge, this is the first work that learns the sentiment-aware word representation under supervision at both document and word levels.

2. Our approach supports several kinds of word-level sentiment annotations such as 1) predefined sentiment lexicon; 2) PMI-SO lexicon with hard sentiment annotation; 3) PMI-SO lexicon with soft sentiment annotation. By using PMI-SO dictionary as word-level sentiment annotation, our approach is totally corpus-based, without any external resource.

3. Our approach obtains the state-of-the-art performance in comparison with several strong sentiment lexicon construction methods, on the benchmark SemEval 2013-2016 datasets for twitter sentiment classification.

2 Related Work

In general, sentiment lexicons construction can be classified into two categories, dictionary-based methods and corpus-based methods.

Dictionary-based methods generally integrate predefined resources, such as WordNet, to construct sentiment lexicons. Hu and Liu (2004) exploited WordNet for sentiment lexicon construction. They first labelled two sets of seed words by polarities, then extended the sets by adding the synonyms for each word to the same set and antonyms to the other. For a given new word, Kim and Hovy (2004) introduced a Naive Bayes model to predict the polarities with .the synonym set obtained from WordNet as features. Kamps et al. (2004) investigated a graph-theoretic model of WordNet's synonymy relation and measured the sentiment orientation by distance between each candidate word and the seed words with different polarities. Heerschop et al. (2011) proposed a method to propagate the sentiment of seed set words through semantic relations of WordNet.

Corpus-based approaches originate from the latent relation hypothesis: "*Pairs of words that cooccur in similar patterns tend to have similar semantic and sentiment relations*" (Turney, 2008).

The primary corpus-based method made the use of PMI. Turney (2002) built a sentiment lexicon by calculating PMI between the candidate word and seed words. The difference of the PMI score between positive and negative seed words is finally used as the sentiment orientation (SO) of each candidate word (Turney, 2002). Many variants of

PMI were proposed afterwards, for example, positive pointwise mutual information (PPMI), second order co-occurrence PMI (SOC-PMI), etc. Hamilton et al. (2016) proposed to build a sentiment lexicon by a propagation method. The key of this method is to build a lexical graph by calculating the PPMI between words. Instead of calculating the PMI between words, Mohammad et al. (2013) proposed to use emoticons as distant supervision and calculate the PMI between words and the distant class labels, and obtained sound performance for tweet sentiment classification.

The latest corpus-based approaches normally utilize the up-to-date machine learning models (e.g. neural networks) to first learn a sentiment-aware distributed representation of words, based on which the sentiment lexicon is then constructed. There were many word representation learning methods such as NNLM (Bengio et al., 2003) and Word2Vec (Mikolov et al., 2013). However, they mainly consider the syntactic relation of words in the context but ignore the sentiment information. Some work were later proposed to deal with this problem by incorporating the sentiment information during representation learning. For example, Tang et al. (2014a) adapted a variant of skip-gram model, which can learn the sentiment information based on distant supervision. Furthermore, Tang et al. (2014b) proposed a new neural network approach called SSWE to train sentiment-aware word representation. Vo and Zhang (2016) exploited a simple and fast neural network to train a 2-dimensional representation. Each dimension is explicitly associated with a sentiment polarity.

The sentiment-aware word representation in these methods was normally trained based on only document-level sentiment supervision. In contrast, the learning algorithm in our approach is supervised under both document-level and word-level sentiment supervision.

3 Our Approach

Our approach is comprised of three base modules: (1) Word-level sentiment learning and annotation; (2) Sentiment-aware word embedding learning; (3) Sentiment lexicon construction.

Our approach depends on document-level sentiment labels. The tweet corpus provides a cheap way to get document-level sentiment annotation, owing to the distant sentiment supervision. But it should be noted that our approach is feasible for any corpus provided with document-level sentiment labels (not merely tweets).

The first module of our method aims to learn the pseudo sentiment distribution for each word and use it as word-level sentiment annotations to supervise word embedding learning.

In the second module, we learn the sentiment-aware embeddings for each word in corpus, based on hierarchical sentiment supervision.

In the last module, we construct a sentiment lexicon by using the sentiment-aware word embeddings as the basis.

3.1 Learning Word-Level Sentiment Supervision

In addition to use a pre-defined sentiment lexicon for word-level annotations, we also propose to learn the word-level sentiment supervision, based on PMI and SO.

(1) PMI and SO

Given a corpus with document-level class labels. We first compute the PMI score between each word t and two class labels

$$PMI(t,+) = \log \frac{p(+|t)}{p(+)}, \tag{1}$$

$$PMI(t,-) = \log \frac{p(-|t)}{p(-)}, \tag{2}$$

where $+$ and $-$ denote the positive and negative document-level class labels, respectively.

Second, we compute the SO score for each word t:

$$SO(t) = PMI(t,+) - PMI(t,-). \tag{3}$$

We call $\{t, SO(t)\}$ as PMI-SO dictionary. The PMI-SO dictionary was widely used as a corpus-based sentiment lexicon for sentiment classification. By contrast, in our approach, it is the first step to learn the sentiment-aware word representation. Our approach supports two kinds of word-level sentiment annotations: 1) PMI-SO dictionary with hard sentiment annotation; 2) PMI-SO dictionary with soft sentiment annotation.

The word-level sentiment annotation is represented as $[\hat{p}(-|t), \hat{p}(+|t)]$. We employ the following two ways to obtain $[\hat{p}(-|t), \hat{p}(+|t)]$.

(2) PMI-SO lexicon with hard sentiment annotation

Notations	Description
e_t	The embedding of word t
de	The document representation of d
b_t	The bias of word-level softmax layer
b_d	The bias of document-level softmax layer
θ_t	Weight of word-level softmax layer
θ_d	Weight of document-level softmax layer
$p(c\|e_t)$	The sentiment distribution of word t predicted by our model
$p(c\|de)$	The sentiment distribution of document d predicted by our model
$\hat{p}(c\|t)$	The word-level sentiment annotation of word t with respect to class c
$\hat{p}(c\|d)$	The document-level sentiment annotation of document d with respect to class c

Table 1: The parameters used in our neural network.

"Hard sentiment annotation" indicates that $[\hat{p}(-|t), \hat{p}(+|t)]$ is a two-dimensional one-hot representation, where the annotation of words is given by the class labels:

$$[\hat{p}(-|t), \hat{p}(+|t)] \\ = \begin{cases} [0,1], & \text{if } SO(t) > 0 \\ [1,0], & \text{if } SO(t) < 0 \\ random\{[1,0] or [0,1]\}, & \text{otherwise} \end{cases}. \tag{4}$$

(3) PMI-SO lexicon with soft sentiment annotation

"Soft sentiment annotation" means that the annotation is given by the probability of two sentiment polarities, rather than the class label. We first use the sigmoid function to map the SO score to the range of a probability, and then define

$$[\hat{p}(-|t), \hat{p}(+|t)] = [1 - \sigma(SO(t)), \sigma(SO(t))] \tag{5}$$

as the PMI-SO soft sentiment distribution of the word t.

3.2 Learning Sentiment-aware Word Representation under Hierarchical Sentiment Supervision

Till now we have obtained both document and word-level sentiment annotations, in the next step, we propose a neural network framework to learn the sentiment-aware word representation by integrating the sentiment supervision at both word and document granularities. We call it "hierarchical sentiment supervision". The architecture of our model is shown in Figure 1. We denote the corpus as $D = \{d_1, d_2, ..., d_N\}$ where N is the size of the corpus. Suppose d_k is k-th document in D, and t_i represents the i-th word in a document d. The parameters used in our neural network are described in Table 1.

We construct a embedding matrix $C \in R^{V \times M}$, of which each row represents the embedding of a word in the vocabulary, where V is the size of the vocabulary and M is the dimension of word embedding. We randomly initialize each element of matrix C with a normal distribution.

(1) Word-Level Sentiment Supervision

We use the word-level sentiment annotation $[\hat{p}(-|t), \hat{p}(+|t)]$ provided in Section 3.1 to supervise word representation learning at the word level.

For each word in document d, we map it to a continuous representation as $e \in C$ and feed e into our model to predict the sentiment distribution of the input word:

$$p(c|e) = softmax(\theta_t \cdot e + b_t). \tag{6}$$

The cost function is defined as the average cross entropy that measures the difference between the sentiment distribution predicted in our model and the sentiment annotations at the word level:

$$f_{word} = -\frac{1}{T} \sum_{k=1}^{N} \sum_{t \in d_k} \sum_{c \in \{+,-\}} \hat{p}(c|t) \log p(c|e_t) \tag{7}$$

where T is the number of words in corpus.

(2) Document-Level Sentiment Supervision

We use the document-level sentiment annotations to supervise word representation learning at the document level.

In order to obtain a continuous representation of a document d, we simply use the average embedding of words in d as de:

$$de = \frac{1}{|d|} \sum_{t \in d} e_t. \tag{8}$$

We feed de into our model to predict the sentiment probability:

$$p(c|de) = softmax(\theta_d \cdot de + b_d). \tag{9}$$

An Element of Embedding

Figure 1: The Architecture of our Neural Network. Given a document d, represented as $[t_1, t_2, \ldots, t_n]$. t_i is the i-th word in d. And e_{t_i} represents the embedding of the word t_i. We take de, the average embedding of $[e_{t_1}, e_{t_2}, \ldots, e_{t_n}]$, as the representation of document d. We get each embedding of words in d as input to predict its sentiment polarities. We also take de as input to predict the sentiment for document d one time per epoch.

Similarly, the cost function is defined as average cross entropy that measures the difference between the sentiment distribution predicted in our model and the sentiment annotation at the document level:

$$f_{doc} = -\frac{1}{N}\sum_{k=1}^{N}\sum_{c\in\{+,-\}}\hat{p}(c|d_k)\log p(c|de_k) \tag{10}$$

where $\hat{p}(c|d_k)$ is the sentiment annotation of document d_k. $\hat{p}(c|d_k) = 1$ denotes the class label of d_k is positive, otherwise $\hat{p}(c|d_k) = 0$.

(3) Word and Document-Level Joint Learning

In order to learn the sentiment-aware word representation at both word and document levels, we integrate the cost function of two levels in a weighted combination way. The final cost function is defined as follows:

$$f = \alpha f_{word} + (1-\alpha) f_{doc} \tag{11}$$

where α is a tradeoff parameter$(0 \leq \alpha \leq 1)$. The weight of f_{word} can be increased by choosing a lager value of α.

We train our neural model with stochastic gradient descent and use AdaGrad (Duchi et al., 2011) to update the parameters.

3.3 From Sentiment Representation to Sentiment Lexicon

In this part, we follow the method proposed by Tang et al. (2014a) to build a classifier to convert the sentiment-aware word representation learned in Section 3.2 to a sentiment lexicon. The word representation is the input of the classifier and word sentiment polarity is the output.

Firstly, we utilize the embedding of 125 positive and 109 negative seed words manually labelled by Tang et al. (2014a) as training data[1].

Secondly, a variant-KNN classifier is also applied to extending the seed words on a web dictionary called Urban Dictionary. Unlike (Tang et al.,

[1] http://ir.hit.edu.cn/ dytang/paper/14coling/data.zip

Dataset	$\#pos$	$\#neg$	$Total$
SemEval2013-train	3632	1449	5081
SemEval2013-dev	482	282	764

2014a), we did not extend the neutral words.

Thirdly, a traditional logistic regression classifier is trained by using the embeddings of extended sentiment words as the inputs. The sentiment score of a word is the difference between its positive and negative probabilities.

Finally, the sentiment lexicon can be collected by using the classifier to predict the other words' sentiment score.

4 Experiment Study

4.1 Datasets and Settings

We utilize the public distant-supervision corpus[2] (Go et al., 2009) to learn our lexicons. We set M, the dimension of embedding, as 50. The learning rate is 0.3 for stochastic gradient descent optimizer. We tune the hyper-parameter α in the training process.

We evaluate the sentiment lexicons in both supervised and unsupervised sentiment classification tasks, on the SemEval 2013-2016 datasets. The statistics of evaluation datasets are shown in Table 2.

Supervised Sentiment Classification Evaluation: To evaluate the effect of the sentiment lexicon in supervised sentiment classification, we report the supervised sentiment classification performance by using some pre-defined lexicon features. We follow (Mohammad et al., 2013) to extract the lexicon features as follows:

- Total count of words in the tweet score of which is greater than 0;
- Total count of words in the tweet score of which is less than 0;
- The sum of scores for all word great than 0;
- The sum of scores for all word less than 0;
- The max score greater than 0;
- The min score less than 0;
- Non-zero score of the last positive word in the tweet;
- Non-zero score of the last negative word in the tweet.

We report the performance of SVM by using these lexicon features. The LIBSVM [3] toolkit is used with a linear kernel and the penalty parameter is set as the default value. The metric is F_1 score.

Unsupervised Sentiment Classification Evaluation: For unsupervised sentiment classification, we sum up the scores of all sentiment words in the document, according to the sentiment lexicon. If the sum is greater than 0, the document will be considered as positive, otherwise negative. The unsupervised learning evaluation metric is accuracy.

4.2 (External) Comparison with Public Lexicons

We compare our HSSWE method with four sentiment lexicons generated by the related work proposed in recent years:

- **Sentiment140** was constructed by Mohammad et al. (2013) on tweet corpus based on PMI between each word and the emoticons.
- **HIT** was constructed by Tang et al. (2014a) with a representation learning approach.
- **NN** was constructed by Vo and Zhang (2016) with a neural network method.
- **ETSL** refers to SemEval-2015 English Twitter Sentiment Lexicon[4] (Rosenthal et al., 2015; Kiritchenko et al., 2014), which is done using Best-Worst Scaling.

Note that Tang et al. (2014a), Vo and Zhang (2016) used incomplete dataset of SemEval2013 in their papers. For fair comparison, we conduct

Table 4: Unsupervised Evaluation for External Comparison (Accuracy)

all the comparison experiments on the complete benchmark datasets.

Supervised Sentiment Classification: We first report the supervised sentiment classification F_1 score of five compared methods on the Semeval 2013-2016 datasets in Table 3. It can be seen that our HSSWE method gets the best result on all four datasets. It outperforms Sentiment140, HIT, NN and ETSL 1.7, 2.8, 1.9, and 3.2 percentages on the average of four datasets. The improvements are significant according to the paired t-test.

Unsupervised Sentiment Classification: We then report the unsupervised sentiment classification accuracy of five methods on the Semeval 2013-2016 datasets in Table 4. In can be seen that HSSWE obtains the best performance on Semeval 2013-2015. On the Semeval 2016 dataset, it is slightly lower than ETSL. Across four datasets, the average accuracy of HSSWE is 6.6, 3.1, 9.6 and 0.94 higher than Sentiment140, HIT, NN and ETSL, respectively.

4.3 (Internal) Comparison within the Model

In order to further verify the effectiveness of our method and analyze which part of our model contributes the most, we carried out the internal comparison within our model. We design the following two simplified versions of our model for comparison:

- **PMI-SO** denotes a PMI-SO based sentiment lexicon with soft sentiment annotation learned in Section 3.1.
- **Doc-Sup** denotes the neural network system with only document-level sentiment supervision. It equals to HSSWE when $\alpha = 0$.

Actually, HSSWE can be viewed as a "combination" of PMI-SO and Doc-Sup. In Tables 5 and 6, we report the comparison results on supervised and unsupervised sentiment classification respectively.

Supervised Sentiment Classification: As is shown in Table 5, two basic models PMI-SO and Doc-Sup show similar performance. They have distinct superiority across different datasets. But both are significantly lower than HSSWE. It shows that by combing the supervision at both document and word levels, it can indeed improve the quality of sentiment-aware word embedding and the subsequent sentiment lexicon.

Unsupervised Sentiment Classification: As is shown in Table 6, the conclusions are similar with that in supervised sentiment classification: HSSWE achieves the significantly better performance.

4.4 Word-level Sentimnt Annotation: Hard vs. Soft

In Section 3.1, we introduce two kinds of word-level sentiment annotation, i.e., soft and hard sentiment annotation. We now compare two methods. The results are reported in Tables 5 and 6. It can be seen that for supervised evaluation, HSSWE (soft) and HSSWE (hard) yield comparative performance. HSSWE (hard) has slight superiority over HSSWE (hard) in Semeval 2013, 2014 and 2016, but HSSWE (hard) is better on Semeval2015. In contrast, for unsupervised evaluation, HSSWE (soft) is significantly better than

Lexicon	Semeval2013	Semeval2014	Semeval2015	Semeval2016	Average
PMI-SO	0.7265	0.7333	0.7008	0.6858	0.7116
Doc-Sup	0.7326	0.7302	0.6814	0.6986	0.7107
HSSWE (soft)	***0.7550***	***0.7424***	0.6921	***0.7097***	***0.7248***
HSSWE (hard)	0.7503	0.7383	***0.7020***	0.7061	0.7242

Table 5: Supervised Evaluation for Internal Comparison (F_1 Score), where HSSWE (hard) and HSSWE (soft) utilize the PMI-SO lexicon with hard sentiment annotation and soft sentiment annotation at the word level, respectively.

Lexicon	Semeval2013	Semeval2014	Semeval2015	Semeval2016	Average
Doc-Sup	0.7252	0.8294	0.7391	0.6859	0.7449
HSSWE (soft)	***0.7734***	***0.8539***	***0.7669***	***0.7206***	***0.7787***
HSSWE (hard)	0.7418	0.8395	0.7633	0.7011	0.7614

Table 6: Unsupervised Evaluation for Internal Comparison (Accuracy)

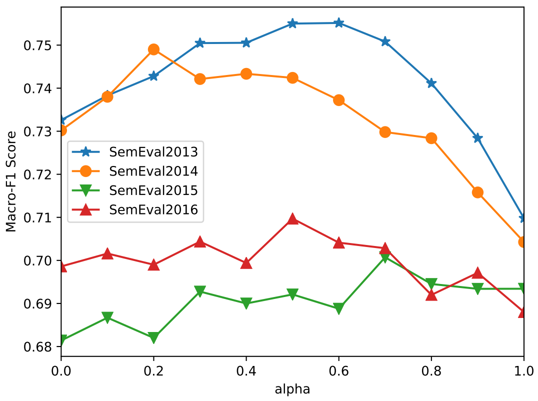

Figure 2: HSSWE (soft) with different α

HSSWE (hard). The average improvement is 1.7 percentage.

4.5 Tuning the Parameter α

In this section, we discuss the tradeoff between two parts of supervisions by turning the tradeoff parameter α. When α is 0, HSSWE only benefits from the document-level sentiment supervision and when α is 1, HSSWE benefits from only word-level sentiment supervision. We observe that HSSWE performs better when α is in the range of [0.45,0.55]. By integrating two component parts of sentiment supervision, HSSWE has significant superiority over that learned from either one.

4.6 Lexicon Analysis

In order to gain more insight of our model and observe the effectiveness of the sentiment lexicon, in Table 7 we extract the positive sentiment score of some representative words learned by different methods. The positive scores are supposed to be: *best*>*better*>*well*. HSSWE captures such comparative sentiment strength but PMI-SO does not. We further observe that in many cases where the results of PMI-SO and Doc-Sup are inconsistent (e.g., Doc-Sup incorrectly predicts *“unreasonable”*, *“boreddddd”* and *“sickkk”* as positive words, but PMI-SO predicts them correctly; PMI-SO incorrectly predicts *“fit”* but Doc-Sup predicts it correctly.), HSSWE often yield the correct results. It shows the advantages of hierarchical sentiment supervision. HSSWE can also correct the sentiment prediction where both PMI-SO and Doc-Sup are inefficient (e.g., *“overplayed”*).

Words	HSSWE	PMI-SO	Doc-Sup
well	0.5740	0.5430	0.7898
better	0.5837	*0.5358 (F)*	0.8440
best	0.9455	0.6823	0.9639
fit	0.2894	*-0.5594 (F)*	0.6076
unreasonable	-0.2441	-0.8421	*0.5275 (F)*
boreddddd	-0.1137	-0.7142	*0.4843 (F)*
sickkkk	-0.3892	-0.7692	*0.1323 (F)*
overplayed	-0.1390	*0.5000 (F)*	*0.8448 (F)*

Table 7: Sentiment Lexicon Analysis, where score with *(F)* means falsely predicted polarity or strength.

5 Conclusion

In this paper, we proposed to construct sentiment lexicons based on a sentiment-aware word representation learning approach. In contrast to traditional methods normally learned based on only the document-level sentiment supervision. We proposed word representation learning via hierarchical sentiment supervision, i.e., under the supervision at both word and document levels. The word-level supervision can be provided based on either predefined sentiment lexicons or the learned PMI-SO based sentiment annotation of words. A wide range of experiments were conducted on several benchmark sentiment classification datasets. The results indicate that our method is quite effective for sentiment-aware word representation, and the sentiment lexicon generated by our approach beats the state-of-the-art sentiment lexicon construction approaches.

Towards a Universal Sentiment Classifier in Multiple languages

Kui Xu and **Xiaojun Wan**
Institute of Computer Science and Technology, Peking University
The MOE Key Laboratory of Computational Linguistics, Peking University
{kuixu, wanxiaojun}@pku.edu.cn

Abstract

Existing sentiment classifiers usually work for only one specific language, and different classification models are used in different languages. In this paper we aim to build a universal sentiment classifier with a single classification model in multiple different languages. In order to achieve this goal, we propose to learn multilingual sentiment-aware word embeddings simultaneously based only on the labeled reviews in English and unlabeled parallel data available in a few language pairs. It is not required that the parallel data exist between English and any other language, because the sentiment information can be transferred into any language via a pivot languages. We present the evaluation results of our universal sentiment classifier in five languages, and the results are very promising even when the parallel data between English and the target languages are not used. Furthermore, the universal single classifier is compared with a few cross-language sentiment classifiers relying on direct parallel data between the source and target languages, and the results show that the performance of our universal sentiment classifier is very promising compared to that of different cross-language classifiers in multiple target languages.

1 Introduction

Nowadays, a large amount of user-generated content (UGC) appears online everyday, such as tweets, comments and product reviews. Sentiment classification on these data has become a popular research topic over the past few years (Pang et al., 2002; Blitzer et al., 2007; Agarwal et al., 2011; Liu, 2012). Distributed representations of words or word embeddings have been widely explored, and have proved its great usability for the sentiment classification task (Tang et al., 2014; Zhou et al., 2015; Xu et al., 2015; Bollegala et al., 2016; Ferreira et al., 2016).

Most existing sentiment classifiers rely on labeled training data and the data are usually language-dependent. In other words, a sentiment classifier is learned from a labeled dataset in a specific language and this sentiment classifier can be used for sentiment classification in this language. However, labeled training data for sentiment classification are not available or not easy to obtain in many languages in the world (e.g., Malaysian, Mongolian, Uighur). Without reliable labeled data, it is hard to build a sentiment classifier in these resource-poor languages.

Fortunately, there are a few studies investigating the task of cross-language sentiment classification (Banea et al., 2008; Wan, 2009; Meng et al., 2012; Xiao and Guo, 2013; Gao et al., 2015; Chen et al., 2015; Zhou et al., 2015; Li et al., 2017; Zhou et al., 2016a,b), which aims to make use of the labeled data in a source language (English in most cases) to build a sentiment classifier in a target language. However, cross-language sentiment classification methods rely on parallel data between the source and target languages[1] In a resource-poor language, the parallel data between this language and the source language may not be available or is not easy to obtain. In this circumstance, previous cross-language sentiment classification meth-

[1] Note that a few methods rely on a machine translation system to produce parallel data between the two languages, while the machine translation system is built on a large amount of parallel data between the two languages. In this sense, the methods rely on both the parallel data for machine translation and the pseudo parallel data produced by machine translation systems.

Proceedings of the 2017 Conference on Empirical Methods in Natural Language Processing, pages 511–520
Copenhagen, Denmark, September 7–11, 2017. ©2017 Association for Computational Linguistics

ods will fail to work.

Another shortcoming of previous cross-language sentiment classification researches is that we have to build an individual cross-language sentiment classifier for each target language, even when we want to perform sentiment classification in a couple of languages at the same time.

In this study, instead of building a sentiment classifier for each target language, we aim to build a universal sentiment classifier in multiple languages and this universal sentiment classifier only learns one single sentiment classification model and it can be applied for sentiment classification in many languages.

In order to achieve this goal, we propose an approach to learn multilingual sentiment-aware word embeddings simultaneously based only on the labeled reviews in English and unlabeled parallel data available in a few language pairs. As mentioned earlier, in some resource-poor languages, there do not exist direct parallel data between these languages and the source English language. In order to address this problem, we propose a pivot-based model to transfer the sentiment information from the source language to any resource-poor language via pivot languages. Finally, a universal sentiment classifier can be built because the multilingual word embeddings are in the same semantic space.

We build three different models (Bilingual Model, Pivot-Driven Bilingual Model and Universal Multilingual Model) and compare them empirically in order to answer two questions in this paper: 1) Can pivot-based models learn bilingual sentiment-aware word embeddings effectively? 2) Can an effective universal sentiment classifier be built for multiple languages?

Without loss of generality, we present and compare the evaluation results of the models in five languages. Evaluation results show that pivot-driven bilingual models perform as well as the bilingual model using direct parallel data, which lays the solid foundation of our universal model. Moreover, it is very promising that our universal sentiment classifier can work well in five languages, and it can achieve very promising classification results as compared to several typical cross-language sentiment classification models.

The main contributions of our study in this paper are summarized as follows:

- We are the first to build a universal sentiment classifier in multiple languages by learning multilingual sentiment-aware word embeddings, which can not be addressed by previous researches on cross-language sentiment classification.
- We propose pivot-based models to bridge two languages in which there do not exist parallel data, and thus the sentiment information can be transferred to any target language.
- Evaluation results on five languages demonstrate the efficacy of our proposed pivot-based models and the universal sentiment classifier.

2 Our Approach

In order to build a universal sentiment classifier, we propose an approach to learn multilingual sentiment-aware word embeddings simultaneously, and then train a universal sentiment classification model in the embedding space by averaging the word embeddings in a document as the document representation. Note that in this study, we focus on only using the labeled data in English and do not make use of any labeled data in other languages, which makes the task more challenging[2]. Formally, we aims to build a single sentiment classifier which can perform sentiment classification in many languages $\{S, T_1, T_2, ..., T_N\}$, where S refers to English language, and T_1 to T_N refer to other N languages.

In our approach, the multilingual sentiment-aware word embeddings play the key role in building the universal sentiment classifier, and now the question is how to learn the multilingual sentiment-aware word embeddings? Inspired by previous studies on cross-lingual sentiment classification and bilingual word embedding learning, we can leverage the labeled data in S (i.e., English) and unlabeled parallel data between S and language T to learn bilingual sentiment-aware word embeddings in both English and T languages with a bilingual model. However, such unlabeled parallel data are not always easy to obtain for all other languages. For a specific language T, if the unlabeled parallel data between T and S do not exist, the bilingual model cannot be applied. In order to address this problem, we propose a pivot-driven bilingual model to leverage pivot languages

[2] Note that the labeled data in other languages can be easily used by our approach in the same way as the English labeled data, and we believe more labeled data will eventually improve the performance of the sentiment classifier.

to bridge T and S. We choose a pivot language P where the parallel data between P and S, and the parallel data between P and T are easy to obtain, and then leverage them to learn the multilingual sentiment-aware word embeddings in the three languages P, T and S. Furthermore, we can leverage more parallel data between multiple languages, some of which are parallel data between S and other languages, and some of which are parallel data within other languages, to build an universal multilingual model. The sentiment information will be directly or indirectly transfered to each language as well, and thus we obtain multilingual sentiment-aware word embeddings in many languages.

The bilingual model, pivot-driven bilingual model and universal multilingual model will be described in next sections, respectively.

2.1 Bilingual Model

The bilingual model tries to induce bilingual word embeddings from a parallel corpus, and in the meantime make similar words from the two languages share adjacent vector representations in the same vector space.

Formally, we assume a source language S with $|S|$ words and a target language T with $|T|$ words. We use s and t to represent a word from S and T, respectively. Given the bilingual parallel corpus $\mathcal{C}$ between language S and T, it can be divided into a corpus $\mathcal{C_S}$ in language S and a corpus $\mathcal{C_T}$ in language T. And we use a notation $S-T$ to indicate a parallel corpus between languages S and T.

Previous studies have proposed some bilingual models for learning bilingual word embeddings, so we extend the well-behaved BiSkip model (Luong et al., 2015) to Bilingual Model (**BM**). This model requires word alignment information, and in this study word alignment is automatically obtained from parallel sentences by using a word alignment tool.

In our bilingual model, every word s in language S is required to predict the adjacent words of itself and the aligned word t in the target language T. For corpus $\mathcal{C_S}$, the monolingual constraint on itself ($\mathcal{C_S} \rightarrow \mathcal{C_S}$) is:

$$Obj(\mathcal{C_S}|\mathcal{C_S}) = \sum_{s\in\mathcal{C_S}} \sum_{w\in adj(s)} \log p(w|s), \quad (1)$$

and the cross-lingual constraint on $\mathcal{C_T}$ ($\mathcal{C_S} \rightarrow \mathcal{C_T}$) is:

$$Obj(\mathcal{C_T}|\mathcal{C_S}) = \sum_{s\in\mathcal{C_S}} \sum_{w\in adj(t), s\leftrightarrow t} \log p(w|s) \quad (2)$$

where $s\leftrightarrow t$ means word $s(\in \mathcal{C_S})$ is aligned to word $t(\in \mathcal{C_T})$ and $adj(s)$ or $adj(t)$ mean the adjacent words of word s or t.

Similarly, for corpus $\mathcal{C_T}$ we can obtain:

$$Obj(\mathcal{C_T}|\mathcal{C_T}) = \sum_{t\in\mathcal{C_T}} \sum_{w\in adj(t)} \log p(w|t), \quad (3)$$

and

$$Obj(\mathcal{C_S}|\mathcal{C_T}) = \sum_{t\in\mathcal{C_T}} \sum_{w\in adj(s), t\leftrightarrow s} \log p(w|t) \quad (4)$$

Combining equations 1, 2, 3 and 4, we get the objective for obtaining bilingual word embeddings from parallel corpus:

$$Obj(\mathcal{C}) = \alpha_1 Obj(\mathcal{C_S}|\mathcal{C_S}) + \alpha_2 Obj(\mathcal{C_T}|\mathcal{C_S})$$
$$+\alpha_3 Obj(\mathcal{C_T}|\mathcal{C_T}) + \alpha_4 Obj(\mathcal{C_S}|\mathcal{C_T})$$

where $\alpha_1, \alpha_2, \alpha_3$ and α_4 are scalar parameters.

We still have to incorporate the sentiment information into the bilingual word embeddings. Similar to previous studies (Zhou et al., 2015), we make use of the sentiment polarity of texts as supervision in the learning process. Given a labeled sentimental corpus $\mathcal{C_L}$[3], we use S^* to represent a sentence in $\mathcal{C_L}$ and w as a word in S^*. And x^T is a sum of word embeddings in S^*. We simply adopt the logistic regression classifier to enforce the sentiment constraint, and thus make the bilingual word embeddings absorb the corresponding sentiment information. The objective function is:

$$L(\mathcal{C_L}) = \sum_{S^*\in\mathcal{C_L}} y \log \sigma(Wx^T + b)$$
$$+ (1-y) \log \sigma(1 - (Wx^T + b)) \quad (5)$$

where y is the label of the sentence S^*, W is a weight vector and b is a bias.

The overall objective function for inducing bilingual sentiment-aware word embeddings is to maximize:

$$Obj(\mathcal{C}) + L(\mathcal{C_L})$$

[3] Note that the labeled corpus is usually provided in the source language S, which means L is S. but the labeled corpus usually does not overlap with the parallel corpus.

2.2 Pivot-Driven Bilingual Model

For some resource-poor target language T, it is quite expensive to get direct parallel corpus between T and the source language S. Without such parallel corpus, it is not possible to apply the above bilingual model to learn bilingual sentiment-aware word embeddings. In order to address this problem we propose our Pivot-Driven Bilingual Model (**PDBM**) by using a pivot language to bridge T and S. The model is inspired by (Wu and Wang, 2007), in which pivot languages are used for phrase-based SMT. A pivot language P is chosen if the parallel corpus between P and S, and the parallel corpus between P and T are easy to obtain. Given two parallel corpora: S-P and P-T, our PDBM model tries to get the trilingual word embeddings by putting constrains on the two corpora. Under the well-designed constraint, the pivot language P can pass the sentiment information from the source language S to the target language T. Similarly, we further assume the pivot language P with $|P|$ words, and use $\mathcal{C_P}$ to denote the corpus in language P.

We design constraints on the two parallel corpora S-P and P-T, instead of direct constraints on S and T. Derived from the BM model, we can get three monolingual constraints $\mathcal{C_S}\rightarrow \mathcal{C_S}$, $\mathcal{C_T}\rightarrow\mathcal{C_T}$, $\mathcal{C_P}\rightarrow\mathcal{C_P}$ and four bilingual constraints $\mathcal{C_S}\rightarrow\mathcal{C_P}$, $\mathcal{C_T}\rightarrow\mathcal{C_P}$, $\mathcal{C_P}\rightarrow\mathcal{C_S}$ and $\mathcal{C_P}\rightarrow\mathcal{C_T}$. The final objective function for learning the trilingual word embeddings can be summarized as:

$$\begin{aligned} Obj_p(\mathcal{C}) = \beta_1 Obj(\mathcal{C_S}|\mathcal{C_S}) + \beta_2 Obj(\mathcal{C_S}|\mathcal{C_P}) \\ +\beta_3 Obj(\mathcal{C_T}|\mathcal{C_T}) + \beta_4 Obj(\mathcal{C_T}|\mathcal{C_P}) \\ +\beta_5 Obj(\mathcal{C_P}|\mathcal{C_S}) + \beta_6 Obj(\mathcal{C_P}|\mathcal{C_T}) \\ +\beta_7 Obj(\mathcal{C_P}|\mathcal{C_P}) \end{aligned}$$

where $\beta_1, \beta_2, \beta_3, \beta_4, \beta_5, \beta_6, \beta_7$ are scalar parameters. Similarly, the objective for enforcing the sentiment constraint is the same as equation 5, so we combine them together to get the overall objective function:

$$Obj_p(\mathcal{C}) + L(\mathcal{C_L})$$

Through the pivot language, the sentiment information can be passed from a source language to a target language by maximizing the above objective function.

2.3 Universal Multilingual Model

The bilingual model and the pivot-driven bilingual model lay the foundations of build a universal multilingual model for sentiment classification in many languages. Given a source language S and a few other languages $\{T_1, T_2, ..., T_N\}$. If there exist parallel data between a language T_i and S, then the bilingual sentiment-aware word embeddings can be learned by the bilingual model. If the parallel data between languages T_i and S are not available, a pivot language can be selected and the pivot-driven model can be applied to learn the trilingual sentiment-aware word embeddings. Even when a single pivot language cannot be found for languages T_i and S, we still can find two or more pivot languages $\{P_1, P_2, ..., P_M\}$ to form a pivot chain and the sentiment information in the source language can be passed through the pivot chain ($S - P_1 - ... - P_M - T_i$) to the target language.

Therefore, in this model, we will make use of all parallel corpora between any pair of languages (including parallel corpora between the source language and any other language, and parallel corpora between other languages) and learn the sentiment-aware word embeddings in all the languages simultaneously. The monolingual objective in each language and the cross-lingual objective for any available parallel corpus are defined in the same way as in the above models, and we sum all the objectives and denote it as $Obj_{universal}(C)$, and this objective is then combined with the sentiment constraint as follows:

$$Obj_{universal}(\mathcal{C}) + L(\mathcal{C_L})$$

By maximizing the above objective function, the sentiment-aware word embeddings in all the languages will be learned.

3 Evaluations

3.1 Dataset

Without loss of generality, we evaluate our models in five languages (including three western languages and two Asian languages): English (en), German (de), French (fr), Japanese (jp) and Chinese (en/zh). Among these languages, the English language is the source language with labeled training data, and we do no use any labeled data in the other languages.

Particularly, we use the multilingual multi-domain Amazon review dataset [4] provided by (Prettenhofer and Stein, 2010) and the NLPCC2013 dataset [5]. The review dataset provided by (Prettenhofer and Stein, 2010) contains labeled data in four languages: English, German, French and Japanese, and the NLPCC2013 dataset further provides labeled data in Chinese. The reviews in each language are divided into three domains: *dvd*, *music* and *books*. Each domain of product reviews contains a balanced training set and test set, each of which consists of 1000 positive and 1000 negative reviews for each language except for Chinese. While for Chinese language, the test set consists of 2000 positive and 2000 negative reviews. We only use English training data as the labeled data in the experiments.

We further obtain unlabeled parallel data from Europarl v7 [6] (Koehn, 2004) (*Eu v7*) and The United Nations Parallel Corpus v1.0 [7] (Ziemski et al., 2016) (*UN v1.0*). The Europarl corpus contains bilingual parallel corpus between English and other 20 Europe languages. The United Nations Parallel Corpus is composed of official records and other parliamentary documents of the United Nations that are in the public domain. These documents are mostly available in the six official languages of the United Nations. Besides, we use the *cldc-2009-004* [8] Chinese-English (*CN-EN*) news parallel corpus and *Japanese-English Bilingual Corpus of Wikipedia's Kyoto Articles Version 2.01* [9] (*JP-EN*), which is created manually by translating Japanese Wikipedia articles (related to Kyoto) into English. In addition, *CJWikiCorpus* (*CN-JP*) is a Chinese-Japanese Parallel Corpus Constructed from Wikipedia [10]

For the the BM model, we use *en-de* ($\in$ *Eu v7*) and *en-fr* ($\in$ *Eu v7*), *en-zh* ($\in$ *CN-EN*), and *en-jp* ($\in$ *JP-EN*).

For the PDBM model, we use *en-fr* ($\in$ *UN v1.0*) with *fr-de* ($\in$ *Eu v7*) to get the case *en-fr-de* (*fr* acts as a pivot), *en-zh* ($\in$ *CN-EN*) with *zh-jp* ($\in$ *CN-JP*) to build the case *en-zh-jp* (*zh* acts as a pivot), *en-zh* ($\in$ *CN-EN*) with *zh-fr* ($\in$ *UN v1.0*) to build *en-zh-fr* (*zh* acts as a pivot), and *en-fr* ($\in$ *Eu v7*) with *zh-fr* ($\in$ *UN v1.0*) to build *en-fr-zh* (*fr* acts as a pivot). Note that any pivot language can be selected if the parallel corpora between the pivot language and other languages can be obtained, but in our experiments, we only use one pivot language in each test case to validate the feasibility of our proposed model. In practice, a popular language (such as English, Chinese) can be used as the pivot because it can act as a link between two unpopular languages.

While for the UMM model, we use all the corpora used in PDBM to build a universal model. All the details can be found in Table 1.

3.2 Comparison Methods

In addition to the comparison between our models, we further compare them with popular cross-lingual (CL) sentiment classification methods.

For comparison in German, French and Japanese, we adopt a few typical CL classification methods, and the results are directly borrowed from the corresponding published papers:

MT-BOW: It is a simple model to train a linear classifier based on the bag-of-words features, and it uses a machine translator to translate the test data into the source language (Prettenhofer and Stein, 2010) .

CL-SCL: It is the cross-lingual structural correspondence learning algorithm proposed by (Prettenhofer and Stein, 2010) and the features in the two languages are mapped to a unified space.

BSE: It is introduced in (Tang and Wan, 2014) by forcing the representations of words from both the source and target languages to share the same feature space. In this way, bilingual word embeddings are learned for cross-lingual sentiment classification.

CR-RL: It is the bilingual word representation learning method of (Xiao and Guo, 2013). It learns different representations for words in different languages. Part of the word vector is shared among different languages and the rest is language dependent. The document representation is calculated by taking average over all words in the document.

Bi-PV: It extends the paragraph vector model into bilingual setting by sharing the document representation of a pair of parallel documents (Pham et al., 2015).

For comparison in Chinese, we adopt several typical CL classification methods:

MT-LR and **MT-SVM**: We use logistic regres-

Model	Parallel corpora with size	Test case
BM	*en-de* (∈ *Eu v7*, 1.92M)	*en-de*
	en-fr (∈ *Eu v7*, 2.0M)	*en-fr*
	en-zh (∈ *CN-EN*, 1.0M)	*en-zh*
	en-jp (∈ *JP-EN*, 0.5M)	*en-jp*
PDBM	*en-fr* (∈ *UN v1.0*, 2.0M) + *fr-de* (∈ *Eu v7*, 1.5M)	*en-fr-de*
	en-zh (∈ *CN-EN*, 1.0M) + *zh-jp* (∈ *CN-JP*, 0.12M)	*en-zh-jp*
	en-zh (∈ *CN-EN*, 1.0M) + *zh-fr* (∈ *UN v1.0*, 2.0M)	*en-zh-fr*
	en-fr (∈ *Eu v7*, 2.0M) + *zh-fr* (∈ *UN v1.0*, 2.0M)	*en-fr-zh*
UMM	*all the corpora used in PDBM*	*en,de,fr,zh,jp*

Table 1: Parallel corpora used in our models.

sion and SVM to learn different classifiers based on the translated Chinese training data. Bag of words features are used for classification.

Bi-PV: The same as that described above.

BSWE: It uses the bilingual sentiment word embedding algorithm based on denoising autoencoders (Zhou et al., 2015) to learns word representations. Each document is then represented by the sentiment words and the corresponding negation words.

3.3 Settings and Preprocessing

We utilize *cdec* (Dyer et al., 2010) as an alignment tool to get word-level alignment, and we also use it to lowercase the characters in western languages. We use the *stanford-segmenter* [11] to segment Chinese words, and use *Mecab* [12] to segment Japanese words. The *SnowNLP* [13] is used to convert traditional words to simplified ones. Besides, we remove all the irregular characters (e.g., ©, £, ♡) in the texts.

For all the three models, we use stochastic gradient descent (SGD) for learning, with a default learning rate of 0.025, negative sampling with 30 samples, skip-gram with context window of size 5, and a subsampling rate of value 1e-4. The embedding size is set to 400. The training epochs are all set to 10. All the parameters of α and β used in the three models are simply set to 1. The word embeddings in a document are averaged to get the document representation, and then the logistic regression classier is adopted for sentiment classification.

3.4 Results

The sentiment classification results of our three models and the CL classification methods in the three domains and in the German, French and Japanese languages are presented in Table 2. The results in the Chinese language are presented in Table 3. Note that the results of the CL methods are not reported on English test sets, and we only compare our three models on English test sets in Table 3.

First and most importantly, we compare our three models. The BM model relies on the direct parallel data between the source and target languages, and it generally works slightly better than the other models, including the PMDB model and the UMM model. The reason is that direct parallel data can be used for transferring the sentiment information from the source language to the target language directly. However, the performance achieved by the PDBM model is very close to the BM model in most test cases. In some cases (DE-DVD, JP-book and EN-music), the PDBM model can even outperform the BM model. Note that the PDBM model does not leverage the direct parallel data between the source and target languages, but uses a pivot language as a bridge. The results demonstrate that the pivot-driven model is very effective for learning bilingual / trilingual sentiment-aware word embeddings. The results also verify the feasibility of using pivot languages to address the problem of sentiment classification in resource-poor languages, which lays a good foundation for building a universal sentiment classifier in multiple languages. When comparing the UMM model with BM and PDBM, the results of UMM are very close to that of BM and PDBM in most cases, Note that the UMM model does not use the direct parallel corpora of *en-de*

and *en-jp*, but relies on pivot-based methods for bridging language gaps. We also find that the different parallel corpora used by the UMM model are of different quality and genres, and if they are used at the same time, they may have some negative influence on each other and thus the learned word embeddings are not always better than the BM and PDBM models using only one or two parallel corpora. What's more, the available parallel data in different language pairs are of various sizes (0.12M $\sim$ 2.0M). Considering all these issues, the results of UMM are promising because the learned single sentiment classifier can work generally well in multiple languages. We believe that if more high-quality and balanced parallel data are used, the performance of the universal sentiment classifier will be improved.

Second, we compare our models with typical CL classification methods. In Table 2, we can see our models can outperform MT-BOW, CL-SCL, and CR-RL in most test cases, and outperform BSE in the German language. Our models can achieve very close results with the other sophisticated CL methods, including Bi-PV. In Table 3, we can see our models can generally outperform MT-LR and MT-SVM, and achieve very competitive results with other strong CL methods, including Bi-PV and BSWE. Most CL classification methods rely on commercial machine translation systems (e.g. Google Translate) for translating the reviews (including the training reviews, the test reviews and additional unlabeled reviews) to get parallel data. Compared with the large amount of parallel data used by commercial machine translation systems, the parallel data used by our models are of a very small size. Though our models are simply based on word embeddings, and the parallel data used by our models are in a small scale, the performance achieved by our models are very competitive.

In Figure 1, we show the visualization of word embeddings learned by the UMM model for some example words. We can see that similar sentiment words in different languages appear nearby with each other. The figure demonstrate that the UMM model are successful in learning sentiment-aware word embeddings in multiple languages.

4 Related Work

The most closely related work is cross-lingual sentiment classification, which aims to leverage the labeled sentiment data from a language with rich sentiment resources (e.g., English) to perform sentiment classification in a target language lacking sentiment resources (e.g., Japanese). Some studies tried to transfer labeled data from the source

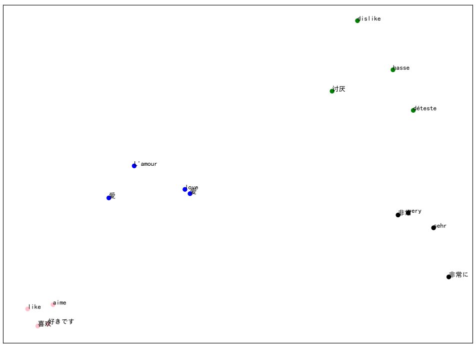

Figure 1: Visualization of word embeddings in UMM (Chinese, Japanese, English, French, German). The similar words are marked in the same color.

language to the target language (Banea et al., 2008; Wan, 2009; Gao et al., 2015; Chen et al., 2015), and some other studies tried to build a unified feature/semantic space in both two languages(Prettenhofer and Stein, 2010; Xiao and Guo, 2013; Zhou et al., 2015, 2016b,a; Li et al., 2017). In the latter case, the sentiment classifier learned in the source language can be used for sentiment classification in both languages. Particularly, Wan (2009) used machine translation to translate the source language to the target language to bridge the gap and applied the co-training approach. Prettenhofer and Stein (2010) provided a CL-SCL model based on structural correspondence learning (SCL) for sentiment classification. Lu et al. (2011) explored to increase the labeled data in both the source and target languages by applying an extra unlabeled parallel data. Xiao and Guo (2013) expected to get cross-lingual discriminative word embeddings to perform the multiple document classification tasks. Their intuitive thought is based on a delicate log-losses function, which aims to increase the probability of the documents with their labels. Like Lu et al. (2011), Meng et al. (2012) also proposed their cross-lingual mixture model to leverage an unlabeled parallel dataset. They intended to learn the previously unseen sentimental words from the big parallel corpus. Some studies have attempted to address multi-lingual sentiment classification (Deriu et al., 2017), but different from our study, they directly leverage training data in multiple languages, by assuming the training data can be obtained directly or in a distant supervision way in each language, and they did not consider the resource or data transfer problem at all.

Word embeddings have shown its great practicable usability in plenty of natural language processing tasks, such as information retrieval (Diaz et al., 2016; Zuccon et al., 2015), machine translation (Shi et al., 2016; Zhang et al., 2014), sentiment analysis (Ren et al., 2016; Xu et al., 2015; Tang et al., 2014) and so on. Bilingual word embeddings have been induced for cross-lingual NLP tasks (Vulić and Moens, 2015; Guo et al., 2014; Zou et al., 2013; Tang et al., 2014; Luong et al., 2015; Zhou et al., 2015). In particular, Luong et al. (2015) proposed the BiSkip model to induce bilingual word embeddings, which is extended from the monolingual skip-gram model in *word2vec* to a bilingual model. They added constraint mutually on both the source language and the target language, while the monolingual model only has constraint on a single language. Zhou et al. (2015) proposed an approach to learning bilingual sentiment word embeddings by using sentiment information of text as supervision, based on labeled corpora and their translations. Ferreira et al. (2016) used a single optimization problem by combining a co-regularizer for the bilingual embeddings with a task-specific loss. However, these methods for inducing bilingual word embeddings usually rely on directly parallel corpus.

5 Conclusion and Future Work

In this paper, we proposed an approach to build a universal sentiment classifier in multiple languages. Particularly we proposed a pivot-based model to transfer the sentiment information from the source language to any resource-poor language via pivot languages. Evaluation results show that the pivot-based model can learn bilingual sentiment-aware word embeddings as well as the bilingual model using direct parallel data. Moreover, the universal sentiment classifier built in the five languages can achieve promising results.

In future work, we will investigate using more advanced document embedding techniques (e.g., CNN, RNN) to directly model document-level sentiment information. We will also extend our model to other languages.

Capturing User and Product Information for Document Level Sentiment Analysis with Deep Memory Network

Zi-Yi Dou
National Key Laboratory for Novel Software Technology, Nanjing University,
Nanjing, 210023, China
141242042@smail.nju.edu.cn

Abstract

Document-level sentiment classification is a fundamental problem which aims to predict a user's overall sentiment about a product in a document. Several methods have been proposed to tackle the problem whereas most of them fail to consider the influence of users who express the sentiment and products which are evaluated. To address the issue, we propose a deep memory network for document-level sentiment classification which could capture the user and product information at the same time. To prove the effectiveness of our algorithm, we conduct experiments on IMDB and Yelp datasets and the results indicate that our model can achieve better performance than several existing methods.

1 Introduction

Sentiment analysis, sometimes known as opinion mining, is the field of study that analyzes people's opinions, sentiments, evaluations, attitudes and emotions from written language. It is one of the most active and critical research areas in natural language processing (Liu, 2012). On the one hand, from the industry point of view, knowing the feelings among consumers based on their comments is beneficial and may support strategic market decisions. On the other hand, potential customers are often interested in other people's opinion in order to find out the choices that best fits their preferences (Moraes et al., 2013).

Previous studies tackled the sentiment analysis problem at various levels of granularity, from document level to sentence level due to different objectives of applications (Zhang et al., 2009). In this work, we mainly focus on document-level sentiment classification Basically, the task is to predict user's overall sentiment or polarity in a document about a product (Pang and Lee, 2008).

Most existing methods mainly utilize local text information whereas ignoring the influences of users and products (Tang et al., 2015). As is often the case, there are certain consistencies for both users and products. To illustrate, lenient users may always give higher ratings than fastidious ones even if they post the same review. Also, it is not surprising that some products may always receive low ratings because of their poor quality and vice versa. Therefore, it is necessary to leverage individual preferences of users and overall qualities of products in order to achieve better performance.

Tang *et al.* (2015) proposed a novel method dubbed User Product Neural Network (UPNN) which capture user- and product-level information for sentiment classification. Their approach has shown great promise but one major drawback of their work is that for users and products with limited information, it is hard to train the representation vector and matrix for them.

Inspired by the recent success of computational models with attention mechanism and explicit memory (Graves et al., 2014; Sukhbaatar et al., 2015), we addressed the aforementioned issue by proposing a method based on deep memory network and Long Short-Term Memory (LSTM) (Hochreiter and Schmidhuber, 1997). The model can be divided into two separate parts. In the first fart, we utilize LSTM to represent each document. Afterwards, we apply deep memory network consists of multiple computational layers to predict the ratings for each document and each layer is a content-based attention model.

To prove the effectiveness of our algorithm, we have conducted experiments on three datasets derived from IMDB and Yelp Dataset Challenge and compare to several other algorithms. Experimental results show that our algorithm can outperform

Proceedings of the 2017 Conference on Empirical Methods in Natural Language Processing, pages 521–526
Copenhagen, Denmark, September 7–11, 2017. ©2017 Association for Computational Linguistics

baseline methods for sentiment classification of documents by leveraging users and products for document-level sentiment classification.

2 Related Work

2.1 Memory Network

In 2014, Weston *et al.* (2014) introduced a new class of learning models called memory networks. Memory networks reason with inference components combined with a long-term memory component. The long-term memory can be read and written to and then it can be used for prediction. Generally, a memory network consists of an array of objects called memory m and four components I, G, O and R, where I converts input to internal feature representation, G updates old memories, O generates an output representation and R outputs a response.

Based on their work, Sukhbaatar *et al.* (2015) proposed a neural network with a recurrent attention model over a possibly large external memory. Unlike previous model, their model is trained end-to-end and hence requires significantly less supervision during training. They have shown that their model yields improved results in language model and question answering.

Inspired by the success of memory network, Tang *et al.* (2016) introduce a deep memory network for aspect-level sentiment classification. The architecture of their model is similar to the previous model and experimental results demonstrate that their approach performs comparable to other state-of-the-art systems. Also, Li *et al.* (2017) decompose the task of attitude identification into two separate subtasks: target detection and polarity classification; and then solve the problem by applying deep memory network so that signals produced in target detection provide clues for polarity classification and the predicted polarity provides feedback to the identification of targets.

2.2 Sentiment Classification

Most existing work tackle the problem of sentiment classification by manually design effective features. such as text topic (Ganu et al., 2009) and bag-of-opinion (Qu et al., 2010) . Some work take user information into consideration. For example, in 2013, Gao *et al.* (2013) design user-specific features to capture user leniency. Also, Li *et al.* (2014) incorporate textual topic and user-word factors with supervised topic modeling.

Tang *et al.* (2015) points out that it is critical to leverage users and products for document-level sentiment classification. They assume there are four types of consistencies for sentiment classification and validate the influences of users and products in terms of sentiment and text on massive IMDB and Yelp reviews. Their model represent each user and product as both vector and matrix in order to capture the consistencies and then apply convolutional neural network to solve the task.

To the best of our knowledge, no one has ever applied deep memory network to capture the user and product information and solve the tasks in sentiment classification at document-level.

3 Proposed Methods

In this section, we present the details of User Product Deep Memory Network (UPDMN) for sentiment classification at document level.

3.1 Basic Symbol and Definition

First we suppose U, P, D is the set of users, products and documents respectively. If user $u \in U$ writes a document $d \in D$ about a product $p \in P$ and give the rating, we denote $U(d) = \{ud | ud \text{ is written by } u, ud \neq d\}$ and $P(d) = \{pd | pd \text{ is written about } p, pd \neq d\}$. Then, our task can be formalized as follows: suppose u write a document d about a product p , we should output the predicted score y for the document d based on the input $< d, U(d), P(d) >$. The detail of these symbols would be illustrated in the following part.

3.2 General Framework of UPDMN

Figure 1 illustrates the general framework of our approach. Basically, inspired by the use of memory network in question answering and aspect-level sentiment analysis (Sukhbaatar et al., 2015; Tang et al., 2016), our model consists of multiple computational layers (hops), each of which contains an attention layer and a linear layer.

For every document in $U(d)$ and $P(d)$, we embed it into a continuous vector d_i and store it in the memory. The model writes all document to the memory up to a fixed buffer size. Suppose we are given $\{d_i\} = \{d_1, ..., d_n\}$ to be stored in memory, for each layer we can convert them into memory vectors $\{m_i\}$ using an embedding matrix. The document d should also be embedded into q. Then, we compute the match $\{p_i\}$ between q and each memory m_i. Afterwards, we embed $\{d_i\}$ into

Dataset	#users	#products	#reviews	#docs/user	#docs/product	#sents/doc	#words/doc
IMDB	1,310	1,635	84,919	64.82	51.94	16.08	394.6
Yelp 2014	4,818	4,194	231,163	47.97	55.11	11.41	196.9
Yelp 2013	1,631	1,633	78, 966	48.42	48.36	10.89	189.3

Table 1: Statistical information of datasets.

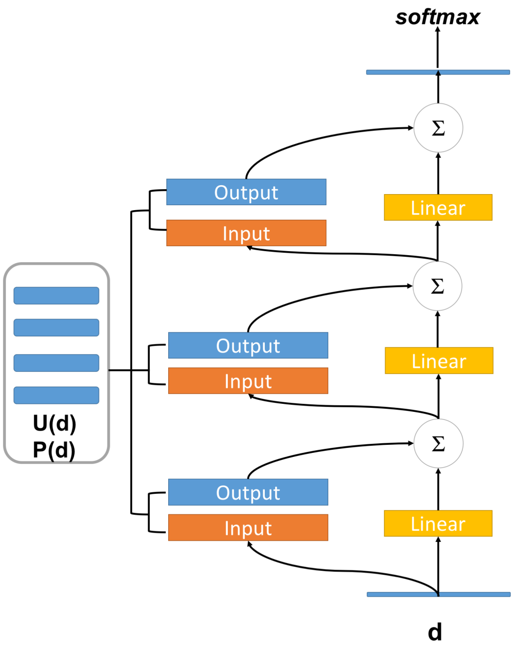

Figure 1: General Framework

output vector $\{c_i\}$ using another embedding matrix and generate the output of attention layer. The output is further summed with the linear transformation of q and considered as the input of next hop. The output vector at last hop is fed into a *softmax* layer and then generates the final prediction y for document-level sentiment classification.

3.3 Embedding Documents

Although there are several state-of-the-art techniques to embed word into vectors (Mikolov et al., 2013a), for document-level sentiment classification, the document we need to classify is usually too long to be represented as a vector. People have tried different ways to solve the task. For example, Kalchbrenner *et al.* (2014) apply convolutional neural network for modeling sentences and Li *et al.* (2015) introduce an LSTM model that hierarchically builds an embedding for a paragraph from embeddings for sentences and words.Some of these work can be incorporated into our methods. However, here we only use the LSTM model to embed each document, *i.e.* every word in the document is fed into LSTM and the final representation is obtained by averaging the hidden state of each word, and the experimental results shows that this simple embedding method can actually obtain satisfactory results.

3.4 Attention Model

After obtaining the embedding vector q for document d the memory vectors $\{m_i\}$ for each memory, we calculate the match between q and m_i using the following equation:

$$p_i = softmax(W_{att}[m_i; q] + b_{att}) \qquad (1)$$

where $softmax(z_i) = e^{z_i} / \sum_j e^{z_j}$.

Afterwards, we compute the corresponding output o for each hop by summing over the c_i, weighted by the probability vector from the input:

$$o = \sum_i p_i c_i \qquad (2)$$

3.5 Final Prediction and Training Strategy

At last hop, the output vector is fed into a *softmax* layer and thus generates a probability distribution $\{y_i\}$ over ratings. The score with the highest probability would be considered as our final prediction py. During training, we try to minimize the cross entropy error of sentiment classification in a supervised manner. The specific equation is shown as follows:

$$Loss = -\sum_{d \in D} \sum_{y_i \in Y} \mathbb{I}(y = y_i|d) log(P(y = y_i|d)) \qquad (3)$$

where Y is the collection of sentiment categories, $\mathbb{I}(y = y_i|d)$ is 1 or 0, indicating whether the correct category for d is y_i, and $P(y = y_i|d)$ represents the probability of classifying document d as category y_i.

4 Experiment

In this section, we will first discuss the experimental setting and then display the results.

	IMDB			Yelp 2014			Yelp 2013

Table 2: Experimental results.

4.1 Experimental Settings

We use the same datasets as Tang *et al.* (2015), which are derived from IMDB (Diao et al., 2014) and Yelp Dataset Challenge in 2013 and 2014 [1]. Statistical information of the datasets are given in Table 1.

In order to measure the performance of our model, here we use three metrics. Specifically, we use $accuracy$ to measure the overall sentiment classification performance, MAE and $RMSE$ to measure the divergences between prediction py and ground truth gy. The formulas for these three metrics are listed as follows:

$$accuracy = \frac{T}{N} \tag{4}$$

$$MAE = \frac{\sum_i |py_i - gy_i|}{N} \tag{5}$$

$$accuracy = \sqrt{\frac{\sum_i (py_i - gy_i)^2}{N}} \tag{6}$$

4.2 Baseline Models

We compare UPDMN with the following models:

(1) **Majority** : it assigns each review in the test dataset with the majority sentiment category in training set.

(2) **Trigram** : it first takes unigrams, bigrams and trigrams as features and then trains a classifier with SVM (Fan et al., 2008).

(3) **TextFeature** : it takes hard-crafted text features such as word/character n-grams, negation features and then trains a classifier with SVM.

(4) **UPF**: it extracts user-leniency features and corresponding product features from training data and then concatenates them with features in model (2) and (3) (Gao et al., 2013).

(5) **AvgWordvec+SVM** : it learns word embeddings from training and development sets with $word2vec$, averages word embeddings and then trains an SVM classifier (Mikolov et al., 2013b).

(6) **SSWE+SVM** : it learns sentiment-specific word embeddings (SSWE), uses max/min/average pooling to generate document representation and then trains an SVM classifier (Tang et al., 2014).

(7) **RNTN+RNN** : it represents each sentence with RNTN, composes document with recurrent neural network , and then averages hidden vectors of recurrent neural network as the features (Socher et al., 2013).

(8) **Paragraph Vector**: it implements the PVDM for document-level sentiment classification (Le and Mikolov, 2014).

(9) **JMARS**: it is the recommendation algorithm which leverages user and aspects of a review with collaborative filtering and topic modeling (Diao et al., 2014).

(10) **UPNN** : as has been stated above, it also leverages user and product information for sentiment classification at document level (Tang et al., 2015).

4.3 Experimental Results and Discussion

The experimental results are given in Table 2. The results of baseline models are reported in (Tang et al., 2015). Our model is abbreviated to UPDMN(k), where k is the number of hops. With the increase of the number of hops, the performance of UPDMN will get better intially, which indicates that multiple hops can indeed capture

[1] http://www.yelp.com/dataset_challenge

more information to improve the performance. However, if there are too many hops, the performance would be not as well as before, which may be caused by over-fitting.

Compared with other models, we can see that with proper setting, our model achieve superior results. All these results prove the effectiveness of UPDMN and the necessity to utilizing user and product information at document level.

It should be noticed that there are still several improvements can be made, such as better representation of documents or more sophisticated attention mechanism. We believe that our model has great potential and can be improved in many ways.

Identifying and Tracking Sentiments and Topics from Social Media Texts during Natural Disasters

Abstract

We study the problem of identifying the topics and sentiments and tracking their shifts from social media texts in different geographical regions during emergencies and disasters. We propose a **l**ocation-based **d**ynamic **s**entiment-**t**opic model (LDST) which can jointly model topic, sentiment, time and Geolocation information. The experimental results demonstrate that LDST performs very well at discovering topics and sentiments from social media and tracking their shifts in different geographical regions during emergencies and disasters[1].

1 Introduction

Social media has become pervasive in our daily life, and it is a great way to spread important information efficiently. Using social media (e.g., Twitter, Facebook, Pinterest), people can conveniently inform others and express support during emergencies and disasters.

Nowadays, the social media is keeping producing a huge amount of information. Unlike before, people are not only interested in identifying the static topics and sentiments from given texts, but also, perhaps more concerned with tracking the evolution of topics and sentiments among different geographical regions. On the one hand, this new requirement can be very helpful, especially in the case of emergencies, such as pre-disaster preparation and post-disaster relief in local natural disasters (Beigi et al., 2016). For example, people's sentiments on the topics related to *medical* and *rescue* may guide the management and distribution of emergency supplies. On the other hand, the existing models do not take the temporal evolution and the impact of location over topics and sentiments into consideration, which makes them unable to fulfill the new requirement of tracking the evolution of topics and sentiments in different geographical places.

In this paper, we aim to identify the topics and sentiments and track their shifts in different geographical regions during emergencies and disasters. We are inspired by several observations. First, people are interested in not only the overall sentiment or topic distribution of the documents but also the sentiments towards specific topics. For example, a person may be happy with that the disaster passed away, but at the meanwhile he/she may be unsatisfied with the post-disaster relief. Second, most existing sentiment-topic models ignore the temporal evolution of topics and sentiment in a time-variant data corpus such as the Twitter stream. There are strong evidences which indicate that people's attitudes toward a disaster will gradually change over time with the distribution of emergency supplies (Beigi et al., 2016; Caragea et al., 2014; Mandel et al., 2012). Third, people in different places tend to have different opinions towards particular topics. This motivated us to find the influence of specific topics and the relationship between different topics in different regions, which may improve people's awareness to help themselves during disasters.

We propose a **l**ocation-based **d**ynamic **s**entiment-**t**opic model (LDST) which generalizes latent Dirichlet allocation (LDA) (Blei et al., 2003), by jointly modeling topic, sentiment, time and geolocation information. After learning the LDST model, we can identify the topics and sentiments held by people in different locations over time. Our model works in an unsupervised way, and we learn the model according to the frequency of terms co-occurring in different

contexts. To leverage the prior knowledge, we construct a small set of seed words for each topic of interest to enable the model to group semantically related terms into the same topic. Consequently, the topic words will be more related to the seed words of the same topic.

We conduct experiments using a Hurricane Sandy Twitter corpus which consists of 159,880 geotagged Twitter posts from the geographic area and time period of the 2012 Hurricane Sandy. We show the evolution of people's topics and sentiments, which change according to not only the time the disaster happens, but also people's locations during the hurricane Sandy.

2 Related work

Sentiment analysis is widely applied in many fields, such as business intelligence, politics, sociology. The papers by Pang and Lee (Pang and Lee, 2008) and Liu (Liu, 2012) described most of the existing techniques for sentiment analysis and opinion mining, which could be categorized into lexicon-based approaches (Kennedy and Inkpen, 2006; Turney, 2002; Yang et al., 2014a,b) and corpus-based approaches (Pang et al., 2002; Yang et al., 2015; Wan, 2009).

Recently, researchers have turned their attention to exploring sentiment analysis on the social media posts of individuals during natural disasters and emergencies (Beigi et al., 2016; Buscaldi and Hernandez-Farias, 2015; Caragea et al., 2014; Kryvasheyeu et al., 2015; Mandel et al., 2012; Shalunts et al., 2014). For example, a sentiment analysis system is applied for Italian to a set of tweets during the Genoa flooding (Buscaldi and Hernandez-Farias, 2015). They attempted to identify trending topics, toponym and sentiments that might be relevant from a disaster management perspective. However, the existing studies only focused on sentiment analysis on the document level, without considering the specific topics in the document.

Meanwhile, topic models, such LDA (Blei et al., 2003), have become popular in extracting interesting topics. Some recent work incorporates context information into LDA, such as time (Wang and McCallum, 2006; Zhao et al., 2014) and authorship (Steyvers et al., 2004; Yang et al., 2016) to make topic models fit expectations better. Some studies also attempt to detect sentiment and topic simultaneously from documents (Dermouche et al., 2015; Lin et al., 2012; Mukherjee et al., 2014; He et al., 2012). Nevertheless, none of existing methods takes advantage of temporal and geographical information to identify and track people's topics and sentiment during emergencies and disasters.

3 Model

In this section, we firstly introduce the generative process of the LDST model. Then we present the inference algorithm for estimating the model parameters.

3.1 Model Description

We assume the corpus consists a set of authors, a set of locations, and a collection of documents with specific timestamps. Formally, we use V and U to denote the sets of locations and authors, respectively. A document $d \in D$ is a short text written by an author $u \in U$ in location $v \in V$ at time t. Also, let S be the number of distinct sentiment labels, and T be the total number of topics, where S and T are predefined constant values. Since each tweet is a short text, studying them individually is not very informative. We thus use pooling methods to construct aggregated documents for each location or each author. For a venue v, we use A_v to define the set of all authors that have written documents in location v, and d_v (location document) to refer to the union of all the documents written in location v. N_{d_v} is the number of words in location document d_v.

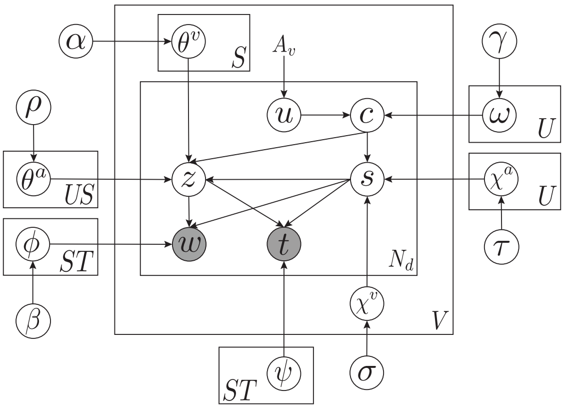

Figure 1: Graphical representation of our algorithm

Our model generalizes LDA by jointly modeling topic, sentiment, time and geolocation information. Figure 1 shows the graphical model of

LDST. The formal definition of the generative process of LDST is as follows:

1. For each sentiment label s,
   a. For each topic z under sentiment s,
      – Draw a word distribution $\phi_{s,z}$ ~ $Dir(\beta_{s,z})$.
2. For each author u,
   a. Draw $\omega_u \sim Beta(\gamma)$
   b. Draw a sentiment distribution $\chi_u^{(a)} \sim Dir(\tau)$
   c. For each sentiment label s,
      – Draw a topic distribution $\theta_{u,s}^{(a)} \sim Dir(\rho)$
3. For each location document d_v,
   a. Draw a sentiment distribution $\chi_{d_v}^{(v)} \sim Dir(\sigma)$
   b. For each sentiment label s,
      – Draw a topic distribution $\theta_{d_v,s}^{(v)}$ ~ $Dir(\alpha)$
   c. For each term $w_{d_v i}$ in the location document d_v,
      – Draw a author $u \sim A_v$ uniformly,
      – Draw a switch $c \sim Bernoulli(\omega_u)$
      – if $c = 0$,
        * Draw a sentiment $s_{d_v i} \sim Mult(\chi_u^{(a)})$
        * Draw a topic $z_{d_v i}$ from $Mult(\theta_{u,s_{d_v i}}^{(a)})$
      – if $c = 1$,
        * Draw a sentiment $s_{d_v i} \sim Mult(\chi_{d_v}^{(v)})$
        * Draw a topic $z_{d_v i} \sim Mult(\theta_{d_v,s_{d_v i}}^{(v)})$
      – Draw a word $w_{d_v i} \sim Mult(\phi_{s_{d_v i}, z_{d_v i}})$
      – Draw a timestamp $t_{d_v i}$ from $Beta(\psi_{s_{d_v i}, z_{d_v i}})$

In the model, α, β, ρ, σ, τ and γ are hyperparameters. The latent sentiments and topics depend on the document venues and personalities of the author. We use ω to control the influence from the venue and the author. In particular, ω is the parameter of a Bernoulli distribution, from which a binary variable c is generated to determine whether the document is influenced by venue or user.

3.2 Inference Algorithm

We use Collapsed Gibbs sampling (Porteous et al., 2008) to estimate the unknown latent variables $\{\phi, \omega, \theta^a, \theta^v, \chi^a, \chi^v, \psi\}$. The posterior distribution of the hidden variables for each word $w_{d_v,i}$ (i-th word in venue document d_v) is calculated as follows (to simplify, we use Θ to refer to <$\mathbf{u}^{-d_v,i}, \mathbf{c}^{-d_v,i}, \mathbf{s}^{-d_v,i}, \mathbf{z}^{-d_v,i}, \mathbf{w}, \mathbf{t}, A_v$>):

$$\begin{aligned}
& P\left(u_{d_v,i} = u, c_{d_v,i} = 0, s_{d_v,i} = s, z_{d_v,i} = z \mid \Theta\right) \\
\propto = & \frac{n_{u,c}^{-d_v,i}(0) + \gamma'}{n_{u,c}^{-d_v,i} + \gamma + \gamma'} \cdot \frac{n_{u,s}^{-d_v,i} + \tau_s}{\sum_{s'} (n_{u,s'}^{-d_v,i} + \tau_{s'})} \\
& \cdot \frac{n_{u,s,z}^{-d_v,i} + \rho_z}{\sum_{z'} (n_{u,s,z'}^{-d_v,i} + \rho_{z'})} \cdot \frac{n_{s,z,w}^{-d_v,i} + \beta_w}{\sum_{w'} (n_{s,z,w'}^{-d_v,i} + \beta_{w'})} \\
& \cdot \frac{(1-t)^{\psi_{s,z}^{(1)}-1} \cdot t^{\psi_{s,z}^{(2)}-1}}{\mathrm{Beta}(\psi_{s,z}^{(1)}, \psi_{s,z}^{(2)})} \qquad (1)
\end{aligned}$$

$$\begin{aligned}
& P\left(u_{d_v,i} = u, c_{d_v,i} = 1, s_{d_v,i} = s, z_{d_v,i} = z \mid \Theta\right) \\
\propto = & \frac{n_{u,c}^{-d_v,i}(1) + \gamma}{n_{u,c}^{-d_v,i} + \gamma + \gamma'} \cdot \frac{n_{v,s}^{-d_v,i} + \sigma_s}{\sum_{s'} (n_{v,s'}^{-d_v,i} + \sigma_{s'})} \\
& \cdot \frac{n_{v,s,z}^{-d_v,i} + \alpha_z}{\sum_{z'} (n_{v,s,z'}^{-d_v,i} + \alpha_{z'})} \cdot \frac{n_{s,z,w}^{-d_v,i} + \beta_w}{\sum_{w'} (n_{s,z,w'}^{-d_v,i} + \beta_{w'})} \\
& \cdot \frac{(1-t)^{\psi_{s,z}^{(1)}-1} \cdot t^{\psi_{s,z}^{(2)}-1}}{\mathrm{Beta}(\psi_{s,z}^{(1)}, \psi_{s,z}^{(2)})} \qquad (2)
\end{aligned}$$

where $n_{u,c}(0)$ and $n_{u,c}(1)$ are the numbers of times that $c = 0$ and $c = 1$ are sampled for user u, respectively, and we have $n_{u,c} \triangleq n_{u,c}(0)$ +$n_{u,c}(1)$. $n_{u,s}$ is the number of times that sentiment s is sampled from the distribution χ_u^a specific to user u, and $n_{v,s}$ is the number of times that sentiment s is sampled from the distribution $\chi_{d_v}^v$ specific to document venue v. $n_{u,s,z}$ is the number of times that topic z is sampled from the distribution $\theta_{u,s}^a$ specific to user u and sentiment s, and $n_{v,s,z}$ is the number of times that topic z is sampled from the distribution$\theta_{d_v s}^v$ specific to document venue v and sentiment s. $n_{s,z,w}$ is the number of times that word w is sampled from the distribution $\phi_{s,z}$ specific to sentiment s and topic z. The superscript $-d_v, i$ denotes a quantity excluding the current word $-d_v, i$.

After Gibbs sampling, $\{\phi, \omega, \theta^a, \theta^v, \chi^a, \chi^v, \psi\}$ can be estimated as follows:

$$\hat{\phi}_{s,z,w} = \frac{n_{s,z,w} + \beta_w}{\sum_{w'} (n_{s,z,w'} + \beta_{w'})},$$

$$\hat{\omega}_u = \frac{n_{uc}(1) + \gamma}{n_{u,c} + \gamma + \gamma'},$$

$$\hat{\theta}_{v,s,z}^v = \frac{n_{v,s,z} + \alpha_z}{\sum_{z'} (n_{v,s,z'} + \alpha_{z'})},$$

$$\hat{\theta}_{u,s,z}^a = \frac{n_{u,s,z} + \rho_z}{\sum_{z'} (n_{u,s,z'} + \rho_{z'})},$$

$$\hat{\chi}_{u,s}^a = \frac{n_{u,s} + \tau_s}{\sum_{s'} (n_{u,s'} + \tau_{s'})},$$

$$\hat{\chi}_{d_v,s}^v = \frac{n_{v,s} + \sigma_s}{\sum_{s'} (n_{v,s'} + \sigma_{s'})},$$

$$\hat{\psi}_{s,z}^{(1)} = \bar{m}_{s,z} \cdot \left(\frac{\bar{m}_{s,z} \cdot (1 - \bar{m}_{s,z})}{\xi_{s,z}^2} - 1 \right),$$

$$\psi_{s,z}^{(2)} = (1 - \bar{m}_{s,z}) \cdot \left(\frac{\bar{m}_{s,z} \cdot (1 - \bar{m}_{s,z})}{\xi_{s,z}^2} - 1 \right).$$

where $\overline{m}_{sz}$ and ξ_{sz}^2 indicate the sample mean and the biased sample variance of the timestamps belonging to sentiment s and topic z, respectively.

3.3 Defining the Prior Knowledge

In our model, the prior knowledge is employed to guide the generative process of topics. The prior knowledge can be obtained from natural disaster experts. We collect a small set of seed words for each topic of interest during emergency and disaster. For each topic, the LDST model draws the word distribution from a biased Dirichlet prior $Dir(\beta)$. Each vector $\beta_{.,z} \in \mathbb{R}^V$ is constructed from the sets of seed words, where

$$\beta_{.,z} := \lambda_1(1^V - \Lambda_{.,z}) + \lambda_2\Lambda_{.,z} \qquad (3)$$

Here, $\Lambda_{.,z,w} = 1$ if and only if word w is a seed word for topic z, otherwise $\Lambda_{.,z,w} = 0$. The scalars λ_1 and λ_2 are hyperparameters. Intuitively, when $\lambda_1 < \lambda_2$, the biased prior ensures that the seed words are more probably drawn from the associated topic.

4 Experiments

4.1 Hurricane Sandy Twitter Datasets

This dataset contains nearly 15 million tweets posted on Twitter while Hurricane Sandy was hitting the United States. Tweets were collected from October 25, 2012 to November 4, using the keywords 'hurricane' and 'sandy' (Zubiaga and Ji, 2014). In this paper, we only keep the geotagged tweets. The final experimental dataset consists of 159,880 geotagged tweets. The original geographical information is expressed by using longitude and latitude in decimal degree. We set the granularity of location as a state via Google Maps Geocoding API[2] and analyze the tweets within the United States.

4.2 Baseline Methods

We evaluate and compare our model with several baseline methods as follows:

LDA: We use gensim toolkit to do inference for LDA model (Blei et al., 2003).

ToT: Topics over Time, a non-Markov continuous time model proposed in (Wang and McCallum, 2006).

JST: The first Joint Sentiment-Topic model to identify the sentiment-topic pairs (Lin and He, 2009) .

TS: Topic-Sentiment model proposed in (Dermouche et al., 2015).

LDST-w/oS: This is the LDST model without employing prior knowledge (seed words). We use this method to evaluate the influence of seed words.

4.3 Implementation details

In our implementation, we set topic number $T = 50$, and the prior hyperparameters $\gamma = 0.5$, $\tau = \sigma = 0.1$, $\rho = \alpha = 50/T$. $\beta_{s,z}$ is calculated using the set of seed words with $\lambda_1 = 0.1$ and $\lambda_2 = 0.8$.

As described in Section 3.3, we use a small set of seed words as our topic prior knowledge. Specifically, the seed words list contains 5 to 10 seed words for each of the five topics of interest[3] about *Hurricane impact, public utility, food, shelter, medical*, respectively. We choose these five topics based on the actual requirements of our project. However, it is important to note that the model is flexible and do not need to have seed words for every topic.

4.4 Experiment results

4.4.1 Quantitative evaluation

We first compare our model with the baseline models in terms of perplexity which is a widely used measurement of how well a probability model predicts a sample. The lower the perplexity, the better the model. We calculate the average perplexity (log-likelihood) using 1000 held-out documents which are randomly selected from the test data. The average test perplexity of each word is calculated as $\exp\{-\frac{1}{N}\sum_w \log p(w)\}$, where N is the total number of words in the held-out test documents. Table 1 shows the perplexity results for Hurricane Sandy dataset. Our model outperforms the baseline models. In particular, the perplexity of our model is 1122, which is 40 and 116 lower than that of JST and TS. The perplexity of LDST is 35 lower than that of LDST-w/oS, which indicates that the seed words can further improve the performance of our model.

LDA	ToT	JST	TS	LDST-w/oS	LDST
1320	1244	1162	1238	1157	1122

Table 1: Comparison of test perplexity per word

Following the same evaluation as in (Lin et al., 2012), we also present and discuss the experimental results of sentiment classification. The docu-

[2] https://developers.google.com/maps/

[3] Details available at https://goo.gl/ykbrXZ

ment sentiment is classified based on the probability of sentiment label given document, which can be approximated by $\hat{\chi}_u^{(a)}$ and $\hat{\chi}_{d_v}^v$. Similar to (Lin et al., 2012), we only consider the probability of positive and negative label given document, with the neutral label probability being ignored. We define that a document d is classified as a positive-sentiment document if its probability of positive sentiment label given document is greater than its probability of negative sentiment label given document, and vice versa. The ground truth of sentiment classification labels of tweets are set by using human annotation. Specifically, we randomly select 1000 documents from the dataset, and label each document as *positive*, *negative* or *neutral* manually. We measure the performance of our model using the tweets with *positive* or *negative* labels. The classification accuracies are summarization in Table 2. LDST significantly outperforms other methods on test data. This verifies the effectiveness of the proposed approach.

LDA	ToT	JST	TS	LDST-w/oS	LDST
0.574	0.592	0.622	0.597	0.635	0.646

Table 2: Sentiment classification accuracy.

4.4.2 Qualitative evaluation

We present the sentiments and topics discovered by LDST to see whether LDST captured meaningful semantics. We analyze the extracted topics under positive and negative sentiment labels. Due to the limited space, we only report *Hurricane impact* and *public utility* topics under positive and negative sentiments for New York and Florida states on Oct. 27, 2012 and Oct. 30, 2012. For each topic, we visualize it using the top 5 words which are most likely generated from the topic. As shown in Table 3, the extracted topics are quite informative and coherent. For example, the first topic (left) is closely related to *Hurricane impact*, and the other one (right) is related to *public utility*. The results show that our model can extract topic and sentiment simultaneously under different time and location. First, at the same period, people in different location had different topics of interest and sentiments. Taking the *public utility* topic as an example, on Oct. 30, people from Florida were concerned with post-disaster relief, while people from New York focused on the outage of the *public utility*. Second, for the people in the same location, they were interested in different topics, and had different sentiments towards the topics. For example, the people in Florida paid close attention to the damage of the *public utility* on Oct. 27, while they changed their attention to post-disaster relief of the *public utility* on Oct. 30.

	New York		Florida	
pos	pray response volunteer usa florida	island careful volunteer preparation state	florida prepare boat protect power	work service island customer system
neg	destroy homeless flood eastcoast damage	rising moves arrival shortages cause	sandy storm broken landfall disaster	power outage damage energy utilities
	New York		Florida	
pos	aid alert rescue york shelter	nation people delivered safety companies	volunteer claimed crew power relief	restore system resources good rebuild
neg	hirricane weatherd death halloween flood	power metro destroyed outage destructive	east criticize eastern election tourism	damage effect weeks millions delay

Table 3: Hurricane impact (left) and public utility (right) topics under positive and negative sentiment labels for New York and Florida states on Oct. 27, 2012 (above) and Oct. 30, 2012 (bottom).

5 Conclusion

In this paper, we propose a location-based dynamic sentiment-topic (LDST) model, which can jointly model sentiment, topic, temporal, and geolocation information.

Abstract

Word embeddings that can capture semantic and syntactic information from contexts have been extensively used for various natural language processing tasks. However, existing methods for learning context-based word embeddings typically fail to capture sufficient sentiment information. This may result in words with similar vector representations having an opposite sentiment polarity (e.g., *good* and *bad*), thus degrading sentiment analysis performance. Therefore, this study proposes a word vector refinement model that can be applied to any pre-trained word vectors (e.g., Word2vec and GloVe). The refinement model is based on adjusting the vector representations of words such that they can be closer to both semantically and sentimentally similar words and further away from sentimentally dissimilar words. Experimental results show that the proposed method can improve conventional word embeddings and outperform previously proposed sentiment embeddings for both binary and fine-grained classification on Stanford Sentiment Treebank (SST).

1 Introduction

Word embeddings are a technique to learn continuous low-dimensional vector space representations of words by leveraging the contextual information from large corpora. Examples include C&W (Collobert and Weston, 2008; Collobert et al., 2011), Word2vec (Mikolov et al., 2013a; 2013b) and GloVe (Pennington et al., 2014). In addition to the contextual information, character-level subwords (Bojanowski et al., 2016) and semantic knowledge resources (Faruqui et al., 2015; Kiela et al., 2015) such as WordNet (Miller, 1995) are also useful information for learning word embeddings. These embeddings have been successfully used for various natural language processing tasks.

In general, existing word embeddings are semantically oriented. They can capture semantic and syntactic information from unlabeled data in an unsupervised manner but fail to capture sufficient sentiment information. This makes it difficult to directly apply existing word embeddings to sentiment analysis. Prior studies have reported that words with similar vector representations (similar contexts) may have opposite sentiment polarities, as in the example of *happy*-*sad* mentioned in (Mohammad et al., 2013) and *good*-*bad* in (Tang et al., 2016). Composing these word vectors may produce sentence vectors with similar vector representations but opposite sentiment polarities (e.g., a sentence containing *happy* and a sentence containing *sad* may have similar vector representations). Building on such ambiguous vectors will affect sentiment classification performance.

To enhance the performance of distinguishing words with similar vector representations but opposite sentiment polarities, recent studies have suggested learning sentiment embeddings from labeled data in a supervised manner (Maas et al., 2011; Labutov and Lipson, 2013; Lan et al., 2016; Ren et al., 2016; Tang et al., 2016). The common goal of these methods is to capture both semantic/syntactic and sentiment information such that sentimentally similar words have similar vector representations. They typically apply an objective function to optimize word vectors based on the sentiment polarity labels (e.g., positive and negative) given by the training instances. The use of such sentiment embeddings has improved the performance of binary sentiment classification.

Proceedings of the 2017 Conference on Empirical Methods in Natural Language Processing, pages 534–539
Copenhagen, Denmark, September 7–11, 2017.

This study adopts another strategy to obtain both semantic and sentiment word vectors. Instead of building a new word embedding model from labeled data, we propose a word vector refinement model to refine existing semantically oriented word vectors using sentiment lexicons. That is, the proposed model can be applied to the pre-trained vectors obtained by any word representation learning models (e.g., Word2vec and GloVe) as a post-processing step to adapt the pre-trained vectors to sentiment applications. The refinement model is based on adjusting the pre-trained vector of each affective word in a given sentiment lexicon such that it can be closer to a set of both semantically and sentimentally similar nearest neighbors (i.e., those with the same polarity) and further away from sentimentally dissimilar neighbors (i.e., those with an opposite polarity).

The proposed refinement model is evaluated by examining whether our refined embeddings can improve conventional word embeddings and outperform previously proposed sentiment embeddings. To this end, several deep neural network classifiers that performed well on the Stanford Sentiment Treebank (SST) (Socher et al., 2013) are selected, including convolutional neural networks (CNN) (Kim, 2014), deep averaging network (DAN) (Iyyer et al., 2015) and long-short term memory (LSTM) (Tai et al., 2015; Looks et al., 2017). The conventional word embeddings used in these classifiers are then replaced by our refined versions and previously proposed sentiment embeddings to re-run the classification for performance comparison. The SST is chosen because it can show the effect of using different word embeddings on fine-grained sentiment classification, whereas prior studies only reported binary classification results.

The rest of this paper is organized as follows. Section 2 describes the proposed word vector refinement model. Section 3 presents the evaluation results. Conclusions are drawn in Section 4.

2 Word Vector Refinement

The refinement procedure begins by giving a set of pre-trained word vectors and a sentiment lexicon annotated with real-valued sentiment scores. Our goal is to refine the pre-trained vectors of the affective words in the lexicon such that they can capture both semantic and sentiment information. To accomplish this goal, we first calculate the semantic similarity between each affective word (target word) and the other words in the lexicon based on the cosine distance of their pre-trained vectors, and then select top-*k* most similar words as the nearest neighbors. These semantically similar nearest neighbors are then re-ranked according to their sentiment scores provided by the lexicon such that the sentimentally similar neighbors can be ranked higher and dissimilar neighbors lower. Finally, the pre-trained vector of the target word is refined to be closer to its semantically and sentimentally similar nearest neighbors and further away from sentimentally dissimilar neighbors. The following subsections provide a detailed description of the nearest neighbor ranking and refinement model.

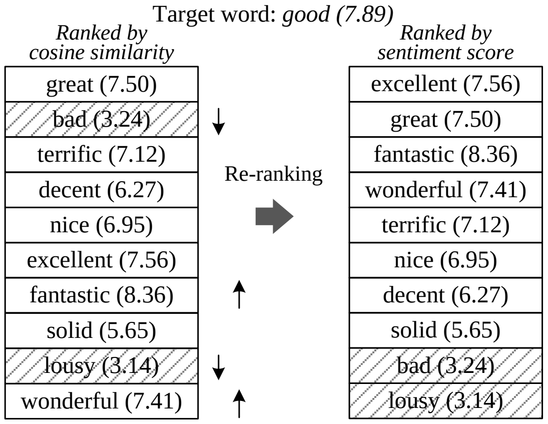

Figure 1: Example of nearest neighbor ranking.

2.1 Nearest Neighbor Ranking

The sentiment lexicon used in this study is the extended version of Affective Norms of English Words (E-ANEW) (Warriner et al., 2013). It contains 13,915 words and each word is associated with a real-valued score in [1, 9] for the dimensions of valence, arousal and dominance. The valence represents the degree of positive and negative sentiment, where values of 1, 5 and 9 respectively denote most negative, neutral and most positive sentiment. In Fig. 1, *good* has a valence score of 7.89, which is greater than 5, and thus can be considered positive. Conversely, *bad* has a valence score of 3.24 and is thus negative. In addition to the E-ANEW, other lexicons such as SentiWordNet (Esuli and Fabrizio, 2006), SoCal (Taboada et al., 2011), SentiStrength (Thelwall et al., 2012), Vader (Hutto et al., 2014), ANTUSD (Wang and Ku, 2016) and SCL-NMA (Kiritchenko and Mohammad, 2016) also provide real-valued sentiment intensity or strength scores like the valence scores.

For each target word to be refined, the top-k semantically similar nearest neighbors are first selected and ranked in descending order of their cosine similarities. In Fig. 1, the left ranked list shows the top 10 nearest neighbors for the target word *good*. The semantically ranked list is then sentimentally re-ranked based on the absolute difference of the valence scores between the target word and the words in the list. A smaller difference indicates that the word is more sentimentally similar to the target word, and thus will be ranked higher. As shown in the right ranked list in Fig. 1, the re-ranking step can rank the sentimentally similar neighbors higher and the dissimilar neighbors lower. In the refinement model, the higher ranked sentimentally similar neighbors will receive a higher weight to refine the pre-trained vector of the target word.

2.2 Refinement Model

Once the word list ranked by both cosine similarity and valence scores for each target word is obtained, its pre-trained vector will be refined to be (1) closer to its sentimentally similar neighbors, (2) further away from its dissimilar neighbors, and (3) not too far away from the original vector.

Let $V = \{v_1, v_2, \ldots, v_n\}$ be a set of the pre-trained vectors corresponding to the affective words in the sentiment lexicon. For each target to be refined, the refinement model iteratively minimizes the distance between the target word and its top-k nearest neighbors. The objective function $\Phi(V)$ can thus be defined as

$$\Phi(V) = \sum_{i=1}^{n}\sum_{j=1}^{k} w_{ij}\,dist(v_i, v_j) \qquad (1)$$

where n denotes the total number of vectors in V to be refined, v_i denotes the vector of a target word, v_j denotes the vector of one of its nearest neighbors in the ranked list, $dist(v_i, v_j)$ denotes the distance between v_i and v_j, and w_{ij} denotes the weight of the target word's nearest neighbor, defined as the reciprocal rank of a ranked list. For example, *excellent* in Fig. 1 will receive a weight of 1, *great* will receive a weight of 1/2, and so on. A word ranked higher will receive a higher weight. This weight is used to control the movement direction of the target word towards to its nearest neighbors. That is, the target word will be moved closer to the higher-ranked sentimentally similar neighbors and further away from lower-ranked dissimilar neighbors, as shown in Fig. 2.

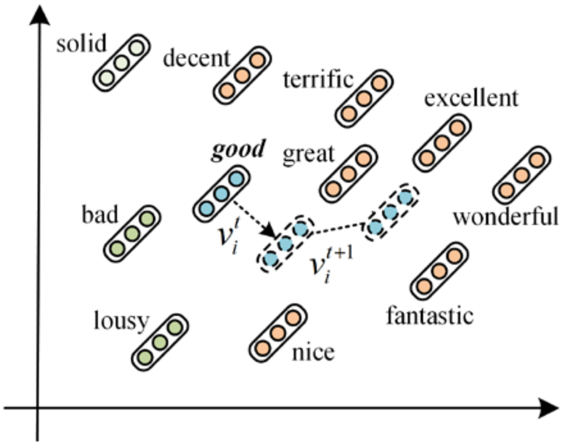

Figure 2: Conceptual diagram of word vector refinement.

To prevent too many words being moved to the same location and thereby producing too many similar vectors, we add a constraint to keep each pre-trained vector within a certain range from its original vector. The objective function is thus divided as two parts:

$$\arg\min \Phi(V) = \arg\min \sum_{i=1}^{n}\left[\alpha\,dist(v_i^{t+1}, v_i^{t}) + \beta\sum_{j=1}^{k} w_{ij}\,dist(v_i^{t+1}, v_j^{t})\right] \qquad (2)$$

where $dist(v_i^{t+1}, v_i^{t})$ denotes the distance between the vector of the target word in step t and t+1, i.e., the distance between the refined vector and its original vector. The later one represents the distance between the vector of the target word and that of its neighbors (similar to Eq. (1)). The parameters α and β together are used as a ratio to control how far the refined vector can be moved away from its original vector and toward its nearest neighbors. A greater ratio indicates a stronger constraint on keeping the refined vector closer to its original vector. For the extreme case of α=1 and β=0, the target word will not be moved (refined). As the ratio decreases, the constraint decreases accordingly and the refined vector can be moved closer to its nearest neighbors. The setting of α=0 and β=1 means that the constraint is disabled.

To facilitate the calculation of the partial derivative of $\Phi(V)$, $dist(v_i, v_j)$ in the above equations is measured by the squared Euclidean distance, defined as

$$dist(v_i, v_j) = \sum_{d=1}^{D} (v_i^d - v_j^d)^2 \qquad (3)$$

where D is the dimensionality of the word vectors. The global optimal solution of $\Phi(V)$ can be found by using an iterative update method. To do so, we solve the partial derivation of Eq. (2) in step t with respect to word vector v_i^t, and by setting $\frac{\partial \Phi(V)}{\partial v_i^t} = 0$ to obtain a new vector v_i^{t+1} in step t+1. The iterative update procedure is defined as

$$v_i^{t+1} = \frac{\gamma v_i^t + \beta \sum_{j=1}^{k} w_{ij} v_j^t}{\gamma + \beta \sum_{j=1}^{k} w_{ij}} \qquad (4)$$

Through the iterative procedure, the vector representation of each target word will be iteratively updated until the change of the location of the target word's vector is converged. The refinement process will be terminated when all target words are refined.

3 Experimental Results

This section evaluates the proposed refinement model, conventional word embeddings and previously proposed sentiment embeddings using several deep neural network models for binary and fine-grained sentiment classification.

Dataset. SST was adopted as the evaluation corpus (Socher et al., 2013). The binary classification subtask (positive and negative) contains 6920/872/1821 samples for the train/dev/test sets, while the fine-grained ordinal classification subtask (very negative, negative, neutral, positive, and very positive) contains 8544/1101/2210 samples of the train/dev/test sets.

Word Embeddings. The word embeddings used for comparison included two conventional word embeddings (GloVe and Word2vec), our refined versions (Re(GloVe) and Re(Word2vec)), and previously proposed sentiment embeddings (HyRank) (Tang et al., 2016). We used the same dimensionality of 300 for all word embeddings.

- GloVe and Word2vec: The respective GloVe and Word2vec (skip-gram) were pre-trained on Common Crawl 840B [1] and GoogleNews[2].
- Re(Glove) and Re(Word2vec): Both the pre-trained GloVe and Word2vec were refined using E-ANEW (Warriner et al., 2013). Each affective word was refined by its top k=10 nearest neighbors with parameters of α:β=0.1 (1:10) (see Eq. (2)).
- HyRank: It was trained using SST, NRC Sentiment140 and IMDB datasets. We compared this method because its code is publicly accessible[3].

Classifiers. The above word embeddings were used by CNN (Kim, 2014) [4], DAN (Iyyer et al., 2015)[5], , bi-directional LSTM (Bi-LSTM) (Tai et al., 2015)[6] and Tree-LSTM (Looks et al., 2017)[7] with default parameter values.

Comparative Results. Table 1 presents the evaluation results of using different word embeddings for different classifiers. For the pre-trained word embeddings, GloVe outperformed Word2vec for DAN, Bi-LSTM and Tree-LSTM, whereas Word2vec yielded better performance for CNN. After the proposed refinement model was applied, both the pre-trained Word2vec and GloVe were improved. The Re(Word2vec) and Re(GloVe) respectively improved Word2vec and GloVe by 1.7% and 1.5% averaged over all classifiers for binary classification, and both 1.6% for fine-grained classification. In addition, both Re(GloVe) and Re(Word2vec) outperformed the sentiment embeddings HyRank for all classifiers on both binary and fine-grained classification, indicating that the real-valued intensity scores used by the proposed refinement model are more effective than the binary polarity labels used by the previously proposed sentiment embedings.

The proposed method yielded better performance because it can remove semantically similar but sentimentally dissimilar nearest neighbors for the target words by refining their vector representations. To demonstrate the effect, we define a measure noise@k to calculate the percentage of top k nearest neighbors with an opposite polarity (i.e., noise) to each word in E-ANEW. For instance, in Fig. 1, the noise@10 for *good* is 20% because there are two words with an opposite polarity to *good* among its top 10 nearest neighbors. Table 2 shows the average noise@10 for different

- HyRank	49.2	88.2

Table 1: Accuracy of different classifiers with different word embeddings for binary and fine-grained classification.

Word Embeddings	Noise@10 (%)
Word2vec	24.3
GloVe	24.0
HyRank	18.5
Re(Word2vec)	14.4
Re(GloVe)	13.8

Table 2: Average percentages of noisy words in the top 10 nearest neighbors for different word embeddings.

word embeddings. For the two semantic-oriented word vectors, GloVe and Word2vec, on average around 24% of the top 10 nearest neighbors for each word are noisy words. After refinement, both Re(GloVe) and Re(Word2vec) can reduce noise@10 to around 14%. The HyRank also yielded better performance than both GloVe and Word2vec.

4 Conclusion

This study presents a word vector refinement model that requires no labeled corpus and can be applied to any pre-trained word vectors. The proposed method selects a set of semantically similar nearest neighbors and then ranks the sentimentally similar neighbors higher and dissimilar neighbors lower based on a sentiment lexicon. This ranked list can guide the refinement procedure to iteratively improve the word vector representations. Experiments on SST show that the proposed method yielded better performance than both conventional word embeddings and sentiment embeddings for both binary and fine-grained sentiment classification. In addition, the performances of various deep neural network models have also been improved. Future work will evaluate the proposed method on another datasets. More experiments will also be conducted to provide more in-depth analysis.

Abstract

In this paper, we propose a novel method for combining deep learning and classical feature based models using a Multi-Layer Perceptron (MLP) network for financial sentiment analysis. We develop various deep learning models based on Convolutional Neural Network (CNN), Long Short Term Memory (LSTM) and Gated Recurrent Unit (GRU). These are trained on top of pre-trained, autoencoder-based, financial word embeddings and lexicon features. An ensemble is constructed by combining these deep learning models and a classical supervised model based on Support Vector Regression (SVR). We evaluate our proposed technique on a benchmark dataset of SemEval-2017 shared task on financial sentiment analysis. The propose model shows impressive results on two datasets, i.e. microblogs and news headlines datasets. Comparisons show that our proposed model performs better than the existing state-of-the-art systems for the above two datasets by 2.0 and 4.1 cosine points, respectively.

1 Introduction

Microblog messages and news headlines are freely available on Internet in vast amount. Dynamic nature of these texts can be utilized effectively to analyze the shift in the stock prices of any company (Goonatilake and Herath, 2007). By keeping a track of microblog messages and news headlines for financial domain one can observe the trend in stock prices, which in turn, allows an individual to predict the future stock prices. An increase in positive opinions towards a particular company would indicate that the company is doing well and this would be reflected in the increase in company stock prices and vice-versa. Benefits of such analysis are two-fold: (i). an individual can take informed decision before buying/selling his/her share; and (ii). an organization can utilize this information to forecast its economic situation.

Sentiment prediction is a core component of an end-to-end stock market forecasting business model. Thus, an efficient sentiment analysis system is required for real-time analysis of financial text originating from the web. Sentiment analysis in financial domain offers more challenges (as compared to product reviews domains etc.) due to the presence of various financial and technical terms along with numerous statistics. Coarse-level sentiment analysis in financial texts usually ignores critical information towards a particular company, therefore making it unreliable for the stock prediction. In fine-grained sentiment analysis, we can emphasize on a given company without losing any critical information. For example, in the following tweet sentiment towards $APPL (APPLE Inc.) is *positive* while *negative* towards $FB (Facebook Inc.).

'$APPL going strong; $FB not so.'

In literature, many methods for sentiment analysis from financial news have been described. O'Hare et al. (2009) used word-based approach on financial blogs to train a sentiment classifier for automatically determining the sentiment towards companies and their stocks. Authors in (Schumaker and Chen, 2009) use the bag-of-words and named entities for predicting stock market. They successfully showed that the stock market behavior is based on the opinions. A fine-grained sentiment annotation scheme was incorporated by (de Kauter et al., 2015) for predicting the explicit

Copenhagen, Denmark, September 7–11, 2017. ©2017 Association for Computational Linguistics

and implicit sentiment in the financial text. An application of multiple regression model was developed by (Oliveira et al., 2013).

In this paper, we propose a novel Multi-Layer Perceptron (MLP) based ensemble technique for fine-grained sentiment analysis. It combines the outputs of four systems, one is feature-driven supervised model and the rest three are deep learning based.

We further propose to develop an enhanced word representation by learning through a stacked denoising autoencoder network (Vincent et al., 2010) using word embeddings of Word2Vec (Mikolov et al., 2013) and GloVe (Pennington et al., 2014) models.

For evaluation purpose we use datasets of SemEval-2017 'Fine-Grained Sentiment Analysis on Financial Microblogs and News' shared task (Keith Cortis and Davis, 2017). The dataset comprises of financial short texts for two domains i.e. microblog messages and news headlines. Comparisons with the state-of-the-art models show that our system produces better performance.

The main contributions of the current work are summarized as follows: a) we effectively combine competing systems to work as a team via MLP based ensemble learning; b) develop an enhanced word representation by leveraging the syntactic and semantic richness of the two distributed word representation through a stacked denoising autoencoder; and c) build a state-of-the-art model for sentiment analysis in financial domain.

2 Proposed Methodology

We propose a Multi-Layer Perceptron based ensemble approach to leverage the goodness of various supervised systems. We develop three deep neural network architecture based models, *viz.* Convolution Neural Network (CNN) (Kim, 2014), Long Short Term Memory (LSTM) network (Hochreiter and Schmidhuber, 1997) and Gated Recurrent Unit (GRU) network (Cho et al., 2014)). The other model is based on Support Vector Regression (SVR) (Smola and Schölkopf, 2004) based feature-driven system.

The classical feature based system utilizes a diverse set of features (c.f. Section 2.D). On the other hand we train a CNN, a LSTM and a GRU network on top of distributed word representations. We utilize Word2Vec and GloVe word representation techniques to learn our financial word embeddings. Since Word2Vec and GloVe models capture syntactic and semantic relations among words using different techniques (Word2Vec: given a context, a word is predicted or vice-versa; GloVe: count-based model utilizing word co-occurrence matrix), some applications adapt well to Word2Vec while others perform well on GloVe model. We, therefore, attempt to leverage the richness of both the models by using a stacked denoising autoencoder.Finally, we combine predictions of these models using the MLP network in order to obtain the final sentiment scores. An overview of the proposed method is depicted in Figure 1.

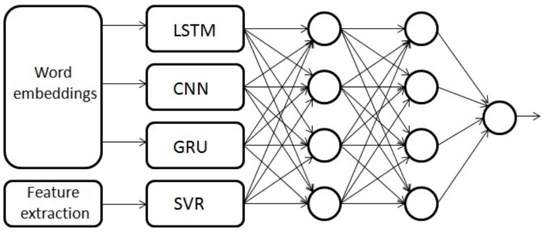

Figure 1: MLP based ensemble architecture.

A. Convolution Neural Network (CNN): Literature suggests that CNN architecture had been successfully applied for sentiment analysis at various level (Kim, 2014; Akhtar et al., 2016; Singhal and Bhattacharyya, 2016). Most of these works involve classification tasks, however, we adopt CNN architecture for solving the regression problem. Our proposed system employs a convolution layer followed by a max pool layer, 2 fully connected layers and an output layer. We use 100 different filters while sliding over 2, 3 and 4 words at a time. We employ all these filters in parallel.

B. Long Short Term Memory Network (LSTM): LSTMs (Hochreiter and Schmidhuber, 1997) are a special kind of recurrent neural network (RNN) capable of learning long-term dependencies by effectively handling the vanishing or exploding gradient problem. We use two LSTM layers on top of each other having 100 neurons in each. This was followed by 2 fully connected layers and an output layer.

C. Gated Recurrent Unit (GRU): GRUs (Cho et al., 2014) are also a special kind of RNN which can efficiently learn long-term dependencies. A key difference of GRU with LSTM is that, GRU's recurrent state is completely exposed at each time step in contrast to LSTM's recurrent state which controls its recurrent state. Thus, comparably GRUs have lesser parameters to learn and training is computationally efficient. We use two GRU layers on top of each other having 100 neurons in each. This was followed by 2 fully connected layers and an output layer.

D. Feature based Model (SVR): We extract and implement following set of features to train a Support Vector Regression (SVR) (Smola and Schölkopf, 2004) for predicting the sentiment score in the continuous range of -1 to +1.

- Word Tf-Idf: Term frequency-inverse document frequency (tf-idf) is a numerical statistic that is intended to reflect how important a word is to a document in a corpus. We consider tf-idf weighted counts of continuous sequences of n-grams (n=2,3,4,5) at a time.

- Lexicon Features: Sentiment lexicons are widely utilized resources in the field of sentiment analysis. Its application and effectiveness in sentiment prediction task had been widely studied. We employ two lexicons i.e. Bing Liu opinion lexicon (Ding et al., 2008) and MPQA (Wilson et al., 2005) subjectivity lexicon for news headlines domain. First we compile a comprehensive list of positive and negative words form these lexicons and then extract the following lexicon driven features.

Agreement Score : This score indicates the polarity of the sentence i.e. whether the sentence takes a polar or neutral stance. If the agreement score is 1 then it implies that the instance is of having either high positive or negative sentiment whereas, a 0 agreement score indicates a mixed or disharmony in the positive and negative sentiment implying the sentence is not polar (Rao and Srivastava, 2012).

$$A = 1 - \sqrt{1 - \left| \frac{T_{pos} - T_{neg}}{T_{pos} + T_{neg}} \right|}$$

Class score : Each text is assigned a class score indicating an overall sentiment value. The class score is -1, 0 or +1 depending on whether T_{pos} is less than, equal to or greater than T_{neg}. This helps in detecting the correct class of the sentence.

We also use four Twitter specific sentiment lexicons. These are NRC (Hashtag Context, Hashtag Sentiment, Sentiment140, Sentiment140 Context) lexicons (Kiritchenko et al., 2014; Mohammad et al., 2013) which associate a positive or negative score to a token. Following features are extracted for each of these: i) *positive*, *negative* and *net* count. ii) maximum of *positive* and *negative* scores. iii) sum of *positive*, *negative* and *net* scores.

- Vader Sentiment: Vader sentiment (Gilbert, 2014) score is a rule-based method that generates a compound sentiment score for each sentence between -1 (extreme negative) and +1 (extreme positive). It also produces ratio of positive, negative and neutral tokens in the sentence. We obtain score and ratio of each instance in the datasets and use as feature for training.

Network parameters for CNN, LSTM & GRU: In the fully connected layers we use 50 and 10 neurons , respectively for the two hidden layers. We use *Relu* activations (Glorot et al., 2011) for intermediate layers and *tanh* activation in the final layer. We employ 20% *Dropout* (Srivastava et al., 2014) in the fully connected layers as a measure of regularization and *Adam* optimizer (Kingma and Ba, 2014) for optimization.

E. MultiLayer Perceptron (MLP) based Ensemble: Ensemble of models improves the prediction accuracy by combining the outputs of all the individual models. It exploits the strengths of all the participating models. Some of these exiting ensemble techniques cover a wide variety of traditional approaches such as bagging, boosting, majority voting, weighted voting (Xiao et al., 2013; Remya and Ramya, 2014; Ekbal and Saha, 2011) etc. In recent times Particle Swarm Optimization based ensemble technique (Akhtar et al., 2017) has been proposed for aspect based sentiment analysis. However, our current work differs significantly *w.r.t.* the methodology that we adapt as well as the problem domain that we focus on.

In this work we propose a new ensemble technique based on MLP which learns on top of the predictions of candidate models. We use a small MLP network consisting of 2 hidden layers (4 neurons in each) and an output layer. We use *Relu* activations for hidden layers and *tanh* activation in the final layer. We employ 25% dropout in the intermediate layers and use Adam optimizer during backpropagation. The output of this network serves as the final prediction value.

We separately train and tune all the four models (Section 2.A - 2.D) for both the domains. Evaluation shows that results of these individual models are encouraging, and an effective combination of these through the proposed ensemble further increases the performance.

Word Embeddings: Distributed representation models such as Word2Vec and Glove are generally very effective in a multitude of natural language processing tasks. Quality of any word embedding directly depends upon two entities: a) in-domain corpus and b) size of the corpus. Pre-trained word embeddings of Word2Vec (PWE-W2V) and GloVe (PWE-GLV) serve general purpose rather than focusing on a specific domain. Since we are addressing the problem in financial text we train and use our own embedding for financial domain corpus (FWE-W2V & FWE-GLV). We collected 126,000 financial news articles from Google News having a total of 92 million tokens. Although the corpus size is not as large as pre-trained word embedding corpus, it works reasonably well (c.f Table 1).

We observe that Word2Vec and GloVe word embeddings are quite competitive. In some cases GloVe has the advantage while in others Word2Vec performs better. Therefore, we derive a new hybrid word embedding model using a stacked denoising autoencoders (DAWE). A denoising autoencoder (Vincent et al., 2010) is a neural network which is trained to reconstruct a clean repaired input from a noisy version of the input. Following (AP et al., 2014), we combine pretrained Word2Vec and GloVe representation of a word and fed it to the network in order to capture the richness of both representations. The input to the network is a combined 600 dimensional vector (300 W2V + 300 GLV) with statistically added *salt-and-pepper* noise.

In total we employ five different word embedding models for both the domains. Dimension of all these word embeddings are set to 300. While training our deep learning models, we keep the word embeddings dynamic so that they can be fine-tuned during the process.

3 Experiments, Results and Analysis

Dataset: We evaluate our proposed approach on the benchmark datasets of SemEval-2017 shared task 5 on 'fine-grained sentiment analysis on financial microblogs and news' (Keith Cortis and Davis, 2017). The two datasets consist of financial texts from Microblogs (Twitter and StockTwits) and News, respectively. There are 1,700 and 1,142 instances of microblog messages and news headlines in the training data. The test dataset comprises of 800 microblog messages and 491 news headlines.

Experiments: We use Python based libraries Keras and Scikit-learn for the implementation. Following the shared task guideline we use cosine similarity as the metric for evaluation. Cosine score represents the degree of agreement between predicted and actual values.

Table 1 shows evaluation of our various models. In microblog dataset we obtain the best cosine similarities of 0.724, 0.727, 0.721 and 0.765 for CNN, LSTM, GRU and feature based systems, respectively. Similarly, for news datasets we obtain the best cosine similarities of 0.722, 0.720, 0.721 and 0.760. It can be observed that results for all the models are numerically comparable, however, on a qualitative side they are quite contrasting in nature. Figure 2 shows the contrasting nature of different models for microblog messages. The predicted output of different models (i.e. CNN, LSTM, GRU and SVR) are often complimentary in nature. In some case, one model predicts correctly (or, closer to the gold output), while other models make incorrect predictions and the *vice-versa*. We also observe the same phenomena for news headline. Motivated by this contrasting behavior we choose to combine the predictions of these models.

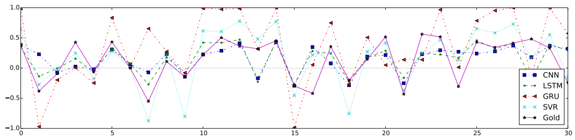

Figure 2: Contrasting nature of different models *w.r.t.* to the gold standard values; Sample size:30.

Consequently, we construct an ensemble by taking the best performing deep learning (CNN, LSTM and GRU each) and classical feature based (SVR) models using a MLP network. The proposed ensemble yields enhanced cosine scores of 0.797 and 0.786 for the microblog messages and news headline, respectively.

For comparison we choose two state-of-the-art systems (ECNU (Lan et al., 2017) and Fortia-FBK (Mansar et al., 2017)) which were the best performing systems at SemEval-2017 shared task 5. ECNU reported to have obtained cosine similarity of 0.777 in microblog as compared to 0.797 cosine similarity of our proposed system, whereas, for news headlines Fortia-FBK reported cosine similarity of 0.745. ECNU employed several regressors on top of optimized feature set obtained through *hill climbing* algorithm. For the final prediction, authors averaged the predictions of different regressors. Fortia-FBK trained a CNN with the assistance of sentiment lexicons for predicting the sentiment score. It should be noted that both the systems (ECNU and Fortia-FBK) utilize different approaches to achieve the stated cosine similarities on two different domains. The proposed approach of ECNU does not perform well for the news headlines, and Fortia-FBK reported results only for the news headlines. Our proposed system performs better compared to these existing systems for both the domains.This shows that our system is more robust and generic in nature in predicting the sentiment scores. We also perform statistical significance test on the obtained results and observe that the performance gain is significant with p-value = 0.00747. Table 2 depicts the comparative results on the test datasets.

3.1 Error Analysis

We also perform qualitative error analysis on the obtained results and observe that the proposed system faces problems in the following scenarios:

• Presence of implicit negation makes it a non-trivial task for the proposed system to predict the sentiment and intensity correctly. For the example given below, the overall negative sentiment is altered because of the presence of the word ‘*breaks*’.

Example : ***Tesco*** *breaks its downward slide by cutting sales decline in half*

Predicted: -0.694 **Actual:** 0.172

• The proposed system often confuses when the input text contains a question (?) mark.

Example : *Is* ***$FB*** *a BUY? Topeka Capital Markets thinks so*

Predicted: 0.363 **Actual:** -0.373.

4 Conclusion

In this paper, we have presented an ensemble network of deep learning and classical feature driven models. Evaluation on the benchmark datasets show that it performs remarkably well to identify bullish and bearish sentiments associated with companies in financial texts. We have implemented a variety of linguistic and semantic features for our analysis of the noisy text in Tweets and news headlines. Our proposed approach achieves state-of-the-art performance with the increments of 2.0 and 4.1 points over the existing systems for the tasks of sentiment prediction of financial microblog and news data. In future, we would like to extend our work by creating an end to end stock prediction system where the system would predict the future stock prices based on the sentiment score and stock value of the company.

Abstract

Identification of intensity ordering among polar (positive or negative) words which have the same semantics can lead to a fine-grained sentiment analysis. For example, *master, seasoned* and *familiar* point to different intensity levels, though they all convey the same meaning (semantics), *i.e.*, *expertise: having a good knowledge of*. In this paper, we propose a semi-supervised technique that uses sentiment bearing word embeddings to produce a continuous ranking among adjectives that share common semantics. Our system demonstrates a strong Spearman's rank correlation of 0.83 with the gold standard ranking. We show that sentiment bearing word embeddings facilitate a more accurate intensity ranking system than other standard word embeddings (word2vec and GloVe). Word2vec is the state-of-the-art for intensity ordering task.

1 Introduction

The interchangeable use of semantically similar words stimulates sentiment intensity variation among sentences. To understand the phenomenon, let us consider the following example:

1. (a) We were *pleased* by the beauty of the island. (Positively low intense)
   (b) We were *delighted* by the beauty of the island. (Positively medium intense)
   (c) We were *exhilarated* by the beauty of the island. (Positively high intense)

Pleased, Exhilarated and *delighted* are the positive words bearing the same semantics, *i.e.*, *directing the emotion*, but their use intensifies the positive sentiment in the sentences 1(a), 1(b) and 1(c) respectively. Identification of intensity ranking among the words which have the same semantics can facilitate such a fine-grained sentiment analysis as exemplified in 1(a), 1(b) and 1(c).[1]

In this paper, we present a semi-supervised approach to establish a continuous intensity ranking among polar adjectives having the same semantics. Essentially, our approach is a refinement of the work done by Sharma et al., (2015). They also built a system that generates intensity of the words that bear the same semantics; however, their system considers only three discrete intensity levels, *viz., low*, *medium* and *high*. The important feature of our approach is that it uses Sentiment Specific Word Embeddings (SSWE). SSWE are an enhancement to the normal word embeddings with respect to the sentiment analysis task (Tang et al., 2014). SSWE capture syntactic, semantic as well as sentiment information, unlike normal word embeddings (word2vec and GloVe), which capture only syntactic and semantic information.

Our Contribution: We propose an approach that generates a continuous (finer) intensity ranking among polar words, which belong to the same semantic category. In addition, we show that SSWE produce a significantly better intensity ranking scale than word2vec (Mikolov et al., 2013) and GloVe (Pennington et al., 2014), which do not capture sentiment information of the words.

The remaining paper is organized as follows. Section 2 describes the previous work related to intensity ranking task. Section 3 describes the different word embeddings explored in the paper. Section 4 gives the description of the data and the resources. Section 5 provides details of the gold

[1] Words which have the different semantic concepts cannot be used interchangeably. For example, *master (expertise)* and *delighted (directing the emotion)* cannot be a replacement of each other. Hence, our understanding is that a comparison between words belonging to different semantic categories does not give any meaningful information.

Proceedings of the 2017 Conference on Empirical Methods in Natural Language Processing, pages 547–552
Copenhagen, Denmark, September 7–11, 2017.

standard data. Section 6 elaborates the proposed intensity ranking approach. Section 7 presents the results and experimental setup. Section 8 concludes the paper.

2 Related Work

Sentiment analysis on adjectives has been extensively explored in NLP literature. However, most of the work addressed the problem of finding polarity orientation of the adjectives (Hatzivassiloglou and McKeown, 1997; Wiebe, 2000; Wilson et al., 2005; Fahrni and Klenner, 2008; Dragut et al., 2010; Taboada and Grieve, 2004; Baccianella et al., 2010).

The task of ranking polar words has received much attention recently due to the vital role of word's intensity in several real world applications. Most of the literature on intensity ranking consists of manual approaches or corpus-based approaches. Affective Norms (Warriner et al., 2013), SentiStrength (Thelwall et al., 2010), SoCAL (Taboada et al., 2011), and LABMT (Dodds et al., 2011), Best–Worst Scaling (Kiritchenko and Mohammad, 2016) are a few such publicly available sentiment intensity lexicons which are manually created.

Corpus-based approaches follow the assumption that the polarity of a new word can be inferred from the corpus (Hatzivassiloglou and McKeown, 1993; Kiritchenko et al., 2014; De Melo and Bansal, 2013). Corpus-based approaches require a huge amount of data, otherwise they suffer from the data sparsity problem. None of the these approaches considers the concept of semantics of adjectives, assuming one single intensity scale for all adjectives. Ruppenhofer et al., (2014) made the first attempt in this direction. They provided ordering among polar adjectives that bear the same semantics using a corpus-based approach. On the contrary, Sharma et al., (2015) used publicly available embeddings (word2vec) of words to assign intensity to words. Learning of word embeddings does not require annotated (labeled) corpus.

The embeddings used in our work are sentiment specific word embeddings. Integration of sentiment information of a word with syntactic and semantic information makes our approach more accurate for fine-grained sentiment intensity ranking of words.

3 Word Embeddings

In recent years, several models have been proposed to learn word embeddings from large corpora. In this paper, we have explored three types of word embeddings, *viz.*, word2vec (Mikolov et al., 2013), Glove (Pennington et al., 2014) and SSWE (Tang et al., 2014). The word embeddings given by word2vec are the distributed vector representation of the words that capture both the syntactic and semantic relationships among words. The Global Vector model, referred as GloVe, combines word2vec with ideas drawn from matrix factorization methods, such as LSA (Deerwester et al., 1990). Word2vec and GloVe model the syntactic context of the words but ignore their sentiment information. For sentiment analysis task, this is problematic as these word embeddings map words with similar syntactic context but opposite polarity, such as *love* and *hate* closer to each other in the vector space.

Sentiment Specific Word Embeddings (SSWE) encode sentiment information along with the syntactic and semantic information in word vector space. These word embeddings are able to separate the words like *love* and *hate* to the opposite ends of the spectrum. Tang et al., (2014) proposed a method to learn sentiment specific word embeddings from tweets with *emoticons* as distant-supervised corpora without any manual annotation. Specifically, they developed three neural networks to effectively incorporate the supervision from sentiment polarity of text in their loss functions.

4 Data and Resources

In this work, we have used the 52 polar semantic categories from the FrameNet data.[2] FrameNet-1.5 (Baker et al., 1998) is a lexical resource which groups words based on their semantics.[3] We also used a star-rated movie review corpus of 5006 files (Pang and Lee, 2005) to extract the pivot for each semantic category.[4] Though our approach uses a corpus, its use is limited to identification of pivot. Intensity ranking of other words of the semantic category is derived by exploiting the cosine-

[2] Sharma et al., (2015) also have presented their results using the same 52 polar semantic categories of the FrameNet data.

[3] Available at: `https://framenet.icsi.berkeley.edu/fndrupal/about`.

[4] Available at: `http://www.cs.cornell.edu/people/pabo/movie-review-data/`.

similarity between word embeddings of the pivot and the other words of the semantic category. For all three types of word embeddings, we have used precomputed 300 dimensional vectors of words.[5][6]

5 Gold Standard Data Preparation

The objective of our work is to obtain a continuous ranking among words having the same semantics as per FrameNet data. We asked 5 annotators[7] to rank words in each semantic category on a scale of -50 to $+50$. Here, -50 represents the most negatively intense point and $+50$ represents the most positively intense point on the scale. 0 represents a neutral (neither positive nor negative) point on the scale. It is hard to get any neutral word in the data as we have used only polar semantic categories of the FrameNet. The final ranking scale in a category is obtained by averaging the score assigned by all 5 annotators. For example, for a word, if annotator-1 gave ranking r1, annotator-2 gave ranking r2, annotator-3 gave ranking r3, annotator-4 gave ranking r4 and annotator-5 gave ranking r5, then final ranking is ((r1+r2+r3+r4+r5)/5).

To check the agreement among 5 annotators, we computed Fleiss' kappa. It is a statistical measure of inter-rater reliability. Fleiss' kappa is chosen over Scott's pi and Cohen's kappa, because these measures work for two raters, whereas Fleiss' kappa works for any number of raters giving categorical ratings to a fixed number of items (Fleiss, 1971). We obtained a Fleiss' kappa score of **0.64** by dividing words of the semantic category into six levels (high-positive, medium-positive, low-positive, low-negative, medium-negative, high-negative).

6 Approach: Derive Intensity Ordering Among Words

Our approach establishes a continuous intensity ranking among words based on the following hypotheses:

Hypothesis-1 The classic *semantic bleaching theory* states that a word which has fewer number of senses (possibly one) tends to have a higher intensity in comparison to words having more senses.

Hypothesis-2 Semantically similar words that have fewer number of senses exhibit higher cosine-similarity with each other in comparison to words having many senses. Essentially, fewer number of senses cause fewer number of context words or vice versa.

Considering hypothesis-1 and 2 as a base, Sharma et al., (2015) claimed that the word embeddings (context vectors) of high intensity words depict higher cosine-similarity with each other than with low or medium intensity words. However, they used word embeddings which capture only syntactic and semantic similarity among words (Mikolov et al., 2013). Our approach uses SSWE, which integrate sentiment information with the normal word embeddings. Use of SSWE in place of normal word embeddings provides a more accurate cosine-similarity scores, which in turn leads to a more accurate continuous intensity scale. Section 6.1 describes how a high intensity word (pivot) for each semantic category is extracted from an intensity annotated corpus. Section 6.2 presents the algorithm that assigns intensity ordering to words of a semantic category using the pivot (high intensity) word.

6.1 Pivot Selection Method

An amalgamation of χ^2 test and Weighted Normalized Polarity Intensity (WNPI) formula extracts a high intensity word as pivot for each semantic category from the 5 star-rated review corpus. χ^2 test assures that no biased word should be selected as the pivot (Oakes and Farrow, 2007).[8] By biased word we mean that a word which has very few occurrences in the corpus, but these occurrences are in the high star-rated reviews. For example, in our corpus, the word *lame* occurs only 3 times in the corpus, and these occurrences happen to be in 1-star (negatively high intense) reviews only. In addition, χ^2 test derives polarity orientation of the pivot from the corpus as it associates a class (positive or negative) label with the word (Sharma and Bhattacharyya, 2013).

The WNPI formula assigns a intensity score to

[5] In this work, we have opted for precomputed word embeddings, because they are trained on sufficiently large corpora and widely tested for NLP applications.

[6] Embeddings are available here: word2vec (trained on news corpus of 320M words): https://drive.google.com/file/d/0B7XkCwpI5KDYNlNUTTlSS21pQmM/edit, GloVe (trained on Wikipedia 2014): http://nlp.stanford.edu/projects/glove/, SSWE (trained on 91M tweets): http://ir.hit.edu.cn/~dytang/.

[7] Two of the annotators are professional linguists of English language and other three are post graduate students.

[8] The details about the *goodness of fit chi*^{2} test: http://stattrek.com/chi-square-test/goodness-of-fit.aspx?Tutorial=AP.

words based on their frequency count in different star ratings. It is defined based on the concept that a high intensity word would occur more frequently in high star-rated reviews, for example, *outstanding* would occur more frequently in 5-star or 4-star reviews in comparison to 1,2,3-star reviews. In the WNPI formula (Algorithm 1), the value of i ranges from 1 to 5, here star rating is used as intensity of the review. The algorithm extracts two pivots for each category, one positive pivot for positive words and one negative pivot for negative words. For the sake of simplicity, we have used the term 'pivot' only in the Algorithm 1. For a positive word '5-star' is treated as 'i=5' (highest positive intensity) and for a negative word '1-star' is treated as 'i=5' (highest negative intensity) in the WNPI formula. A word which gets the highest score by the χ^2 test and the WNPI formula is set as positive (or negative) pivot.

6.2 Algorithm

Algorithm 1 illustrates the sequence of steps carried out to obtain the intensity ordering of words within a semantic category. c_p^w and c_n^w are the counts of a word w in the positive and negative documents respectively. μ^w is an average of c_p^w and c_n^w. To obtain the values of c_p^w and c_n^w, we divided the 5 star-rated review corpus in two equal parts as the positive corpus and the negative corpus. C_i is the count of a word in i intensity documents. Polarity of the words other than the pivot words is inferred by computing the cosine-similarity between SSWE of other words with the SSWE of the pivot word. Since SSWE have sentiment information, a positive pivot gives *positive* cosine-similarity with the positive words and *negative* cosine-similarity with the negative words.[9] Cosine-similarity order between SSWE of the pivot and other words establishes intensity ranking among words of a semantic category.

7 Results and Experimental Setup

To evaluate the efficacy of our SSWE-based approach over word2vec-based system (state-of-the-art) (Sharma et al., 2015) and GloVe-based system, we compute rank correlation and Macro-F1 between the intensity ranking produced by the embeddings and the gold standard intensity ranking.

Algorithm 1: Generating an Intensity ordering of words within a semantic category

```
Input: Set of words within a semantic
       category $W_{sc}$ ;
       Intensity ($i$) annotated corpus $C$ ;
       Pre-trained Sentiment embeddings
       $SSWE$.
Output: Ranking of words based on intensity.
for each word $w_i \in W_{sc}$ do
    $\chi^2(w_i) = ((c_p^w - \mu^w)^2 + (c_n^w - \mu^w)^2)/\mu^w$
    $WNPI(w_i) = \frac{\sum_{i=1}^{5} i*C_i}{5*\sum_{i=1}^{5} C_i}$

7.1 Rank Correlation

Table 1 shows the average rank correlation coefficient obtained for 52 polar semantic categories of the FrameNet data using Spearman's ρ and Kendall's τ. Spearman's ρ measures the degree of association between the two rankings. Kendall's τ finds the number of concordant and discordant pairs in the rankings to measure association. We observed that SSWE-based system results in a significantly better ρ and τ as per t-test.

Embeddings	**Spearman's ρ**	**Kendall's τ**
Glove	0.525	0.425
Word2vec	0.71	0.565
SSWE	**0.82**	**0.70**

Table 1: Spearman's ρ and Kendall's τ rank correlations.

7.2 F1 Measure

In order to compare our work with the state-of-the-art (Sharma et al., 2015), the intensity ordering of words within a semantic category is divided into 3 levels, i.e, *low*, *medium* and *high* for both the positive and negative words respectively. In order to create three levels, we placed 2 break points in

[9] Sharma et al., (Sharma et al., 2015) used Bing Liu's lexicon in their approach to identify polarity orientation of words. The use of SSWE in our approach helped us to remove the need of a sentiment lexicon to identify polarity of words.

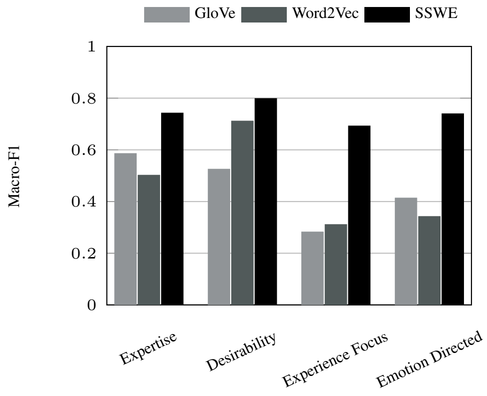

Figure 1: Individual Macro-F1 score for the 4 semantic categories.

the intensity ordering sequence where consecutive similarity scores differ the most.[10] Comparison of Macro-F1 scores for 4 different categories is shown in Figure 1. SSWE outperforms word2vec and GloVe by a big margin in all 4 cases. In addition, we obtain an average Macro-F1 score of 74.32% with SSWE, 54.38% with word2vec and 45.10% with GloVe for the 52 semantic categories.

7.3 Error Analysis

In a few semantic categories of the FrameNet data, words are not confined to any one sentiment and to say that one kind of sentiment has a higher intensity than the other is difficult at times. For example, it is difficult to compare *sadness* and *embarrassment* relatively in terms of intensity, whereas both the words belong to the same semantic category, that is, *emotion directed* as per FrameNet data. In addition, annotators mutually agreed on the fact that when there are limited number of words then it is easier and logical to scale them. More separation based on the finer semantic property within the existing semantic category of the FrameNet data may bring on improvement in the performance of automatic intensity ranking systems.

8 Conclusion

In this paper, we have given a technique that uses Sentiment Specific Word Embeddings (SSWE) to produce a fine-grained intensity ordering among polar words which bear the same semantics. In addition, the use of sentiment embeddings reduces the need of sentiment lexicon for identification of polarity orientation of words. Results show that SSWE are significantly better than word2vec and GloVe, which do not capture sentiment information of words for intensity ranking task. Sentiment intensity information of words can be used in various NLP applications, for example, star-rating prediction, normalization of over-expressed or under-expressed texts, *etc*.

Abstract

Although many sentiment lexicons in different languages exist, most are not comprehensive. In a recent sentiment analysis application, we used a large Chinese sentiment lexicon and found that it missed a large number of sentiment words used in social media. This prompted us to make a new attempt to study sentiment lexicon expansion. This paper first formulates the problem as a *PU learning* problem. It then proposes a new PU learning method suitable for the problem based on a neural network. The results are further enhanced with a new dictionary lookup technique and a novel polarity classification algorithm. Experimental results show that the proposed approach greatly outperforms baseline methods.

1 Introduction

Sentiment lexicons contain words (such as *good*, *beautiful*, *bad*, and *awful*) that convey positive or negative sentiments. They are instrumental for many sentiment analysis applications. So far many algorithms have been proposed to generate such lexicons (Liu, 2012). These algorithms are either dictionary-based or corpus-based. In the dictionary-based approach, one exploits synonym and antonym relations in the dictionary to bootstrap a given seed set of sentiment words (Hu and Liu, 2004; Kim and Hovy, 2004; Kamps et al., 2004), or learns a classifier to classify the gloss of each word in the dictionary (Esuli and Sebastiani, 2005). The corpus-based approach uses various linguistic rules or patterns (Hatzivassiloglou and McKeown, 1997; Kanayama and Nasukawa, 2006; Qiu et al., 2011; Tang et al., 2014). We will discuss these and other existing methods in the related work section.

Despite many existing studies, the problem is far from being solved. In a recent application, we used a popular Chinese sentiment lexicon for sentiment classification of Weibo posts (similar to Twitter), and found that it missed a large number of sentiment words. As the lexicon was compiled using formal text such as news, it misses a large number of sentiment words used in social media. Due to the informal nature, many "low class" words are used in social media but seldom used in formal media. New words are also created constantly. Note that new words in Chinese are easier to create from individual characters than in other languages. Thus many of these words are not in the dictionary. All these prompted us to make a new attempt to study *sentiment lexicon expansion*.

In this paper, we solve the problem in two steps: (1) identify sentiment words from a given corpus, and (2) classify their polarity. We formulate Step 1 as a *PU learning* problem (*learning from positive unlabeled examples*). To our knowledge, this is the first such formulation. This is important because it gives us a formal model to tackle the problem. PU learning is stated as follows (Liu et al., 2002): given a set P of examples of a particular class (we also use P to denote the class) and a set U of unlabeled examples which contains hidden instances from both classes P and *not-P* (called N), we want to build a classifier using P and U to classify the data in U or future test data into the two classes, i.e., P and N (or *not-P*). In our case, P is the existing sentiment lexicon, and U is a set of candidate words from a social media corpus. We identify those words in U that are also sentiment words.

A typical PU learning algorithm works by first identifying a small set of *reliable* N class examples (*RN*) from the unlabeled set U and then running a supervised learning method (e.g., SVM) it-

Proceedings of the 2017 Conference on Empirical Methods in Natural Language Processing, pages 553–563
Copenhagen, Denmark, September 7–11, 2017. ©2017 Association for Computational Linguistics

eratively to add more and more data to the *RN* set to finally build a classifier (Liu, 2011).

In this work, we first adapt a popular such approach to an *augmented multilayer perceptron* (AMP) method and use it to replace SVM, and show that using SVM as the learning method is inferior to using AMP. However, we can do much better. We then propose a new PU learning method, called SE-AMP (*Spy-based Elimination of P class instances using AMP*), which can better exploit the specific nature of our problem. SE-AMP goes in the opposite direction to the existing approach. It starts by treating U as the class N (*not-P*) data, and then runs the AMP learning method on P and U iteratively to gradually remove potential P class instances from U to purify U so that as iterations progress, fewer and fewer P class instances are still in U. We detail the method in Sec. 3.3. Note that SE-AMP is general and not limited to our task of sentiment lexicon expansion.

We also propose a new method based on dictionary lookup, called *Double dictionary Lookup* (DL), to enhance the results from the proposed PU learning method. The DL method is also in the framework of PU learning. Our final proposed method for Step 1 is called SE-AMP-DL.

For polarity classification (Step 2, after sentiment words are found), we propose a novel method that is based on polarity association of individual (Chinese) characters in each word.

In summary, this paper has several innovations:

1. It formulates Step 1 of sentiment lexicon expansion as a PU learning problem. To the best of our knowledge, this is the first such formulation.

2. It proposes a new neural learning method AMP and shows that AMP outperforms the traditional SVM based PU learning approach.

3. It further proposes a new and general PU learning strategy that works in the opposite direction to the popular existing approach to suit our task.

4. It also proposes a double dictionary lookup technique to improve the result further.

5. It proposes a novel polarity classification method to classify the polarity of each word.

Experimental results show that the proposed approach makes considerable improvement over existing baseline methods.

2 Related Work

There are two main approaches for sentiment lexicon generation (Liu, 2012): the *dictionary-based approach* and the *corpus-based approach*. Under the dictionary-based approach, one method is to use synonym and antonym relations and WordNet graph in the dictionary to bootstrap a set of given seed sentiment words. There are numerous variations of and enhancements to this approach (Hu and Liu, 2004; Valitutti et al., 2004; Kim and Hovy, 2004; Takamura et al., 2007; Andreevskaia and Bergler, 2006; Kaji and Kitsuregawa, 2007; Blair-Goldensohn et al., 2008; Cambria et al., 2016; Rao and Ravichandran, 2009; Perez-Rosas et al., 2012). For example, (Valitutti et al., 2004; Kim and Hovy, 2004) tried to remove error words and assign a sentiment strength to each word. Mohammad et al. (2009) exploited many antonym-generating affix patterns, Kamps et al. (2004) used a WordNet distance, and Hassan and Radev (2010) used a Markov random walk model over a word relatedness graph. Dragut et al. (2010) used a set of inference rules to determine word sentiment polarity through a deductive process, and Schneider and Dragut (2015) employed a linear programming approach. Another method is to build a supervised sentiment classifier to classify the gloss text of each word in the dictionary (Esuli and Sebastiani, 2005, 2006). Xu et al. (2010a) integrated both dictionaries and corpora to find emotion words based on label-propagation. Perez-Rosas et al. (2012) also worked on cross lingual lexicon construction.

In the corpus-based approach, one key idea is to exploit some linguistic conventions on connectives such as AND and OR Hatzivassiloglou and McKeown (1997). For example, in the sentence “This car is beautiful and spacious,” if “beautiful” is known to be positive, it can be inferred that “spacious” is also positive. Kanayama and Nasukawa (2006) extended the idea to the sentence level by exploiting adversative expressions such as “but” and “however.” Qiu et al. (2011) proposed a double propagation (DP) method that uses both sentiment and target relation and various connectives to extract sentiment words. (Wang and Wang, 2008) did similar works. Huang et al. (2014) detected new sentiment words using lexical patterns. Wilson et al. (2005), Ding et al. (2008), Choi and Cardie (2008) and Zhang and Liu (2011) studied contextual sentiments at the phrase or expression level. We do not study contextual sentiments.

Another idea for the corpus-based approach is to use word co-occurrences. Turney (2002) computed the Pointwise Mutual Information (PMI) between the target word and seed words to decide its sentiment polarity. This method was extended in (Mohammad et al., 2013; Yang et al., 2014). (Hamilton et al., 2016; Xu et al., 2010b) constructed domain lexicons using lexical graphs.

Recent works also exploited neural networks and word embedding, and treated lexicon generation as a classification problem like us. Tang et al. (2014) expanded a sentiment lexicon using a softmax classifier with the proposed sentiment-specific embedding. Vo and Zhang (2016) obtained sentiment attribute scores of each word through a neural network model to predict tweets emoticons. Bravo-Marquez et al. (2015) classified words using manual features and emoticon-annotated tweets. However, all these works require different kinds of labeled data. We do not rely on emoticons or other forms of annotations.

The problem of adapting a general lexicon to a domain specific one was studied in (Choi and Cardie, 2009; Jijkoun et al., 2010; Du et al., 2010). Feng et al. (2011) also generated a connotation lexicon. These are clearly different from our work.

3 The Proposed Approach

As mentioned in Sec. 1, our problem is solved in two steps: (1) identify sentiment words and (2) classify their polarity. In the following, we first introduce a traditional PU learning method using SVM (Sec. 3.1), and the augmented multilayer perceptron (AMP) method (Sec. 3.2) to set the background for the proposed technique. The proposed PU learning algorithm is presented in Sec. 3.3 for performing the task of step 1, which uses AMP. After that, a dictionary based method called Double Dictionary Lookup (Sec. 3.4) is presented to further improve the result of the first step. The proposed polarity classification method for the second step is discussed in (Sec. 3.5).

3.1 Traditional PU Learning

PU learning has been investigated by several researchers (Liu et al., 2002; Denis et al., 2002; Li and Liu, 2003; Yu et al., 2002; Elkan and Noto, 2008; Hsieh et al., 2015). A popular approach follows a two-stage strategy: (i) identifying a set of reliable N class instances RN from the unlabeled set U; and (ii) building a classifier using P (P class) and RN (N class) and $Q = U - RN$ (unlabeled) by applying a learning algorithm (e.g., SVM) iteratively.

To understand the difference between the proposed algorithm and the above two-stage approach, we give more details to an existing algorithm (Liu, 2011). In the first stage, a *Spy* technique is used to identify the set of reliable N class instances (or examples) RN from U. It works as follows: 10% of P class instances (in our cases, they are words) is first randomly selected as a *spy* set S and put in the unlabeled set U. Then SVM is run using the set $P - S$ as the P class training data and $U \cup S$ as the N class training data. After training, the resulting classifier assigns a probability to each instance in S to decide a probability threshold th. Instances in U that has a lower probability than th are selected as RN. As suggested in (Liu, 2011), th is set to the probability that separates the last 15% instances in S. We also experimented with 10% and 20%, but the results are similar.

In the second stage, we run SVM iteratively. In each iteration, a classifier trained using P and RN is used to classify the instances in $Q = U - RN$. Those instances assigned the N class in Q are removed and added to RN. Iterations stop when no instance in Q is classified to the N class.

3.2 Augmented Multilayer Perceptron

We now present the proposed AMP (*Augmented Multilayer Perceptron*) method, which we will use to replace SVM in PU learning as AMP produces better results. AMP has three layers (Figure 1). The first layer takes the *word vector* of each word as input with an output of 50 dimensions. The second layer takes the output of the first layer as input to produce an output of 2 dimensions. Both the first and second layers use the RELU activation function. The 2 dimension output of the second layer concatenates with 5 POS features (see Sec. 4.1.3) to form a 7 dimension feature vector as input of the third layer, which is the final layer with the activation function of Sigmoid.

We note that instead of putting POS features in the first layer, we first reduce the dimension of word vector from 200 to 2 with two layers, then compose a vector with POS features as the input to the third layer. This enables POS features to play a more important role. This method gives better results than combining the word vector and POS

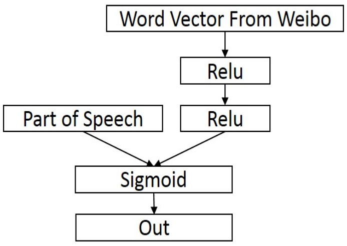

Figure 1: Aumented Multilayer Perceptron

tag features as the input in the first layer. Our experimental results also show that using AMP to replace SVM above in PU learning produces much better results.

3.3 Proposed New PU Learning Algorithm

We now present the proposed new PU learning strategy, which has only one stage that runs a supervised learning algorithm iteratively using P and U by treating U as the N class data. This strategy is more suitable for our task as we will explain in Sec. 4.1.4. The general idea is to remove words from U that are likely to belong to the P class until some stopping criterion is satisfied. The proposed algorithm is called SE-AMP (*Spy-based Elimination of P class instances using AMP*), which is given in Algorithm 1. Note that in the algorithm, we use $+1$ to denote class P (line 1) and -1 to denote class N (line 5). We don't use SVM any more as AMP performs much better. We now detail the working of the algorithm.

The algorithm still uses *Spies* and also works iteratively, but in a very different way. It first randomly sample a small proportion γ of words from set P to form the spy set S (line 2), which is added to the current U set to form U_s (line 4). The U set is updated in each iteration. An AMP classifier is trained using set P (with the class label $+1$) and set U_s (regarded as class N with the class label -1) (line 6). The resulting classifier or model M is used to score or assign a probability to each instance in U and in S (line 7).

Now we come to the crucial steps of the proposed algorithm. It tries to remove likely P class instances from U. U is essentially regarded as an noisy N class data, i.e., it has a lot of errors (which are hidden P class instances). Thus this step effectively aims to purify the N class set. In line 8, the algorithm determines a threshold θ to remove some likely P class instances from U. We will discuss the function for determining θ below.

Based on the probability threshold θ, the algorithm removes those instances in U with greater probability than θ (lines 9-13) and those instances in the spy set S (line 14-18).

The algorithm stops when the stopping criteria is met (lines 19 and 20); otherwise, it goes to the next iteration with the updated U and S. We determine the threshold δ using a validation set (Sec. 4.1.1).

Determine θ: In this new algorithm, each iteration removes instances that are likely to be of P class from the unlabeled set U. One simple way is to remove the top $k\%$ of U based on the classifier result of each iteration. However, this method is undesirable because we cannot control the probabilities of the eliminated instances. We propose to use Gaussian fitting to determine the threshold θ.

After each iteration, every spy word $w_i \in S$ is assigned a probability x_i $(= Pr(P|w_i))$ to be in class P by the classifier M, a Gaussian fitting is done on these probabilities. Parameters of Gaussian distribution are obtained using Maximum Likelihood Estimate (MLE) as follows: $\mu = \frac{1}{n}\sum_{i=1}^{n} x_i$, and $\sigma^2 = \frac{1}{n}\sum_{i=1}^{n}(x_i - \mu)^2$. We set the threshold $\theta = \mu + \sigma$. Thus those words have probabilities higher than θ are considered very likely to belong to the P class. This threshold is very conservative and only allows those very likely P class instances to be removed from U.

We will discus why the proposed SE-AMP is better than S-AMP in Sec. 4.1.4 after we see the experiment results. Note that S-AMP uses the traditional PU-learning strategy discussed in Sec. 3.1 but it replaces SVM with AMP.

3.4 Double Dictionary Lookup

To improve PU learning of SE-AMP further, we propose to employ a dictionary. Using a dictionary is natural because human beings always use dictionaries to understand a word. The proposed *Double Lookup* (DL) technique is given in Algorithm 2. Why *double lookup* is needed will be clear shortly.

The algorithm works as follows. Let the set of given sentiment lexicon be P, the given dictionary be D, and the set of candidate words be U (in this case, it is the test set). For each candidate word $w \in U$, we first look w up in the dictionary D (lines 1-2). If w can be found in D (line 2), we use a lexicon-based sentiment classifier (C) (see below) to classify the gloss or explanation note (G_w) of w (lines 3-4). The function *classify* returns a set of sentiment words O_1 from G_w (line 4), which are also in P. If O_1 is not empty, it means that G_w

Algorithm 1 SE-AMP(P, U)

```
1:  Every instance in $P$ is assigned the class label $+1$
2:  $S = Sample(P, \gamma)$;   // $\gamma = 0.1$ in this experiment; instances in $S$ are spies
3:  **loop**
4:      $U_s = U \cup S$
5:      Every instance $u$ in $U_s$ is assigned the class label $-1$   // $-1$ denotes the $N$ class
6:      $M$ = AMP($P$, $U_s$)   // Build a binary AMP classifier $M$
7:      score($M, U, S$)   // Score each instance *i* in $U$ and $S$ using $M$ to give each *i* a probability score
8:      $\theta$ = DetermineThreshold($S$)   // decide a probability threshold $\theta$ using $S$;
9:      **for** each instance $u \in U$ **do**
10:         **if** its probability $Pr(+1|u) > \theta$ **then**
11:             $U = U - \{u\}$
12:         **end if**
13:     **end for**
14:     **for** each instance $s \in S$ **do**
15:         **if** its probability $Pr(+1|s) > \theta$ **then**
16:             $S = S - \{s\}$
17:         **end if**
18:     **end for**
19:     **if** $|S| \leq \delta(\gamma|P|)$ **then**   // Stopping criterion; $\gamma|P|$ is actually the original size of $S$ in line 2
20:         exit-loop
21:     **end if**
22: **end loop**
```

is classified to the sentiment class. If it is empty, it is classified to the non-sentiment class.

This one dictionary lookup is not safe to determine whether word w is a sentiment word or not because some sentiment words in the lexicon P are noisy and don't have clear sentiments. This gives us too low precision. That is why we perform the second dictionary lookup, which is on the words in O_1 to ensure that at least one word in O_1 is very likely to be a true sentiment word because a noisy sentiment word in P is unlikely to be explained by another word in P. But a true sentiment word in P is very likely to be explained by another sentiment word in P.

Line 7 looks up each word $o \in O_1$ in D and finds its gloss or explanation note G_o. G_o is then classified in line 8, which returns a list of sentiment words O_2 from G_o, also in P. If O_2 is not empty, meaning that G_o is a sentiment sentence (line 9), we return w as a sentiment word (line 10).

Lexicon-based sentiment classifier (*C*): C is a binary classifier with two classes *sentiment* or *non-sentiment*. Given a sentence s (e.g., the explanation note of a word in the dictionary), it simply finds sentiment words in s that are also in the given sentiment lexicon P. If some sentiment words are found, it returns them in a set indicating the sentence s is a sentiment sentence. Although simple, this works quite well because the explanation note of a word in a dictionary is usually quite simple.

Integrating SE-AMP and DL: Our final proposed method (SE-AMP-DL) combines SE-AMP and DL. As we will see that DL has high precision but low recall because most of the new words cannot be found in the dictionary, we use the results of DL to correct the results of the SE-AMP algorithm. Words that are classified as belong to the N class by SE-AMP are moved to the P class if the DL method believes them to be sentiment words.

3.5 Polarity Classification

After sentiment words are discovered, this step determines the polarity (positive or negative) of each discovered sentiment word. We propose a new classification method exploiting the fact that new Chinese words are created with 2 or more Chinese characters. The meaning of a Chinese word is closely related to the meaning of each individual character of the word. So the polarity of a Chinese word is strongly related to the polarity of the characters that form the word, which is the motivation of the new classification method. We use the polarity association of the characters in each word to predict the polarity of the word based on super-

Algorithm 2 DL(P, D, U, C)

```
for each candidate word $w \in U$ do
    if $w$ can be found in $D$ then    // First dictionary lookup; $D$ is the dictionary
        Let $G_w$ be the gloss or explanation of word $w$ in $D$
        $O_1$ = classify($G_w$, $C$)    // $O_1$ is the set of sentiment words in $G_w$ and $O_1 \subseteq P$ (lexicon)
        if $O_1 \neq \emptyset$ then    // $G_w$ is classified to the sentiment class
            for each word $o \in O_1 (\subseteq P)$ do
                Let $G_o$ be the gloss or explanation of word $o$ in $D$    // Second dictionary lookup
                $O_2$ = classify($G_o$, $C$)    // $O_2 \subseteq P$ (lexicon) and $C$ is the sentiment classifier
                if $O_2 \neq \emptyset$ then    // $G_o$ is classified as a sentiment sentence
                    $w$ is a new sentiment word
                end if
            end for
        end if
    end if
end for
```

vised learning. We call the method CPA (*Character Polarity Association*). This method is very useful for languages whose words are constructed by characters such as Chinese and Japanese.

Feature Vector: For a character, we calculate the percentages of it appearing in the positive words and negative words in the existing lexicon P to form a 2-dimensional polarity vector. For example, the polarity vector (0.9, 0.1) means that 90% of the words in the existing lexicon that contains the character are positive and the other 10% are negative. Thus, for a word with 2 characters, which covers most cases in Chinese, a 4-dimensional vector is formed. For those words with more than 2 characters, we choose 2 characters with the strongest polarity to form a 4-dimensional vector.

Classifier Building: Using all positive and negative words in the existing lexicon P as the training sample, each word represented as a vector of four features, we apply a Naive Bayesian Classifier to build a polarity classifier. For testing, a word is represented in the same way. If a test word contains charters that don't exist in the lexicon, we give each character (0.5, 0.5) as the polarity vector.

4 Experimental Evaluation

We now evaluate the proposed technique SE-AMP-DL to expand an existing Chinese sentiment lexicon, DUTIR (Dalian University of Technology, Information Retrieve Lab) Affective Lexicon Ontology (Xu et al., 2008). DUTIR lexicon is perhaps the largest Chinese sentiment lexicon with 27466 words. Although large, since it was built based on formal text such as news, essays, and novels, it does not contain many sentiment words often used in social media as we will see later. We will also see that many new sentiment words that we discovered are not even in an authoritative Chinese language dictionary. Thus, compiling a comprehensive sentiment lexicon is needed. Below, we first evaluate sentiment words discovery (Step 1) and then polarity classification (Step 2).

4.1 Sentiment Words Discovery

4.1.1 Data and Parameter Settings

We use a large Chinese Weibo corpus (Chinese version of Twitter) from (Wang et al., 2013) for our lexicon expansion, which has about 4.4 million pairs of post and response messages. Although it was originally used to study natural language conversations, it is quite suitable for our purpose as online conversations are sentiment rich.

Word embedding: We first used the Stanford Chinese word segmenter to split sentences into sequences of words (the POS-tag of each word is also obtained in the process). For word embedding, we used word2vec (Mikolov et al., 2013). Each word vector has 200 dimensions.

P **set,** U **set, validation set, and test set**: We randomly sampled 200K messages, and used all 54303 words contained in them as our experiment dataset. Out of the 54303 words (stopwords have been removed), 4957 of them also appear in the DUTIR lexicon and are thus sentiment words. The remaining 49346 words are unlabeled.

Validation set: The validation set consists of randomly selected 300 words from the 4957 sentiment words and 700 words from the 46742 unlabeled words. Although the 700 words are unlabeled, they are treated as N class words.

Test set: 1000 words are randomly sampled from 48646 ($= 49346 - 700$) unlabeled words as the test set, which is labeled manually. Two native speakers labeled the 1000 test words. The Kappa agreement score is 0.695. For any word with disagreement, the annotators discussed to come to a final decision. The annotated test set has 199 sentiment words, 78 positive and 121 negative words.

P set and U set: The remaining 4657 ($= 4957 - 300$ sentiment words serve as the P set and the remaining 45042 ($= 46742 - 700 - 1000$) words serve as the U set for learning.

Parameter settings: As indicated earlier, 10% (γ) of the P class examples are randomly selected as spies S (465). The probability threshold θ is set using the Gaussian fitting (Sec. 3.3). The iteration stopping criterion of SE-AMP (Sec. 3.3) is decided using the validation set ($\delta = 30\%$).

Evaluation measures: We use the classic $precision$, $recall$, and F score for evaluation.

4.1.2 Compared Systems

We compare the following seven (7) techniques:

DP: The Double Propagation (DP) Method in (Qiu et al., 2011). This method uses dependency patterns for extraction.

PMI: The classic PMI method (Turney, 2002) using the full Weibo corpus and 100 positive and 100 negative words in the DUTIR sentiment lexicon as the reference words. These words appear most frequently in the Weibo corpus. In (Turney, 2002), only 1 positive and 1 negative reference words are used. We also tried to use 1, 50, 150, 200, and all words in the positive and negative classes as reference words, respectively. However, they give poorer results. Since the PMI method can only determine the polarity, but cannot decide whether a test word is a sentiment word or not. We make that decision by using the mean score the PMI method of all positive words in the lexicon as the positive threshold and the mean score of all negative words as the negative threshold.

S-SVM: The traditional PU learning method described in Sec. 3.1 using SVM.

S-AMP: Same as S-SVM, but SVM is replaced with AMP.

SE-AMP: The proposed PU learning method without DL.

DL: Only the double dictionary lookup method, using the Contemporary Chinese Dictionary.

SE-AMP-DL: This is our final proposed method, which combines SE-AMP and DL.

We could not compare with recent approaches Tang et al. (2014); Vo and Zhang (2016); Bravo-Marquez et al. (2015) as they all require some supervised information on the data. Our method is unsupervised except the use of the lexicon. These methods were also evaluated indirectly based on the social media post sentiment or emotion classification results. None reported precision, recall, or F score of the discovered sentiment words.

We do not compare with a dictionary-based approach because most of the test words are not even in the dictionary. Only 87 of 199 sentiment words in the test set can be found in the Contemporary Chinese dictionary. Note that in Chinese, one can form a word using characters fairly easily.

4.1.3 Features

For both SVM and AMP, the feature vector for each word is the word vector and POS tags. POS tags are divided into 5 classes (noun, verb, adjective, adverb, others) and form a 5 dimension binary vector (e.g. $[1, 0, 0, 0, 0]$ for noun). In the SVM approach, POS tags are concatenated to the word embedding features to form a 205 dimension feature vector (5 POS tags and 200 word embedding features). We used the RBF kernel, which gives the best result as compared to other kernels.

4.1.4 Experiment Results

We now present and discuss the results. The syntactic pattern based DP approach performed very poorly because social media posts are brief and the use of patterns to link sentiment words are quite infrequent. Thus, we will not include its results. Below, we first compare PMI, S-SVM and S-AMP, and then the results of the proposed PU learning method SE-AMP (without using DL). The results of incorporating DL are discussed last.

Existing Approach - PMI vs. S-SVM vs. S-AMP: S-SVM and S-AMP use the traditional PU learning approach described in Sec. 3.1 for model building. 10% of P class examples are sampled as spies to produce the RN set.

Table 1 shows the results of S-SVM and S-AMP iterations. We observe that the AMP version performs much better than the SVM version. The first three iterations improve the results. But after that, the results deteriorate for both systems.

Thus the table only shows the first few iterations since the results keep deteriorating after iteration 2. The best results are obtained by S-AMP, which is 0.548 in F score. S-SVM's best F score is only 0.509, which is poorer. We also see that the precision and recall of S-AMP are both consistently better than those of S-SVM.

We note that these two algorithms cannot catch the best results when they stop following the algorithm in (Liu, 2011). We did not use the validation set here to find the best stopping criterion because even their best results are poorer than those of SE-AMP. PMI does similarly to S-AMP.

Proposed Approach - SE-AMP: Table 2 shows the results of the proposed PU learning approach (SE-AMP). As noted above, the iteration stopping criterion δ is determined using the validation set. Iteration 0 means the classifier uses all unlabeled examples in U as the N set. Compared with iteration 0 of the traditional strategy (S-AMP), the F score of SE-AMP improves slightly (from 52.0% to 54.8%), but both are low. This is because the reliable N set RN for the traditional approach is too small (not representative of all N class examples) while for the proposed approach, the N set has too many hidden P class instances. The traditional PU learning tries to include more and more likely N examples iteratively to move to the P direction while the proposed approach doing the opposite, eliminating likely P instances from the unlabeled set U. As the table shows, the results of SE-AMP gets better and better after each iteration (it stops when the stopping condition is met). Precision, recall and F score all improve consistently, which result in improvements of 12.0%, 8.5% and 9.6% respectively. Compared with the best result of S-AMP, the precision of SE-AMP improves from 55.4% to 67.4%, recall improves from 51.8% to 59.3% and the F score improves from 53.5% to 63.1%.

We now explain why SE-AMP is better than S-AMP. We believe that the main reason is the high level of noise in P, i.e., many words in P don't have clear sentiments. The traditional PU learning (S-AMP) tries to add classified N class instances into the RN set in each iteration. This works fine for the first few iterations but then goes wrong because the noise in P resulted in a lot of hidden P instances added into the RN set. Then the results deteriorate as more and more wrong instances are added as iterations progress. In contrast, the proposed SE-AMP removes likely P instances (including those noisy ones) from the U set to obtain a purer and purer N set. Due to the very conservative setting of the θ parameter (see Sec. 3.3), the number of words removed from U in each iteration is small, so is the number of spy words removed from S as we can see in Table 2. Thus, U becomes purer and purer slowly, and the validation set helps find a good stopping iteration.

	Iteration	Precision	Recall	F-score
S-SVM	0	46.1	41.7	43.8
	1	49.7	45.7	47.6
	2	52.7	49.2	50.9
	3	48.9	46.2	47.5
S-AMP	0	52.8	51.3	52.0
	1	54.4	52.8	53.6
	2	56.4	53.3	54.8
	3	54.2	52.3	53.2
PMI		56.7	50.8	53.6

Table 1: Results of PMI and the traditional PU learning approach: S-SVM and S-AMP.

Iteration	Precision	Recall	F-score	Spy Words
0	55.4	51.8	53.5	456
1	57.1	52.8	54.8	372
2	59.8	53.8	56.6	268
...	...	...	...	...
6	67.4	59.3	63.1	143

Table 2: Results of the proposed SE-AMP.

Incorporating Double Dictionary Lookup (DL) - SE-AMP-DL: The double dictionary lookup (DL) method improves the results further. DL uses the most authoritative Chinese dictionary: The Contemporary Chinese Dictionary. However, only 379 out of the 1000 test words are in the dictionary, among which 87 are sentiment words. As Table 3 shows, the DL method alone has a high precision but low recall as a lot of sentiment words are not in the dictionary. After correction of the results from SE-AMP by DL, the F score improves from 63.1 of SE-AMP to 65.6 of SE-AMP-DL.

Note: We also tried to clean up the lexicon first using DL to reduce the noise in the P set

	Precision	Recall	F-score
DL	74.1	20.1	31.6
SE-AMP	67.4	59.3	63.1
SE-AMP-DL	69.3	62.3	65.6

Table 3: Results with double dictionary lookup.

			Prec.	Rec.	F-score
PMI	199 set	pos.	60.7	65.4	63.0
		neg.	76.5	72.7	74.6
	identified set	pos.	43.8	35.9	39.2
		neg.	45.1	42.1	43.6
CPA	199 set	pos.	83.8	79.5	81.6
		neg.	87.2	90.1	88.6
	identified set	pos.	60.9	50.0	54.9
		neg.	65.2	60.3	62.6

Table 4: PMI and CPA classification results.

before performing the proposed algorithms. But after cleaning, only 1968 sentiment words out of 4957 remained. We inspected the result and found that the cleaning removed a lot of true sentiment words, making the P set too small for our algorithms and thus produced much poorer results.

4.2 Polarity Classification

Here we use the well-known PMI method in (Turney, 2002) as the baseline, which was designed for polarity classification. Again, for PMI computation, we use 100 positive and 100 negative words in our lexicon that appear most frequently in the Weibo corpus as the reference words, and compute the PMI scores between the candidate words and the references. Using many other numbers of sentiment words in the lexicon as the reference words give poorer results (see also Sec. 4.1.2). A word is considered as a positive sentiment word if its score is positive, or negative if the score is negative.

We apply the proposed CPA method and PMI to all 199 true sentiment words in the test set (199 set), and the sentiment words identified by SE-AMP-DL (identified set), which has many errors, i.e., non-sentiment words, Experimental results in Table 4 show that CPA outperforms PMI greatly in both cases. Those non-sentiment words are considered wrong in the "identified set" case.

5 Conclusion

This paper made a new attempt to study sentiment lexicon expansion based on a social media corpus. It first showed that the problem can be formulated as PU learning. It then proposed an *augmented multilayer perceptron* method to give PU learning an neural network solution. It then proposed a new PU learning method, which outperforms a classic existing PU learning method. To improve the results further, it proposed a double dictionary lookup technique. Additionally, a novel polarity classification method was also designed. Experimental results demonstrated the effectiveness of these proposed methods.

Abstract

We study the problem of learning to reason in large scale knowledge graphs (KGs). More specifically, we describe a novel reinforcement learning framework for learning multi-hop relational paths: we use a policy-based agent with continuous states based on knowledge graph embeddings, which reasons in a KG vector space by sampling the most promising relation to extend its path. In contrast to prior work, our approach includes a reward function that takes the **accuracy**, **diversity**, and **efficiency** into consideration. Experimentally, we show that our proposed method outperforms a path-ranking based algorithm and knowledge graph embedding methods on Freebase and Never-Ending Language Learning datasets.[1]

1 Introduction

In recent years, deep learning techniques have obtained many state-of-the-art results in various classification and recognition problems (Krizhevsky et al., 2012; Hinton et al., 2012; Kim, 2014). However, complex natural language processing problems often require multiple inter-related decisions, and empowering deep learning models with the ability of learning to reason is still a challenging issue. To handle complex queries where there are no obvious answers, intelligent machines must be able to reason with existing resources, and learn to infer an unknown answer.

More specifically, we situate our study in the context of multi-hop reasoning, which is the task of learning explicit inference formulas, given a large KG. For example, if the KG includes the beliefs such as *Neymar* plays for *Barcelona*, and *Barcelona* are in the *La Liga* league, then machines should be able to learn the following formula: *playerPlaysForTeam(P,T)* $\wedge$ *teamPlaysInLeague(T,L)* $\Rightarrow$ *playerPlaysInLeague(P,L)*. In the testing time, by plugging in the learned formulas, the system should be able to automatically infer the missing link between a pair of entities. This kind of reasoning machine will potentially serve as an essential components of complex QA systems.

In recent years, the Path-Ranking Algorithm (PRA) (Lao et al., 2010, 2011a) emerges as a promising method for learning inference paths in large KGs. PRA uses a random-walk with restarts based inference mechanism to perform multiple bounded depth-first search processes to find relational paths. Coupled with elastic-net based learning, PRA then picks more plausible paths using supervised learning. However, PRA operates in a fully discrete space, which makes it difficult to evaluate and compare similar entities and relations in a KG.

In this work, we propose a novel approach for controllable multi-hop reasoning: we frame the path learning process as reinforcement learning (RL). In contrast to PRA, we use translation-based knowledge based embedding method (Bordes et al., 2013) to encode the continuous state of our RL agent, which reasons in the vector space environment of the knowledge graph. The agent takes incremental steps by sampling a relation to extend its path. To better guide the RL agent for learning relational paths, we use policy gradient training (Mnih et al., 2015) with a novel reward function that jointly encourages accuracy, diversity, and efficiency. Empirically, we show that our method outperforms PRA and embedding based methods on a Freebase and a Never-Ending Language Learning (Carlson et al., 2010a) dataset.

[1] Code and the NELL dataset are available at https://github.com/xwhan/DeepPath.

Proceedings of the 2017 Conference on Empirical Methods in Natural Language Processing, pages 564–573
Copenhagen, Denmark, September 7–11, 2017. ©2017 Association for Computational Linguistics

Our contributions are three-fold:

- We are the first to consider reinforcement learning (RL) methods for learning relational paths in knowledge graphs;
- Our learning method uses a complex reward function that considers accuracy, efficiency, and path diversity simultaneously, offering better control and more flexibility in the path-finding process;
- We show that our method can scale up to large scale knowledge graphs, outperforming PRA and KG embedding methods in two tasks.

In the next section, we outline related work in path-finding and embedding methods in KGs. We describe the proposed method in Section 3. We show experimental results in Section 4. Finally, we conclude in Section 5.

2 Related Work

The Path-Ranking Algorithm (PRA) method (Lao et al., 2011b) is a primary path-finding approach that uses random walk with restart strategies for multi-hop reasoning. Gardner et al. (2013; 2014) propose a modification to PRA that computes feature similarity in the vector space. Wang and Cohen (2015) introduce a recursive random walk approach for integrating the background KG and text—the method performs structure learning of logic programs and information extraction from text at the same time. A potential bottleneck for random walk inference is that supernodes connecting to large amount of formulas will create huge fan-out areas that significantly slow down the inference and affect the accuracy.

Toutanova et al. (2015) provide a convolutional neural network solution to multi-hop reasoning. They build a CNN model based on lexicalized dependency paths, which suffers from the error propagation issue due to parse errors. Guu et al. (2015) uses KG embeddings to answer path queries. Zeng et al. (2014) described a CNN model for relational extraction, but it does not explicitly model the relational paths. Neelakantan et al. (2015) propose a recurrent neural networks model for modeling relational paths in knowledge base completion (KBC), but it trains too many separate models, and therefore it does not scale. Note that many of the recent KG reasoning methods (Neelakantan et al., 2015; Das et al., 2017) still rely on first learning the PRA paths, which only operates in a discrete space. Comparing to PRA, our method reasons in a continuous space, and by incorporating various criteria in the reward function, our reinforcement learning (RL) framework has better control and more flexibility over the path-finding process.

Neural symbolic machine (Liang et al., 2016) is a more recent work on KG reasoning, which also applies reinforcement learning but has a different flavor from our work. NSM learns to compose programs that can find answers to natural language questions, while our RL model tries to add new facts to knowledge graph (KG) by reasoning on existing KG triples. In order to get answers, NSM learns to generate a sequence of actions that can be combined as a executable program. The action space in NSM is a set of predefined tokens. In our framework, the goal is to find reasoning paths, thus the action space is relation space in the KG. A similar framework (Johnson et al., 2017) has also been applied to visual reasoning tasks.

3 Methodology

In this section, we describe in detail our RL-based framework for multi-hop relation reasoning. The specific task of relation reasoning is to find reliable predictive paths between entity pairs. We formulate the path finding problem as a sequential decision making problem which can be solved with a RL agent. We first describe the environment and the policy-based RL agent. By interacting with the environment designed around the KG, the agent learns to pick the promising reasoning paths. Then we describe the training procedure of our RL model. After that, we describe an efficient path-constrained search algorithm for relation reasoning with the paths found by the RL agent.

3.1 Reinforcement Learning for Relation Reasoning

The RL system consists of two parts (see Figure 1). The first part is the external environment $\mathcal{E}$ which specifies the dynamics of the interaction between the agent and the KG. This environment is modeled as a Markov decision process (MDP). A tuple $< \mathcal{S}, \mathcal{A}, \mathcal{P}, \mathcal{R} >$ is defined to represent the MDP, where $\mathcal{S}$ is the continuous state space, $\mathcal{A} = \{a_1, a_2, ..., a_n\}$ is the set of all available actions, $\mathcal{P}(S_{t+1} = s^{'}|S_t = s, A_t = a)$ is the transition probability matrix, and $\mathcal{R}(s, a)$ is the reward

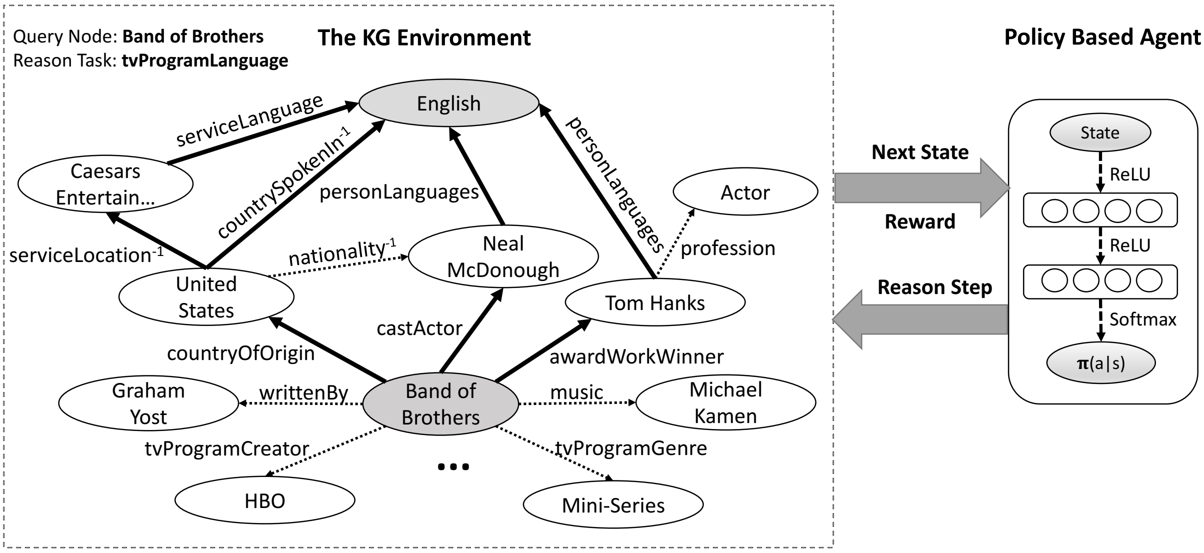

Figure 1: Overview of our RL model. **Left:** The KG environment $\mathcal{E}$ modeled by a MDP. The dotted arrows (partially) show the existing relation links in the KG and the bold arrows show the reasoning paths found by the RL agent. $^{-1}$ denotes the inverse of an relation. **Right:** The structure of the policy network agent. At each step, by interacting with the environment, the agent learns to pick a relation link to extend the reasoning paths.

function of every (s, a) pairs.

The second part of the system, the RL agent, is represented as a policy network $\pi_\theta(s, a) = p(a|s; \theta)$ which maps the state vector to a stochastic policy. The neural network parameters θ are updated using stochastic gradient descent. Compared to Deep Q Network (DQN) (Mnih et al., 2013), policy-based RL methods turn out to be more appropriate for our knowledge graph scenario. One reason is that for the path finding problem in KG, the action space can be very large due to complexity of the relation graph. This can lead to poor convergence properties for DQN. Besides, instead of learning a greedy policy which is common in value-based methods like DQN, the policy network is able to learn a stochastic policy which prevent the agent from getting stuck at an intermediate state. Before we describe the structure of our policy network, we first describe the components (actions, states, rewards) of the RL environment.

Actions Given the entity pairs (e_s, e_t) with relation r, we want the agent to find the most informative paths linking these entity pairs. Beginning with the source entity e_s, the agent use the policy network to pick the most promising relation to extend its path at each step until it reaches the target entity e_t. To keep the output dimension of the policy network consistent, the action space is defined as all the relations in the KG.

States The entities and relations in a KG are naturally discrete atomic symbols. Since existing practical KGs like Freebase (Bollacker et al., 2008) and NELL (Carlson et al., 2010b) often have huge amounts of triples. It is impossible to directly model all the symbolic atoms in states. To capture the semantic information of these symbols, we use translation-based embeddings such as TransE (Bordes et al., 2013) and TransH (Wang et al., 2014) to represent the entities and relations. These embeddings map all the symbols to a low-dimensional vector space. In our framework, each state captures the agent's position in the KG. After taking an action, the agent will move from one entity to another. These two are linked by the action (relation) just taken by the agent. The state vector at step t is given as follows:

$$\mathbf{s}_t = (\mathbf{e}_t, \mathbf{e}_{target} - \mathbf{e}_t)$$

where $\mathbf{e}_t$ denotes the embeddings of the current entity node and $\mathbf{e}_{target}$ denotes the embeddings of the target entity. At the initial state, $\mathbf{e}_t = \mathbf{e}_{source}$. We do not incorporate the reasoning relation in the state, because the embedding of the reasoning relation remain constant during path finding, which is not helpful in training. However, we find out that by training the RL agent using a set of positive samples for one particular relation, the agent can successfully discover the relation semantics.

Rewards There are a few factors that contribute to the quality of the paths found by the RL agent. To encourage the agent to find predictive paths, our reward functions include the following scoring criteria:

Global accuracy: For our environment settings, the number of actions that can be taken by the agent can be very large. In other words, there are much more incorrect sequential decisions than the correct ones. The number of these incorrect decision sequences can increase exponentially with the length of the path. In view of this challenge, the first reward function we add to the RL model is defined as follows:

$$r_{\text{GLOBAL}} = \begin{cases} +1, & \text{if the path reaches } e_{target} \\ -1, & \text{otherwise} \end{cases}$$

the agent is given an offline positive reward $+1$ if it reaches the target after a sequence of actions.

Path efficiency: For the relation reasoning task, we observe that short paths tend to provide more reliable reasoning evidence than longer paths. Shorter chains of relations can also improve the efficiency of the reasoning by limiting the length of the RL's interactions with the environment. The efficiency reward is defined as follows:

$$r_{\text{EFFICIENCY}} = \frac{1}{length(p)}$$

where path p is defined as a sequence of relations $r_1 \rightarrow r_2 \rightarrow ... \rightarrow r_n$.

Path diversity: We train the agent to find paths using positive samples for each relation. These training sample (e_{source}, e_{target}) have similar state representations in the vector space. The agent tends to find paths with similar syntax and semantics. These paths often contains redundant information since some of them may be correlated. To encourage the agent to find diverse paths, we define a diversity reward function using the cosine similarity between the current path and the existing ones:

$$r_{\text{DIVERSITY}} = -\frac{1}{|F|}\sum_{i=1}^{|F|} cos(\mathbf{p}, \mathbf{p}_i)$$

where $\mathbf{p} = \sum_{i=1}^{n} \mathbf{r}_i$ represents the path embedding for the relation chain $r_1 \rightarrow r_2 \rightarrow ... \rightarrow r_n$.

Policy Network We use a fully-connected neural network to parameterize the policy function $\pi(s;\theta)$ that maps the state vector $\mathbf{s}$ to a probability distribution over all possible actions. The neural network consists of two hidden layers, each followed by a rectifier nonlinearity layer (ReLU). The output layer is normalized using a softmax function (see Figure 1).

3.2 Training Pipeline

In practice, one big challenge of KG reasoning is that the relation set can be quite large. For a typical KG, the RL agent is often faced with hundreds (thousands) of possible actions. In other words, the output layer of the policy network often has a large dimension. Due to the complexity of the relation graph and the large action space, if we directly train the RL model by trial and errors, which is typical for RL algorithms, the RL model will show very poor convergence properties. After a long-time training, the agents fails to find any valuable path. To tackle this problem, we start our training with a supervised policy which is inspired by the imitation learning pipeline used by *AlphaGo* (Silver et al., 2016). In the Go game, the player is facing nearly 250 possible legal moves at each step. Directly training the agent to pick actions from the original action space can be a difficult task. *AlphaGo* first train a supervised policy network using experts moves. In our case, the supervised policy is trained with a randomized breadth-first search (BFS).

Supervised Policy Learning For each relation, we use a subset of all the positive samples (entity pairs) to learn the supervised policy. For each positive sample (e_{source}, e_{target}), a two-side BFS is conducted to find same correct paths between the entities. For each path p with a sequence of relations $r_1 \rightarrow r_2 \rightarrow ... \rightarrow r_n$, we update the parameters θ to maximize the expected cumulative reward using Monte-Carlo Policy Gradient (RE-

INFORCE) (Williams, 1992):

$$\begin{aligned} J(\theta) &= \mathbb{E}_{a\sim\pi(a|s;\theta)}(\sum_t R_{s_t,a_t}) \\ &= \sum_t \sum_{a\in\mathcal{A}} \pi(a|s_t;\theta) R_{s_t,a_t} \end{aligned} \qquad (1)$$

where $J(\theta)$ is the expected total rewards for one episode. For supervised learning, we give a reward of $+1$ for each step of a successful episode. By plugging in the paths found by the BFS, the approximated gradient used to update the policy network is shown below:

$$\begin{aligned} \nabla_\theta J(\theta) &= \sum_t \sum_{a\in\mathcal{A}} \pi(a|s_t;\theta) \nabla_\theta \log \pi(a|s_t;\theta) \\ &\approx \nabla_\theta \sum_t \log \pi(a = r_t|s_t;\theta) \end{aligned} \qquad (2)$$

where r_t belongs to the path p.

However, the vanilla BFS is a biased search algorithm which prefers short paths. When plugging in these biased paths, it becomes difficult for the agent to find longer paths which may potentially be useful. We want the paths to be controlled only by the defined reward functions. To prevent the biased search, we adopt a simple trick to add some random mechanisms to the BFS. Instead of directly searching the path between e_{source} and e_{target}, we randomly pick a intermediate node e_{inter} and then conduct two BFS between (e_{source}, e_{inter}) and (e_{inter}, e_{target}). The concatenated paths are used to train the agent. The supervised learning saves the agent great efforts learning from failed actions. With the learned experience, we then train the agent to find desirable paths.

Retraining with Rewards To find the reasoning paths controlled by the reward functions, we use reward functions to retrain the supervised policy network. For each relation, the reasoning with one entity pair is treated as one episode. Starting with the source node e_{source}, the agent picks a relation according to the stochastic policy $\pi(a|s)$, which is a probability distribution over all relations, to extend its reasoning path. This relation link may lead to a new entity, or it may lead to nothing. These failed steps will cause the agent to receive negative rewards. The agent will stay at the same state after these failed steps. Since the agent is following a stochastic policy, the agent will not get stuck by repeating a wrong step. To improve the training efficiency, we limit the episode length with an upper bound max_length. The episode ends if the agent fails to reach the target entity within max_length steps. After each episode, the policy network is updated using the following gradient:

Algorithm 1: Retraining Procedure with reward functions

```
Restore parameters $\theta$ from supervised policy;
for episode ← 1 to N do
    Initialize state vector $s_t \leftarrow s_0$
    Initialize episode length $steps \leftarrow 0$
    while $num\_steps < max\_length$ do
        Randomly sample action $a \sim \pi(a|s_t)$
        Observe reward $\mathcal{R}_t$, next state $s_{t+1}$
        // if the step fails
        if $\mathcal{R}_t = -1$ then
            Save $< s_t, a >$ to $\mathcal{M}_{neg}$
        if success or $steps = max\_length$
          then
            break
        Increment $num\_steps$
    // penalize failed steps
    Update $\theta$ using
      $g \propto \nabla_\theta \sum_{\mathcal{M}_{neg}} \log \pi(a = r_t|s_t;\theta)(-1)$
    if success then
        $R_{total} \leftarrow \lambda_1 r_{\text{GLOBAL}} + \lambda_2 r_{\text{EFFICIENCY}} + \lambda_3 r_{\text{DIVERSITY}}$
        Update $\theta$ using
          $g \propto \nabla_\theta \sum_t \log \pi(a = r_t|s_t;\theta) R_{total}$
```

$$\nabla_\theta J(\theta) = \nabla_\theta \sum_t \log \pi(a = r_t|s_t;\theta) R_{total} \qquad (3)$$

where R_{total} is the linear combination of the defined reward functions. The detail of the retrain process is shown in Algorithm 1. In practice, θ is updated using the Adam Optimizer (Kingma and Ba, 2014) with L_2 regularization.

3.3 Bi-directional Path-constrained Search

Given an entity pair, the reasoning paths learned by the RL agent can be used as logical formulas to predict the relation link. Each formula is verified using a bi-directional search. In a typical KG, one entity node can be linked to a large number of neighbors with the same relation link. A simple example is the relation *personNationality*$^{-1}$, which denotes the inverse of *personNationality*. Following this link, the entity *United States* can reach numerous neighboring entities. If the for-

Algorithm 2: Bi-directional search for path verification

```
Given a reasoning path
  $p : r_1 \rightarrow r_2 \rightarrow ... \rightarrow r_n$
for $(e_i, e_j)$ in test set $\mathcal{D}$ do
    start ← 0; end ← n
    $left \leftarrow \emptyset; right \leftarrow \emptyset$
    while start < end do
        $leftEx \leftarrow \emptyset; rightEx \leftarrow \emptyset$
        if len(left) < len(right) then
            Extend path on the left side
            Add connected nodes to $leftEx$
            $left \leftarrow leftEx$
        else
            Extend path on the right side
            Add connected nodes to $rightEx$
            $right \leftarrow rightEx$
    if $left \cap right \neq \emptyset$ then
        return True
    else
        return False
```

mula consists of such links, the number of intermediate entities can exponentially increase as we follow the reasoning formula. However, we observe that for these formulas, if we verify the formula from the inverse direction. The number of intermediate nodes can be tremendously decreased. Algorithm 2 shows a detailed description of the proposed bi-directional search.

4 Experiments

To evaluate the reasoning formulas found by our RL agent, we explore two standard KG reasoning tasks: link prediction (predicting target entities) and fact prediction (predicting whether an unknown fact holds or not). We compare our method with both path-based methods and embedding based methods. After that, we further analyze the reasoning paths found by our RL agent. These highly predictive paths validate the effectiveness of the reward functions. Finally, we conduct a experiment to investigate the effect of the supervised learning procedure.

4.1 Dataset and Settings

Table 1 shows the statistics of the two datasets we conduct our experiments on. Both of them are subsets of larger datasets. The triples in FB15K-237 (Toutanova et al., 2015) are sampled from FB15K (Bordes et al., 2013) with redundant relations removed. We perform the reasoning tasks on 20 relations which have enough reasoning paths. These tasks consists of relations from different domains like *Sports*, *People*, *Locations*, *Film*, etc. Besides, we present a new NELL subset that is suitable for multi-hop reasoning from the 995th iteration of the NELL system. We first remove the triples with relation *generalizations* or *haswikipediaurl*. These two relations appear more than 2M times in the NELL dataset, but they have no reasoning values. After this step, we only select the triples with Top-200 relations. To facilitate path finding, we also add the inverse triples. For each triple (h, r, t), we append (t, r^{-1}, h) to the datasets. With these inverse triples, the agent is able to step backward in the KG.

Dataset	# Ent.	# R.	# Triples	# Tasks
FB15K-237	14,505	237	310,116	20
NELL-995	75,492	200	154.213	12

Table 1: Statistics of the Datasets. # Ent. denotes the number of unique entities and # R. denotes the number of relations

For each reasoning task r_i, we remove all the triples with r_i or r_i^{-1} from the KG. These removed triples are split into train and test samples. For the link prediction task, each h in the test triples $\{(h, r, t)\}$ is considered as one query. A set of candidate target entities are ranked using different methods. For fact prediction, the true test triples are ranked with some generated false triples.

4.2 Baselines and Implementation Details

Most KG reasoning methods are based on either path formulas or KG embeddings. we explore methods from both of these two classes in our experiments. For path based methods, we compare our RL model with the PRA (Lao et al., 2011a) algorithm, which has been used in a couple of reasoning methods (Gardner et al., 2013; Neelakantan et al., 2015). PRA is a data-driven algorithm using random walks (RW) to find paths and obtain path features. For embedding based methods, we evaluate several state-of-the-art embeddings designed for knowledge base completion, such as TransE (Bordes et al., 2013), TransH (Wang et al., 2014), TransR (Lin et al., 2015) and TransD (Ji et al., 2015) .

The implementation of PRA is based on the

code released by (Lao et al., 2011a). We use the TopK negative mode to generate negative samples for both train and test samples. For each positive samples, there are approximately 10 corresponding negative samples. Each negative sample is generated by replacing the true target entity t with a faked one $t^{'}$ in each triple (h, r, t). These positive and negative test pairs generated by PRA make up the test set for all methods evaluated in this paper. For TransE,R,H,D, we learn a separate embedding matrix for each reasoning task using the positive training entity pairs. All these embeddings are trained for 1,000 epochs. [2]

Our RL model make use of TransE to get the continuous representation of the entities and relations. We use the same dimension as TransE, R to embed the entities. Specifically, the state vector we use has a dimension of 200, which is also the input size of the policy network. To reason using the path formulas, we adopt a similar linear regression approach as in PRA to re-rank the paths. However, instead of using the random walk probabilities as path features, which can be computationally expensive, we simply use binary path features obtained by the bi-directional search. We observe that with only a few mined path formulas, our method can achieve better results than PRA's data-driven approach.

4.3 Results

4.3.1 Quantitative Results

Link Prediction This task is to rank the target entities given a query entity. Table 2 shows the mean average precision (MAP) results on two datasets. Since path-based methods generally work better than embedding methods for this task, we do not include the other two embedding baselines in this table. Instead, we spare the room to show the detailed results on each relation reasoning task.

For the overall MAP shown in the last row of the table, our approach significantly outperforms both the path-based method and embedding methods on two datasets, which validates the strong reasoning ability of our RL model. For most relations, since the embedding methods fail to use the path infor-

[2] The implementation we used can be found at https://github.com/thunlp/Fast-TransX

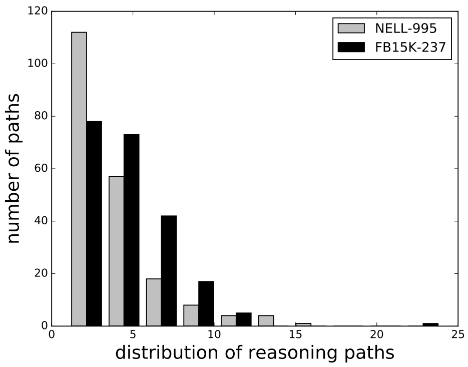

Figure 2: The distribution of paths lengths on two datasets

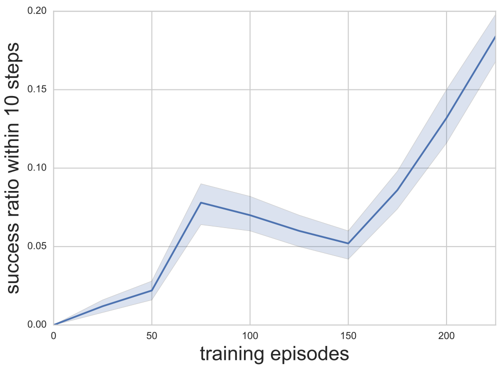

Figure 3: The success ratio ($succ_{10}$) during training. Task: athletePlaysForTeam.[3]

mation in the KG, they generally perform worse than our RL model or PRA. However, when there are not enough paths between entities, our model and PRA can give poor results. For example, for the relation *filmWrittenBy*, our RL model only finds 4 unique reasoning paths, which means there is actually not enough reasoning evidence existing in the KG. Another observation is that we always get better performance on the NELL dataset. By analyzing the paths found from the KGs, we believe the potential reason is that the NELL dataset has more short paths than FB15K-237 and some of them are simply synonyms of the reasoning relations.

Fact Prediction Instead of ranking the target entities, this task directly ranks all the positive and negative samples for a particular relation. The PRA is not included as a baseline here, since the PRA code only gives a target entity ranking for each query node instead of a ranking of all triples. Table 3 shows the overall results of all the methods. Our RL model gets even better results on this task. We also observe that the RL model beats all the embedding baselines on most reasoning tasks.

4.3.2 Qualitative Analysis of Reasoning Paths

To analyze the properties of reasoning paths, we show a few reasoning paths found by the agent in Table 5. To illustrate the effect of the efficiency reward function, we show the path length distributions in Figure 2. To interpret these paths, take the *personNationality* relation for example, the first reasoning path indicates that if we know facts *placeOfBirth(x,y)* and *locationContains(z,y)* then it is highly possible that person x has nationality z. These short but predictive paths indicate the effectiveness of the RL model. Another important observation is that our model use much fewer reasoning paths than PRA, which indicates that our model can actually extract the most reliable reasoning evidence from KG. Table 4 shows some comparisons about the number of reasoning paths. We can see that, with the pre-defined reward functions, the RL agent is capable of picking the strong ones and filter out similar or irrelevant ones.

4.3.3 Effect of Supervised Learning

As mentioned in Section 3.2, one major challenge for applying RL to KG reasoning is the large action space. We address this issue by applying supervised learning before the reward retraining step. To show the effect of the supervised training, we evaluate the agent's success ratio of reaching the target within 10 steps ($succ_{10}$) after different number of training episodes. For each training episode, one pair of entities (e_{source}, e_{target}) in the train set is used to find paths. All the correct paths linking the entities will get a $+1$ global reward. We then plug in some true paths for training. The $succ_{10}$ is calculated on a held-out test set that consists of 100 entity pairs. For the NELL-995 dataset, since we have 200 unique relations, the dimension of the action space will be 400 after we add the backward actions. This means that random walks will get very low $succ_{10}$ since there may be nearly 400^{10} invalid paths. Figure 3 shows the $succ_{10}$ during training. We see that even the agent has not seen the entity before, it can actually pick the promising relation to extend its path. This also validates the effectiveness of our state representations.

5 Conclusion and Future Work

In this paper, we propose a reinforcement learning framework to improve the performance of relation reasoning in KGs. Specifically, we train a RL agent to find reasoning paths in the knowledge base. Unlike previous path finding models that are based on random walks, the RL model allows us to control the properties of the found paths. These effective paths can also be used as an alternative to PRA in many path-based reasoning methods. For two standard reasoning tasks, using the RL paths as reasoning formulas, our approach generally outperforms two classes of baselines.

For future studies, we plan to investigate the possibility of incorporating adversarial learning (Goodfellow et al., 2014) to give better rewards than the human-defined reward functions used in this work. Instead of designing rewards according to path characteristics, a discriminative model can be trained to give rewards. Also, to address the problematic scenario when the KG does not have enough reasoning paths, we are interested in applying our RL framework to joint reasoning with KG triples and text mentions.

Abstract

Search engines play an important role in our everyday lives by assisting us in finding the information we need. When we input a complex query, however, results are often far from satisfactory. In this work, we introduce a query reformulation system based on a neural network that rewrites a query to maximize the number of relevant documents returned. We train this neural network with reinforcement learning. The actions correspond to selecting terms to build a reformulated query, and the reward is the document recall. We evaluate our approach on three datasets against strong baselines and show a relative improvement of 5-20% in terms of recall. Furthermore, we present a simple method to estimate a conservative upper-bound performance of a model in a particular environment and verify that there is still large room for improvements.

Figure 1: A graphical illustration of the proposed framework for query reformulation. A set of documents D_0 is retrieved from a search engine using the initial query q_0. Our reformulator selects terms from q_0 and D_0 to produce a reformulated query q' which is then sent to the search engine. Documents D' are returned, and a reward is computed against the set of ground-truth documents. The reformulator is trained with reinforcement learning to produce a query, or a series of queries, to maximize the expected return.

1 Introduction

Search engines help us find what we need among the vast array of available data. When we request some information using a long or inexact description of it, these systems, however, often fail to deliver relevant items. In this case, what typically follows is an iterative process in which we try to express our need differently in the hope that the system will return what we want. This is a major issue in information retrieval. For instance, Huang and Efthimiadis (2009) estimate that 28-52% of all the web queries are modifications of previous ones.

To a certain extent, this problem occurs because search engines rely on matching words in the query with words in relevant documents, to perform retrieval. If there is a mismatch between them, a relevant document may be missed.

One way to address this problem is to automatically rewrite a query so that it becomes more likely to retrieve relevant documents. This technique is known as *automatic query reformulation*. It typically expands the original query by adding terms from, for instance, dictionaries of synonyms such as WordNet (Miller, 1995), or from the initial set of retrieved documents (Xu and Croft, 1996). This latter type of reformulation is known as pseudo (or blind) relevance feedback (PRF), in which the relevance of each term of the retrieved documents is automatically inferred.

The proposed method is built on top of PRF but differs from previous works as we frame the query

Proceedings of the 2017 Conference on Empirical Methods in Natural Language Processing, pages 574–583
Copenhagen, Denmark, September 7–11, 2017. ©2017 Association for Computational Linguistics

reformulation problem as a reinforcement learning (RL) problem. An initial query is the natural language expression of the desired goal, and an agent (i.e. reformulator) *learns* to reformulate an initial query to maximize the expected return (i.e. retrieval performance) through actions (i.e. selecting terms for a new query). The environment is a search engine which produces a new state (i.e. retrieved documents). Our framework is illustrated in Fig. 1.

The most important implication of this framework is that a search engine is treated as a *black box* that an agent learns to use in order to retrieve more relevant items. This opens the possibility of training an agent to use a search engine for a task other than the one it was originally intended for. To support this claim, we evaluate our agent on the task of question answering (Q&A), citation recommendation, and passage/snippet retrieval.

As for training data, we use two publicly available datasets (TREC-CAR and Jeopardy) and introduce a new one (MS Academic) with hundreds of thousands of *query/relevant document* pairs from the academic domain.

Furthermore, we present a method to estimate the upper bound performance of our RL-based model. Based on the estimated upper bound, we claim that this framework has a strong potential for future improvements.

Here we summarize our main contributions:

- A reinforcement learning framework for automatic query reformulation.
- A simple method to estimate the upper-bound performance of an RL-based model in a given environment.
- A new large dataset with hundreds of thousands of *query/relevant document* pairs.[1]

2 A Reinforcement Learning Approach

2.1 Model Description

In this section we describe the proposed method, illustrated in Fig. 2.

The inputs are a query q_0 consisting of a sequence of words $(w_1, ..., w_n)$ and a candidate term t_i with some context words $(t_{i-k}, ..., t_{i+k})$, where $k \geq 0$ is the context window size. Candidate terms are from $q_0 \cup D_0$, the union of the terms in the original query and those from the documents D_0 retrieved using q_0.

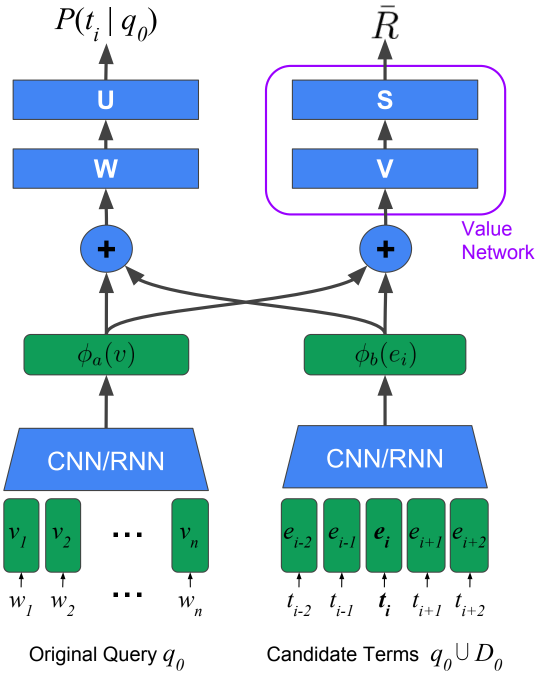

Figure 2: An illustration of our neural network-based reformulator.

We use a dictionary of pretrained word embeddings (Mikolov et al., 2013) to convert the symbolic terms w_j and t_i to their vector representations v_j and $e_i \in \mathbb{R}^d$, respectively. We map out-of-vocabulary terms to an additional vector that is learned during training.

We convert the sequence $\{v_j\}$ to a fixed-size vector $\phi_a(v)$ by using either a Convolutional Neural Network (CNN) followed by a max pooling operation over the entire sequence (Kim, 2014) or by using the last hidden state of a Recurrent Neural Network (RNN).[2]

Similarly, we fed the candidate term vectors e_i to a CNN or RNN to obtain a vector representation $\phi_b(e_i)$ for each term t_i. The convolutional/recurrent layers serve an important role of capturing context information, especially for out-of-vocabulary and rare terms. CNNs can process candidate terms in parallel, and, therefore, are faster for our application than RNNs. RNNs, on the other hand, can encode longer contexts.

Finally, we compute the probability of selecting

[1] The dataset and code to run the experiments are available at `https://github.com/nyu-dl/QueryReformulator`.

[2] To deal with variable-length inputs in a mini-batch, we pad smaller ones with zeros on both ends so they end up as long as the largest sample in the mini-batch.

t_i as:

$$P(t_i|q_0) = \sigma(U^\mathsf{T} \tanh(W(\phi_a(v) \| \phi_b(e_i)) + b)), \tag{1}$$

where σ is the sigmoid function, $\|$ is the vector concatenation operation, $W \in \mathbb{R}^{d \times 2d}$ and $U \in \mathbb{R}^d$ are weights, and $b \in \mathbb{R}$ is a bias.

At test time, we define the set of terms used in the reformulated query as $T = \{t_i \mid P(t_i|q_0) > \epsilon\}$, where ϵ is a hyper-parameter. At training time, we sample the terms according to their probability distribution, $T = \{t_i \mid \alpha = 1 \wedge \alpha \sim P(t_i|q_0)\}$. We concatenate the terms in T to form a reformulated query q', which will then be used to retrieve a new set of documents D'.

2.2 Sequence Generation

One problem with the method previously described is that terms are selected independently. This may result in a reformulated query that contains duplicated terms since the same term can appear multiple times in the feedback documents. Another problem is that the reformulated query can be very long, resulting in a slow retrieval.

To solve these problems, we extend the model to sequentially generate a reformulated query, as proposed by Buck et al. (2017). We use a Recurrent Neural Network (RNN) that selects one term at a time from the pool of candidate terms and stops when a special token is selected. The advantage of this approach is that the model can remember the terms previously selected through its hidden state. It can, therefore, produce more concise queries.

We define the probability of selecting t_i as the k-th term of a reformulated query as:

$$P(t_i^k|q_0) \propto \exp(\phi_b(e_i)^\mathsf{T} h_k), \tag{2}$$

where h_k is the hidden state vector at the k-th step, computed as:

$$h_k = \tanh(W_a \phi_a(v) + W_b \phi_b(t^{k-1}) + W_h h_{k-1}), \tag{3}$$

where t^{k-1} is the term selected in the previous step and $W_a \in \mathbb{R}^{d \times d}$, $W_b \in \mathbb{R}^{d \times d}$, and $W_h \in \mathbb{R}^{d \times d}$ are weight matrices. In practice, we use an LSTM (Hochreiter and Schmidhuber, 1997) to encode the hidden state as this variant is known to perform better than a vanilla RNN.

We avoid normalizing over a large vocabulary by using only terms from the retrieved documents. This makes inference faster and training practical since learning to select words from the whole vocabulary might be too slow with reinforcement learning, although we leave this experiment for a future work.

2.3 Training

We train the proposed model using REINFORCE (Williams, 1992) algorithm. The per-example stochastic objective is defined as

$$C_a = (R - \bar{R}) \sum_{t \in T} - \log P(t|q_0), \tag{4}$$

where R is the reward and $\bar{R}$ is the baseline, computed by the value network as:

$$\bar{R} = \sigma(S^\mathsf{T} \tanh(V(\phi_a(v) \| \bar{e}) + b)), \tag{5}$$

where $\bar{e} = \frac{1}{N} \sum_{i=1}^{N} \phi_b(e_i)$, $N = |q_0 \cup D_0|$, $V \in \mathbb{R}^{d \times 2d}$ and $S \in \mathbb{R}^d$ are weights and $b \in \mathbb{R}$ is a bias. We train the value network to minimize

$$C_b = \alpha ||R - \bar{R}||^2, \tag{6}$$

where α is a small constant (e.g. 0.1) multiplied to the loss in order to stabilize learning. We conjecture that the stability is due to the slowly evolving value network which directly affects the learning of the policy. This effectively prevents the value network to fit extreme cases (unexpectedly high or low reward.)

We minimize C_a and C_b using stochastic gradient descent (SGD) with the gradient computed by backpropagation (Rumelhart et al., 1988). This allows the entire model to be trained end-to-end directly to optimize the retrieval performance.

Entropy Regularization We observed that the probability distribution in Eq.(1) became highly peaked in preliminary experiments. This phenomenon led to the trained model not being able to explore new terms that could lead to a better-reformulated query. We address this issue by regularizing the negative entropy of the probability distribution. We add the following regularization term to the original cost function in Eq. (4):

$$C_H = -\lambda \sum_{t \in q_0 \cup D_0} P(t|q_0) \log P(t|q_0), \tag{7}$$

where λ is a regularization coefficient.

3 Related Work

Query reformulation techniques are either based on a global method, which ignores a set of documents returned by the original query, or a local method, which adjusts a query relative to the documents that initially appear to match the query. In this work, we focus on local methods.

A popular instantiation of a local method is the *relevance model*, which incorporates pseudo-relevance feedback into a language model form (Lavrenko and Croft, 2001). The probability of adding a term to an expanded query is proportional to its probability of being generated by the language models obtained from the original query and the document the term occurs in. This framework has the advantage of not requiring *query/relevant documents* pairs as training data since inference is based on word co-occurrence statistics.

Unlike the relevance model, algorithms can be trained with supervised learning, as proposed by Cao et al. (2008). A training dataset is automatically created by labeling each candidate term as relevant or not based on their individual contribution to the retrieval performance. Then a binary classifier is trained to select expansion terms. In Section 4, we present a neural network-based implementation of this supervised approach.

A generalization of this supervised framework is to *iteratively* reformulate the query by selecting one candidate term at each retrieval step. This can be viewed as navigating a graph where the nodes represent queries and associated retrieved results and edges exist between nodes whose queries are simple reformulations of each other (Diaz, 2016). However, it can be slow to reformulate a query this way as the search engine must be queried for each newly added term. In our method, on the contrary, the search engine is queried with multiple new terms at once.

An alternative technique based on supervised learning is to learn a common latent representation of queries and relevant documents terms by using a *click-through* dataset (Sordoni et al., 2014). Neighboring document terms of a query in the latent space are selected to form an expanded query. Instead of using a *click-through* dataset, which is often proprietary, it is possible to use an alternative dataset consisting of anchor text/title pairs. In contrast, our approach does not require a dataset of paired queries as it learns term selection strategies via reinforcement learning.

Perhaps the closest work to ours is that by Narasimhan et al. (2016), in which a reinforcement learning based approach is used to reformulate queries iteratively. A key difference is that in their work the reformulation component uses domain-specific template queries. Our method, on the other hand, assumes open-domain queries.

4 Experiments

In this section we describe our experimental setup, including baselines against which we compare the proposed method, metrics, reward for RL-based models, datasets and implementation details.

4.1 Baseline Methods

Raw: The original query is given to a search engine without any modification. We evaluate two search engines in their default configuration: Lucene[3] (Raw-Lucene) and Google Search[4] (Raw-Google).

Pseudo Relevance Feedback (PRF-TFIDF): A query is expanded with terms from the documents retrieved by a search engine using the original query. In this work, the top-N TF-IDF terms from each of the top-K retrieved documents are added to the original query, where N and K are selected by a grid search on the validation data.

PRF-Relevance Model (PRF-RM): This is a popular relevance model for query expansion by Lavrenko and Croft (2001). The probability of using a term t in an expanded query is given by:

$$\begin{aligned} P(t|q_0) = (1-\lambda)P'(t|q_0) \\ + \lambda \sum_{d \in D_0} P(d)P(t|d)P(q_0|d), \end{aligned} \quad (8)$$

where $P(d)$ is the probability of retrieving the document d, assumed uniform over the set, $P(t|d)$ and $P(q_0|d)$ are the probabilities assigned by the language model obtained from d to t and q_0, respectively. $P'(t|q_0) = \frac{\text{tf}(t \in q)}{|q|}$, where $\text{tf}(t,d)$ is the term frequency of t in d. We set the interpolation parameter λ to 0.5, following Zhai and Lafferty (2001).

We use a Dirichlet smoothed language model (Zhai and Lafferty, 2001) to compute a language model from a document $d \in D_0$:

$$P(t|d) = \frac{\text{tf}(t,d) + uP(t|C)}{|d| + u}, \quad (9)$$

[3] https://lucene.apache.org/

[4] https://cse.google.com/cse/

where u is a scalar constant ($u = 1500$ in our experiments), and $P(t|C)$ is the probability of t occurring in the entire corpus C.

We use the N terms with the highest $P(t|q_0)$ in an expanded query, where N is a hyper-parameter.

Embeddings Similarity: Inspired by the methods proposed by Roy et al. (2016) and Kuzi et al. (2016), the top-N terms are selected based on the cosine similarity of their embeddings against the original query embedding. Candidate terms come from documents retrieved using the original query (PRF-Emb), or from a fixed vocabulary (Vocab-Emb). We use pretrained embeddings from Mikolov et al. (2013), and it contains 374,000 words.

4.2 Proposed Methods

Supervised Learning (SL): Here we detail a deep learning-based variant of the method proposed by Cao et al. (2008). It assumes that query terms contribute independently to the retrieval performance. We thus train a binary classifier to select a term if the retrieval performance increases beyond a preset threshold when that term is added to the original query. More specifically, we mark a term as relevant if $(R' - R)/R > 0.005$, where R and R' are the retrieval performances of the original query and the query expanded with the term, respectively.

We experiment with two variants of this method: one in which we use a convolutional network for both original query and candidate terms (SL-CNN), and the other in which we replace the convolutional network with a single hidden layer feed-forward neural network (SL-FF). In this variant, we average the output vectors of the neural network to obtain a fixed size representation of q_0.

Reinforcement Learning (RL): We use multiple variants of the proposed RL method. RL-CNN and RL-RNN are the models described in Section 2.1, in which the former uses CNNs to encode query and term features and the latter uses RNNs (more specifically, bidirectional LSTMs). RL-FF is the model in which term and query vectors are encoded by single hidden layer feed-forward neural networks. In the RL-RNN-SEQ model, we add the sequential generator described in Section 2.2 to the RL-RNN variant.

4.3 Datasets

We summarize in Table 1 the datasets.

TREC - Complex Answer Retrieval (TREC-CAR) This is a publicly available dataset automatically created from Wikipedia whose goal is to encourage the development of methods that respond to more complex queries with longer answers (Dietz and Ben, 2017). A query is the concatenation of an article title and one of its section titles. The ground-truth documents are the paragraphs within that section. For example, a query is "*Sea Turtle, Diet*" and the ground truth documents are the paragraphs in the section "*Diet*" of the "*Sea Turtle*" article. The corpus consists of all the English Wikipedia paragraphs, except the abstracts. The released dataset has five predefined folds, and we use the first three as the training set and the remaining two as validation and test sets, respectively.

Jeopardy This is a publicly available Q&A dataset introduced by Nogueira and Cho (2016). A query is a question from the *Jeopardy!* TV Show and the corresponding document is a Wikipedia article whose title is the answer. For example, a query is *"For the last eight years of his life, Galileo was under house arrest for espousing this mans theory"* and the answer is the Wikipedia article titled *"Nicolaus Copernicus"*. The corpus consists of all the articles in the English Wikipedia.

Microsoft Academic (MSA) This dataset consists of academic papers crawled from Microsoft Academic API.[5] The crawler started at the paper Silver et al. (2016) and traversed the graph of references until 500,000 papers were crawled. We then removed papers that had no reference within or whose abstract had less than 100 characters. We ended up with 480,000 papers.

A query is the title of a paper, and the ground-truth answer consists of the papers cited within. Each document in the corpus consists of its title and abstract.[6]

4.4 Metrics and Reward

Three metrics are used to evaluate performance:

Recall@K: Recall of the top-K retrieved documents:

$$\text{R@}K = \frac{|D_K \cap D^*|}{|D^*|}, \tag{10}$$

[5] https://www.microsoft.com/cognitive-services/en-us/academic-knowledge-api

[6] This was done to avoid a large computational overhead for indexing full papers.

			Queries			Relevant Docs/Query		Words/Doc	
Dataset	Corpus	Docs	Train	Valid	Test	Avg.	Std.	Avg.	Std.
TREC-CAR	Wikipedia Paragraphs	3.5M	585k	195k	195k	3.6	5.7	84	68

Table 2: Results on Test sets. We use R@40 as a reward to the RL-based models.

where D_K are the top-K retrieved documents and D^* are the relevant documents. Since one of the goals of query reformulation is to increase the proportion of relevant documents returned, recall is our main metric.

Precision@K: Precision of the top-K retrieved documents:

$$\text{P@}K = \frac{|D_K \cap D^*|}{|D_K|} \tag{11}$$

Precision captures the proportion of relevant documents among the returned ones. Despite not being the main goal of a reformulation method, improvements in precision are also expected with a good query reformulation method. Therefore, we include this metric.

Mean Average Precision: The average precision of the top-K retrieved documents is defined as:

$$\text{AP@}K = \frac{\sum_{k=1}^{K} \text{P@}k \times \text{rel}(k)}{|D^*|}, \tag{12}$$

where

$$\text{rel}(k) = \begin{cases} 1, & \text{if the k-th document is relevant;} \\ 0, & \text{otherwise.} \end{cases} \tag{13}$$

The mean average precision of a set of queries Q is then:

$$\text{MAP@}K = \frac{1}{|Q|} \sum_{q \in Q} \text{AP@}K_q, \tag{14}$$

where AP@K_q is the average precision at K for a query q. This metric values the position of a relevant document in a returned list and is, therefore, complementary to precision and recall.

Reward We use R@K as a reward when training the proposed RL-based models as this metric has shown to be effective in improving the other metrics as well.

SL-Oracle In addition to the baseline methods and proposed reinforcement learning approach, we report two oracle performance bounds. The first oracle is a supervised learning oracle (SL-Oracle). It is a classifier that perfectly selects terms that will increase performance according to the procedure described in Section 4.2. This measure serves as an upper-bound for the supervised methods. Notice that this heuristic assumes that each term contributes independently from all the other terms to the retrieval performance. There may be, however, other ways to explore the dependency of terms that would lead to a higher performance.

	TREC-CAR	Jeopardy	MSA
SL-Oracle	13%	5%	11%
RL-Oracle	29%	27%	31%

Table 3: Percentage of relevant terms over all the candidate terms according to SL- and RL-Oracle.

RL-Oracle Second, we introduce a reinforcement learning oracle (RL-Oracle) which estimates a conservative upper-bound performance for the RL models. Unlike the SL-Oracle, it does not assume that each term contributes independently to the retrieval performance. It works as follows: first, the *validation* or *test* set is divided into N small subsets $\{A_i\}_{i=1}^N$ (each with 100 examples, for instance). An RL model is trained on each subset A_i until it overfits, that is, until the reward R_i^* stops increasing or an early stop mechanism ends training.[7] Finally, we compute the oracle performance R^* as the average reward over all the subsets: $R^* = \frac{1}{N}\sum_{i=1}^N R_i^*$.

This upper bound by the RL-Oracle is, however, conservative since there might exist better reformulation strategies that the RL model was not able to discover.

4.5 Implementation Details

Search engine We use Lucene and BM25 as the search engine and the ranking function, respectively, for all PRF, SL and RL methods. For Raw-Google, we restrict the search to the *wikipedia.org* domain when evaluating its performance on the Jeopardy dataset. We could not apply the same restriction to the two other datasets as Google does not index Wikipedia paragraphs, and as it is not trivial to match papers from MS Academic to the ones returned by Google Search.

Candidate terms We use Wikipedia articles as a source for candidate terms since it is a well curated, clean corpus, with diverse topics.

At training and test times of SL methods, and at test time of RL methods, the candidate terms are from the first M words of the top-K Wikipedia articles retrieved. We select M and K using grid search on the validation set over $\{50, 100, 200, 300\}$ and $\{1, 3, 5, 7\}$, respectively. The best values are $M = 300$ and $K = 7$. These correspond to the maximum number of terms we could fit in a single GPU.

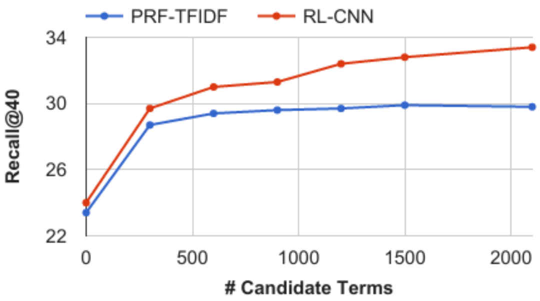

Figure 3: Our RL-based model continues to improve recall as more candidate terms are added, whereas a classical PRF method saturates.

At training time of an RL model, we use only *one* document uniformly sampled from the top-K retrieved ones as a source for candidate terms, as this leads to a faster learning.

For the PRF methods, the top-M terms according to a relevance metric (i.e., TF-IDF for PRF-TFIDF, cosine similarity for PRF-Emb, and conditional probability for PRF-RM) from each of the top-K retrieved documents are added to the original query. We select M and K using grid search over $\{10, 50, 100, 200, 300, 500\}$ and $\{1, 3, 5, 9, 11\}$, respectively. The best values are $M = 300$ and $K = 9$.

Multiple Reformulation Rounds Although our framework supports multiple rounds of search and reformulation, we did not find any significant improvement in reformulating a query more than once. Therefore, the numbers reported in the results section were all obtained from models running two rounds of search and reformulation.

Neural Network Setup For SL-CNN and RL-CNN variants, we use a 2-layer convolutional network for the original query. Each layer has a window size of 3 and 256 filters. We use a 2-layer convolutional network for candidate terms with window sizes of 9 and 3, respectively, and 256 filters in each layer. We set the dimension d of the weight matrices W, S, U, and V to 256. For the optimizer, we use ADAM (Kingma and Ba, 2014) with $\alpha = 10^{-4}$, $\beta_1 = 0.9$, $\beta_2 = 0.999$, and $\epsilon = 10^{-8}$. We set the entropy regularization coefficient λ to 10^{-3}.

For RL-RNN and RL-RNN-SEQ, we use a 2-layer bidirectional LSTM with 256 hidden units in each layer. We clip the gradients to unit norm. For RL-RNN-SEQ, we set the maximum possible

[7] The subset should be small enough, or the model should be large enough so it can overfit.

number of generated terms to 50 and we use beam search of size four at test time.

We fix the dictionary of pre-trained word embeddings during training, except the vector for out-of-vocabulary words. We found that this led to faster convergence and observed no difference in the overall performance when compared to learning embeddings during training.

5 Results and Discussion

Table 2 shows the main result. As expected, reformulation based methods work better than using the original query alone. Supervised methods (SL-FF and SL-CNN) have in general a better performance than unsupervised ones (PRF-TFIDF, PRF-RM, PRF-Emb, and Emb-Vocab), but perform worse than RL-based models (RL-FF, RL-CNN, RL-RNN, and RL-RNN-SEQ).

RL-RNN-SEQ performs slightly worse than RL-RNN but produces queries that are three times shorter, on average (15 vs 47 words). Thus, RL-RNN-SEQ is faster in retrieving documents and therefore might be a better candidate for a production implementation.

The performance gap between the oracle and best performing method (Table 2, RL-Oracle vs. RL-RNN) suggests that there is a large room for improvement. The cause for this gap is unknown but we suspect, for instance, an inherent difficulty in learning a good selection strategy and the partial observability from using a black box search engine.

5.1 Relevant Terms per Document

The proportion of relevant terms selected by the SL- and RL-Oracles over the total number of candidate terms (Table 3) indicates that only a small subset of terms are useful for the reformulation. Thus, we may conclude that the proposed method was able to learn an efficient term selection strategy in an environment where relevant terms are infrequent.

5.2 Scalability: Number of Terms vs Recall

Fig. 3 shows the improvement in recall as more candidate terms are provided to a reformulation method. The RL-based model benefits from more candidate terms, whereas the classical PRF method quickly saturates. In our experiments, the best performing RL-based model uses the maximum number of candidate terms that we could fit on a single GPU. We, therefore, expect further improvements with more computational resources.

(Reformulated) *Daikon Cultivation root seed grow fast-growing Chinese leaves*	“*...many types of pickles are “made with daikon, includ...*” “***Certain varieties of daikon can be grown as a winter...***” “***The Chinese and Indian varieties tolerate higher....***”

Table 4: Top-3 retrieved documents using the original query and a query reformulated by our RL-CNN model. In the first example, we only show the titles of the retrieved MSA papers. In the second example, we only show some words of the retrieved TREC-CAR paragraphs. **Bold** corresponds to ground-truth documents.

5.3 Qualitative Analysis

We show two examples of queries and the probabilities of each candidate term of being selected by the RL-CNN model in Fig. 4.

Trained on	Selected Terms
TREC-CAR	*serves american national Winsted accreditation*
Jeopardy	*Tunxis Quinebaug Winsted NCCC*
MSA	*hospital library arts center cancer center summer programs*

Table 5: Given the query *“Northwestern Connecticut Community College”*, models trained on different tasks choose different terms.

Notice that terms that are more related to the query have higher probabilities, although common words such as ”*the*” are also selected. This is a consequence of our choice of a reward that does

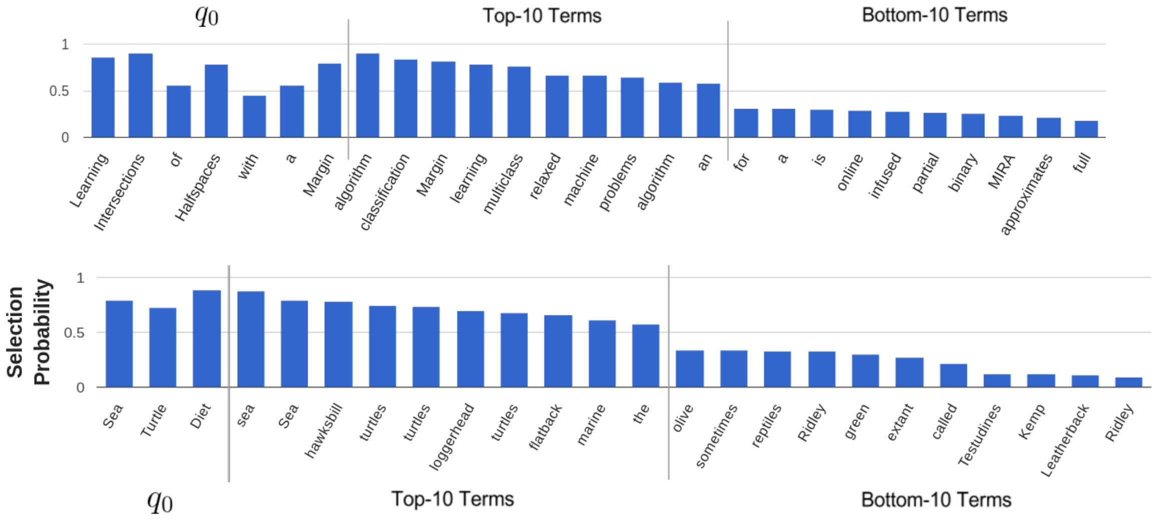

Figure 4: Probabilities assigned by the RL-CNN to candidate terms of two sample queries: "*Learning Intersections of Halfspaces with a Margin*" (top) and "*Sea Turtle Diet*" (bottom). We show the original query terms and the top-10 and bottom-10 document terms with respect to their probabilities.

not penalize the selection of neutral terms.

In Table 4 we show an original and reformulated query examples extracted from the MS Academic and TREC-CAR datasets, and their top-3 retrieved documents. Notice that the reformulated query retrieves more relevant documents than the original one. As we conjectured earlier, we see that a search engine tends to return a document simply with the largest overlap in the text, necessitating the reformulation of a query to retrieve semantically relevant documents.

Same query, different tasks We compare in Table 5 the reformulation of a sample query made by models trained on different datasets. The model trained on TREC-CAR selects terms that are similar to the ones in the original query, such as "*serves*" and "*accreditation*". These selections are expected for this task since similar terms can be effective in retrieving similar paragraphs. On the other hand, the model trained on Jeopardy prefers to select proper nouns, such as "*Tunxis*", as these have a higher chance of being an answer to the question. The model trained on MSA selects terms that cover different aspects of the entity being queried, such as "*arts center*" and "*library*", since retrieving a diverse set of documents is necessary for the task the of citation recommendation.

5.4 Training and Inference Times

Our best model, RL-RNN, takes 8-10 days to train on a single K80 GPU. At inference time, it takes approximately one second to reformulate a batch of 64 queries. Approximately 40% of this time is to retrieve documents from the search engine.

6 Conclusion

We introduced a reinforcement learning framework for task-oriented automatic query reformulation. An appealing aspect of this framework is that an agent can be trained to use a search engine for a specific task. The empirical evaluation has confirmed that the proposed approach outperforms strong baselines in the three separate tasks. The analysis based on two oracle approaches has revealed that there is a meaningful room for further development. In the future, more research is necessary in the directions of (1) iterative reformulation under the proposed framework, (2) using information from modalities other than text, and (3) better reinforcement learning algorithms for a partially-observable environment.

Abstract

Sentence simplification aims to make sentences easier to read and understand. Most recent approaches draw on insights from machine translation to learn simplification rewrites from monolingual corpora of complex and simple sentences. We address the simplification problem with an encoder-decoder model coupled with a deep reinforcement learning framework. Our model, which we call DRESS (as shorthand for **D**eep **RE**inforcement **S**entence **S**implification), explores the space of possible simplifications while learning to optimize a reward function that encourages outputs which are simple, fluent, and preserve the meaning of the input. Experiments on three datasets demonstrate that our model outperforms competitive simplification systems.[1]

1 Introduction

The main goal of *sentence simplification* is to reduce the linguistic complexity of text, while still retaining its original information and meaning. The simplification task has been the subject of several modeling efforts in recent years due to its relevance for NLP applications and individuals alike (Siddharthan, 2014; Shardlow, 2014). For instance, a simplification component could be used as a preprocessing step to improve the performance of parsers (Chandrasekar et al., 1996), summarizers (Beigman Klebanov et al., 2004), and semantic role labelers (Vickrey and Koller, 2008; Woodsend and Lapata, 2014). Automatic simplification would also benefit people with low-literacy skills (Watanabe et al., 2009), such as children and non-native speakers as well as individuals with autism (Evans et al., 2014), aphasia (Carroll et al., 1999), or dyslexia (Rello et al., 2013).

The most prevalent rewrite operations which give rise to simplified text include substituting rare words with more common words or phrases, rendering syntactically complex structures simpler, and deleting elements of the original text (Siddharthan, 2014). Earlier work focused on individual aspects of the simplification problem. For example, several systems performed syntactic simplification only, using rules aimed at sentence splitting (Carroll et al., 1999; Chandrasekar et al., 1996; Vickrey and Koller, 2008; Siddharthan, 2004) while others turned to lexical simplification by substituting difficult words with more common WordNet synonyms or paraphrases (Devlin, 1999; Inui et al., 2003; Kaji et al., 2002).

Recent approaches view the simplification process more holistically as a monolingual text-to-text generation task borrowing ideas from statistical machine translation. Simplification rewrites are learned automatically from examples of complex-simple sentences extracted from online resources such as the ordinary and simple English Wikipedia. For example, Zhu et al. (2010) draw inspiration from syntax-based translation and propose a model similar to Yamada and Knight (2001) which additionally performs simplification-specific rewrite operations (e.g., sentence splitting). Woodsend and Lapata (2011) formulate simplification in the framework of Quasi-synchronous grammar (Smith and Eisner, 2006) and use integer linear programming to score the candidate translations/simplifications. Wubben et al. (2012) propose a two-stage model: initially, a standard phrase-based machine translation (PBMT) model is trained on complex-simple sentence pairs. During inference, the K-best outputs of the PBMT model are reranked according

Copenhagen, Denmark, September 7–11, 2017. ©2017 Association for Computational Linguistics

to their dis-similarity to the (complex) input sentence. The hybrid model developed in Narayan and Gardent (2014) also operates in two phases. Initially, a probabilistic model performs sentence splitting and deletion operations over discourse representation structures assigned by Boxer (Curran et al., 2007). The resulting sentences are further simplified by a model similar to Wubben et al. (2012). Xu et al. (2016) train a syntax-based machine translation model on a large scale paraphrase dataset (Ganitkevitch et al., 2013) using simplification-specific objective functions and features to encourage simpler output.

In this paper we propose a simplification model which draws on insights from neural machine translation (Bahdanau et al., 2015; Sutskever et al., 2014). Central to this approach is an encoder-decoder architecture implemented by recurrent neural networks. The encoder reads the source sequence into a list of continuous-space representations from which the decoder generates the target sequence. Although our model uses the encoder-decoder architecture as its backbone, it must also meet constraints imposed by the simplification task itself, i.e., the predicted output must be simpler, preserve the meaning of the input, and grammatical. To incorporate this knowledge, the model is trained in a reinforcement learning framework (Williams, 1992): it explores the space of possible simplifications while learning to maximize an expected reward function that encourages outputs which meet simplification-specific constraints. Reinforcement learning has been previously applied to extractive summarization (Ryang and Abekawa, 2012), information extraction (Narasimhan et al., 2016), dialogue generation (Li et al., 2016), machine translation, and image caption generation (Ranzato et al., 2016).

We evaluate our system on three publicly available datasets collated automatically from Wikipedia (Zhu et al., 2010; Woodsend and Lapata, 2011) and human-authored news articles (Xu et al., 2015b). We experimentally show that the reinforcement learning framework is the key to successful generation of simplified text bringing significant improvements over strong simplification models across datasets.

2 Neural Encoder-Decoder Model

We will first define a basic encoder-decoder model for sentence simplification and then explain how to embed it in a reinforcement learning framework. Given a (complex) *source* sentence $X = (x_1, x_2, \ldots, x_{|X|})$, our model learns to predict its simplified *target* $Y = (y_1, y_2, \ldots, y_{|Y|})$. Inferring the target Y given the source X is a typical sequence to sequence learning problem, which can be modeled with attention-based encoder-decoder models (Bahdanau et al., 2015; Luong et al., 2015). Sentence simplification is slightly different from related sequence transduction tasks (e.g., compression) in that it can involve splitting operations. For example, a long source sentence (*In 1883, Faur married Marie Fremiet, with whom he had two sons.*) can be simplified as two sentences (*In 1883, Faur married Marie Fremiet. They had two sons.*). Nevertheless, we still view the target as a sequence, i.e., two or more sequences concatenated with full stops.

The encoder-decoder model has two parts (see left hand side in Figure 1). The *encoder* transforms the source sentence X into a sequence of hidden states $(\mathbf{h}_1^S, \mathbf{h}_2^S, \ldots, \mathbf{h}_{|X|}^S)$ with a Long Short-Term Memory Network (LSTM; Hochreiter and Schmidhuber 1997), while the *decoder* uses another LSTM to generate one word y_{t+1} at a time in the simplified target Y. Generation is conditioned on all previously generated words $y_{1:t}$ and a dynamically created context vector $\mathbf{c}_t$, which encodes the source sentence:

$$P(Y|X) = \prod_{t=1}^{|Y|} P(y_t|y_{1:t-1}, X) \tag{1}$$

$$P(y_{t+1}|y_{1:t}, X) = \text{softmax}(g(\mathbf{h}_t^T, \mathbf{c}_t)) \tag{2}$$

where $g(\cdot)$ is a one-hidden-layer neural network with the following parametrization:

$$g(\mathbf{h}_t^T, \mathbf{c}_t) = \mathbf{W}_o \tanh(\mathbf{U}_h \mathbf{h}_t^T + \mathbf{W}_h \mathbf{c}_t) \tag{3}$$

where $\mathbf{W}_o \in \mathbb{R}^{|V| \times d}$, $\mathbf{U}_h \in \mathbb{R}^{d \times d}$, and $\mathbf{W}_h \in \mathbb{R}^{d \times d}$; $|V|$ is the output vocabulary size and d the hidden unit size. $\mathbf{h}_t^T$ is the hidden state of the decoder LSTM which summarizes $y_{1:t}$, i.e., what has been generated so far:

$$\mathbf{h}_t^T = \text{LSTM}(y_t, \mathbf{h}_{t-1}^T) \tag{4}$$

The dynamic context vector $\mathbf{c}_t$ is the weighted sum of the hidden states of the source sentence:

$$\mathbf{c}_t = \sum_{i=1}^{|X|} \alpha_{ti} \mathbf{h}_i^S \tag{5}$$

whose weights α_{ti} are determined by an *attention* mechanism:

$$\alpha_{ti} = \frac{\exp(\mathbf{h}_t^T \cdot \mathbf{h}_i^S)}{\sum_i \exp(\mathbf{h}_t^T \cdot \mathbf{h}_i^S)} \quad (6)$$

where $\cdot$ is the dot product between two vectors. We use the dot product here mainly for efficiency reasons; alternative ways to compute attention scores have been proposed in the literature and we refer the interested reader to Luong et al. (2015). The model sketched above is usually trained by minimizing the negative log-likelihood of the training source-target pairs.

3 Reinforcement Learning for Sentence Simplification

In this section we present DRESS, our **D**eep **RE**inforcement **S**entence **S**implification model. Despite successful application in numerous sequence transduction tasks (Jean et al., 2015; Chopra et al., 2016; Xu et al., 2015a), a vanilla encoder-decoder model is not ideal for sentence simplification. Although a number of rewrite operations (e.g., copying, deletion, substitution, word reordering) can be used to simplify text, copying is by far the most common. We empirically found that 73% of the target words are copied from the source in the Newsela dataset. This number further increases to 83% when considering Wikipedia-based datasets (we provide details on these datasets in Section 5). As a result, a generic encoder-decoder model learns to copy all too well at the expense of other rewrite operations, often parroting back the source or making only a few trivial changes.

To encourage a wider variety of rewrite operations while remaining fluent and faithful to the meaning of the source, we employ a reinforcement learning framework (see Figure 1). We view the encoder-decoder model as an agent which first reads the source sentence X; then at each step, it takes an action $\hat{y}_t \in V$ (where V is the output vocabulary) according to a policy $P_{RL}(\hat{y}_t|\hat{y}_{1:t-1}, X)$ (see Equation (2)). The agent continues to take actions until it produces an **E**nd **O**f **S**entence (EOS) token yielding the action sequence $\hat{Y} = (\hat{y}_1, \hat{y}_2, \ldots, \hat{y}_{|\hat{Y}|})$, which is also the simplified output of our model. A reward r is then received and the REINFORCE algorithm (Williams, 1992) is used to update the agent. In the following, we first introduce our reward and then present the details of the REINFORCE algorithm.

3.1 Reward

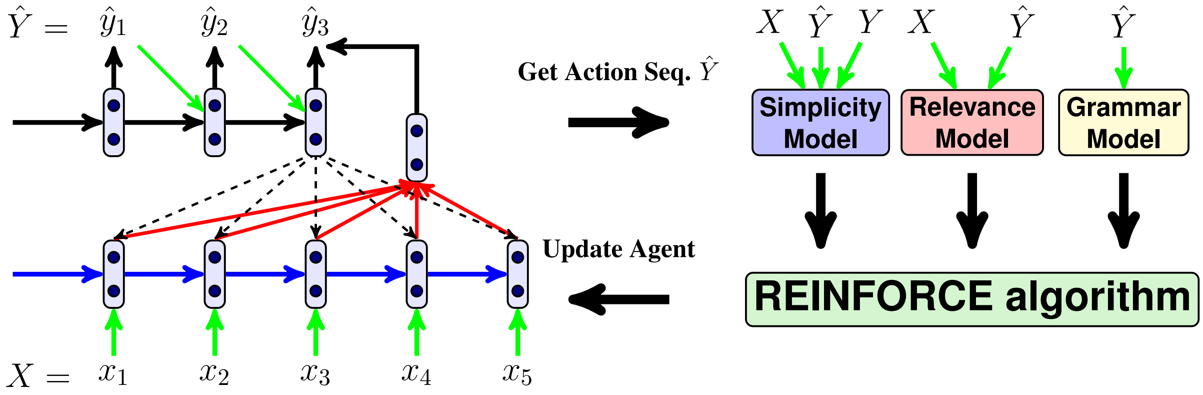
The reward $r(\hat{Y})$ for system output $\hat{Y}$ is the weighted sum of the three components aimed at capturing key aspects of the target output, namely simplicity, relevance, and fluency:

$$r(\hat{Y}) = \lambda^S r^S + \lambda^R r^R + \lambda^F r^F \quad (7)$$

where $\lambda^S, \lambda^R, \lambda^F \in [0, 1]$; $r(\hat{Y})$ is a shorthand for $r(X, Y, \hat{Y})$ where X is the source, Y the reference (or target), and $\hat{Y}$ the system output. r^S, r^R, and r^F are shorthands for simplicity $r^S(X, Y, \hat{Y})$, relevance $r^R(X, \hat{Y})$, and fluency $r^F(\hat{Y})$. We provide details for each reward summand below.

Simplicity To encourage the model to apply a wide range of simplification operations, we use SARI (Xu et al., 2016), a recently proposed metric which compares **S**ystem output **A**gainst **R**eferences and against the **I**nput sentence. SARI is the arithmetic average of n-gram precision and recall of three rewrite operations: addition, copying, and deletion. It rewards addition operations where system output was not in the input but occurred in the references. Analogously, it rewards words retained/deleted in both the system output and the references. In experimental evaluation Xu et al. (2016) demonstrate that SARI correlates well with human judgments of simplicity, whilst correctly rewarding systems that both make changes and simplify the input.

One caveat with using SARI as a reward is the fact that it relies on the availability of multiple references which are rare for sentence simplification. Xu et al. (2016) provide eight references for 2,350 sentences, but these are primarily for system tuning and evaluation rather than training. The majority of existing simplification datasets (see Section 5 for details) have a single reference for each source sentence. Moreover, they are unavoidably noisy as they are mostly constructed automatically, e.g., by aligning sentences from the ordinary and simple English Wikipedias. When relying solely on a single reference, SARI will try to reward accidental n-grams that should never have occurred in it. To countenance the effect of noise, we apply SARI$(X, \hat{Y}, Y)$ in the expected direction, with X as the source, $\hat{Y}$ the system output, and Y the reference as well as in the reverse direction with Y as the system output and $\hat{Y}$ as the reference. Assuming our system can produce reasonably good simplifications, by swapping the output



$\hat{Y} = \hat{y}_1 \; \hat{y}_2 \; \hat{y}_3$
Get Action Seq. $\hat{Y}$

Simplicity Model
Relevance Model
Grammar Model
Update Agent
REINFORCE algorithm
$X = x_1 \; x_2 \; x_3 \; x_4 \; x_5$

Figure 1: Deep reinforcement learning simplification model. X is the complex sentence, Y the reference (simple) sentence and $\hat{Y}$ the action sequence (simplification) produced by the encoder-decoder model.

and the reference, reverse SARI can be used to estimate how good a reference is with respect to the system output. Our first reward is therefore the weighted sum of SARI and reverse SARI:

$$r^S = \beta\, \textsc{Sari}(X, \hat{Y}, Y) + (1-\beta)\, \textsc{Sari}(X, Y, \hat{Y}) \quad (8)$$

Relevance While the simplicity-based reward r^S tries to encourage the model to make changes, the relevance reward r^R ensures that the generated sentences preserve the meaning of the source. We use an LSTM sentence encoder to convert the source X and the predicted target $\hat{Y}$ into two vectors $\mathbf{q}_X$ and $\mathbf{q}_{\hat{Y}}$. The relevance reward r^R is simply the cosine similarity between these two vectors:

$$r^R = \cos(\mathbf{q}_X, \mathbf{q}_{\hat{Y}}) = \frac{\mathbf{q}_X \cdot \mathbf{q}_{\hat{Y}}}{||\mathbf{q}_X||\;||\mathbf{q}_{\hat{Y}}||} \quad (9)$$

We use a sequence auto-encoder (SAE; Dai and Le 2015) to train the LSTM sentence encoder on both the complex and simple sentences. Specifically, the SAE uses sentence $X = (x_1, \ldots, x_{|X|})$ to infer itself via an encoder-decoder model (without an attention mechanism). Firstly, an encoder LSTM converts X into a sequence of hidden states $(\mathbf{h}_1, \ldots, \mathbf{h}_{|X|})$. Then, we use $\mathbf{h}_{|X|}$ to initialize the hidden state of the decoder LSTM and recover/generate X one word at a time.

Fluency Xu et al. (2016) observe that SARI correlates less with fluency compared to other metrics such as BLEU (Papineni et al., 2002). The fluency reward r^F models the well-formedness of the generated sentences explicitly. It is the normalized sentence probability assigned by an LSTM language model trained on simple sentences:

$$r^F = \exp\left(\frac{1}{|\hat{Y}|}\sum_{i=1}^{|\hat{Y}|} \log P_{LM}(\hat{y}_i|\hat{y}_{0:i-1})\right) \quad (10)$$

We take the exponential of $\hat{Y}$'s perplexity to ensure that $r^F \in [0, 1]$ as is the case with r^S and r^R.

3.2 The REINFORCE Algorithm

The goal of the REINFORCE algorithm is to find an agent that maximizes the expected reward. The training loss for one sequence is its negative expected reward:

$$\mathcal{L}(\theta) = -\mathbb{E}_{(\hat{y}_1,\ldots,\hat{y}_{|\hat{Y}|})\sim P_{RL}(\cdot|X)}[r(\hat{y}_1, \ldots, \hat{y}_{|\hat{Y}|})]$$

where P_{RL} is our policy, i.e., the distribution produced by the encoder-decoder model (see Equation(2)) and $r(\cdot)$ is the reward function of an action sequence $\hat{Y} = (\hat{y}_1, \ldots, \hat{y}_{|\hat{Y}|})$, i.e., a generated simplification. Unfortunately, computing the expectation term is prohibitive, since there is an infinite number of possible action sequences. In practice, we approximate this expectation with a single sample from the distribution of $P_{LR}(\cdot|X)$. We refer to Williams (1992) for the full derivation of the gradients. The gradient of $\mathcal{L}(\theta)$ is:

$$\nabla\mathcal{L}(\theta) \approx \\ \textstyle\sum_{t=1}^{|\hat{Y}|} \nabla \log P_{RL}(\hat{y}_t|\hat{y}_{1:t-1}, X)[r(\hat{y}_{1:|\hat{Y}|}) - b_t]$$

To reduce the variance of gradients, we also introduce a baseline linear regression model b_t to estimate the expected future reward at time t (Ranzato et al., 2016). b_t takes the concatenation of $\mathbf{h}_t^T$ and $\mathbf{c}_t$ as input and outputs a real value as the expected reward. The parameters of the regressor are trained by minimizing mean squared error. We do not back-propagate this error to $\mathbf{h}_t^T$ or $\mathbf{c}_t$ during training (Ranzato et al., 2016).

3.3 Learning

Presented in its original form, the REINFORCE algorithm starts learning with a random policy. This assumption can make model training challenging for generation tasks like ours with large vocabularies (i.e., action spaces). We address this issue by pre-training our agent (i.e., the encoder-decoder model) with a negative log-likelihood objective (see Section 2), making sure it can produce reasonable simplifications, thereby starting off with a policy which is better than random. We follow prior work (Ranzato et al., 2016) in adopting a curriculum learning strategy. In the beginning of training, we give little freedom to our agent allowing it to predict the last few words for each target sentence. For every target sequence, we use negative log-likelihood to train the first L (initially, $L = 24$) tokens and apply the reinforcement learning algorithm to the $(L + 1)$th tokens onwards. Every two epochs, we set $L = L - 3$ and the training terminates when L is 0.

4 Lexical Simplification

Lexical substitution, the replacement of complex words with simpler alternatives, is an integral part of sentence simplification (Specia et al., 2012). The model presented so far learns lexical substitution and other rewrite operations *jointly*. In some cases, words are predicted because they seem natural in the their context, but are poor substitutes for the content of the complex sentence. To countenance this, we learn lexical simplifications *explicitly* and integrate them with our reinforcement learning-based model.

We use an *pre-trained* encoder-decoder model (which is trained on a parallel corpus of complex and simple sentences) to obtain probabilistic word alignments, aka attention scores (see α_t in Equation (6)). Let $X = (x_1, x_2, \ldots, x_{|X|})$ denote a source sentence and $Y = (y_1, y_2, \ldots, y_{|Y|})$ a target sentence. We convert X into $|X|$ hidden states $(\mathbf{v}_1, \mathbf{v}_2, \ldots, \mathbf{v}_{|X|})$ with an LSTM. Note that $\mathbf{v}_t \in \mathbb{R}^{d \times 1}$ corresponds to the context dependent representation of x_t. Let α_t denote the alignment scores $\alpha_{t1}, \alpha_{t2}, \ldots, \alpha_{t|X|}$. The lexical simplification probability of y_t given the source sentence and the alignment scores is:

$$P_{LS}(y_t|X, \alpha_t) = \text{softmax}(\mathbf{W}_l\, \mathbf{s}_t) \tag{11}$$

where $\mathbf{W}_l \in \mathbb{R}^{|V| \times d}$ and $\mathbf{s}_t$ represents the source:

$$\mathbf{s}_t = \sum_{i=1}^{|X|} \alpha_{ti} \mathbf{v}_i \tag{12}$$

The lexical simplification model on its own encourages lexical substitutions, without taking into account what has been generated so far (i.e., $y_{1:t-1}$) and as a result fluency could be compromised. A straightforward solution is to integrate lexical simplification with our reinforcement learning trained model (Section 3) using linear interpolation, where $\eta \in [0, 1]$:

$$\begin{aligned} P(y_t|y_{1:t-1}, X) = (1 - \eta)\, P_{RL}(y_t|y_{1:t-1}, X) \\ + \eta\, P_{LS}(y_t|X, \alpha_t) \end{aligned} \tag{13}$$

5 Experimental Setup

In this section we present our experimental setup for assessing the performance of the simplification model described above. We give details on our datasets, model training, evaluation protocol, and the systems used for comparison.

Datasets We conducted experiments on three simplification datasets. *WikiSmall* (Zhu et al., 2010) is a parallel corpus which has been extensively used as a benchmark for evaluating text simplification systems (Wubben et al., 2012; Woodsend and Lapata, 2011; Narayan and Gardent, 2014; Zhu et al., 2010). It contains automatically aligned complex and simple sentences from the ordinary and simple English Wikipedias. The test set consists of 100 complex-simple sentence pairs. The training set contains 89,042 sentence pairs (after removing duplicates and test sentences). We randomly sampled 205 pairs for development and used the remaining sentences for training.

We also constructed *WikiLarge*, a larger Wikipedia corpus by combining previously created simplification corpora. Specifically, we aggregated the aligned sentence pairs in Kauchak (2013), the aligned and revision sentence pairs in Woodsend and Lapata (2011), and Zhu's (2010) WikiSmall dataset described above. We used the development and test sets created in Xu et al. (2016). These are complex sentences taken from WikiSmall paired with simplifications provided by Amazon Mechanical Turk workers. The dataset contains 8 (reference) simplifications for 2,359 sentences partitioned into 2,000 for development and 359 for testing. After removing duplicates and sentences in development and test sets, the resulting training set contains 296,402 sentence pairs.

Our third dataset is *Newsela*, a corpus collated by Xu et al. (2015b) who argue that Wikipedia-based resources are suboptimal due to the automatic sentence alignment which unavoidably introduces errors, and their uniform writing style which leads to systems that generalize poorly. Newsela[2] consists of 1,130 news articles, each rewritten four times by professional editors for children at different grade levels (0 is the most complex level and 4 is simplest). Xu et al. (2015b) provide multiple aligned complex-simple pairs within each article. We removed sentence pairs corresponding to levels 0–1, 1–2, and 2–3, since they were too similar to each other. The first 1,070 documents were used for training (94,208 sentence pairs), the next 30 documents for development (1,129 sentence pairs) and the last 30 documents for testing (1,076 sentence pairs).[3] We are not aware of any published results on this dataset.

Training Details We trained our models on an Nvidia GPU card. We used the same hyper-parameters across datasets. We first trained an encoder-decoder model, and then performed reinforcement learning training (Section 3), and trained the lexical simplification model (Section 4). Encoder-decoder parameters were uniformly initialized to $[-0.1, 0.1]$. We used Adam (Kingma and Ba, 2014) to optimize the model with learning rate 0.001; the first momentum coefficient was set to 0.9 and the second momentum coefficient to 0.999. The gradient was rescaled when the norm exceeded 5 (Pascanu et al., 2013). Both encoder and decoder LSTMs have two layers with 256 hidden neurons in each layer. We regularized all LSTMs with a dropout rate of 0.2 (Zaremba et al., 2014). We initialized the encoder and decoder word embedding matrices with 300 dimensional Glove vectors (Pennington et al., 2014).

During reinforcement training, we used plain stochastic gradient descent with a learning rate of 0.01. We set $\beta = 0.1$, $\lambda_S = 1$, $\lambda_R = 0.25$ and $\lambda_F = 0.5$.[4] Training details for the lexical simplification model are identical to the encoder-decoder model except that word embedding matrices were randomly initialized. The weight of the lexical simplification model was set to $\eta = 0.1$.

To reduce vocabulary size, named entities were tagged with the Stanford CoreNLP (Manning et al., 2014) and anonymized with a NE@N token, where NE $\in \{\text{PER}, \text{LOC}, \text{ORG}, \text{MISC}\}$ and N indicates NE@N is the N-th distinct NE typed entity. For example, "John and Bob are ..." becomes "PER@1 and PER@2 are ...". At test time, we de-anonymize NE@N tokens in the output by looking them up in their source sentences. Note that the de-anonymization may fail, but the chance is small (around 2% of the time on the Newsela development set). We replaced words occurring three times or less in the training set with UNK. At test time, when our models predict UNK, we adopt the UNK replacement method proposed in Jean et al. (2015).

Evaluation Following previous work (Woodsend and Lapata, 2011; Xu et al., 2016) we evaluated system output automatically adopting metrics widely used in the simplification literature. Specifically, we used BLEU[5] (Papineni et al., 2002) to assess the degree to which generated simplifications differed from gold standard references and the Flesch-Kincaid Grade Level index (FKGL; Kincaid et al. 1975) to measure the readability of the output (lower FKGL[6] implies simpler output). In addition, we used SARI (Xu et al., 2016), which evaluates the quality of the output by comparing it against the source and reference simplifications.[7] BLEU, FKGL, and SARI are all measured at corpus-level. We also evaluated system output by eliciting human judgments via Amazon's Mechanical Turk. Specifically (self-reported) native English speakers were asked to rate simplifications on three dimensions: *Fluency* (is the output grammatical and well formed?), *Adequacy* (to what extent is the meaning expressed in the original sentence preserved in the output?) and *Simplicity* (is the output simpler than the original sentence?). All ratings were obtained using a five point Likert scale.

Comparison Systems We compared our model against several systems previously proposed in the literature. These include PBMT-R, a mono-

[2] https://newsela.com

[3] If a sentence has multiple references in the development or test set, we use the reference with highest simplicity level.

[4] Weights were tuned on the development set of the Newsela dataset and kept fixed for the other two datasets.

[5] With the default mteval-v13a.pl settings.

[7] We used he implementation of SARI in Xu et al. (2016).

Newsela	BLEU	FKGL	SARI
PBMT-R	18.19	7.59	15.77
Hybrid	14.46	**4.01**	**30.00**
EncDecA	21.70	5.11	24.12
Dress	23.21	4.13	27.37
Dress-Ls	**24.30**	4.21	26.63

WikiSmall	BLEU	FKGL	SARI
PBMT-R	46.31	11.42	15.97
Hybrid	**53.94**	9.20	**30.46**
EncDecA	47.93	11.35	13.61
Dress	34.53	**7.48**	27.48
Dress-Ls	36.32	7.55	27.24

WikiLarge	BLEU	FKGL	SARI
PBMT-R	81.11	8.33	38.56
Hybrid	48.97	**4.56**	31.40
SBMT-SARI	73.08	7.29	**39.96**
EncDecA	**88.85**	8.41	35.66
Dress	77.18	6.58	37.08
Dress-Ls	80.12	6.62	37.27

Table 1: Automatic evaluation on Newsela, WikiSmall, and WikiLarge test sets.

lingual phrase-based machine translation system with a reranking post-processing step[8] (Wubben et al., 2012) and Hybrid, a model which first performs sentence splitting and deletion operations over discourse representation structures and then further simplifies sentences with PBMT-R (Narayan and Gardent, 2014). Hybrid[9] is state of the art on the WikiSmall dataset. Comparisons with SBMT-SARI, a syntax-based translation model trained on PPDB (Ganitkevitch et al., 2013) and tuned with SARI (Xu et al., 2016), are problematic due to the size of PPDB which is considerably larger than any of the datasets used in this work (it contains 106 million sentence pairs with 2 billion words). Nevertheless, we compare[10] against SBMT-SARI, but only models trained on Wikilarge, our largest dataset.

6 Results

Since Newsela contains high quality simplifications created by professional editors, we performed the bulk of our experiments on this dataset. Specifically, we set out to answer two questions: (a) which neural model performs best and (b) how do neural models which are resource lean and do not have access to linguistic annotations fare against more traditional systems. We therefore compared the basic attention-based encoder-decoder model (EncDecA), with the deep reinforcement learning model (Dress; Section 3), and a linear combination of Dress and the lexical simplification model (Dress-Ls; Section 4). Neural models were further compared against two strong baselines, PBMT-R and Hybrid. Table 3 shows example output of all models on the Newsela dataset.

Newsela	Fluency	Adequacy	Simplicity	All
PBMT-R	3.56	**3.58****	2.09**	3.08**
Hybrid	2.70**	2.51**	2.99	2.73**
EncDecA	3.63	2.99	2.56**	3.06**
Dress	3.65	2.94	**3.10**	3.23
Dress-Ls	**3.71**	3.07	3.04	**3.28**
Reference	3.90	2.81**	3.42**	3.38

WikiSmall	Fluency	Adequacy	Simplicity	All
PBMT-R	3.91	**3.74****	2.80**	3.48*
Hybrid	3.26**	3.42	2.82**	3.17**
Dress-Ls	**3.92**	3.36	**3.55**	**3.61**
Reference	3.74*	3.34	3.13**	3.41**

WikiLarge	Fluency	Adequacy	Simplicity	All
PBMT-R	3.68	**3.63***	2.70**	3.34*
Hybrid	2.60**	2.42**	**3.52**	2.85**
SBMT-SARI	3.34**	3.51*	2.77**	3.21**
Dress-Ls	**3.70**	3.28	3.42	**3.46**
Reference	3.79	3.72**	2.86**	3.46

Table 2: Mean ratings elicited by humans on Newsela, WikiSmall, and WkiLarge test sets. Ratings significantly different from Dress-Ls are marked with * ($p < 0.05$) and ** ($p < 0.01$). Significance tests were performed using a student t-test.

The top block in Table 1 summarizes the results of our automatic evaluation. As can be seen, all neural models obtain higher BLEU, lower FKGL and higher SARI compared to PBMT-R. Hybrid has the lowest FKGL and highest SARI. Compared to EncDecA, Dress scores lower on FKGL and higher on SARI, which indicates that the model has indeed learned to optimize the reward function which includes SARI. Integrating lexical simplification (Dress-Ls) yields better BLEU, but slightly worse FKGL and SARI.

The results of our human evaluation are presented in the top block of Table 2. We elicited judgments for 100 randomly sampled test sentences. Aside from comparing system output (PBMT-R, Hybrid, EncDecA, Dress, and Dress-Ls), we also elicited ratings for the gold standard Reference as an upper bound. We report results for Fluency, Adequacy, and Simplicity individually and in combination (All is the average rating of the three dimensions). As can be seen, Dress and Dress-Ls outperform PBMT-R and

[8] We made a good-faith effort to re-implement their system following closely the details in Wubben et al. (2012).

[9] We are grateful to Shashi Narayan for running his system on our three datasets.

[10] The output of SBMT-SARI is publicly available.

Complex	There’s just one major hitch: the primary purpose of education is to develop citizens with a wide variety of skills.
Reference	The purpose of education is to develop a wide range of skills.
PBMT-R	It’s just one major hitch: the purpose of education is to **make people** with a wide variety of skills.
Hybrid	one hitch the purpose is to develop citizens.
EncDecA	The **key** of education is to develop **people** with a wide variety of skills.
Dress	There’s just one major hitch: the **main goal** of education is to develop **people** with **lots of** skills.
Dress-Ls	There’s just one major hitch: the **main goal** of education is to develop citizens with **lots of** skills.
Complex	“They were so burdened by the past they couldn’t think about the future,” said Barnet, 62, who was president of Columbia Records, the No.1 record label in the United States, before joining Capitol.
Reference	Capitol was stuck in the past. It could not think about the future, Barnett said.
PBMT-R	“They were so **affected** by the past they couldn’t think about the future,” said Barnett, 62, was president of Columbia Records, before joining Capitol **building**.
Hybrid	‘They were so burdened by the past they couldn’t think about the future,” said Barnett, 62, who was Columbia Records, president of the No.1 record label in the united states, before joining Capitol.
EncDecA	“They were so burdened by the past they couldn’t think about the future,” said Barnett, who was president of Columbia Records, the No.1 record labels in the United States.
Dress	“They were so **sicker** by the past they couldn’t think about the future,” said Barnett, who was president of Columbia Records.
Dress-Ls	“They were so burdened by the past they couldn’t think about the future,” said Barnett, who was president of Columbia Records.

Table 3: System output for two sentences (Newsela development set). Substitutions are shown in bold.

Hybrid on Fluency, Simplicity, and overall. The fact that neural models (EncDecA, Dress and Dress-Ls) fare well on Fluency, is perhaps not surprising given the recent success of LSTMs in language modeling and neural machine translation (Zaremba et al., 2014; Jean et al., 2015).

Neural models obtain worse ratings on Adequacy but are closest to the human references on this dimension. Dress-Ls (and Dress) are significantly better ($p < 0.01$) on Simplicity than EncDecA, PBMT-R, and Hybrid which indicates that our reinforcement learning based model is effective at creating simpler output. Combined ratings (All) for Dress-Ls are significantly different compared to the other models but not to Dress and the Reference. Nevertheless, integration of the lexical simplification model boosts performance as ratings increase almost across the board (Simplicity is slightly worse). Returning to our original questions, we find that neural models are more fluent than comparison systems, while performing non-trivial rewrite operations (see the SARI scores in Table 1) which yield simpler output (see the Simplicity column in Table 2). Based on our judgment elicitation study, neural models trained with reinforcement learning perform best, with Dress-Ls having a slight advantage.

We further analyzed model performance by computing various statistics on the simplified output. We measured average sentence length and the degree to which Dress and comparison systems perform rewriting operations. We approximated the latter with Translation Error Rate (TER; Snover et al. 2006), a measure commonly used to automatically evaluate the quality of machine translation output. We used TER to compute the (average) number of edits required to change an original complex sentence to simpler output. We also report the number of edits by type, i.e., the number of insertions, substitutions, deletions, and shifts needed (on average) to convert complex to simple sentences.

As shown in Table 4, Hybrid obtains the highest TER, followed by our models (Dress and

Models	Len	TER	Ins	Del	Sub	Shft
PBMT-R	23.1	0.13	0.68	0.68	1.50	0.09
Hybrid	12.4	0.90	0.01	10.19	0.12	0.41
EncDecA	17.0	0.36	0.13	5.96	1.69	0.09
Dress	14.2	0.46	0.07	8.53	1.37	0.11
Dress-Ls	14.4	0.44	0.07	8.38	1.11	0.09
Reference	12.7	0.67	0.40	10.26	3.44	0.73

Table 4: Output length (average number of tokens), TER scores and number of edits by type (Ins*ertions*, Del*etions*, Sub*stitutions*, Sh*i*ft*s*) on the Newsela test set. Higher TER means that more rewriting operations are performed.

Dress-Ls), which indicates that they actively perform rewriting. Perhaps Hybrid is too aggressive when simplifying a sentence, it obtains low Fluency and Adequacy scores in human evaluation (Table 2). There is a strong correlation between sentence length and number of deletion operations (i.e., more deleteions lead to shorter sentences) and PBMT-R performs very few deletions. Overall, reinforcement learning encourages deletion (see Dress and Dress-Ls), while performing a reasonable amount of additional operations (e.g., substitutions and shifts) compared to EncDecA and PBMT-R.

The middle blocks in Tables 1 and 2 report results on the WikiSmall dataset. FKGL and SARI follow a similar pattern as on Newsela. BLEU scores for PBMT-R, Hybrid, and EncDecA are much higher compared to Dress and Dress-Ls. Hybrid obtains best BLEU and SARI scores, while Dress and Dress-Ls do very well on FKGL. In human evaluation, we elicited judgments on the entire WikiSmall test set (100 sentences). We compared Dress-Ls, with PBMT-R, Hybrid, and gold standard Reference simplifications. As human experiments are time consuming and expensive, we did not include other neural models besides Dress-Ls based on our Newsela study which showed that EncDecA is inferior to variants trained with reinforcement learning and that Dress-Ls is the better performing model (however, we do compare *all* models in Table 1). Dress-Ls is significantly better on Simplicity than PBMT-R, Hybrid, and the Reference. It performs on par with PBMT-R on Fluency and worse on Adequacy (but still closer to the human Reference than PBMT-R or Hybrid). When combining all ratings (All in Table 2), Dress-Ls is significantly better than PBMT-R, Hybrid, and the Reference.

The bottom blocks in Tables 1 and 2 report results on Wikilarge. We compared our models with PBMT-R, Hybrid, and SBMT-SARI (Xu et al., 2016). The FKGL follows a similar pattern as in the previous datasets. PBMT-R and our models are best in terms of BLEU while SBMT-SARI outperforms all other systems on SARI.[11] Because there are 8 references for each complex sentence in the test set, BLEU scores are much higher compared to Newsela and WikiSmall. In human evaluation, we again elicited judgments for 100 randomly sampled test sentences. We randomly selected one of the 8 references as the Reference upper bound. On Simplicity, Dress-Ls is significantly better than all comparison systems, except Hybrid. On Adequacy, it is better than Hybrid but significantly worse than other comparison systems. On Fluency, it is on par with PBMT-R[12] but better than Hybrid and SBMT-SARI. On All dimension Dress-Ls significantly outperforms all comparison systems.

7 Conclusions

We developed a reinforcement learning-based text simplification model, which can jointly model simplicity, grammaticality, and semantic fidelity to the input. We also proposed a lexical simplification component that further boosts performance. Overall, we find that reinforcement learning offers a great means to inject prior knowledge to the simplification task achieving good results across three datasets. In the future, we would like to explicitly model sentence splitting and simplify entire documents (rather than individual sentences). Beyond sentence simplification, the reinforcement learning framework presented here is potentially applicable to generation tasks such as sentence compression (Chopra et al., 2016), generation of programming code (Ling et al., 2016), or poems (Zhang and Lapata, 2014).

Acknowledgments We would like to thank Li Dong, Jianpeng Cheng, Shashi Narayan and the EMNLP reviewers for their valuable feedback. We are also grateful to Shashi Narayan for supplying us with the output of his system and Wei Xu for her help with this work. The authors acknowledge the support of the European Research Council (award number 681760).

[11] BLEU and SARI scores reported in Xu et al. (2016) are 72.36 and 37.91, and measured at sentence-level.

[12] We used more data to train PBMT-R and maybe that is why PBMT-R performs better than Xu et al. (2016) reported.

Abstract

Active learning aims to select a small subset of data for annotation such that a classifier learned on the data is highly accurate. This is usually done using heuristic selection methods, however the effectiveness of such methods is limited and moreover, the performance of heuristics varies between datasets. To address these shortcomings, we introduce a novel formulation by reframing the active learning as a reinforcement learning problem and explicitly learning a data selection policy, where the policy takes the role of the active learning heuristic. Importantly, our method allows the selection policy learned using simulation on one language to be transferred to other languages. We demonstrate our method using cross-lingual named entity recognition, observing uniform improvements over traditional active learning.

1 Introduction

For most Natural Language Processing (NLP) tasks, obtaining sufficient annotated text for training accurate models is a critical bottleneck. Thus active learning has been applied to NLP tasks to minimise the expense of annotating data (Thompson et al., 1999; Tong and Koller, 2001; Settles and Craven, 2008). Active learning aims to reduce cost by identifying a subset of unlabelled data for annotation, which is selected to maximise the accuracy of a supervised model trained on the data (Settles, 2010). There have been many successful applications to NLP, e.g., Tomanek et al. (2007) used an active learning algorithm for CoNLL corpus to get an F_1 score 84% with a reduction of annotation cost of about 48%. In prior work most active learning algorithms are designed for English based on heuristics, such as using uncertainty or informativeness. There has been comparatively little work done about how to learn the active learning strategy itself.

It is no doubt that active learning is extremely important for other languages, particularly low-resource languages, where annotation is typically difficult to obtain, and annotation budgets more modest (Garrette and Baldridge, 2013). Such settings are a natural application for active learning, however there is little work to this end. A potential reason is that most active learning algorithms require a substantial 'seed set' of data for learning a basic classifier, which can then be used for active data selection. However, given the dearth of data in the low-resource setting, this assumption can make standard approaches infeasible.

In this paper,[1] we propose PAL, short for *Policy based Active Learning*, a novel approach for learning a dynamic active learning strategy from data. This allows for the strategy to be applied in other data settings, such as cross-lingual applications. Our algorithm does not use a fixed heuristic, but instead learns how to actively select data, formalised as a reinforcement learning (RL) problem. An intelligent agent must decide whether or not to select data for annotation in a streaming setting, where the decision policy is learned using a deep Q-network (Mnih et al., 2015). The policy is informed by observations including sentences' content information, the supervised model's classifications and its confidence. Accordingly, a rich and dynamic policy can be learned for annotating new data based on the past sequence of annotation decisions.

Furthermore, in order to reduce the dependence on the data in the target language, which may be low resource, we first learn the policy of active

learning on another language and then transfer it to the target language. It is easy to learn a policy on a high resource language, where there is plentiful data, such as English. We use cross-lingual word embeddings to learn compatible data representations for both languages, such that the learned policy can be easily ported into the other language.

Our work is different for prior work in active learning for NLP. Most previous active learning algorithms developed for NER tasks is based on one language and then applied to the language itself. Another main difference is that many active learning algorithms use a fixed data selection heuristic, such as uncertainty sampling (Settles and Craven, 2008; Stratos and Collins, 2015; Zhang et al., 2016). However, in our algorithm, we implicitly use uncertainty information as one kind of observations to the RL agent.

The remainder of this paper is organised as follows. In Section 2, we briefly review some related work. In Section 3, we present active learning algorithms, which cross multiple languages. The experimental results are presented in Section 4. We conclude our work in Section 5.

2 Related work

As supervised learning methods often require a lot of training data, active learning is a technique that selects a subset of data to annotate for training the best classifier. Existing active learning (AL) algorithms can be generally considered as three categories: 1) uncertainty sampling (Lewis and Gale, 1994; Tong and Koller, 2001), which selects the data about which the current classifier is the most uncertain; 2) query by committee (Seung et al., 1992), which selects the data about which the "committee" disagree most; and 3) expected error reduction (Roy and McCallum, 2001), which selects the data that can contribute the largest model loss reduction for the current classifier once labelled. Applications of active learning to NLP include text classification (McCallumzy and Nigamy, 1998; Tong and Koller, 2001), relation classification (Qian et al., 2014), and structured prediction (Shen et al., 2004; Settles and Craven, 2008; Stratos and Collins, 2015; Fang and Cohn, 2017). Qian et al. used uncertainty sampling to jointly perform on English and Chinese. Stratos and Collins and Zhang et al. deployed uncertainty-based AL algorithms for languages with the minimal supervision.

Deep reinforcement learning (DRL) is a general-purpose framework for decision making based on representation learning. Recently, there are some notable examples include deep Q-learning (Mnih et al., 2015), deep visuomotor policies (Levine et al., 2016), attention with recurrent networks (Ba et al., 2015), and model predictive control with embeddings (Watter et al., 2015). Other important works include massively parallel frameworks (Nair et al., 2015), dueling architecture (Wang et al., 2016) and expert move prediction in the game of Go (Maddison et al., 2015), which produced policies matching those of the Monte Carlo tree search programs, and squarely beaten a professional player when combined with search (Silver et al., 2016). DRL has been also studied in NLP tasks. For example, recently, DRL has been studied for information extraction problem (Narasimhan et al., 2016). They designed a framework that can decide to acquire external evidence and the framework is under the reinforcement learning method. However, there has been fairly little work on using DRL to learn active learning strategies for language processing tasks, especially in cross-lingual settings.

Recent deep learning work has also looked at transfer learning (Bengio, 2012). More recent work in deep learning has also considered transferring policies by reusing policy parameters between environments (Parisotto et al., 2016; Rusu et al., 2016), using either regularization or novel neural network architectures, though this work has not looked at transfer active learning strategies between languages with shared feature space in state.

3 Methodology

We now show how active learning can be formalised as as a decision process, and then show how this allows for the active learning selection policy to be learned from data using deep reinforcement learning. Later we introduce a method for transferring the policy between languages.

3.1 Active learning as a decision process

Active learning is a simple technique for labelling data, which involves first selecting some instances from an unlabelled dataset, which are then annotated by a human oracle, which is then repeated many times until a termination criterion is satisfied, e.g., the annotation budget is exhausted. Most often the selection function is based on the predictions of a trained model, which has been fit to the labelled dataset at each stage in the algorithm, where datapoints are selected based on the model's predictive uncertainty (Lewis and Gale, 1994), or divergence in predictions over an ensemble (Seung et al., 1992). The key idea of these methods is to find the instances on which the model is most likely to make errors, such that after their labelling and inclusion in the training set, the model becomes more robust to these types of errors on unseen data.

The steps in active learning can be viewed as a decision process, a means of formalising the active learning algorithm as a sequence of decisions, where the stages of active learning correspond to the state of the system. Accordingly, the *state* corresponds to the selected data for labelling and their labels, and each step in the active learning algorithm corresponds to a selection *action*, wherein the heuristic selects the next items from a pool. This process terminates when the budget is exhausted.

Effectively the active learning heuristic is operating as a decision *policy*, a form of function taking as input the current state — comprising the labelled data, from which a model is trained — and a candidate unlabelled data point — e.g., the model uncertainty. This raises the opportunity to consider general policy functions, based on the state and data point inputs, and resulting in a labelling decision, and, accordingly a mechanism for learning such functions from data. We now elaborate on the components of this process, namely the formulation of the decision process, architecture of the policy function, and means of learning the decision policy automatically from data.

3.2 Stream-based learning

For simplicity, we make a streaming assumption, whereby unlabelled data (sentences) arrive in a stream (Lewis and Gale, 1994).[2] As each instance arrives, an agent must decide the action to take, namely whether or not the instance should be manually annotated. This process is illustrated in Figure 1, which illustrates the space of decision sequences for a small corpus. As part of this process, a separate model, p_ϕ, is trained on the labelled data, and updated accordingly as the labelled dataset is expanded as new annotations arrive. This model is central to the policy for choosing the labelling actions at each stage, and for determining the reward for a sequence of actions.

terminate
terminate

Figure 1: Example illustrating sequential active learning as a Markov Decision process. Data arrives sequentially, and at each time the active learning policy, π, must decide whether it should be labelled or not, based on the state which includes a predictive model parameterised by ϕ, and an unlabelled data instance $\mathbf{x}$. The process continues until termination, e.g., when the annotation budget is exhausted. The solid green path shows the maximum scoring decision sequence.

This is a form of Markov Decision Process (MDP), which allows the learning of a policy that can dynamically select instances that are most informative. As illustrated in Figure 1 at each time, the agent observes the current state s_i which includes the sentence $\mathbf{x}_i$, and the learned model ϕ. The agent selects a binary action a_i, denoting whether to label $\mathbf{x}_i$, according to the policy π. For $a_i = 1$, the corresponding sentence is labelled and added to the labelled data, and the model p_ϕ updated to include this new training point. The process then repeats, terminating when either the dataset is exhausted or a fixed annotation budget is reached. After termination a reward is computed based on the accuracy of the final model, ϕ. We represent the MDP framework as a tuple $\langle S, A, Pr(s_{i+1}|s_i, a), R\rangle$, where $S = \{s\}$ is the space of all possible states, $A = \{0, 1\}$ is the set of actions, $R(s, a)$ is the reward function, and $Pr(s_{i+1}|s_i, a)$ is the transition function.

[2] This is different to pool-based active learning, where one of several options is chosen for annotation. Our setup permits simpler learning, while remaining sufficiently general.

3.2.1 State

The state at time i comprises the candidate instance being considered for annotation and the labelled dataset constructed in steps $1 \ldots i$. We represent the state using a continuous vector, using the concatenation of the vector representation of $\mathbf{x}_i$, and outputs of the model p_ϕ trained over the labelled data. These outputs use both the predictive marginal distributions of the model on the instance, and a representation of the model's confidence. We now elaborate on each component.

Content representation A key input to the agent is the content of the sentence, $\mathbf{x}_i$, which we encode using a convolutional neural network to arrive at a fixed sized vector representation, following Kim (2014). This involves embedding each of the n words in the sentence to produce a matrix $X_i = \{x_{i,1}, x_{i,2}, \cdots, x_{i,n}\}$, after which a series of wide convolutional filters is applied, using multiple filters with different gram sizes. Each filter uses a linear transformation with a rectified linear unit activation function. Finally the filter outputs are merged using a max-pooling operation to yield a hidden state $\mathbf{h}_c$, which is used to represent the sentence.

Representation of marginals The prediction outputs of the training model, $p_\phi(\mathbf{y}|\mathbf{x}_i)$, are central to all active learning heuristics, and accordingly, we include this in our approach. In order to generalise existing techniques, we elect to use the predictive marginals directly, rather than only using statistics thereof, e.g., entropy. This generality allows for different and more nuanced concepts to be learned, including patterns of probabilities that span several adjacent positions in the sentence (e.g., the uncertainty about the boundary of a named entity).

We use another convolutional neural network to process the predictive marginals, as shown in Figure 2. The convolutional layer contains j filters with ReLU activation, based on a window of width 3 and height equal to the number of classes, and with a stride of one token. We use a wide convolution, by padding the input matrix to either size with vectors of zeros. These j feature maps are then subsampled with mean pooling, such that the network is easily able to capture the average uncertainty in each window. The final hidden layer $\mathbf{h}_e$ is used to represent the predictive marginals.

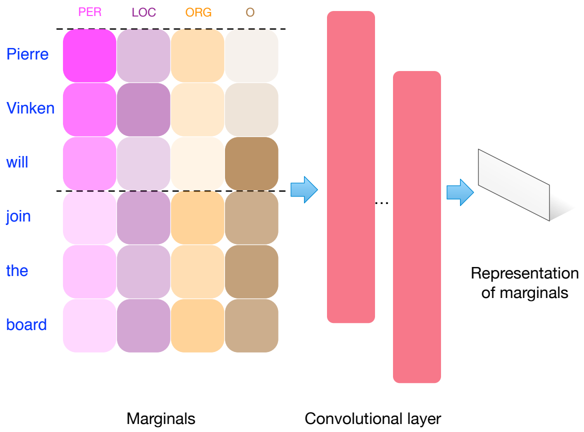

Figure 2: The architecture for representing predictive marginal distributions, $p_\phi(\mathbf{y}|\mathbf{x}_i)$, as a fixed dimensional vector, to form part of the MDP state.

Confidence of sequential prediction The last component is a score C which indicates the confidence of the model prediction. This is defined based on the most probable label sequence under the model, e.g., using Viterbi algorithm with a CRF, and the probability of this sequence is used to represent the confidence, $C = \sqrt[n]{\max_{\mathbf{y}} p_\phi(\mathbf{y}|\mathbf{x}_i)}$, where $n = |\mathbf{x}_i|$ is the length of the sentence.

3.2.2 Action

We now turn to the action, which denotes whether the human oracle must annotate the current sentence. The agent selects either to annotate $\mathbf{x}_i$, in which case $a_i = 1$, or not, with $a_i = 0$, after which the agent proceeds to consider the next instance, $\mathbf{x}_{i+1}$. When action $a_i = 1$ is chosen, an oracle is requested to annotate the sentence, and the newly annotated sentence is added to the training data, and ϕ updated accordingly. A special 'terminate' option applies when no further data remains or the annotation budget is exhausted, which concludes the active learning run (referred to as an 'episode' or 'game' herein).

3.2.3 Reward

The training signal for learning the policy takes the form of a scalar 'reward', which provides feedback on the quality of the actions made by the agent. The most obvious reward is to wait for a game to conclude, then measure the held-out performance of the model, which has been trained on the labelled data. However, this reward is delayed, and is difficult to related to individual actions after a long game. To compensate for this, we use reward shaping, whereby small intermediate rewards are assigned which speeds up the learning process (Ng, 2003; Lample and Chaplot, 2016). At each step, the intermediate reward is defined as the change in held-out performance, i.e., $R(s_{i-1}, a) = \text{Acc}(\phi_i) - \text{Acc}(\phi_{i-1})$, where Acc denotes predictive accuracy (here F1 score), and ϕ_i is the trained model after action a has take place, which may include an additional training instance. Accordingly, when considering the aggregate reward over a game, the intermediate terms cancel, such that the total reward measures the performance improvement over the whole game. Note that the value of $R(s, a)$ can be positive or negative, indicating a beneficial or detrimental effect on the performance.

3.2.4 Budget

There is a fixed budget $\mathcal{B}$ for the total number of instances annotated, which corresponds to the terminal state in the MDP. It is a predefined number and chosen according to time and cost constraints. A game is finished when the data is exhausted or the budget reached, and with the final result being the dataset thus created, upon which the final model is trained.

3.2.5 Reinforcement learning

The remaining question is how the above components can be used to *learn* a good policy. Different policies make different data selections, and thus result in models with different performance. We adopt a reinforcement learning (RL) approach to learn a policy resulting a highly accurate model.

Having represented the problem as a MDP, episode as a sequence of transitions (s_i, a, r, s_{i+1}). One episode of active learning produces a finite sequence of states, actions and rewards. We use a deep Q-learning approach (Mnih et al., 2015), which formalises the policy using function $Q^\pi(s, a) \to \mathcal{R}$ which determines the utility of taking a from state s according to a policy π. In Q-learning, the agent iteratively updates $Q(s, a)$ using rewards obtained from each episode, with updates based on the recursive Bellman equation for the optimal Q:

$$Q^\pi(s, a) = \mathbb{E}[R_i | s_i = s, a_i = a, \pi]. \quad (1)$$

Here, $R_i = \sum_{t=i}^{T} \gamma^{t-i} r_t$ is the discounted future reward and $\gamma \in [0, 1]$ is a factor discounting the value of future rewards and the expectation is taken over all transitions involving state s and action a.

Algorithm 1 Learn an active learning policy

```
Input: data $\mathcal{D}$, budget $\mathcal{B}$
Output: $\pi$
for episode = $1, 2, \ldots, N$ do
    $\mathcal{D}_l \leftarrow \emptyset$ and shuffle $\mathcal{D}$
    $\phi \leftarrow$ Random
    for $i \in \{0, 1, 2, \ldots, |\mathcal{D}|\}$ do
        Construct the state $s_i$ using $\mathbf{x}_i$
        The agent makes a decision according to
        $a_i = \arg\max Q^\pi(s_i, a)$
        if $a_i = 1$ then
            Obtain the annotation $\mathbf{y}_i$
            $\mathcal{D}_l \leftarrow \mathcal{D}_l + (\mathbf{x}_i, \mathbf{y}_i)$
            Update model $\phi$ based on $\mathcal{D}_l$
        end if
        Receive a reward $r_i$ using held-out set
        if $|\mathcal{D}_l| = \mathcal{B}$ then
            Store $(s_i, a_i, r_i, \text{Terminate})$ in $\mathcal{M}$
            Break
        end if
        Construct the new state $s_{i+1}$
        Store transition $(s_i, a_i, r_i, s_{i+1})$ in $\mathcal{M}$
        Sample random minibatch of transitions
        $\{(s_j, a_j, r_j, s_{j+1})\}$ from $\mathcal{M}$, and per-
        form gradient descent step on $\mathcal{L}(\theta)$
        Update policy $\pi$ with $\theta$
    end for
end for
return the latest policy $\pi$
```

Following Deep Q-learning (Mnih et al., 2015), we make use of a deep neural network to compute the expected Q-value, in order to update the parameters. We implement the Q-function using a single hidden layer neural network, taking as input the state representation $(\mathbf{h}_c, \mathbf{h}_e, C)$ (defined in §3.2.1), and outputting two scalar values corresponding to the values $Q(s, a)$ for $a \in \{0, 1\}$. This network uses a rectified linear unit (ReLU) activation function in its hidden layer.

The parameters in the DQN are learnt using stochastic gradient descent, based on a regression objective to match the Q-values predicted by the DQN and the expected Q-values from the Bellman equation, $r_i + \gamma \max_a Q(s_{i+1}, a; \theta)$. Following (Mnih et al., 2015), we use an experience replay memory $\mathcal{M}$ to store each transition (s, a, r, s') as it is used in an episode, after which

Algorithm 2 Active learning by policy transfer

```
Input: unlabelled data $\mathcal{D}$, budget $\mathcal{B}$, policy $\pi$
Output: $\mathcal{D}_l$
$\mathcal{D}_l \leftarrow \emptyset$
$\phi \leftarrow$ Random
for $|\mathcal{D}_l| \neq \mathcal{B}$ and $\mathcal{D}$ not empty do
    Randomly sample $\mathbf{x}_i$ from the data pool $\mathcal{D}$ and construct the state $s_i$
    The agent chooses an action $a_i$ according to $a_i = \arg\max Q^{\pi}(s_i, a)$
    if $a_i = 1$ then
        Obtain the annotation $\mathbf{y}_i$
        $\mathcal{D}_l \leftarrow \mathcal{D}_l + (\mathbf{x}_i, \mathbf{y}_i)$
        Update model $\phi$ based on $\mathcal{D}_l$
    end if
    $\mathcal{D} \leftarrow \mathcal{D} \backslash \mathbf{x}_i$
    Receive a reward $r_i$ using held-out set
    Update policy $\pi$
end for
return $\mathcal{D}_l$
```

we sample a mini-batch of transitions from the memory and then minimize the loss function:

$$\mathcal{L}(\theta) = \mathbb{E}_{s,a,r,s'}\left[\left(y_i(r,s') - Q(s,a;\theta)\right)^2\right], \quad (2)$$

where $y_i(r,s') = r + \gamma \max_{a'} Q(s',a';\theta_{i-1})$ is the target Q-value, based on the current parameters θ_{i-1}, and the expectation is over the mini-batch. Learning updates are made every training step, based on stochastic gradient descent to minimise Eq. 2 w.r.t. parameters θ.

The algorithm for learning is summarised in Algorithm 1. We train the policy by running multiple active learning episodes over the training data, where each episode is a simulated active learning run. For each episode, we shuffle the data, and hide the known labels, which are revealed as requested during the run. A disjoint held-out set is used to compute the reward, i.e., model accuracy, which is fixed over the episodes. Between each episode the model is reset to its initialisation condition, with the main changes being the different (random) data ordering and the evolving policy function.

3.3 Cross-lingual policy transfer

We now turn to the question of how the learned policy can be applied to another dataset. Given the extensive use of the training dataset, the policy application only makes sense when employed in a different data setting, e.g., where the domain, task or language is different. For this paper, we consider a cross-lingual application of the same task (NER), where we train a policy on a source language (e.g., English), and then transfer the learned policy to a different target language. Cross-lingual word embeddings provide a common shared representation to facilitate application of the policy to other languages.

Algorithm 3 Active learning by policy *and* model transfer, for 'cold-start' scenario

```
Input: unlabelled data $\mathcal{D}$, budget $\mathcal{B}$, policy $\pi$, model $\phi$
Output: $\mathcal{D}_l$
$\mathcal{D}_l \leftarrow \emptyset$
for $|\mathcal{D}_l| \neq \mathcal{B}$ and $\mathcal{D}$ not empty do
    Randomly sample $\mathbf{x}_i$ from the data pool $\mathcal{D}$ and construct the state $s_i$
    The agent chooses an action $a_i$ according to $a_i = \arg\max Q^{\pi}(s_i, a)$
    if $a_i = 1$ then
        $\mathcal{D}_l \leftarrow \mathcal{D}_l + (\mathbf{x}_i, -)$
    end if
    $\mathcal{D} \leftarrow \mathcal{D} \backslash \mathbf{x}_i$
end for
Obtain all the annotations for $\mathcal{D}_l$
return $\mathcal{D}_l$
```

We illustrate the policy transfer algorithm in Algorithm 2. This algorithm is broadly similar to Algorithm 1, but has two key differences. Firstly, Algorithm 2 makes only one pass over the data, rather than several passes, as befits an application to a low-resource language where oracle labelling is costly. Secondly, the algorithm also assumes an initial policy, π, which is fine tuned during the episode based on held-out performance such that the policy can adapt to the test scenario.[3]

3.4 Cold-start transfer

The above transfer algorithm has some limitations, which may not be realistic for low-resource settings: the requirement for held-out evaluation data and the embedding of the oracle annotator inside the learning loop. The former implies more supervision than is ideal in a low-resource setting,

[3] Moreover, the algorithm can be extended to a traditional batch setting by evaluating a batch of data instances and selectinag the best k instances for labelling under the policy. This could be applied in either the transfer step (Algorithm 2) or initial policy training (Algorithm 1), or both.

while the latter places limitations on the communication with annotator as well as a necessity for real-time processing, both which are unlikely in a field linguistics setting.

For this data and- communication-impoverished setting, denoted as *cold-start*, we allow only one chance to request labels for the target data, and, having no held-out data, do not allow policy updates. The agent needs to select a batch of unlabelled target instances for annotations, but cannot use these resulting annotations or any other feedback to refine the selection. In this, more difficult cold-start setting, we bootstrap the process with an initial model, such that the agent can make informative decisions in the absence of feedback.

The procedure is outlined in Algorithm 3. Using the cross-lingual word embeddings, we transfer both a policy and a model into the target language. The model, ϕ, is trained on one source language, and the policy is learned on a different source language. Policy learning uses Alg 1, with the small change that in step 3 the model is initialised using ϕ. Consequently the learned policy can exploit the knowledge from cross-lingual initialisation, such that it can figure out which aspects that need to be corrected using target annotated data. Overall this allows for estimates and confidence values to be produced by the model, thus providing the agent with sufficient information for data selection.

4 Experiments

We conduct experiments to validate the proposed active learning method in a cross-lingual setting, whereby an active learning policy trained on a source language is transferred to a target language. We allow repeated active learning simulations on the source language, where annotated corpora are plentiful, to learn a policy, while for target languages we only permit a single episode, to mimic a language without existing resources.

We use NER corpora from CoNLL2002/2003 shared tasks,[4] which comprise NER annotated text in English (en), German (de), Spanish (es), and Dutch (nl), each annotated using the IOB1 labelling scheme, which we convert to the IO labeling scheme. We use the existing corpus partions, with `train` used for policy training, `testb` used as held-out for computing rewards, and final results are reported on `testa`.

Bilingual		Multilingual		Cold-start		
tgt	**src**	**tgt**	**src**	**tgt**	**src**	**pre**
de	en	de	en,nl,es	de	nl	en
nl	en	nl	en,de,es	nl	de	en
es	en	es	en,de,nl	es	de	en
-	-	-	-	de	es	en
-	-	-	-	nl	es	en
-	-	-	-	es	nl	en

Table 1: Experimental configuration for the three settings, showing target language (**tgt**), source language (**src**) as used for policy learning, and language used for pre-training the model (**pre**).

We consider three experimental conditions, as illustrated in Table 1:

bilingual where English is the source (used for policy learning) and we vary the target language;

multilingual where several source languages are the used in joint learning of the policy, and a separate language is used as target; and

cold-start where a pretrained English NER tagger is used to initialise policy learning on a source language, and in cold-start application to a separate target language.

Configuration We now outline the parameter settings for the experimental runs. For learning an active learning policy, we run $N = 10,000$ episodes with budget $\mathcal{B} = 200$ sentences using Alg. 1. Content representations use three convolutional filters of size $3, 4$ and 5, using 128 filters for each size, while for predictive marginals, the convolutional filters are of width 3, using 20 filters. The size of the last hidden layer is 256. The discount factor is set to $\gamma = 0.99$. We used the ADAM algorithm with mini-batches of size 32 for training the neural network. To report performance, we apply the learned policy to the target training set (using Alg. 2 or 3, again with budget 200),[5] after which we use the final trained model for which we report F_1 score.

For word embeddings, we use off the shelf CCA trained multilingual embeddings (Ammar et al.,

[4] http://www.cnts.ua.ac.be/conll2002/ner/, http://www.cnts.ua.ac.be/conll2003/ner/

[5] Although it is possible the policy may learn not to use the full budget, this does not occur in practise.

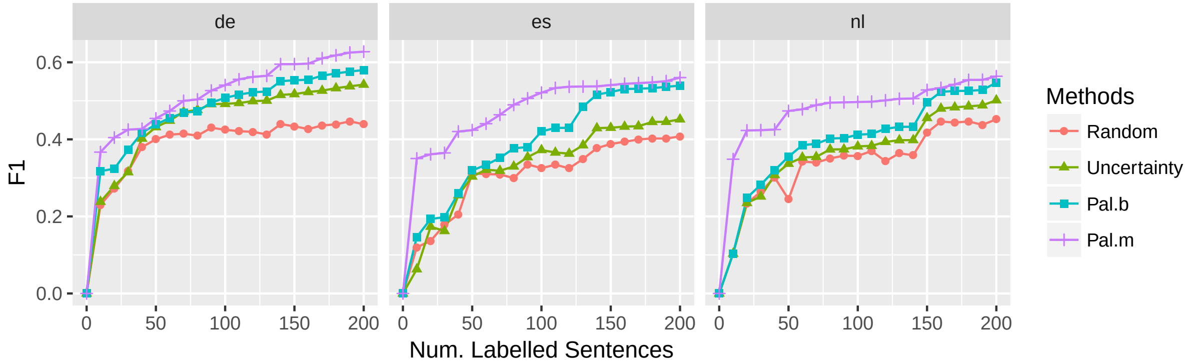

Figure 3: The performance of active learning methods on the bilingual and multilingual settings for three target languages, whereby the active learning policy is trained on only en, or all other languages excluding the target, respectively.

2016),[6] using a 40 dimensional embedding and fixing these during training of both the policy and model. As the model, we use a standard linear chain CRF (Lafferty et al., 2001) for the first two sets of experiments, while for cold-start case we use a basic RNN classifier with the same multilingual embeddings as before, and a 128 dimensional hidden layer.

The proposed method is referred to as PAL, as shorthand *Policy based Active Learning*. Subscripts b, m, c are used to denote the bilingual, multilingual and cold-start experimental configurations. For comparative baselines, we use the following methods:

Uncertainty sampling we use the total token entropy measure (Settles and Craven, 2008), which takes the instance $\mathbf{x}$ maximising $\sum_{t=1}^{|\mathbf{x}|} H(y_t|\mathbf{x}, \phi)$, where H is the token entropy. We use the whole training set as the data pool, and select a single instance for labelling in each active learning step. This method was shown to achieve the best result among model-independent active learning methods on the CoNLL data.

Random sampling which randomly selects examples from the unlabelled pool.

Results Figure 3 shows results the bilingual case, where PAL$_b$ consistently outperforms the Random and Uncertainty baselines across the three target languages. Uncertainty sampling is ineffective, particularly towards the start of the run, as a consequence of its dependence on a high quality model. The use of content information allows PAL$_b$ to make a stronger start, despite the poor initial model.

Also shown in Figure 3 are results for multilingual policy learning, PAL$_m$, which outperform all other approaches including PAL$_b$. This illustrates that the additional training over several languages gives rise to a better policy, than only using one source language. The superior performance is particularly marked in the early stages of the runs for Spanish and Dutch, which may indicate that the approach was better able to learn to exploit the sentence content information.

We evaluate the cold-start setting in Figure 4. Recall that in this setting there are no policy or model updates, as no heldout data is used, and all annotations arrive in a batch. The model, however, is initialised with a NER tagger trained on a different language, which explains why the performance for all methods starts from around 40% rather than 0%. Even in this challenging evaluation setting, our algorithm PAL$_c$ outperforms both baseline methods, showing that deep Q learning allows for better exploitation of the pretrained classifier, alongside the sentence content.

Lastly, we report the results for all approaches in Table 2, based on training on the full 200 labelled sentences as selected under the different methods. It is clear that the PAL methods all outperform the baselines, and among these the multilingual training of PAL$_m$ outperforms the bilingual setting in PAL$_b$. Surprisingly, PAL$_c$ gives the overall best results, despite using a static policy and model during target application, underscoring the importance of model pretraining. Table 2 also re-

ports the cost reduction versus random sampling, showing that the PAL methods can reduce the annotation burden to as low as 10%.

5 Conclusion

In this paper, we have proposed a new active learning algorithm capable of learning active learning strategies from data. We formalise active learning under a Markov decision framework, whereby active learning corresponds to a sequence of binary annotation decisions applied to a stream of data. Based on this, we design an active learning algorithm as a policy based on deep reinforcement learning. We show how these learned active learning policies can be transferred between languages, which we empirically show provides consistent and sizeable improvements over baseline methods, including traditional uncertainty sampling. This holds true even in a very difficult cold-start setting, where no evaluation data is available, and there is no ability to react to annotations.

Abstract

We propose a new sentence simplification task (Split-and-Rephrase) where the aim is to split a complex sentence into a meaning preserving sequence of shorter sentences. Like sentence simplification, splitting-and-rephrasing has the potential of benefiting both natural language processing and societal applications. Because shorter sentences are generally better processed by NLP systems, it could be used as a preprocessing step which facilitates and improves the performance of parsers, semantic role labelers and machine translation systems. It should also be of use for people with reading disabilities because it allows the conversion of longer sentences into shorter ones. This paper makes two contributions towards this new task. First, we create and make available a benchmark consisting of 1,066,115 tuples mapping a single complex sentence to a sequence of sentences expressing the same meaning.[1] Second, we propose five models (vanilla sequence-to-sequence to semantically-motivated models) to understand the difficulty of the proposed task.

1 Introduction

Several sentence rewriting operations have been extensively discussed in the literature: sentence compression, multi-sentence fusion, sentence paraphrasing and sentence simplification.

Sentence compression rewrites an input sentence into a shorter paraphrase (Knight and Marcu, 2000; Cohn and Lapata, 2008; Filippova and Strube, 2008; Pitler, 2010; Filippova et al., 2015; Toutanova et al., 2016). Sentence fusion consists of combining two or more sentences with overlapping information content, preserving common information and deleting irrelevant details (McKeown et al., 2010; Filippova, 2010; Thadani and McKeown, 2013). Sentence paraphrasing aims to rewrite a sentence while preserving its meaning (Dras, 1999; Barzilay and McKeown, 2001; Bannard and Callison-Burch, 2005; Wubben et al., 2010; Mallinson et al., 2017). Finally, sentence (or text) simplification aims to produce a text that is easier to understand (Siddharthan et al., 2004; Zhu et al., 2010; Woodsend and Lapata, 2011; Wubben et al., 2012; Narayan and Gardent, 2014; Xu et al., 2015; Narayan and Gardent, 2016; Zhang and Lapata, 2017). Because the vocabulary used, the length of the sentences and the syntactic structures occurring in a text are all factors known to affect readability, simplification systems mostly focus on modelling three main text rewriting operations: simplifying paraphrasing, sentence splitting and deletion.

We propose a new sentence simplification task, which we dub Split-and-Rephrase, where the goal is to split a complex input sentence into shorter sentences while preserving meaning. In that task, the emphasis is on sentence splitting and rephrasing. There is no deletion and no lexical or phrasal simplification but the systems must learn to split complex sentences into shorter ones and to make the syntactic transformations required by the split (e.g., turn a relative clause into a main clause). Table 1 summarises the similarities and differences between the five sentence rewriting tasks.

Like sentence simplification, splitting-and-rephrasing could benefit both natural language processing and societal applications. Because shorter sentences are generally better processed by NLP systems, it could be used as a preprocess-

ing step which facilitates and improves the performance of parsers (Tomita, 1985; Chandrasekar and Srinivas, 1997; McDonald and Nivre, 2011; Jelínek, 2014), semantic role labelers (Vickrey and Koller, 2008) and statistical machine translation (SMT) systems (Chandrasekar et al., 1996). In addition, because it allows the conversion of longer sentences into shorter ones, it should also be of use for people with reading disabilities (Inui et al., 2003) such as aphasia patients (Carroll et al., 1999), low-literacy readers (Watanabe et al., 2009), language learners (Siddharthan, 2002) and children (De Belder and Moens, 2010).

Contributions. We make two main contributions towards the development of Split-and-Rephrase systems.

Our first contribution consists in creating and making available a benchmark for training and testing Split-and-Rephrase systems. This benchmark (WEBSPLIT) differs from the corpora used to train sentence paraphrasing, simplification, compression or fusion models in three main ways.

First, it contains a high number of splits and rephrasings. This is because (i) each complex sentence is mapped to a rephrasing consisting of at least two sentences and (ii) as noted above, splitting a sentence into two usually imposes a syntactic rephrasing (e.g., transforming a relative clause or a subordinate into a main clause).

Second, the corpus has a vocabulary of 3,311 word forms for a little over 1 million training items which reduces sparse data issues and facilitates learning. This is in stark contrast to the relatively small size corpora with very large vocabularies used for simplification (cf. Section 2).

Third, complex sentences and their rephrasings are systematically associated with a meaning representation which can be used to guide learning. This allows for the learning of semantically-informed models (cf. Section 5).

Our second contribution is to provide five models to understand the difficulty of the proposed Split-and-Rephrase task: (i) A basic encoder-decoder taking as input only the complex sentence; (ii) A hybrid probabilistic-SMT model taking as input a deep semantic representation (Discourse representation structures, Kamp 1981) of the complex sentence produced by Boxer (Curran et al., 2007); (iii) A multi-source encoder-decoder taking as input both the complex sentence and the corresponding set of RDF (Resource Description Format) triples; (iv,v) Two partition-and-generate approaches which first, partition the semantics (set of RDF triples) of the complex sentence into smaller units and then generate a text for each RDF subset in that partition. One model is multi-source and takes the input complex sentence into account when generating while the other does not.

2 Related Work

We briefly review previous work on sentence splitting and rephrasing.

Sentence Splitting. Of the four sentence rewriting tasks (paraphrasing, fusion, compression and simplification) mentioned above, only sentence simplification involves sentence splitting. Most simplification methods learn a statistical model (Zhu et al., 2010; Coster and Kauchak, 2011; Woodsend and Lapata, 2011; Wubben et al., 2012; Narayan and Gardent, 2014) from the parallel dataset of complex-simplified sentences derived by Zhu et al. (2010) from Simple English Wikipedia[2] and the traditional one[3].

For training Split-and-Rephrase models, this dataset is arguably ill suited as it consists of 108,016 complex and 114,924 simplified sentences thereby yielding an average number of simple sentences per complex sentence of 1.06. Indeed, Narayan and Gardent (2014) report that only 6.1% of the complex sentences are in fact split in the corresponding simplification. A more detailed evaluation of the dataset by Xu et al. (2015) further shows that (i) for a large number of pairs, the

[2] Simple English Wikipedia (http://simple.wikipedia.org) is a corpus of simple texts targeting "children and adults who are learning English Language" and whose authors are requested to "use easy words and short sentences".

[3] English Wikipedia (http://en.wikipedia.org).

simplifications are in fact not simpler than the input sentence, (ii) automatic alignments resulted in incorrect complex-simplified pairs and (iii) models trained on this dataset generalised poorly to other text genres. Xu et al. (2015) therefore propose a new dataset, Newsela, which consists of 1,130 news articles each rewritten in four different ways to match 5 different levels of simplicity. By pairing each sentence in that dataset with the corresponding sentences from simpler levels (and ignoring pairs of contiguous levels to avoid sentence pairs that are too similar to each other), it is possible to create a corpus consisting of 96,414 distinct complex and 97,135 simplified sentences. Here again however, the proportion of splits is very low.

As we shall see in Section 3.3, the new dataset we propose differs from both the Newsela and the Wikipedia simplification corpus, in that it contains a high number of splits. In average, this new dataset associates 4.99 simple sentences with each complex sentence.

Rephrasing. Sentence compression, sentence fusion, sentence paraphrasing and sentence simplification all involve rephrasing.

Paraphrasing approaches include bootstrapping approaches which start from slotted templates (e.g.,"X is the author of Y") and seed (e.g.,"X = Jack Kerouac, Y = "On the Road"") to iteratively learn new templates from the seeds and new seeds from the new templates (Ravichandran and Hovy, 2002; Duclaye et al., 2003); systems which extract paraphrase patterns from large monolingual corpora and use them to rewrite an input text (Duboue and Chu-Carroll, 2006; Narayan et al., 2016); statistical machine translation (SMT) based systems which learn paraphrases from monolingual parallel (Barzilay and McKeown, 2001; Zhao et al., 2008), comparable (Quirk et al., 2004) or bilingual parallel (Bannard and Callison-Burch, 2005; Ganitkevitch et al., 2011) corpora; and a recent neural machine translation (NMT) based system which learns paraphrases from bilingual parallel corpora (Mallinson et al., 2017).

In sentence simplification approaches, rephrasing is performed either by a machine translation (Coster and Kauchak, 2011; Wubben et al., 2012; Narayan and Gardent, 2014; Xu et al., 2016; Zhang and Lapata, 2017) or by a probabilistic model (Zhu et al., 2010; Woodsend and Lapata, 2011). Other approaches include symbolic approaches where hand-crafted rules are used e.g., to split coordinated and subordinated sentences into several, simpler clauses (Chandrasekar and Srinivas, 1997; Siddharthan, 2002; Canning, 2002; Siddharthan, 2010, 2011) and lexical rephrasing rules are induced from the Wikipedia simplification corpus (Siddharthan and Mandya, 2014).

Most sentence compression approaches focus on deleting words (the words appearing in the compression are words occurring in the input) and therefore only perform limited paraphrasing. As noted by Pitler (2010) and Toutanova et al. (2016) however, the ability to paraphrase is key for the development of abstractive summarisation systems since summaries written by humans often rephrase the original content using paraphrases or synonyms or alternative syntactic constructions. Recent proposals by Rush et al. (2015) and Bingel and Søgaard (2016) address this issue. Rush et al. (2015) proposed a neural model for abstractive compression and summarisation, and Bingel and Søgaard (2016) proposed a structured approach to text simplification which jointly predicts possible compressions and paraphrases.

None of these approaches requires that the input be split into shorter sentences so that both the corpora used, and the models learned, fail to adequately account for the various types of specific rephrasings occurring when a complex sentence is split into several shorter sentences.

Finally, sentence fusion does induce rephrasing as one sentence is produced out of several. However, research in that field is still hampered by the small size of datasets for the task, and the difficulty of generating one (Daume III and Marcu, 2004). Thus, the dataset of Thadani and McKeown (2013) only consists of 1,858 fusion instances of which 873 have two inputs, 569 have three and 416 have four. This is arguably not enough for learning a general Split-and-Rephrase model.

In sum, while work on sentence rewriting has made some contributions towards learning to split and/or to rephrase, the interaction between these two subtasks have never been extensively studied nor are there any corpora available that would support the development of models that can both split and rephrase. In what follows, we introduce such a benchmark and present some baseline models which provide some interesting insights on how to address the Split-and-Rephrase problem.

3 The WEBSPLIT Benchmark

We derive a Split-and-Rephrase dataset from the WEBNLG corpus presented in Gardent et al. (2017).

3.1 The WEBNLG Dataset

In the WEBNLG dataset, each item consists of a set of RDF triples (M) and one or more texts (T_i) verbalising those triples.

An RDF (Resource Description Format) triple is a triple of the form *subject|property|object* where the subject is a URI (Uniform Resource Identifier), the property is a binary relation and the object is either a URI or a literal value such as a string, a date or a number. In what follows, we refer to the sets of triples representing the meaning of a text as its meaning representation (MR). Figure 1 shows three example WEBNLG items with M_1, M_2, M_3 the sets of RDF triples representing the meaning of each item, and $\{T_1^1, T_1^2\}$, $\{T_2\}$ and $\{T_3\}$ listing possible verbalisations of these meanings.

The WEBNLG dataset[4] consists of 13,308 MR-Text pairs, 7049 distinct MRs, 1482 RDF entities and 8 DBpedia categories (Airport, Astronaut, Building, Food, Monument, SportsTeam, University, WrittenWork). The number of RDF triples in MRs varies from 1 to 7. The number of distinct RDF tree shapes in MRs is 60.

3.2 Creating the WEBSPLIT Dataset

To construct the Split-and-Rephrase dataset, we make use of the fact that the WEBNLG dataset (i) associates texts with sets of RDF triples and (ii) contains texts of different lengths and complexity corresponding to different subsets of RDF triples. The idea is the following. Given a WEBNLG MR-Text pair of the form (M, T) where T is a single complex sentence, we search the WEBNLG dataset for a set $\{(M_1, T_1), \ldots, (M_n, T_n)\}$ such that $\{M_1, \ldots, M_n\}$ is a partition of M and $\langle T_1, \ldots, T_n \rangle$ forms a text with more than one sentence. To achieve this, we proceed in three main steps as follows.

Sentence segmentation We first preprocess all 13,308 distinct verbalisations contained in the WEBNLG corpus using the Stanford CoreNLP pipeline (Manning et al., 2014) to segment each verbalisation T_i into sentences.

Sentence segmentation allows us to associate each text T in the WEBNLG corpus with the number of sentences it contains. This is needed to identify complex sentences with no split (the input to the Split-and-Rephrase task) and to know how many sentences are associated with a given set of RDF triples (e.g., 2 triples may be realised by a single sentence or by two). As the CoreNLP sentence segmentation often fails on complex/rare named entities thereby producing unwarranted splits, we verified the sentence segmentations produced by the CoreNLP sentence segmentation module for each WEBNLG verbalisation and manually corrected the incorrect ones.

Pairing Using the semantic information given by WEBNLG RDF triples and the information about the number of sentences present in a WEBNLG text produced by the sentence segmentation step, we produce all items of the form $\langle (M_C, C), \{(M_1, T_1) \ldots (M_n, T_n)\} \rangle$ such that:

- C is a single sentence with semantics M_C.
- $T_1 \ldots T_n$ is a sequence of texts that contains at least two sentences.
- The disjoint union of the semantics $M_1 \ldots M_n$ of the texts $T_1 \ldots T_n$ is the same as the semantics M_C of the complex sentence C. That is, $M_C = M_1 \uplus \ldots \uplus M_n$.

This pairing is made easy by the semantic information contained in the WEBNLG corpus and includes two subprocesses depending on whether complex and split sentences come from the same WEBNLG entry or not.

Within entries. Given a set of RDF triples M_C, a WEBNLG entry will usually contain several alternative verbalisations for M_C (e.g., T_1^1 and T_1^2 in Figure 1 are two possible verbalisations of M_1). We first search for entries where one verbalisation T_C consists of a single sentence and another verbalisation T contains more than one sentence. For such cases, we create an entry of the form $\langle (M_C, T_C), \{(M_C, T)\} \rangle$ such that, T_C is a single sentence and T is a text consisting of more than one sentence. The second example item for WEBSPLIT in Figure 1 presents this case. It uses different verbalisations (T_1^1 and T_1^2) of the same meaning representation M_1 in WEBNLG to construct

</table>

Figure 1: Example entries from the WebNLG benchmark and their pairing to form entries in the WebSplit benchmark.

a WebSplit item associating the complex sentence (T_1^1) with a text (T_1^2) made of three short sentences.

Across entries. Next we create $\langle (M, C), \{(M_1, T_1) \ldots (M_n, T_n)\}\rangle$ entries by searching for all WebNLG texts C consisting of a single sentence. For each such text, we create all possible partitions of its semantics M_C and for each partition, we search the WebNLG corpus for matching entries i.e., for a set S of (M_i, T_i) pairs such that (i) the disjoint union of the semantics M_i in S is equal to M_C and (ii) the resulting set of texts contains more than one sentence. The first example item for WebSplit in Figure 1 is a case in point. $C(= T_1^1)$ is the single, complex sentence whose meaning is represented by the three triples M. $\langle T_2, T_3\rangle$ is the sequence of shorter texts C is mapped to. And the semantics M_2 and M_3 of these two texts forms a partition over M.

Ordering. For each item $\langle (M_C, C), \{(M_1, T_1) \ldots (M_n, T_n)\}\rangle$ produced in the preceding step, we determine an order on $T_1 \ldots T_n$ as follows. We observed that the WebNLG texts mostly[5] follow the order in which the RDF triples are presented. Since this order corresponds to a left-to-right depth-first traversal of the RDF tree, we use this order to order the sentences in the T_i texts.

3.3 Results

By applying the above procedure to the WebNLG dataset, we create 1,100,166 pairs of the form $\langle (M_C, T_C), \{(M_1, T_1) \ldots (M_n, T_n)\}\rangle$ where T_C is a complex sentence and $T_1 \ldots T_n$ is a sequence of texts with semantics $M_1, \ldots M_n$ expressing the same content M_C as T_C. 1,945 of these pairs were of type "Within entries" and the rest were of type "Across entries". In total, there are 1,066,115 distinct $\langle T_C, T_1 \ldots T_n\rangle$ pairs with 5,546 distinct complex sentences. Complex sentences are associated with 192.23 rephrasings in average (min: 1, max: 76283, median: 16). The number of sentences in the rephrasings varies between 2 and 7 with an average of 4.99. The vocabulary size is 3,311.

[5] As shown by the examples in Figure 1, this is not always the case. We use this constraint as a heuristic to determine an ordering on the set of sentences associated with each input.

4 Problem Formulation

The Split-and-Rephrase task can be defined as follows. Given a complex sentence C, the aim is to produce a simplified text T consisting of a sequence of texts $T_1 \dots T_n$ such that T forms a text of at least two sentences and the meaning of C is preserved in T. In this paper, we proposed to approach this problem in a supervised setting where we aim to maximise the likelihood of T given C and model parameters θ: $P(T|C;\theta)$. To exploit the different levels of information present in the WEBSPLIT benchmark, we break the problem in the following ways:

$$\begin{aligned} P(T|C;\theta) &= \sum_{M_C} P(T|C;M_C;\theta)P(M_C|C;\theta) && (1) \\ &= P(T|C;M_C;\theta), \text{if } M_C \text{ is known.} && (2) \\ &= \sum_{M_{1-n}} \begin{matrix} P(T|C;M_C;M_{1-n};\theta)\times \\ P(M_{1-n}|C;M_C;\theta) \end{matrix} && (3) \end{aligned}$$

where, M_C is the meaning representation of C and M_{1-n} is a set $\{M_1, \dots, M_n\}$ which partitions M_C.

5 Split-and-Rephrase Models

In this section, we propose five different models which aim to maximise $P(T|C;\theta)$ by exploiting different levels of information in the WEBSPLIT benchmark.

5.1 A Probabilistic, Semantic-Based Approach

Narayan and Gardent (2014) describes a sentence simplification approach which combines a probabilistic model for splitting and deletion with a phrase-based statistical machine translation (SMT) and a language model for rephrasing (reordering and substituting words). In particular, the splitting and deletion components exploit the deep meaning representation (a Discourse Representation Structure, DRS) of a complex sentence produced by Boxer (Curran et al., 2007).

Based on this approach, we create a Split-and-Rephrase model (aka HYBRIDSIMPL) by (i) including only the splitting and the SMT models (we do not learn deletion) and (ii) training the model on the WEBSPLIT corpus.

5.2 A Basic Sequence-to-Sequence Approach

Sequence-to-sequence models (also referred to as encoder-decoder) have been successfully applied to various sentence rewriting tasks such as machine translation (Sutskever et al., 2011; Bahdanau et al., 2014), abstractive summarisation (Rush et al., 2015) and response generation (Shang et al., 2015). They first use a recurrent neural network (RNN) to convert a source sequence to a dense, fixed-length vector representation (encoder). They then use another recurrent network (decoder) to convert that vector to a target sequence.

We use a three-layered encoder-decoder model with LSTM (Long Short-Term Memory, (Hochreiter and Schmidhuber, 1997)) units for the Split-and-Rephrase task. Our decoder also uses the local-p attention model with feed input as in (Luong et al., 2015). It has been shown that the local attention model works better than the standard global attention model of Bahdanau et al. (2014). We train this model (SEQ2SEQ) to predict, given a complex sentence, the corresponding sequence of shorter sentences.

The SEQ2SEQ model is learned on pairs $\langle C, T\rangle$ of complex sentences and the corresponding text. It directly optimises $P(T|C;\theta)$ and does not take advantage of the semantic information available in the WEBSPLIT benchmark.

5.3 A Multi-Source Sequence-to-Sequence Approach

In this model, we learn a multi-source model which takes into account not only the input complex sentence but also the associated set of RDF triples available in the WEBSPLIT dataset. That is, we maximise $P(T|C;M_C;\theta)$ (Eqn. 2) and learn a model to predict, given a complex sentence C and its semantics M_C, a rephrasing of C.

As noted by Gardent et al. (2017), the shape of the input may impact the syntactic structure of the corresponding text. For instance, an input containing a path $(X|P_1|Y)(Y|P_2|Z)$ equating the object of a property P_1 with the subject of a property P_2 may favour a verbalisation containing a subject relative ("x V_1 y who V_2 z"). Taking into account not only the sentence C that needs to be rephrased but also its semantics M_C may therefore help learning.

We model $P(T|C;M_C;\theta)$ using a multi-source sequence-to-sequence neural framework (we refer to this model as MULTISEQ2SEQ). The core idea comes from Zoph and Knight (2016) who show that a multi-source model trained on trilingual translation pairs $((f,g),h)$ outperforms sev-

Model	Task	Training Size
HYBRIDSIMPL	Given C, predict T	886,857
SEQ2SEQ	Given C, predict T	886,857
MULTISEQ2SEQ	Given C and M_C, predict T	886,866
SPLIT-MULTISEQ2SEQ	Given C and M_C, predict $M_1 \dots M_n$	13,051
	Given C and M_i, predict T_i	53,470
SPLIT-SEQ2SEQ	Given C and M_C, predict $M_1 \dots M_n$	13,051
	Given M_i, predict T_i	53,470

Table 2: Tasks modelled and training data used by Split-and-Rephrase models.

eral strong single source baselines. We explore a similar "trilingual" setting where f is a complex sentence (C), g is the corresponding set of RDF triples (M_C) and h is the output rephrasing (T).

We encode C and M_C using two separate RNN encoders. To encode M_C using RNN, we first linearise M_C by doing a depth-first left-right RDF tree traversal and then tokenise using the Stanford CoreNLP pipeline (Manning et al., 2014). Like in SEQ2SEQ, we model our decoder with the local-p attention model with feed input as in (Luong et al., 2015), but now it looks at both source encoders simultaneously by creating separate context vector for each encoder. For a detailed explanation of multi-source encoder-decoders, we refer the reader to Zoph and Knight (2016).

5.4 Partitioning and Generating

As the name suggests, the Split-and-Rephrase task can be seen as a task which consists of two subtasks: (i) splitting a complex sentence into several shorter sentences and (ii) rephrasing the input sentence to fit the new sentence distribution. We consider an approach which explicitly models these two steps (Eqn. 3). A first model $P(M_1, \dots, M_n|C; M_C; \theta)$ learns to partition a set M_C of RDF triples associated with a complex sentence C into a disjoint set $\{M_1, \dots, M_n\}$ of sets of RDF triples. Next, we generate a rephrasing of C as follows:

$$
\begin{aligned}
& P(T|C; M_C; M_1, \dots, M_n; \theta) && (4)\\
& \approx P(T|C; M_1, \dots, M_n; \theta) && (5)\\
& = P(T_1, \dots, T_n|C; M_1, \dots, M_n; \theta) && (6)\\
& = \prod_i^n P(T_i|C; M_i; \theta) && (7)
\end{aligned}
$$

where, the approximation from Eqn. 4 to Eqn. 5 derives from the assumption that the generation of T is independent of M_C given $(C; M_1, \dots, M_n)$. We propose a pipeline model to learn parameters θ. We first learn to split and then learn to generate from each RDF subset generated by the split.

Learning to split. For the first step, we learn a probabilistic model which given a set of RDF triples M_C predicts a partition $M_1 \dots M_n$ of this set. For a given M_C, it returns the partition $M_1 \dots M_n$ with the highest probability $P(M_1, \dots, M_n|M_C)$.

We learn this split module using items $\langle (M_C, C), \{(M_1, T_1) \dots (M_n, T_n)\} \rangle$ in the WEBSPLIT dataset by simply computing the probability $P(M_1, \dots, M_n|M_C)$. To make our model robust to an unseen M_C, we strip off named-entities and properties from each RDF triple and only keep the tree skeleton of M_C. There are only 60 distinct RDF tree skeletons, 1,183 possible split patterns and 19.72 split candidates in average for each tree skeleton, in the WEBSPLIT dataset.

Learning to rephrase. We proposed two ways to estimate $P(T_i|C; M_i; \theta)$: (i) we learn a multi-source encoder-decoder model which generates a text T_i given a complex sentence C and a set of RDF triples $M_i \in M_C$; and (ii) we approximate $P(T_i|C; M_i; \theta)$ by $P(T_i|M_i; \theta)$ and learn a simple sequence-to-sequence model which, given M_i, generates a text T_i. Note that as described earlier, M_i's are linearised and tokenised before we input them to RNN encoders. We refer to the first model by SPLIT-MULTISEQ2SEQ and the second model by SPLIT-SEQ2SEQ.

6 Experimental Setup and Results

This section describes our experimental setup and results. We also describe the implementation details to facilitate the replication of our results.

6.1 Training, Validation and Test sets

To ensure that complex sentences in validation and test sets are not seen during training, we split the 5,546 distinct complex sentences in the WEBSPLITdata into three subsets: Training set (4,438, 80%), Validation set (554, 10%) and Test set (554, 10%).

Table 2 shows, for each of the 5 models, a summary of the task and the size of the training corpus. For the models that directly learn to map a complex sentence into a meaning preserving sequence of at least two sentences (HybridSimpl, Seq2Seq and MultiSeq2Seq), the training set consists of 886,857 $\langle C, T \rangle$ pairs with C a complex sentence and T, the corresponding text. In contrast, for the pipeline models which first partition the input and then generate from RDF data (Split-MultiSeq2Seqand Split-Seq2Seq), the training corpus for learning to partition consists of 13,051 $\langle M_C, \langle M_1 \dots M_n \rangle \rangle$ pairs while the training corpus for learning to generate contains 53,470 $\langle M_i, T_i \rangle$ pairs.

6.2 Implementation Details

For all our neural models, we train RNNs with three-layered LSTM units, 500 hidden states and a regularisation dropout with probability 0.8. All LSTM parameters were randomly initialised over a uniform distribution within [-0.05, 0.05]. We trained our models with stochastic gradient descent with an initial learning rate 0.5. Every time perplexity on the held out validation set increased since it was previously checked, then we multiply the current learning rate by 0.5. We performed mini-batch training with a batch size of 64 sentences for Seq2Seq and MultiSeq2Seq, and 32 for Split-Seq2Seq and Split-MultiSeq2Seq. As the vocabulary size of the WebSplit data is small, we train both encoder and decoder with full vocabulary. We randomly initialise word embeddings in the beginning and let the model train them during training. We train our models for 20 epochs and keep the best model on the held out set for the testing purposes. We used the system of Zoph and Knight (2016) to train both simple sequence-to-sequence and multi-source sequence-to-sequence models[6], and the system of Narayan and Gardent (2014) to train our HybridSimpl model.[7]

Model	BLEU	#S/C	#Tokens/S
Source	55.67	1.0	21.11
HybridSimpl	39.97	1.26	17.55
Seq2Seq	48.92	2.51	10.32
MultiSeq2Seq	42.18	2.53	10.69
Split-MultiSeq2Seq	77.27	**2.84**	11.63
Split-Seq2Seq	**78.77**	**2.84**	**9.28**

Table 3: Average BLEU scores for rephrasings, average number of sentences in the output texts (#S/C) and average number of tokens per output sentences (#Tokens/S). Source are the complex sentences from the WebSplit corpus.

6.3 Results

We evaluate all models using multi-reference BLEU-4 scores (Papineni et al., 2002) based on all the rephrasings present in the Split-and-Rephrase corpus for each complex input sentence.[8] As BLEU is a metric for n-grams precision estimation, it is not an optimal metric for the Split-and-Rephrase task (sentences even without any split could have a high BLEU score). We therefore also report on the average number of output simple sentences per complex sentence and the average number of output words per output simple sentence. The first one measures the ability of a system to split a complex sentence into multiple simple sentences and the second one measures the ability of producing smaller simple sentences.

Table 3 shows the results. The high BLEU score for complex sentences (Source) from the WebSplit corpus shows that using BLEU is not sufficient to evaluate splitting and rephrasing. Because the short sentences have many n-grams in common with the source, the BLEU score for complex sentences is high but the texts are made of a single sentence and the average sentence length is high. HybridSimpl performs poorly – we conjecture that this is linked to a decrease in semantic parsing quality (DRSs) resulting from complex named entities not being adequately recognised. The simple sequence-to-sequence model does not perform very well neither does the multi-source model trained on both complex sentences and their semantics. Typically, these two models often produce non-meaning preserving outputs (see example in Table 4) for input of longer length. In contrast, the two partition-and-generate models outperform all other models by a wide mar-

Table 4: Example outputs from different models.

gin. This suggests that the ability to split is key to a good rephrasing: by first splitting the input semantics into smaller chunks, the two partition-and-generate models permit reducing a complex task (generating a sequence of sentences from a single complex sentence) to a series of simpler tasks (generating a short sentence from a semantic input).

Unlike in neural machine translation setting, multi-source models in our setting do not perform very well. SEQ2SEQ and SPLIT-SEQ2SEQ outperform MULTISEQ2SEQ and SPLIT-MULTISEQ2SEQ respectively, despite using less input information than their counterparts. The multi-source models used in machine translation have as a multi-source, two translations of the same content (Zoph and Knight, 2016). In our approach, the multi-source is a complex sentence and a set of RDF triples, e.g., $(C; M_C)$ for MULTISEQ2SEQ and $(C; M_i)$ for SPLIT-MULTISEQ2SEQ. We conjecture that the poor performance of multi-source models in our case is due either to the relatively small size of the training data or to a stronger mismatch between RDF and complex sentence than between two translations.

Table 4 shows an example output for all 5 systems highlighting the main differences. HYBRIDSIMPL's output mostly reuses the input words suggesting that the SMT system doing the rewriting has limited impact. Both the SEQ2SEQ and the MULTISEQ2SEQ models “hallucinate” new information (“served as a test pilot”, “born on Nov 18, 1983”). In contrast, the partition-and-generate models correctly render the meaning of the input sentence (SOURCE), perform interesting rephrasings (“X was born in Y” $\rightarrow$ “X's birth place was Y”) and split the input sentence into two.

7 Conclusion

We have proposed a new sentence simplification task which we call “Split-and-Rephrase”. We have constructed a new corpus for this task which is built from readily-available data used for NLG (Natural Language Generation) evaluation. Initial experiments indicate that the ability to split is a key factor in generating fluent and meaning preserving rephrasings because it permits reducing a complex generation task (generating a text consisting of at least two sentences) to a series of simpler tasks (generating short sentences). In future work, it would be interesting to see whether and if so how, sentence splitting can be learned in the absence of explicit semantic information in the input.

Another direction for future work concerns the exploitation of the extended WebNLG corpus. While the results presented in this paper use a version of the WebNLG corpus consisting of 13,308 MR-Text pairs, 7049 distinct MRs and 8 DBpedia categories, the current WebNLG corpus encompasses 43,056 MR-Text pairs, 16,138 distinct MRs and 15 DBpedia categories. We plan to exploit this extended corpus to make available a correspondingly extended WEBSPLIT corpus, to learn optimised Split-and-Rephrase models and to explore sentence fusion (converting a sequence of sentences into a single complex sentence).

Acknowledgements

We thank Bonnie Webber and Annie Louis for early discussions on the ideas presented in the paper. We thank Rico Sennrich for directing us to multi-source NMT models. This work greatly benefited from discussions with the members of the Edinburgh NLP group. We also thank the three anonymous reviewers for their comments to improve the paper. The research presented in this paper was partially supported by the H2020 project SUMMA (under grant agreement 688139) and the French National Research Agency within the framework of the WebNLG Project (ANR-14-CE24-0033).

Abstract

This paper presents a Generative Adversarial Network (GAN) to model single-turn short-text conversations, which trains a sequence-to-sequence (Seq2Seq) network for response generation simultaneously with a discriminative classifier that measures the differences between human-produced responses and machine-generated ones. In addition, the proposed method introduces an approximate embedding layer to solve the non-differentiable problem caused by the sampling-based output decoding procedure in the Seq2Seq generative model. The GAN setup provides an effective way to avoid non-informative responses (a.k.a "safe responses"), which are frequently observed in traditional neural response generators. The experimental results show that the proposed approach significantly outperforms existing neural response generation models in diversity metrics, with slight increases in relevance scores as well, when evaluated on both a Mandarin corpus and an English corpus.

1 Introduction

After achieving remarkable successes in Machine Translation (Sutskever et al., 2014; Cho et al., 2014), neural networks with the encoder-decoder architectures (a.k.a sequence-to-sequence models, Seq2Seq) have been proven to be a functioning method to model short-text conversations (Vinyals and Le, 2015; Shang et al., 2015), where the corresponding task is often called Neural Response Generation. The advantage of applying Seq2Seq models to conversation generation is that the training procedure can be performed end-to-end in an unsupervised manner, based on human-generated conversational utterances (typically query-response pairs mined from social networks). One of the potential applications of such neural response generators is to improve the capability of existing conversational interfaces (informally also known as chatbots) by enabling them to go beyond predefined tasks and chat with human users in an open domain.

However, previous research has indicated that naïve implementations of Seq2Seq based conversation models tend to suffer from the so-called "safe response" problem (Li et al., 2016a), i.e. such models tend to generate non-informative responses that can be associated to most queries, e.g. "I don't know", "I think so", etc. This is due to the fundamental nature of statistical models, which fit sufficiently observed examples better than insufficiently observed ones. Concretely, the space of open-domain conversations is so large that in any sub-sample of it (i.e. a training set), the distribution of most pieces of information are relatively much sparser when compared to safe response patterns. Furthermore, since a safe response can be of relevance to a large amount of diverse queries, a statistical learner will tend to minimize its empirical risk in the response generation process by capturing those safe responses if naïve relevance-oriented loss metrics are employed.

Frequent occurrences of safe responses can dramatically reduce the attractiveness of a chat agent, which therefore should be avoided to the best extent possible when designing the learning algorithms. The pathway to achieve this purpose is to seek a more expressive model with better capacity that can take relevance and diversity (or informativeness) into account simultaneously

when modelling the underlying distribution of human conversations.

Generative Adversarial Nets (GANs) (Goodfellow et al., 2014; Chen et al., 2016) offers an effective architecture of jointly training a generative model and a discriminative classifier to generate sharp and realistic images. This architecture could also potentially be applied to conversational response generation to relieve the safe response problem, where the generative part can be an Seq2Seq-based model that generates response utterances for given queries, and the discriminative part can evaluate the quality of the generated utterances from diverse dimensions according to human-produced responses. However, unlike the image generation problems, training such a GAN for text generation here is not straightforward. The decoding phase of the Seq2Seq model usually involves sampling discrete words from the predicted distributions, which will be fed into the training of the discriminator. The sampling procedure is non-differentiable, and will therefore break the back-propagation.

To the best of our knowledge, Reinforcement Learning (RL) is first introduced to address the above problem (Li et al., 2017; Yu et al., 2017), where the score predicted by a discriminator was used as the reinforcement to train the generator, yielding a hybrid model of GAN and RL. But to train the RL phrase, Li et al. (2017) introduced two approximations for reward computing at each action (word) selection step, including a Markov Chain Monte Carlo (MCMC) sampling method and a partial utterance scoring approach. It has been stated in their work that the former approach is time-consuming and the latter one will result in lower performance due to the overfitting problem caused by adding a large amount of partial utterances into the training set. Nevertheless, we also want to argue that, besides the time complexity issue of MCMC, RL itself is not an optimal choice either. As shown in our experimental results in Section 5.1, a more elegant design of an end-to-end differentiable GAN can significantly increase the model's performance in this text generation task.

In this paper, we propose a novel variant of GAN for conversational response generation, which introduces an approximate embedding layer to replace the sampling-based decoding phase, such that the entire model is continuous and differentiable. Empirical experiments are conducted based on two datasets, of which the results show that the proposed method significantly outperforms three representative existing approaches in both relevance and diversity oriented automatic metrics. In addition, human evaluations are carried out as well, demonstrating the potential of the proposed model.

2 Related Work

Inspired by recent advances in Neural Machine Translation (NMT), Ritter et al. (2011) and Vinyals and Le (2015) have shown that single-turn short-text conversations can be modelled as a generative process trained using query-response pairs accumulated on social networks. Earlier works focused on paired word sequences only, while Zhou et al. (2016) and Iulian et al. (2017) have demonstrated that the comprehensibility of the generated responses can benefit from multi-view training with respect to words, coarse tokens and utterances. Moreover, Sordoni et al. (2015) proposed a context-aware response generation model that goes beyond single-turn conversations.

In addition, attention mechanisms were introduced to Seq2Seq-based models to capture topic and dialog focus information by Shang et al. (2015) and Chen et al. (2017), which had been proven to be helpful for improving query-response relevance (Wu et al., 2016). Additional features such as persona information (Li et al., 2016b) and latent semantics (Zhou et al., 2017; Serban et al., 2017) have also been proven beneficial within this context.

When compared to previous work, this paper is focused on single-turn conversation modeling, and employs a GAN to yield informative responses.

3 Building a Conversational Response Generator via GAN

3.1 Notations

Let $\mathcal{D} = \{(q_i, r_i)\}_{i=1}^{N}$ be a set of N single-turn human-human conversations, where $q_i = (w_{q_i,1}, \ldots, w_{q_i,t}, \ldots, w_{q_i,m})$ is a query, $r_i = (w_{r_i,1}, \ldots, w_{r_i,t}, \ldots, w_{r_i,n})$ stands for the response to q_i, and $w_{q_i,t}$ and $w_{r_i,t}$ denote the t-th words in q_i and r_i, respectively. This paper aims to learn a generative model $G(r|q)$ based on a discriminator D that can predict informative responses with good diversity for arbitrary input queries.

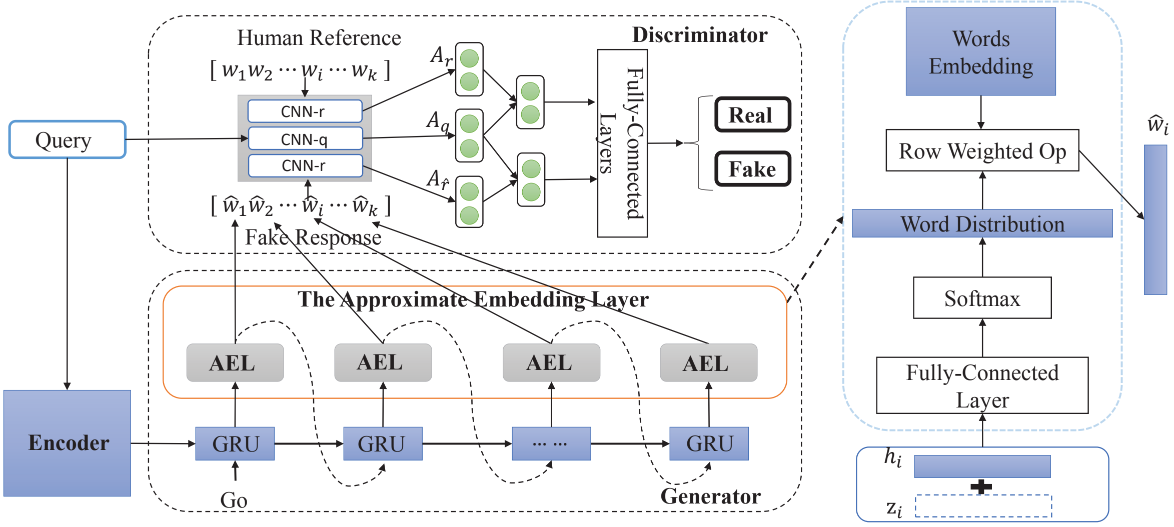

Figure 1: The Framework of GAN for the Response Generator.

3.2 Model Overview

We name the proposed model Generative Adversarial Network with an Approximate Embedding Layer (GAN-AEL), of which Figure 1 illustrates the overall framework. Generally speaking, the whole framework consists of a response generator G, a discriminator D and an embedding approximation layer that connects the G and the D. We explain each of the components in detail as follows. The generator adopts the Gated Recurrent Unit (GRU) (Cho et al., 2014) based encoder-decoder architecture, where the encoder projects the input query (a discrete word sequence) into a real-valued vector, on which the output will be generated conditionally in the decoding process, activated by a starting signal (denoted as "Go" in Figure 1). An approximate embedding layer is designed to guarantee that the response generation procedure is continuous and differentiable, serving as an interface for the discriminator to propagate its loss to the generator. The Convolutional Neural Network (CNN) based discriminator is attached on top of the approximation layer, which aims to distinguish the fake responses output by the approximation layer and the corresponding human-generated references, conditioned on the input query. The judgement of the CNN can be propagated to the Seq2Seq generator through the proposed approximate embedding layer, and forces the generator to be fine-tuned to produce more attractive results.

The proposed GAN framework possesses several advantages over existing conversational response generation models. Firstly, both the generator and the discriminator are conditioned on the input query, which guarantees the relevance of the generated responses. Secondly, the discriminator enforces the generator to produce a response according to the true distribution in better granularity, such that the state of promoting safe responses is leaped out. Thirdly, the approximation layer yields a smooth connection between the generator and the discriminator, avoiding the non-differentiable discrete sampling process.

3.3 Pre-training the Generator by MLE

In our proposed encoder-decoder framework, both the encoder and the generator (i.e. the decoder) G is composed of GRU (Cho et al., 2014) units, which is designed to generate responses $r = \{w_{r,1}, w_{r,2}, \cdots, w_{r,K}\}$ conditioned on an input query $q = \{w_{q,1}, w_{q,2}, \cdots, w_{q,J}\}$. For a given query-response pair (q, r), the target is to maximum the conditional probability $p(r|q)$ in the generative process. Concretely, in this model, q is firstly encoded into a vector representation q_v by the GRU-based encoder as shown in Figure 1, which is actually the last hidden state of the encoder. Then the generator estimates the probability of each word occurring in r conditioned on q_v. Hence $p(r|q)$ can be formulated as follows:

$$p(r|q) = \prod_{t=1}^{K} p(w_{r,t}|q_v, w_{r,1}, \cdots, w_{r,t-1}) \quad (1)$$

Taking the logarithm of the probabilities for effective computation, the generator is trained by optimising the Maximum Likelihood Estimation (MLE) objective defined as:

$$\frac{1}{|\mathcal{D}|}\sum_{(q,r)\in\mathcal{D}}\sum_{t=1}^{K}\log p(w_{r,t}|q_v, w_{r,1},\cdots,w_{r,t-1}) \tag{2}$$

Note here, we need to pre-train the generator using Equation 2 as the loss function to guarantee the generator to produce grammatical utterances. Otherwise, the discriminator will tend to learn a rule with ease to distinguish human-produced utterances from those ungrammatical responses generated in the early stages of the training phase, which would cause the failure of the training in satisfying Nash Equilibrium (Goodfellow et al., 2014).

3.4 The Approximate Embedding Layer

In order to smoothly connect the output layer of the generator to the input layer of the discriminator to yield an end-to-end differentiable GAN, one needs to solve the following critical problem. The output of the generator is a sequence of discrete words, which is usually sampled from the distributions predicted by the decoder's RNN units in the Softmax layer, and is non-differentiable.

Since afterward those words will be projected into embedding vectors to feed the CNN-based discriminator, we introduce an embedding approximation layer to merge the generation process of the decoder and the word embedding phrase of the discriminator. This can be done by multiplying the word probabilities in the distributions obtained from the decoder's Softmax layer to the corresponding word vectors, to directly yield an approximately vectorized representation of the generated word sequences for further convolutional computations in the discriminative process. This approximation is based on the assumption that ideally the word distributions should be trained to reasonably approach the one-hot representations of the discrete words.

The structure of the approximation layer is illustrated on the right-hand side of Figure 1. Concretely, the approximation layer takes the output h_i of the generator and a random noise z_i as the input, and reuses the word projection layer (pre-trained in the standard generator) to estimate the probability distribution of w_i. Note that, the noise z_i added to h_i forms a latent feature for the word embedding approximation process to enforce the diversity of the generated responses. The overall word embedding approximation is computed as:

$$\hat{e}_{w_i} = \sum_{j=1}^{V} e_j \cdot \text{Softmax}(W_p(h_i + z_i) + b_p)_j \tag{3}$$

where W_p and b_p are the weight and bias parameters of the word projection layer, respectively, and h_i is the hidden representation of word w_i, from the decoding procedure of the generator G, which is computed as:

$$h_i = g(h_{i-1}, \hat{e}_{w_{i-1}}) \tag{4}$$

where $g(\cdot)$ is the standard GRU inference step in G (Cho et al., 2014).

3.5 Pre-training the CNN-based Discriminator

CNN has been proven to be an appropriate classifier for many NLP tasks, such as sentence classification (Kim, 2014) and matching (Hu et al., 2014). Therefore, in this paper we adopt a CNN-based discriminator as shown in Figure 1.

For the convenience of further discussions, we introduce $\hat{r}$ to denote the underlying (distributional) fake response produced by the decoder. In other words, $\hat{r}$ stands for a sequence of word distributions projected from the hidden layers of the decoder RNN, based on which one would sample the output response utterance in a traditional Seq2Seq generator. The detailed architecture of the discriminator is described as follows. Firstly, the input of the discriminator consist of the word embedding vector sequence V_q for a given query q and the word embedding vector sequence V_r for its human-produced response r, as well as the approximate word embedding vector sequence $V_{\hat{r}}$ produced by the approximate embedding layer for the corresponding fake response $\hat{r}$. All the word embedding vector sequences here are zero-padded or truncated to a same fixed length. After this, two CNNs with shared parameters are employed to encode V_r and $V_{\hat{r}}$ into higher-level abstractions, respectively. In addition, a separate CNN is used to abstract V_q in a similar way. We denote such abstraction layers (i.e. the max-pooling layers before the fully-connected layers) in the above CNNs as A_r, $A_{\hat{r}}$ and A_q, corresponding to r, $\hat{r}$ and q, respectively. Finally, we concatenate A_q

to A_r and $A_{\hat{r}}$ separately, and feed the resulting vectors to their respective fully-connected layers, as illustrated in Figure 1. Here, we make the two fully-connected layers share common parameters and predict probabilities $D(r|q)$ and $D(\hat{r}|q)$, respectively, for r and $\hat{r}$ being true responses of the given q.

In practice, when the Seq2Seq generative network G is pre-trained, we also pre-train the above discriminator D by maximising the following objective function:

$$D_{loss} = \log D(r|q) + \log(1 - D(\hat{r}|q)) \qquad (5)$$

with the parameters of G frozen, before the adversarial training procedure described in Section 3.6.

3.6 Adversarial Training of the Generator

After the pre-training of the generator G and the discriminator D as described above, the entire network is trained adversarially. Concretely, we iteratively train G and D, where at each iteration, the parameters of the non-training network will be frozen. The following tricks are utilised in the adversarial training phase to achieve better convergence. Firstly, when training G, we replace the objective function given in Equation 5 with the l_2-loss between A_r and $A_{\hat{r}}$, to maintain a reasonable scale of the gradient. Secondly, we freeze the parameters of the encoder network and the projection layer of the decoder network, but only tune the parameters of decoder's hidden layers. This is based on the assumption that, in principle, after the pre-training, the encoder network is sufficiently effective to represent the entire input utterance, while the projection layer of the decoder is also adequate to decode words from its hidden states. Therefore, the adversarial training here is to adjust the "wording strategy" of the generative model, i.e. the way it organises the semantic contents during the decoding (or in other words, the way it realises the hidden states). Preliminary experiments show that this trick significantly improves the grammaticalness of the generated responses.

The gradient of the generator can be computed as:

$$\begin{aligned} \nabla_{g_{D,G}(\theta_G)} &= \frac{\partial G_{loss}}{\partial V_{\hat{r}}} \frac{\partial V_{\hat{r}}}{\partial \theta_G} \\ &= \frac{\partial G_{loss}}{\partial V_{\hat{r}}} \frac{\partial V_{\hat{r}}}{\partial G} \frac{\partial G}{\partial \theta_G} \end{aligned} \qquad (6)$$

where θ_G denotes the active parameters of the generator G, $G_{loss} = \|A_r - A_{\hat{r}}\|$ and $g_{D,G}(\cdot)$ stands for the inference step of the entire GAN. It can be seen that the feedback signals from D can be propagated to G effectively through the approximate embedding layer, which connects G and D smoothly, and avoids the discrete sampling procedure.

4 Experiment Setup

4.1 Datasets

We test our model on two datasets: **Baidu Tieba** and **OpenSubtitles** (Lison and Tiedemann, 2016). The Baidu Tieba dataset is composed of single-turn conversations collected from the threads of Baidu Tieba[1], of which the utterance length ranging from 3 to 30 words. The OpenSubtitles dataset contains movie scripts organised by characters, where we follow Li et al. (2016a) to retain subtitles containing 5-50 words in the following experiments. From each of the two datasets, we sample 5,000,000 unique single-turn conversations as the training data, 200,000 additional unique pairs for validation, and another 10,000 as the test set.

4.2 Baselines

To illustrate the performance of the proposed model, we introduce three existing approaches as baselines.

- **Seq2Seq:** the standard sequence-to-sequence model (Sutskever et al., 2014).
- **MMI-anti:** a Seq2Seq model with a Maximum Mutual Information (MMI) criterion (implemented as an anti-language model) (Li et al., 2016a) in the decoding process, which reduces the probability of generating "safe responses".
- **Adver-REGS:** another adversarial strategy proposed by Li et al. (2017)[2], which links the generator and the discriminator together with a reinforcement learning framework, and takes the discriminator's output probability as the reward to train the generator.

4.3 Evaluation Metrics

For automatic evaluations, the following commonly accepted metrics are employed. Note here, the goal of our model is to obtain responses not only semantically relevant to the corresponding queries, but also of good diversity and novelty. Therefore, in this work, embedding-based metrics (Liu et al., 2016) are adopted to evaluate semantic the relevance between queries and their corresponding generated responses, while **dist-1**, **dist-2** (Li et al., 2016a) are used as diversity measures. In addition, we also introduce a **Novelty** measure as detailed below.

Relevance Metrics: The following three word embedding based metrics[3] are used to compute the semantic relevance of two utterances. The **Greedy** metric is to greedily match words in two given utterances based on the cosine similarities of their embeddings, and to average the obtained scores (Rus and Lintean, 2012). Alternatively, an utterance representation can be obtained by averaging the embeddings of all the words in that utterance, of which the cosine similarity gives the **Average** metric (Mitchell and Lapata, 2008). In addition, one can also achieve an utterance representation by taking the largest extreme values among the embedding vectors of all the words it contains, before computing the cosine similarities between utterance vectors, which yields the **Extreme** metric (Forgues et al., 2014).

Diversity Metrics: To measure the informativeness and diversity of the generated responses, we follow the **dist-1** and **dist-2** metrics proposed by Li et al. (2016a) and Chen et al. (2017), and introduce a **Novelty** metric. The **dist-1** (**dist-2**) is defined as the number of unique unigrams (bigrams for dist-2). A common drawback of dist-1 and dist-2 is that in the computation, less informative words (such as "I", "is", etc.) are considered equally with those more informative ones. Therefore, in this paper, we define an extra **Novelty** metric, which is the number of infrequent words observed in the generated responses. Here we take all the words except the top 2000 most frequent ones in the vocabulary as infrequent words. Note here, the dist-1 and Novelty values are normalised by utterance length, and dist-2 is normalised by the total number of bigrams in the generated response.

Human Evaluation: To evaluate the performance of our model from human perspectives, this paper conducts a human subject experiement by comparing the responses generated by Adver-REGS (which is one of the most competitive existing approaches) with those by the proposed model. Three experienced annotators are invited to evaluate 200 groups of examples. In the evaluation, for every given query, the annotators will see 10 generated responses from each model. Since the proposed method aims at improving the diversity of the responses generated by Seq2Seq models, while maintaining their relevance to the input queries, we ask the annotators to evaluate the diversity performance of the two systems only if there is no obvious difference between the performance of their relevance. This experimental setting is due to the following two reasons. Firstly, it is difficult to judge a systems diversity based on one single response (Li et al., 2016a; Zhou et al., 2017). Secondly, the practical deployment of a chat-oriented conversational system will usually decode an N-best list of candidate responses, from which it random samples the final reply. Considering that all the annotators use Mandarin as their first language, the above evaluation is only done on the Tieba dataset.

4.4 Hyperparameters & Training Strategies

Hyperparameter Settings: The hyperparameters of the networks used in all the experiments below are described as follows. The vocabulary sizes for Tieba and OpenSubtitles are truncated to 100,000 and 150,000, respectively. The dimensions of word embedding vectors are set to 100 for Tieba and 300 for OpenSubtitles. The size of the hidden layers in the generator is set to 200 in the all experiments on both datasets. We experiments subsets of {1,2,3,4} for the filter sizes of the CNNs, and fixed the filter number to 128. As shown in subsection 5.3, CNNs with filter sizes {1,2} are the best choice here. Max-pooling is used in all the CNN settings here. The noise Z is sampled from a normal distribution with 0 mean and 0.1 variance.

Training Strategies: To train the proposed GAN, the parameters of the generator G are initialised based on the pre-training mentioned in subsection 3.3, while those of the discriminator D are randomly initialised. The adversarial training

[3] The implementation of all these metrics follows the code at https://github.com/julianser/hed-dlg-truncated/tree/master/Evaluation.

starts from pre-training D with the parameters of G fixed. After this, G and D will be trained iteratively with different learning rates, which are 0.0001 for D and 0.00002 for G. In addition, we update D at a frequency of every 5 batches instead of every single batch.

5 Experimental Results

5.1 Automatic Evaluation & Analysis

From Table 1 and 2, it can be observed that the proposed GAN-AEL model outperforms the baselines on both datasets in all metrics, especially for the diversity oriented scores. The improvements can be explained from the following two angles.

a) Since a vanilla Seq2Seq model does not take diversity, novelty or informativeness into account, the discriminator tends to capture such information to distinguish model-generated responses and human responses. By backpropagating the discriminator's feedback to the generator, the adversarially trained generator gains significantly better performance in such aspects. On the other hand, the relevance is also retained during the adversarial training, as one can imagine that the human produced references given to the discriminator are usually semantically highly relevant to the corresponding queries.

b) The proposed approximation layer is an effective way to couple the response generator and the discriminator. Through this differentiable component, the loss of the discriminator is properly propagated to the generator and guide the tuning of the latter's parameters.

It can also be seen from the results that the performance of all the models on the three semantic relevance oriented metrics are comparable to each other. This implies that all the models, including the baseline methods and the proposed model, have the capability to generate responses of reasonable relevance to given queries, which satisfies the primary goal of the response generation task. It further suggests that the Seq2Seq architecture works properly in modelling the semantics of entire utterances. Nevertheless, although the decoder mechanism can select topic-relevant words to construct responses based on the given query, the limitation of naïve Seq2Seq models tend to yield less diverse or informative outputs.

Furthermore, when compared to Adver-REGS, the proposed GAN-AEL gains 30%-60% relative improvement in the dist-1, dist-2 and novelty metrics on both datasets, which indicates that coupling the generator and the discriminator with a differentiable component is a more preferable methodology for text generation tasks, and is a meaningful analogy to standard GANs for image generation. Interestingly, all the models achieve significantly higher novelty scores on the Tieba dataset than on the OpenSubtitle dataset. This is due to the difference of the coverages of high-frequency words in the two corpora. Concretely, since we exclude top 2,000 most frequent words when computing the novelty scores on both datasets, which covers 70% and 82% of the words in Tieba and OpenSubtitle respectively, it is more likely to observe novel words on the Tieba data.

In addition, it can be seen that GAN-AEL improves the greedy score to a much greater extent than the average and extreme scores, which further suggests that the responses generated by GAN-AEL are more informative. Concretely, the calculations of the average and extreme scores may be dominated by generic non-informative words. By contrast, since the greedy metric is computed based on a (simple and greedy) word-wise semantic alignments between two utterances, the influence of those generic words will be reduced.

5.2 Human Evaluation Results

Table 3 gives the human evaluation results, which indicates that the proposed GAN-AEL is more preferable than Adver-REGS from human perspectives. This again implies that the approximate embedding layer is more effective in propagating the discriminator's feedback to the generator than the reinforcement learning mechanism of (Li et al., 2017). The result is statistically significant with $p < 0.01$ according to sign test.

GAN-AEL vs Adver-REGS		
Wins	Losses	Ties
0.61	0.13	0.26

Table 3: Evaluations of GAN-AEL and Adver-REGS based on human subjects,

5.3 The Influence of the Discriminator to Adversarial Training

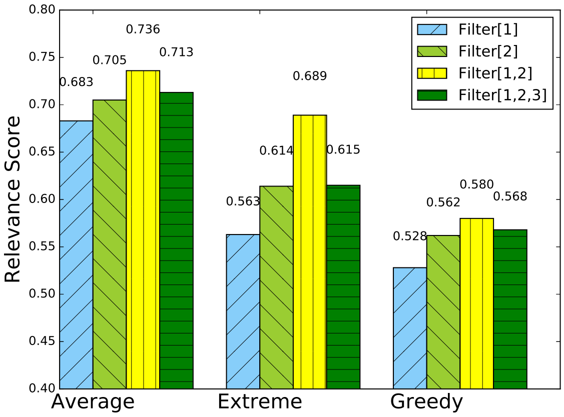

Figure 2: Relevance scores of GAN-AEL on the Tieba corpus with respect to different CNN window sizes.

The discriminator plays an important role in the adversarial training process, which determines whether the GAN model converges to a Nash Equilibrium (Chen et al., 2016). We conduct a set of experiments to explore the influence of the discriminator's capacities to the adversarial training. Figure 2 shows the relevance scores with respect to different convolution window sizes for the CNN discriminator, where "Filter[x]" denotes the CNN with its convolution window(s) set to x.

It can be found that the discriminator with "Filter[1, 2]" achieves the best performance. Two facts based on the principle of GAN could be taken to explain this observation: On one hand, a discriminator with too low capacity (such as "Filter[1]") is less capable in distinguishing human responses from generated ones, which will backpropagate inappropriate signals that misleads the generator. On the other hand, if the capacity of the discriminator is too high (such as "Filter[1, 2, 3]"), in the adversarial training, the training of the discriminator will converge too fast before the generator being sufficiently trained (Durugkar et al., 2016). A similar phenomenon is also observed on the OpenSubtitles dataset. Since the relevance between queries and their corresponding responses is essential in this task, discriminators with "Filter[1,2]" are adopted in the experiments reported in subsections 5.1 and 5.2.

5.4 Case Study

To demonstrate the intuitive performance of the proposed model in comparison with the naïve Seq2Seq model, we provide some example cases in Figure 3, where for each query the response is the top hypothesis obtained via beam search. Especially, we show that when the vanilla approach generates safe responses such as "I don't know what to do", the adversarially trained method can still yield more informative outputs. Furthermore, when both models produces informative responses, the utterance generated by GAN-AEL tends to be of more interestingness, which is a reflection of novelty and diversity.

6 Conclusion

In this paper, we proposed a GAN framework to model single-turn short-text conversations. An approximation embedding layer is introduced to force the entire network differentiable, which significantly overcomes the drawbacks found in

Example responses generated based on the OpenSubtitle data	Example responses generated based on the Baidu Tieba data
Query: You swore an oath when you put that uniform on. **Seq2Seq:** I don't know what to do. **GAN-AEL:** I think I had a good reason.	**Query:** 你喜欢猫还是狗？Do you like cats or dogs? **Seq2Seq:** 喜欢养猫。I Like cats. **GAN-AEL:** 我喜欢金毛。I like golden retriever.
Query: Entire town knows your son is a goon. **Seq2Seq:** What do you mean? **GAN-AEL:** His life is really a sad story.	**Query:** 你像奥巴马的妻子。You look like Obama's wife. **Seq2Seq:** 哈哈哈哈哈哈。Haha... **GAN-AEL:** 我是大众脸。I have a common face.
Query: Turn his face away from me. **Seq2Seq:** I don't know what to do. **GAN-AEL:** Let me explain to you about the mistake.	**Query:** 我不光搭讪，还请吃饭呢。 I wish to invite you to dinner rather than chat up only. **Seq2Seq:** 我也想吃。I want to have dinner too. **GAN-AEL:** 我是胖子，减肥。I am fat, and I am on a diet.

the previous RL-based attempts (Li et al., 2017). The superiority of the proposed method has been demonstrated by empirical experiments based on both automatic evaluation metrics and human judgements. Further explorations of GAN-based techniques to model contextual information in dialogue problems will be addressed in our future research.

Abstract

In this paper we explore the effect of architectural choices on learning a variational autoencoder (VAE) for text generation. In contrast to the previously introduced VAE model for text where both the encoder and decoder are RNNs, we propose a novel hybrid architecture that blends fully feed-forward convolutional and deconvolutional components with a recurrent language model. Our architecture exhibits several attractive properties such as faster run time and convergence, ability to better handle long sequences and, more importantly, it helps to avoid the issue of the VAE collapsing to a deterministic model.

1 Introduction

Generative models of texts are currently at the cornerstone of natural language understanding enabling recent breakthroughs in machine translation (Bahdanau et al., 2014; Wu et al., 2016), dialogue modelling (Serban et al., 2016), abstractive summarization (Rush et al., 2015), etc.

Currently, RNN-based generative models hold state-of-the-art results in both unconditional (Józefowicz et al., 2016; Ha et al., 2016) and conditional (Vinyals et al., 2014) text generation. At a high level, these models represent a class of autoregressive models that work by generating outputs sequentially one step at a time where the next predicted element is conditioned on the history of elements generated thus far.

Variational autoencoders (VAE), recently introduced by (Kingma and Welling, 2013; Rezende et al., 2014), offer a different approach to generative modeling by integrating stochastic latent variables into the conventional autoencoder architecture. The primary purpose of learning VAE-based generative models is to be able to generate realistic examples as if they were drawn from the input data distribution by simply feeding noise vectors through the decoder. Additionally, the latent representations obtained by applying the encoder to input examples give a fine-grained control over the generation process that is harder to achieve with more conventional autoregressive models. Similar to compelling examples from image generation, where it is possible to condition generated human faces on various attributes such as hair, skin color and style (Yan et al., 2015; Larsen et al., 2015), in text generation it should be possible to also control various attributes of the generated sentences, such as, for example, sentiment or writing style.

While training VAE-based models seems to pose little difficulty when applied to the tasks of generating natural images (Bachman, 2016; Gulrajani et al., 2016) and speech (Fraccaro et al., 2016), their application to natural text generation requires additional care (Bowman et al., 2016; Miao et al., 2015). As discussed by Bowman et al. (2016), the core difficulty of training VAE models is the collapse of the latent loss (represented by the KL divergence term) to zero. In this case the generator tends to completely ignore latent representations and reduces to a standard language model. This is largely due to the high modeling power of the RNN-based decoders which with sufficiently small history can achieve low reconstruction errors while not relying on the latent vector provided by the encoder.

In this paper, we propose a novel VAE model for texts that is more effective at forcing the decoder to make use of latent vectors. Contrary to existing work, where both encoder and decoder layers are LSTMs, the core of our model is a feed-forward architecture composed of one-dimensional convolutional and deconvolutional (Zeiler et al., 2010) layers. This choice of architecture helps to gain

Proceedings of the 2017 Conference on Empirical Methods in Natural Language Processing, pages 627–637
Copenhagen, Denmark, September 7–11, 2017. ©2017 Association for Computational Linguistics

more control over the KL term, which is crucial for training a VAE model. Given the difficulty of generating long sequences in a fully feed-forward manner, we augment our network with an RNN language model layer. To the best of our knowledge, this paper is the first work that successfully applies deconvolutions in the decoder of a latent variable generative model of natural text. We empirically verify that our model is easier to train than its fully recurrent alternative, which, in our experiments, fails to converge on longer texts. To better understand why training VAEs for texts is difficult we carry out detailed experiments, discuss optimization difficulties, and propose effective ways to address them. Finally, we demonstrate that sampling from our model yields realistic texts.

2 Related Work

So far, the majority of neural generative models of text are built on the autoregressive assumption (Larochelle and Murray, 2011; van den Oord et al., 2016). Such models assume that the current data element can be accurately predicted given sufficient history of elements generated thus far. The conventional RNN based language models fall into this category and currently dominate the language modeling and generation problem in NLP. Neural architectures based on recurrent (Józefowicz et al., 2016; Zoph and Le, 2016; Ha et al., 2016) or convolutional decoders (Kalchbrenner et al., 2016; Dauphin et al., 2016) provide an effective solution to this problem.

A recent work by Bowman et al. (2016) tackles language generation problem within the VAE framework (Kingma and Welling, 2013; Rezende et al., 2014). The authors demonstrate that with some care it is possible to successfully learn a latent variable generative model of text. Although their model is slightly outperformed by a traditional LSTM (Hochreiter and Schmidhuber, 1997) language model, their model achieves a similar effect as in computer vision where one can (i) sample realistic sentences by feeding randomly generated novel latent vectors through the decoder and (ii) linearly interpolate between two points in the latent space. Miao et al. (2015) apply VAE to bag-of-words representations of documents and the answer selection problem achieving good results on both tasks. Yang et al. (2017) discuss a VAE consisting of RNN encoder and CNN decoder so that the decoder's receptive field is limited. They demonstrate that this allows for a better control of KL and reconstruction terms. Hu et al. (2017) build a VAE for text generation and design a cost function that encourages interpretability of the latent variables. Zhang et al. (2016), Serban et al. (2016) and Zhao et al. (2017) apply VAE to sequence-to-sequence problems, improving over deterministic alternatives. Chen et al. (2016) propose a hybrid model combining autoregressive convolutional layers with the VAE. The authors make an argument based on the Bit-Back coding (Hinton and van Camp, 1993) that when the decoder is powerful enough the best thing for the encoder to do is to make the posterior distribution equivalent to the prior. While they experiment on images, this argument is very relevant to the textual data. A recent work by Bousquet et al. (2017) approaches VAEs and GANs from the optimal transport point of view. The authors show that commonly known blurriness of samples from VAEs trained on image data are a necessary property of the model. While the implications of their argument to models combining latent variables and autoregressive layers trained on non-image data are still unclear, the argument supports the hypothesis of Chen et al. (2016) that difficulty of training a hybrid model is not caused by a simple optimization difficulty but rather may be a more principled issue.

Various techniques to improve training of VAE models where the total cost represents a trade-off between the reconstruction cost and KL term have been used so far: KL-term annealing and input dropout (Bowman et al., 2016; Sønderby et al., 2016), imposing structured sparsity on latent variables (Yeung et al., 2016) and more expressive formulations of the posterior distribution (Rezende and Mohamed, 2015; Kingma et al., 2016). A work by (Mescheder et al., 2017) follows the same motivation and combines GANs and VAEs allowing a model to use arbitrary complex formulations of both prior and posterior distributions. In Section 3.4 we propose another efficient technique to control the trade-off between KL and reconstruction terms.

3 Model

In this section we first briefly explain the VAE framework of Kingma and Welling (2013), then describe our hybrid architecture where the feed-

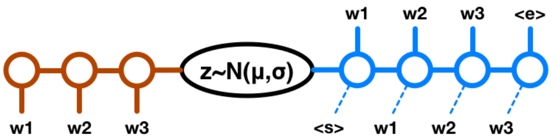

Figure 1: LSTM VAE model of (Bowman et al., 2016)

forward part is composed of a fully convolutional encoder and a decoder that combines deconvolutional layers and a conventional RNN. Finally, we discuss optimization recipes that help VAE to respect latent variables, which is critical training a model with a meaningful latent space and being able to sample realistic sentences.

3.1 Variational Autoencoder

The VAE is a recently introduced latent variable generative model, which combines variational inference with deep learning. It modifies the conventional autoencoder framework in two key ways. Firstly, a deterministic internal representation $\mathbf{z}$ (provided by the encoder) of an input $\mathbf{x}$ is replaced with a posterior distribution $q(\mathbf{z}|\mathbf{x})$. Inputs are then reconstructed by sampling $\mathbf{z}$ from this posterior and passing them through a decoder. To make sampling easy, the posterior distribution is usually parametrized by a Gaussian with its mean and variance predicted by the encoder. Secondly, to ensure that we can sample from any point of the latent space and still generate valid and diverse outputs, the posterior $q(\mathbf{z}|\mathbf{x})$ is regularized with its KL divergence from a prior distribution $p(\mathbf{z})$. The prior is typically chosen to be also a Gaussian with zero mean and unit variance, such that the KL term between posterior and prior can be computed in closed form (Kingma and Welling, 2013). The total VAE cost is composed of the reconstruction term, i.e., negative log-likelihood of the data, and the KL regularizer:

$$\begin{aligned} J_{vae} = & KL(q(\mathbf{z}|\mathbf{x})||p(\mathbf{z})) \\ & -\mathbb{E}_{q(\mathbf{z}|\mathbf{x})}[\log\ p(\mathbf{x}|\mathbf{z})] \end{aligned} \quad (1)$$

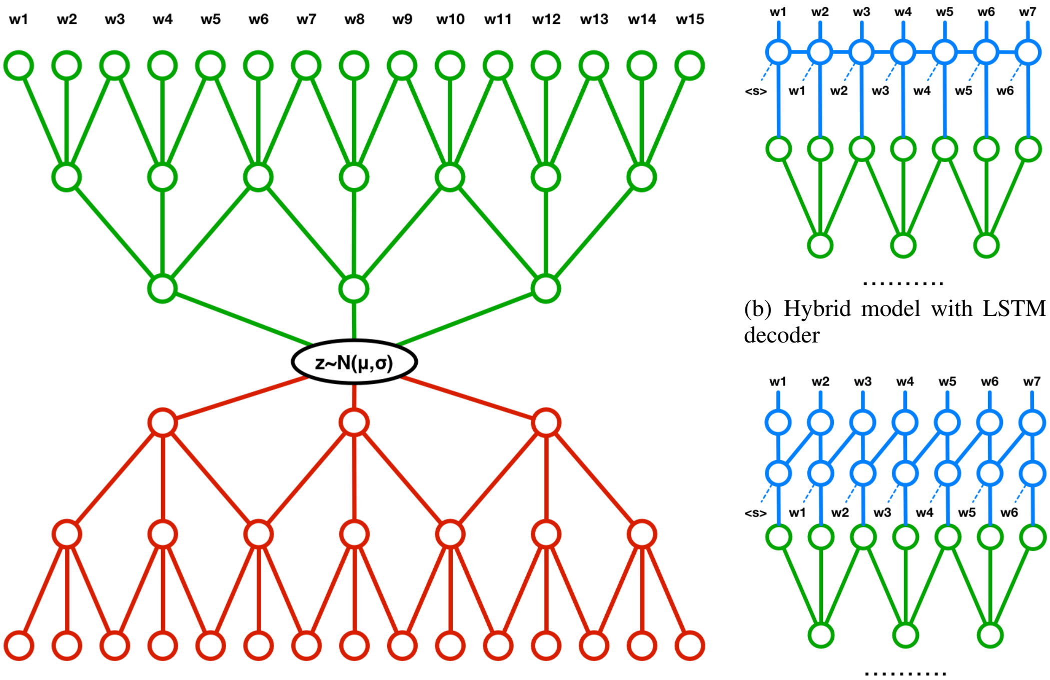
Kingma and Welling (2013) show that the loss function from Eq (1) can be derived from the probabilistic model perspective and it is an upper bound on the true negative likelihood of the data.

One can view a VAE as a traditional Autoencoder with some restrictions imposed on the internal representation space. Specifically, using a sample from the $q(\mathbf{z}|\mathbf{x})$ to reconstruct the input instead of a deterministic $\mathbf{z}$, forces the model to map an input to a region of the space rather than to a single point. The most straight-forward way to achieve a good reconstruction error in this case is to predict a very sharp probability distribution effectively corresponding to a single point in the latent space (Raiko et al., 2014). The additional KL term in Eq (1) prevents this behavior and forces the model to find a solution with, on one hand, low reconstruction error and, on the other, predicted posterior distributions close to the prior. Thus, the decoder part of the VAE is capable of reconstructing a sensible data sample from every point in the latent space that has non-zero probability under the prior. This allows for straightforward generation of novel samples and linear operations on the latent codes. Bowman et al. (2016) demonstrate that this does not work in the fully deterministic Autoencoder framework . In addition to regularizing the latent space, KL term indicates how much information the VAE stores in the latent vector.

Bowman et al. (2016) propose a VAE model for text generation where both encoder and decoder are LSTM networks (Figure 1). We will refer to this model as LSTM VAE in the remainder of the paper. The authors show that adapting VAEs to text generation is more challenging as the decoder tends to ignore the latent vector (KL term is close to zero) and falls back to a language model. Two training tricks are required to mitigate this issue: (i) KL-term annealing where its weight in Eq (1) gradually increases from 0 to 1 during the training; and (ii) applying dropout to the inputs of the decoder to limit its expressiveness and thereby forcing the model to rely more on the latent variables. We will discuss these tricks in more detail in Section 3.4. Next we describe a deconvolutional layer, which is the core element of the decoder in our VAE model.

3.2 Deconvolutional Networks

A deconvolutional layer (also referred to as transposed convolutions (Gulrajani et al., 2016) and fractionally strided convolutions (Radford et al., 2015)) performs spatial up-sampling of its inputs and is an integral part of latent variable generative models of images (Radford et al., 2015; Gulrajani et al., 2016) and semantic segmentation algorithms (Noh et al., 2015). Its goal is to perform an “inverse” convolution operation and increase spatial size of the input while decreasing the number of feature maps. This operation can be viewed as



(a) Fully feed-forward component of our VAE model

(b) Hybrid model with LSTM decoder

(c) Hybrid model with ByteNet decoder

Figure 2: Illustrations of our proposed models.

a backward pass of a convolutional layer and can be implemented by simply switching the forward and backward passes of the convolution operation. In the context of generative modeling based on global representations, the deconvolutions are typically used as follows: the global representation is first linearly mapped to another representation with small spatial resolution and large number of feature maps. A stack of deconvolutional layers is then applied to this representation, each layer progressively increasing spatial resolution and decreasing the amount of feature channels. The output of the last layer is an image or, in our case, a text fragment. A notable example of such a model is the deep network of (Radford et al., 2015) trained with adversarial objective. Our model uses a similar approach but is instead trained with the VAE objective.

There are two primary motivations for choosing deconvolutional layers instead of the dominantly used recurrent ones: firstly, such layers have extremely efficient GPU implementations due to their fully parallel structure. Secondly, feed-forward architectures are typically easier to optimize than their recurrent counterparts, as the number of back-propagation steps is constant and potentially much smaller than in RNNs. Both points become significant as the length of the generated text increases. Next, we describe our VAE architecture that blends deconvolutional and RNN layers in the decoder to allow for better control over the KL-term.

3.3 Hybrid Convolutional-Recurrent VAE

Our model is composed of two relatively independent modules. The first component is a standard VAE where the encoder and decoder modules are parametrized by convolutional and deconvolutional layers respectively (see Figure 2(a)). This architecture is attractive for its computational efficiency and simplicity of training.

The other component is a recurrent language model consuming activations from the deconvolutional decoder concatenated with the previous output characters. We consider two flavors of recurrent functions: a conventional LSTM network (Figure 2(b)) and a stack of masked convolutions also known as the ByteNet decoder from Kalchbrenner et al. (2016) (Figure 2(c)). The primary reason for having a recurrent component in the decoder is to capture dependencies between elements of the text sequences – a hard task for a fully feed-forward architecture. Indeed, the conditional distribution $P(\mathbf{x}|\mathbf{z}) = P(x_1, \ldots, x_n|\mathbf{z})$ of generated sentences cannot be richly represented with a feed-forward network. Instead, it factorizes as: $P(x_1, \ldots, x_n|\mathbf{z}) = \prod_i P(x_i|\mathbf{z})$ where components are independent of each other and are conditioned only on $\mathbf{z}$. To minimize the reconstruction cost the model is forced to encode every detail of a text fragment. A recurrent language model instead models the full joint distribution of output sequences without having to make independence assumptions $P(x_1, \ldots, x_n|\mathbf{z}) = \prod_i P(x_i|x_{i-1}, \ldots, x_1, \mathbf{z})$. Thus, adding a recurrent layer on top of our fully feed-forward encoder-decoder architecture relieves it from encoding every aspect of a text fragment into the latent vector and allows it to instead focus on more high-level semantic and stylistic features.

Note that the feed-forward part of our model is different from the existing fully convolutional approaches of Dauphin et al. (2016) and Kalchbrenner et al. (2016) in two respects: firstly, while being fully parallelizable during training, these models still require predictions from previous time steps during inference and thus behave as a variant of recurrent networks. In contrast, expansion of the z vector is fully parallel in our model (except for the recurrent component). Secondly, our model down- and up-samples a text fragment during processing while the existing fully convolutional decoders do not. Preserving spatial resolution can be beneficial to the overall result, but comes at a higher computational cost. Lastly, we note that our model imposes an upper bound on the size of text samples it is able to generate. While it is possible to model short texts by adding special padding characters at the end of a sample, generating texts longer than certain thresholds is not possible by design. This is not an unavoidable restriction, since the model can be extended to generate variable sized text fragments by, for example, variable sized latent codes. These extensions however are out of scope of this work.

3.4 Optimization Difficulties

The addition of the recurrent component results in optimization difficulties that are similar to those described by Bowman et al. (2016). In most cases the model converges to a solution with a vanishingly small KL term, thus effectively falling back to a conventional language model. Bowman et al. (2016) have proposed to use input dropout and KL term annealing to encourage their model to encode meaningful representations into the $\mathbf{z}$ vector. We found that these techniques also help our model to achieve solutions with non-zero KL term.

KL term annealing can be viewed as a gradual transition from conventional deterministic Autoencoder to a full VAE. In this work we use linear annealing from 0 to 1. We have experimented with other schedules but did not find them to have a significant impact on the final result. As long as the KL term weight starts to grow sufficiently slowly, the exact shape and speed of its growth does not seem to affect the overall result. We have found the following heuristic to work well: we first run a model with KL weight fixed to 0 to find the number of iterations it needs to converge. We then configure the annealing schedule to start after the unregularized model has converged and last for no less than 20% of that amount.

While helping to regularize the latent vector, input dropout tends to slow down convergence. We propose an alternative technique to encourage the model to compress information into the latent vector: in addition to the reconstruction cost computed on the outputs of the recurrent language model, we also add an auxiliary reconstruction term computed from the activations of the last deconvolutional layer:

$$\begin{aligned} J_{aux} &= -\mathbb{E}_{q(\mathbf{z}|\mathbf{x})}[\log\ p(\mathbf{x}|\mathbf{z})] \\ &= -\mathbb{E}_{q(\mathbf{z}|\mathbf{x})}[\sum_t \log\ p(x_t|\mathbf{z})]. \end{aligned} \tag{2}$$

Since at this layer the model does not have access to previous output elements it needs to rely on the $\mathbf{z}$ vector to produce a meaningful reconstruction. The final cost minimized by our model is:

$$J_{hybrid} = J_{vae} + \alpha J_{aux} \tag{3}$$

where α is a hyperparameter, J_{aux} is the intermediate reconstruction term and J_{vae} is the bound from Eq (1). Expanding the two terms from Eq (3) gives:

$$\begin{aligned} J_{hybrid} &= KL(q(\mathbf{z}|\mathbf{x})||p(\mathbf{z})) \\ &-\mathbb{E}_{q(\mathbf{z}|\mathbf{x})}[\sum_t \log\ p(x_t|\mathbf{z}, x_{<t})] \\ &-\alpha\mathbb{E}_{q(\mathbf{z}|\mathbf{x})}[\sum_t \log p(x_t|\mathbf{z})]. \end{aligned} \tag{4}$$

The objective function from Eq (4) puts a mild constraint on the latent vector to produce features useful for historyless reconstruction. Since the autoregressive part reuses these features, it also improves the main reconstruction term. We are thus able to encode information in the latent vector without hurting expressiveness of the decoder.

One can view the objective function in Eq 4 as a joint objective for two VAEs: one only feed-forward, as in Figure 2(a), and the other combining feed-forward and recurrent parts, as in Figures 2(b) and 2(c), that partially share parameters. Since the feed-forward VAE is incapable of producing reasonable reconstructions without making use of the latent vector, the full architecture also gains access to the latent vector through shared parameters. We note that this trick comes at a cost of worse result on the density estimation task, since part of the parameters of the full model are trained to optimize an objective that does not capture all the dependencies that exist in the textual data. However, the gap between purely deterministic LM and our model is small and easily controllable by the α hyperparameter. We refer the reader to Figure 4 for quantitative results regarding the effect of α on the performance of our model on the LM task.

4 Experiments

We use KL term annealing and input dropout when training the LSTM VAE models from Bowman et al. (2016) and KL term annealing and regularized objective function from Eq (3) when training our models. All models were trained with the Adam optimization algorithm (Kingma and Ba, 2014) with decaying learning rate. We use Layer Normalization (Ba et al., 2016) in LSTM layers and Batch Normalization (Ioffe and Szegedy, 2015) in convolutional and deconvolutional layers. To make our results easy to reproduce we have released the source code of all our experiments[1].

Data. Our first task is character-level language generation performed on the standard Penn Treebank dataset (Marcus et al., 1993). One of the goals is to test the ability of the models to successfully learn the representations of long sequences. For training, fixed-size data samples are selected from random positions in the standard training and validation sets.

4.1 Comparison with LSTM VAE

Historyless decoding. We start with an experiment where the decoder is forced to ignore the history and has to rely fully on the latent vector. By conditioning the decoder only on the latent vector $\mathbf{z}$ we can directly compare the expressiveness of the compared models. For the LSTM VAE model historyless decoding is achieved by using the dropout on the input elements with the dropout rate equal to 1 so that its decoder is only conditioned on the $\mathbf{z}$ vector and, implicitly, on the number tokens generated so far. We compare it to our fully-feedforward model without the recurrent layer in the decoder (Figure 2(a)). Both networks are parametrized to have comparable number of parameters.

To test how well both models can cope with the stochasticity of the latent vectors, we minimize only the reconstruction term from Eq. (1). This is equivalent to a pure autoencoder setting with stochastic internal representation and no regularization of the latent space. This experiment corresponds to an initial stage of training with KL term annealing when its weight is set to 0. We pursue two goals with this experiment: firstly, we investigate how do the two alternative encoders behave in the beginning of training and establish a lower bound on the quality of the reconstructions. Secondly, we attempt to put the Bit Back coding argument from Chen et al. (2016) in context. The authors assume the encoder to be powerful enough to produce a good representation of the data. One interpretation of this argument applied to textual data is that factorizing the joint probability as $p(\mathbf{x}) = \prod_t p(x_t|x_{<t})$ provides the model with a sufficiently powerful decoder that does not need the latent variables. However, our experimental results suggest that LSTM encoder may not be a sufficiently expressive encoder for VAEs for textual data, potentially making the argument inapplicable.

The results are presented in Figure 3. Note that when the length of input samples reaches 30 characters, the historyless LSTM autoencoder fails to fit the data well, while the convolutional architecture converges almost instantaneously. The results appear even worse for LSTMs on sequences of 50 characters. To make sure that this effect is not caused by optimization difficulties, i.e. exploding gradients (Pascanu et al., 2013), we have searched over learning rates, gradient clipping thresholds and sizes of LSTM layers but were only able to get results comparable to those shown in Figure 3. Note that LSTM networks make use of Layer Nor-

Figure 3: Training curves of LSTM autoencoder and our model on samples of different length. Solid and dashed lines show training and validation curves respectively. Note that the model exhibits little to no overfitting since the validation curve follows the training one almost perfectly.

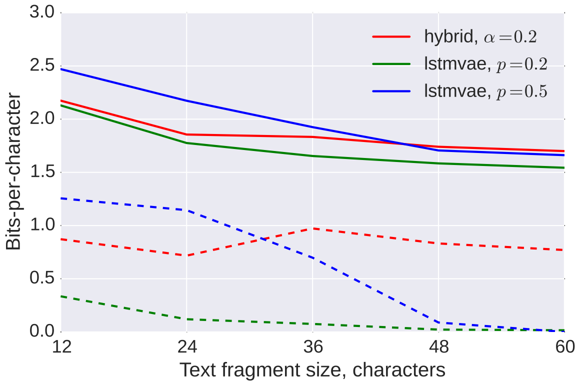

Figure 4: The full cost (solid lines) and its KL component (dashed lines) in bits-per-character of our Hybrid model trained with 0.2 α hyper-parameter vs. LSTM based VAE trained with 0.2 and 0.5 input dropout, measured on validation partition.

malization (Ba et al., 2016) which has been shown to make training of such networks easier. These results suggest that our model is easier to train than the LSTM-based model, especially for modeling longer pieces of text. Additionally, our model is computationally faster by a factor of roughly two, since we run only one recurrent network per sample and time complexity of the convolutional part is negligible in comparison.

Decoding with history. We now move to a case where the decoder is conditioned on both the latent vector and previous output elements. In these experiments we pursue two goals: firstly, we verify whether the results obtained on the historyless decoding task also generalize to a less restricted case. Secondly, we study how well the models cope with stochasticity introduced by the latent variables. Note that we do not attempt to improve the state-of-the-art result on the Language Modeling task but instead focus on providing an approach capable of generating long and diverse sequences. We experiment on the task to obtain a detailed picture of how are our model and LSTM VAE affected by various choices and compare the two models, focusing on how effective is the encoder at producing meaningful latent vector. However, we note that our model performs fairly well on the LM task and is only slightly worse than purely deterministic Language Model, trained in the same environment, and is comparable to the one of Bowman et al. (2016) in this regard.

We fix input dropout rates at 0.2 and 0.5 for LSTM VAE and use auxiliary reconstruction loss (Section 3.4) with 0.2 weight in our Hybrid model. The bits-per-character scores on differently sized text samples are presented in Figure 4. As discussed in Section 3.1, the KL term value indicates how much information the network stores in the latent vector. We observe that the amount of information stored in the latent vector by our model and the LSTM VAE is comparable when we train on short samples and largely depends on hyper-parameters α and p. When the length of a text fragment increases, LSTM VAE is able to put less information into the latent vector (i.e., the KL component is small) and for texts longer than 48 characters, the KL term drops to almost zero while for our model the ratio between KL and reconstruction terms stays roughly constant. This suggests that our model is better at encoding latent representations of long texts since the amount of information in the latent vector does not decrease as the length of a text fragment grows. In contrast, there is a steady decline of the KL term of the LSTM VAE model. This result is consistent with our findings from the historyless decoding experiment. Note that in both of these experiments the LSTM VAE model fails to produce meaningful latent vectors with inputs over 50 characters long. This further suggests that our Hybrid model en-

codes long texts better than the LSTM VAE.

4.2 Controlling the KL term

We study the effect of various training techniques that help control the KL term which is crucial for training a generative VAE model.

Aux cost weight. First, we provide a detailed view of how optimization tricks discussed in Section 3.4 affect the performance of our Hybrid model. Figure 5 presents results of our model trained with different values of α from Eq. (3). Note that the inclusion of the auxiliary reconstruction loss slightly harms the bound on the likelihood of the data but helps the model to rely more on the latent vector as α grows. A similar effect on model's bound was observed by Bowman et al. (2016): increased input dropout rates force their model to put more information into the $\mathbf{z}$ vector but at the cost of increased final loss values. This is a trade-off that allows for sampling outputs in the VAE framework. Note that our model can find a solution with non-trivial latent vectors when trained with the full VAE loss provided that the α hyper-parameter is large enough. Combining it with KL term annealing helps to find non-zero KL term solutions at smaller α values.

Receptive field. The goal of this experiment is to study the relationship between the KL term values and the expressiveness of the decoder. Without KL term annealing and input dropout, the RNN decoder in LSTM VAE tends to completely ignore information stored in the latent vector and essentially falls back to an RNN language model. To have a full control over the receptive field size of the recurrent component in our decoder, we experiment with masked convolutions (Figure 2(c)), which is similar to the decoder in ByteNet model from Kalchbrenner et al. (2016). We fix the size of the convolutional kernels to 2 and do not use dilated convolutions and skip connections as in the original ByteNet.

The resulting receptive field size of the recurrent layer in our decoder is equal to $N + 1$ characters, where N is the number of convolutional layers. We vary the number of layers to find the amount of preceding characters that our model can consume without collapsing the KL term to zero.

Results of these experiments are presented in Figure 6. Interestingly, with the receptive field size larger than 3 and without the auxiliary reconstruction term from Eq. (3) ($\alpha = 0$) the KL term collapses to zero and the model falls back to a pure language model. This suggests that the training signal received from the previous characters is much stronger than that from the input to be reconstructed. Using the auxiliary reconstruction term, however, helps to find solutions with non-zero KL term component irrespective of receptive field size. Note that increasing the value of α results in stronger values of KL component. This is consistent with the results obtained with LSTM decoder in Figure 5.

Table 1: Random sample tweets generated by LSTM VAE (top) and our Hybrid model (bottom).

	Rec	KL
LSTM, $p = 0.2$	67.4	1.0
LSTM, $p = 0.5$	77.1	2.1
LSTM, $p = 0.8$	93.7	3.8
Hybrid, $\alpha = 0.2$	58.5	12.5

Table 2: Breakdown into KL and reconstruction terms for char-level tweet generation. p refers to input dropout rate.

4.3 Generating Tweets

In this section we present qualitative results on the task of generating tweets.

Data. We use 1M tweets[2] to train our model and test it on a held out dataset of 10k samples. We minimally preprocess tweets by only replacing user ids and urls with "@userid" and "url".

Setup. We use 5 convolutional layers with the ReLU non-linearity, kernel size 3 and stride 2 in the encoder. The number of feature maps is [128, 256, 512, 512, 512] for each layer respectively. The decoder is configured equivalently but with the amount of feature maps decreasing in each consecutive layer. The top layer is an LSTM with 1000 units. We have not observed significant overfitting. The baseline LSTM VAE model contained two distinct LSTMs both with 1000 cells. The models have comparable number of parameters: 10.5M for the LSTM VAE model and 10.8M for our hybrid model.

Results. Both VAE models are trained on the character-level generation. The breakdown of total cost into KL and reconstruction terms is given in Table 2. Note that while the total cost values are comparable, our model puts more information into the latent vector, further supporting our observations from Section 4.1. This is reflected in the random samples from both models, presented in Table 1. We perform greedy decoding during generation so any variation in samples is only due to the latent vector. LSTM VAE produces very limited range of tweets and tends to repeat "@userid" sequence, while our model produces much more diverse samples.

5 Conclusions

We have introduced a novel generative model of natural texts based on the VAE framework. Its core components are a convolutional encoder and a deconvolutional decoder combined with a recurrent layer. We have shown that the feed-forward part of our model architecture makes it easier to train a VAE and avoid the problem of KL-term collapsing to zero, where the decoder falls back to a standard language model thus inhibiting the sampling ability of VAE. Additionally, we propose an efficient way to encourage the model to rely on the latent vector by introducing an additional cost term in the training objective. We observe that it works well on long sequences which is hard to achieve with purely RNN-based VAEs using the previously proposed tricks such as KL-term annealing and input dropout. Finally, we have extensively evaluated the trade-off between the KL-term and the reconstruction loss. In particular, we investigated the effect of the receptive field size on the ability of the model to respect the latent vector which is crucial for being able to generate realistic and diverse samples. In future work we plan to apply our VAE model to semi-supervised NLP tasks and experiment with conditioning generation on text attributes such as sentiment and writing style.

Acknowledgments

Abstract

Computerized generation of humor is a notoriously difficult AI problem. We develop an algorithm called *Libitum* that helps humans generate humor in a Mad Lib®, which is a popular fill-in-the-blank game. The algorithm is based on a machine learned classifier that determines whether a potential fill-in word is funny in the context of the Mad Lib story. We use Amazon Mechanical Turk to create ground truth data and to judge humor for our classifier to mimic, and we make this data freely available. Our testing shows that Libitum successfully aids humans in filling in Mad Libs that are usually judged funnier than those filled in by humans with no computerized help. We go on to analyze why some words are better than others at making a Mad Lib funny.

1 Introduction

As technologists attempt to build more natural human-computer interfaces, the inclusion of computer-generated humor becomes more important for creating personable interactions. However, computational humor remains a long-standing challenge in AI. Despite decades devoted to theories and algorithms for humor, the best computerized humor is still mediocre compared to humans. Humor requires creativity, sophistication of language, world knowledge, empathy and cognitive mechanisms, which are extremely difficult to model theoretically. A more modest goal for computational humor is to build machines that help humans create humor rather than replace them.

noun

Figure 1: Example of a Mad Lib sentence. The original words for the blanks, in order, were "apartment", "impatient" and "gallery".

We develop and test an algorithm, called Libitum[1], for a computer-aided approach to humor generation. Its aim is to help a human player fill in the blanks of a Mad Lib® story to make it funny. The algorithm generates candidate words, and its core component is a machine-trained classifier that can assess whether a potential fill-in-the-blank word is funny, based on several features, including the blank's surrounding context. We trained the classifier on Mad Lib stories that were filled in and judged by humans. We note that in our work, we give players, both human and computer, access to the full Mad Lib story, including the sentences surrounding the blanks. In regular Mad Libs, players do not see the surrounding sentences. Figure 1 shows a sentence from a typical Mad Lib, completed by a human player.

The work presented here makes three contributions. The first is the creation of a challenging benchmark for humor generation, a vital aspect of human communication which has received relatively little attention in the NLP community. This benchmark, based on Mad Libs, (i) is challenging, but doable by both humans and machines, (ii) provides quantitative results so that progress can be measured, and (iii) cannot be gamed by trivial strategies, such as filling in random words. The benchmark dataset is annotated and judged us-

[1] Libitum is Latin for "pleased". Mad Lib is a humorous variation of the Latin ad lib, where lib is short for Libitum.

Proceedings of the 2017 Conference on Empirical Methods in Natural Language Processing, pages 638–647
Copenhagen, Denmark, September 7–11, 2017. ©2017 Association for Computational Linguistics

ing Amazon Mechanical Turk, with several steps taken to reduce effects of human variation in humor taste. Our second contribution is that we create and demonstrate a computer-aided humor algorithm that, in most cases, allows humans to generate funnier Mad Lib stories than they can on their own without computer assistance. The third contribution is an analysis of our test data and algorithm that helps to quantitatively explain what makes our results humorous.

Our work goes beyond the modeling and generation of language to simply convey information. Instead, we are trying to create a pleasurable feeling using humor. This is analogous to the Story Cloze Test (Mostafazadeh et al., 2017), where the task is to choose a *satisfying* ending to a story.

We note the previous work called "Visual Madlibs" (Yu et al., 2015). Although its title implies similarity to our work, it is about an image data set augmented with fill-in-the-blank questions, such as "This place is a park."

2 Related Work

Developing a general humor recognizer or generator is hard, and some researchers consider it an AI-complete problem (Stock and Strapparava, 2003), *i.e.*, "solving" computational humor is as difficult as making computers as intelligent as people.

While our goal is generating humor, there is a growing literature of projects for recognizing humor, mostly aimed at specific types of jokes.

Taylor and Mazlack's (2004) work on knock-knock jokes is based on Raskin's (2012) "semantic theory of verbal humor", which says that humor comes from script opposition. Here, the joke posits two different interpretations that oppose each other, resulting in humor. They analyze the two key parts of knock-knock jokes to discover the wordplay that results in the humorous opposition.

Mihalcea and Strapparava (2006) developed a classifier to recognize one-liner jokes by looking for alliteration, antonymy, and adult slang. Compared to different classes of non-jokes, they achieved an accuracy of between 79% and 97%.

Davidov *et al.* (2010) decompose potential sarcastic sentences into specialized parts of speech and match them against sentence patterns that they discovered in their corpus of sarcasm. Like us, they used Mechanical Turk to find ground truth.

Kiddon and Brun (2011) present a classifier that recognizes double entendres that become funny after adding "That's what she said" at the end.

Other humor recognition efforts do not start with constraints on the type of humor they recognize. For instance, Zhang and Liu's (2014) system recognized humorous tweets based on 50 linguistic features from humor theory, achieving a classification accuracy of 82%. Raz (2012) shows how to classify humorous tweets into one of 12 joke categories. Betero and Fung (2016) take on the challenging task of recognizing humor from TV sitcoms, using a neural network. They use the sitcom's laugh track to identify ground truth.

Our work is aimed at generating humor rather than recognizing it. As with previous work on humor recognition, humor generation has been largely limited to specific types of jokes. The three examples below, along with ours, show that automatically generating humor still relies on specializing around a subgenre of jokes with customized approaches that have yet to yield a general method for generating humor.

Binsted *et al.*'s Joke Analysis and Production Engine (JAPE) produced punning riddles, such as:

Question: What do you call a weird market?

Answer: A bizarre bazaar. (Binsted et al., 1997)

JAPE worked by discovering candidate ambiguities in either spelling (*e.g.*, cereal *vs.* serial) or word sense (e.g. river bank vs. savings bank). Evaluated by children, JAPEs jokes were funnier than non-jokes, but not as funny as human-generated jokes.

Petrovic and Matthews (2013) created an algorithm to generate jokes such as "I like my coffee like I like my war, cold," filling in the three blanks. They encoded four assumptions about what makes a joke funny, using discrete probability tables learned from a large corpus of regular text data along with part-of-speech tagging and an estimate of different possible senses of the words. 16% of their automatically generated jokes were considered funny, compared to 33% when the same type of jokes were generated by people.

HAHAcronyn, from Stock and Strapparava (2003) attempted to take existing acronyms (e.g. DMSO for Defense Modeling and Simulation Office) and make an alternate, funny version (e.g. Defense Meat-eating and Salivation Office). Their algorithm keeps part of the acronym and then looks for what to change in the remainder, with goals of different semantics, rhymes, antonyms, and extreme-sounding adverbs.

Besides the novelty of looking at Mad Libs, our work is different in that it seeks to generate humor for *longer* passages than the acronyms, one-liners, and short riddles of previous work.

In addition to algorithmic work, there is a long history of research into general theories of humor (O'Shannon, 2012; Weems, 2014; Wilkins and Eisenbraun, 2009). One of the main thrusts is incongruity theory, which says that a joke is funny when it has a surprise that violates the conventional expectation. According to the Benign Violation Theory (Raskin, 2008), the unexpected must logically follow from the set up and must not be offensive to the reader, otherwise the reader is left confused and the joke is not funny. Similarly, the Sematic Script Theory of Humor (SSTH) says that a joke emerges when it can be interpreted according to two different, generic scripts, one of which is less obvious (Attardo and Raskin, 1991). Labutov and Lipson make a first step at exploiting the SSTH theory to automatically generate two-line jokes (Labutov and Lipson, 2012).

In general, it is difficult to apply these theories directly to humor recognition and generation, however, because they require a high degree of common sense understanding of the world. Because of this, most successful algorithmic work on humor is limited to using relatively shallow linguistic rules on specific types of jokes. This is also true of our work, which concentrates on filling the blanks in Mad Libs, described next.

3 Mad Libs®

Invented in 1953 by Roger Price and Leonard Stern (2008a), Mad Libs is a fill-in-the blank game intended to be humorous. A Mad Lib consists of a story of several sentences and a title. Some of the words are replaced with blanks, each of which has a **hint** belonging to a certain **hint type**, such as a part of speech. Players fill in each blank with a word that agrees with the hint. A player can see only the story's title and the list of blanks with hints. The resulting filled-in Mad Lib is usually funny, because players fill in the blanks with no knowledge of the story (except for its title). The humor comes from the nonsensical filled-in words in the context of a sensible, coherent story. Figure 1 shows part of a filled-in Mad Lib created from a story describing the theft of the Mona Lisa.

Filling in Mad Libs is a novel challenge for automatic humor generation. The title and words surrounding the blanks in a Mad Lib provide a contextual scaffolding that an algorithm can exploit to choose appropriate words for the blanks that make the resulting story humorous.

In order to incorporate such context, our rules for playing Mad Libs differ from the original ones: both our algorithmic and human players are allowed to look at the story as a guide to filling in the blanks. This makes the problem much richer, because players can take advantage of the story's text in choosing which words to fill in. Without looking at the story, our algorithm would be reduced to one that chooses only *a priori* funny words.

3.1 Fun Libs Generation

Mad Libs are copyrighted, and therefore it is difficult to release a data set by using stories from Mad Libs books. Instead we studied original Mad Libs to develop our own dataset, which we call **Fun Libs**. This data set, including filled-in words and funniness assessments from Mechanical Turkers, is available online.[2]

Designing Mad Lib-like stories requires skill, because the Mad Lib context is usually designed in a way to help generate humor. To create our own stories, we first examined 50 Mad Libs from one of the many Mad Libs books (Price and Stern, 2008b). We found that the mean number of blanks, observed words and sentences per Mad Lib were, respectively, 16.0 ($\sigma = 2.25$), 114.84 ($\sigma = 20.58$) and 9.04 ($\sigma = 2.38$). There were 14 unique hint types.

One of our main goals is to build a system that can create meaningful, diverse, and funny stories which apply to a broad audience. However, in pilot tests with human players, we found that six of the original hint types restricted the variety of humor that can be generated by filling in their blanks, by: (i) not affording a variety of possibilities to fill in (hint types: color, silly word, exclamation) and subtlety in humor generation (number), and (ii) generally requiring the audience to have knowledge of cultural references and specifics (person name, place). Hence, we discarded them, leaving eight hint types in our Fun Libs dataset, as shown in Table 1. Some of them have variants such as plurality for nouns and tenses for verbs.

Next, we created our dataset of 50 Fun Libs using simple Wikipedia articles because, similar to

[2] Fun Libs dataset: https://www.microsoft.com/en-us/download/details.aspx?id=55593

Hint Type	**Mad Libs**	**Fun Libs**
Noun	7.06	7.00
Adjective	4.06	3.12
Verb	1.22	3.10
Part of the Body	0.98	0.46
Adverb	0.44	0.38
Type of Food	0.22	0.20
Animal	0.20	0.36
Type of Liquid	0.18	0.16
All Blanks	**16.0***	**14.78**

Table 1: Mean hint types per story in the two datasets. *The mean number of blanks in the Mad Libs dataset was computed based on 14 hint types.

Mad Libs, these articles have a title and text. Creating the stories involved finding a Wikipedia article and picking sentences which have potential to generate humor (with very minimal edits such as reducing verbosity), and then replacing some words with blanks in a way such that the overall blank, sentence, word and hint type distributions are similar to their respective distributions in the 50 original Mad Libs. Table 1 shows the means of the hint type distributions for the two datasets. We randomly sampled 40 Fun Libs for training and kept the remaining 10 for evaluation.

4 Data Annotation

With a set of Mad Lib-like stories in place, our next task was to objectively create filled-in stories to use as the basis for the remainder of our analysis. We used Amazon Mechanical Turk workers, bootstrapping from an initial set of filled-in stories, to then finding qualified turker judges, and then finding qualified turker players to fill in the blanks. Our goal was to create a labeled dataset with filled-in blanks and a **funniness grade** for each filled-in word. We selected turkers who are native English speakers (from USA, Canada, Great Britain and Australia), have a HIT approval rate above 97%, and have completed at least 10,000 HITs. We now describe how we further selected qualified turkers and the methods we applied to obtain better quality for the labeled data.

4.1 Judge Selection

To grade how funny a filled-in story is, we needed turker judges who were unbiased referees of general humor. We selected judges before players, because we used the judges to find qualified players. Finding good judges is challenging, because humor is subjective. We launched a qualification task to select qualified judges, with clear instructions on what makes a desirable judge. This task involved giving turkers a set of seven filled-in stories to be graded for funniness. Out of these seven, three were direct excerpts from Wikipedia articles with some words marked as filled-in blanks. Except for designating some words as filled-in, these stories were unaltered from Wikipedia, and therefore were not funny. The remaining four stories were filled in by humans to make them funny. Turkers were allowed to select, for each story, a grade from $\{0,1,2,3\}$ (a scale which we used throughout our work) described as follows:

0 - Not funny
1 - Somewhat funny
2 - Moderately funny
3 - Funny

We marked the ground-truth grade of the Wikipedia excerpts as 0, and we used volunteers from our research group to decide the ground-truth grade of the other four stories between one and three. We used 60 candidate turkers to do this qualification task, out of which 27 successfully assigned 0 to all the Wikipedia excerpts and 1-3 to the other four stories. We selected all of them as qualified judges. 16 others graded all the Wikipedia excerpts as 0 but considered 1 of the other four stories to be "Not funny". We sorted these turkers using the total Euclidean distance of their grades from the ground truth, and chose the top 13 among them to get 40 judges in total. To make sure that turkers read each story, we also asked a question that could be answered correctly only by understanding the story's context. During our initial tests, we removed two judges who were repeatedly failing to answer these questions correctly and took very little time to grade. Therefore, our final judge pool included 38 judges. This selection process was designed to find judges that were careful, consistent, and representative in objectively judging the funniness of a filled-in story.

4.2 Player Selection

Players are the people who fill in the blanks in a story. Our goal was to find turker players who were good at creating funny stories by filling in blanks. There was no overlap between the qualified judges and the qualified players. To select qualified players, we created two extra fill-in-the-blank stories to be used for player selection alone. We gave both stories to 50 candidate turkers to fill in. We instructed candidate turkers to avoid using slang words, sexual references or bathroom humor as these are crude, easy techniques for generating humor, and do not require creativity. Further, we required turkers to fill in each blank with exactly one word (using alphabetic characters only) that can be found in a US English dictionary, that is grammatically correct, and that is not colloquial.

To lessen the impact of story contexts and to have a variety in the humor generated, another task was launched with two new stories and 30 new candidate turkers. For each filled-in story, we graded the funniness of each story on our 0-3 scale using 10 qualified judges (described above) to mitigate the effects of variations in humor taste. We ranked the potential players and selected the highest ranked as qualified players. A total of 25 qualified players were obtained from the two batches.

For both the judge and player selection phase, we launched several small pilot tests and used turkers' feedback to design a better data labeling phase, which we cover next.

4.3 Labeling Fun Libs

Our goal in labeling filled-in stories was to assess the funniness of the overall filled-in story, the funniness contribution of each filled-in word, and other aspects of the humor. For each of the 40 stories in the training set, we used 5 players to fill the blanks, giving us a total of 200 filled-in stories. The players also self-graded the humor in their completed stories.

Each of these stories was graded by 9 judges to represent an audience rather than an individual and to reduce effects of different humor tastes. Judges answered the following:

- Which of the filled-in words caused humor.
- Funniness of the story (integer scale of 0-3).
- How coherent the story is, with the filled-in words (integer scale of 0-3).
- To what extent the filled-in words caused the story to deviate from its original topic as suggested by the title (integer scale of 0-3).
- Whether the humor generation technique of **incongruity**[3] was applied by the player.
- A verification quiz, which can be answered using the context of the story, to help ensure that judges read the filled-in story carefully.

We asked judges about coherence because we expected incongruity would play a significant role in the humor of Mad Libs due to their nature.

Judges and players each received 60 U.S. cents per HIT. We also announced bonuses for the top 10 judges selected based on other judges' agreements with them and the top 10 players based on how funny their filled-in stories were, as graded by the judges. The total Mechanical Turk cost, including the bonuses, was approximately US$2000.

5 Computer-aided Humor

In this section, we will discuss our machine learning approach to generating humorous Fun Libs. First we trained a random forest classifier (Breiman, 2001) to predict whether a filled-in word is funny using features from the story and the title. Then our technique for generating complete, funny Fun Libs involves, for each blank:

1. Use a language model to generate words
2. Keep the top 20 funny candidate words as ranked by our classifier
3. Use humans to decide which candidate to fill in the blank with

5.1 Language Model

To supply reasonable words for each blank, we used the Microsoft Web Language Models API (Wang et al., 2010), trained using Web Page titles and available as a Web service. To generate candidate words for a blank, we use the API's word completion tool to get a list of all possible candidate words using context windows up to four previous words. Next, for each word we computed the **joint probability score**, using the API's joint probability tool to get a probability estimate of how well each candidate fits into the containing sentence. Then we ranked candidates using this score. We expect the words with high scores to be the more fitting (less humorous) words for the context, while those with low scores are more likely to be the incongruous words that may generate surprise or humor when used in the sentence.

5.1.1 Candidate Refinement

Since Web page titles for our language model are not forced to be grammatically correct, the generated words are not all appropriate. Thus we applied the following constraints to get a cleaner candidate list:

[3] Incongruity theory of humor says that a joke is funny when it has a surprise, often at the end, that violates the conventional expectation, often set up at the start (Weems, 2014).

- The candidate must be in WordNet (Fellbaum, 1998) or a US English dictionary.
- For a blank that is a sub-category of nouns (*e.g.*, “animal”), the candidate must have the same sub-category as its WordNet hypernym.
- The candidate must have a part of speech tag that agrees with the hint.
- The candidate must not be a word with non-alphabetic characters or a stop word.
- The candidates for nouns and sub-categories have to fit the context in terms of plurality .
- Candidate must not be a slang, adult or bathroom-related word (filtered using a list of 4,012 words), because such words would be too crude, producing shallow, easy humor.

5.2 Features

To predict whether a filled-in word is funny or not, our classifier uses the following ten features extracted from the **(word, story)** pair:

1. Hint type.
2. Length of the word.
3. Language model’s joint probability for the containing sentence with the word filled-in.
4. The word’s relative position, in terms of joint probability, in the ranked candidate list generated by the language model: a value in the interval [0,1], with 0 implying the candidate has the highest joint probability in the list.
5. Minimum, maximum and average letter trigram probabilities using letter bigram and letter trigram counts from the Google Web Trillion Word Corpus (Brants and Franz, 2006). The purpose of these features is to capture the *phonetic funniness* of words (*e.g.*, “whacking” instead of “fighting”).
6. The candidate’s similarity to the three contexts — title, overall story, and the containing sentence. This is the cosine similarity of the candidate’s word embedding vector with the average word embedding vector for each context. The vectors were computed using GloVe vectors (Pennington et al., 2014) trained with 840 billion tokens from Web data.

5.3 Classification

The full training dataset includes 40 labeled Fun Libs, each filled in by 5 different players, each of which was graded by 9 different judges. We split the data randomly by story titles, keeping 30 for training and 10 in a validation set. This ensures that the classifier does not see the validation stories’ contexts during training. Thus, our training set consisted of features and funniness labels for filled-in words from 150 stories. Further, we assigned labels using a **vast majority** vote, *i.e.*, a filled-in word having, out of nine judges’ votes:

- six or more “funny votes” is **funny**
- three or fewer funny votes is **not funny**

Otherwise the word was discarded. As a result, the final dataset includes 1939 instances of filled-in words: 1449 for training and 490 for validation.

	Train	**Validation**
Precision (Funny)	0.712	0.715
Recall (Funny)	0.856	0.801
F1 score (Funny)	0.778	0.756
Accuracy	**0.727**	**0.695**

Table 2: Filled-in word classification results.

We experimented with several machine learning models, including linear regression, to predict the number of positive votes for each word. Among these, the random forest classifier worked best. We performed 10-fold cross validation to train this classifier, optimizing based on the F1 score. The results are shown in Table 2. On the validation data, the classifier has an F1 score of 0.756 and an overall classification accuracy of 69.5%. While these quality measures leave room for improvement, they show that the classifier is clearly biased toward choosing funnier words.

We show results from three baseline classifiers in Table 3. Among these, the “Chance” classifiers always predict the most frequent class found in the training set, and “Chance Hint” predicts the most frequent class for each hint type. The other baseline is a Linear SVM classifier trained using the three most important features of the trained random forest as shown in Figure 2. The SVM’s learned weights for the similarity features between the word and the containing sentence, the entire story, and the title, respectively, were -0.449,

Baseline	**Train**	**Validation**
Chance	0.571	0.543
Chance Hint	0.595	0.591
Linear SVM (3 feat.)	0.606	0.600

Table 3: Baseline classification accuracies.

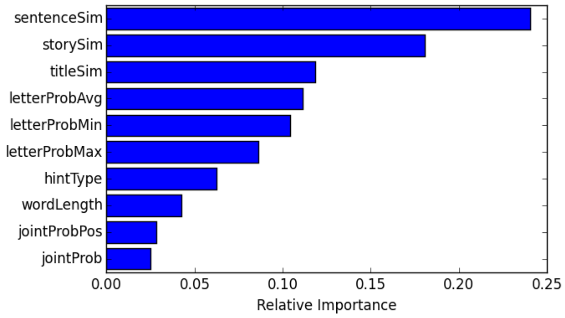

Figure 2: Feature importance for our classifier.

-0.883 and 1.344, showing that funnier filled-in words are similar to the title but not to the body of the story. This suggests that incongruity is playing a significant role in generating humor.

6 Evaluation and Discussion

In this section, we define three approaches for generating humor in Mad Libs, and then we compare and analyze the results we obtain from them. These approaches are:

1. **FreeText**: players fill in the blanks without any restrictions.
2. **LMC** (Language Model + Multiple Choice): for each blank, players choose a word from up to 20 candidate words generated by the language model and sorted by their joint probability score[4].
3. **Libitum**: Similar to the LMC method, except here we rank all the words up to the top 500 words generated by the language model using our classifier, keeping up to the top 20 "humorous" candidates[4].

These methods are designed to study the outcome of humor generated by humans only vs. humans with machine help. The purpose of the LMC model is to study whether the language model alone is a good aid to humans when creating humor, and the benefit of adding machine learning.

For evaluation, we used our ten test Fun Libs, and for each of our three approaches, each of the ten stories was completed by three players. Figure 3 shows the mean grade for these 30 stories. In the figure, the titles are sorted left to right based on the maximum mean story grade among the titles in the Libitum approach. The stories per title are also sorted left to right in descending mean grade. In only one story (ID = 21), the Libitum model receives a lower mean grade than the LMC model, suggesting that adding the machine learning to the language model helps generate significantly more humor than the language model alone. The FreeText model is fairly consistent in generating more humor than the LMC model, which beats the FreeText model in only 7 out of 30 instances. However, the Libitum approach frequently outperforms the FreeText (human only) approach, and it achieves significant gain in generating humor in the stories with the titles "Valentine's Day" and "Cats".

Interestingly, the two stories that received the highest mean grade ("Batman" and "Ducks") are from the FreeText format. This suggests that given more freedom, humans are capable of generating a stronger degree of humor than when they are restricted to a limited number of choices. Excerpts from the best "Batman" story are shown in Figure 4. Here, the strategy employed by the FreeText player is to consistently portray Batman as an obese person obsessed with eating, exploiting the superiority theory of humor[5] (Mulder and Nijholt, 2002). This is remarkable, because it shows how skilled humans are at finding and relating multiple coherent concepts, achieving meaningful and steady humor via continuity, something which is very difficult for machines to do. Much of the humor generated by the Libitum approach here is via incongruity — the filled-in words are quite humorous mainly because they fit their contexts but do not match the expectation of the reader (*e.g.*, Batman is an inefficient superhero). At times, some of the filled-in words in the Libitum approach coherently generate humor, for instance, in the last sentence when Batman is described as wearing a veil to fight acne.

Since each human has a bias towards his/her own understanding of humor, we also studied how the stories appealed to the judges individually by counting the total number of judges for each grade in the three approaches. Table 4 shows the results, where the difference between the mean fun-

[4] In rare cases, for a blank, the language model was only able to generate less than 20 candidate words that pass the candidate refinement step. For such cases, the LMC candidate list was expanded to at least 10 words by adding words randomly from all possible words in WordNet that fit the blank's hint type, if necessary. For Libitum, WordNet was used to randomly add words fitting the blank's hint type to make a list of 50 words that pass the candidate refinement phase. These words were sorted using Libitum and used to ensure the final candidate list had at least 10 words.

[5] Superiority humor comes from the misfortunes or shortcomings of others

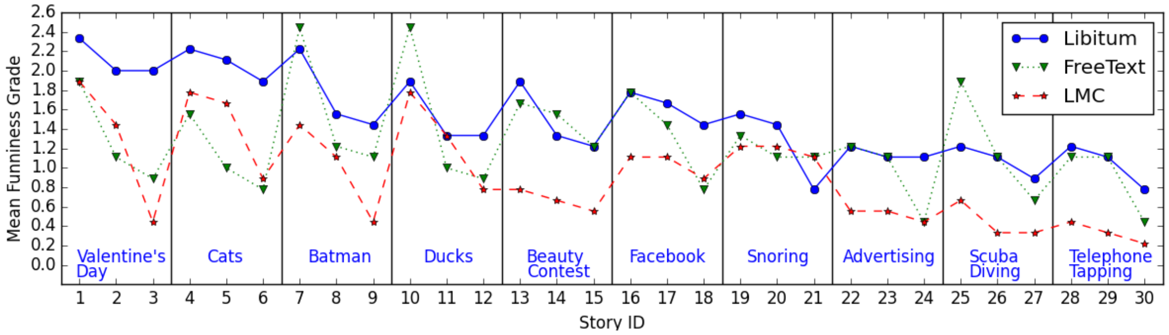

Figure 3: Mean funniness grade for the 30 test stories and their titles. The maximum mean grade for a story in the Libitum format was used to order the titles. For each title, the three stories are sorted in descending mean grade.

Grade	FreeText	LMC	Libitum
0	65	102	37
1	97	100	103
2	84	56	86
3	24	12	44
mean	**1.25**	**0.92**	**1.51**

Table 4: Funniness grades for the 30 stories for the three humor generation formats.

niness grades for each pair of approaches is statistically significant with $p < 0.005$ when a 2-sample t-test was performed. Using Krippendorff's Alpha (Krippendorff, 1970), we also found positive agreements between judges for these and training set ratings.

As expected, the LMC model is the poorest in terms of generating humor. Further, for each non-zero grade, the Libitum model received more votes than the FreeText model. A possible reason is that the judges and players have different perceptions of humor. In the FreeText approach, the common technique employed by players was to use words that are coherent, belonging to a specific topic or domain, and to guide the story towards one conclusion (*e.g.*, the Batman story in Table 4). When this technique worked well, the humor generated was very strong. However, the players have their own biases towards what is humorous, and having more freedom in the FreeText format allowed them to explore their own concept of humor, which could be too narrow to appeal to a broader audience. The Libitum approach, by restricting the players, prevented them from inserting words that they themselves thought were funny, but were not actually funny to people in general.

Table 5 shows passages from stories containing filled-in words that received 9 funniness votes (the maximum possible) from the judges. The story ID and the algorithm used are also provided. Here, in the "Ducks" story, the FreeText player chose to generate humor by developing a steady mockery by satirizing ducks as politicians, whereas the LMC player chose the incongruity approach. The "Beauty Contest" story shows the outstanding skills of humans in generating humor when two blanks are directly connected to each other (*i.e.*, "brawler" and "deadly"). For the same segment, Libitum was also able to aid the players in generating a very funny word, however, the coherence between the blanks does not appear strong. With the computer aided approaches, it is quite difficult to suggest candidates for pairs of (or more) blanks such that the choices are coherent.

6.1 Correlations

Table 6 shows correlations between different ratings by judges (coherence, topic change and incongruity) and the stories' funniness grades. Incongruity had the strongest positive, and statistically significant (with $p < 0.001$), correlation with the graded humor of a story. Coherence also appears very important for generating humor in all the datasets except LMC, where it is difficult to generate coherent words using a language model only. Libitum is likely aiding players in achieving funniness by providing coherent words. In LMC, most of the words generating humor are probably random, incongruous words since the change of topic strongly positively correlates with increasing the humor but coherence does not. Lastly, the player's self grade of humor has no significant relationship with the judges' grade of humor, suggesting that each person has his/her own biases about what is humorous.

Alg.	ID	Text
FText	10	Most ducks are `republican` (adjective) birds, they can be found in both saltwater and fresh **vodka** (liquid). Ducks are omnivorous, eating **talkative** (adjective) plants . . . People commonly feed ducks in ponds stale **jokes** (noun), thinking that the ducks will like to have something to **ridicule** (verb)
LMC	10	Most ducks are `evil` (adjective) birds, they can be found in both saltwater and fresh **coffee** (liquid) . . . Some ducks are not `evil` (adjective), and they are bred and kept by **jesus** (noun).
FText Libtm	14 15	A beauty contest is a/an `elaborate` (adj) contest to decide which **brawler** (n) is the most **deadly** (adj) `observational` `organism` **flammable**
Libtm	5	Cats are the most **barbaric** (adjective) pets in the world. They were probably first kept because they ate **humans** (animal). Later cats were `bullied` (verb [past]) because they are **corrupt** (adjective) . . . Cats are active carnivores, meaning they hunt **online** (adjective) prey.

Table 5: Excerpts from test set stories, showing filled-in words receiving 9 (out of 9) funniness votes (boldfaced) from our judges. The story ID and the approach provided can be used to trace the mean funniness grade of the story in Figure 3.

Batman is a fictional character and one of the most famous / **obese** / sexiest / **inefficient** (adjective) superheroes . . . Batman began in comic books and he was later used / liposuctioned / arrested / imprisoned (verb [past]) in several movies, TV programs, and books. Batman lives in the fictional / edible / holy / abyssal (adjective) city of Gotham. . . . Batman's origin story is that as a/an young / obnoxious / adult / algebraic (adjective) child, Bruce Wayne saw a robber murder / eat / play / prank (verb) his parents after the family left a/an theater / sauna / trail / bag (noun). Bruce decided that he did not want that kind of violence / meal / luck / poem (noun) to happen to anyone else. He dedicated his life to protect / devouring / pronounce / demolish (verb) Gotham City. Wayne learned many different ways to fight / nibble / spell / crochet (verb) as he grew up. As an adult, he wore a/an costume / prosthesis / wig / **veil** (noun) to protect his identity / belly / head / jaw (noun) while fighting crime / gelatin / poverty / **acne** (noun) in Gotham.

Figure 4: Portions of the best "Batman" story, with the filled-in words ordered based on their sources as follows: Original / FreeText / LMC / Libitum. Each boldfaced word was rated "funny" by all 9 judges.

Assessment	Train	FText	LMC	Libtm
Coherence	**0.390**	**0.345**	0.023	**0.578**
Topic change	**0.266**	**0.281**	**0.467**	0.028
Self-grade	0.001	-0.054	0.024	0.151
Incongruity	**0.638**	**0.620**	**0.650**	**0.515**

Table 6: Correlation of different assessments of stories with their funniness grade. The boldfaced and underlined correlations are statistically significant, respectively, with $p < 0.001$ and $p < 0.05$.

6.2 Fully Automated System

We also tested an automated Mad Lib humor generation system, where we filled-in each test blank with the most funny candidate word from Libitum. The results were poor, with the stories having a mean funny grade of 0.80. This is expected, because without human support, Libitum cannot analyze complex word associations in order to come up with words that preserve meaning and coherence. This is evidenced by the statistically significant correlation ($p < 0.001$) of 0.456 between coherence and mean funniness grade scores from judges, suggesting that the judges mostly found those stories funny which were coherent.

7 Conclusion

Our goal was to create and explore a new benchmark for computational humor research. We created a copyright-free dataset that approximately matches the statistical characteristics of Mad Libs. Then we vetted a pool of Mechanical Turk judges and players to create ground truth data. We developed an algorithm called Libitum that generates and classifies potential blank-filling words as either funny or not in the context of a Mad Lib. For each blank, Libitum supplied a list of potentially funny words from which a human could choose. As judged by humans, the Libitum-aided words easily worked better than words from a simple language model and were usually better than even words generated by human players who could fill in the blanks in whichever way they liked.

Our three contributions, the benchmark, Libitum, and the analysis of what makes it funny, advance the state of the art in computer humor by demonstrating a successful computer aided humor technique and quantitatively analyzing what makes for funny fill-in-the-blank words for Mad Libs. These analyses show that coherent stories have tremendous potential in making a Mad Lib humorous, a promising direction for future work.

Abstract

In this paper, we introduce a new distributional method for modeling predicate-argument thematic fit judgments. We use a syntax-based DSM to build a prototypical representation of verb-specific roles: for every verb, we extract the most salient *second order contexts* for each of its roles (i.e. the most salient dimensions of *typical role fillers*), and then we compute thematic fit as a *weighted overlap* between the top features of candidate fillers and role prototypes. Our experiments show that our method consistently outperforms a baseline re-implementing a state-of-the-art system, and achieves better or comparable results to those reported in the literature for the other unsupervised systems. Moreover, it provides an explicit representation of the features characterizing verb-specific semantic roles.

1 Introduction

Several psycholinguistic studies in the last two decades have brought extensive evidence that humans activate a rich array of event knowledge during sentence processing: verbs (e.g. *arrest*) activate expectations about their typical arguments (e.g. *cop, thief*) (McRae et al., 1998; Altmann and Kamide, 1999; Ferretti et al., 2001; McRae et al., 2005; Hare et al., 2009; Matsuki et al., 2011), and nouns activate other nouns typically co-occurring in the same events (Kamide et al., 2003; Bicknell et al., 2010). Subjects are able to determine the plausibility of a noun for a given argument role and quickly use this knowledge to anticipate upcoming linguistic input (McRae and Matsuki, 2009). This phenomenon is referred to in the literature as *thematic fit*. Thematic fit estimation has been extensively used in sentence comprehension studies on constraint-based models, mainly as a predictor variable allowing to disambiguate between possible structural analyses.[1] More in general, thematic fit is considered as a key factor in a variety of studies concerned with structural ambiguity (Vandekerckhove et al., 2009).

Starting from the work of Erk et al. (2010), several distributional semantic methods have been proposed to compute the extent to which nouns fulfill the requirements of verb-specific thematic roles, and their performances have been evaluated against human-generated judgments (Baroni and Lenci, 2010; Lenci, 2011; Sayeed and Demberg, 2014; Sayeed et al., 2015, 2016; Greenberg et al., 2015a,b). Most research on thematic fit estimation has focused on *count-based* vector representations (as distinguished from *prediction-based* vectors).[2] Indeed, in their comparison between high-dimensional explicit vectors and low-dimensional neural embeddings, Baroni et al. (2014) found that thematic fit estimation is the only benchmark on which prediction models are lagging behind state-of-the-art performance. This is consistent with Sayeed et al. (2016)'s observation that "thematic fit modeling is particularly sensitive to linguistic detail and interpretability of the vector space".

The present work sets itself among the unsupervised approaches to thematic fit estimation. By relying on explicit and interpretable *count-based* vector representations, we propose a simple, cognitively-inspired, and efficient thematic fit model using information extracted from dependency-parsed corpora. The key features of our proposal are *a*) prototypical representations of verb-specific thematic roles, based on feature weighting and filtering of *second order contexts*

[1] For an overview on constraint-based models, see MacDonald and Seidenberg (2006).

[2] We adopt the terminology from Baroni et al. (2014).

Proceedings of the 2017 Conference on Empirical Methods in Natural Language Processing, pages 648–658
Copenhagen, Denmark, September 7–11, 2017. ©2017 Association for Computational Linguistics

(i.e. contexts that are salient for many of the typical fillers of a given verb-specific thematic role), and *b*) a similarity measure which computes the *Weighted Overlap* (WO) between prototypes and candidate fillers.[3]

2 Related Work

Erk et al. (2010) were, at the best of our knowledge, the first authors to measure the correlation between human-elicited thematic fit ratings and the scores assigned by a syntax-based Distributional Semantic Model (DSM). More specifically, their gold standard consisted of the human judgments collected by McRae et al. (1998) and Padó (2007). The plausibility of each verb-filler pair was computed as the similarity between new candidate nouns and previously attested exemplars for each specific verb-role pairing (as already proposed in Erk (2007)).

Baroni and Lenci (2010) evaluated their Distributional Memory (henceforth DM)[4] framework on the same datasets, adopting an approach to the task that has become dominant in the literature: for each verb role, they built a prototype vector by averaging the dependency-based vectors of its most typical fillers. The higher the similarity of a noun with a role prototype, the higher its plausibility as a filler for that role. Lenci (2011) has later extended the model to account for the dynamic update of the expectations on an argument, depending on how another role is filled. By using the same DM tensor, this study tested an additive and a multiplicative model (Mitchell and Lapata, 2010) to compose and update the expectations on the patient filler of the subject-verb-object triples of the Bicknell dataset (Bicknell et al., 2010).

The thematic fit models proposed by Sayeed and Demberg (2014) and Sayeed et al. (2015) are similar to Baroni and Lenci's, but their DSMs were built by using the roles assigned by the SENNA semantic role labeler (Collobert et al., 2011) to define the feature space. These authors argued that the prototype-based method with dependencies works well when applied to the agent and to the patient role (which are almost always syntactically realized as subjects and objects), but that it might be problematic to apply it to different roles, such as instruments and locations, as the construction of the prototype would have to rely on prepositional complements as typical fillers, and the meaning of prepositions can be ambiguous. Comparing their results with Baroni and Lenci (2010), the authors showed that their system outperforms the syntax-based model DepDM and almost matches the scores of the best performing TypeDM, which uses hand-crafted rules. Moreover, they were the first to evaluate thematic role plausibility for roles other than agent and patient, as they computed the scores also for the instruments and for the locations of the Ferretti datasets (Ferretti et al., 2001).

Greenberg et al. (2015a,b) further developed the TypeDM and the role-based models, investigating the effects of verb polysemy on human thematic fit judgments and introducing a hierarchical agglomerative clustering algorithm into the prototype creation process. Their goal was to cluster together typical fillers into multiple prototypes, corresponding to different verb senses, and their results showed constant improvements of the performance of the DM-based model.

Finally, Tilk et al. (2016) presented two neural network architectures for generating probability distributions over selectional preferences for each thematic role. Their models took advantage of supervised training on two role-labeled corpora to optimize the distributional representation for thematic fit modeling, and managed to obtain significant improvements over the other systems on almost all the evaluation datasets. They also evaluated their model on the task of composing and updating verb argument expectations, obtaining a performance comparable to Lenci (2011).

3 Methodology

As pointed out by Sayeed et al. (2016), most works on unsupervised thematic fit estimation vary in the method adopted for constructing the prototypes. The semantic role prototype is usually a vector, obtained by averaging the most typical fillers, and plausibility of new fillers depends on their similarity to the prototype, assessed by means of vector cosine (the standard similarity measure for DSMs; see Turney and Pantel (2010)).

Its merits notwithstanding, we argue that this method is not optimal for characterizing roles. Distributional vectors are typically built as out-of-

[3] Code: https://github.com/esantus/Thematic_Fit

[4] In this paper, we will make reference to two different models of DM: DepDM and TypeDM. DepDM counts the frequency of dependency links between words (e.g. *read, obj, book*), while TypeDM uses the variety of surface forms that express the link between words, rather than the link itself.

context representations, and they conflate different senses. By building the prototype as the centroid of a cluster of vectors and measuring then the thematic fit with vector cosine, the plausibility score is inevitably affected by many contexts that are irrelevant for the specific verb-argument combination.[5] This is likely to be one of the main reasons behind the difficulties of modeling roles other than agent and patient with syntax-based DSMs. We claim that improving the prototype representation might lead to a better characterization of thematic roles, and to a better treatment of polysemy.

When a verb and an argument are composed, humans are intuitively able to select only the part of the potential meaning of the words that is relevant for the concept being expressed (e.g. in *The player hit the ball*, humans would certainly exclude from the meaning of *ball* semantic dimensions that are strictly related to its dancing sense). In other words, not all the features of the semantic representations are active, and the composition process makes some features more 'prominent', while moving others to the background.[6]

Although we are not aware of experimental works specifically dedicated to verb-argument composition, a similar idea has been supported in studies on conceptual combinations (Hampton, 1997, 2007): when a head and a modifier are combined, their interaction affects the saliency of the features in the original concepts. For example, in *racing car*, the most salient properties would be those related to SPEED, whereas in *family car* SPACE properties would probably be more prominent. Yeh and Barsalou (2006) used a property priming experiment to show how the concept features activated during language comprehension vary across the background situations described by the sentence they occur in. When concepts are combined in a sentence, the features that are relevant for the specific combination are activated and are then easier to verify for human subjects.

The same could be true for linguistically-derived properties of lexical meaning: Simmons et al. (2008) brought neuroimaging evidence of the early activation of word association areas during property generation tasks, and Santos et al. (2011) showed that word associates are often among the properties generated for a given concept. Such findings suggest that, while we combine concepts, both embodied simulations and word distributions influence property salience (Barsalou et al., 2008).

Our model makes the following assumptions:

- the composition between a verb role representation and an argument shares the same cognitive mechanism underlying conceptual combinations;

- at least part of semantic representations is derived from, and/or mirrored in, linguistic data.[7] Consistently, the process of selecting the relevant features of the concepts being composed corresponds to modify the salience of the dimensions of distributional vectors;

- thematic fit computation is carried out on the basis of the activation and selection of salient features of a verb thematic role prototype and of the candidate argument filler vectors.

We rely on syntax-based DSMs, using dependency relations to approximate verb-specific roles and to identify their most typical fillers: for agents/patients, we extract the most frequent subjects/objects, for instruments we use the prepositional complements introduced by *with*, and for locations those introduced by either *on, at* or *in*.

Assuming that the linguistic features of distributional vectors correspond to the properties of conceptual composition processes, a candidate filler can be represented as a sorted distributional vector of the filler term, in which the most salient contexts occupy the top positions. Similarly, the abstract representation of a verb-specific role is a sorted prototype-vector, whose features derive from the sum of the most typical filler vectors for that verb-specific role.

Differently from Baroni and Lenci, the core and novel aspect of our proposal, described in the following subsections, is that we do not simply measure the correlation between all the features of candidate and prototype vectors (as vector cosine would do on unsorted vectors), but rather we *rank* and *filter* the features, computing the *weighted overlap* with a rank-based similarity measure inspired by $APSyn$, a recent proposal by Santus

[5] For an overview on the limitations of vector cosine, see: Li and Han (2013); Dinu et al. (2015); Schnabel et al. (2015); Faruqui et al. (2016); Santus et al. (2016a).

[6] An early proposal going in this direction is the predication theory by Kintsch (2001), which exploited Latent Semantic Analysis to select only the vector features that are appropriate for predicate-argument composition.

[7] See also the so-called 'strong version' of the Distributional Hypothesis (Miller and Charles, 1991; Lenci, 2008).

et al. (2016a,b,c) which has shown interesting results in synonymy detection and similarity estimation. As we will show in the next sections, the new metric assigns high scores to candidate fillers sharing many salient contexts with the verb-specific role prototype.

3.1 Typical Fillers

The first step of our method consists in identifying the typical fillers of a verb-specific role. Following Baroni and Lenci (2010), we weighted the raw co-occurrences between verbs, syntactic relations and fillers in the TypeDM tensor of DM with Positive Local Mutual Information (PLMI; Evert (2004)).

Given the co-occurrence count O_{vrf} of the verb v, a syntactic relation r and the filler f, we computed the expected count E_{vrf} under the assumption of statistical independence:

$$PLMI(v,r,f) = log\left(\frac{O_{v,r,f}}{E_{v,r,f}}\right) * O_{v,r,f} \tag{1}$$

From the ranked list of *(v,r,f)* tuples, for each slot, we selected as typical fillers the top k lexemes with the highest PLMI scores (see examples in Table 1, *Typical Fillers* column). In our experiments, we report results for $k = \{10, 30, 50\}$.

3.2 Role Prototype Vectors

To represent the typical fillers, the candidate fillers and the verb-specific role prototypes (which are obtained by summing their typical filler vectors), we built a syntax-based DSM. This includes *relation:word* contexts, like *sbj:dog, obj:apple, etc.*.

Contexts were weighted with Positive Pointwise Mutual Information (PPMI; Church and Hanks (1990), Bullinaria and Levy (2012), Levy et al. (2015)). Given a context c and a word w, the PPMI is defined as follows:

$$PPMI(w,c) = max(PMI(w,c), 0) \tag{2}$$

$$PMI(w,c) = log\left(\frac{P(w,c)}{P(w)P(c)}\right) = log\left(\frac{|w,c|D}{|w||c|}\right) \tag{3}$$

where *w* is the target word, *c* is the given context, *P(w,c)* is the probability of co-occurrence, and *D* is the collection of observed word-context pairs.[8]

The context c of the prototype vector P representing a thematic role has a value corresponding to the sum of the values of c for each of the k typical fillers used to build P. The contexts of P are then sorted according to their weight. Desirably, the highest-ranking contexts for a role prototype will be those that are more strongly associated with many of its typical fillers. Such *second order contexts* correspond to the most salient features of the verb-specific thematic role, as they are salient for many role fillers (some examples are reported in Table 1, *Top Second Order Contexts* column).

In summary, we built centroid vectors for our verb-specific thematic roles by means of *second order contexts*, which are first order dependency-based contexts of the most typical fillers of a verb-specific role. Since we are interested only in the most salient contexts, we ranked the centroid contexts according to their PPMI score, and we took the resulting rank as a distributional characterization of the thematic roles.

3.3 Filtering the Contexts

Filtering the prototype dimensions according to syntactic criteria might be useful to improve our role representations. It is, indeed, reasonable to hypothesize that predicates co-occurring with the typical patients of a verb are more relevant for the characterization of its patient role than – let's say – prepositional complements, as they correspond to other actions that are typically performed on the same patients.

Imagine that *apple, pizza, cake* etc. are among the most salient fillers for the OBJ slot of *to eat*, and that *OBJ-1:slice-v, OBJ-1:devour-v, SBJ:kid-n, INSTRUMENT:fork-n, LOCATION:table-n* are some of the most salient contexts of the prototype.[9] Things that are typically *sliced* and/or *devoured* are more likely to be good fillers for the patient role *to eat* than things that are simply located on a *table* or that are patients of actions performed by *kids*. To test this hypothesis, we evaluated the performance of the system in three different settings, each of which selecting:

[8] A variant of this DSM weighted with PLMI (which is simply the PPMI multiplied by the word-context frequency) was also built, but because of its lower and inconsistent performance we will not discuss it further. Santus et al. (2016c) previously showed that their rank-based measure performs worse on PLMI-weighted vectors, as they are biased towards frequent contexts.

[9] Our DSM also makes use of inverse syntactic dependencies: *target SYN-1 context* means that *target* is linked to *context* by the dependency relation *SYN* (e.g. *meal OBJ-1 devour* means that *meal* is *OBJ* of *devour*).

	Typical Fillers	Top Second Order Contexts
subject: cure-v	treatment-n, drug-n, resin-n, doctor-n, surgery-n, medicine-n, therapy-n, antibiotic-n, dose-n, operation-n, water-n...	obj-1:prescribe-v, sbj-1:prescribe-v, sbj-1:prevent-v, sbj-1:contraindicate-v, [...]
object: abandon-v	plan-n, idea-n, project-n, attempt-n, position-n, principle-n, policy-n, ship-n, practice-n, hope-n, fort-n, claim-n...	obj-1:revive-v, obj-1:defend-v, obj-1:renounce-v, obj-1:espouse-v, sbj-1:entail-v...
instrument: eat-v	bread-n, hand-n, spoon-n, sauce-n, relish-n, fork-n, finger-n, meal-n, knife-n, friend-n, chopstick-n, rice-n, food-n...	obj-1:flavour-v, obj-1:taste-v, obj-1:spoon-v, sbj-1:taste-v, obj-1:slice-v in:bowl-n...
location: walk-v	in:direction-n, at:time, at:pace-n, on:path-n, at:night, on:side-n, at:end, on:beach-n, on:leg, in:area, in:way...	obj-1:wander-v, obj-1:stroll-v, obj-1:litter-v, obj-1:sweep-v, sbj-1:slope-v, obj-1:tread-v...

Table 1: Typical fillers and top *second order contexts* for several verb-specific roles.

- only predicates in a subject/object relation (**SO** setting);
- only prepositional complements (**PREP** setting);
- both of them (**ALL** setting).

3.4 Computing the Thematic Fit

Our hypothesis is that fillers whose salience-ranked vector has a large overlap with the prototype representation should have a high thematic fit. Such overlap should take into account not only the number of shared features, but also their respective ranks in the salience-ranked vectors.

When the prototype has been computed and the candidate filler vector has also been sorted, we can measure the *Weighted Overlap* by adapting $APSyn$ (Santus et al., 2016a,b,c) to our needs:

$$WO(w_x, w_y) = \sum_{\forall f \epsilon (x_{[1:N]} \cap y_{[1:N]})} \frac{1}{avg(r_x(f), r_y(f))} \qquad (4)$$

where for every feature f in the intersection between the top N features of the sorted vectors x, $x_{[1:N]}$, and y, $y_{[1:N]}$, we sum 1 divided by the average rank of the shared feature in x and y, $r_x(f)$ and $r_y(f)$ (N is a tunable parameter).

This measure assigns the maximum score to vectors sharing exactly the same dimensions, in the same salience ranking. The lower the rank of a shared context in the sorted vector, the smaller its contribution to the thematic fit score. If the feature set intersection is empty, the score will be 0.

Differently from cosine similarity, which conflates multiple senses, measuring the *Weighted Overlap* between prototype and candidate filler can improve the estimation of the thematic fit by favoring the appropriate word senses: for example, for a verb-argument pair like *embrace-v–communism-n*, *communism-n* is likely to intersect and to increase the saliency (through the average rank) only of the second-order features of *embrace-v* referring to its abstract sense.

Data	Our system	BL2010	SD2014	G2015	T2016
Padó	96	100	99	100	99

Instr.	100	93	94	93	94
Loc.	96	99	100	99	100

Table 2: Dataset coverage (%) for all systems.

4 Experiments

Datasets. We tested our method on three popular datasets for thematic fit estimation, namely McRae et al. (1998), Ferretti et al. (2001) and Padó (2007). All the datasets contain human plausibility judgments for verb-role-filler triples. McRae and Padó include scores for agent and patient roles, whereas Ferretti includes instruments and locations (see Table 2 for the coverage of each system for the datasets).

Metrics. Performance is evaluated as the Spearman correlation between the scores of the systems and the human plausibility judgments.

Fillers. In order to make our results more comparable with previous studies, the typical fillers for each verb role were extracted from the TypeDM tensor of the Distributional Memory framework (see Section 3.1).[10] Those were the same fillers used by Baroni and Lenci (2010) and Greenberg et al. (2015b).

DSM. Distributional information is derived from the concatenation of two corpora: the British National Corpus (Leech, 1992) and Ukwac (Baroni et al., 2009). Both were parsed with the Maltparser (Nivre and Hall, 2005). From this concatenation, we built a dependency-based DSMs, weighted with PPMI, containing 20,145 targets (i.e. nouns and verbs with frequency above 1000) and 94,860 contexts. The syntactic relations taken into account were: *sbj, sbj-1, obj, obj-1, at-1, in-1, on-1, with-1*.

Settings. To prove our hypotheses and verify the consistency of the system, we tested a large range of settings, varying:

[10] http://clic.cimec.unitn.it/dm/

Table 3: Results for Padó, McRae and Ferretti, Instruments and Locations, with WO computed on PPMI matrix, varying the number of fillers (i.e. 10, 30 and 50) and the types of dependency contexts (i.e. ALL, SO and PREP). The best results of our system are in bold. A baseline reimplementing Baroni and Lenci (2010) – with 10, 30 and 50 fillers – and state of the art results from previous literature are reported for comparison.

- the number of fillers used to build the prototype, with the most typical values in the literature ranging between 10 and 50. We report the results for 10, 30 and 50 fillers
- the types of the dependency relations used for calculating the overlap: we report results for the SO, PREP and ALL settings;
- the value of N, that is the number of top contexts that we take into account when computing the weighted overlap. Table 3 reports the scores for our best setting, while the performances for other values of N are discussed in the Section 5.

Baseline and State of the Art. As a baseline, we use the thematic fit model by Baroni and Lenci (2010), with no ranking of the features of the prototypes and with vector cosine as a similarity metric.[11] Results are reported for 10, 30 and 50 fillers. For reference, we also report the results of state-of-the-art models, both the unsupervised (Baroni and Lenci, 2010; Sayeed and Demberg, 2014; Greenberg et al., 2015b) and the supervised ones (Tilk et al., 2016).

5 Results

Table 3 describes the performance of the best setting (weight: PPMI; N=2000). In the first three rows, the table shows the scores obtained by our system varying the types of dependency contexts (i.e. ALL, SO, PREP) and the number of fillers considered for the prototype (i.e. 10, 30 and 50). The other rows respectively show i) the scores obtained by calculating the vector cosine between the role prototype vector (i.e. the vector obtained by summing the most typical fillers, with no salience ranking of the dimensions) and the candidate filler vector and ii) the scores reported in the literature for the best unsupervised and supervised models.

At a glance, our best scores always outperform the reimplementation of Baroni and Lenci, being mostly competitive with the state of the art models. More precisely, for agents and patients the performance is close to the reported scores for DM, when only predicates are used in the WO calculation, as hypothesized in Section 3.3. The neural network of Tilk and colleagues retains a significant advantage on our models only for the McRae dataset. Our system, however, shows a remarkable improvements on the Ferretti's datasets, and specifically on Ferretti-Instruments, when only complements are used (see Section 3.3), outperforming even the supervised and more complex model by Tilk et al. (2016), which has access to semantic roles information. Compared to the other unsupervised models, our system has a statistically significant advantage over Baroni and Lenci (2010) on the locations dataset and over Sayeed and Demberg (2014) on the locations and on the instruments dataset ($p < 0.05$).[12]

At the best of our knowledge, the result for the

[11] This baseline is equivalent to the approach of Baroni and Lenci (2010), except for the fact that it is applied on a standard dependency-based DSM and not on TypeDM, which combines dependency links and handcrafted lexico-syntactic patterns: see Section 2.

[12] p-values computed with Fisher's r-to-z transformation.

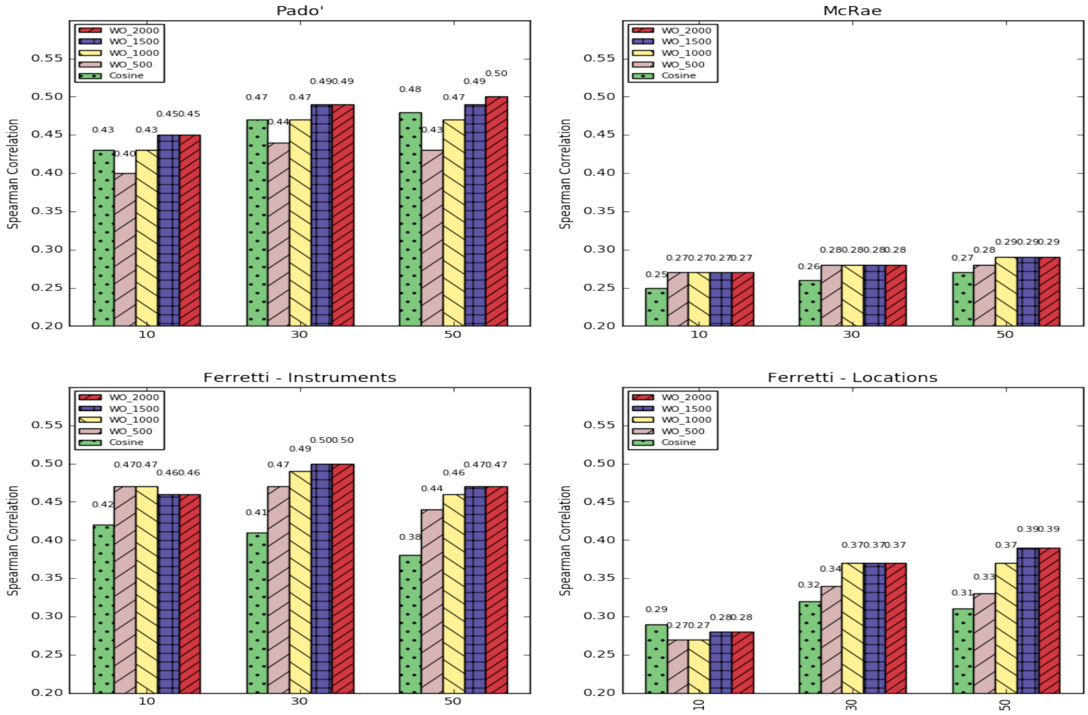

Figure 1: Results for Padó, McRae and Ferretti, Instruments and Locations, with WO (respectively SO and PREP) computed on PPMI matrix, varying the number of fillers (i.e. 10, 30 and 50) and the value of N (i.e. 500, 1000, 1500 and 2000). A baseline reimplementing Baroni and Lenci (2010) – with 10, 30 and 50 fillers – is also reported in every test for comparison.

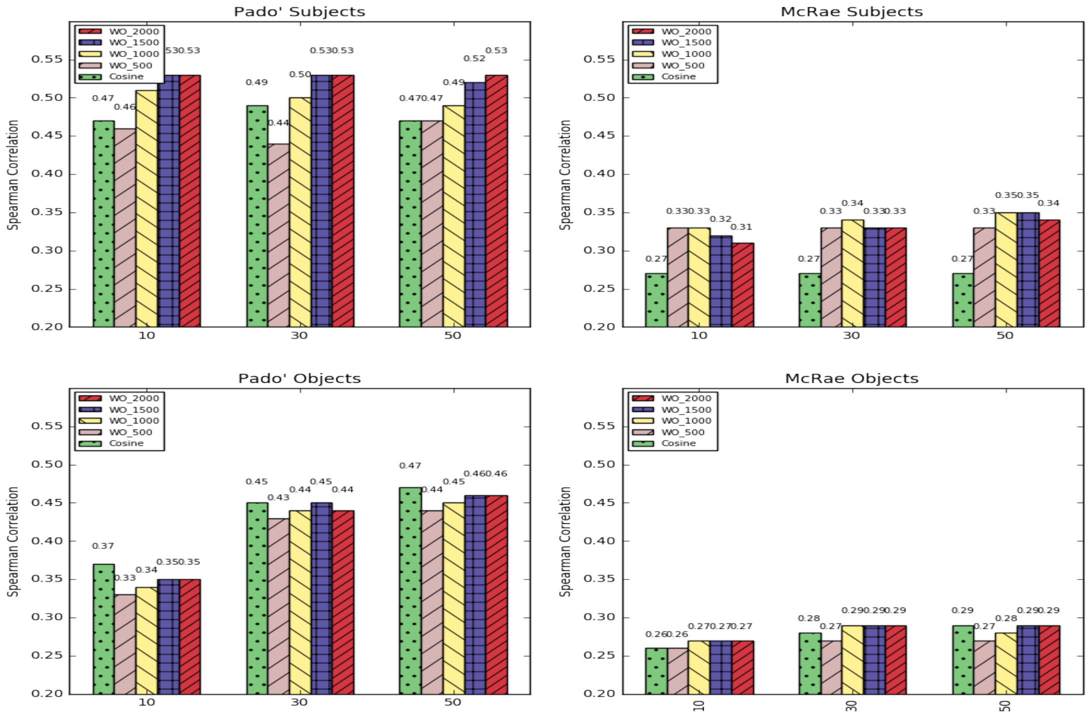

Figure 2: Results for the agent and patient roles in Padó and McRae, with WO (SO) computed on PPMI matrix, varying the number of fillers (i.e. 10, 30 and 50) and the value of N (i.e. 500, 1000, 1500 and 2000). A baseline reimplementing Baroni and Lenci (2010) – with 10, 30 and 50 fillers – is also reported in every test for comparison.

		BEST 35				WORST 35			
	Metric	Avg. Gold	Overlap	Syntax	Lexemes	Avg. Gold	Overlap	Syntax	Lexemes
McRae (k=50, Pred)	Cos	4.90	3	14 sbj, 21 obj	3 sentence, 2 devour, 2 scratch...	4.75	26	24 sbj, 11 obj	2 consider, 2 entertain, 2 scrub
	WO 2000	4.20	4	17 sbj, 18 obj	2 haunt	4.15	26	23 sbj, 12 obj	2 admire, 2 arrest, 2 consider, 2 entertain
Padó (k=50, Pred)	Cos	4.07	10	12 sbj, 23 obj	4 advise, 4 eat, 4 embarrass	4.77	16	17 sbj, 18 obj	9 tell, 7 kill, 4 see
	WO 2000	4.35	10	21 sbj, 14 obj	3 confuse, 3 hear, 3 promise, 3 raise	4.68	16	15 sbj, 20 obj	7 resent, 5 increase, 4 hear, 4 see
Ferretti - Instruments (k=30, Compl)	Cos	4.53	16	35 with	3 hung, 3 eat, 3 teach	4.51	22	35 with	4 repair, 3 teach, 3 inflate

	WO 2000	4.97	11	35 on/at/in	3 browse, 3 eat, 3 mingle, 3 rescue	4.47	23	35 on/at/in	3 run, 2 draw, 2 exercise, 2 shower, 2 wait...

Table 4: Average gold values, number of items listed for both metrics, and distribution of syntactic and lexical forms among the 35 best and worst correlated items for every measure in the given datasets.

instruments is the best reported until now in the literature. This is particularly interesting because – as pointed out by Sayeed and Demberg (2014) – instruments and locations are difficult to model for a dependency-based system, given the ambiguity of prepositional phrases (e.g. *with* does not only encode instruments, but it can also encode other roles, such as in *I ate a pizza with Mark*). We think this is the main reason behind the different trend observed for the Instruments datasets with respect to the number of the fillers (see Table 3 and Figure 1). Unlike all the other datasets, instrument prototypes built with more fillers tend to be more noisy and therefore to pull down both the vector cosine and WO performance (this is partially true also for locations, where the performances – for cosine and WO with a lower number of contexts – drop with more than 30 fillers: see Figure 1). Systems based on semantic role labeling have an advantage in this sense, as they do not have to deal with prepositional ambiguity.

Our results show that, by weighting and filtering the features of the role prototype, dependency-based approaches can be successful in modeling roles other than agent and patient, eventually dealing also with the ambiguity of prepositional phrases.

Settings. Apart from the above-mentioned exceptions, the best scores are obtained building the prototypes with a higher number of fillers, typically with 50, and calculating the WO only with a syntactically-filtered set of contexts. More specifically, Padó and McRae benefit from the calculation of WO using only second order subject-object predicates (i.e. SO), while Ferretti-Instruments and Ferretti-Locations benefit from the exclusive use of prepositional complements (i.e. PREP). On the other hand, the opposite setting (e.g. SO for Ferretti-Instruments and Ferretti-Locations and PREP for Padó and McRae) leads to much lower scores, whereas the full vectors (i.e. ALL) tend to have a stable-but-not-excellent performances on all datasets.

As briefly mentioned above, in our experiments, we tested both PPMI and PLMI as weighting measures. Table 3 only reports PPMI scores because it performs more regularly than PLMI, whose behaviour is often unpredictable.

A parameter that has an impact on the performance of our system is the value of N, which is the number of *second order contexts* that are considered when calculating the WO. We have noticed that the performance of WO is directly related to the growth of N, and this can be noticed in Figure 1, where WO is plotted for the different values of N with every combination of dataset and number of fillers. For space reasons, the plot only contains the performance for the best type of *second order contexts* for each dataset (i.e. SO for Padó and McRae and COMP for Ferretti-Locations and Ferretti-Instruments). As it can be seen in Figure 1, the scores of WO tend to grow with the growth of N in all datasets. Interestingly, they are largely above the competitive baseline in most of the cases, the only exceptions being Padó (where a large N is necessary to outperform the baseline) and Ferretti-Locations with 10 fillers (prepositional ambiguity might have caused the introduction of noisy fillers among the top ones).

Agent & Patient. In order to further evaluate our system, we have split Padó and McRae datasets into agent and patient subsets. Figure 2 describes the performance of WO and vector cosine baseline while varying N and the number of fillers. The plot shows a clearly better performance of WO for the agent role (i.e. *subject*), especially when N is equal or over 1000 (note that the value of N has little impact in the agent subset of the McRae dataset). Such advantage, however, is reduced for the patient role (i.e. *object*). This is particularly interesting because we do not observe large drops in performance for the vector cosine between agent and patient role (except for Padó, $k = 10$). The drop is particularly noticeable in Padó, a dataset which has several non-constraining verbs (especially for the patient role: a similar observation was also made by Tilk et al. (2016)). As the constraints on the typical fillers of such verbs are very loose, we hypothesize that it is more difficult to find a set of salient features that are shared by many typical fillers. Therefore, estimations based on the whole vectors turn out to be more reliable. This can be confirmed by looking at the worst correlated words reported in *Lexemes* column, in Table 4.

5.1 Error Analysis

We performed an error analysis to verify – for the best settings of WO in each dataset – the correlation between vector cosine and WO scores (see Table 5), and the peculiarities of the entries with the strongest and the weakest correlation (see Table 4).

We found that WO and vector cosine always have a high correlation (i.e. above 0.80), with the highest correlations reported for McRae and Ferretti-Instruments. Looking at Table 4 we can also observe that:

- the average gold value of the 35 most (4.65) and least (4.56) correlated items does not substantially differ from the average gold value calculated on the full datasets (4.31), meaning that the distribution of likely and unlikely fillers among the best and worst correlated items is similar to the one in the datasets (i.e. no bias can be identified);
- both measures have difficulties on the same test items (probably because of loose semantic constraints), but report their best performances on different pairs (see *Overlap* and *Lexemes* columns);
- syntactically, vector cosine correlates better with objects, while WO is more balanced between objects and subjects, often showing a preference for the latter (see the distribution in *Syntax* column).

6 Conclusions

In this paper, we have introduced an unsupervised distributional method for modeling predicate-argument thematic fit judgments which works purely on syntactic information.

Dataset	Correlation
McRae	0.88
Padó	0.81
Ferretti - Instruments	0.90
Ferretti - Locations	0.83

Table 5: Correlation between WO and vector cosine in WO best settings for all datasets

The method, inspired by cognitive and psycholinguistic findings, consists in: i) extracting and filtering the most salient *second order contexts* for each verb-specific role, i.e. the most salient semantic dimensions of *typical verb-specific role fillers*; and then ii) estimating the thematic fit as a *weighted overlap* between the top features of the candidate fillers and of the prototypes. Once tested on some popular datasets of thematic fit judgments, our method consistently outperforms a baseline re-implementing the thematic fit model of Baroni and Lenci (2010) and proves to be competitive with state of the art models. It even registered the best performance on the Ferretti-Instruments dataset and it is the second best on the Ferretti-Locations, which were known to be particularly hard to model for dependency-based approaches.

Our method is simple, economic and efficient, it works purely on syntactic dependencies (so it does not require a role-labeled corpus) and achieves good results even with no supervised training. Finally, it offers linguistically and cognitively grounded insights on the process of prototype creation and contextual feature salience, preparing the ground for further speculations and optimizations. For example, future work might aim at identifying strategies for tuning the parameter N to account for the different degrees of selectivity of each verb-specific role. Another possible extension would be the inclusion of a mechanism for updating the role prototypes depending on how the other roles are filled, which would be the key for a more realistic and dynamic model of thematic fit expectations (Lenci, 2011).

Abstract

We present a feature vector formation technique for documents - Sparse Composite Document Vector (SCDV) - which overcomes several shortcomings of the current distributional paragraph vector representations that are widely used for text representation. In SCDV, word embeddings are clustered to capture multiple semantic contexts in which words occur. They are then chained together to form document topic-vectors that can express complex, multi-topic documents. Through extensive experiments on multi-class and multi-label classification tasks, we outperform the previous state-of-the-art method, NTSG (Liu et al., 2015a). We also show that SCDV embeddings perform well on heterogeneous tasks like Topic Coherence, context-sensitive Learning and Information Retrieval. Moreover, we achieve significant reduction in training and prediction times compared to other representation methods. SCDV achieves best of both worlds - better performance with lower time and space complexity.

1 Introduction

Distributed word embeddings represent words as dense, low-dimensional and real-valued vectors that can capture their semantic and syntactic properties. These embeddings are used abundantly by machine learning algorithms in tasks such as text classification and clustering. Traditional bag-of-word models that represent words as indices into a vocabulary don't account for word ordering and long-distance semantic relations. Representations based on neural network language models (Mikolov et al., 2013b) can overcome these flaws and further reduce the dimensionality of the vectors. The success of the method is recently mathematically explained using the random walk on discourses model (Arora et al., 2016a). However, there is a need to extend word embeddings to entire paragraphs and documents for tasks such as document and short-text classification.

Representing entire documents in a dense, low-dimensional space is a challenge. A simple weighted average of the word embeddings in a large chunk of text ignores word ordering, while a parse tree based combination of embeddings (Socher et al., 2013) can only extend to sentences. (Le and Mikolov, 2014) trains word and paragraph vectors to predict context but shares word-embeddings across paragraphs. However, words can have different semantic meanings in different contexts. Hence, vectors of two documents that contain the same word in two distinct senses need to account for this distinction for an accurate semantic representation of the documents. (Ling et al., 2015), (Liu et al., 2015a) map word embeddings to a latent topic space to capture different senses in which words occur. However, they represent complex documents in the same space as words, reducing their expressive power. These methods are also computationally intensive.

In this work, we propose the Sparse Composite Document Vector(SCDV) representation learning technique to address these challenges and create efficient, accurate and robust semantic representations of large texts for document classification tasks. SCDV combines syntax and semantics learnt by word embedding models together with a latent topic model that can handle different senses of words, thus enhancing the expressive power of document vectors. The topic space is learnt efficiently using a soft clustering technique over embeddings and the final document vectors are made

sparse for reduced time and space complexity in tasks that consume these vectors.

The remaining part of the paper is organized as follows. Section 2 discusses related work in document representations. Section 3 introduces and explains SCDV in detail. This is followed by extensive and rigorous experiments together with analysis in section 4 and 5 respectively.

2 Related Work

(Le and Mikolov, 2014) proposed two models for distributional representation of a document, namely, *Distributed Memory Model Paragraph Vectors (PV-DM)* and *Distributed BoWs paragraph vectors (PV-DBoW)*. In *PV-DM*, the model is learned to predict the next context word using word and paragraph vectors. In *PV-DBoW*, the paragraph vector is directly learned to predict randomly sampled context words. In both models, word vectors are shared across paragraphs. While word vectors capture semantics across different paragraphs of the text, documents vectors are learned over context words generated from the same paragraph and potentially capture only local semantics (Singh and Mukerjee, 2015). Moreover, a paragraph vector is embedded in the same space as word vectors though it can contain multiple topics and words with multiple senses. As a result, doc2vec (Le and Mikolov, 2014) doesn't perform well on Information Retrieval as described in (Ai et al., 2016a) and (Roy et al., 2016). Consequently, we expect a paragraph vector to be embedded in a higher dimensional space.

A paragraph vector also assumes all words contribute equally, both quantitatively (weight) and qualitatively (meaning). They ignore the importance and distinctiveness of a word across all documents (Singh and Mukerjee, 2015). Mukerjee et al. (Singh and Mukerjee, 2015) proposed idf-weighted averaging of word vectors to form document vectors. This method tries to address the above problem. However, it assumes that all words within a document belong to the same semantic topic. Intuitively, a paragraph often has words originating from several semantically different topics. In fact, Latent Dirichlet Allocation (Blei et al., 2003) models a document as a distribution of multiple topics.

These shortcomings are addressed in three novel composite document representations called *Topical word embedding (TWE-1,TWE-2 and TWE-3)* by (Liu et al., 2015a). *TWE-1* learns word and topic embeddings by considering each topic as a pseudo word and builds the topical word embedding for each word-topic assignment. Here, the interaction between a word and the topic to which it is assigned is not considered. *TWE-2* learns a topical word embedding for each word-topic assignment directly, by considering each word- topic pair as a pseudo word. Here, the interaction between a word and its assigned topic is considered but the vocabulary of pseudo-words blows up. For each word and each topic, *TWE-3* builds distinct embeddings for the topic and word and concatenates them for each word-topic assignment. Here, the word embeddings are influenced by the corresponding topic embeddings, making words in the same topic less discriminative.

(Liu et al., 2015a) proposed an architecture called *Neural tensor skip-gram model (NTSG-1, NTSG-2, NTSG-3, NTSG-4)*, that learns multi-prototype word embeddings and uses a tensor layer to model the interaction of words and topics to capture different senses. $NTSG$ outperforms other embedding methods like $TWE-1$ on the 20 newsgroup data-set by modeling context-sensitive embeddings in addition to topical-word embeddings. $LTSG$ (Law et al., 2017) builds on $NTSG$ by jointly learning the latent topic space and context-sensitive word embeddings. All three, TWE, $NTSG$ and $LTSG$ use LDA and suffer from computational issues like large training time, prediction time and storage space. They also embed document vectors in the same space as terms. Other works that harness topic modeling like WTM (Fu et al., 2016), $w2v-LDA$ (Nguyen et al., 2015), $TV + MeanWV$ (Li et al., 2016a), $LTSG$ (Law et al., 2017), $Gaussian - LDA$ (Das et al., 2015), $Topic2Vec$ (Niu et al., 2015), (Moody, 2016) and $MvTM$ (Li et al., 2016b) also suffer from similar issues.

(Gupta et al., 2016) proposed a method to form a composite document vector using word embeddings and tf-idf values, called the *Bag of Words Vector (BoWV)*. In $BoWV$, each document is represented by a vector of dimension $D = K*d+K$, where K is the number of clusters and d is the dimension of the word embeddings. The core idea behind $BoWV$ is that semantically different words belong to different topics and their word vectors should not be averaged. Further, $BoWV$ computes inverse cluster frequency of each cluster (icf) by averaging the idf values of its member terms to capture the importance of words in the corpus. However, $BoWV$ does hard clustering using K-means algorithm, assigning each word to only one cluster or semantic topic but a word can belong to multiple topics. For example, the word *apple* belongs to topic *food* as a fruit, and belongs to topic *Information Technology* as an IT company. Moreover, $BoWV$ is a non-sparse, high dimensional continuous vector and suffers from computational problems like large training time, prediction time and storage requirements.

3 Sparse Composite Document Vectors

In this section, we present the proposed Sparse Composite Document Vector (SCDV) representation as a novel document vector learning algorithm. The feature formation algorithm can be divided into three steps.

3.1 Word Vector Clustering

We begin by learning d dimensional word vector representations for every word in the vocabulary V using the skip-gram algorithm with negative sampling (SGNS) (Mikolov et al., 2013a). We then cluster these word embeddings using the Gaussian Mixture Models(GMM) (Reynolds, 2015) soft clustering technique. The number of clusters, *K*, to be formed is a parameter of the SCDV model. By inducing soft clusters, we ensure that each word belongs to every cluster with some probability $P(c_k|w_i)$.

$$p(c_k = 1) = \pi_k$$

$$p(c_k = 1|w) = \frac{\pi_k \mathcal{N}(w|\mu_k, \Sigma_k)}{\Sigma_{j=1}^{K} \pi_j \mathcal{N}(w|\mu_j, \Sigma_j)}$$

3.2 Document Topic-vector Formation

For each word w_i, we create K different word-cluster vectors of d dimensions ($\vec{wcv_{ik}}$) by weighting the word's embedding with its probability distribution in the kth cluster, $P(c_k|w_i)$. We then concatenate all K word-cluster vectors ($\vec{wcv_{ik}}$) into a K×d dimensional embedding and weight it with inverse document frequency of w_i to form a word-topics vector ($\vec{wtv_i}$). Finally, for all words appearing in document D_n, we sum their word-topic vectors $\vec{wtv_i}$ to obtain the document vector $\vec{dv_{D_n}}$.

$$\vec{wcv_{ik}} = \vec{wv_i} \times P(c_k|w_i)$$

Algorithm 1: Sparse Composite Document Vector

```
Data: Documents $D_n$, n = 1 ... N
Result: Document vectors $\vec{SCDV}_{D_n}$, n = 1
        ... N
1  Obtain word vector ($\vec{wv_i}$), for each word $w_i$;
2  Calculate idf values, $idf(w_i)$, $i = 1..|V|$ ;
     /* $|V|$ is vocabulary size */
3  Cluster word vectors $\vec{wv}$ using GMM
     clustering into K clusters;
4  Obtain soft assignment $P(c_k|w_i)$ for word $w_i$
     and cluster $c_k$;
   /* Loop 5-10 can be
      pre-computed                          */
5  for each word $w_i$ in vocabulary $V$ do
6      for each cluster $c_k$ do
7          $\vec{wcv_{ik}} = \vec{wv_i} \times P(c_k|w_i)$;
8      end
9      $\vec{wtv_i} = idf(w_i) \times \bigoplus_{k=1}^{K} \vec{wcv_{ik}}$ ;
       /* $\bigoplus$ is concatenation      */
10 end
11 for $n \in (1..N)$ do
12     Initialize document vector $\vec{dv_{D_n}} = \vec{0}$;
13     for word $w_i$ in $D_n$ do
14         $\vec{dv_{D_n}}$ += $\vec{wtv_i}$;
15     end
16     $\vec{SCDV}_{D_n}$ = make-sparse($\vec{dv_{D_n}}$);
       /* as mentioned in sec 3     */
17 end
```

$$\vec{wtv_i} = idf(w_i) \times \bigoplus_{k=1}^{K} \vec{wcv_{ik}}$$

where, $\bigoplus$ is concatenation

3.3 Sparse Document Vectors

After normalizing the vector, we observed that most values in $\vec{dv_{D_n}}$ are very close to zero. Figure 3 verifies this observation. We utilize this fact to make the document vector $\vec{dv_{D_n}}$ sparse by zeroing attribute values whose absolute value is close to a threshold (specified as a parameter), which results in the Sparse Composite Document Vector $\vec{SCDV}_{D_n}$.

In particular, let p be percentage sparsity threshold parameter, a_i the value of the i^{th} attribute of the non-Sparse Composite Document Vector and n represent the n^{th} document in the training set:

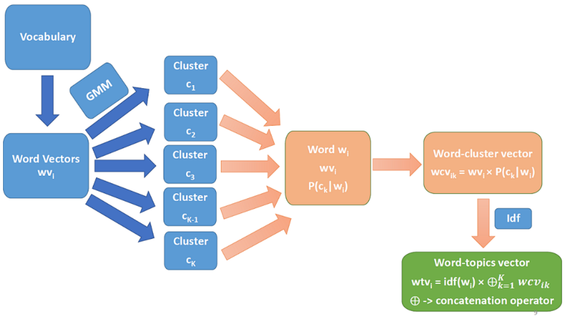

Figure 1: Word-topics vector formation.

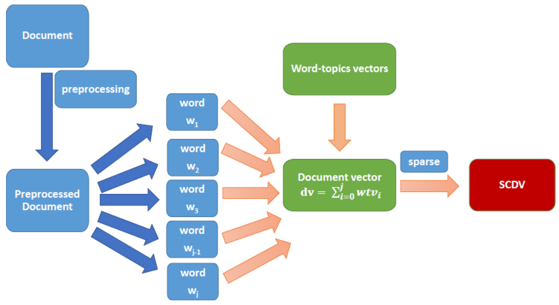

Figure 2: Sparse Composite Document Vector formation.

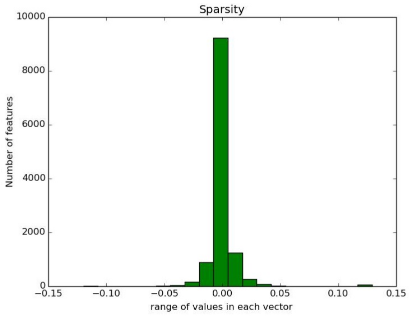

Figure 3: Distribution of attribute feature vector values.

$$a_i = \begin{cases} a_i & \text{if } |a_i| \geq \frac{p}{100} * t \\ 0 & \text{otherwise} \end{cases}$$

$$t = \frac{|a_{min}| + |a_{max}|}{2}$$

$$a_{min} = avg_n(min_i(a_i))$$

$$a_{max} = avg_n(max_i(a_i))$$

Flowcharts depicting the formation of word-topics vector and Sparse Composite Document Vectors are shown in figure 1 and figure 2 respectively. Algorithm 1 describes SCDV in detail.

4 Experiments

We perform multiple experiments to show the effectiveness of SCDV representations for multi-class and multi-label text classification. For all experiments and baselines, we use Intel(R) Xeon(R) CPU E5-2670 v2 @ 2.50GHz, 40 working cores, 128GB RAM machine with Linux Ubuntu 14.4. However, we utilize multiple cores only during Word2Vec training and when we run the one-vs-rest classifier for Reuters.

4.1 Baselines

We consider the following baselines: Bag-of-Words (BoW) model (Harris, 1954), Bag of Word Vector (BoWV) (Gupta et al., 2016) model, paragraph vector models (Le and Mikolov, 2014), Topical word embeddings (TWE-1) (Liu et al., 2015b), Neural Tensor Skip-Gram Model (NTSG-1 to NTSG-3) (Liu et al., 2015a), tf-idf weighted average word-vector model (Singh and Mukerjee, 2015) and weighted Bag of Concepts (weight-BoC) (Kim et al., 2017), where we build topic-document vectors by counting the member words in each topic.

We use the best parameter settings as reported in all our baselines to generate their results. We use 200 dimensions for tf-idf weighted word-vector model, 400 for paragraph vector model, 80 topics and 400 dimensional vectors for TWE, NTSG, LTSG and 60 topics and 200 dimensional word vectors for BOWV. We also compare our results with reported results of other topic modeling based document embedding methods like WTM (Fu et al., 2016), $w2v-LDA$ (Nguyen et al., 2015), LDA (Chen and Liu, 2014), $TV+MeanWV$ (Li et al., 2016a), $LTSG$ (Law et al., 2017), $Gaussian-LDA$ (Das et al., 2015), $Topic2Vec$ (Niu et al., 2015), (Moody, 2016) and $MvTM$ (Li et al., 2016b). Implementation of SCDV and related experiments is available here [1].

4.2 Text Classification

We run multi-class experiments on 20NewsGroup dataset [2] and multi-label classification experiments on Reuters-21578 dataset [3]. We use the script[4] for preprocessing the Reuters-21578 dataset. We use LinearSVM for multi-class classi-

[4] https://gist.github.com/herrfz/7967781

fication and Logistic regression with OneVsRest setting for multi-label classification in baselines and SCDV.

For SCDV, we set the dimension of word-embeddings to 200 and the number of mixture components in GMM to 60. All mixture components share the same spherical co-variance matrix. We learn word vector embedding using Skip-Gram with window size of 10, Negative Sampling (SGNS) of 10 and minimum word frequency as 20. We use 5-fold cross-validation on F1 score to tune parameter C of SVM and the sparsity threshold for SCDV.

4.2.1 Multi-class classification

We evaluate classifier performance using standard metrics like accuracy, macro-averaging precision, recall and F-measure. Table 1 shows a comparison with the current state-of-art (NTSG) document representations on the 20Newsgroup dataset. We observe that SCDV outperforms all other current models by fair margins. We also present the class-wise precision and recall for 20Newsgroup on an almost balanced dataset with SVM over Bag of Words model and the SCDV embeddings in Table 2 and observe that SCDV improves consistently over all classes.

Table 1: Performance on multi-class classification (Values in red show best performance, the SCDV algorithm of this paper)

Model	Acc	Prec	Rec	F-mes

4.2.2 Multi-label classification

We evaluate multi-label classification performance using Precision@K, nDCG@k (Bhatia et al., 2015), Coverage error, Label ranking average precision score (LRAPS)[5] and F1-score. All measures are extensively used for the multi-label classification task. However, F1-score is an appropriate metric for multi-label classification as it considers label biases when train-test splits are random. Table 3 show evaluation results for multi-label text classification on the Reuters-21578 dataset.

4.2.3 Effect of Hyper-Parameters

SCDV has three parameters: the number of clusters, word vector dimension and sparsity threshold parameter. We vary one parameter by keeping the other two constant. Performance on varying all three parameters in shown in Figure 4. We observe that performance improves as we increase the number of clusters and saturates at 60. The performance improves until a word vector dimension of 300 after which it saturates. Similarly, we observe that the performance improves as we increase p till 4 after which it declines. At 4% thresholding, we reduce the storage space by 80% compared to the dense vectors. We observe that SCDV is robust to variations in training Word2Vec

tfidf AvgVec	89.33	35.04	46.83	9.42	87.90	71.97

and GMM. The performance metrics reported in Tables 1, 3 are the average values obtained across 5 separate runs of $SCDV$, each run training a different Word2Vec and GMM model with identical hyper-parameters.

4.3 Topic Coherence

We evaluate the topics generated by GMM clustering on 20NewsGroup for quantitative and qualitative analysis. Instead of using perplexity (Chang et al., 2011), which doesn't correlate with semantic coherence and human judgment of individual topics, we used the popular topic coherence (Mimno et al., 2011), (Arora et al., 2013), (Chen and Liu, 2014) measure. A higher topic coherence score indicates a more coherent topic.

We used Bayes rule to compute the $P(w_k|c_i)$ for a given topic c_i and given word w_j and compute the score of the top 10 words for each topic.

$$P(w_k|c_i) = \frac{P(c_i|w_k)P(w_k)}{P(c_i)}$$

where,

$$P(c_i) = \sum_{i=1}^{K} P(c_i|w_k)P(w_k)$$

$$P(w_k) = \frac{\#(w_k)}{\sum_{i=1}^{V} \#(w_i)}$$

Here, $\#(w_k)$ denotes the number of times word w_k appears in the corpus and V represents vocabulary size.

We calculated the topic coherence score for all topics for $SCDV$, LDA and $LTSG$ (Law et al., 2017). Averaging the score of all 80 topics, GMM clustering scores -85.23 compared to -108.72 of LDA and -92.23 of LTSG. Thus, SCDV creates more coherent topics than both LDA and LTSG.

Table 4 shows top 10 words of 3 topics from GMM clustering, LDA model and $LTSG$ model on 20NewsGroup and $SCDV$ shows higher topic coherence. Words are ranked based on their probability distribution in each topic. Our results also support the qualitative results of (Randhawa et al., 2016), (Sridhar, 2015) paper, where k-means, GMM was used respectively over word vectors to find topics.

4.4 Context-Sensitive Learning

In order to demonstrate the effects of soft clustering (GMM) during SCDV formation, we select some words (w$_j$) with multiple senses from 20Newsgroup and their soft cluster assignments to find the dominant clusters. We also select top scoring words (w$_k$) from each cluster (c$_i$) to represent the meaning of that cluster. Table 5 shows polysemic words and their dominant clusters with assignment probabilities. This indicates that using soft clustering to learn word vectors helps combine multiple senses into a single embedding vector. (Arora et al., 2016b) also reported similar results for polysemous words.

4.5 Information Retrieval

(Ai et al., 2016b) used (Mikolov et al., 2013b)'s paragraph vectors to enhance the basic language model based retrieval model. The language model(LM) probabilities are estimated from the corpus and smoothed using a Dirichlet prior (Zhai and Lafferty, 2004). In (Ai et al., 2016b), this language model is then interpolated with the paragraph vector (PV) language model as follows.

$$P(w|d) = (1 - \lambda)P_{LM}(w|d) + \lambda P_{PV}(w|d)$$

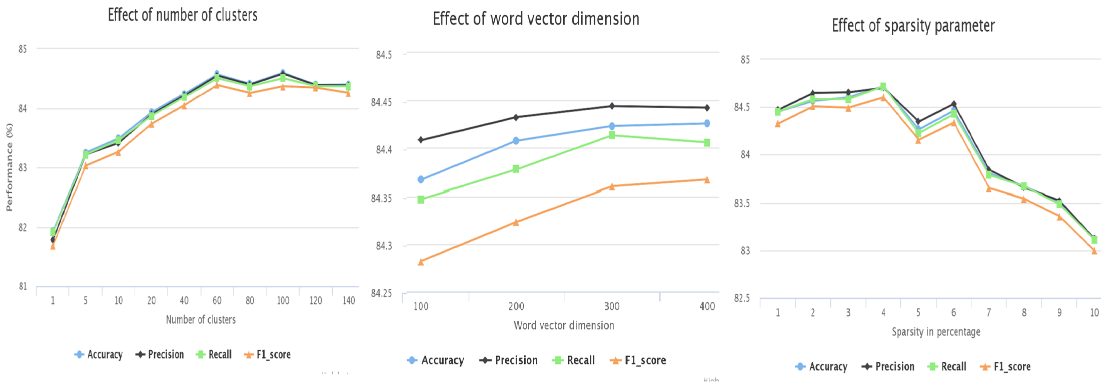

Figure 4: Effect of varying number of clusters (left), varying word vector dimension (center) and varying sparsity parameter (right) on performance for 20NewsGroup with SCDV

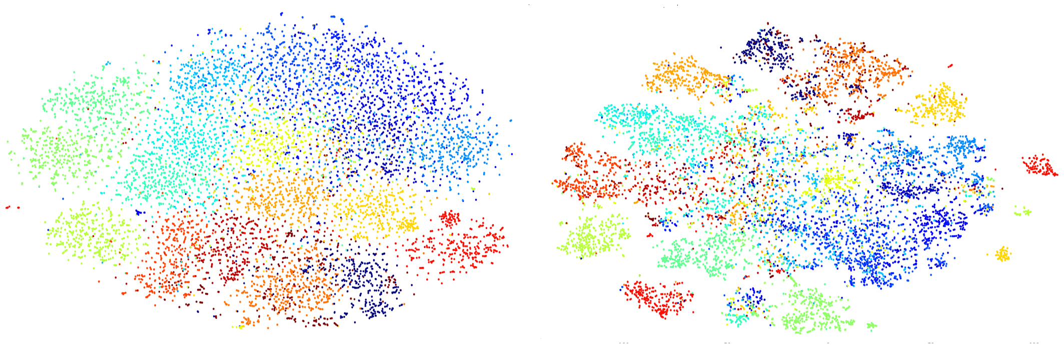

Figure 5: Visualization of paragraph vectors(left) and SCDV(right) using t-SNE

where,

$$P_{PV}(w|d) = \frac{exp(\vec{w}.\vec{d})}{\sum_{i=1}^{V} exp(\vec{w_i}.\vec{d})}$$

and the score for document d and query string Q is given by

$$score(q,d) = \sum_{w \in Q} P(w) P(w|d)$$

where $P(w)$ is obtained from the unigram query model and $score(q,d)$ is used to rank documents. (Ai et al., 2016b) do not directly make use of paragraph vectors for the retrieval task, but improve the document language model. To directly make use of paragraph vectors and make computations more tractable, we directly interpolate the language model query-document score $score(q,d)$ with the similarity score between the normalized query and document vectors to generate $score_{PV}(q,d)$, which is then used to rank documents.

$$score_{PV}(q,d) = (1-\lambda) score(q,d) + \lambda \vec{q}.\vec{d}$$

Directly evaluating the document similarity score with the query paragraph vector rather than collecting similarity scores for individual words in the query helps avoid confusion amongst distinct query topics and makes the interpolation operation faster. In Table 6, we report Mean Average Precision(MAP) values for four datasets, Associated Press 88-89 (topics 51-200), Wall Street Journal (topics 51-200), San Jose Mercury (topics 51-150) and Disks 4 & 5 (topics 301-450) in the TREC collection. We learn λ on a held out set of topics. We observe consistent improvement in MAP for all datasets. We marginally improve the MAP reported by (Ai et al., 2016b) on the Robust04 task. In addition, we also report the improvements in MAP score when Model based relevance feedback (Zhai and Lafferty, 2001) is applied over the initially retrieved results from both models. Again, we notice a consistent improvement in MAP.

5 Analysis and Discussion

SCDV overcomes several challenges encountered while training document vectors, which we had mentioned above.

Table 4: Top words of some topics from GMM and LDA on 20NewsGroup for K = 80. Higher score represent better coherent topics.

Topic Image			Topic Health			Topic Mail

break:3	if, elseif, endif, loop, continue	0.23
unit:1	calculation, distance, mass, length	0.25
unit:2	electronics, KWH, digital, signal	0.69

1. Clustering word-embeddings to discover topics improves performance of classification as Figure 4 (left) indicates, while also generating coherent clusters of words (Table 4). Figure 5 shows that clustering gives more discriminative representations of documents than paragraph vectors do since it uses K × d dimensions while paragraph vectors embed documents and words in the same space. This enables SCDV to represent complex documents. Fuzzy clustering allows words to belong to multiple topics, thereby recognizing polysemic words, as Table 5 indicates. Thus it mimics the word-context interaction in NTSG and LTSG.

2. Semantically different words are assigned to different topics. Moreover, a single document can contain words from multiple different topics. Instead of a weighted averaging of word embeddings to form document vectors, as in most previous work, concatenating word embeddings for each topic (cluster) avoids merging of semantically different topics.

3. It is well-known that in higher dimensions, structural regularizers such as sparsity help overcome the curse of dimensionality (Wainwright, 2014).Figure 3 demonstrates this, since majority of the features are close to zero. Sparsity also enables linear SVM to scale to large dimensions. On 20NewsGroups, BoWV model takes up 1.1 GB while SCDV takes up only 236MB(80% decrease). Since GMM assigns a non-zero probability to every topic in the word embedding, noise can accumulate when document vectors are created and tip the scales in favor of an unrelated topic. Sparsity helps to reduce this by zeroing out very small values of probability.

4. SCDV uses Gaussian Mixture Model (GMM) while TWE, $NTSG$ and $LTSG$ use LDA for finding semantic topics respectively. GMM time complexity is $\mathcal{O}(VNT^2)$ while that of LDA is $\mathcal{O}(V^2NT)$. Here, V = Vocabulary size, N = number of documents and T = number of topics. Since number of topics T $<$ vocabulary size V, GMM is faster. Empirically, compared to TWE, $SCDV$ reduces document vector formation, training and prediction time significantly. Table 7 shows training and prediction times for BoWV, SCDV and TWE models.

6 Conclusion

In this paper, we propose a document feature formation technique for topic-based document representation. SCDV outperforms state-of-the-art models in multi-class and multi-label classification tasks. SCDV introduces sparsity in document vectors to handle high dimensionality. Table 7 in-

Table 6: Mean average precision (MAP) for IR on four IR datasets

Dataset	LM	LM+SCDV	MB	MB + SCDV
AP	0.2742	**0.2856**	0.3283	**0.3395**
SJM	0.2052	**0.2105**	0.2341	**0.2409**
WSJ	0.2618	**0.2705**	0.3027	**0.3126**
Robust04	0.2516	**0.2684**	0.2819	**0.2933**

Table 7: Time Comparison (20NewsGroup) (Values in red show least time, the SCDV algorithm of this paper)

Time (sec)	BoWV	TWE-1	SCDV
DocVec Formation	1250	700	**160**
Total Training	1320	740	**200**
Total Prediction	780	120	**25**

dicates that SCDV shows considerable improvements in feature formation, training and prediction times for the 20NewsGroups dataset. We show that fuzzy GMM clustering on word-vectors lead to more coherent topic than LDA and can also be used to detect Polysemic words. SCDV embeddings also provide a robust estimation of the query and document language models, thus improving the MAP of language model based retrieval systems. In conclusion, SCDV is simple, efficient and creates a more accurate semantic representation of documents.

Abstract

Many modern NLP systems rely on word embeddings, previously trained in an unsupervised manner on large corpora, as base features. Efforts to obtain embeddings for larger chunks of text, such as sentences, have however not been so successful. Several attempts at learning unsupervised representations of sentences have not reached satisfactory enough performance to be widely adopted. In this paper, we show how universal sentence representations trained using the supervised data of the Stanford Natural Language Inference datasets can consistently outperform unsupervised methods like SkipThought vectors (Kiros et al., 2015) on a wide range of transfer tasks. Much like how computer vision uses ImageNet to obtain features, which can then be transferred to other tasks, our work tends to indicate the suitability of natural language inference for transfer learning to other NLP tasks. Our encoder is publicly available[1].

1 Introduction

Distributed representations of words (or word embeddings) (Bengio et al., 2003; Collobert et al., 2011; Mikolov et al., 2013; Pennington et al., 2014) have shown to provide useful features for various tasks in natural language processing and computer vision. While there seems to be a consensus concerning the usefulness of word embeddings and how to learn them, this is not yet clear with regard to representations that carry the meaning of a full sentence. That is, how to capture the relationships among multiple words and phrases in a single vector remains an question to be solved.

In this paper, we study the task of learning universal representations of sentences, i.e., a sentence encoder model that is trained on a large corpus and subsequently transferred to other tasks. Two questions need to be solved in order to build such an encoder, namely: what is the preferable neural network architecture; and how and on what task should such a network be trained. Following existing work on learning word embeddings, most current approaches consider learning sentence encoders in an unsupervised manner like SkipThought (Kiros et al., 2015) or FastSent (Hill et al., 2016). Here, we investigate whether supervised learning can be leveraged instead, taking inspiration from previous results in computer vision, where many models are pretrained on the ImageNet (Deng et al., 2009) before being transferred. We compare sentence embeddings trained on various supervised tasks, and show that sentence embeddings generated from models trained on a natural language inference (NLI) task reach the best results in terms of transfer accuracy. We hypothesize that the suitability of NLI as a training task is caused by the fact that it is a high-level understanding task that involves reasoning about the semantic relationships within sentences.

Unlike in computer vision, where convolutional neural networks are predominant, there are multiple ways to encode a sentence using neural networks. Hence, we investigate the impact of the sentence encoding architecture on representational transferability, and compare convolutional, recurrent and even simpler word composition schemes. Our experiments show that an encoder based on a bi-directional LSTM architecture with max pooling, trained on the Stanford Natural Language Inference (SNLI) dataset (Bowman et al., 2015), yields state-of-the-art sentence embeddings com-

pared to all existing alternative unsupervised approaches like SkipThought or FastSent, while being much faster to train. We establish this finding on a broad and diverse set of transfer tasks that measures the ability of sentence representations to capture general and useful information.

2 Related work

Transfer learning using supervised features has been successful in several computer vision applications (Razavian et al., 2014). Striking examples include face recognition (Taigman et al., 2014) and visual question answering (Antol et al., 2015), where image features trained on ImageNet (Deng et al., 2009) and word embeddings trained on large unsupervised corpora are combined.

In contrast, most approaches for sentence representation learning are unsupervised, arguably because the NLP community has not yet found the best supervised task for embedding the semantics of a whole sentence. Another reason is that neural networks are very good at capturing the biases of the task on which they are trained, but can easily forget the overall information or semantics of the input data by specializing too much on these biases. Learning models on large unsupervised task makes it harder for the model to specialize. Littwin and Wolf (2016) showed that co-adaptation of encoders and classifiers, when trained end-to-end, can negatively impact the generalization power of image features generated by an encoder. They propose a loss that incorporates multiple orthogonal classifiers to counteract this effect.

Recent work on generating sentence embeddings range from models that compose word embeddings (Le and Mikolov, 2014; Arora et al., 2017; Wieting et al., 2016b) to more complex neural network architectures. SkipThought vectors (Kiros et al., 2015) propose an objective function that adapts the skip-gram model for words (Mikolov et al., 2013) to the sentence level. By encoding a sentence to predict the sentences around it, and using the features in a linear model, they were able to demonstrate good performance on 8 transfer tasks. They further obtained better results using layer-norm regularization of their model in (Ba et al., 2016). Hill et al. (2016) showed that the task on which sentence embeddings are trained significantly impacts their quality. In addition to unsupervised methods, they included supervised training in their comparison—namely, on machine translation data (using the WMT'14 English/French and English/German pairs), dictionary definitions and image captioning data from the COCO dataset (Lin et al., 2014). These models obtained significantly lower results compared to the unsupervised Skip-Thought approach.

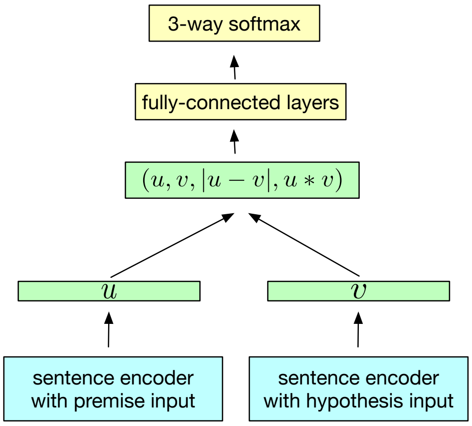
Recent work has explored training sentence encoders on the SNLI corpus and applying them on the SICK corpus (Marelli et al., 2014), either using multi-task learning or pretraining (Mou et al., 2016; Bowman et al., 2015). The results were inconclusive and did not reach the same level as simpler approaches that directly learn a classifier on top of unsupervised sentence embeddings instead (Arora et al., 2017). To our knowledge, this work is the first attempt to fully exploit the SNLI corpus for building generic sentence encoders. As we show in our experiments, we are able to consistently outperform unsupervised approaches, even if our models are trained on much less (but human-annotated) data.

3 Approach

This work combines two research directions, which we describe in what follows. First, we explain how the NLI task can be used to train universal sentence encoding models using the SNLI task. We subsequently describe the architectures that we investigated for the sentence encoder, which, in our opinion, covers a suitable range of sentence encoders currently in use. Specifically, we examine standard recurrent models such as LSTMs and GRUs, for which we investigate mean and max-pooling over the hidden representations; a self-attentive network that incorporates different views of the sentence; and a hierarchical convolutional network that can be seen as a tree-based method that blends different levels of abstraction.

3.1 The Natural Language Inference task

The SNLI dataset consists of 570k human-generated English sentence pairs, manually labeled with one of three categories: entailment, contradiction and neutral. It captures natural language inference, also known in previous incarnations as Recognizing Textual Entailment (RTE), and constitutes one of the largest high-quality labeled resources explicitly constructed in order to require understanding sentence semantics. We hypothesize that the semantic nature of NLI makes it a good candidate for learning universal sentence embeddings in a supervised way. That is, we aim to demonstrate that sentence encoders trained on natural language inference are able to learn sentence representations that capture universally useful features.



3-way softmax
fully-connected layers
$(u, v, |u - v|, u * v)$
u
v
sentence encoder with premise input
sentence encoder with hypothesis input

Figure 1: **Generic NLI training scheme.**

Models can be trained on SNLI in two different ways: (i) sentence encoding-based models that explicitly separate the encoding of the individual sentences and (ii) joint methods that allow to use encoding of both sentences (to use cross-features or attention from one sentence to the other).

Since our goal is to train a generic sentence encoder, we adopt the first setting. As illustrated in Figure 1, a typical architecture of this kind uses a shared sentence encoder that outputs a representation for the premise u and the hypothesis v. Once the sentence vectors are generated, 3 matching methods are applied to extract relations between u and v : (i) concatenation of the two representations (u, v); (ii) element-wise product $u * v$; and (iii) absolute element-wise difference $|u - v|$. The resulting vector, which captures information from both the premise and the hypothesis, is fed into a 3-class classifier consisting of multiple fully-connected layers culminating in a softmax layer.

3.2 Sentence encoder architectures

A wide variety of neural networks for encoding sentences into fixed-size representations exists, and it is not yet clear which one best captures generically useful information. We compare 7 different architectures: standard recurrent encoders with either Long Short-Term Memory (LSTM) or Gated Recurrent Units (GRU), concatenation of last hidden states of forward and backward GRU, Bi-directional LSTMs (BiLSTM) with either mean or max pooling, self-attentive network and hierarchical convolutional networks.

3.2.1 LSTM and GRU

Our first, and simplest, encoders apply recurrent neural networks using either LSTM (Hochreiter and Schmidhuber, 1997) or GRU (Cho et al., 2014) modules, as in sequence to sequence encoders (Sutskever et al., 2014). For a sequence of T words $(w_1, \ldots, w_T)$, the network computes a set of T hidden representations $h_1, \ldots, h_T$, with $h_t = \overrightarrow{\text{LSTM}}(w_1, \ldots, w_T)$ (or using GRU units instead). A sentence is represented by the last hidden vector, h_T.

We also consider a model BiGRU-last that concatenates the last hidden state of a forward GRU, and the last hidden state of a backward GRU to have the same architecture as for SkipThought vectors.

3.2.2 BiLSTM with mean/max pooling

For a sequence of T words $\{w_t\}_{t=1,\ldots,T}$, a bidirectional LSTM computes a set of T vectors $\{h_t\}_t$. For $t \in [1, \ldots, T]$, h_t, is the concatenation of a forward LSTM and a backward LSTM that read the sentences in two opposite directions:

$$\begin{aligned}\overrightarrow{h_t} &= \overrightarrow{\text{LSTM}}_t(w_1, \ldots, w_T)\\ \overleftarrow{h_t} &= \overleftarrow{\text{LSTM}}_t(w_1, \ldots, w_T)\\ h_t &= [\overrightarrow{h_t}, \overleftarrow{h_t}]\end{aligned}$$

We experiment with two ways of combining the varying number of $\{h_t\}_t$ to form a fixed-size vector, either by selecting the maximum value over each dimension of the hidden units (max pooling) (Collobert and Weston, 2008) or by considering the average of the representations (mean pooling).

3.2.3 Self-attentive network

The self-attentive sentence encoder (Liu et al., 2016; Lin et al., 2017) uses an attention mechanism over the hidden states of a BiLSTM to generate a representation u of an input sentence. The attention mechanism is defined as :

$$\begin{aligned}\bar{h}_i &= \tanh(Wh_i + b_w)\\ \alpha_i &= \frac{e^{\bar{h}_i^T u_w}}{\sum_i e^{\bar{h}_i^T u_w}}\\ u &= \sum_t \alpha_i h_i\end{aligned}$$

Figure 2: **Bi-LSTM max-pooling network.**

where $\{h_1, \ldots, h_T\}$ are the output hidden vectors of a BiLSTM. These are fed to an affine transformation (W, b_w) which outputs a set of keys $(\bar{h}_1, \ldots, \bar{h}_T)$. The $\{\alpha_i\}$ represent the score of similarity between the keys and a learned context query vector u_w. These weights are used to produce the final representation u, which is a weighted linear combination of the hidden vectors.

Following Lin et al. (2017) we use a self-attentive network with multiple views of the input sentence, so that the model can learn which part of the sentence is important for the given task. Concretely, we have 4 context vectors $u_w^1, u_w^2, u_w^3, u_w^4$ which generate 4 representations that are then concatenated to obtain the sentence representation u. Figure 3 illustrates this architecture.

w_1 w_2 w_3 w_4
The
movie
was
great

Figure 3: **Inner Attention network architecture.**

3.2.4 Hierarchical ConvNet

One of the currently best performing models on classification tasks is a convolutional architecture termed *AdaSent* (Zhao et al., 2015), which concatenates different representations of the sentences at different level of abstractions. Inspired by this architecture, we introduce a faster version consisting of 4 convolutional layers. At every layer, a representation u_i is computed by a max-pooling operation over the feature maps (see Figure 4).

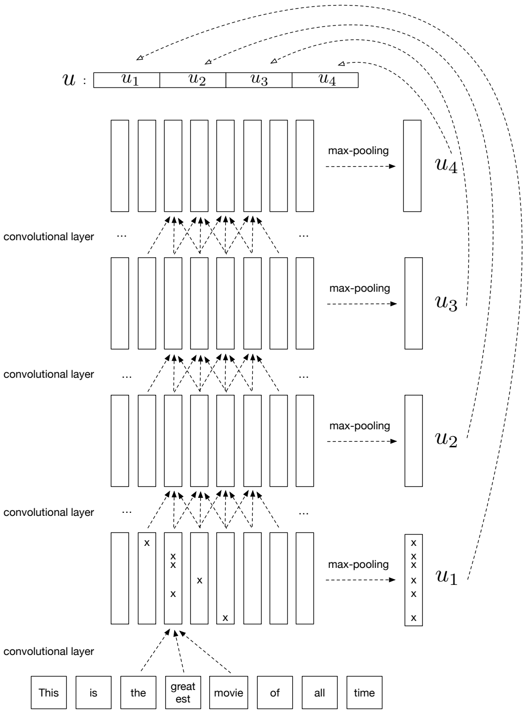

Figure 4: **Hierarchical ConvNet architecture.**

The final representation $u = [u_1, u_2, u_3, u_4]$ concatenates representations at different levels of the input sentence. The model thus captures hierarchical abstractions of an input sentence in a fixed-size representation.

3.3 Training details

For all our models trained on SNLI, we use SGD with a learning rate of 0.1 and a weight decay of 0.99. At each epoch, we divide the learning rate by 5 if the dev accuracy decreases. We use mini-batches of size 64 and training is stopped when the learning rate goes under the threshold of 10^{-5}. For the classifier, we use a multi-layer perceptron with 1 hidden-layer of 512 hidden units. We use open-source GloVe vectors trained on Common Crawl 840B[2] with 300 dimensions as fixed word embeddings.

4 Evaluation of sentence representations

Our aim is to obtain general-purpose sentence embeddings that capture generic information that is

Table 1: **Classification tasks**. C is the number of class and N is the number of samples.

useful for a broad set of tasks. To evaluate the quality of these representations, we use them as features in 12 transfer tasks. We present our sentence-embedding evaluation procedure in this section. We constructed a sentence evaluation tool[3] to automate evaluation on all the tasks mentioned in this paper. The tool uses Adam (Kingma and Ba, 2014) to fit a logistic regression classifier, with batch size 64.

Binary and multi-class classification We use a set of binary classification tasks (see Table 1) that covers various types of sentence classification, including sentiment analysis (MR, SST), question-type (TREC), product reviews (CR), subjectivity/objectivity (SUBJ) and opinion polarity (MPQA). We generate sentence vectors and train a logistic regression on top. A linear classifier requires fewer parameters than an MLP and is thus suitable for small datasets, where transfer learning is especially well-suited. We tune the L2 penalty of the logistic regression with grid-search on the validation set.

Entailment and semantic relatedness We also evaluate on the SICK dataset for both entailment (SICK-E) and semantic relatedness (SICK-R). We use the same matching methods as in SNLI and learn a Logistic Regression on top of the joint representation. For semantic relatedness evaluation, we follow the approach of (Tai et al., 2015) and learn to predict the probability distribution of relatedness scores. We report Pearson correlation.

STS14 - Semantic Textual Similarity While semantic relatedness is supervised in the case of SICK-R, we also evaluate our embeddings on the 6 unsupervised SemEval tasks of STS14 (Agirre et al., 2014). This dataset includes subsets of news articles, forum discussions, image descriptions and headlines from news articles containing pairs of sentences (lower-cased), labeled with a similarity score between 0 and 5. These tasks evaluate how the cosine distance between two sentences correlate with a human-labeled similarity score through Pearson and Spearman correlations.

Paraphrase detection The Microsoft Research Paraphrase Corpus is composed of pairs of sentences which have been extracted from news sources on the Web. Sentence pairs have been human-annotated according to whether they capture a paraphrase/semantic equivalence relationship. We use the same approach as with SICK-E, except that our classifier has only 2 classes.

Caption-Image retrieval The caption-image retrieval task evaluates joint image and language feature models (Hodosh et al., 2013; Lin et al., 2014). The goal is either to rank a large collection of images by their relevance with respect to a given query caption (Image Retrieval), or ranking captions by their relevance for a given query image (Caption Retrieval). We use a pairwise ranking-loss $\mathcal{L}_{\text{cir}}(x, y)$:

$$\sum_y \sum_k \max(0, \alpha - s(Vy, Ux) + s(Vy, Ux_k)) + \\ \sum_x \sum_{k'} \max(0, \alpha - s(Ux, Vy) + s(Ux, Vy_{k'}))$$

where (x, y) consists of an image y with one of its associated captions x, $(y_k)_k$ and $(y_{k'})_{k'}$ are negative examples of the ranking loss, α is the margin and s corresponds to the cosine similarity. U and V are learned linear transformations that project the caption x and the image y to the same embedding space. We use a margin $\alpha = 0.2$ and 30 contrastive terms. We use the same splits as in (Karpathy and Fei-Fei, 2015), i.e., we use 113k images from the COCO dataset (each containing 5 captions) for training, 5k images for validation and 5k images for test. For evaluation, we split the 5k images in 5 random sets of 1k images on which we compute Recall@K, with K $\in \{1, 5, 10\}$ and

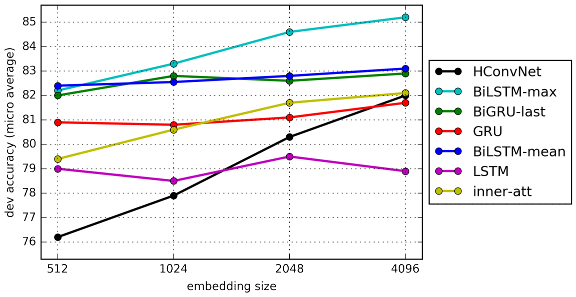

Figure 5: **Transfer performance w.r.t. embedding size** using the micro aggregation method.

5 Empirical results

In this section, we refer to ”micro” and ”macro” averages of development set (dev) results on transfer tasks whose metrics is accuracy: we compute a ”macro” aggregated score that corresponds to the classical average of dev accuracies, and the ”micro” score that is a sum of the dev accuracies, weighted by the number of dev samples.

5.1 Architecture impact

Model We observe in Table 3 that different models trained on the same NLI corpus lead to different transfer tasks results. The BiLSTM-4096 with the max-pooling operation performs best on both SNLI and transfer tasks. Looking at the micro and macro averages, we see that it performs significantly better than the other models LSTM, GRU, BiGRU-last, BiLSTM-Mean, inner-attention and the hierarchical-ConvNet.

Table 3 also shows that better performance on the training task does not necessarily translate in better results on the transfer tasks like when comparing inner-attention and BiLSTM-Mean for instance.

We hypothesize that some models are likely to over-specialize and adapt too well to the biases of a dataset without capturing general-purpose information of the input sentence. For example, the inner-attention model has the ability to focus only on certain parts of a sentence that are useful for the SNLI task, but not necessarily for the transfer tasks. On the other hand, BiLSTM-Mean does not make sharp choices on which part of the sentence is more important than others. The difference between the results seems to come from the different abilities of the models to incorporate general information while not focusing too much on specific features useful for the task at hand.

For a given model, the transfer quality is also sensitive to the optimization algorithm: when training with Adam instead of SGD, we observed that the BiLSTM-max converged faster on SNLI (5 epochs instead of 10), but obtained worse results on the transfer tasks, most likely because of the model and classifier’s increased capability to over-specialize on the training task.

Embedding size Figure 5 compares the overall performance of different architectures, showing the evolution of micro averaged performance with

Table 4: **Transfer test results for various architectures trained in different ways**. Underlined are best results for transfer learning approaches, in bold are best results among the models trained in the same way. † indicates methods that we trained, other transfer models have been extracted from (Hill et al., 2016). For best published supervised methods (no transfer), we consider AdaSent (Zhao et al., 2015), TF-KLD (Ji and Eisenstein, 2013), Tree-LSTM (Tai et al., 2015) and Illinois-LH system (Lai and Hockenmaier, 2014). (*) Our model trained on SST obtained 83.4 for MR and 86.0 for SST (MR and SST come from the same source), which we do not put in the tables for fair comparison with transfer methods.

regard to the embedding size.

Since it is easier to linearly separate in high dimension, especially with logistic regression, it is not surprising that increased embedding sizes lead to increased performance for almost all models. However, this is particularly true for some models (BiLSTM-Max, HConvNet, inner-att), which demonstrate unequal abilities to incorporate more information as the size grows. We hypothesize that such networks are able to incorporate information that is not directly relevant to the objective task (results on SNLI are relatively stable with regard to embedding size) but that can nevertheless be useful as features for transfer tasks.

5.2 Task transfer

We report in Table 4 transfer tasks results for different architectures trained in different ways. We group models by the nature of the data on which they were trained. The first group corresponds to models trained with unsupervised unordered sentences. This includes bag-of-words models such as word2vec-SkipGram, the Unigram-TFIDF model, the Paragraph Vector model (Le and Mikolov, 2014), the Sequential Denoising Auto-Encoder (SDAE) (Hill et al., 2016) and the SIF model (Arora et al., 2017), all trained on the Toronto book corpus (Zhu et al., 2015). The second group consists of models trained with unsu-

Table 5: **COCO retrieval results**. SkipThought is trained either using 82k training samples with VGG19 features, or with 113k samples and ResNet-101 features (our setting). We report the average results on 5 splits of 1k test images.

pervised ordered sentences such as FastSent and SkipThought (also trained on the Toronto book corpus). We also include the FastSent variant "FastSent+AE" and the SkipThought-LN version that uses layer normalization. We report results from models trained on supervised data in the third group, and also report some results of supervised methods trained directly on each task for comparison with transfer learning approaches.

Comparison with SkipThought The best performing sentence encoder to date is the SkipThought-LN model, which was trained on a very large corpora of ordered sentences. With much less data (570k compared to 64M sentences) but with high-quality supervision from the SNLI dataset, we are able to consistently outperform the results obtained by SkipThought vectors. We train our model in less than a day on a single GPU compared to the best SkipThought-LN network trained for a month. Our BiLSTM-max trained on SNLI performs much better than released SkipThought vectors on MR, CR, MPQA, SST, MRPC-accuracy, SICK-R, SICK-E and STS14 (see Table 4). Except for the SUBJ dataset, it also performs better than SkipThought-LN on MR, CR and MPQA. We also observe by looking at the STS14 results that the cosine metrics in our embedding space is much more semantically informative than in SkipThought embedding space (pearson score of 0.68 compared to 0.29 and 0.44 for ST and ST-LN). We hypothesize that this is namely linked to the matching method of SNLI models which incorporates a notion of distance (element-wise product and absolute difference) during training.

NLI as a supervised training set Our findings indicate that our model trained on SNLI obtains much better overall results than models trained on other supervised tasks such as COCO, dictionary definitions, NMT, PPDB (Ganitkevitch et al., 2013) and SST. For SST, we tried exactly the same models as for SNLI; it is worth noting that SST is smaller than NLI. Our representations constitute higher-quality features for both classification and similarity tasks. One explanation is that the natural language inference task constrains the model to encode the semantic information of the input sentence, and that the information required to perform NLI is generally discriminative and informative.

Domain adaptation on SICK tasks Our transfer learning approach obtains better results than previous state-of-the-art on the SICK task - can be seen as an out-domain version of SNLI - for both entailment and relatedness. We obtain a pearson score of 0.885 on SICK-R while (Tai et al., 2015) obtained 0.868, and we obtain 86.3% test accuracy on SICK-E while previous best hand-engineered models (Lai and Hockenmaier, 2014) obtained 84.5%. We also significantly outperformed previous transfer learning approaches on SICK-E (Bowman et al., 2015) that used the parameters of an LSTM model trained on SNLI to fine-tune on SICK (80.8% accuracy). We hypothesize that our embeddings already contain the information learned from the in-domain task, and that learning only the classifier limits the number of parameters learned on the small out-domain task.

Image-caption retrieval results In Table 5, we report results for the COCO image-caption retrieval task. We report the mean recalls of 5 random splits of 1K test images. When trained with

ResNet features and 30k more training data, the SkipThought vectors perform significantly better than the original setting, going from 33.8 to 37.9 for caption retrieval R@1, and from 25.9 to 30.6 on image retrieval R@1. Our approach pushes the results even further, from 37.9 to 42.4 on caption retrieval, and 30.6 to 33.2 on image retrieval. These results are comparable to previous approach of (Ma et al., 2015) that did not do transfer but directly learned the sentence encoding on the image-caption retrieval task. This supports the claim that pre-trained representations such as ResNet image features and our sentence embeddings can achieve competitive results compared to features learned directly on the objective task.

MultiGenre NLI The MultiNLI corpus (Williams et al., 2017) was recently released as a multi-genre version of SNLI. With 433K sentence pairs, MultiNLI improves upon SNLI in its coverage: it contains ten distinct genres of written and spoken English, covering most of the complexity of the language. We augment Table 4 with our model trained on both SNLI and MultiNLI (AllNLI). We observe a significant boost in performance overall compared to the model trained only on SLNI. Our model even reaches AdaSent performance on CR, suggesting that having a larger coverage for the training task helps learn even better general representations. On semantic textual similarity STS14, we are also competitive with PPDB based paragram-phrase embeddings with a pearson score of 0.70. Interestingly, on caption-related transfer tasks such as the COCO image caption retrieval task, training our sentence encoder on other genres from MultiNLI does not degrade the performance compared to the model trained only SNLI (which contains mostly captions), which confirms the generalization power of our embeddings.

6 Conclusion

This paper studies the effects of training sentence embeddings with supervised data by testing on 12 different transfer tasks. We showed that models learned on NLI can perform better than models trained in unsupervised conditions or on other supervised tasks. By exploring various architectures, we showed that a BiLSTM network with max pooling makes the best current universal sentence encoding methods, outperforming existing approaches like SkipThought vectors.

We believe that this work only scratches the surface of possible combinations of models and tasks for learning generic sentence embeddings. Larger datasets that rely on natural language understanding for sentences could bring sentence embedding quality to the next level.

Abstract

Determining semantic textual similarity is a core research subject in natural language processing. Since vector-based models for sentence representation often use shallow information, capturing accurate semantics is difficult. By contrast, logical semantic representations capture deeper levels of sentence semantics, but their symbolic nature does not offer graded notions of textual similarity. We propose a method for determining semantic textual similarity by combining shallow features with features extracted from natural deduction proofs of bidirectional entailment relations between sentence pairs. For the natural deduction proofs, we use ccg2lambda, a higher-order automatic inference system, which converts Combinatory Categorial Grammar (CCG) derivation trees into semantic representations and conducts natural deduction proofs. Experiments show that our system was able to outperform other logic-based systems and that features derived from the proofs are effective for learning textual similarity.

1 Introduction

Determining semantic textual similarity (STS) is one of the most critical tasks in information retrieval and natural language processing. Vector-based sentence representation models have been widely used to compare and rank words, phrases or sentences using various similarity and relatedness scores (Wong and Raghavan, 1984; Mitchell and Lapata, 2010; Le and Mikolov, 2014). Recently, neural network-based sentence representation models (Mueller and Thyagarajan, 2016; Hill et al., 2016) have been proposed for learning textual similarity. However, these vector-based models often use shallow information, such as words and characters, and whether they can account for phenomena such as negation and quantification is not clear. Consider the sentences: *Tom did not meet some of the players* and *Tom did not meet any of the players*. If functional words such as *some* or *any* are ignored or represented as the same vector, then these sentences are to be represented by identical vectors. However, the first sentence implies that there is a player who Tom did not meet, whereas the second sentence means that Tom did not meet anyone, so the sentences have different meanings.

Conversely, logic-based approaches have been successful in representing the meanings of complex sentences, having had a positive impact for applications such as recognizing textual entailment (Mineshima et al., 2015, 2016; Abzianidze, 2015, 2016). However, purely logic-based approaches only assess entailment or contradiction relations between sentences and do not offer graded notions of semantic similarity.

In this paper, we propose to leverage logic cues to learn textual similarity. Our hypothesis is that *observing proof processes when testing the semantic relations is predictive of textual similarity*. We show that our approach can be more effective than systems that ignore these logic cues.

2 Related Work

Vector-based models of semantic composition have been widely studied with regards to calculating STS. Mitchell and Lapata (2008, 2010) pro-

Proceedings of the 2017 Conference on Empirical Methods in Natural Language Processing, pages 681–691
Copenhagen, Denmark, September 7–11, 2017.

posed a sentence vector model involving word vector addition or component-wise multiplication. Addition and multiplication are commutative and associative and thus ignore word order. Polajnar et al. (2015) proposed a discourse-based sentence vector model considering extra-intra sentential context. Also, a categorical compositional distributional semantic model has been developed for recognizing textual entailment and for calculating STS (Grefenstette and Sadrzadeh, 2011; Kartsaklis et al., 2014; Kartsaklis and Sadrzadeh, 2016). However, these previous studies are mostly concerned with the structures of basic phrases or sentences and do not address logical and functional words such as negations and connectives. Neural network-based models of semantic composition (Mueller and Thyagarajan, 2016; Hill et al., 2016) have also been proposed. Although these models achieve higher accuracy, their end-to-end nature introduces challenges in the diagnosis of the reasons that make two sentences to be similar or dissimilar to each other. These diagnosis capabilities may play an important role in making the system explainable and also to guide future system improvements in a more precise manner. Our approach presented in this paper is partially inspired by the latter two objectives.

Meanwhile, some previous studies have proposed logic systems for capturing the semantic relatedness of sentences. The Meaning Factory (Bjerva et al., 2014) uses both shallow and logic-based features for learning textual similarity. In this system, the overlap of predicates and entailment judgments are extracted as logic-based features. UTexas (Beltagy et al., 2014b) uses Probabilistic Soft Logic for learning textual similarity. In this system, each ground atom in the logical formulas has a probability based on distributional semantics of a word. The weights of the logical formulas are calculated from the probabilities of their ground atoms and are extracted as features. These previous studies improved the accuracy by using logic-based features derived from the entailment results of first-order theorem proving in addition to using shallow features such as sentence lengths.

In our study, we determine the semantic similarity of sentences based on the conception of proof-theoretic semantics (Bekki and Mineshima, 2017). The key idea is that not only the entailment results but also the *theorem proving process* can be considered as features for learning textual similarity. That is, by taking into account not only whether a theorem is proved but also *how* it is proved, we can capture the semantic relationships between sentence pairs in more depth.

Another difference between our study and previous logic systems is that we use higher-order predicate logic. Higher-order predicate logic is able to represent complex sentence semantics such as generalized quantifiers more precisely than first-order predicate logic. In addition, higher-order predicate logic makes the logical structure of a sentence more explicit than first-order predicate logic does, so it can simplify the process of proof search (Miller and Nadathur, 1986).

3 System Overview

Figure 1 shows an overview of the system which extracts features for learning textual similarity from logical proofs. To produce semantic representations of sentences and prove them automatically, we use ccg2lambda (Martínez-Gómez et al., 2016), which is a semantic parser combined with an inference system based on natural deduction.

First, sentences are parsed into syntactic trees based on Combinatory Categorial Grammar (CCG) (Steedman, 2000). CCG is a syntactic theory suitable for semantic composition from syntactic structures. Meaning representations are obtained based on semantic templates and combinatory rules for the CCG trees. Semantic templates are defined manually based on formal semantics. Combinatory rules specify the syntactic behaviors of words and compositional rules for the CCG trees. In ccg2lambda, two wide-coverage CCG parsers, C&C (Clark and Curran, 2007) and EasyCCG (Lewis and Steedman, 2014), are used for converting tokenized sentences into CCG trees robustly. According to a previous study (Martínez-Gómez et al., 2017), EasyCCG achieves higher accuracy. Thus, when the output of both C&C and EasyCCG can be proved, we use EasyCCG's output for creating features.

Second, the meanings of words are described using lambda terms. Semantic representations are obtained by combining lambda terms in accordance with the meaning composition rules specified in the CCG tree. The semantic representations are based on Neo-Davidsonian event semantics (Parsons, 1990; Mineshima et al., 2015), in which every verb is decomposed into a predicate over events and a set of functional expressions

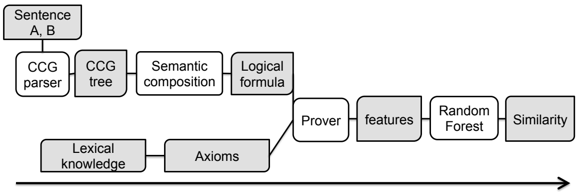

Figure 1: System overview.

relating the events. Adverbs and prepositions are also represented as predicates over events.

Third, we attempt to prove entailment relations between sentence pairs. For this purpose, we use Coq (Bertot and Castran, 2010), which can be used for efficient theorem-proving for natural language inference using both first-order and higher-order logic (Mineshima et al., 2015). Coq's proof calculus is based on natural deduction (Prawitz, 1965), a proof system based on inference rules called introduction and elimination rules for logical connectives. The inference system implemented in ccg2lambda using Coq achieves efficient automatic inference by feeding a set of predefined tactics and user-defined proof-search tactics to its interactive mode. The natural deduction system is particularly suitable for injecting external axioms during the theorem-proving process (Martínez-Gómez et al., 2017).

Finally, features for learning textual similarity are extracted from the proofs produced by ccg2lambda during the theorem-proving process. In this study, we experimented with logistic regression, support vector regression and random forest regression, finding that random forest regression was the most effective. We therefore chose random forest regression for learning textual similarity, with its hyperparameters being optimized by grid search. The mean squared error (MSE) was used to measure the prediction performance of our system.

4 Proof Strategy for Learning Textual Similarity

4.1 Overview of the proof strategy

Sentence similarity depends on complex elements, such as word overlaps and semantic relations. We capture the similarity between the sentence pair (A, B) as a function of the provability of bidirectional entailment relations for (A, B) and combine it with shallow features. After obtaining logical formulas A' and B' from A and B, we attempt to prove the bidirectional entailment relations, $A' \Rightarrow B'$ and $B' \Rightarrow A'$. If the initial natural deduction proofs fail, we re-run the proof, adding relevant external axioms or skipping unproved sub-goals until the proof is completed. After that, features for learning textual similarity are extracted by quantifying the provability of the bidirectional entailment relations.

The details of the procedure are as follows. First, we attempt a natural deduction proof without using external axioms, aiming to prove entailment relations, $A' \Rightarrow B'$ and $B' \Rightarrow A'$. If both fail, then we check whether A' contradicts B', which amounts to proving the negation of the original conclusion, namely $A' \Rightarrow \neg B'$ and $B' \Rightarrow \neg A'$.

The similarity of a sentence pair tends to be higher when the negation of the conclusion can be proved, compared with the case where neither the conclusion nor its negation can be proved. In the SICK (Sentences Involving Compositional Knowledge) dataset (Marelli et al., 2014) (see Section 6.1 for details), 70% of the sentence pairs annotated as contradictory are assigned a relatedness score in $[3, 5)$.

Next, if we fail to prove entailment or contradiction, that is, we cannot prove the conclusion or its negation, we identify an unproved sub-goal which is not matched by any predicate in the premise. We then attempt to prove $A' \Rightarrow B'$ and $B' \Rightarrow A'$ using axiom injection, following the method introduced in Martínez-Gómez et al. (2017). In axiom injection, unproved sub-goals are candidates to form axioms. We focus only on predicates that share at least one argument with both the premise and the conclusion. This means that an axiom can be generated only if there is a predicate p in the pool of premises and a predicate q in a sub-goal and p and q share a variable in an argument position, possibly with the same case (e.g., Subject or Object).

In generating axioms, the semantic relationships between the predicates in the premise and those in the conclusion are checked using lexical knowledge. In this study, we use WordNet (Miller, 1995) as the source of lexical knowledge. Linguistic relations between predicates are checked in the following order: inflections, derivationally related forms, synonyms, antonyms, hypernyms, similarities, and hyponyms. If any one of these relations is found in the lexical knowledge, an axiom can be generated. Again, if the proof fails, we attempt

$$\begin{tikzcd}

G_1 : \mathcal{A}(x) & P_1 : \mathcal{A}(x) & P : \mathcal{A}(u)
\end{tikzcd}$$

Figure 2: Example of the inference rules used in natural deduction. $P, P_1, \ldots P_n$ are formulas in the premise, while G, G_1, G_2 are formulas in the goal. The initial formulas are at the top, with the formulas obtained by applying the inference rules shown below.

to prove the negation of the conclusion using the axiom injection mechanism.

If the proof by axiom injection fails because of a lack of lexical knowledge, we obtain sentence similarity information from partial proofs by simply accepting the unproved sub-goals and forcibly completing the proof. After the proof is completed, information about the generated axioms and skipped sub-goals is used to create features.

4.2 Proving entailment relations

As an illustration of how our natural deduction proof works, consider the case of proving entailment for the following sentence pair:

A: A man is singing in a bar.
B: A man is singing.

The sentences A and B are mapped onto logical formulas A' and B' based on event semantics via CCG-based semantic composition, as follows.

$$A' : \exists e_1 x_1 x_2 (\mathbf{man}(x_1) \wedge \mathbf{sing}(e_1) \wedge (\mathbf{subj}(e_1) = x_1) \wedge \mathbf{bar}(x_2) \wedge \mathbf{in}(e_1, x_2))$$
$$B' : \exists e_1 x_1 (\mathbf{man}(x_1) \wedge \mathbf{sing}(e_1) \wedge (\mathbf{subj}(e_1) = x_1))$$

First, we attempt a natural deduction proof of $A' \Rightarrow B'$, setting A' as the premise and B' as the goal of the proof. Then A' and B' are decomposed according to the inference rules.

Figure 2 shows the major inference rules we use in the proofs. Inference rules in natural deduction are divided into two types: introduction rules and elimination rules. Introduction rules specify how to prove a formula in the goal, decomposing a goal formula into smaller sub-goals. Elimination rules specify how to use a premise, decomposing a formula in the pool of premises into smaller ones.

$$\begin{tikzcd}
\begin{array}{l} P_0 : \exists e_1 x_1 x_2 (\mathbf{man}(x_1) \wedge \mathbf{sing}(e_1) \wedge (\mathbf{subj}(e_1) = x_1) \\ \quad \wedge\, \mathbf{bar}(x_2) \wedge \mathbf{in}(e_1, x_2)) \\ G_0 : \exists e_1 x_1 (\mathbf{man}(x_1) \wedge \mathbf{sing}(e_1) \wedge (\mathbf{subj}(e_1) = x_1)) \end{array} \arrow[d, "\exists\text{-ELIM } (P_0),\ \exists\text{-INTRO } (G_0)"] \\
\begin{array}{l} P_1 : \mathbf{man}(x_1) \wedge \mathbf{sing}(e_1) \wedge (\mathbf{subj}(e_1) = x_1) \\ \quad \wedge\, \mathbf{bar}(x_2) \wedge \mathbf{in}(e_1, x_2) \\ G_1 : \mathbf{man}(x_1) \wedge \mathbf{sing}(e_1) \wedge (\mathbf{subj}(e_1) = x_1) \end{array} \arrow[d, "\wedge\text{-ELIM } (P_1),\ \wedge\text{-INTRO } (G_1)"] \\
\begin{array}{l} P_2 : \mathbf{man}(x_1),\ P_3 : \mathbf{sing}(e_1),\ P_4 : \mathbf{subj}(e_1) = x_1 \\ \quad P_5 : \mathbf{bar}(x_2),\ P_6 : \mathbf{in}(e_1, x_2), \\ G_2 : \mathbf{man}(x_1),\ G_3 : \mathbf{sing}(e_1),\ G_4 : \mathbf{subj}(e_1) = x_1 \end{array}
\end{tikzcd}$$

Figure 3: The proof process for the example entailment relation.

The proof process for $A' \Rightarrow B'$ is shown in Figure 3. Here A' is initially set to the premise P_0 and B' to the goal G_0. P_0 and G_0 are then decomposed using elimination rules (∧-ELIM, ∃-ELIM) and introduction rules (∧-INTRO, ∃-INTRO). Then we obtain a set of premise formulas $\mathcal{P} = \{P_2, P_3, P_4, P_5, P_6\}$, and a set of sub-goals $\mathcal{G} = \{G_2, G_3, G_4\}$. The proof is performed by searching for a premise P_i whose predicate and arguments match those of a given sub-goal G_j. If such a logical premise is found, the sub-goal is removed. In this example, the sub-goals G_2, G_3, and G_4 match the premises P_2, P_3, and P_4, respectively. Thus, $A' \Rightarrow B'$ can be proved without introducing axioms.

Second, we attempt the proof in the opposite direction, $B' \Rightarrow A'$, by switching P_0 and G_0 in Figure 3. Again, by applying inference rules, we obtain the following sets of premises $\mathcal{P}$ and sub-goals $\mathcal{G}$:

$$\begin{aligned} \mathcal{P} = \{&P_2 : \mathbf{man}(x_1),\ P_3 : \mathbf{sing}(e_1), \\ &P_4 : \mathbf{subj}(e_1) = x_1\} \\ \mathcal{G} = \{&G_2 : \mathbf{man}(x_1),\ G_3 : \mathbf{sing}(e_1), \\ &G_4 : \mathbf{subj}(e_1) = x_1, \\ &G_5 : \mathbf{bar}(x_2), G_6 : \mathbf{in}(e_1, x_2))\} \end{aligned}$$

Here, the two sub-goals G_5 and G_6 do not match any of the premises, so the attempted proof of $B' \Rightarrow A'$ fails. We therefore attempt to inject additional axioms, but in this case no predicate in $\mathcal{P}$ shares the argument x_2 of the predicates $\mathbf{bar}(x_2)$ and $\mathbf{in}(e_1, x_2)$ in $\mathcal{G}$. Thus, no axiom can be generated. To obtain information from a partial proof, we forcibly complete the proof of $B' \Rightarrow A'$ by skipping the unproved sub-goals $\mathbf{bar}(x)$ and $\mathbf{in}(e_1, x_2)$.

4.3 Proving the contradiction

The proof strategy illustrated here can be straightforwardly applied to proving the contradiction. In natural deduction, a negative formula of the form $\neg A$ can be defined as $A \rightarrow \textbf{False}$ ("the formula A implies the contradiction"), by using a propositional constant **False** to encode the contradiction. Thus, the inference rules for negation can be taken as special cases of implication rules, as shown in Figure 4.

As an illustration, let us consider the following sentence pair:

A: No man is singing.

B: There is a man singing loudly.

Figure 5 shows the proof process. The sentences A and B are mapped to P_0 and P_1, respectively, via compositional semantics and the goal G_0 is set to **False**. By decomposing P_1 using elimination rules and then by combining P_2, P_3, and P_4, we can obtain P_6. From P_0 and P_6 we can then derive the contradiction.

These proofs are performed by an automated prover implemented on Coq, using tactics for first-order theorem proving. When a proof is successful, Coq outputs the resulting proof (a proof term), from which we can extract detailed information such as the number of proof steps and the types of inference rules used. In addition to the entailment/contradiction result, information about the proof process is used to create features.

5 Description of the Features

To maximize accuracy when learning textual similarity, we adopt a hybrid approach that uses both logic-based features extracted from the natural deduction proof and other, non-logic-based features. All features are scaled to the $[0, 1]$ range.

5.1 Logic-based Features

We propose 15 features consisting of nine different types of logic-based features. Six of these feature types are derived from the bidirectional natural deduction proofs: six features are extracted from the direct proof ($A' \Rightarrow B'$) and another six from the reverse proof ($B' \Rightarrow A'$). The remaining three feature types are derived from semantic representations of the sentence pairs. The feature types are as follows.

Logical inference result. As stated in Section 4, we include features to distinguish the case where either the conclusion or its negation can be proved from the one where neither can be proved. If the conclusion can be proved, the feature is set to 1.0. If the negation of the conclusion can be proved, the feature is set to 0.5. If neither can be proved, the feature is set to 0.0.

$$\begin{array}{ccc} \begin{array}{l} G : \neg\mathcal{A} \\ \quad\Big\downarrow \neg\text{-}\textsc{Intro} \\ P : \mathcal{A} \\ G : \textbf{False} \end{array} & \qquad & \begin{array}{l} P_1 : \neg\mathcal{A} \\ P_2 : \mathcal{A} \\ \quad\Big\downarrow \neg\text{-}\textsc{Elim} \\ P : \textbf{False} \end{array} \end{array}$$

Figure 4: Inference rules of negation.

$$\begin{array}{l} P_0 : \neg\exists e_1 \exists x_1 (\mathbf{man}(x_1) \land \mathbf{sing}(e_1) \land (\mathbf{subj}(e_1) = x_1)) \\ P_1 : \exists e_1 \exists x_1 (\mathbf{man}(x_1) \land \mathbf{sing}(e_1) \land (\mathbf{subj}(e_1) = x_1) \\ \quad \land\, \mathbf{loudly}(e_1)) \\ G_0 : \textbf{False} \\ \qquad\qquad\qquad\Big\downarrow \exists\text{-}\textsc{Elim}, \land\text{-}\textsc{Elim}\ (P_2) \\ P_2 : \mathbf{man}(x_1),\ P_3 : \mathbf{sing}(e_1),\ P_4 : \mathbf{subj}(e_1) = x_1, \\ P_5 : \mathbf{loudly}(e_1) \\ \qquad\qquad\qquad\Big\downarrow \exists\text{-}\textsc{Intro}, \land\text{-}\textsc{Intro}\ (P_2) \\ P_6 : \exists e_1 \exists x_1 (\mathbf{man}(x_1) \land \mathbf{sing}(e_1) \land \mathbf{subj}(e_1) = x_1) \end{array}$$

Figure 5: Proof process for the contradiction example.

Axiom probabilities. The probability of an axiom and the number of axioms appearing in the proof are used to create features. The probability of an axiom is defined as the inverse of the length of the shortest path that connects the senses in the is-a (hypernym/hyponym) taxonomy in WordNet. When multiple axioms are used in the proof, the average of the probabilities of the axioms is extracted as a feature. If the proof can be completed without using axioms, the feature is set to 1.0.

Proved sub-goals. Given that proofs can be obtained either by proving all the sub-goals or skipping unproved sub-goals, we use the proportion of proved sub-goals as a feature. Our assumption is that if there are more unproved sub-goals then the sentence pair is less similar. When there are m logical formulas in the premise pool and n proved sub-goals, we set the feature to n/m. If the theorem can be proved without skipping any sub-goals, the feature is set to 1.0. It may be the case that the number of sub-goals is so large that some sub-goals remain unproved even after axiom injection. Since the proportion of unproved sub-goals is decreased by axiom injection, we use the proportion of unproved sub-goals both with and without axiom injection as features.

Cases in unproved sub-goals. Subject or object words can affect the similarity of sentence pairs. Therefore, the number of each case in unproved sub-goals, like $\mathbf{subj}(e_1)$ in Figures 3 and 5, is used as a feature. Here, we count subjective, objective, and dative cases.

Proof steps. In general, complex theorems are difficult to prove and in such cases the sentence pairs are considered to be less similar. We therefore use the number of Coq's proof steps, namely the number of inference rule applications in a given proof, as a feature.

Inference rules. The complexity of a natural deduction proof can be measured in terms of the inference rules used for each proof step. We therefore extract the relative frequency with which each inference rule is used in the proof as a feature. We check seven inference rules for natural deduction using Coq (cf. Figure 2): introduction and elimination rules for conjunction ($\wedge$-INTRO, $\wedge$-ELIM), implication ($\rightarrow$-INTRO, $\rightarrow$-ELIM), and existential quantification ($\exists$-INTRO, $\exists$-ELIM), and the elimination rule for equality ($=$-ELIM).

Predicate overlap. Intuitively, the more predicates overlap between the premise and the conclusion, the more likely it is that the inference can be proved. We therefore use the proportion of predicates that overlap between the premise and the conclusion as a feature.

Semantic type overlap. Each semantic representation in higher-order logic has a semantic type, such as Entity for entities and Prop for propositions. As with predicates, we use the degree of semantic type overlap between the premise and the conclusion as a feature.

Existence of negative clauses. Whether or not the premise or conclusion contain negative clauses is an effective measure of similarity. In semantic representations, negative clauses are represented by the negation operator $\neg$, so we check for negation operators in the premise and the conclusion and set this feature to 1.0 if either contains one.

5.2 Non-logic-based Features

We also use the following eight non-logic-based features.

Noun/verb overlap. We extract and lemmatize all nouns and verbs from the sentence pairs and use the degrees of overlap of the noun and verb lemmas as features.

Part-of-speech overlap. We obtain part-of-speech (POS) tags for all words in the sentence pairs by first tokenizing them with the Penn Treebank Project tokenizer[1] and then POS tagging them with C&C POS tagger (Curran and Clark, 2003). The degree of overlap between the sentences' POS tags is used as a feature.

Synset overlap. For each sentence in the pair, we obtain the set containing all the synonym lemmas (the synset) for the words in the sentence. The degree of overlap between the sentences' synsets is used as a feature.

Synset distance. For each word in the first sentence, we compute the maximum path similarity between its synset and the synset of any other word in the second sentence. Then, we use the average of maximum path similarities as a feature.

Sentence length. If the conclusion sentence is long, there will possibly be many sub-goals in the proof. We therefore use the average of the sentence lengths and the difference in length between the premise and the conclusion sentences as features.

String similarity. We use the similarity of the sequence of characters within the sentence pairs as a feature. The Python *Difflib*[2] function returns the similarity between two sequences as a floating-point value in $[0, 1]$. This measure is given by $2.0 * M/T$, where T is the total number of elements in both sequences and M is the number of matches. This feature is 1.0 if the sequences are identical and 0.0 if they have nothing in common.

Sentence similarity from vector space models. We calculate sentence similarity by using three major vector space models, TF-IDF, latent semantic analysis (LSA) (Deerwester et al., 1990), and latent Dirichlet allocation (LDA) (Blei et al., 2003). We use these cosine similarities as features.

Existence of passive clauses. Passive clauses have an influence on similarity. In CCG trees, passive clauses are represented using the syntactic category $S_{pss}\backslash NP$. We check for the occurrence of passive clauses in the premise and conclusion, and if either of them contains a passive clause then the feature is set to 1.0.

6 Experiments and Evaluation

6.1 Experimental Conditions

We evaluated our system[3] using two datasets: the SemEval-2014 version of the SICK dataset (Marelli et al., 2014) and the SemEval-2012 version of the MSR-paraphrase video corpus dataset (MSR-vid) (Agirre et al., 2012). The experimental conditions were as follows.

6.1.1 The SICK dataset

The SICK dataset is a dataset for studying STS as well as for recognizing textual entailment (RTE). It was originally developed for evaluating compositional distributional semantics, so it contains logically challenging expressions such as quantifiers, negations, conjunctions and disjunctions. The dataset contains 9927 sentence pairs with a 5000/4927 training/test split. These sentence pairs are manually annotated with three types of labels *yes* (entailment), *no* (contradiction), or *unknown* (neutral) as well as a semantic relatedness scores in $[1, 5]$ (see Table 1 for a sample).

In this dataset, sentence pairs whose gold entailment labels are *no* tend to be scored a little more highly than the average, whereas those whose labels are *unknown* have a wide range of scores. Thus, we set the baseline of the relatedness score to 5 when the gold entailment label was *yes* and to 3 when the label was *no* or *unknown*.

We compared our system with the following systems: the state-of-the-art neural network-based system (Mueller and Thyagarajan, 2016); the best system (Zhao et al., 2014) from SemEval-2014; and two of the logic-based systems stated in Section 2: namely The Meaning Factory (Bjerva et al., 2014) and UTexas (Beltagy et al., 2014b). The Pearson correlation coefficient γ, Spearman's rank correlation coefficient ρ, and the MSE were used as the evaluation metrics.

6.1.2 The MSR-vid dataset

The MSR-vid dataset is our second dataset for the STS task and contains 1500 sentence pairs with a 750/750 training/test split. All sentence pairs are annotated with semantic relatedness scores in the range [0, 5]. We used this dataset to compare our system with the best system from SemEval-2012 (Bär et al., 2012) and the logic-based UTexas system (Beltagy et al., 2014a). We used the Pearson correlation coefficient γ as the evaluation metric.

6.2 Results

Table 2 shows the results of our experiments with the SICK dataset. Although the state-of-the-art neural network-based system yielded the best results overall, our system achieved higher scores than SemEval-2014 submissions, including the two logic-based systems (The Meaning Factory and UTexas), in terms of Pearson correlation and Spearman's correlation.

The main reason for our system's lower performance in terms of MSE is that some theorems could not be proved because of a lack of lexical knowledge. In the current work, we only consider word-level knowledge (word-for-word paraphrasing); we may expand the knowledge base in the future by using more external resources.

As we mentioned above, the sentence pairs annotated as *unknown* produced a wide range of scores. The Pearson correlation of the *unknown* portion of the SICK dataset was 0.766, which suggests that our logic-based system can also be applied to neutral sentence pairs.

Table 3 shows the results of our experiments with the MSR-vid dataset. These results also indicate that our logic-based system achieved higher accuracy than the other logic-based systems.

Table 4: Results when training our regressor with each feature group in isolation.

Table 4 shows evaluation results for each feature group in isolation, showing that inference rules and predicate overlaps are the most effective features. Compared with the non-logic-based features, the logic-based features achieved a slightly higher accuracy, a point that will be analyzed in more detail in the next section. Overall, our results show that combining logic-based features with non logic-based ones is an effective method for determining textual similarity.

6.3 Positive examples and error analysis

Table 5 shows some examples for which the prediction score was better when using logic-based features than when using non-logic-based ones.

For IDs 642 and 1360, one sentence contains a passive clause while the other sentence does not. In such cases, the sentence pairs are not superficially similar. By using logical formulas based on event semantics we were able to interpret the sentence containing the passive clause correctly and judge that the passive and non-passive sentences are similar to each other.

In ID 891, one sentence contains a negative clause while the other does not. Using shallow features, the word overlap is small and the prediction score was much lower than the correct score. Our logic-based method, however, interpreted the first sentence as a negative existential formula of the form $\neg\exists x\mathcal{P}(x)$ and the second sentence as an existential formula $\exists x\mathcal{P}'(x)$. Thus, it could easily handle the semantic difference between the positive and negative sentences.

In ID 1158, by contrast, the proportion of word overlap is so high that the prediction score with non-logic-based features was much higher than the correct score. Our method, however, was able to prove the contradiction using an antonym axiom of the form $\forall x(\mathbf{remove}(x) \rightarrow \neg\mathbf{add}(x))$ from WordNet and thus predict the score correctly.

In ID 59, the proportion of word overlap is low, so the prediction score with non-logic-based features was lower than the correct score. Our method, however, was able to prove the partial entailment relations for the sentence pair and thus predict the score correctly. Here the logic-based method captured the common meaning of the sentence pair: both sentences talk about the kids playing in the leaves.

Finally, in ID 71, the prediction score with non-logic-based features was much higher than the correct score. There are two reasons for this phenomenon: negations tend to be omitted in non-logic-based features such as TF-IDF and the proportion of word overlap is high. However, as logical formulas and proofs can handle negative clauses correctly, our method was able to predict the score correctly.

Table 6 shows examples where using only logic-based features produced erroneous results. In ID 3974, the probability of axiom $\forall x(\mathbf{awaken}(x) \rightarrow \mathbf{up}(x))$ was low (0.25) and thus the prediction score was lower than the correct score. Likewise, in ID 4833, the probability of axiom $\forall x(\mathbf{file}(x) \rightarrow \mathbf{do}(x))$ was very low (0.09) and thus the prediction score was negatively affected. In these cases, we need to consider phrase-level axioms such as $\forall x(\mathbf{awaken}(x) \rightarrow \mathbf{wake\_up}(x))$ and $\forall x(\mathbf{file\_nail}(x) \rightarrow \mathbf{do\_manicure}(x))$ using a paraphrase database. This, however, is an issue for future study. In ID 1941, the system wrongly proved the bidirectional entailment relations by

ID	Sentence Pair	Gold	Pred +logic	Pred -logic	Entailment
642	A person is climbing a rock with a rope, which is pink. A rock is being climbed by a person with a rope, which is pink.	5.0	4.9	4.1	Yes
1360	The machine is shaving the end of a pencil. A pencil is being shaved by the machine.	4.7	4.6	3.8	Yes
891	There is no one on the shore. A bunch of people is on the shore.	3.6	3.7	2.6	No
1158	A woman is removing ingredients from a bowl. A woman is adding ingredients to a bowl.	3.3	3.5	4.1	No
59	Kids in red shirts are playing in the leaves. Three kids are jumping in the leaves.	3.9	3.8	3.1	Unknown
71	There is no child lying in the snow and making snow angels. Two people in snowsuits are lying in the snow and making snow angels.	3.3	3.3	4.1	Unknown

Table 5: Examples for which our regressor trained only with logic-based features performs better than when using non-logic features. “Gold”: correct score, “Pred+logic”: prediction score only with logic-based features, “Pred-logic”: prediction score only with non-logic-based features.

ID	Sentence Pair	Gold	System	Axiom
3974	A girl is awakening. A girl is waking up.	4.9	3.6	$\forall x(\mathbf{awaken}(x) \rightarrow \mathbf{wake}(x))$ $\forall x(\mathbf{awaken}(x) \rightarrow \mathbf{up}(x))$
4833	A girl is filing her nails. A girl is doing a manicure.	4.2	1.8	$\forall x(\mathbf{nail}(x) \rightarrow \mathbf{manicure}(x))$ $\forall x(\mathbf{file}(x) \rightarrow \mathbf{do}(x))$
1941	A woman is putting the baby into a trash can. A person is putting meat into a skillet.	1.0	3.3	$\forall x(\mathbf{woman}(x) \rightarrow \mathbf{person}(x))$ $\forall x(\mathbf{trash}(x) \rightarrow \mathbf{skillet}(x))$ $\forall x(\mathbf{baby}(x) \rightarrow \mathbf{meat}(x))$

Table 6: Error examples when training the regressor only with logic-based features.

adding external axioms, so the prediction score was much higher than the correct score. Setting the threshold for the probability of an axiom may be an effective way of improving our axiom-injection method.

7 Conclusion

We have developed a hybrid method for learning textual similarity by combining features based on logical proofs of bidirectional entailment relations with non-logic-based features. The results of our experiments on two datasets show that our system was able to outperform other logic-based systems. In addition, the results show that information about the natural deduction proof process can be used to create effective features for learning textual similarity. Since these logic-based features provide accuracy improvements that are largely additive with those provided by non-logic-based features, neural network-based systems may also benefit from using them.

In future work, we will refine our system so that it can be applied to other tasks such as question answering. Compared with neural network-based systems, our natural deduction-based system can not only assess how similar sentence pairs are, but also explain what the sources of similarity/dissimilarity are by referring to information about sub-goals in the proof. Given this interpretative ability, we believe that our logic-based system may also be of benefit to other natural language processing tasks, such as question answering and text summarization.

Multi-Grained Chinese Word Segmentation

Abstract

Traditionally, word segmentation (WS) adopts the single-granularity formalism, where a sentence corresponds to a single word sequence. However, Sproat et al. (1996) show that the inter-native-speaker consistency ratio over Chinese word boundaries is only 76%, indicating single-grained WS (SWS) imposes unnecessary challenges on both manual annotation and statistical modeling. Moreover, WS results of different granularities can be complementary and beneficial for high-level applications.

This work proposes and addresses multi-grained WS (MWS). First, we build a large-scale pseudo MWS dataset for model training and tuning by leveraging the annotation heterogeneity of three SWS datasets. Then we manually annotate 1,500 test sentences with true MWS annotations. Finally, we propose three benchmark approaches by casting MWS as constituent parsing and sequence labeling. Experiments and analysis lead to many interesting findings.

1 Introduction

As the first processing step of Chinese language processing, word segmentation (WS) has been extensively studied and made great progress during the past decades, thanks to the annotation of large-scale benchmark datasets, among which the most widely-used are Microsoft Research Corpus (MSR) (Huang et al., 2006), Peking University People Daily Corpus (PPD) (Yu et al., 2003), and Penn Chinese Treebank (CTB) (Xue et al., 2005). Table 1 gives an example sentence segmented in different guidelines. Meanwhile, WS approaches gradually evolve from maximum matching based on lexicon dictionaries (Liu and Liang, 1986), to path searching from segmentation graphs based on language modeling scores and other statistics (Zhang and Liu, 2002), to character-based sequence labeling (Xue, 2003), to shift-reduce incremental parsing (Zhang and Clark, 2007). Recently, neural network models have also achieved success by effectively learning representation of characters and contexts (Zheng et al., 2013; Pei et al., 2014; Ma and Hinrichs, 2015; Chen et al., 2015; Zhang et al., 2016; Cai and Zhao, 2016; Liu et al., 2016).

</table>

Table 1: An example of annotation heterogeneity: 全 (all) 国 (country) 各 (every) 地 (place) 医学 (medical science) 界 (field) 专家 (experts) 走 (walk) 出 (out) 人民 (people) 大会堂 (great hall).

To date, all the labeled datasets adopt the single-granularity formalization, and previous research mainly focuses on single-grained WS (SWS), where one sentence is segmented into a single word sequence. Although different WS guidelines share the same high-level criterion of word boundaries – a character string combined closely and used steadily forms a word, people greatly diverge due to individual differences on knowledge and living environments, etc. An anonymous reviewer kindly points

out that Vladímir Skalička of the Prague School claimed that unlike the “isolating” languages such as French and English, Chinese belongs to the “polysynthetic” type, in which compound words are normally produced from indigenous morphemes (Jernudd and Shapiro, 1989). The vague distinction between morphemes and compounds also contribute to the cognition divergence on the concept of words. Sproat et al. (1996) show that the consensus ratio over word boundaries is only 76% among Chinese native speakers without trained on a common guideline.To fill this gap, WS guidelines need to further group words into many types and provide illustration examples for each type. Nevertheless, it is very challenging even for well-trained annotators to fully grasp the guidelines and to be consistent on uncovered cases. For example, Xiu (2013) (in Tables 1-3) shows that about 3% characters are inconsistently segmented in the PPD training data used in SIGHAN Bakeoff 2005 (Emerson, 2005). We have also observed many inconsistency cases in all MSR/PPD/CTB during this work. In a word, SWS imposes great challenge on data annotation, and as a side effect, enforces statistical models to learn subtleness of annotation guidelines rather than the true WS ambiguities.

From another perspective, WS results of different granularities may be complementary in supporting applications such as information retrieval (IR) (Liu et al., 2008) and machine translation (MT) (Su et al., 2017). On the one hand, coarse-grained words enable statistical models to perform more exact matching and analyzing. On the other hand, fine-grained words are helpful in both reducing data sparseness and supporting deeper understanding of language.[1]

To solve the above two issues for SWS, this paper proposes and addresses multi-grained WS (MWS). Given an input sentence, the goal is to produce a hierarchy structure of all words of different granularities, as illustrated in Figure 1. To tackle the lack of labeled data, we build a large-scale pseudo MWS dataset for model training and tuning by automatically converting annotations of three heterogeneous SWS datasets (i.e. MSR/PPD/CTB) based on the recently proposed coupled sequence labeling approach of Li et al. (2015). In order to fully investigate the problem, we manually annotate 1,500 test sentences with true MWS annotations. Finally, we propose three benchmark approaches by casting MWS as constituent parsing and sequence labeling problems. Experiments and data analysis lead to many interesting findings.

We will release the newly annotated data and the codes of the benchmark approaches at http://hlt.suda.edu.cn/~zhli. However, due to the license issue, we may not directly release all the pseudo MWS datasets. Instead, we will launch a web service for obtaining MWS annotations given a sentence with one of MSR/PPD/CTB annotations.

2 Pseudo MWS Data Conversion

This section introduces the process of gathering pseudo MWS data by making use of the annotation heterogeneity of the three existing datasets, i.e., MSR/PPD/CTB.

2.1 Annotation Heterogeneity

MSR is a manually labeled corpus with word boundaries and named entity tags, and is annotated by Microsoft Research Asia for supporting Chinese text processing (Huang et al., 2006). The key characteristic of MSR is treating named entities as single words. For example, “人民大会堂 (Great Hall of the People)” is a location and forms a word in Table 1. In general, MSR is more coarse-grained than PPD and CTB. PPD is a large-scale corpus with word boundaries, POS tagging, and phonetic notations to facilitate Chi-

[1] Words in CTB are generally more fine-grained than those in PPD and MSR, probably due to the requirement of annotating syntactic structures.

nese information processing, and is annotated by Institute of Computational Linguistics at Peking University (Yu et al., 2003). Based on the Penn Chinese Treebank Project, CTB is built to create a Mandarin Chinese corpus with syntactic bracketing (Xue et al., 2005). We find that CTB is more fine-grained in word boundaries than MSR and PPD, since syntactic annotation tends to require deeper understanding of a sentence. For example, Table 5 reports the averaged number of characters per word in each corpus, and confirms our observations.

For better understanding of annotation heterogeneity, we summarize high-frequency differences among the three datasets observed and gathered during this study in Appendix A. However, it is difficult to obtain a complete list of annotation correspondences among the three datasets, since there are too many low-frequency and irregular cases. Moreover, we also observe a lot of inconsistency annotations of the same word or words with similar structures in all three datasets, as shown in Appendix B.

2.2 Coupled WS for Conversion: MSR/PPD as Example

This section introduces how to automatically produce high-quality PPD-side WS labels for a sentence with MSR-side gold-standard WS labels, by leveraging the two non-overlapping SWS data of MSR and PPD with the coupled sequence labeling approach of Li et al. (2015) and Li et al. (2016). Figure 2 shows the workflow.

Given a sentence $\mathbf{x} = [c_1, ..., c_i, ..., c_n]$, the coupled model aims to produce a sequence of bundled tags $\mathbf{t} = [t_1^a t_1^b, ..., t_i^a t_i^b, ..., t_n^a t_n^b]$, where t_i^a and t_i^b are two labels corresponding to two heterogeneous guidelines respectively. Table 2 gives an example of coupled WS on MSR/PPD. We employ the standard four-tag label set to mark word boundaries of one granularity, among which B, I, E respectively represent that the concerned character situates at the *beginning, inside, end* position of a word, and *S* represents a single-character word. The bottom row shows the gold-standard bundled tag sequence.

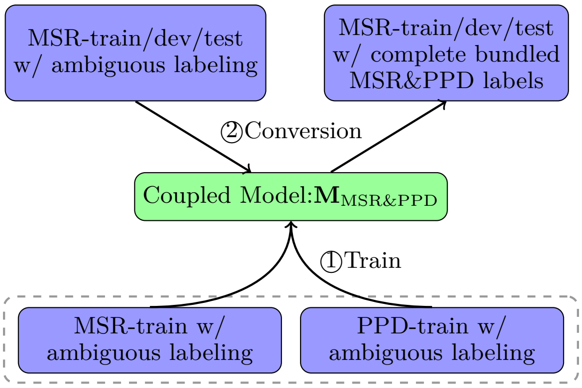

Figure 2: Conversion between MSR/PPD.

Input	全	国	各	地	医	学	界	专	家	...

Conversion	BS	IS	IS	ES	BS	ES	SS	BS	ES	...
Output	BB	IE	IB	EE	BB	EI	SE	BB	EE	...

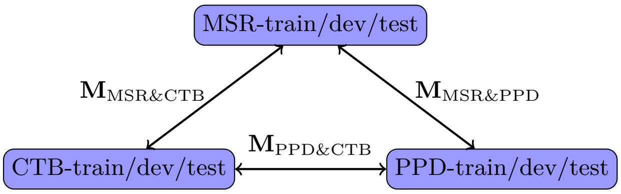
Table 2: Coupled WS (MSR/PPD as example). Two WS labels are bundled to represent MSR/PPD annotations for a character. Ambiguous labeling is gained supposing this sentence has MSR-side gold-standard annotations.

One key advantage of the coupled model is to directly learn from two *non-overlapping* heterogeneous training datasets, where each dataset only contains single-side gold-standard labels. To deal with this partial (or incomplete) labeling issue, they project each single-side label to a set of bundled labels by considering all labels at the missing side, as shown in the second row in Table 2. Such *ambiguous labelings* are used for model supervision.

Under a traditional CRF, the coupled model defines the score of a bundled tag sequence as

$$
\begin{aligned}
Score(\mathbf{x}, \mathbf{t}; \theta) &= \theta \cdot \mathbf{f}(\mathbf{x}, \mathbf{t}) \\
&= \sum_{i=1}^{n+1} \theta \cdot \begin{bmatrix} \mathbf{f}_{joint}(\mathbf{x}, i, t_{i-1}^a t_{i-1}^b, t_i^a t_i^b) \\ \mathbf{f}_{sep\_a}(\mathbf{x}, i, t_{i-1}^a, t_i^a) \\ \mathbf{f}_{sep\_b}(\mathbf{x}, i, t_{i-1}^b, t_i^b) \end{bmatrix}
\end{aligned}
$$

where $\mathbf{f}_{joint}(.)$ are the *joint features* whereas $\mathbf{f}_{sep\_a/sep\_b}(.)$ are the separate features. Li et al. (2015) demonstrate that the joint features capture the implicit mappings between heterogeneous annotations, while the back-off separate features work as a remedy for the sparseness of the joint features.



MSR-train/dev/test
$\mathbf{M}_{\text{MSR\&CTB}}$
$\mathbf{M}_{\text{MSR\&PPD}}$
$\mathbf{M}_{\text{PPD\&CTB}}$
CTB-train/dev/test
PPD-train/dev/test

Figure 3: Producing pseudo MWS data.

In their case study of POS tagging, Li et al. (2015) show the coupled model improves tagging accuracy by 95.0 − 94.1 = 0.9% on CTB5-test over the baseline non-coupled model trained on a single training data.

More importantly, they show that the coupled model can be naturally used for the task of annotation conversion, where second-side labels are automatically annotated, given one-side gold-standard labels. The given one-side tags are used to obtain ambiguous labelings, as shown in Table 2, and the coupled model finds the best bundled tag sequence in the *constrained search space*, instead of in the whole bundled tag space, hence greatly reducing the difficulty. Li et al. (2015) report that the coupled model can improve conversion accuracy on POS tagging by 93.9 − 90.6 = 3.3% over the non-coupled model.[2]

2.3 Producing Pseudo MWS Data

Figure 3 shows the workflow of producing pseudo MWS data with three separately trained coupled models. Please note that one coupled model is able to perform conversion between one pair of annotation standards, and thus three coupled models are required for three kinds of annotation standards. Another alternative is that we could directly train one coupled model on MSR/PPD/CTB by extending the approach of Li et al. (2015) from two guidelines into three, which would lead to a much larger bundled tag space. For simplicity, we directly employ their released codes in this work, and leave that for future exploration.

After conversion, we obtain 9 pseudo MWS datasets (i.e., MSR/PPD/CTB-train/dev/test) and represent each sentence in a hierarchy structure as shown in Figure 1. Please kindly note that the guideline-specific information are thrown away, since we do not care which word belongs to which guideline.

In the resulting pseudo MWS data, we find about 0.08% of words overlap with other words, meaning a string "ABC" is segmented into "A/BC" and "AB/C" in two different annotations. We have manually checked these words, and find almost all those cases are caused by conversion errors. This confirms that our treatment of MWS as a hierarchy structure is reasonable.

3 Manual Annotation

In order to fully investigate the MWS problem, we have manually created a true MWS data of 1,500 sentences for final evaluation. From each test dataset in Table 5, we randomly sample 500 sentences with converted pseudo MWS annotations for manual correction. First, two coauthors of this work spent about two hours each day on manual correction of the pseudo MWS annotations for two weeks. During this period, we have summarized a list of high-frequency corresponding patterns among the three guidelines (see Appendix A), and have also written a simple program to automatically detect inconsistent annotations of given words in different training datasets, so that annotators can use the outputs of the program to decide ambiguous cases, which we find is extremely helpful for annotation.

Then, we employ 10 postgraduate students as our annotators who are at different familiarity in WS annotation. Before formal annotation, the annotators are trained for two hours on the basic concepts of MWS, high-frequency correspondences among the three guidelines, and the use of the outputs of the program. We also encourage the annotators to access the three training datasets directly for studying concrete cases under real contexts. Moreover, annotators are asked to recheck their annotations before final submission to improve quality.

To measure the inter-annotator consistency, 150 sentences (10%) are sampled for double annotation, and are grouped into four batches for four pairs of annotators. After annotation, two annotators on the same batch compare

[2] The accuracy seems quite low. The reason is only the 20% most ambiguous words of each sentence are manually labeled and evaluated in their experiments.

	#Words	Granularities Distrbution (%)		
		Single	Two	Three
Before	44,593	74.5	24.0	1.5
After	45,279	71.6	26.8	1.6

Table 3: Data statistics of the MWS test data before and after manual annotation.

their results and produce a consensus submission through discussion.

The annotation process lasts for four days, and each annotator spends about 8 hours in total on completing 160 sentences on average. Table 3 compares data statistics on the $1,500$ sentences before and after manual annotation. The second column reports the number of words, and the last three columns report the distribution of words according to their granularity levels. To illustrate how to gain the distribution, we take Figure 1 as an example, which contains 1 single-grained words, 9 two-grained words, and 7 three-grained words.[3]

Table 3 shows that only 71.6% of all words are single-grained, which is somehow roughly consistent with the inter-native-speaker consistency ratio (76%) in Sproat et al. (1996). Among multi-grained words, $\frac{26.8}{26.8+1.6} = 94.4\%$ are two-grained. It is clear that manual annotation increases both the number of words by $\frac{45{,}279-44{,}593}{44{,}593} = 1.5\%$, and the number of multi-grained words by $74.5 - 71.6 = 2.9\%$. In fact, during annotation, we also feel that multi-granularity phenomena are under-represented in the pseudo MWS data. The reason may be two-fold. First, the conversion models incline to suppress granularity differences, since most words have the same granularity in different datasets. Second, the exist of many inconsistencies in the same dataset also makes the conversion models more reluctant to produce multi-grained words.

The inter-annotator consistency ratio is $\frac{3859}{3935} = 98.07\%$, where the denominator is the word number after merging the submission of all annotator pairs, and the numerator is the consensus word number. We argue that the consistency ratio is not high, considering most words do not need correction in the pseudo MWS annotations. In fact, we find that this annotation task is actually very difficult, since the annotators must consider three guidelines simultaneously. The main inconsistency source of all four annotator pairs are due to the situation where one annotator notices a mistake while another annotator overlooks it. To solve this issue, our long-term plan is to compile a unified MWS guideline by integrating existing SWS guidelines, and gradually improve it by more manual MWS annotation.[4]

4 Benchmark MWS Approaches

There has recently been a surge of interest in applying neural network models to both parsing and sequence labeling tasks. In this work, we propose three simple benchmark approaches for MWS, inspired by recently neural models for constituent parsing (Cross and Huang, 2016) and SWS (Pei et al., 2014).

4.1 MWS as Constituent Parsing

Due to its hierarchy structure shown in Figure 1, we naturally cast MWS as a constituent parsing problem, where characters are leaf nodes; “C” represent a character, “W” represent a word; “X” means that the spanning word cannot be further merged into a more coarse-grained word.

We employ the recently proposed transition-based constituent parser of Cross and Huang (2016) due to its simplicity and competitive performance on different parsing benchmark datasets. In the transition system, a stack S stores processed tokens and partial trees collected so far; a queue Q contains unprocessed tokens; structural[5] and labeling[6] decisions are alternatively made to advance the state until a complete tree forms. The network architecture is composed of two parts: 1) two cascaded

[3] Formally, we call a word s three-grained if there are two other words $s1$ and $s2$ satisfying any one conditions: 1) $s2 \in s1 \in s$ (like “全国各地” in Figure 1); 2) $s2 \in s \in s1$ (like “全国”); 3) $s \in s1 \in s2$ (like “全”), where $\in$ means substring. The definition of two-grained words is analogous; otherwise single-grained.

[4] Although this work has been confined to the three guidelines of MSR/PPD/CTB, we feel that the three guidelines can well capture most multi-granularity phenomena of words. During manual annotation, we have found very few cases where an obvious multi-granularity structure is not covered by the three guidelines.

[5] Shifting the first token in Q into S, or combining the top two items in S

Table 4: MWS as sequence labeling. SWS labels for the same character are organized fine-to-coarse.

bidirectional LSTM layers to encode the input token sequence, as shown in Figure 4; 2) two separate multilayer perceptrons (MLPs) to make structural/labeling decisions based on 4/3 simple LSTM span features. A span feature represents a sentence span (i, j) by concatenating the element-wise differences of BiLSTM outputs:

$$\mathbf{r}_{(i,j)} = [\mathbf{f}^1_j - \mathbf{f}^1_{i-1}; \mathbf{b}^1_i - \mathbf{b}^1_{j+1}; \mathbf{f}^2_j - \mathbf{f}^2_{i-1}; \mathbf{b}^2_i - \mathbf{b}^2_{j+1}]$$

To adapt the original parsing model to our MWS task, we concatenate bichar embeddings $\mathbf{e}_{c_{i-1}c_i}$ with single char embedding $\mathbf{e}_{c_i}$ as inputs to the first-layer BiLSTM, inspired by Pei et al. (2014), who show that bichar embeddings are very helpful for SWS.

4.2 MWS as Sequence Labeling

It is also straightforward to model MWS as a sequence labeling task by replacing SWS labels with MWS labels for each character. Table 4 encodes the MWS structure in Figure 1 with a sequence of MWS labels. The idea is to concatenate multiple SWS tags simultaneously for one character to denote the positions of the character under words of different granularities. Please note that each MWS label contains at most three SWS labels since we only consider three SWS datasets in this work. Here, we organize the SWS labels in the order of fine-to-coarse granularities.

For simplicity and fair comparison, we adopt a similar network architecture as the parsing model described in Section 4.1. To decide the MWS label of a character c_i in the input sentence, we feed the outputs of the two-layer BiLSTM outputs $[\mathbf{f}^1_i;\mathbf{b}^1_i,\mathbf{f}^2_i;\mathbf{b}^2_i]$ into a single-hidden-layer MLP.

	Train	Dev	Test	#Char per Word
MSR	78,232	8,692	3,985	1.71
PPD	46,815	2,000	5,000	1.67
CTB	16,091	803	1910	1.63

Table 5: Data statistics (in sentence number). The last column reports the averaged character number of each word.

4.3 MWS as SWS Aggregation

Instead of directly training a MWS model on the three pseudo MWS training datasets, we can also train three separate SWS models on the three SWS training datasets. Given an input sentence, we apply the three SWS models and then merge their outputs as MWS results.

The network architecture is the same with the sequence labeling model in Section 4.2, except the MLP outputs correspond to SWS labels instead of MWS labels.

5 Experiments

Data: for MSR, we adopt the training/test datasets of the SIGHAN Bakeoff 2005 (Emerson, 2005), and cut off 10% random training sentences as the dev data following Zhang et al. (2016); for PPD and CTB, we follow Li et al. (2015) and directly adopt their datasets and data split. Table 5 shows the data statistics.[7]

Evaluation Metrics: the goal of MWS is to precisely produce all words of different granularities given the input sentence. Therefore, to reach a balance of both precision ($P = \frac{\#Word_{gold \cap sys}}{\#Word_{sys}}$) and recall ($R = \frac{\#Word_{gold \cap sys}}{\#Word_{gold}}$), we use the F1 score ($= \frac{2PR}{P+R}$) as in SWS.

Hyper-parameter: we implement all our approaches based on the codes released by Cross and Huang (2016), by making extensions such as adding bichar embeddings and

[7] A DBC-to-SBC (double/single-byte characters) case preprocessing is performed on all datasets to avoid encoding inconsistency.

	Dev (Pseudo)			Test (Manual)							
	P	R	F	P	R	F	#Words	Single	Two	Three	Overlapping
Parsing	96.55	96.40	96.48	97.00	95.16	**96.07**	44,408	74.9%	23.5%	1.6%	–
w/o Bichar Emb	95.58	95.04	95.51	96.37	94.11	95.22	44,434	74.2%	24.1%	1.7%	–
Sequence Labeling	**96.86**	96.26	**96.59**	**97.01**	94.96	95.97	44,323	75.8%	22.7%	1.5%	–
w/o Bichar Emb	95.88	94.94	95.41	96.56	94.18	95.35	44,162	75.7%	22.8%	1.5%	–
SWS Aggregation	90.43	**97.44**	93.80	92.11	**96.59**	94.30	47,478	64.6%	31.4%	4.0%	1.0%

Table 6: Performance of different MWS approaches.

supporting sequence labeling.[8] For simplicity, char and bichar embeddings are randomly initialized following Cross and Huang (2016). The dimensions of char and bichar embeddings are both 50 and other hyper-parameters are the same with Cross and Huang (2016). In our preliminary experiments, we observe that under their neural network framework, the MWS performance is quite stable when rerunning under random initialization or reasonably altering other hyper-parameters. Due to time limitation, we leave the use of pre-trained embeddings and more hyper-parameter tuning for future exploration.

Training/test settings: when training the parsing and sequence labeling based MWS models (not SWS aggregation) on MSR/PPD/CTB-train, we adopt the simple corpus weighting strategy used in Li et al. (2015) to balance the contributions of each training dataset. Before each iteration, we randomly sample 10,000 sentences from each training dataset, and merge and shuffle them for one-iteration training. We use merged MSR/PPD/CTB-dev as the MWS dev data for model selection.[9]

For the SWS aggregation model, three SWS models are separately trained on the three training/dev datasets. For evaluation, three SWS outputs produced independently are merged as one MWS result given a sentence.

In all experiments, training stops when F-score on the dev data does not improve in 20 consecutive iterations, and we choose the model that performs best on the dev data for final evaluation.

Main results: Table 6 reports the performance of different approaches on both the pseudo MWS dev data and the manually annotated MWS test data. The “#Word” column reports the total number of words returned by the corresponding model; the following three columns show the percentages of words of different granularities; the last “Overlapping” column gives the percent of words that overlap with other words, which only happens in the “SWS aggregation” approach, since no constraint can be applied to the three separate SWS models during testing. From the results, we can draw the following findings.

First, the results suggest that using pseudo training and dev datasets to build a MWS model is feasible, based on two evidences: 1) our simple benchmark model can reach a high F-score of 96.07% on the manually annotated test data, which is 1.77% higher than directly aggregating outputs of three SWS models; 2) the P/R/F scores on the pseudo dev data and on the manually labeled test data are quite consistent in general, indicating that it is reliable to use the pseudo dev data for model selection and tuning.

Second, the parsing approach and the sequence labeling approach (with or without bichar embeddings) achieve very similar performance (within 0.15% vibration), More importantly, the parsing approach produces more words and more multi-grained words than the sequence labeling approach, indicating that it is potentially more proper to model MWS as a parsing problem in order to better capture and represent multi-granularity structures. Another possible disadvantage of the sequence labeling approach is that the trained model cannot produce more granularity levels (e.g., four-grained) beyond

[8] https://github.com/jhcross/span-parser. We are very grateful for their helping us solve some code issues at the early stage of this work.

[9] For MSR-dev, only the first 3,000 sentences are used during training due to efficiency concern.

those in the training data. Nevertheless, compared against the manual annotations in Table 3, both the parsing and sequence labeling approaches retrieve much less multi-grained words, which is caused by the under-representation issue of the pseudo training data, as discussed in Section 3.

Third, the SWS aggregation approach achieves the best recall at the price of very low precision on both dev/test data. We believe the reason is that training three SWS models separately on one of the three training datasets has two disadvantages: 1) connections among different guidelines are totally ignored, leading to many overlapping words (1.0%); 2) smaller training data also degrades the performance of each SWS model.

Finally, using bichar embeddings turns out very helpful for MWS, and leads to 0.97 ∼ 1.18% F-score improvement on dev data and 0.62 ∼ 0.85% on test data, which is consistent with the SWS results in Pei et al. (2014).

6 Related Work

As far as we know, this is the first work that formally proposes and addresses the problem of Chinese MWS under the data-driven machine learning framework. It is true that the industrial community, driven by practical demand, has long been interested in retrieving words of different granularities from the engineering perspective, based on lexicon dictionaries and heuristic rules (Zhu and Li, 2008; Hou et al., 2010). We also discover two publicly released toolkits, i.e., IKAnalyzer[10] and PoolWord[11], which consider all substrings in a sentence and return those above a threshold probability as candidate words. In contrast, this paper defines MWS as a strict hierarchy structure, and propose a supervised learning framework for the problem.

To alleviate the high OOV-ratio issue of character-based sequence labeling, Zhang et al. (2006) and Zhao and Kit (2007) propose subword-based sequence labeling for word segmentation by extracting high-frequency subword and treating them as the basic labeling units. Li (2011) and Li and Zhou (2012) propose to jointly parse the internal structures of words and syntactic structure of a sentence. Their definition of internal structures mainly considers prefix or suffix information. They manually annotate the internal structures of words that have high-frequency prefixes or suffixes and left other words with flat structures in CTB. Zhang et al. (2013) further annotate internal structures of all words in CTB and then perform character-level parsing with WS labels. Cheng et al. (2015) propose to cope with the multiple WS standard problem based on internal word structures. After close study of the above works, we find that the MWS annotations automatically built in this work actually capture a lot of subwords and word internal structures in previous works. Most importantly, the main focus of previous works is to improve SWS or parsing performance, whereas this work aims to build a hierarchy structure of multi-grained words. We leave the integration of MWS and parsing for future work.

It has been a long debate whether there exists an optimal WS granularity for MT, which is further complicated by the inevitable mistakes contained in 1-best WS outputs. Dyer et al. (2008) propose an MT model based on source-language word lattices, obtained by merging the outputs of different segmenters. Xiao et al. (2010) propose joint SWS and MT based on word lattices. Recently, Su et al. (2017) propose a word lattice-based neural MT model. They train many segmenters on MSR/PPD/CTB, and merge the outputs to produce word lattices for source-language sentences, which is similar to our SWS aggregation approach. All above works show the usefulness of word lattices instead of a single SWS output. In help IR, Liu et al. (2008) propose a ranking based WS approach for producing words of different granularities. We believe this work can further help both IR and MT by supplying with more accurate MWS results.

7 Conclusion

This work proposes and addresses the problem of MWS, so that all words of different granularities can be captured in a hierarchy structure given a sentence. We can draw the

[10] https://github.com/medcl/elasticsearch-analysis-ik

[11] http://pullword.com/

following interesting findings.

(1) Our annotation conversion approach can gather high-quality pseudo MWS training/dev datasets, and hence it is feasible to use them for model training and tuning.

(2) Manual MWS data annotation tells us that about 28.4% words are multi-grained, and among them 94.4% are two-grained words.

(3) The parsing and sequence labeling approaches achieve very similar performance, and outperform the SWS aggregation approach by a large margin.

We believe there are many exploration directions for this new task, among which we are particularly interested in three in the near future: 1) improving our benchmark approaches by considering task-specific features and neural network architectures, 2) verifying the usefulness of MWS to high-level applications such as MT, 3) integrating MWS with syntactic parsing in some way by exploiting existing treebanks.

Acknowledgments

The authors would like to thank the anonymous reviewers for the helpful comments. We are greatly grateful to all students in LA group for their hard work as annotators. Especially, we thank Jiawei Sun for her extensive participant and support through this work. We also thank Wenliang Chen and Guodong Zhou for the helpful discussions. Don't Throw Those Morphological Analyzers Away Just Yet: Neural Morphological Disambiguation for Arabic

Nasser Zalmout **Nizar Habash**
Computational Approaches to Modeling Language Lab
New York University Abu Dhabi
United Arab Emirates
{nasser.zalmout,nizar.habash}@nyu.edu

Abstract

This paper presents a model for Arabic morphological disambiguation based on Recurrent Neural Networks (RNN). We train Long Short-Term Memory (LSTM) cells in several configurations and embedding levels to model the various morphological features. Our experiments show that these models outperform state-of-the-art systems without explicit use of feature engineering. However, adding learning features from a morphological analyzer to model the space of possible analyses provides additional improvement. We make use of the resulting morphological models for scoring and ranking the analyses of the morphological analyzer for morphological disambiguation. The results show significant gains in accuracy across several evaluation metrics. Our system results in 4.4% absolute increase over the state-of-the-art in full morphological analysis accuracy (30.6% relative error reduction), and 10.6% (31.5% relative error reduction) for out-of-vocabulary words.

1 Introduction

Recurrent Neural Networks (RNN) in general, and Long Short-Term Memory (LSTM) cells in particular, have been proven very successful for various Natural Language Processing (NLP) tasks, especially those involving sequential data tagging. RNN models can produce near or above state-of-the-art performance with minimal language-specific feature engineering. These models have the capacity of capturing syntactic and semantic features through the lexical word-level embeddings, and subword features through character-level embeddings.

Morphologically rich languages pose many challenges to NLP through their high degree of ambiguity and sparsity. These challenges are exacerbated for languages with limited resources. Morphological analyzers help reduce sparsity by providing several out-of-context morpheme-based analyses for words, but they usually introduce ambiguity by returning multiple analyses for the same surface form. Therefore, the model would require a further step of morphological disambiguation to choose the correct analysis in context.

Morphological modeling involves heavy use of sequential tagging, so using an LSTM-based model would be highly advantageous. LSTM models are also optimal for long-sequence tagging in particular, so such systems should be able to outperform other deep learning models with fixed window-based modeling. Morphological disambiguation is a well studied problem in the literature, but LSTM-based contributions are still relatively scarce. In this paper we use Bidirectional-LSTM (Bi-LSTM) models for morphological tagging and language modeling, and use the results of these models in ranking the analyses of the morphological analyzer. We incorporate various subword and morphological features at different linguistic depths in the tagger, along with both word-based and character-based embeddings.

Our results show significant accuracy gains for all the morphological features we study, and across several evaluation metrics. We compare our system against a strong baseline and a state-of-the-art-system. We achieve 4.4% absolute over the state-of-the-art in full morphological analysis accuracy (30.6% relative error reduction). When evaluated for the out-of-vocabulary (OOV) words alone, the system achieves 10.6% absolute increase (31.5% relative error reduction), and shows significant performance boost across all evaluation metrics.

Copenhagen, Denmark, September 7–11, 2017.

2 Linguistic Issues

What distinguishes morphologically rich languages (MRL), like Arabic, from other languages is that their words include more morphemes (such as prefixes and suffixes) representing a number of morphological features, e.g., gender, number, person, mood, as well as attachable clitics. Table 1 shows the set of 16 Arabic morphological features we model As a result, MRLs tend to have more fully inflected words (types) than their poor counterparts. For instance when comparing Modern Standard Arabic (an MRL) with English (not an MRL), the total number of Arabic words in a large corpus is 20% less than the English parallel version of the corpus; however the the total number of unique Arabic types is twice that of English (El Kholy and Habash, 2010).

Feature	Definition
diac	Diacratization
lex	Lemma
pos	Basic part-of-speech tags (34 tags)
gen	Gender
num	Number
cas	Case
stt	State
per	Person
asp	Aspect
mod	Mood
vox	Voice
prc0	Proclitic 0, article proclitic
prc1	Proclitic 1, preposition proclitic
prc2	Proclitic 2, conjunction proclitic
prc3	Proclitic 3, question proclitic
enc0	Enclitic

Table 1: The morphological features we use in the various models. The first two groups are lexical features; and the last two groups are inflectional and clitic features respectively, in addition to the part-of-speech tag.

Furthermore, MRLs have a tendency towards a higher degree of ambiguity, stemming from different interpretations of the same surface morphemes. In Modern Standard Arabic (MSA), this ambiguity is exacerbated by the language's diacritzation-optional orthography-leading a word to have about 12 analyses per word on average (Habash, 2010). These two issues, form richness and form ambiguity, are at the heart of why MRLs are challenging to NLP. Richness of form increases model sparsity, and ambiguity makes disambiguation harder. Table 2 shows an example of the various in-context and out-of-context morphological analyses of the word قيمتها *qymtha*[1] ('its value' among other readings).

A potential solution is to build a morphological analyzer, also known as morphological dictionary, that encodes all the word inflections in the language. A good morphological dictionary should cover all the inflected forms of a word lemma (richness); and return all the possible analyses of a surface word (ambiguity). Finally, both richness and ambiguity are more challenging when an MRL has limited data, and when the data is noisy.

3 Background and Related Work

Deep learning models have recently emerged as a viable approach for several morphological modeling tasks in general. Neural approaches are particularly appealing due to their generic modeling capabilities that can be scaled to multiple tasks, and for less reliance on specific feature engineering. Notable contributions include the work of Collobert et al. (2011), where they present a learning model that is applicable to several NLP tasks, like chunking, named entity recognition, and part-of-speech (POS) tagging, by deliberately avoiding task-specific feature engineering. They use a window-based deep neural network. The fixed window size, however, limits access to further parts of the sentence that might be relevant to the target word. Moreover, the analysis is applied on the surface word level only, without considering any subword features. Several other contributions utilize somewhat similar approaches, with various neural architectures (Wang et al., 2015; Huang et al., 2015). Dos Santos and Zadrozny (2014), on the other hand, argue that subword information is useful for certain NLP tasks, like POS tagging. They propose a character-based embedding along with the word embeddings, to be able to capture internal morphemic structures. Character embeddings, capturing subword features, are well studied in other contributions too (Labeau et al., 2015; Rei et al., 2016; Belinkov and Glass, 2015).

Morphological disambiguation, however, has

[1] All Arabic transliterations are provided in the Habash-Soudi-Buckwalter transliteration scheme (Habash et al., 2007).

Table 2: An example highlighting Arabic's rich morphology and ambiguous orthography. The word قيمتها *qiymatahA* 'its value' has a specific analysis in the context of the sentence shown at the top of the table; but it has many other analyses and diacritizations out of context. The correct analysis is bolded (4th from the bottom of the list).

relatively fewer deep learning contributions. Yildiz et al. (2016) presented a disambiguation model for Turkish based on Convolutional Neural Networks (CNN). Their model creates a representation for the surface form of a word from the root along with a set of morphemic features. Then they train a model to predict the optimal analysis of a word given the annotations within a context window. Shen et al. (2016), on the other hand, use a character-based Bi-LSTM model for morphological disambiguation of morphologically complex languages, without using a morphological analyzer. The LSTM cells have the advantage of capturing a longer sequence window than those of the fixed window and CNN approaches.

Arabic morphological analysis and disambiguation have seen a considerable amount of work, spanning both MSA (Habash and Rambow, 2005; Diab et al., 2004; Khalifa et al., 2016; Abdelali et al., 2016), and Dialectal Arabic (Duh and Kirchhoff, 2005; Al-Sabbagh and Girju, 2012; Habash et al., 2013). The current state-of-the-art system is MADAMIRA (Pasha et al., 2014); which uses SVMs to disambiguate among a target word's various morphological analyses provided by a morphological dictionary.

Neural-based contributions for Arabic, however, are also relatively scarce. Among the contributions that utilize morphological structures to enhance the neural models in different NLP tasks, we note Guzmán et al. (2016) for machine translation, and Abandah et al. (2015) for diacritization. Darwish et al. (2017) use Bi-LSTM models to train a POS tagger, and compare it against SVM-based models. The SVM models in their system outperform the neural model, even with incorporating pre-trained embeddings. Heigold et al. (2016) developed character-based neural models for morphological tagging for 14 different languages, including Arabic, using the UD treebank. Most related to our work though is by Shen et al. (2016), who applied their Bi-LSTM morphological disambiguation model on MSA, but did not present any improvements over the state-of-the-art.

Occurring in parallel to our work, Inoue et al. (2017) used multi-task learning to model fine-grained POS tags, using the individual morphosyntactic features. They also use dictionary information concatenated to the word embeddings, similar to the approach we use in this paper, and use the same dataset. Our approach provides slightly higher accuracy scores for the individual features, but the joint features score in their system is higher.

In this paper we study various architectures for neural based morphological tagging. We then use these architectures, along with neural language modeling systems, to train models for various Arabic morphological features. We utilize these models for morphological disambiguation of the optimal analysis for each given word in context.

4 Approach

The morphological disambiguation task involves choosing the correct morphological analysis from the set of potential analyses, obtained from the analyzer. Towards that end, we train several models for the individual morphological features, and use their results to score and rank the different analyses and choose an optimal overall analysis. These features can be grouped into non-lexical features, where a tagger is used to obtain the relevant morphological tag, or **morphological feature tagging**, and lexical features that need a language model (Roth et al., 2008), or **neural language models**. Table 1 shows the set of morphological features we work with. The lexical features are handled with a language model, while the inflectional, clitic, and part-of-speech features are handled with a tagger.

We use Bi-LSTM-based taggers for the morphological feature tagging tasks, with various embedding levels and morphological features. We investigate the different architectures and design options in detail in Section 5. We then use the best design to build 14 different taggers, each specific to an individual feature. We also use LSTM-based neural language models for the lexical features. We discuss the neural language models in more detail in Section 6.

We then use the results for these various models to score the potential morphological analyses from the analyzer for each given word. These scores are used to rank the analyses and return the one with the highest result. The process of scoring is also tuned through tuning weights for the used features. The details of the ranking and disambiguation process are provided in Section 6.

Dataset: We use the Penn Arabic Treebank (PATB parts 1,2 and 3) (Maamouri et al., 2004) for all the experiments in this paper. We follow the data splits recommend by Diab et al. (2013) for training, dev, and testing sets. We use Alif/Ya and Hamza normalization, and we remove all diacritics. The pre-trained word embeddings are trained using the LDC's Gigaword corpus for MSA (Parker et al., 2011). Table 3 shows the overall data sizes.

Dataset	Size (words)
Train	503,015
Dev	63,137
Test	63,172
Gigaword corpus	2,154M

Table 3: Dataset statistics

Evaluation: We use accuracy as the evaluation metric for all experiments reported in the paper.

Baselines: We use the Maximum Likelihood Estimation (MLE) baseline, calculated by counting the frequency scores for each given word/tag out of context, with backoff to the most frequent tag for unknown words. We also use the MADAMIRA (release-2.1) scores as another baseline, designated as the state-of-the-art system. Unless otherwise specified, MADAMIRA was configured in the ADD_PROP backoff mode, which adds a proper noun analysis to all words. We use this configuration to match the analyzer format we used in training the deep learning system, and to match the models in previous contributions.

5 Neural Morphological Feature Tagging Architectures

The task of morphological tagging in general relies on the context for accurate analysis. Such tasks can be modeled as a sequential data tagging problem, with both word and subword embeddings. While word embeddings are used to convey syntactic and semantic features, subword embeddings convey morphological features.

We present our morphological tagging model in this section, and use the POS feature as a test case. We then generalize our findings for all the other features for the morphological disambiguation process in Section 6. The POS tag set we use is the MADAMIRA tag set presented at (Pasha et al., 2014), and covered in detail at the MADAMIRA manual (Pasha et al., 2013), comprised of 34 tags.

5.1 Deep Learning Model

Given a sentence consisting of N words $\{w_1, w_2, ..., w_N\}$, every word w_i is converted into a vector

$$v_i = [r^{wrd}; r^{morph}]$$

which is composed of the word (or character sequence) embedding vector r^{wrd}, and the morphological features embedding vector r^{morph}. The morphological features vector can be constructed through various constructs, representing morphological and/or subword units.

We then use two LSTM layers to model the relevant context for both directions of the target word, where the input is represented by the v_n vectors mentioned above:

$$\overrightarrow{c}_i = g(v_i, \overrightarrow{c}_{i-1})$$

$$\overleftarrow{c}_i = g(v_i, \overleftarrow{c}_{i+1})$$

We join both sides, apply a non-linearity function, and softmax to get a probability distribution. We use two hidden layers of size 800. Each layer is composed of two LSTM layers for each direction, and a dropout wrapper with keep probability of 0.8, and peephole connections. We use Adam optimizer (Kingma and Ba, 2014) with a learning rate of 0.003, and cross-entropy cost function. We use Tensorflow as the development environment.

subword and Morphological Features Several features can be used to represent the r^{morph} vectors mentioned before. These features are utilized to convey morphological information that are not represented at the word-level embeddings. We use various features with various linguistic depth:

(a) Fixed-width affixes We represent the prefixes and suffixes through a fixed character length substring from the beginning and the end of every word. This requires no linguistic information. We use a subset of three characters on both ends.

(b) Language-specific affixes (*lightstemmer*) We use regular expressions to maximally match affix patterns at the word's beginning and end. This requires basic linguistic knowledge of the target language, but doesn't require any large-scale lexical resources or annotated corpora.

(c) Potential POS tags from a morphological dictionary We use a high coverage morphological dictionary to obtain all possible POS tags of the target word. This requires advanced resources/annotations of the language. We include the set of potential tags in a vector representation and concatenate it with the word embedding.

The vector representation of these features is made up of the sum of the one-hot vectors for each individual component.

5.2 Word and Character Embeddings

Using character-level embeddings has recently been proven proficient for various NLP problems. In this paper we also study the effect of using word-level vs character-level embeddings on the overall morphological tagging problem, especially in light of the various subword and morphological features that we utilize. For word-level embeddings, we pre-train the word vectors using Word2Vec (Mikolov et al., 2013) on the Gigaword corpus mentioned in Section 4 (and Table 3), and the text of the training dataset. The embedding dimension for the words is 250. For the character-level embeddings, we concatenate the word embeddings with the sequence of character embeddings, initialized with their one-hot representation.

5.3 Results

Model	**Accuracy**
MLE Baseline	92.5
MADAMIRA (no backoff)	95.9
MADAMIRA (with backoff)	97.0

Table 4: Maximum Likelihood Estimation (MLE) and MADAMIRA baselines for POS tagging.

Model	**Embedding**	
	Word	Char
No Morphology	96.4	96.7
Fixed Character Affixes	96.6	NA
Lightstemmer	96.7	96.8
Morphological Dictionary	97.5	97.5
+ Fixed Character Affixes	**97.6**	NA
+ Lightstemmer	**97.6**	**97.6**

Table 5: Results for word embeddings (Word) and character-level embeddings (Char) for POS tagging. We don't provide character-level embeddings results for the Fixed Character Affixes approach, because such features would be redundant with the character embeddings themselves.

Table 4 shows the baseline scores for the systems, including the results for MADAMIRA with and without backoff. Table 5 shows the results for all systems. The results show clear improvement for all systems over the baseline and state-of-the-art without using subword. In fact, our system with no morphology outperforms MADAMIRA without using backoff. While our best result outperforms both MADAMIRA systems. Affixes (fixed length or lightstemmer) in general increase the accuracy across all systems. We notice, however, that the performance doesn't vary much between the fixed-width and lightstemmer affixes. This proves that the Bi-LSTM model is powerful enough to identify relevant features from a character-stream only, without the need for language-specific affixes. Using the morphological dictionary has the largest effect of improvement across all systems (among the three morphology features used): 0.8% over the next best approach (absolute score difference). We obtain the highest accuracy scores when incorporating both the morphological dictionary tags, and affixes, whether for the fixed-width or the lightstemmer approaches. This system shows 20.0% error reduction over MADAMIRA with backoff, and 41% error reduction without backoff.

The character-level embedding system shows a somewhat similar behavior in terms of relative performance. We do not provide the results for the Fixed Character Affixes approach here since the character embeddings would capture these fixed affixes within the overall embedding vector anyway. Hence, it will only provide redundant representation without any additional information.

We observe that the character-based system, without any additional features, outperforms the word-based system. This is expected, since the system has access to subword features, conveyed in the characters stream, that are not available for the word-based system. The same behavior persists with the lightstemmer, but the performance gap is smaller, since the word-based system is now provided with similar subword features that the character stream conveys. These subword features are somewhat redundant for the character-based system, so the performance is only slightly better.

Surprisingly, however, both systems perform exactly the same when using the morphological dictionary features. This indicates that the morphological features are powerful enough to convey and exceed the subword features that a character stream can convey.

5.4 POS Tagging Error Analysis

We analyzed the resulting tag predictions against the gold tags by transforming the POS tag set space into four categories: nominals, verbs, particles, and punctuation, and observed the resulting error patterns. We noticed that the errors' distribution across all developed systems is somewhat similar throughout the four different categories. Nominals dominate almost 80.0% of all errors, even though they constitute 61.5% only of the total tokens. When introducing the morphological dictionary tags as features, all four categories increase in accuracy (except for the punctuation, being tagged almost correctly at all systems). Verbs, however, have the highest accuracy increase, at 1.5%, relative to 1.0% for nominals and 0.8% for particles. This can be the result of verbs being the least common category in the dataset at 8.0% (vs 64.0%, 14.0%, and 12.0% for nominals, particles, and punctuation, respectively). The nominals set is also relatively bigger than the other categories, which makes it internally confusable with errors within the nominals' options, like noun_adj or noun_num/noun_quant, among others.

6 Morphological Disambiguation

In this section we apply the morphological feature tagging architecture we discussed earlier for POS tagging to the remaining morphological features. We use the results of these taggers, along with the language models for *diac* and *lex*, as the input to the scoring and ranking process.

6.1 Morphological Tagging Models

Section 5 shows that the best performing neural architecture for POS tagging, as an example of morphological tagging in general, is using the embeddings (either character-based or word-based) with the relevant morphological tags from the dictionary, along with fixed or lightstemmer affixes. The performance of both word and character embeddings in this architecture was similar, so we opt for the word embeddings due to the excessive computational overhead affiliated with training character-level embeddings.

We apply the same architecture for the 14 morphological, non-lexical, features we study in this paper. Table 6 shows the results for the different taggers, relative to the MLE and MADAMIRA baselines that we used in the previous section. All features show significant performance boost.

Notable features though include case and state, where good tagging requires a relatively wide analysis window surrounding the target word. These features have the biggest performance gap between the baselines and the Bi-LSTM approach among the various other features. This is mainly due to the fact that LSTM cells have the capability of maintaining a longer sequence memory than the other approaches, hence capturing more of the sentence structure when tagging, compared to traditional window-based approaches.

System	pos	cas	num	gen	vox	mod	stt	asp	per	enc0	prc0	prc1	prc2	prc3
MLE	92.5	80.5	98.3	97.5	97.7	97.4	90.2	97.9	97.9	98.3	97.9	98.5	97.9	99.6
MADAMIRA	97.0	91.1	99.5	99.4	99.1	99.1	97.0	99.3	99.2	99.6	99.6	99.6	99.6	**99.9**
Bi-LSTM	97.6	94.5	99.6	99.5	99.2	99.4	97.9	99.4	99.4	99.7	99.7	99.8	**99.7**	**99.9**
Disambiguated Bi-LSTM	**97.9**	**94.8**	**99.7**	**99.7**	**99.4**	**99.6**	**98.3**	**99.6**	**99.6**	**99.8**	**99.8**	**99.9**	**99.7**	**99.9**

Error Reduction	30.0	42.0	40.0	50.0	33.0	56.0	43.0	43.0	50.0	50.0	50.0	75.0	25.0	0.0

Table 6: Morphological tagging results. The absolute increase and error reduction are of the disambiguated Bi-LSTM against MADAMIRA.

6.2 Neural Language Models

In addition to the morphological taggers for the non-lexical features, we use neural language models for the lemmatization and diacritization features. Lemmas and diacratized forms are lexical in nature, and cannot be modeled directly using a classifier. We use an LSTM-based neural language model (Enarvi and Kurimo, 2016), with class-based input rather than words. Using a class-based approach speeds convergence drastically and improves the overall perplexity, especially for the *diac* (diacritization) language model, which has a relatively large type count.

We use the MKCLS tool (Och, 1999), through GIZA++ (Och and Ney, 2003), to train the word classes. We use two hidden layers of size 500 and input layer of size 300, and use Nesterov Momentum as the optimization algorithm.

We encode the testing set in the HTK Standard Lattice Format (SLF), with a word mesh representation for the various options of each word.

Table 7 shows the accuracy results of the language models for *lex* and *diac* for both MADAMIRA (which uses SRILM (Stolcke, 2002) for language modeling), and the LSTM model we use here. All models are trained on the same ATB training dataset used in the paper. The LSTM results outperform MADAMIRA's vastly, proving the superiority of neural language models.

Feature	*lex*	*diac*
3-gram model	76.7	68.2
3-gram model disambiguated	96.2	87.7
Our system (LSTM)	89.6	73.5
Our system disambiguated	**96.9**	**91.7**

Table 7: The language model accuracy scores for both MADAMIRA and the LSTM models, for the *lex* and *diac* features.

6.3 Disambiguation

We use a similar morphological disambiguation approach to the model proposed by Habash and Rambow (2005) and Roth et al. (2008), where the resulting morphological features are matched and scored against the morphological analyzer options, as a way to rank the different analyses, and tuned using feature weights. If the analysis and the predicted morphological tag for a feature of a given word match, the analysis score for that analysis is incremented by the weight corresponding to that feature.

The morphological analysis with the highest score is chosen as the disambiguated option. Any tie-breaking after the disambiguation is handled through random selection among the reduced options[2]. For feature weight tuning we use the approach presented by Roth et al. (2008), using the Downhill Simplex Method (Nelder and Mead, 1965). A tuning dataset of almost 2K lines (∼63K words) is randomly selected from the training dataset. We retrain all the systems using the remaining training dataset, to be used in the tuning process. We finally use the resulting optimal weights in the original systems, trained on the full training dataset.

6.4 Evaluation

We use the following accuracy metrics to evaluate the disambiguation model, which Pasha et al. (2014) also use in their evaluation:

- EVALFULL: The percentage of correctly analyzed words across all morphological features. This is the strictest possible metric.
- EVALDIAC: The percentage of words where the chosen analysis has the correct fully diacritized form.

[2] This results in %0.02 variation range only in the EVALFULL end result.

Evalustion Metric	All Words			Out-Of-Vocabulary Words		
	MADAMIRA	Our System	Error Reduction	MADAMIRA	Our System	Error Reduction
EVALFULL	85.6	**90.0**	30.6	66.3	**76.9**	31.5
EVALDIAC	87.7	**91.7**	32.5	70.2	**79.8**	32.8
EVALLEX	96.2	**96.8**	15.8	82.9	**87.8**	28.7
EVALPOS	97.0	**97.9**	30.0	89.9	**96.0**	60.4
EVALATBTOK	99.4	**99.6**	33.3	94.2	**97.8**	60.2

Table 8: Accuracy results of the disambiguation system, evaluated using different metrics, for all words and out-of-vacbulary (OOV) words alone. OOV percentage of all words is 7.9%.

- EVALLEX: The percentage of words where the chosen analysis has the correct lemma.
- EVALPOS: The percentage of words where the chosen analysis has the correct part-of-speech.
- EVALATBTOK: The percentage of words that have a correct ATB tokenization.[3]

Deep learning models, through word embeddings, provide an advantage in terms of the analysis of unseen words. So, in addition to calculating the metrics for all the words in the testing set, we also calculate these metrics for the out-of-vocabulary (OOV) words alone.

Table 8 shows the accuracy scores for MADAMIRA and our system. All evaluation metrics indicate the performance boost of our system relative to MADAMIRA, with significant relative error reduction. The same trend stands for the OOV words, with even higher absolute and relative error reduction scores, especially for EVALLEX, EVALPOS, and EVALATBTOK. This increase in OOV analysis accuracy is the result of modeling the data on a semantic level, with the embeddings and neural networks, instead of pure lexical approach.

6.5 Discussion

We conducted additional data analysis over the test set comparing the performance of our system to MADAMIRA.

Comparative Error Patterns When considering full analyses, we observe that our system still makes some errors in words where MADAMIRA is correct. However, the number of times our system is correct and MADAMIRA is not is over twice as the reverse (MADAMIRA is correct and our system is not). From a manual analysis of a sample of 500 words, we observe the majority of the instances where MADAMIRA was correct and our system failed involved the case features. This is not surprising since case is one the features our system still struggles with although we have made major improvements beyond MADAMIRA. Shahrour et al. (2015) used syntax as an additional model to improve the analysis of case. Our model still improves the accuracy beyond theirs, but this highlights the value of using syntax in future work.

Minority Feature-Value Pairs While we show a lot of improvements across the board above in terms of accuracy, we also observe very large improvements in the performance on some minority feature-value pairs. For example, among the values of the *case* feature, the nominative (cas:n) and accusative (cas:a) appear about 7.0% and 11.0% of all words, respectively, of all the values of case. We improve the F-1 score from 70.4% in MADAMIRA to 84.1% in our system for (cas:n); and we similarly improve the F-1 score from 76.7% in MADAMIRA to 85.5% in our system for (cas:a). We also observe similar improvement in the *mood* feature, with the F-1 score for subjunctive mood (occurring 0.55% of all words) increasing from 76.9% in MADAMIRA to 89.5%.

This great increase was not observed across all features. The F1-score of the passive voice feature-value pair (vox:p) occurring 0.6% of all words (and 7.0% of all verbs) only increased from 70.1% in MADAMIRA to 73.4% in our system. Voice in Arabic is harder to model than mood and case since some verbal constructions can be rather ambiguous even for human readers; for example, the noun phrase الكاتبة التي نشرت مقالتها *AlkAtbħ Alty nšrt mqAlthA* has two readings 'the writer who published her article' (active voice) or 'the writer whose article was published' (passive voice). Case and mood are more likely to be de-

[3] ATB scheme tokenizes all clitics except the +ال *Al* 'the' determiner.

terminable from the context using long and short-distance syntactic clues. In the example above the case of the noun مقالتها *mqAlthA* 'her article' is dependent on the voice reading of the verb, which determines if the noun is the subject or object of the verb. For another example, the F1-score of the 2nd person feature-value pair (per:2) occurring 0.05% of all words (and 0.5% of all verbs) only increased from 29.7% in MADAMIRA to 31.7% in our system. The very low performance in the 2nd person makes sense, since the corpus we used is a news corpus where the 2nd person is hardly ever used. We would expect more training data to help such feature-value pairs.

7 Conclusion and Future Work

In this paper we presented an LSTM-based morphological disambiguation system for Arabic. The system significantly outperforms a state-of-the-art system. Our experiments showed that enriching the input word embedding with additional morphological features increases the morphological tagging accuracy drastically, beyond the capabilities of even character-level embeddings. We also showed that using an LSTM based system provides a significant performance boost for syntax based features, which often require wide context window for accurate tagging.

Future directions include exploring additional deep learning architectures for morphological modeling and disambiguation, especially joint and sequence-to-sequence models. We also intend to further investigate the role of syntax features in morphological disambiguation, and explore additional techniques for more accurate tagging. Finally, we aim at applying our models to Arabic dialects and other languages. We expect that character-level embeddings will have a bigger role in scenarios with noisy input, such as non-standard spontaneous orthography used in social media.

Abstract

The generation of complex derived word forms has been an overlooked problem in NLP; we fill this gap by applying neural sequence-to-sequence models to the task. We overview the theoretical motivation for a paradigmatic treatment of derivational morphology, and introduce the task of derivational paradigm completion as a parallel to inflectional paradigm completion. State-of-the-art neural models, adapted from the inflection task, are able to learn a range of derivation patterns, and outperform a non-neural baseline by 16.4%. However, due to semantic, historical, and lexical considerations involved in derivational morphology, future work will be needed to achieve performance parity with inflection-generating systems.

1 Introduction

Unlike inflectional morphology, which produces grammatical variants of the same core lexical item (e.g., *take*↦*takes*), derivational morphology is one of the key processes by which new lemmata are created. For example, the English verb *corrode* can evolve into the noun *corrosion*, the adjective *corrodent*, and numerous other complex derived forms such as *anticorrosive*. Derivational morphology is often highly productive, leading to the ready creation of neologisms such as *Rao-Blackwellize* and *Rao-Blackwellization*, both originating from the Rao-Blackwell theorem. Despite the prevalence of productive derivational morphology, however, there has been little work on its generation. Commonly used derivational resources such as NomBank (Meyers et al., 2004) are still finite. Moreover, the complex phonological and historical changes (e.g., the adjectivization *corrode*↦*corrosive*) and affix selection (e.g., choosing between English deverbal suffixes *-ment* and *-tion*) make generation of derived forms an interesting and challenging problem for NLP.

In this work, we show that viewing derivational morphological processes as paradigmatic may be fruitful for generation. This means that there are a number of well-defined form-function pairs associated with a core word. For example, a typical English verb may have five forms in its inflectional paradigm, corresponding to its base (*take*), past tense (*took*), past participle (*taken*), progressive (*taking*) and third-person singular (*takes*) forms. These forms are related by a consistent set of relations, such as affixation. Similarly, a verb may have several slots in its derivational paradigm: The form *take* has the agentive nominalization *taker*, and the abilitative adjectivization *takable*. Note there are also consistent patterns associated with each derivational slot, e.g., the *-er* suffix regularly produces the agentive.

Exploiting this paradigmatic characterization of derivational morphology allows us to create a statistical model capable of generating derivationally complex forms. We apply state-of-the-art models for inflection generation, which learn mappings from fixed paradigm slots to derived forms. Empirically, we compare results for two models on the new task of derivational paradigm completion: a neural sequence-to-sequence model and a standard non-neural baseline. Our best neural model for derivation achieves 71.7% accuracy, beating the non-neural baseline by 16.4 points. Nevertheless, we note this is about 25 points lower than the equivalent model on the English inflection task (and even 20 points lower than the model's performance on the harder Finnish inflection generation). These results point to additional complications in derivation that require more elaborate models or data annotation to overcome. While inflection generation is

becoming a solved problem (Cotterell et al., 2017), derivation generation is still very much open.

2 Derivational Morphology

The generation of derived forms is structurally similar to the generation of inflectional variants, but presents additional challenges for NLP. Here, we provide linguistic background comparing the two types of morphological processes.

Inflection and Derivation. Inflectional morphology primarily marks semantic features that are necessary for syntax, e.g., gender, tense and aspect. Thus, it follows that in most languages inflection never changes the part of speech of the word and often does not change its basic meaning. The set of inflectional forms for a given lexeme is said to form a paradigm, e.g., the full paradigm for the verb *to take* is ⟨*take*, *taking*, *takes*, *took*, *taken*⟩. Each entry in an inflectional paradigm is termed a slot and is indexed by a syntacto-semantic category, e.g., the PAST form of *take* is *took*. We may reasonably expect that all English verbs—including neologisms—have these five forms.[1] Furthermore, there is typically a fairly regular relationship between a paradigm slot and its form (e.g., add *-s* for the third person singular form). Derivational morphology, on the other hand, often changes the core part of speech of a word and makes more radical changes in meaning. In fact, derivational processes are often subcategorized by the part-of-speech change they engender, e.g., *corrode*↦*corrosion* is a deverbal nominalization.

Derivational Paradigms. Much like inflection, derivational processes may be organized into paradigms, with slots corresponding to more abstract lexico-semantic categories for an associated part of speech (Corbin, 1987; Booij, 2008; Štekauer, 2014). Lieber (2004) presents one of the first theoretical frameworks to enumerate a set of derivational paradigm slots, motivated by previous studies of semantic primitives by Wierzbicka (1988). A partial listing of possible derivational paradigm slots for base English adjectives, nouns, and verbs is given in Table 1. The list contains several productive cases. A key difficulty comes from the the fact that the mapping between semantics and suffixes is not always clean; Lieber (2004) points out the category AGENT could be expressed by the suffix *-er* (as in *runner*) or by *-ee* (as in *escapee*). However, both *-er* and *-ee* may have the PATIENT role; consider *burner* ("a cheap phone intended to be disposed of, i.e. burned") and *employee* ("one being employed"), respectively. We flesh out partial derivational paradigms for several English verbs in Table 2.

Unlike in inflectional paradigms, where we expect most cells to be filled for any given base form, derivational paradigms often contain base-slot combinations that are not semantically compatible, leading to the gaps in Table 2.[2] We also observe increased paradigm irregularity due to some derived forms becoming lexicalized at different points in history, differences in the language from which the base word entered the target language (e.g., English roots of Germanic and Latinate origin behave differently (Bauer, 1983)), as well as other factors that are not obvious from the characters in the base word (e.g., gender or number of the resulting noun).

As an example of how difficult these factors can make derivation, consider the wide variety of potential nominalizations corresponding to the RESULT of a verb, e.g., *-ion*, *-al* and *-ment*, (Jackendoff, 1975). While any particular English verb will almost exclusively employ exactly one of these suffixes (e.g., we have *refuse*↦*refusal* and other candidates **refusion* and **refusement* are illicit),[3] the information required to choose the correct suffix may be both arbitrary or not easily available.

[1] Only a handful of English irregulars distinguish between the past tense and the past participle, e.g., *took* and *taken*, and thus have five *unique* forms in their verbal paradigms; most English verbs have four *unique* forms.

[2] For instance, if suffix *-ee* marks a PATIENT it is semantically not compatible with intransitive verbs, i.e., **sneezee* cannot be derived from intransitive *sneeze*.

[3] Note some forms appear to have multiple nominalizations, e.g., *deport*↦{*deportation*,*deportment*}, but closer inspection shows there is one regular semantic transformation per word sense: *deportation* is eviction, but *deportment* is behavior.

Base	-er/-or	-ee	-ment/-tion	-able/-ible
POS	V↦N	V↦N	V↦N	V↦J
Semantic	AGENT	PATIENT	RESULT	POTENTIAL
animate	*animator*	—	*animation*	*animatable*
attract	*attractor*	*attractee*	*attraction*	*attractable*

escape	*escapee*	—	—	*escapable*
corrode	*corroder*	—	*corrosion*	*corrosible*
derive	*deriver*	*derivee*	*derivation*	*derivable*

Table 2: Partial derivational paradigm for several English verbs; semantic gaps are indicated with —.

Productivity. There is a general agreement in linguistics that frequently used complex words become part of the lexicon as wholes, while most others are likely to be constructed from constituents (Bauer, 2001; Aronoff and Lindsay, 2014); the latter ones typically follow derivational patterns, or rules, such as adding *-able* to express potential or ability or applying *-ly* to convert adjectives into adverbs. These patterns typically present two essential properties: productivity and restrictedness. Productivity relates to the ability of a pattern to be applied to any novel base form to create a new word, potentially on-the-fly. One example of such a productive transformation is adding *-less* (privative construction), which may attach to almost any noun to form an adjective. Moreover, the resulting form's meaning is compositional and predictable. Many derivational suffixes in English are of this type. On the other hand, some patterns are subject to semantic, pragmatic, morphological or phonological restrictions. Consider the English patient suffix *-ee*, which cannot be attached to a base ending in /i(:)/, e.g., it cannot be attached to the verb *free* to form *freeee*. Restrictedness is closely related to productivity, i.e., highly productive rules are less restricted. A parsimonious model of derivational morphology would describe forms using productive rules when possible, but may store forms with highly restricted patterns directly as full lexical items.

A Note On Terminology. We would like to make a subtle, but important point regarding terminology: the phrase *morphologically rich* in the NLP community almost exclusively refers to *inflectional*, rather than *derivational* morphology. For example, English is labeled as morphologically impoverished, whereas German and Russian are considered morphologically rich, e.g., see the introduction of Tsarfaty et al. (2010). As regards derivation, English is quite complex and even similar in richness to German or Russian as it contains productive formations from two substrata: Germanic and Latinate. From this perspective, English is very much a morphologically rich language. Indeed, a corpus study on the Brown Corpus showed that the *majority* of English words are morphologically complex when derivation is considered (Light, 1996). Note that there many languages that have exhibit neither rich inflection, nor rich derivational morphology, e.g., Chinese, which most commonly employs compounding for word word formation (Chung et al., 2014).

3 Task and Models

We discuss our two systems for derivational paradigm completion and the results they achieve.

3.1 Data

We experiment on English derivational triples extracted from NomBank (Meyers et al., 2004).[4] Each triple consists of a base form, the semantics of the derivation and a corresponding derived form e.g., ⟨*ameliorate*, RESULT, *amelioration*⟩. Note that in this task we do not predict whether a slot exists, merely what form it would take given the base and the slot. In terms of current study, we consider the following derivational types: verb nominalization such as RESULT, AGENT and PATIENT, adverbalization and adjective-noun transformations. We intentionally avoid zero-derivations. We also

[4] There are few resources annotated for derivation in non-English languages, making wider experimentation difficult.

	baseline		*1-best seq2seq*		*10-best seq2seq*
	acc	edit	acc	edit	*acc*
all	55.3%	2.01	71.7%	0.97	84.5%
NOMINAL (J↦N)	23.1%	3.45	35.1%	2.67	70.2%
RESULT (V↦N)	40.0%	2.24	52.9%	1.86	72.6%
AGENT (V↦N)	52.2%	0.94	65.6%	0.78	82.2%
ADVERB (J↦R)	90.0%	0.21	93.3%	0.18	96.5%

Table 3: Results under two metrics (accuracy and Levenshtein distance) comparing the non-neural baseline from the 201 SIGMORPHON shared task and the neural sequence-to-sequence model (both for 1-best and 10-best output).

exclude overly orthographically distant pairs by filtering out those for which the Levenshtein distance exceeds half the sum of their lengths, which appear to be misannotations in NomBank. The final dataset includes 6,029 derivational samples, which we split into train (70%), development (15%), and test (15%).[5] We also note that NomBank annotations are often semantically more coarse-grained.

3.2 Evaluation Metrics

We evaluate on 3 metrics: accuracy, average edit distance, and F_1. Accuracy measures how often system output exactly matches the gold string. Edit distance, by comparison, measures the Levenshtein distance between system output and the gold string. Finally, we calculate affix F_1 scores for individual derivational affixes. E.g., for *-ment* precision is the number of words where the model correctly predicted *-ment* (out of total predictions) and recall is the number of words where the model correctly predicted out of the number of true words.

3.3 Baseline Transducer

We train a simple transducer for each base-to-paradigm slot mapping in the training set, identical to the baseline described in Cotterell et al. (2016). This uses an averaged perceptron classifier to greedily apply an output transformation (substitution, deletion, or insertion) to each input character given the surrounding characters and previous decisions.

3.4 RNN Encoder-Decoder

Following Kann and Schütze (2016) on the morphological inflection task, we use an encoder-decoder gated recurrent neural network (Bahdanau et al., 2015). First, an encoder network encodes a sequence: the concatenation of the characters of the input word and a tag describing the desired transformation—both represented by embeddings. This encoder is bidirectional and consists of two gated RNNs (Cho et al., 2014), one encoding the input in the forward direction, the other one encoding in the backward direction. The output of the two RNNs is the resulting hidden vectors $\overrightarrow{h_i}$ and $\overleftarrow{h_i}$. The hidden state is a concatenation of the forward and backward hidden vectors, i.e., $h_i = [\overrightarrow{h_i}\overleftarrow{h_i}]$.

The decoder also consists of an RNN, but is additionally equipped with an attention mechanism. The latter computes a weight for each of the encoder hidden vectors for each character or subtag, which can be roughly understood as giving a certain importance to each of the inputs. The probability of the target sequence $y = (y_1, \ldots, y_{|y|})$ given the input sequence $x = (x_1, \ldots, x_{|x|})$ is modeled by

$$\begin{aligned} p(y \mid x_1, \ldots, x_{|x|}) &= \prod_{t=1}^{|y|} p(y_t \mid \{y_1, \ldots, y_{t-1}\}, c_t) \\ &= \prod_{t=1}^{|y|} g(y_{t-1}, s_t, c_t), \qquad (1) \end{aligned}$$

where g is a multi-layer perceptron, s_t is the hidden state of the decoder and c_t is the sum of the encoder states h_i, scored by attention weights $\alpha_i(s_{t-1})$ that depend on the decoder state: $c_t = \sum_i \alpha_i(s_{t-1})h_i$.

Input Encoding. We model this problem as a character translation problem, with special encodings for the transformation tags that indicate the type of derivation. For example, we treat the triple: ⟨*ameliorate*, RESULT, *amelioration*⟩ as the source string `a m e l i o r a t e RESULT` and target string `a m e l i o r a t i o n`. This is similar to the encoding in Kann and Schütze (2016).

Training. We use the Nematus toolkit (Sennrich et al., 2017).[6] We exactly follow the recipe in Kann and Schütze (2016), the winning submission on the 2016 SIGMORPHON shared task for inflectional morphology. Accordingly, we use a character embedding size of 300, 100 hidden units in both the encoder and decoder, Adadelta (Zeiler, 2012) with a minibatch size of 20, and a beam size of 12. We train for 300 epochs and select the test model based on the performance on the development set.

4 Experimental Results

Table 3 compares the accuracy of our baseline system with the accuracy of our sequence-to-sequence

[5] The dataset is available at `http://github.com/ryancotterell/derviational-paradigms`.

[6] `https://github.com/rsennrich/nematus/`

neural network using the data splits discussed in §3.1. In all cases, the network outperforms the baseline. While 1-best performance is not nearly as high as that expected from a state-of-the-art inflectional generation system, the key point is that performance significantly increases when considering the 10-best outputs. This suggests that the network is indeed learning the correct set of possible nominalization patterns. However, the information needed to correctly choose among these patterns for a given input is not necessarily available to the network. In particular, the network is only aware of important disambiguating historical (e.g., is the input of Latin or Greek origin) and lexical-semantic (e.g., is the input verb transitive or intransitive) factors to the extent that they are implicitly encoded in the input character sequence. We speculate that making these additional pieces of information directly available as input features will significantly improve 1-best accuracy.

Unfortunately, NomBank does not provide the necessary annotations in most cases. For instance, there is no way to differentiate *actor* and *actress* without gender. It also does not distinguish the semantics of some adjective nominalizations, e.g., *activism* and *activity*. Future work will reannotate NomBank to make these finer-grained distinctions.

Error Analysis. We observe mistakes on less frequent suffixes, e.g., *-age*—we predict **draination* instead of *drainage*. Also, there are several cases where NomBank only lists one available form, e.g., *complexity*, and our model predicts *complexness*. We also see mistakes on irregular adverbs, e.g., we generate *advancely* from *advance*, rather than *in-advance*, as well as in PATIENT nominalizations, e.g., the model produces *containee* in place of *content*—this last distinction is unpredictable.

5 Related Work

Previous work in unsupervised morphological *segmentation* and has implicitly incorporated derivational morphology. Such systems attempt to segment words into all constituent morphs, treating inflectional and derivational affixes as equivalent. The popular Morfessor tool (Creutz and Lagus, 2007) is one example of such an unsupervised segmentation system, but many others exist, e.g., Poon et al. (2009), Narasimhan et al. (2015) *inter alia*. Supervised segmentation and analysis models in the literature can also break down derivationally complex forms into their morphs, provided presegmented and labeled data is available for training (Ruokolainen et al., 2013; Cotterell et al., 2015; Cotterell and Schütze, 2017). Our work, however, builds directly upon recent efforts in the *generation* of inflectional morphology (Durrett and DeNero, 2013; Nicolai et al., 2015; Ahlberg et al., 2015; Rastogi et al., 2016; Faruqui et al., 2016). We differ in that we focus on derivational morphology. In another recent line of work, Vylomova et al. (2017) predict derivationally complex forms using sentential context. Our work differs from their approach in that we attempt to generate derivational forms divorced from the context, but the underlying neural sequence-to-sequence architecture is quite similar.

Table 4: F_1 for various suffix attachments with the sequence-to-sequence model

6 Conclusion

We have presented a statistical model for the generation of derivationally complex forms, a task that has gone essentially unexplored in the literature. Viewing derivational morphology as paradigmatic, where slots refer to semantic categories, e.g., *corrode*+RESULT↦*corrosion*, we draw upon recent advances in the generation of inflectional morphology. Applying this method works well, achieving an overall accuracy of 71.71%, and beating a non-neural baseline. Performance, however, is lower than on the task of paradigm completion for inflectional morphology, indicating that paradigm completion for derivational morphology is more challenging than its inflectional counterpart.

A Sub-Character Architecture for Korean Language Processing

Karl Stratos
Toyota Technological Institute at Chicago
stratos@ttic.edu

Abstract

We introduce a novel sub-character architecture that exploits a unique compositional structure of the Korean language. Our method decomposes each character into a small set of primitive phonetic units called jamo letters from which character- and word-level representations are induced. The jamo letters divulge syntactic and semantic information that is difficult to access with conventional character-level units. They greatly alleviate the data sparsity problem, reducing the observation space to 1.6% of the original while increasing accuracy in our experiments. We apply our architecture to dependency parsing and achieve dramatic improvement over strong lexical baselines.

1 Introduction

Korean is generally recognized as a language isolate: that is, it has no apparent genealogical relationship with other languages (Song, 2006; Campbell and Mixco, 2007). A unique feature of the language is that each character is composed of a small, fixed set of basic phonetic units called **jamo** letters. Despite the important role jamo plays in encoding syntactic and semantic information of words, it has been neglected in existing modern Korean processing algorithms. In this paper, we bridge this gap by introducing a novel compositional neural architecture that explicitly leverages the sub-character information.

Specifically, we perform Unicode decomposition on each Korean character to recover its underlying jamo letters and construct character- and word-level representations from these letters. See Figure 1 for an illustration of the decomposition. The decomposition is *deterministic*; this is a crucial departure from previous work that uses language-specific sub-character information such as radical (a graphical component of a Chinese character). The radical structure of a Chinese character does not follow any systematic process, requiring an incomplete dictionary mapping between characters and radicals to take advantage of this information (Sun et al., 2014; Yin et al., 2016). In contrast, our Unicode decomposition does not need any supervision and can extract correct jamo letters for all possible Korean characters.

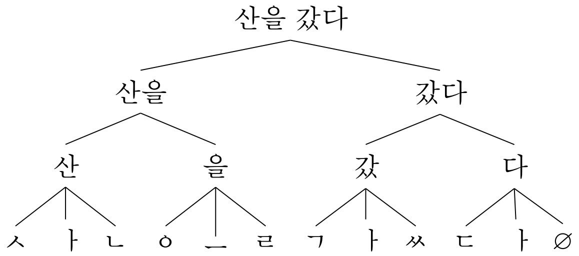

Figure 1: Korean sentence "산을 갔다" (*I went to the mountain*) decomposed to words, characters, and jamos.

Our jamo architecture is fully general and can be plugged in any Korean processing network. For a concrete demonstration of its utility, in this work we focus on dependency parsing. McDonald et al. (2013) note that "Korean emerges as a very clear outlier" in their cross-lingual parsing experiments on the universal treebank, implying a need to tailor a model for this language isolate. Because of the compositional morphology, Korean suffers extreme data sparsity at the word level: 2,703 out of 4,698 word types ($> 57\%$) in the held-out portion of our treebank are OOV. This makes the language challenging for simple lexical parsers even when

Proceedings of the 2017 Conference on Empirical Methods in Natural Language Processing, pages 721–726
Copenhagen, Denmark, September 7–11, 2017. ©2017 Association for Computational Linguistics

augmented with a large set of pre-trained word representations.

While such data sparsity can also be alleviated by incorporating more conventional character-level information, we show that incorporating jamo is an effective and economical new approach to combating the sparsity problem for Korean. In experiments, we decisively improve the LAS of the lexical BiLSTM parser of Kiperwasser and Goldberg (2016) from 82.77 to 91.46 while reducing the size of input space by 98.4% when we replace words with jamos. As a point of reference, a strong feature-rich parser using *gold* POS tags obtains 88.61.

To summarize, we make the following contributions.

- To our knowledge, this is the first work that leverages jamo in end-to-end neural Korean processing. To this end, we develop a novel sub-character architecture based on deterministic Unicode decomposition.

- We perform extensive experiments on dependency parsing to verify the utility of the approach. We show clear performance boost with a drastically smaller set of parameters. Our final model outperforms strong baselines by a large margin.

- We release an implementation of our jamo architecture which can be plugged in any Korean processing network.[1]

2 Related Work

We make a few additional remarks on related work to better situate our work. Our work follows the successful line of work on incorporating sub-lexical information to neural models. Various *character*-based architectures have been proposed. For instance, Ma and Hovy (2016) and Kim et al. (2016) use CNNs over characters whereas Lample et al. (2016) and Ballesteros et al. (2015) use bidirectional LSTMs (BiLSTMs). Both approaches have been shown to be profitable; we employ a BiLSTM-based approach.

Many previous works have also considered *morphemes* to augment lexical models (Luong et al., 2013; Botha and Blunsom, 2014; Cotterell et al., 2016). Sub-character models are substantially rarer; an extreme case is considered by Gillick et al. (2016) who process text as a sequence of bytes. We believe that such byte-level models are too general and that there are opportunities to exploit natural sub-character structure for certain languages such as Korean and Chinese.

There exists a line of work on exploiting graphical components of Chinese characters called radicals (Sun et al., 2014; Yin et al., 2016). For instance, 足 (*foot*) is the radical of 跑 (*run*). While related, our work on Korean is distinguished in critical ways and should not be thought of as just an extension to another language. First, as mentioned earlier, the compositional structure is fundamentally different between Chinese and Korean. The mapping between radicals and characters in Chinese is nondeterministic and can only be loosely approximated by an incomplete dictionary. In contrast, the mapping between jamos and Korean characters is deterministic (Section 3.1), allowing for systematic decomposition of all possible Korean characters. Second, the previous work on Chinese radicals was concerned with learning word embeddings. We develop an end-to-end compositional model for a downstream task: parsing.

3 Method

3.1 Jamo Structure of the Korean Language

Let $\mathcal{W}$ denote the set of word types and $\mathcal{C}$ the set of character types. In many languages, $c \in \mathcal{C}$ is the most basic unit that is meaningful. In Korean, each character is further composed of a small fixed set of phonetic units called jamo letters $\mathcal{J}$ where $|\mathcal{J}| = 51$. The jamo letters are categorized as head consonants $\mathcal{J}_h$, vowels $\mathcal{J}_v$, or tail consonants $\mathcal{J}_t$. The composition is completely systematic. Given any character $c \in \mathcal{C}$, there exist $c_h \in \mathcal{J}_h$, $c_v \in \mathcal{J}_v$, and $c_t \in \mathcal{J}_t$ such that their composition yields c. Conversely, any $c_h \in \mathcal{J}_h$, $c_v \in \mathcal{J}_v$, and $c_t \in \mathcal{J}_t$ can be composed to yield a valid character $c \in \mathcal{C}$.

As an example, consider the word 갔다 (`went`). It is composed of two characters, 갔, 다 $\in \mathcal{C}$. Each character is furthermore composed of three jamo letters as follows:

- 갔 $\in \mathcal{C}$ is composed of ㄱ $\in \mathcal{J}_h$, ㅏ $\in \mathcal{J}_v$, and ㅆ $\in \mathcal{J}_t$.

- 다 $\in \mathcal{C}$ is composed of ㄷ $\in \mathcal{J}_h$, ㅏ $\in \mathcal{J}_v$, and an empty letter $\varnothing \in \mathcal{J}_t$.

The tail consonant can be empty; we assume a special symbol $\varnothing \in \mathcal{J}_t$ to denote an empty letter.

[1] https://github.com/karlstratos/koreannet

Figure 1 illustrates the decomposition of a Korean sentence down to jamo letters.

Note that the number of possible characters is combinatorial in the number of jamo letters, loosely upper bounded by $51^3 = 132,651$. This upper bound is loose because certain combinations are invalid. For instance, ㅁ $\in \mathcal{J}_h \cap \mathcal{J}_t$ but ㅁ $\notin \mathcal{J}_v$ whereas ㅏ $\in \mathcal{J}_v$ but ㅏ $\notin \mathcal{J}_h \cup \mathcal{J}_t$.

The combinatorial nature of Korean characters motivates the compositional architecture below. For completeness, we describe the entire forward pass of the transition-based BiLSTM parser of Kiperwasser and Goldberg (2016) that we use in our experiments.

3.2 Jamo Architecture

The parameters associated with the jamo layer are

- Embedding $e^l \in \mathbb{R}^d$ for each letter $l \in \mathcal{J}$
- $U^{\mathcal{J}}, V^{\mathcal{J}}, W^{\mathcal{J}} \in \mathbb{R}^{d \times d}$ and $b^{\mathcal{J}} \in \mathbb{R}^d$

Given a Korean character $c \in \mathcal{C}$, we perform Unicode decomposition (Section 3.3) to recover the underlying jamo letters $c_h, c_v, c_t \in \mathcal{J}$. We compose the letters to induce a representation of c as

$$h^c = \tanh\left(U^{\mathcal{J}} e^{c_h} + V^{\mathcal{J}} e^{c_v} + W^{\mathcal{J}} e^{c_t} + b^{\mathcal{J}}\right)$$

This representation is then concatenated with a character-level lookup embedding, and the result is fed into an LSTM to produce a word representation. We use an LSTM (Hochreiter and Schmidhuber, 1997) simply as a mapping $\phi : \mathbb{R}^{d_1} \times \mathbb{R}^{d_2} \to \mathbb{R}^{d_2}$ that takes an input vector x and a state vector h to output a new state vector $h' = \phi(x, h)$. The parameters associated with this layer are

- Embedding $e^c \in \mathbb{R}^{d'}$ for each $c \in \mathcal{C}$
- Forward LSTM $\phi^f : \mathbb{R}^{d+d'} \times \mathbb{R}^d \to \mathbb{R}^d$
- Backward LSTM $\phi^b : \mathbb{R}^{d+d'} \times \mathbb{R}^d \to \mathbb{R}^d$
- $U^{\mathcal{C}} \in \mathbb{R}^{d \times 2d}$ and $b^{\mathcal{C}} \in \mathbb{R}^d$

Given a word $w \in \mathcal{W}$ and its character sequence $c_1 \ldots c_m \in \mathcal{C}$, we compute

$$f_i^c = \phi^f\left(\begin{bmatrix} h^{c_i} \\ e^{c_i} \end{bmatrix}, f_{i-1}^c\right) \qquad \forall i = 1 \ldots m$$
$$b_i^c = \phi^b\left(\begin{bmatrix} h^{c_i} \\ e^{c_i} \end{bmatrix}, b_{i+1}^c\right) \qquad \forall i = m \ldots 1$$

and induce a representation of w as

$$h^w = \tanh\left(U^{\mathcal{C}} \begin{bmatrix} f_m^c \\ b_1^c \end{bmatrix} + b^{\mathcal{C}}\right)$$

Lastly, this representation is concatenated with a word-level lookup embedding (which can be initialized with pre-trained word embeddings), and the result is fed into a BiLSTM network. The parameters associated with this layer are

- Embedding $e^w \in \mathbb{R}^{d_{\mathcal{W}}}$ for each $w \in \mathcal{W}$
- Two-layer BiLSTM Φ that maps $h_1 \ldots h_n \in \mathbb{R}^{d+d_{\mathcal{W}}}$ to $z_1 \ldots z_n \in \mathbb{R}^{d^*}$
- Feedforward for predicting transitions

Given a sentence $w_1 \ldots w_n \in \mathcal{W}$, the final d^*-dimensional word representations are given by

$$(z_1 \ldots z_n) = \Phi\left(\begin{bmatrix} h^{w_1} \\ e^{w_1} \end{bmatrix} \ldots \begin{bmatrix} h^{w_n} \\ e^{w_n} \end{bmatrix}\right)$$

The parser then uses the feedforward network to greedily predict transitions based on words that are active in the system. The model is trained end-to-end by optimizing a max-margin objective. Since this part is not a contribution of this paper, we refer to Kiperwasser and Goldberg (2016) for details.

By setting the embedding dimension of jamos d, characters d', or words $d_{\mathcal{W}}$ to zero, we can configure the network to use any combination of these units. We report these experiments in Section 4.

3.3 Unicode Decomposition

Our architecture requires dynamically extracting jamo letters given any Korean character. This is achieved by simple Unicode manipulation. For any Korean character $c \in C$ with Unicode value $U(c)$, let $\overline{U}(c) = U(c) - 44032$ and $T(c) = \overline{U}(c) \bmod 28$. Then the Unicode values $U(c_h)$, $U(c_v)$, and $U(c_t)$ corresponding to the head consonant, vowel, and tail consonant are obtained by

$$U(c_h) = 1 + \left\lfloor \frac{\overline{U}(c)}{588} \right\rfloor + \texttt{0x10ff}$$
$$U(c_v) = 1 + \left\lfloor \frac{(\overline{U}(c) - T(c)) \bmod 588}{28} \right\rfloor + \texttt{0x1160}$$
$$U(c_t) = 1 + T(c) + \texttt{0x11a7}$$

where c_t is set to $\varnothing$ if $T(c_t) = 0$.

Table 1: Treebank statistics. Upper: Number of trees in the split. Lower: Number of unit types in the training portion. For simplicity, we include non-Korean symbols (e.g., @, 正, a) as characters/jamos.

3.4 Why Use Jamo Letters?

The most obvious benefit of using jamo letters is alleviating data sparsity by flattening the combinatorial space of Korean characters. We discuss some additional explicit benefits. First, jamo letters often indicate syntactic properties of words. For example, a tail consonant ㅆ strongly implies that the word is a past tense verb as in 갔다 (went), 왔다 (came), and 했다 (did). Thus a jamo-level model can identify unseen verbs more effectively than word- or character-level models. Second, jamo letters dictate the sound of a character. For example, 갔 is pronounced as got because the head consonant ㄱ is associated with the sound g, the vowel ㅏ with o, and the tail consonant ㅆ with t. This is clearly critical for speech recognition/synthesis and indeed has been investigated in the speech community (Lee et al., 1994; Sakti et al., 2010). While speech processing is not our focus, the phonetic signals can capture useful lexical correlation (e.g., for onomatopoeic words).

4 Experiments

Data We use the publicly available Korean treebank in the universal treebank version 2.0 (McDonald et al., 2013).[2] The dataset comes with a train/development/test split; data statistics are shown in Table 1. Since the test portion is significantly smaller than the dev portion, we report performance on both.

As expected, we observe severe data sparsity with words: 24,814 out of 31,060 elements in the vocabulary appear only *once* in the training data. On the dev set, about 57% word types and 3% character types are OOV. Upon Unicode decomposition, we obtain the following 48 jamo types:

ㄱ ㄳ ㄲ ㄵ ㄴ ㄷ ㄶ ㄹ ㄸ ㄻ ㄺ ㄼ ㅁ
ㅀ ㅃ ㅂ ㅅ ㅄ ㅇ ㅆ ㅉ ㅈ ㅋ ㅊ ㅍ ㅌ
ㅏ ㅎ ㅑ ㅐ ㅓ ㅒ ㅕ ㅔ ㅗ ㅖ ㅙ ㅘ ㅛ ㅚ
ㅝ ㅜ ㅟ ㅞ ㅡ ㅠ ㅣ ㅢ

none of which is OOV in the dev set.

Implementation and baselines We implement our jamo architecture using the DyNet library (Neubig et al., 2017) and plug it into the BiLSTM parser of Kiperwasser and Goldberg (2016).[3] For Korean syllable manipulation, we use the freely available toolkit by Joshua Dong.[4] We train the parser for 30 epochs and use the dev portion for model selection. We compare our approach to the following baselines:

- McDonald13: A cross-lingual parser originally reported in McDonald et al. (2013).
- Yara: A beam-search transition-based parser of Rasooli and Tetreault (2015) based on the rich non-local features in Zhang and Nivre (2011). We use beam width 64. We use 5-fold jackknifing on the training portion to provide POS tag features. We also report on using *gold* POS tags.
- K&G16: The basic BiLSTM parser of Kiperwasser and Goldberg (2016) without the sublexical architecture introduced in this work.
- Stack LSTM: A greedy transition-based parser based on stack LSTM representations. Dyer15 denotes the word-level variant (Dyer et al., 2015). Ballesteros15 denotes the character-level variant (Ballesteros et al., 2015).

For pre-trained word embeddings, we apply the spectral algorithm of Stratos et al. (2015) on a 2015 Korean Wikipedia dump to induce 285,933 embeddings of dimension 100.

Parsing accuracy Table 2 shows the main result. The baseline test LAS of the original cross-lingual parser of McDonald13 is 55.85. Yara achieves 85.17 with predicted POS tags and 88.61 with gold POS tags. The basic BiLSTM model of K&G16 obtains 82.77 with pre-trained word embeddings (78.95 without). The stack LSTM parser is comparable to K&G16 at the word level

Table 2: Main result. Upper: Accuracy with baseline models. Lower: Accuracy with different configurations of our parser network (word-only is identical to K&G16).

(Dyer15), but it performs significantly better at the character level (Ballesteros15) reaching 86.25 test LAS.

We observe decisive improvement when we incorporate sub-lexical information into the parser of K&G16. In fact, a *strictly* sub-lexical parser using only jamos or characters clearly outperforms its lexical counterpart despite the fact that the model is drastically smaller (e.g., 90.77 with 500 × 100 jamo embeddings vs 82.77 with 298115 × 100 word embeddings). Notably, jamos alone achieve 91.46 which is not far behind the best result 92.31 obtained by using word, character, and jamo units in conjunction. This demonstrates that our compositional architecture learns to build effective representations of Korean characters and words for parsing from a minuscule set of jamo letters.

5 Discussion of Future Work

We have presented a natural sub-character architecture to model the unique compositional orthography of the Korean language. The architecture induces word-/sentence-level representations from a small set of phonetic units called jamo letters. This is enabled by efficient and deterministic Unicode decomposition of characters.

We have focused on dependency parsing to demonstrate the utility of our approach as an economical and effective way to combat data sparsity. However, we believe that the true benefit of this architecture will be more evident in speech processing as jamo letters are definitions of sound in the language. Another potentially interesting application is informal text on the internet. Ill-formed words such as ㅎㅎㅎ (shorthand for 하하하, an onomatopoeic expression of laughter) and ㄴㄴ (shorthand for 노노, a transcription of `no no`) are omnipresent in social media. The jamo architecture can be useful in this scenario, for instance by correlating ㅎㅎㅎ and 하하하 which might otherwise be treated as independent.

Acknowledgments

The author would like to thank Lingpeng Kong for his help with using the DyNet library, Mohammad Rasooli for his help with using the Yara parser, and Karen Livescu for helpful comments.

Do LSTMs really work so well for PoS tagging? – A replication study

Abstract

A recent study by Plank et al. (2016) found that LSTM-based PoS taggers considerably improve over the current state-of-the-art when evaluated on the corpora of the Universal Dependencies project that use a *coarse-grained* tagset. We replicate this study using a fresh collection of 27 corpora of 21 languages that are annotated with *fine-grained* tagsets of varying size. Our replication confirms the result in general, and we additionally find that the advantage of LSTMs is even bigger for larger tagsets. However, we also find that for the very large tagsets of morphologically rich languages, hand-crafted morphological lexicons are still necessary to reach state-of-the-art performance.

1 Introduction

Part-of-Speech (PoS) tagging is an important processing step for many NLP applications. When researchers want to use a PoS tagger, they would ideally choose an off-the-shelf PoS tagger which is optimized for a specific language. If a suited tagger is not available two options remain: a) implementation of your own tagger, which requires technical knowledge and experience, or b) using an existing tagger and hope that the resulting model will be sufficiently accurate. One can assume that many taggers fit more languages than the one for which they have been constructed originally. Ideally, researchers should be able to fall back to a well-evaluated language-independent tagger if no reference implementation for a language is available.

A recent study by Plank et al. (2016) evaluated an LSTM PoS tagger and compared the results to Conditional Random Fields (CRF) (Lafferty et al., 2001) and Hidden-Markov (HMM) implementations on corpora of various languages. Their evaluation concludes that the LSTM tagger reaches better results than the CRF and HMM tagger. The evaluation corpora were all annotated with a *coarse-grained* tagset with 17 tags. Thus, this LSTM tagger seems to be a well-performing, language-independent choice for learning models on coarse-grained tagsets. While for many tasks a coarse-grained tagset might be sufficient some tasks require more fine-grained tagsets.

We, thus, consider it worthwhile to explore if the results are reproducible using corpora with fine-grained tagsets. We use the LSTM tagger provided by Plank et al. (2016) and compare the results likewise to CRF and an off-the-shelf HMM tagger implementation. We compile a fresh set of 27 corpora of 21 languages which uses the commonly used *fine-grained* tagset of the respective language. We suggest these corpora as evaluation set for tasks which require fine-grained PoS tags, as all corpora are freely available for research purposes. Our intention is to replicate the findings of Plank et al. (2016), which have been achieved on a coarse-grained tagset and investigate if they transfer to fine-grained tagsets.

2 PoS Tagger Paradigms

We distinguish two PoS tagger paradigms, which can be used to implement a tagger: The first one is *Feature Engineering*, in which a classifier learns a mapping from human-defined features to a PoS tag. Defining good features is often a non-trivial task, which furthermore requires a lot of experience. For instance a suffix feature which checks a word-ending for “ing” is highly discriminative for English gerunds, but might not provide any useful information for other languages. The details of the feature implementation might render a

Table 1: Corpora used in our experiments

tagger unsuited for learning models for other languages or tagsets. We will, thus, experiment with features and their configurations, and investigate how well they perform in combination for learning fine-grained tagsets of various languages. We implement those experiments using CRF which are frequently used for PoS tagging (Remus et al., 2016; Ljubešić et al., 2016).

The second paradigm is *Architecture Engineering*, which relies on methods to learn the input representation by themselves. The challenge lies in finding an architecture that supports this self-learning process. Most recent representatives of this paradigm are neural networks of which we use the LSTM tagger provided by Plank et al. (2016).

In our experiments, we will focus on how to provide word- and character-level information to the classifiers as these two types of information are most relevant and most frequently used for training PoS tagger models. Furthermore, we will evaluate the performance on Out-Of-Vocabulary (OOV) words to learn if the taggers generalize to unseen words.

To provide a reference value to a well-known PoS tagger, we will compare all results to the HMM-based HunPos (Halácsy et al., 2007) tagger, which is a freely available re-implementation of the TNT tagger (Brants, 2000). HunPos has been used before for training models of various languages and tagsets (Seraji, 2011; Attardi et al., 2010; Hládek et al., 2012) which is why we consider this tagger to be a suitable baseline.

3 Evaluation Corpora Dataset

Table 1 shows the fine-grained annotated corpora we collected by screening the literature. We do not claim that this list is complete, but the provided corpora are all reasonably easy to access and can be freely used for research purposes.

Selection To ensure reproducibility, we preferably selected corpora which are directly available via the Internet except *German-3, Hungarian* and *Swedish-2*. We intentionally exclude languages such as Chinese or Japanese, which do not provide whitespace delimiters to mark word boundaries. Tagging those languages requires a morpho-

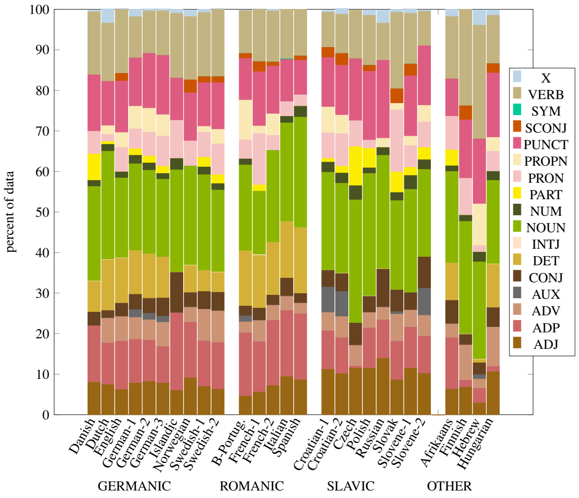

Figure 1: Coarse-grained PoS tag distribution of corpora by language group

logical analysis which is a different task than the tagging task on which we are focusing here. Most corpora are manually annotated or were at least human-verified. There are four exceptions which we decided to add anyway to increase the number of languages represented in our setup. The tagset granularity of the corpora ranges from coarse (12 tags) to morphologically fine (1574 tags) to evaluate all taggers on various stages of granularity.

Language & Corpora Diversity We analyzed the distribution of PoS tags in the corpora by mapping all tags to the 17 coarse-grained PoS tags of the Universal Dependencies (UD) project (Nivre et al., 2015) in Figure 1. The mappings to the UD tagset have been manually created. The partly large differences between the syntactical classes help to better understand the challenge in construction a tagger that is suited for all those languages. For instance, Germanic and Romanic languages have a lot of determiners while they do not occur at all in Slavic languages.

Corpus Size & Tagset The corpora have varying sizes which makes a direct comparison between corpora difficult. To run our experiments under fully controlled conditions, we extract a randomized sub-sample of sentences from each corpus, which accounts for 50k tokens, and run all our experiments with 10fold cross-validation (CV).[1] Results reported use the fine-grained tagset of the respective corpus.

We deliberately do not use the corpora from the UD Treebank project in order to provide results on a fresh dataset. Additionally, UD uses a coarse-grained tagset for all its corpora. While this granularity is sufficient for many tasks, linguistic analysis often requires more fine-grained tagsets, and it is not clear whether results achieved on coarse-grained tagsets transfer well to more fine-grained tagsets. The collected corpora, thus, also represent an alternative dataset, which we suggest in case the UD tagset is too coarse-grained.

4 CRF Experiments

We reviewed the recent literature to determine the most commonly used features for training PoS taggers. As re-occurring features, we found word ngrams, fixed character sequences focusing on either pre-, in-, or suffixes of words and word distributional knowledge for PoS taggers of various languages (Brants, 2000; Horsmann and Zesch, 2016; Ljubešić et al., 2016). Word- and character-ngrams have been used with various parametrizations depending on the language and there is no agreement which parameters are most advisable. We will, hence, run a series of parameter-search experiments over the word- and character-ngram parametrization to determine a configuration applicable to all languages. For this, we evaluate all permutations of the subsequently introduced feature configurations with 10fold cross-validation. The objective is to find a configuration that works well on all corpora, languages, and tagsets.

Word Features We experiment with adding the $1,2,3$ words to the right and left of the current word as lower-cased string features.

Character Features Which character-ngram is discriminative for a PoS tag strongly depends on the language. To avoid a language bias, we use a frequency-based approach in which we select the N most frequently occurring character-ngrams of length $1,2,3,4$ from the training dataset. We experiment with the following frequency cut-off values of $N \ \varepsilon \ \{250, 500, 750, 1000\}$ to select only frequent and potentially informative character-ngrams as features. These N features are boolean and are set to 1 if the respective character-ngram occurs in the current word.

Semantic Features We use Brown clustering (Brown et al., 1992) to create word clusters. The

[1] While randomization prohibits exact reproducibility, it is no barrier to the more interesting replicability. It is also less prone to continued overfitting on the known test set.

Table 2: Accuracy of CRF taggers (10fold CV)

unlabelled text is obtained from the Leipzig Corpus Collection (Quasthoff et al., 2006), which provides large text quantities crawled from the web for many languages. We use $15 \cdot 10^6$ tokens to create the clusters from the same amount of text for all languages. We provide the cluster ids in substrings of varying length to the classifier (Owoputi et al., 2013).

Results In Figure 2, we show the results of our parameter search experiment. The triangles mark the results of the various feature configurations. The diamond symbol shows the configuration which works best over all corpora. We refer to this best working configuration as *Best CRF* subsequently, it uses a word-context window of 1 word to the left and right and the 750 most frequent character [1..4] grams with additionally adding word clusters. Especially for morphologically-rich languages, the spread is quite large which is caused by the lower number of character-ngrams in those configurations. For corpora such as *Slovene-1*, we see that more accurate configurations exist than *Best CRF* but more importantly, the selected configuration is always among the best working ones.

We show the results of *Best CRF* and the performance of the individual features for each language in Table 2, and compare the results to HunPos, the highest accuracies are highlighted in grey. When evaluating the features separately, the character-ngrams reach the highest accuracy on OOV words. Especially on the Slavic language family the character-ngrams perform much better than using only word-ngrams or clusters. Furthermore, using only character-ngrams is often competitive to using only word-ngrams. Hence, a rather naïve strategy to achieving a decent performance on almost any language is to just use

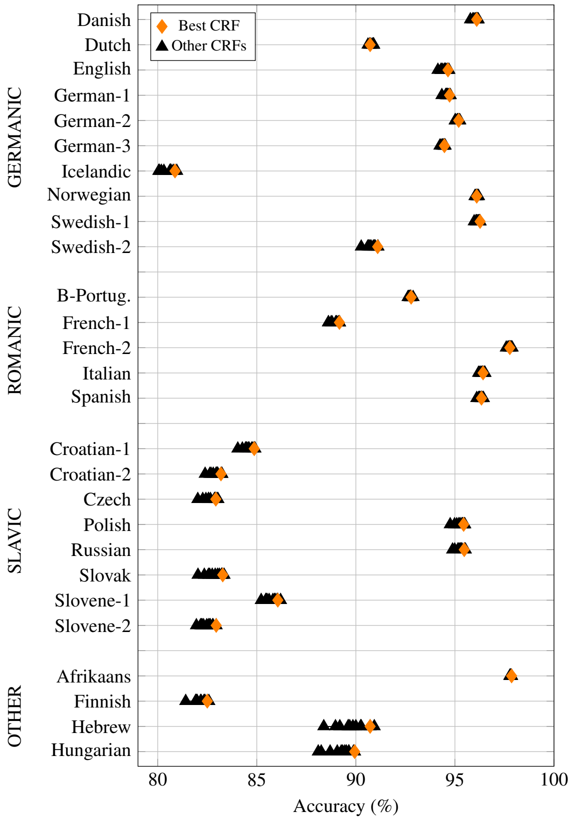

Figure 2: Variance of CRF taggers (10fold CV)

all kinds of character-ngrams. The cluster feature also performs better than the word-ngrams. Considering that we had to limit the amount of data for creating the clusters for comparability, this feature assumedly has more potential when using larger data sizes (Derczynski et al., 2015). The combination of all features in the column *Best CRF* shows that the features address quite different information and add up well, so unsurprisingly, this configuration reaches the overall best accuracies. The difference to HunPos is, with often less than one percent point difference, only small. Off-the-shelf taggers do, hence, not necessary have a disadvantage over constructing an own tagger. In the remainder of this work, we will use the *Best CRF* configuration when discussing CRF tagger results.

5 LSTM Experiments

When using neural networks, the details of how word and character information is provided greatly influences the learning success of the network. We will reproduce network setups which have also been used in Plank et al. (2016) to ensure comparability to the coarse-grained results to which we compare our results:

Word In this setup, we train a network on the word embeddings only and provide them to a bidirectional LSTM. This setup will serve as baseline.

Char The character embeddings of a word are provided to a bidirectional LSTM. The last state of the forward and the backward character LSTM are combined (Ling et al., 2015) and provided to another bidirectional LSTM layer.

Word-Char This architecture is a combination of the previous two architectures. The last state of the character LSTMs is added to the word embedding information before it is provided to the next LSTM layer.

Word-Char+ The architecture by Plank et al. (2016) combines word and character level information and additionally considers the log-frequency of the next word during training. This tagger reported state-of-the-art results and we use the provided reference implementation of this tagger in our setup.

LSTMs have the reputation to require larger amounts of training data. With the 50k tokens we use this is barely fulfilled, however, Plank et al. (2016) find this sensitivity to be less severe and set a corpus size of 60k tokens as lower bound for their coarse-grained tagging experiments. We will come back to this data size issue in Section 7, where we evaluate using all tokens in a corpus (and arriving at the same conclusions as for our 50k token datasets). Furthermore, in many cases only smaller dataset sizes are available, sometimes even less than 50k tokens. It is, thus, important to know if considering neural network taggers makes sense at all (on fine-grained tagsets), thus we will train LSTM models on smaller dataset sizes.

We implement the LSTM taggers in DyNet (Neubig et al., 2017) and use the hyper-parameter settings by Plank et al. (2016), i.e. we train 20 epochs using Statistical-Gradient-Descent with a learning rate of 0.1 and adding Gaussian noise of 0.2 to the embedding layer. We train word embeddings on the data we already used for the *semantic feature* in the CRF experiments by using *fastText* (Bojanowski et al., 2016) . The the character-level embeddings are trained on-the-fly.

Results In Figure 3, we show the results for the LSTM architectures. The *Word-Char+* tagger performs best followed by *Word-Char*, which is not surprising as *Word-Char+* is based on this

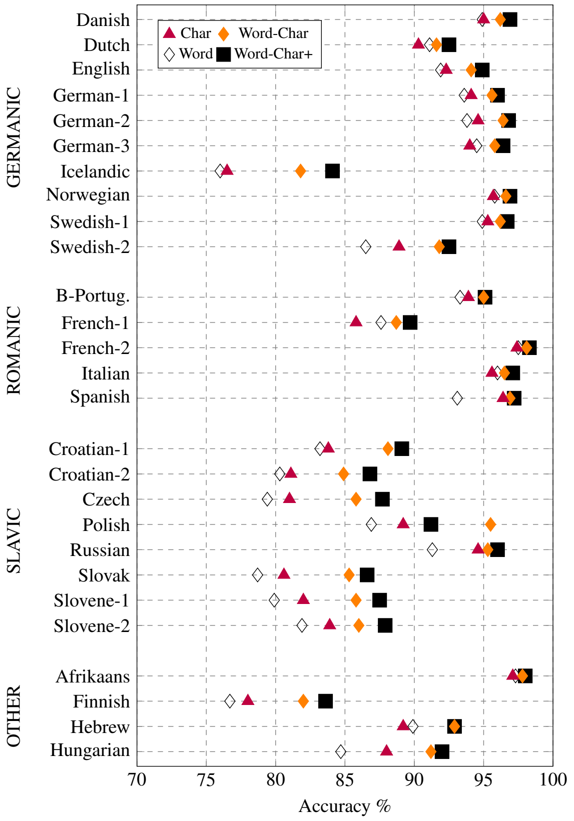

Figure 3: Variance of LSTM taggers (10fold CV)

architecture. For the Germanic and Romanic languages, the accuracy of the various architectures is similar but for Slavic languages, which use much more fine-grained tagsets, the differences are rather large. For instance, the *Char* architecture reaches only small improvements over the *Word* baseline on *Croatian or Czech* while on *Spanish, or Hungarian* the character architecture is clearly better than the baseline. Table 3 shows the detailed results and additionally reports the accuracy values on OOV with best results highlighted in grey. The *Char* architecture is in many cases competitive to the HunPos reference system. This shows that the performance of many off-the-shelf taggers is rather easy to approximate by relying only on character-level information.

The results by the *Char* architecture also explains why the *Word-Char* architecture performs so well although the amount of syntactical information is quite limited with 50k tokens. A large part of the necessary information is already obtained by the character model, which requires a lot less training data than a model on the word level. Thus, the results of Plank et al. (2016) on coarse-tagsets are reproducible for fine-grained tagsets with the *Word-Char* architecture being the essential property to achieving high accuracy.

6 Influence of Tagset Size

A researcher who works with morphologically rich languages will often be interested in additional morphologic details such as case or gender. This drastically complicates the task, as a few hundred instead of a few dozen PoS tag distinctions have to be learned. In this experiment, we will examine the impact of an increasing number of PoS tags on the accuracy of the taggers to provide reference values of how much performance a tagger seems to loose with an increasing tagset size.

Results In Figure 4, we show a comparison of the tagging accuracy in relation to the number of PoS tags. We show the best performing LSTM tagger *Word-Char+*, the *CRF* tagger and *HunPos*. Each data point represents the averaged CV result on one corpus with the respective tagger. We see a certain clustering of the data points for the small tagset sizes, which shows that the taggers tend to perform highly similarly for many languages. This means that the tagset size has a larger effect on the accuracy than the language of the corpus.

For each PoS tagger, a regression trendline is plotted which indicates the average loss in accuracy with an increasing tagset size. For one-hundred additional PoS tags, *Word-Char+* loses 0.35 points in accuracy, while *CRF* and *HunPoS* have a much steeper decay of 0.45 points. Hence, with growing tagset size the tagger choice becomes increasingly more important. Furthermore, the benefit of more sophisticated tagger architectures becomes only apparent on large PoS tagsets.

7 Comparison with Reference Taggers

In this experiment, we compare our results to reference taggers from the literature that are tailored towards certain languages. Our experiments until now were limited to the fixed dataset size that we set at the beginning for comparability. Especially for the morphologically fine-grained tagsets this might have been problematic, as it is doubtful if all PoS tags of a morphological tagset do even occur on 50k tokens. Thus, in order to evaluate the taggers using all available data, we will reproduce setups reported in the literature and compare the performance of the taggers to those results.

This experiment limits the number of comparisons we can make drastically, as we need to have

Table 3: Accuracy of LSTM taggers (10fold CV)

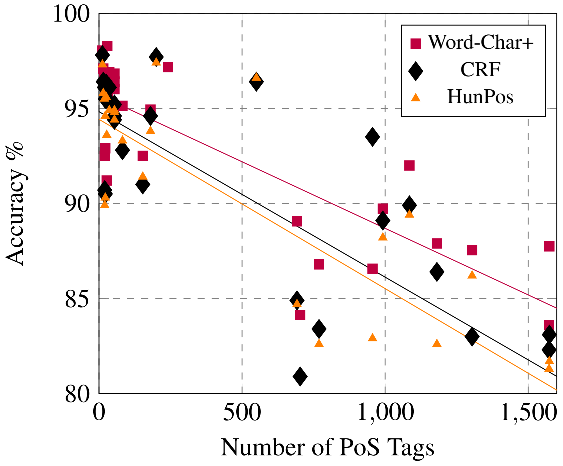

Figure 4: Influence of tagset size on accuracy

the same corpora as used in the literature. We, thus, reproduce for *Czech* the setup by Spoustová et al. (2009) with training on 10^6 and evaluation on $2 \cdot 10^5$ tokens, for *German-2* the setup by Giesbrecht and Evert (2009) and for *Swedish-2* the setup by Östling (2013), which both use 10fold cross-validation over the full corpus size.

Taggers for Slavic languages often make use of additional resources such as morphological dictionaries, which we intentionally do not include to avoid human-crafted resources that are not available for all languages. Thus, we do not expect to reach state-of-the-art performance, but we want to quantify the size of the gap.

Results In Table 4, we show a comparison of our results to the results reported in the literature. On *German-2* and *Swedish-2*, the Word-Char+ tagger is able to reach better results than the reported reference values except for *Czech* which uses a morphologically fine-grained tagset. Thus, language-

			Δ to reference tagger		
Corpus Id	# Tags	Acc (%)	HunPos	CRF	Word-Char+
Czech	1,574	95.9	-4.7	-3.2	-1.5
German-2	54	97.6	-0.1	-0.2	0.9
Swedish-2	153	96.1	0.0	-0.6	0.1

Table 4: Results of reproducing setups in the literature using the *full corpus size*

fitted PoS taggers reach better results than neural networks when training models on corpora with extremely fine-grained PoS tagsets. However, for smaller tagsets sizes the need for using language-fitting is negligible.

8 Conclusion

We replicated a study in which LSTM PoS taggers are compared to CRF and HMM taggers on corpora with a coarse-grained tagset. Our replication focused on whether results reported for coarse-grained tagsets do also hold when training models on fine-grained tagsets. Therefore, we collected a large set of 27 evaluation corpora that are annotated with the commonly used fine-grained tagset of 21 languages. The replication confirmed the superior performance of the LSTM tagger reported by Plank et al. (2016) also on fine-grained tagsets. However, we also found that for smaller tagset sizes the differences between the LSTM, our self-implemented CRF and the HMM tagger are often only small. The advantages of the LSTM tagger over other taggers grow proportionally with the tagsets size of the corpus. On morphologically fine tagsets, even the LSTM tagger fails to reach results reported in the literature when reproducing those setups.

Abstract

We introduce the task of *book structure labeling*: segmenting and assigning a fixed category (such as TABLE OF CONTENTS, PREFACE, INDEX) to the document structure of printed books. We manually annotate the page-level structural categories for a large dataset totaling 294,816 pages in 1,055 books evenly sampled from 1750–1922, and present empirical results comparing the performance of several classes of models. The best-performing model, a bidirectional LSTM with rich features, achieves an overall accuracy of 95.8 and a class-balanced macro F-score of 71.4.

1 Introduction

The availability of large-scale book corpora (such as those created by Google Books, the Internet Archive and the HathiTrust) has driven a flurry of work in cultural analytics over the past decade, in which the text contained in historical books has provided the raw material for the analysis of genre (Underwood, 2016), literary character (Bamman et al., 2014), geographic attention (Wilkens, 2013), fame (Michel et al., 2010), and much more.

Books, however, are not undifferentiated streams of text in the same way that born-digital documents like tweets or emails are; they are physical objects with materiality (Werner, 2012) and are arranged in a complex structure steeped in a long design tradition, with the core content of the work placed between structured frontmatter (such as a table of contents and introduction) and backmatter (such as an appendix and index). Not all of this content is desirable for all analyses; as we show below, 11% of all pages in books belong to the peritext (Genette, 1987) that surrounds the core content, with wide variability from book to book. For other analyses, such as those addressing questions in book history (Kirschenbaum and Werner, 2014), isolating this structure in a consistent way across historical documents can enable research into how the form of the printed book has, for example, changed over time.

While other work has focused on extracting the idiosyncratic structure inherent in each book, such as recognizing chapter boundaries in order to automatically generate a table of contents, or link a parsed table of contents to positions in a book (Déjean and Meunier, 2005, 2009; Wu et al., 2013; Gao et al., 2009), labeling document segments with a fixed typology has complementary benefits, allowing researchers to identify consistent categories in all books regardless of the names assigned by a specific author or publisher, or popular at a given time.[1]

At the same time, book structure labeling presents real challenges to automatic identification. While large-scale digital collections originate in page scans of the books, the most common form of access by researchers is through the output of OCR; raw image files are prohibitively expensive both in terms of disk space (15.1 million books from the HathiTrust consumes 677 ter-

[1] For example, a section whose function is to outline the structural regions of a book and list the pages on which they begin may be known at different points in history as a "table of contents," "index," or several other terms.

PREFACE.

THE importance and novelty of a ſubject, of which we have hitherto had imperfect and inaccurate accounts, induced me to ſeize every opportunity of making myſelf acquainted with the tranſactions in the Eaſt-Indies by the peruſal of authentic Papers. The ſatisfaction I received from thoſe I had already ſeen, excited an eager deſire for further enquiry, and urged me to agree to any conditions under which I might be enabled to gratify my curioſity.

Nothing but a determination to write ſome account of India, could have entitled me to the ſight of ſuch materials as I have been favoured with, or have properly introduced me to the free converſation of the perſons principally concerned; which, as it has afforded me the greateſt pleaſure, as well as inſtruction, I ought never to mention without due acknowledgments. As I eſteem it a ſingular honour to have been indulged ſo much beyond my expectation, by all whom I have taken the liberty to trouble on this occaſion, I am bound to declare, that every perſon to whom I have applied, without exception, has given me full ſatisfaction in every point on which I had occaſion to conſult him, and has done it with the utmoſt politeneſs.

After this, I need not dwell upon any further inducements to write; and yet the great reputation which the nation, and ſo many individuals have acquired in the Eaſt-Indies, has doubtleſs been another very inviting circumſtance.

abytes of space[2]) and in the resources required for computational processing. While people are able to distinguish the different sections of a book with ease, the degraded nature of the OCR output (especially for historical books) blurs the clear markers that signal the category to human readers—both in terms of the lexical signals like "Preface" or "Index" that head a page, and its visual structure as well. Figure 1 illustrates an example of three pages from a single book drawn from the HathiTrust; figure 2 displays the corresponding OCR output; the degradation introduced by OCR affects not only the accuracy of character and word identification, but also the structural layout as well.

To address these limitations and enable research that depends on reasoning over fine-grained document structure within books, we introduce the task of labeled segmentation, and make the following contributions:

- We create an human-annotated gold standard of 294,816 pages in 1,055 printed books drawn from the HathiTrust Digital Library.
- We approach this problem in the most common resource-deficient scenario researchers most frequently encounter: with access only to the pre-existing output of OCR.
- We compare several different classes of models, including a fast independent predictor (a random forest), a simple linear sequence labeling model (CRF), and a sequence labeling bidirectional LSTM that can capture non-linearities in the feature space. All data and pre-trained models are openly available to the public at https://github.com/dbamman/book-segmentation.

2 Data

In order to support the analysis and prediction of labeled document structure, we present a manually annotated dataset of 1,055 books, where each page has been labeled according to one of 10 categories described in §2.1 below. All books originate in the HathiTrust Digital Library. In order to capture historically representative phenomena, we use the decade-stratified sample of 1,075 books from Bamman et al. (2017), in which each decade from 1750-1922 is roughly equally represented. From this sample of 1,075 apparent books, we exclude all non-book records (including digitized newspaper clippings, unbound pamphlets and reports, opera programs, etc.) to yield a total labeled dataset of 294,816 pages in 1,055 books.

2.1 Categories

While there is no codified form of the standard categories that are present in print books, modern book designers generally adhere to a tradition involving a typical sequence of parts (Wilson, 1993; Lee, 2009). We draw on this tradition to inform our set of the following ten categories; to contextualize its prevalence, each category is listed with its description and the fraction of the 1,055 books

(c) Index.

Figure 2: OCR output for the page scans illustrated in fig. 1.

in our dataset in which it appears (for example, 47.8% of books have an annotated preface).

- Title page (93.0%), which lists the title of the work and (optionally) other information including the names of the author, translator, and others involved in its creation. In this category we group the primary title page along with the Half-title (a page that generally only presents the title of the work, often preceding the main title page or first chapter).
- Ad card (18.1%), which lists other works by the author or publisher; or, more generally, any other object that is advertised for sale.
- Publisher (39.9%), which includes the modern Copyright page (typically on the verso side of the title page) and also the Colophon (an imprint often appearing at the end of a work).
- Dedication (17.5%), an inscription by the author dedicating the work to another.
- Preface (47.8%), which includes a Foreword, Preface, and Introduction. While modern designers articulate prescriptive distinctions among these categories primarily in their subject matter and authorial voice,[3] we do not find a strong distinction among these sub-categories evident when labeling the text. We therefore follow Genette (1987) in grouping all together as prefatory material.
- Table of contents (46.8%), which includes "an accurate listing of all textual matter which follows it and the page on which the parts of the book commence" (Wilson, 1993).
- Text (99.3%), which includes the main contents of the book. Text is naturally the most frequent category, but only accounts for 89.4% of pages in all books in our dataset. We also see wide variability from book to book; the average Text ratio in books is 0.82, with a standard deviation of 0.18.
- Appendix (14.4%) includes a heterogeneous mix of other minor categories that appear infrequently in different books. These include: Notes (1.1%) (which "have the character of footnotes which, because of their extent, are placed at the back of the book" (Wilson, 1993)); Bibliography (1.7%), "a listing of the books and periodicals, etc., which the author has used as source material or which he recommends as supplementary reading matter" (Wilson, 1993); Glossary (0.6%), "a list of definitions of terms used in the text" (Wilson, 1993), Errata (4.1%), mistakes corrected in the printing of the book, and Subscribers (1.7%), a list of individuals who have committed to purchasing the work in advance (a historical category not frequently seen in modern texts). We annotate each of these subcategories individually for future work, but collapse them into the single category of Appendix for the work below.
- Index (19.2%), which "serves to catalogue,

[3] "A preface is written by the author and is generally about the writing of the book. A foreword is a comment on the book and/or the author by another person. An introduction, which may by the author or another, may contain such matter, but it's primarily a preparation for, or explanation of, the content" (Lee, 2009)

with page indications, all the references which an author wishes to identify" (Wilson, 1993).

- N/A. For each of the nine categories above, we annotate the beginning and end pages present in a book; any page not contained within a labeled section receives the label N/A.

As Genette (1987) articulates, each of these structural categories mediates the relationship between the text and its audience, and each serves a different illocutionary purpose. The TITLE is addressed to the general public (not necessarily the readers) and is not only informational (informing of the name of the work), but also serves as important marketing material as well; PREFACES are addressed to readers, and may be written either by the author of the core content (*authorial*) or by another (*allographic*) and communicate the intention or interpretation of the work; the illocutionary force of a DEDICATION, in contrast, is performative: its very presence is a speech act that serves to dedicate the work to another.

Figure 3: Table of contents page listed as "Index."

For all categories, we label based on the tenor of the category's meaning, and not on the title of the section that may appear on the page. Figure 3 illustrates one such example of this distinction—a page whose function is to serve as a table of contents but is headed as an "Index" (and also appears at the back of the book, like contemporary indices); rather than functioning as an index in providing references to concepts within the text, it outlines the organizational structure of the sections (as a table of contents does).

Human judgments of these ten categories are relatively uncontroversial; to calculate the coherence of the task, we calculated the inter-annotator agreement rate for two annotators on 25 books, and find a chance-corrected Cohen's $\kappa = 0.83$, suggesting a very high level of agreement.[4] All books then receive a single judgment of page-level annotations by a single annotator.

3 Methods

To explore our ability to label book structure automatically, we test three different feature-rich classifiers. All make use of the same set of features.

3.1 Features

Keywords. Most words on a page are not predictive of the category to which it belongs; a word like *Britain* in a biography of Churchill may distinguish that book from other books, but will also equally be found on the title page, table of contents, preface, content, index, or any other category. Some words, however, are discriminative, such as the titles of the categories ("index," "preface," "dedication," etc.). To identify these terms, we train a unigram logistic regression classifier on the training-only partition of the data (described in section 4 below) and manually select keywords with high face validity. We create two sets of features from these keywords: presence of a keyword in the header of the page (the first four lines) and the presence of a keyword anywhere on the page.

Longest increasing subsequence. As figure 3 shows, tables of contents are distinguished from indices in that the page numbers generally increase from the top of the page to the bottom, corresponding to the linear order of the book. To capture this, we create a feature for the longest increasing subsequence (LIS) of numbers on the page. The LIS for any set of n randomly permuted numbers converges to a Tracy-Widom distribution (Baik et al., 1999); to enable feature value comparisons across pages with different total numbers, we conduct a permutation test by shuffling the numbers on the page and recalculating the LIS for that resample; we set the feature value to be 1 only when the observed LIS is greater than 5% of the LIS scores for the permutations (i.e., $p < 0.05$).

[4] Using the non-parametric bootstrap to account for the size of the sample in our confidence of the agreement rate, we find a 95% confidence interval for κ to be within the interval [0.65, 0.94].

Alphabetical sort. Indices, in contrast, are distinguished from tables of contents in that their lines are sorted alphabetically (from the top to the bottom of the page). To capture this, we create a feature measuring the degree to which the lines on a page are sorted, operationalized as the Spearman rank correlation coefficient (ρ) between the set of lines in their original order and the lines in sorted order. Perfectly sorted lines have a $\rho = 1$; inversely sorted lines have $\rho = -1$ and randomly ordered lines have an expected $\rho = 0$. To account for random sorting that take place by chance, we set this feature value to be ρ only when its p value (rejecting $H_0 \equiv \rho = 0) < 0.01$.

Letter distribution. In addition to measuring the degree which the full page is alphabetized, we can also capture important structural qualities of indices by measuring the degree to which initial letters in words are overrepresented on the page. We calculate this by measuring the empirical distribution of initial downcased letters `[a-z]` for all words in the book, and measure the degree to which the empirical distribution on the page overrepresents any individual letter. Rather than comparison the full distributions (using e.g., Jensen-Shannon divergence), we calculate the number of letters whose frequency on the page deviates from the book frequency for that letter by a z-score (accounting for the number of times we observe the letter) corresponding to a critical value $\alpha \leq 0.05$.

Roman numerals. Frontmatter preceding the main content is often paginated with roman numerals, rather than the arabic numerals found in the content. To capture this, we create a binary feature identifying the presence of roman numerals in the first four lines (header) or last four lines (footer) of the page, using the resources of Underwood (2017).

Page density. Content pages are relatively dense with characters (both letters and numbers); title pages and tables of contents are defined by greater volume of whitespace. To capture this differential, we introduce features for the ratio of words and numbers among all (whitespace-delimited) tokens and for the overall number of tokens observed.

Position. We create a set of binary features marking the position of the page within the book (appearance in the first ten pages, last ten pages, and in which quintile it appears), and its real-valued positional ratio within the book (page number divided by the total pages).

Page Sequence. Not all books distinguish frontmatter from the main content with roman numerals; to address this, we identify the page with the first marked page number and create a feature that captures whether a page appears before or after that first marked page.

TextTiling While all words are not indicative of the categories on their own, they can provide a natural segmentation of the book into discrete discourse chunks, in that the language that characterizes a given main content section may differ from that within an introduction (and certainly from more structured sections like indices or tables of contents). To capture this, we create a feature for each page derived from TextTiling (Hearst, 1997): for a given page at position i, we calculate the cosine similarity between the intervals [page$_1$, page$_{i-1}$] and [page$_i$, page$_n$].

The feature classes above total 172 features for each individual page. When representing a page as input to the models below, we also conjoin information about all pages within a window of three pages around the target page; each page is thus represented by a total of 7 × 172 distinct features. All non-binary features are standardized to standard normals, whose means and variances are estimated using the distribution observed in the training-only partition of the data.

3.2 Models

We compare three different model classes: a random forest (Breiman, 2001), which can capture complex nonlinearities in the feature space but is constrained to make independent predictions; an ℓ_2-regularized conditional random field (Lafferty et al., 2001), which can account for temporal dependencies in the predictions but is limited to linear relationships; and a bidirectional sequence labeling LSTM (Graves, 2012; Ma and Hovy, 2016), which can reason over sequential information while also capturing more complex non-linearities. The observed input to all methods for each page x_i is the same feature representation $f(x_i)$; the CRF also includes information about label transition features, decoding the entire sequence using Viterbi decoding; and the bidirectional LSTM captures persistent state information for each page as two H-dimensional hidden layers, one for the forward direction h_f and one for

Method	Accuracy	Macro precision	Macro recall	Macro F
Majority class	0.888	0.089	0.100	0.094

BiLSTM	0.958 [0.947, 0.968]	0.776 [0.741, 0.807]	0.670 [0.630, 0.709]	0.714 [0.679, 0.747]

Table 1: Full segment labeling, along with 95% bootstrap confidence intervals.

the backward direction h_b (we set $H = 25$ in these experiments). Predictions for each time step i are made using the vector concatenation of $[h^i_f; h^i_b]$.

4 Evaluation

We compare the performance of the three models described above at the task of page-level labeling: both the multiclass classification problem of predicting which of the 10 labels applies to each page, and the binary task of {TEXT, NON-TEXT} prediction, in which the nine front- and backmatter labels are collapsed into the single label NON-TEXT; while the former allows access to fine-grained categories of (e.g.) indices and tables of contents, the latter covers the common scenario where researchers are interested only in isolating where the core text begins and ends.

Experimentally, we divide the full training data into two partitions: a training-only partition of 400 books, on which we experiment with feature and model development, and a test partition of the remaining 655 books. All results presented below are the result of tenfold cross-validation on the test partition. Each fold trains on $\frac{8}{10}$ of the test data, uses $\frac{1}{10}$ of the 655 books as development for model selection (e.g., to optimize the ℓ_2 regularization parameter for the CRF, terminate training for the BiLSTM, and optimize the depth of the random forest), and uses $\frac{1}{10}$ of the 655 for test. We supplement each training fold with the 400 books from the training-only partition, but this data is never used for evaluation below.

In total, we evaluate the performance on 655 books and calculate 95% confidence intervals for each metric using the non-parametric bootstrap, drawing $B = 10,000$ resamples of books (not individual pages) in order to account for the statistical dependence between page-level predictions.

4.1 Full segment labeling

Table 1 presents the results for full multiclass segment labeling. To contextualize these results, we also provide a simple baseline of predicting the majority class (TEXT) for all pages; since most pages in a book are core content, this yields a high absolute accuracy against which to compare, but a low macro precision/recall/F score (which evenly weights the importance of each class).

All three methods achieve relatively similar performance when measured by absolute accuracy (though the room for improvement over the baseline is small). When treating all classes as equally important and measuring by the macro F score, both sequence labeling methods (CRF and bidirectional LSTM) show slight improvements over the independent predictions of a random forest, but not significantly so, suggesting that the feature representation of the book (which they all share as identical input) is perhaps a strong enough signal that mitigates the label dependencies.

Category	Precision	Recall	F	True n
Title	0.782	0.751	0.766	887
Dedication	0.630	0.489	0.551	188
Pubinfo	0.697	0.590	0.639	261

Appendix	0.688	0.412	0.515	2,460
N/A	0.894	0.801	0.845	9,791

Table 2: Individual category results, BiLSTM.

Table 2 lists the precision, recall and F-score results by category for the best-performing model (bidirectional LSTM). Several categories are worth calling out: the precision and recall for recognizing table of contents is high (≥ 0.84 for both metrics), suggesting that this method may provide a solid foundation for work in book structure extraction that relies on an identified table of contents in order to recognize the idiosyncratic structure of books. Title page and index recognition are also relatively high (0.89 precision/0.63 recall); what these three categories have in common are strong structural features (the distribution of ink and whitespace on the page; regularities in the numbers and the degree of alphabetization).

While dedications and publication information

Method	Accuracy	Macro P	Macro R	Macro F
Majority class	0.888	0.444	0.500	0.470
Chop	0.857	0.804	0.692	0.725
Random Forest	0.966 [0.953, 0.976]	0.947 [0.937, 0.956]	0.877 [0.836, 0.911]	0.908 [0.877, 0.931]
CRF	0.963 [0.949, 0.973]	0.887 [0.843, 0.921]	0.920 [0.896, 0.941]	0.902 [0.872, 0.926]
BiLSTM	0.965 [0.953, 0.974]	0.938 [0.924, 0.951]	0.881 [0.843, 0.913]	0.907 [0.880, 0.928]

Table 3: Content/non-content labeling, along with 95% bootstrap confidence intervals.

are both relatively infrequent (often occupying a single page in a book), the greatest point of confusion is in separating the main content from the structurally similar pages that typically precede it (in the preface) and follow it (in the appendix). While confusion between PREFACE/TEXT and APPENDIX/TEXT account for most of the errors, figure 4 illustrates several difficult cases and exemplary mistakes in the other categories: fig. 4a is a page that blurs the line between an index and table of contents; fig. 4b is an advertisement for a book "in the press and speedily will be published"; and fig. 4c is a dedication that, without strong lexical indicators, is mistaken for a title page.

In order to understand the contribution that individual features make on the predictions, we carry out an ablation test for each feature class, in which we remove a feature class from the model and perform exactly the same training and test procedure as described in section 4: we train a model on the training fold supplemented with the 400 books in the training partition, perform hyperparameter optimization on development data, and report accuracy on the held-out test fold, repeating ten times, once for each fold in cross-validation.

Feature	Δ Macro F-score
–Keywords	-0.15
–Position	-0.03
–Density	-0.02
–Window	-0.01
–Roman	-0.01
–Letter	-0.01
–LIS	0.00
–TextTiling	0.00
–Page sequence	0.00
–Alphabetical	0.01

Table 4: Feature ablation results for the BiLSTM model, illustrating the change in macro F-score that results by removing a given feature class from the full model.

The simplest features are the most informative: the small set of keywords learned from the training partition (which include common section labels like *preface*, *content*, *index*, *advertisement*, other informative markers such as *dedicated*, *copyright*, and currency markers like $, £), the position of the page in the book, and the density of characters (including words and numbers) on the page.

4.2 Content/non-content segment labeling

In order to assess the ability of these different features and models to demarcate the core text of a work, we binarize the multiclass label, assigning TEXT to all pages labeled TEXT in the multiclass setting, and NON-TEXT to all other pages. We train all three classifiers again on these binarized labels and repeat the training procedure for each model outlined in section 4.

Table 3 shows the results for the binary task of {TEXT, NOT-TEXT} prediction. Here again we contextualize these results with two simpler baselines: a simple majority class predictor (always predict TEXT), and a model that identifies the average start and end positions in a book for the first and last text page (respectively) within the training data, and predicts TEXT for pages within that range (roughly within the [0.10, 0.94] interval), and NON-TEXT for all pages outside of it. This corresponds to a heuristic that chops off the first 10% of a book and the last 6% as NON-TEXT.

The chop heuristic performs worse than the majority class predictor in terms of absolute accuracy, but improves over the class-balanced macro scores. All three feature-rich models show substantial improvements over all metrics, but are indistinguishable from each other, each achieving nearly identical performance. For this reduced purpose, any of the three classifiers are sufficient for segmenting TEXT from NON-TEXT, even a random forest making independent predictions for each page.

5 Related work

The work described here has points of intersection with several other threads of research. The most direct originates in work that grows out of the INEX and ICDAR book structure extraction com-

petitions (Kazai et al., 2009, 2010; Doucet et al., 2011, 2013), in which participants are challenged to recognize the fine-grained structure present in documents (recognizing, for example, that the current article has sections entitled "Abstract," "Introduction," "Data, "References," etc.). The most successful systems recognize structure by parsing the table of contents (Déjean and Meunier, 2005, 2009; Wu et al., 2013; Gao et al., 2009) rather than relying on the content of the book itself. Our work primarily differs in the fundamental design choice of prescribing a fix set of categories into which we classify pages (in order to enable comparison across documents) rather than prioritizing the idiosynractic structure of a book (which is useful for generating new tables of contents).

Given the relatively constant page-level categories that printers use to describe book design, we formulate our problem as a classification task into a set of pre-established categories. An alternative is to take an unsupervised approach, and learn the set of categories empirically from the data; this general problem of book segmentation in its unlabeled form shares functional similarity with other work in general unsupervised topic or discourse segmentation (Hearst, 1997; Utiyama and Isahara, 2001; Chen et al., 2009)—most notably, the work of Eisenstein and Barzilay (2008) (for whom the section labels may be considered a form of "cue words" akin to discourse markers). Given the amount of data in large-scale book collections, we see this as an interesting path forward (either in a fully unsupervised or semi-supervised setting); an unsupervised approach that includes aspects of metadata such as country of publication or publisher may also be fruitful in accommodating variation in printer's rules as a function of time and geographical location (books by French publishers, for example, often place the table of contents at the back of the book).

As figure 2 illustrates, one of the primary challenges that we face with the labeled segmentation of books is the degraded nature of the input; unlike contemporary business documents for which OCR is largely a solved problem, historical books present several challenges due to their binding, age, and significant variation in font and printing. Much work has focused on overcoming these limitations from several perspectives, including creating ground truth for historical books (Papadopoulos et al., 2013), bootstrapping their alignment with existing resources (Feng and Manmatha, 2006; Yalniz and Manmatha, 2011), exploiting the fact that books often have multiple scans or printings that could be leveraged (Smith et al., 2011; Wemhoener et al., 2013) or developing methods that account for variation in the printing process (Berg-Kirkpatrick et al., 2013; Berg-Kirkpatrick and Klein, 2014).

Large-scale book corpora are increasingly being used as the raw material for linguistic analysis, especially those focused on measuring historical change (Hamilton et al., 2016a,b; Kulkarni et al., 2015; Mitra et al., 2014; Mihalcea and Nastase, 2012; Kim et al., 2014). These studies use not only the observed word frequencies provided by the Google Ngram dataset, but also increasingly structured representations of language as well (Lin et al., 2012; Goldberg and Orwant, 2013). The task of labeled book segmentation may be helpful in reducing the noise inherent in the use of statistics aggregated from these large datasets—both in terms of filtering out the 11% of all pages that are not the core content (e.g., such as indices), and also in grounding the text at the appropriate date for historical analysis (such as deriving statistics only from the core content, and not from an introduction written years afterward).

6 Conclusion

We introduce in this work the task of *book structure labeling*, the problem of assigning to each page in a printed book its membership in one of a set of predetermined categories. In annotating a large dataset of books, we are able to empirically assess the ability to accurately segment and label books from a range of historical time periods.

The ten categories that form our typology are drawn from printers' guides and informed by contemporary criticism, but still reflect our historical present; while we have in part let our categories be shaped by our experience labeling texts (so that we have preserved in our annotations historical categories not in contemporary use, such as SUBSCRIBERS), we recognize that the act of categorization glosses over meaningful distinctions—for example, while we have grouped sections marked ADVERTISEMENT, TO THE READER, PREFACE, INTRODUCTION, FOREWORD and others into the single category of PREFACE, such labels may have historically significant differences that may be worth preserving for some analyses. Nevertheless, we expect the coarse distinctions we outline here to occasion research that requires access to those broad categories. Potential uses of this work include using the categories directly to answer questions in book history (e.g., charting the historical prevalence of advertisements and their variation across time), improving the task of idiosyncratic structure detection by identifying tables of contents, and identifying the fine-grained topics of books by parsing recognized indices.

In this work, we deliberately focus on the resource-deficient scenario most commonly encountered by researchers working with large book corpora, in which books are represented as the output of errorful OCR. In providing a labeled dataset for others to use, we hope to encourage other work that reasons about the structure present in alternative representations (such as images) as well.

Abstract

Even for common NLP tasks, sufficient supervision is not available in many languages—morphological tagging is no exception. In the work presented here, we explore a transfer learning scheme, whereby we train character-level recurrent neural taggers to predict morphological taggings for high-resource languages and low-resource languages together. Learning joint character representations among multiple related languages successfully enables knowledge transfer from the high-resource languages to the low-resource ones, improving accuracy by up to 30%.

1 Introduction

State-of-the-art morphological taggers require thousands of annotated sentences to train. For the majority of the world's languages, however, sufficient large-scale annotation is not available and obtaining it would often be infeasible. Accordingly, an important road forward in low-resource NLP is the development of methods that allow for the training of high-quality tools from smaller amounts of data. In this work, we focus on transfer learning—we train a recurrent neural tagger for a low-resource language jointly with a tagger for a related high-resource language. Forcing the models to share character-level features among the languages allows large gains in accuracy when tagging the low-resource languages, while maintaining (or even improving) accuracy on the high-resource language.

Recurrent neural networks constitute the state of the art for a myriad of tasks in NLP, e.g., multilingual part-of-speech tagging (Plank et al., 2016), syntactic parsing (Dyer et al., 2015; Zeman et al., 2017), morphological paradigm completion (Cotterell et al., 2016, 2017) and language modeling (Sundermeyer et al., 2012; Melis et al., 2017); recently, such models have also improved morphological tagging (Heigold et al., 2016, 2017). In addition to increased performance over classical approaches, neural networks also offer a second advantage: they admit a clean paradigm for multitask learning. If the learned representations for all of the tasks are embedded jointly into a shared vector space, the various tasks reap benefits from each other and often performance improves for all (Collobert et al., 2011b). We exploit this idea for language-to-language transfer to develop an approach for cross-lingual morphological tagging.

We experiment on 18 languages taken from four different language families. Using the Universal Dependencies treebanks, we emulate a low-resource setting for our experiments, e.g., we attempt to train a morphological tagger for Catalan using primarily data from a related language like Spanish. Our results demonstrate the successful transfer of morphological knowledge from the high-resource languages to the low-resource languages without relying on an externally acquired bilingual lexicon or bitext. We consider both the single- and multi-source transfer case and explore how similar two languages must be in order to enable high-quality transfer of morphological taggers.[1]

2 Morphological Tagging

Many languages in the world exhibit rich inflectional morphology: the form of individual words mutates to reflect the syntactic function. For example, the Spanish verb *soñar* will appear as *sueño* in the first person present singular, but *soñáis* in the second person present plural, depending on the bundle of syntaco-semantic attributes associated with

[1] While we only experiment with languages in the same family, we show that closer languages within that family are better candidates for transfer. We remark that future work should consider the viability of more distant language pairs.

2	*sueñas*	*soñáis*	*soñaste*	*soñasteis*
3	*sueña*	*sueñan*	*soñó*	*soñaron*

Table 1: Partial inflection table for the Spanish verb *soñar*

the given form (in a sentential context). For concreteness, we list a more complete table of Spanish verbal inflections in Table 1. Note that some languages, e.g., Archi, Northeast Caucasian language, display a veritable cornucopia of potential forms with the size of the verbal paradigm exceeding 10,000 (Kibrik, 1998).

Standard NLP annotation, e.g., the scheme in Sylak-Glassman et al. (2015), marks forms in terms of *universal* key-attribute pairs, e.g., the first person present singular is represented as [pos=V, per=1, num=SG, tns=PRES]. This bundle of key-attributes pairs is typically termed a morphological tag and we may view the goal of morphological tagging to label each word in its sentential context with the appropriate tag (Oflazer and Kuruöz, 1994; Hajič and Hladká, 1998). As the part-of-speech (POS) is a component of the tag, we may view morphological tagging as a strict generalization of POS tagging, where we have significantly refined the set of available tags. All of the experiments in this paper make use of the universal morphological tag set available in the Universal Dependencies (UD) (Nivre et al., 2016). As an example, we have provided a Russian sentence with its UD tagging in Figure 1.

Transferring Morphology. The transfer of morphology is arguably more dependent on the relatedness of the languages in question than other annotations in NLP, such as POS and named entity recognition (NER). POS lends itself nicely to a universal annotation scheme (Petrov et al., 2012) and traditional NER is limited to a small number of cross-linguistically compliant categories, e.g., PERSON and PLACE. Even universal dependency arcs employ cross-lingual labels (Nivre et al., 2016).

Morphology, on the other hand, typically requires more fine-grained annotation, e.g., grammatical case and tense. It is often the case that one language will make a semantic distinction in the form (or at all) that another does not. For example, the Hungarian noun overtly marks 17 grammatical cases and Slavic verbs typically distinguish two aspects through morphology, while English marks none of these distinctions. If the word form in the source language does not overtly mark a grammatical category in the target language, it is nigh-impossible to expect a successful transfer. For this reason, much of our work focuses on the transfer of related languages—specifically exploring *how* close two languages must be for a successful transfer. Note that the language-specific nature of morphology does not contradict the universality of the annotation; each language may mark a different subset of categories, i.e., use a different set of the universal keys and attributes, but there is a single, universal set, from which the key-attribute pairs are drawn. See Newmeyer (2007) for a linguistic treatment of cross-lingual annotation.

Notation. We will discuss morphological tagging in terms of the following notation. We will consider two (related) languages: a high-resource *source* language ℓ_s and a low-resource *target* language ℓ_t. Each of these languages will have its own (potentially overlapping) set of morphological tags, denoted $\mathcal{T}_s$ and $\mathcal{T}_t$, respectively. We will work with the union of both sets $\mathcal{T} = \mathcal{T}_s \cup \mathcal{T}_t$. An individual tag $m_i = [k_1{=}v_1, \ldots, k_M{=}v_M] \in \mathcal{T}$ is comprised of universal keys and attributes, i.e., the pairs (k_i, v_i) are completely language-agnostic. In the case where a language does not mark a distinction, e.g., case on English nouns, the corresponding keys are excluded from the tag. Typically, $|\mathcal{T}|$ is large (see Table 3). We denote the set of training sentences for the high-resource source language as $\mathcal{D}_s$ and the set of training sentences for the low-resource target language as $\mathcal{D}_t$. In the experimental section, we will also consider a multi-source setting where we have multiple high-resource languages, but, for ease of explication, we stick to the single-source case in the development of the model.

3 Character-Level Neural Transfer

Our formulation of transfer learning builds on work in multi-task learning (Caruana, 1997; Collobert et al., 2011b). We treat each individual language as a task and train a joint model for all the tasks. We first discuss the current state of the art in morphological tagging: a character-level recurrent neural network. After that, we explore three augmentations to the architecture that allow for the transfer learning scenario. All of our proposals force the embedding of the characters for both the source and the target language to share the same vector space, but involve different mechanisms, by which the model may learn language-specific features.

3.1 Character-Level Neural Networks

Character-level neural networks currently constitute the state of the art in morphological tagging (Heigold et al., 2017). We draw on previous work in defining a conditional distribution over taggings $\boldsymbol{t}$ for a sentence $\boldsymbol{w}$ of length $|\boldsymbol{w}| = N$ as

$$p_{\boldsymbol{\theta}}(\boldsymbol{t} \mid \boldsymbol{w}) = \prod_{i=1}^{N} p_{\boldsymbol{\theta}}(t_i \mid \boldsymbol{w}), \tag{1}$$

which may be seen as a 0^{th} order conditional random field (CRF) (Lafferty et al., 2001) with parameter vector $\boldsymbol{\theta}$.[2] Importantly, this factorization of the distribution $p_{\boldsymbol{\theta}}(\boldsymbol{t} \mid \boldsymbol{w})$ also allows for efficient exact decoding and marginal inference in $\mathcal{O}(|\mathcal{T}| \cdot N)$-time, but at the cost of not admitting any explicit interactions in the output structure, i.e., between adjacent tags.[3] We parameterize the distribution over tags at each time step as

$$p_{\boldsymbol{\theta}}(t_i \mid \boldsymbol{w}) = \text{softmax}\left(W\boldsymbol{e}_i + \boldsymbol{b}\right), \tag{2}$$

where $W \in \mathbb{R}^{|\mathcal{T}| \times n}$ is an embedding matrix, $\boldsymbol{b} \in \mathbb{R}^{|\mathcal{T}|}$ is a bias vector and positional embeddings $\boldsymbol{e}_i$[4] are taken from a concatenation of the output of two long short-term memory recurrent neural networks (LSTMs) (Hochreiter and Schmidhuber, 1997), folded forward and backward, respectively, over a sequence of input vectors. This constitutes a bidirectional LSTM (Graves and Schmidhuber, 2005). We define the positional embedding vector as follows

$$\boldsymbol{e}_i = \left[\text{LSTM}(\boldsymbol{v}_{1:i}); \text{LSTM}(\boldsymbol{v}_{N,i+1})\right], \tag{3}$$

where each $\boldsymbol{v}_i \in \mathbb{R}^n$ is, itself, a word embedding. Note that the function LSTM returns the *last* final hidden state vector of the network. This architecture is the *context* bidirectional recurrent neural network of Plank et al. (2016). Finally, we derive each word embedding vector $\boldsymbol{v}_i$ from a character-level bidirectional LSTM embedder. Namely, we define each word embedding as the concatenation

$$\begin{aligned}\boldsymbol{v}_i = \Big[&\text{LSTM}\left(\langle c_{i_1}, \ldots, c_{i_{M_i}}\rangle\right); \\ &\text{LSTM}\left(\langle c_{i_{M_i}}, \ldots, c_{i_1}\rangle\right)\Big].\end{aligned} \tag{4}$$

In other words, we run a bidirectional LSTM over the character stream. This bidirectional LSTM is the *sequence* bidirectional recurrent neural network of Plank et al. (2016). Note a concatenation of the sequence of character symbols $\langle c_{i_1}, \ldots, c_{i_{M_i}}\rangle$ results in the word string w_i. Each of the M_i characters c_{i_k} is a member of the set Σ. We take Σ to be the union of sets of characters in the languages considered.

We direct the reader to Heigold et al. (2017) for a more in-depth discussion of this and various additional architectures for the computation of $\boldsymbol{v}_i$; the architecture we have presented in Equation (5) is competitive with the best performing setting in Heigold et al.'s study.

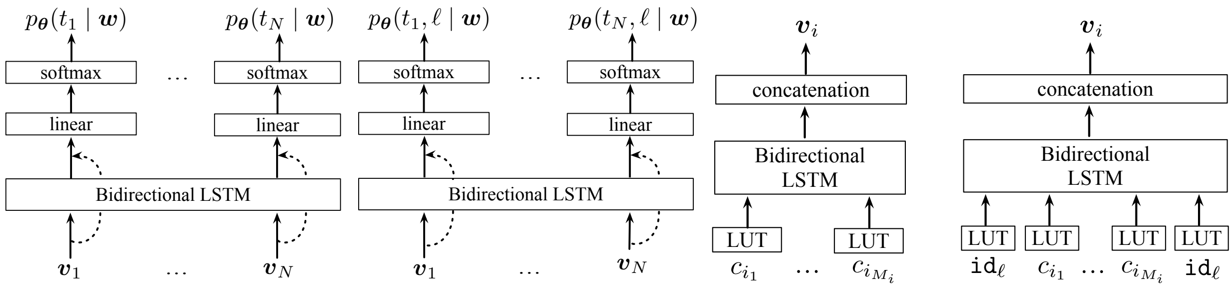
3.2 Cross-Lingual Morphological Transfer as Multi-Task Learning

Cross-lingual morphological tagging may be formulated as a multi-task learning problem. We seek to learn a set of shared character embeddings for taggers in both languages together through optimization of a joint loss function that combines the high-resource tagger and the low-resource one. The first loss function we consider is the following:

[2] The parameter vector $\boldsymbol{\theta}$ is a vectorization of all the parameters discussed below.

[3] As an aside, it is quite interesting that a model with the factorization in Equation (1) outperforms the MARMOT model (Müller et al., 2013), which focused on modeling higher-order interactions between the morphological tags, e.g., they employ up to a (pruned) 3rd order CRF. That such a model achieves state-of-the-art performance indicates, however, that richer source-side features, e.g., those extracted by our character-level neural architecture, are more important for morphological tagging than higher-order tag interactions, which come with the added unpleasantness of exponential (in the order) decoding.

[4] Note that $|\boldsymbol{e}_i| = n$; see §4.4 for the exact values used in the experimentation.



(a) Vanilla architecture for neural morphological tagging.

(b) Joint morphological tagging and language identification.

(c) Character-level biLSTM embedder.

(d) Language-specific biLSTM embedder.

Figure 2: We depict four subarchitectures used in the models we develop in this work. Combining (a) with the character embeddings in (c) gives the vanilla morphological tagging architecture of Heigold et al. (2017). Combining (a) with (d) yields the language-universal softmax architecture and (b) and (c) yields our joint model for language identification and tagging.

$$\mathcal{L}_{multi}(\boldsymbol{\theta}) = \sum_{(\boldsymbol{t},\boldsymbol{w})\in\mathcal{D}_s} \log p_{\boldsymbol{\theta}}(\boldsymbol{t} \mid \boldsymbol{w}, \ell_s) + \sum_{(\boldsymbol{t},\boldsymbol{w})\in\mathcal{D}_t} \log p_{\boldsymbol{\theta}}\left(\boldsymbol{t} \mid \boldsymbol{w}, \ell_t\right). \quad (5)$$

Crucially, our cross-lingual objective forces both taggers to share part of the parameter vector $\boldsymbol{\theta}$, which allows it to represent morphological regularities between the two languages in a common embedding space and, thus, enables transfer of knowledge. This is no different from monolingual multi-task settings, e.g., jointly training a chunker and a tagger for the transfer of syntactic information (Collobert et al., 2011b). We point out that, in contrast to our approach, almost all multi-task transfer learning, e.g., for dependency parsing (Guo et al., 2016), has shared word-level embeddings rather than character-level embeddings. See §6 for a more complete discussion.

We consider two parameterizations of this distribution $p_{\boldsymbol{\theta}}(t_i \mid \boldsymbol{w}, \ell)$. First, we modify the initial character-level LSTM embedding such that it also encodes the identity of the language. Second, we modify the softmax layer, creating a language-specific softmax.

Language-Universal Softmax. Our first architecture has one softmax, as in Equation (2), over all morphological tags in $\mathcal{T}$ (shared among all the languages). To allow the architecture to encode morphological features specific to one language, e.g., the third person present plural ending in Spanish is *-an*, but *-ão* in Portuguese, we modify the creation of the character-level embeddings. Specifically, we augment the character alphabet Σ with a distinguished symbol that indicates the language: $\mathtt{id}_\ell$. We then pre- and postpend this symbol to the character stream for every word before feeding the characters into the bidirectional LSTM Thus, we arrive at the new *language-specific* word embeddings,

$$\boldsymbol{v}_i^\ell = \Big[\text{LSTM}\left(\langle \mathtt{id}_\ell, c_{i_1}, \ldots, c_{i_{M_i}}, \mathtt{id}_\ell \rangle\right); \text{LSTM}\left(\langle \mathtt{id}_\ell, c_{i_{M_i}}, \ldots, c_{i_1}, \mathtt{id}_\ell \rangle\right)\Big]. \quad (6)$$

This model creates a language-specific embedding vector $\boldsymbol{v}_i$, but the individual embeddings for a given character are shared among the languages jointly trained on. The remainder of the architecture is held constant.

Language-Specific Softmax. Next, inspired by the architecture of Heigold et al. (2013), we consider a language-specific softmax layer, i.e., we define a new output layer for every language:

$$p_{\boldsymbol{\theta}}\left(t_i \mid \boldsymbol{w}, \ell\right) = \text{softmax}\left(W_\ell \boldsymbol{e}_i + \boldsymbol{b}_\ell\right), \quad (7)$$

where $W_\ell \in \mathbb{R}^{|\mathcal{T}|\times n}$ and $\boldsymbol{b}_\ell \in \mathbb{R}^{|\mathcal{T}|}$ are now *language-specific*. In this architecture, the embeddings $\boldsymbol{e}_i$ are the same for all languages—the model has to learn language-specific behavior exclusively through the output softmax of the tagging LSTM.

Joint Morphological Tagging and Language Identification. The third model we exhibit is a joint architecture for tagging and language identification. We consider the following loss function:

$$\mathcal{L}_{joint}(\boldsymbol{\theta}) = \sum_{(\boldsymbol{t},\boldsymbol{w})\in\mathcal{D}_s} \log p_{\boldsymbol{\theta}}(\ell_s, \boldsymbol{t} \mid \boldsymbol{w}) + \sum_{(\boldsymbol{t},\boldsymbol{w})\in\mathcal{D}_t} \log p_{\boldsymbol{\theta}}\left(\ell_t, \boldsymbol{t} \mid \boldsymbol{w}\right), \quad (8)$$

where we factor the joint distribution as

$$p_{\boldsymbol{\theta}}\left(\ell, \boldsymbol{t} \mid \boldsymbol{w}\right) = p_{\boldsymbol{\theta}}\left(\ell \mid \boldsymbol{w}\right) \cdot p_{\boldsymbol{\theta}}\left(\boldsymbol{t} \mid \boldsymbol{w}, \ell\right). \quad (9)$$

Table 2: Number of tokens in each of the train, development and test splits (organized by language family).

Just as before, we define $p_{\boldsymbol{\theta}}(\boldsymbol{t} \mid \boldsymbol{w}, \ell)$ above as in Equation (7) and we define

$$p_{\boldsymbol{\theta}}(\ell \mid \boldsymbol{w}) = \text{softmax}\left(\boldsymbol{u}^\top \tanh(V\boldsymbol{e}_i)\right), \qquad (10)$$

which is a multi-layer perceptron with a binary softmax (over the two languages) as an output layer; we have added the additional parameters $V \in \mathbb{R}^{|\mathcal{T}|\times n}$ and $\boldsymbol{u} \in \mathbb{R}^{|\mathcal{T}|}$. In the case of multi-source transfer, this is a softmax over the set of languages.

Comparative Discussion. The first two architectures discussed in §3.2 represent two possibilities for a multi-task objective, where we condition on the language of the sentence. The first integrates this knowledge at a lower level and the second at a higher level. The third architecture discussed in §3.2 takes a different tack—rather than conditioning on the language, it predicts it. The joint model offers one interesting advantage over the two architectures proposed. Namely, it allows us to perform a morphological analysis on a sentence where the language is unknown. This effectively alleviates an early step in the NLP pipeline, where language id is performed and is useful in conditions where the language to be tagged may not be known *a-priori*, e.g., when tagging social media data.

While there are certainly more complex architectures one could engineer for the task, we believe we have found a relatively diverse sampling, enabling an interesting experimental comparison. Indeed, it is an important empirical question which architectures are most appropriate for transfer learning. Since transfer learning affords the opportunity to reduce the sample complexity of the "data-hungry" neural networks that currently dominate NLP research, finding a good solution for cross-lingual transfer in state-of-the-art neural models will likely be a boon for low-resource NLP in general.

Table 3: Number of unique morphological tags for each of the experimental languages (organized by language family).

4 Experiments

Empirically, we ask three questions of our architectures. i) How well can we transfer morphological tagging models from high-resource languages to low-resource languages in each architecture? (Does one of the three outperform the others?) ii) How many annotated data in the low-resource language do we need? iii) How closely related do the languages need to be to get good transfer?

4.1 Experimental Languages

We experiment with the language families: Romance (Indo-European), Northern Germanic (Indo-European), Slavic (Indo-European) and Uralic. In the Romance sub-grouping of the wider Indo-European family, we experiment on Catalan (ca), French (fr), Italian (it), Portuguese (pt), Romanian (ro) and Spanish (es). In the Northern Germanic family, we experiment on Danish (da), Norwegian (no) and Swedish (sv). In the Slavic family, we experiment on Bulgarian (bg), Czech (bg), Polish (pl), Russian (ru), Slovak (sk) and Ukrainian (uk). Finally, in the Uralic family we experiment on Estonian (et), Finnish (fi) and Hungarian (hu).

4.2 Datasets

We use the morphological tagging datasets provided by the Universal Dependencies (UD) treebanks (the concatenation of the 4th and 6th columns of the file format) (Nivre et al., 2016). We list the size of the training, development and test splits of the UD treebanks we used in Table 2. Also, we list the number of unique morphological tags in each language in Table 3, which serves as an approximate measure of the morphological complexity each language exhibits. Crucially, the data are annotated in a cross-linguistically consistent manner, such that words in the different languages that have the same syntacto-semantic function have the same bundle of tags (see §2 for a discussion). Potentially, further gains would be possible by using a more universal scheme, e.g., the UNIMORPH scheme.

4.3 Baselines

We consider two baselines in our work. First, we consider the MARMOT tagger (Müller et al., 2013), which is currently the best performing non-neural model. The source code for MARMOT is freely available online,[5] which allows us to perform fully controlled experiments with this model. Second, we consider the alignment-based projection approach of Buys and Botha (2016).[6] We discuss each of the two baselines in turn.

4.3.1 Higher-Order CRF Tagger

The MARMOT tagger is the leading non-neural approach to morphological tagging. This baseline is important since non-neural, feature-based approaches have been found empirically to be more efficient, in the sense that their learning curves tend to be steeper. Thus, in the low-resource setting we would be remiss to not consider a feature-based approach. Note that this is not a transfer approach, but rather only uses the low-resource data.

4.3.2 Alignment-based Projection

The projection approach of Buys and Botha (2016) provides an alternative method for transfer learning. The idea is to construct pseudo-annotations for bitext given cross-lingual alignments (Och and Ney, 2003). Then, one trains a standard tagger using the projected annotations. The specific tagger employed is the WSABIE model of Weston et al. (2011), which—like our approach— is a 0th-order discriminative neural model. In contrast to ours, however, their network is shallow. We compare the two methods in more detail in §6.

4.3.3 Architecture Study

Additionally, we perform a thorough study of the neural transfer learner, considering all three architectures. A primary goal of our experiments is to determine which of our three proposed neural transfer techniques is superior. Even though our experiments focus on morphological tagging, these architectures are more general in that they may be easily applied to other tasks, e.g., parsing or machine translation. We additionally explore the viability of multi-source transfer, i.e., the case where we have multiple source languages. All of our architectures generalize to the multi-source case without any complications.

4.4 Experimental Details

We train our models with the following conditions.

Evaluation Metrics. We evaluate using average per token accuracy, as is standard for both POS tagging and morphological tagging, and per feature F_1 as employed in Buys and Botha (2016). The per feature F_1 calculates a key F_1^k for each key in the target language's tags by asking if the key-attribute pair $k_i{=}v_i$ is in the predicted tag. Then, the key-specific F_1^k values are averaged equally. Note that F_1 is a more flexible metric as it gives partial credit for getting some of the attributes in the bundle correct, where accuracy does not.

Hyperparameters. Our networks are four layers deep (two LSTM layers for the character embedder, i.e., to compute $\boldsymbol{v}_i$ and two LSTM layers for the tagger, i.e., to compute $\boldsymbol{e}_i$) and we use an embedding size of 128 for the character input vector size and hidden layers of 256 nodes in all other cases. All networks are trained with the stochastic gradient method RMSProp (Tieleman and Hinton, 2012), with a fixed initial learning rate and a learning rate decay that is adjusted for the other languages according to the amount of training data. The batch size is always 16. Furthermore, we use dropout (Srivastava et al., 2014). The dropout probability is set to 0.2. We used Torch 7 (Collobert et al., 2011a) to configure the computation graphs implementing the network architectures.

5 Results and Discussion

We report our results in three tables. First, we report a detailed cross-lingual evaluation in Table 4. Secondly, we report a comparison against two baselines in Table 5 (accuracy) and Table 6 (F_1). We see two general trends of the data. First, we find that genetically closer languages yield better source languages. Second, we find that the multi-softmax architecture is the best in terms of transfer ability, as evinced by the results in Table 4. We find a wider gap between our model and the baselines under the accuracy than under F_1. We attribute this

[5] http://cistern.cis.lmu.de/marmot/

[6] We do not have access to the code as the model was developed in industry, so we compare to the numbers reported in the original paper, as well as additional numbers provided to us by the first author in a personal communication. The numbers will not be, strictly speaking, comparable. However, we hope they provide insight into the relative performance of the tagger.

(d) Results for the Uralic languages.

Table 4: Results for transfer learning with our joint model. The tables highlight that the best source languages are often genetically and typologically closest. Also, we see that multi-source often helps, albeit more often in the $|\mathcal{D}_t| = 100$ case.

to the fact that F_1 is a softer metric in that it assigns credit to partially correct guesses.

Source Language. As discussed in §2, the transfer of morphology is language-dependent. This intuition is borne out in the results from our study (see Table 4). We see that in the closer grouping of the Western Romance languages, i.e., Catalan, French, Italian, Portuguese, and Spanish, it is easier to transfer than with Romanian, an Eastern Romance language. Within the Western grouping, we see that the close pairs, e.g., Spanish and Portuguese, are amenable to transfer. We find a similar pattern in the other language families, e.g., Russian is the best source language for Ukrainian, Czech is the best language source for Slovak and Finnish is the best source language for Estonian.

Multi-Source Transfer. In many cases, we find that multiple sources noticeably improve the results over the single-source case. For instance, when we have multiple Romance languages as a source language, we see gains of up to 2%. We also see gains in the Northern Germanic languages when using multiple source languages. From a linguistic point of view, this is logical as different source languages may be similar to the target language along different dimensions, e.g., when transferring among the Slavic languages, we note that Russian retains the complex nominal case system of Serbian, but south Slavic Bulgarian is lexically more similar.

Performance Against the Two Baselines. As shown in Table 5 and Table 6, our model outperforms the projection tagger of Buys and Botha (2016) even though our approach does not utilize bitext, large-scale alignment or monolingual corpora—rather, all transfer between languages happens through the forced sharing of character-level features.[7] Our model, does, however, require

[7] We would like to highlight some issues of comparability with the results in Buys and Botha (2016). Strictly speaking, the results are not comparable and our improvement over their method should be taken with a grain of salt. As the source code is not publicly available and developed in industry, we resorted to numbers in their published work and additional numbers

Table 5: Comparison of our approach to various baselines for low-resource tagging under token-level accuracy. We compare on only those languages in Buys and Botha (2016). Note that tag-level accuracy was not reported in the original B&B paper, but was acquired through personal communication with the first author. All architectures presented in this work are used in their multi-source setting. The B&B and MarMoT models are single-source.

annotation of a small number of sentences in the target language for training. We note, however, that this does not necessitate a large number of human annotation hours (Garrette and Baldridge, 2013).

Reducing Sample Complexity. Another interesting a point about our model that is best evinced in Figure 3 is the feature-based CRF approach seems to be a better choice for the low-resource setting, i.e., the neural model has greater sample complexity. However, in the multi-task scenario, we find that the neural tagger's learning curve is even steeper. In other words, if we have to train a tagger on very little data, we are better off using a neural multi-task approach than a feature-based approach; preliminary attempts to develop a multi-task version of MarMoT failed (see Figure 3).

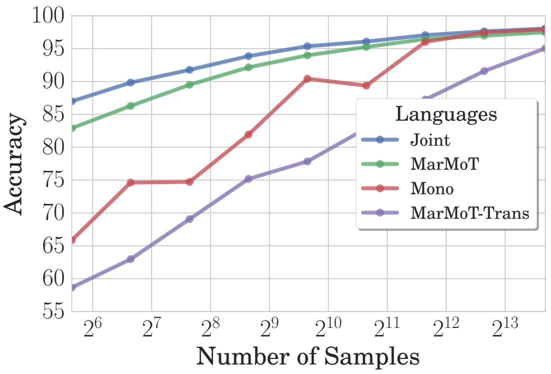

Figure 3: Learning Curve for Spanish and Catalan comparing our monolingual model, our joint model and two MarMoT models. The first MarMoT model is identical to those trained in the rest of the paper and the second attempts a multi-task approach, which failed so no further experimentation was performed with this model.

6 Related Work

We divide the discussion of related work topically into three parts for ease of intellectual digestion.

6.1 Alignment-Based Distant Supervision.

Most cross-lingual work in NLP—focusing on morphology or otherwise—has concentrated on indirect supervision, rather than transfer learning. The goal in such a regime is to provide noisy labels for training the tagger in the low-resource language through annotations projected over aligned bitext with a high-resource language. This method of projection was first introduced by Yarowsky and Ngai (2001) for the projection of POS annotation. While follow-up work (Fossum and Abney, 2005; Das and Petrov, 2011; Täckström et al., 2012) has continually demonstrated the efficacy of projecting simple part-of-speech annotations, Buys and Botha (2016) were the first to show the use of bitext-based projection for the training of a *morphological* tagger for low-resource languages.

As we also discuss the training of a morphological tagger, our work is most closely related to Buys and Botha (2016) in terms of the task itself. We contrast the approaches. The main difference lies therein, that our approach is not projection-based and, thus, does not require the construction of a bilingual lexicon for projection based on bitext.

obtained through direct communication with the authors. First, we used a slightly newer version of UD to incorporate more languages: we used v2 whereas they used v1.2. There are minor differences in the morphological tagset used between these versions. Also, in the $|\mathcal{D}_t| = 1000$ setting, we are training on significantly more data than the models in Buys and Botha (2016). A much fairer comparison is to our models with $|\mathcal{D}_t| = 100$. Also, we compare to their method using their standard (non) setup. This method is fair in so far as we evaluate in the same manner, but it disadvantages their approach, which cannot predict tags that are not in the source language.

Table 6: Comparison of our approach to various baselines for low-resource tagging under F_1 to allow for a more complete comparison to the model of Buys and Botha (2016). All architectures presented in this work are used in their multi-source setting. The B&B and MarMoT models are single-source. We only compare on those languages used in B&B.

Rather, our method jointly learns multiple taggers and forces them to share features—a true transfer learning scenario. In contrast to projection-based methods, our procedure always requires a minimal amount of annotated data in the low-resource target language—in practice, however, this distinction is non-critical as projection-based methods without a small mount of seed target language data perform poorly (Buys and Botha, 2016).

6.2 Character-level NLP.

Our work also follows a recent trend in NLP, whereby traditional word-level neural representations are being replaced by character-level representations for a myriad tasks, e.g., POS tagging dos Santos and Zadrozny (2014), parsing (Ballesteros et al., 2015), language modeling (Ling et al., 2015), sentiment analysis (Zhang et al., 2015) as well as the tagger of Heigold et al. (2017), whose work we build upon. Our work is also related to recent work on character-level morphological generation using neural architectures (Faruqui et al., 2016; Rastogi et al., 2016).

6.3 Neural Cross-lingual Transfer in NLP.

In terms of methodology, however, our proposal bears similarity to recent work in speech and machine translation–we discuss each in turn. In speech recognition, Heigold et al. (2013) train a cross-lingual neural acoustic model on five Romance languages. The architecture bears similarity to our multi-language softmax approach. Dependency parsing benefits from cross-lingual learning in a similar fashion (Guo et al., 2015, 2016).

In neural machine translation (Sutskever et al., 2014; Bahdanau et al., 2015), recent work (Firat et al., 2016; Zoph and Knight, 2016; Johnson et al., 2016) has explored the possibility of jointly train translation models for a wide variety of languages. Our work addresses a different task, but the undergirding philosophical motivation is similar, i.e., attack low-resource NLP through multi-task transfer learning. Kann et al. (2017) offer a similar method for cross-lingual transfer in morphological inflection generation.

7 Conclusion

We have presented three character-level recurrent neural network architectures for multi-task cross-lingual transfer of morphological taggers. We provided an empirical evaluation of the technique on 18 languages from four different language families, showing wide-spread applicability of the method. We found that the transfer of morphological taggers is an eminently viable endeavor among related language and, in general, the closer the languages, the easier the transfer of morphology becomes. Our technique outperforms two strong baselines proposed in previous work. Moreover, we define standard low-resource training splits in UD for future research in low-resource morphological tagging. Future work should focus on extending the neural morphological tagger to a joint lemmatizer (Müller et al., 2015) and evaluate its functionality in the low-resource setting.

Abstract

Neural parsers have benefited from automatically labeled data via dependency-context word embeddings. We investigate training character embeddings on a word-based context in a similar way, showing that the simple method significantly improves state-of-the-art neural word segmentation models, beating tri-training baselines for leveraging auto-segmented data.

1 Introduction

Neural network Chinese word segmentation (CWS) models (Zhang et al., 2016; Liu et al., 2016; Cai and Zhao, 2016) appeal for their strong ability of feature representation, employing unigram and bigram character embeddings as input features (Zheng et al., 2013; Pei et al., 2014; Ma and Hinrichs, 2015; Chen et al., 2015a). They give state-of-the-art performances. We investigate leveraging automatically segmented texts for enhancing their accuracies.

Such semi-supervised methods can be divided into two main categories. The first one is *bootstrapping*, which includes *self-training* and *tri-training*. The idea is to generate more training instances by automatically labeling large-scale data. Self-training (Yarowsky, 1995; McClosky et al., 2006; Huang et al., 2010; Liu and Zhang, 2012) labels additional data by using the base classifier itself, and tri-training (Zhou and Li, 2005; Li et al., 2014) uses two extra classifiers, taking the instances with the same labels for additional training data. A second semi-supervised learning method in NLP is *knowledge distillation*, which extracts knowledge from large-scale auto-labeled data as features.

Tri-training has been used in neural parsing, giving considerable improvements for both of dependency (Weiss et al., 2015) and constituent parsing (Vinyals et al., 2015; Choe and Charniak, 2016). Knowledge from auto-labeled data has also been used for parsing (Bansal et al., 2014; Melamud et al., 2016), where word embeddings are trained on automatic dependency tree context. Such knowledge has also been proved effective in conventional discrete CWS models, such as *label distribution information* (Wang et al., 2011; Zhang et al., 2013). However, it has not been investigated for neural CWS.

We propose *word-context character embeddings* (WCC), using segmentation label information in the pre-training of unigram and bigram character embeddings. The method packs the label distribution information into the embeddings, which could be regarded as a way for knowledge parameterization. Our idea follows Levy and Goldberg (2014), who use *dependency contexts* to train *word embeddings*. Additionally, motivated by co-training, we propose *multi-view word-context character embeddings* for cross-domain segmentation, which pre-trains two types of embedding for in-domain and out-of-domain data, respectively. In-domain embeddings are used for solving data sparseness, and out-of-domain embeddings are used for domain adaptation.

Our proposed model is simple, efficient and effective, giving average 1% accuracy improvement on in-domain data and 3.5% on out-of-domain data, respectively, significantly out-performing self-training and tri-training methods for leveraging auto-segmented data.

2 Baseline Segmentation Model

Chinese word segmentation can be regarded as a character sequence labeling task, where each char-

Copenhagen, Denmark, September 7–11, 2017.

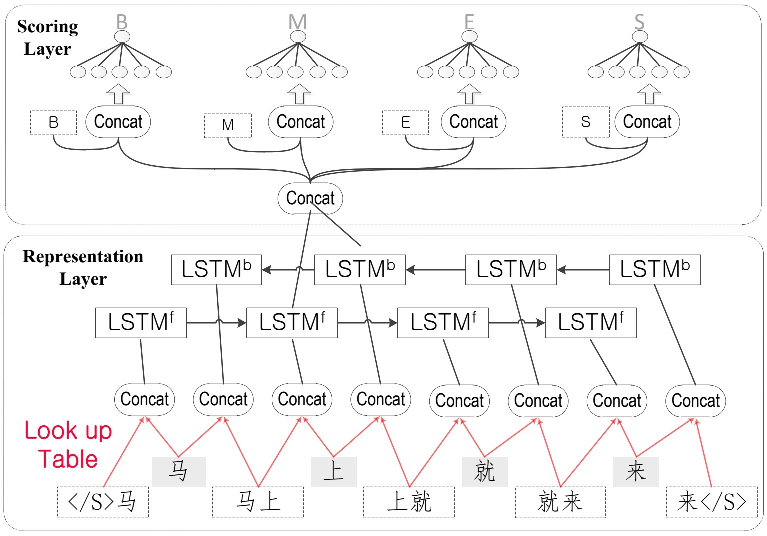

Figure 1: Baseline model architecture.

acter in the sentence is assigned a *segment label* from left to right, including {*B, M, E, S*}, to indicate the segmentation (Xue, 2003; Low et al., 2005; Zhao et al., 2006). *B, M, E* represent the character is the beginning, middle or end of a multi-character word, respectively. *S* represents that the current character is a single character word.

Following Chen et al. (2015b), a standard bi-LSTM model (Graves, 2008) is used to assign segmentation label for each character. As shown in Figure 1, our model consists of a *representation layer* and a *scoring layer*. The representation layer utilizes a bi-LSTM to capture the context of each character in the sentence. Given a sentence $\{w_1, w_2, w_3, \cdots, w_N\}$, where w_i is the i_{th} character in the sentence, and N is the sentence length, we have a corresponding embedding e_{w_i} and $e_{w_{i-1}w_i}$ for each character unigram w_i and character bigram $w_{i-1}w_i$, respectively. A forward word representation e_i^f is calculated as follows:

$$\begin{aligned} e_i^f &= concat_1(e_{w_i}, e_{w_{i-1}w_i}), \\ &= \tanh(W_1[e_{w_i}; e_{w_{i-1}w_i}]) \end{aligned}$$

A backward representation e_i^b can be obtained in the same way. Then e_i^f and e_i^b are fed into forward and backward LSTM units at current position, obtaining the corresponding forward and backward LSTM representations r_i^{lstm-f} and r_i^{lstm-b}, respectively.

In the *scoring layer*, we first obtain a linear combination of r_i^{lstm-f} and r_i^{lstm-b}, which is the final representation at the i_{th} position.

$$\begin{aligned} r_i &= concat_2(r_i^{lstm-f}, r_i^{lstm-b}) \\ &= \tanh(W_2[r_i^{lstm-f}; r_i^{lstm-b}]) \end{aligned}$$

Given the representation r_i, we use a scoring unit to score for each potential segment label. Given r_i, the score of segment label *M* is:

$$f_M^i = W_M h,$$

where

$$\begin{aligned} h &= concat_3(r_i, e_M), \\ &= \tanh(W_3[r_i; e_M]) \end{aligned}$$

W_M is the score matrix for label *M*, and e_M is the label embedding for label *M*.

3 Word-Context Character Embeddings

Our model structure is a derivation from the skip-gram model (Mikolov et al., 2013), similar to Levy and Goldberg (2014). Given a sentence with length n: $\{w_1, w_2, w_3, \cdots w_n\}$ and its corresponding segment labels: $\{l_1, l_2, l_3, \cdots l_n\}$, the pre-training context of current character w_t is the around characters in the windows with size c, together with their corresponding segment labels (Figure 2). Characters w_i and labels l_i in the context are represented by vectors $e^c_{w_i} \in \mathbb{R}^d$ and $e^c_{l_i} \in \mathbb{R}^d$, respectively, where d is the embedding dimensionality.

The word-context embedding of character w_t is represented as $e_{w_t} \in \mathbb{R}^d$, which is trained by predicting the surrounding context representations $e^c_{w'}$, and $e^c_{l_i}$, parameterizing the labeled segmentation information in the embedding parameters. To capture order information (Ling et al., 2015), we use different embedding matrices for context embedding in different context positions, training different embeddings for the same word when they reside on different locations as the context word. In particular, our context window size is five. As a result, each word has four different versions of e^c, namely e^c_{-1}, e^c_{-2}, e^c_{+1}, and e^c_{+2}, each taking a distinct embedding matrix. Given the context window $[w_{-2}, w_{-1}, w, w_{+1}, w_{+2}]$, w_{-1} is the left first context word of the focus word w, e^c_{-1,w_i} will be selected from embedding matrix E_{-1}, and w_{+1} is the right first word of w, e^c_{+1,w_i} will be selected from embedding matrix E_{+1}.

Note that each character has two types of embeddings, where e_{w_i} is the embedding form of w_i when w_i is the focus word, and $e^c_{w_i}$ is the embedding form of w_i when w_i is used as a surrounding context word. We do not have e_{l_i} because l_i only acts as the surrounding context. After pre-training, e_{w_i} will be used as the WCC embeddings.

The objective of our model is to maximize the average log probability of the context:

$$\frac{1}{T}\sum_{t=1}^{T}\sum_{-c\leq j\leq c, j\neq 0}\log p(w_{t+j}|w_t)+\log p(t_{t+j}|w_t)$$

Negative sampling (Mikolov et al., 2013) is used, where $\log p(w_{t+j}|w_t)$ and $\log p(t_{t+j}|w_t)$ are computed as:

$$\begin{aligned}p(w_{t+j}|w_t) &= \log\sigma({e^c_{w_{t+j}}}^{\top} e_{w_t}) \\ &\quad + \sum_{i=1}^{k}\mathbb{E}_{w_i\sim P_n(w)}[\log\sigma(-{e^c_{w_i}}^{\top} e_{w_t})]\end{aligned}$$

and

$$\begin{aligned}p(t_{t+j}|w_t) &= \log\sigma({e^c_{l_{t+j}}}^{\top} e_{w_t}) \\ &\quad + \sum_{i=1}^{k}\mathbb{E}_{l_i\sim P_n(l)}[\log\sigma(-{e^c_{l_i}}^{\top} e_{w_t})],\end{aligned}$$

respectively, where $P_n(w)$ and $P_n(l)$ is the noise distributions and k is the size of negative samples for each data sample.

Bigram embeddings are trained in the same way as unigram character embeddings. For out-of-domain segmentation, we pre-train two embeddings for each token, extracting knowledge from the two domains, respectively.

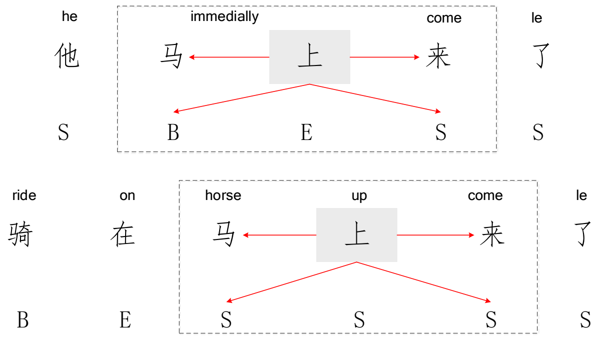

Figure 2: Word-context for the character ’ 上’ in two different sentences. The windows size $c = 3$.

4 Experiments

4.1 Set-up

We perform experiments on three standard datasets for Chinese word segmentation: PKU and MSR from the second SIGHAN bakeoff shared task, and Chinese Treebank 6.0 (CTB6). For PKU and MSR, 10% of the training data are randomly selected as development data. We follow Zhang et al. (2016) to split the CTB6 corpus into training, development and testing sections. For evaluating cross-domain performance, we also experiment on Chinese novel data. Following Zhang et al. (2014), the training set of CTB5 is selected for training, and the manually annotated sentences of free Internet novel ’Zhuxian’ (ZX) are selected as the development and test data (Liu and Zhang, 2012)[1].

Chinese Gigaword (LDC2011T13, 4M) is used for in-domain unlabeled data. For out-of-domain data, 20K raw sentences of Zhuxian is used. We take self-training and tri-training as baselines, which also use large-scale auto-segmented data. For self-training, skip-gram pre-training and word-context character embedding, unlabeled corpus is segmented automatically by our baseline model. For tri-training, we additionally use the ZPar (Zhang and Clark, 2007) and ICTCLAS[2] as our base classifiers .

We use F1 to evaluate segmentation accuracy. The recalls of in-vocabulary (IV) and out-of-vocabulary (OOV) are also measured.

4.2 Hyper-Parameters

The hyper-parameters used in this work are listed in Table 1. The values are selected according

to the development set of CTB6. Many previous character-based CWS models use a transition matrix to model the tag dependency and CRF for structured inference (Pei et al., 2014; Chen et al., 2015a). However, we find that, the greedy model obtains comparable segmentation accuracies across CTB6, PKU and MSR, yet giving much fast speed (Table 2). Hence we adopt the greedy model as our baseline segmentation model.

4.3 Utilizing Varying-Scale Data

The results of self-training and tri-training with varying-scale training data are list in Table 3, where +4X means adding 4 times the size of supervised training data into the training set. We find that self-training does not work well, and tri-training with 16X gives a 0.5% accuracy improvement. We adopt this setting for our baseline in the remaining experiments[3].

We also try to choose more effective examples for self-training and tri-training, by selecting training instances according to the base segmentation model score. However, the segmentation performances do not get improved. A possible reason is that the training instances with higher confidence are always shorter than the original sampled sentences, which may not be very helpful for semi-spervised segmentation.

4.4 In-Domain Results

As shown in Table 4, pre-training with conventional skip-gram embeddings gives only small improvements, which is consistent as findings of previous work (Chen et al., 2015a; Ma and Hinrichs, 2015; Cai and Zhao, 2016). Segmentation with self-training even shows accuracy drops on PKU and MSR. We speculate that the self-training by the neural CWS baseline is sensitive to the segmentation errors of the auto-labeled data. On average, our method obtains an absolute 1% accuracy improvement over the baseline, outperforming other semi-supervised method significantly[4].

We compare our model with other state-of-the-art segmentation models[5], which are grouped into 3 classes, namely traditional segmentation models (*non-nn*), neural segmentation models (*nn*), and the combination of both neural and traditional discrete features (*comb*). Our simple model gives top accuracies compared with related work. Liu et al. (2016), Cai and Zhao (2016) and Zhang et al. (2016) propose to incorporate word embedding features in the neural CWS, pre-training the word embeddings in the large-scale labeled data. Different to them, we employ a simpler character level model containing word information, yet obtaining higher F1 scores.

[3] For out-of-domain experiments, we include both the +16X and the 20K out-of-domain data for self-training and tri-training.

[4] The p-values are below 0.01 using pairwise t-test.

[5] Results with † are obtained from Cai and Zhao (2016), because results in the original paper use dictionary resources.

4.5 Out-of-Domain Results

We test out-of-domain performance of our model on the ZX dataset. We also use the multi-view word-context character embeddings (WCC) for cross domain segmentation, which uses two types of embeddings by simple vector concatenation. One type of embeddings is pre-trained on in-domain data, and the other type is pre-trained on out-of-domain data. In such case, the multi-view embeddings includes cross-domain information, which may enhance the cross-domain segmentation performance (Mou et al., 2016).

As shown in Table 5, using word-context character (*WCC*) embeddings and multi-view word-context character embeddings both give significantly higher accuracy improvements compared with other semi-supervised methods. Additionally, we find that multi-view WCC embeddings give an extra 1% F1 score improvement over WCC embeddings. Our proposed model also significantly improves the OOV recall (ROOV) and IV recall (RIV). By studying the cases of segmented output (Figure 3), we find that our model can recognize OOV words such as '鬼王', '七星剑' and the IV word '器重', which are incorrectly labeled by the baseline. This confirms that our proposed model is helpful for the data sparseness problem on closed domain and domain adaptation on across domain.

We also list the results of Zhang et al. (2014) and Liu et al. (2014) on this dataset. Liu et al. (2014) obtains better out-of-domain performance than our model. However, their results cannot be compared directly with ours because they use partial labeled URL link data from Chinese Wikipedia data for training.

5 Conclusion

We proposed word-context character embeddings for semi-supervised neural CWS, which makes the segmentation model more accurate on in-domain data, and more robust on the out-of-domain data. Our segmentation model is simple yet effective, achieving state-of-the-art segmentation accuracies on standard benchmarks. It can also be useful for other NLP tasks with small labeled training data, but a large unlabeled data. Our code could be downloaded at `https://github.com/zhouh/WCC-Segmentation`.

Segmentation-Free Word Embedding for Unsegmented Languages[*]

Takamasa Oshikiri

`mail@oshikiri.org`

Abstract

In this paper, we propose a new pipeline of word embedding for unsegmented languages, called *segmentation-free word embedding*, which does not require word segmentation as a preprocessing step. Unlike space-delimited languages, unsegmented languages, such as Chinese and Japanese, require word segmentation as a preprocessing step. However, word segmentation, that often requires manually annotated resources, is difficult and expensive, and unavoidable errors in word segmentation affect downstream tasks. To avoid these problems in learning word vectors of unsegmented languages, we consider word co-occurrence statistics over all possible candidates of segmentations based on frequent character n-grams instead of segmented sentences provided by conventional word segmenters. Our experiments of noun category prediction tasks on raw Twitter, Weibo, and Wikipedia corpora show that the proposed method outperforms the conventional approaches that require word segmenters.

1 Introduction

Word embedding, which learns dense vector representation of words from large text corpora, has received much attention in the natural language processing (NLP) community in recent years. It is reported that the representation of words well captures semantic and syntactic properties of words (Bengio et al., 2003; Mikolov et al., 2013; Pennington et al., 2014), and is useful for many downstream NLP tasks, including part-of-speech tagging, syntactic parsing, and machine translation (Huang et al., 2011; Socher et al., 2013; Sutskever et al., 2014).

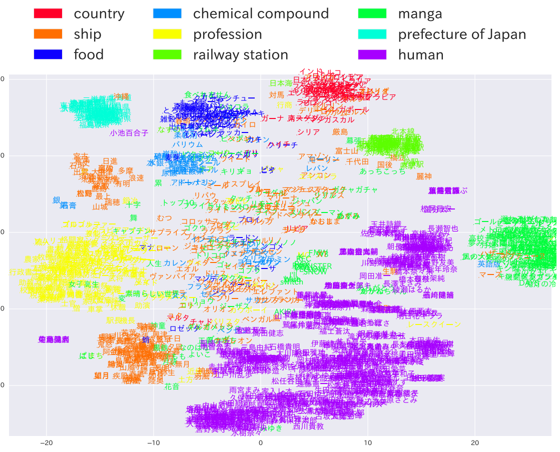

Figure 1: t-SNE projections of vector representation of Japanese nouns that generated by our proposed method without word dictionary. These proper nouns are color-coded according to its categories which extracted from Wikidata.

In order to train word embedding models on a raw text corpus, we have to do word segmentation as a preprocessing step. In space-delimited languages such as English and Spanish, simple rule-based and co-occurrence-based approaches offer reasonable segmentations. On the other hands, these approaches are impractical for unsegmented languages such as Chinese, Japanese, and Thai. Therefore, machine learning-based approaches are widely used in NLP for unsegmented languages. Conditional random field (CRF)-based supervised word segmentation (Kudo et al., 2004; Tseng et al., 2005) is still the most used one in Japanese and Chinese NLP (Prettenhofer and Stein, 2010; Funaki and Nakayama, 2015; Ishiwatari et al.,

[*] This work was done while the author was at Shimodaira laboratory, Division of Mathematical Science, Graduate School of Engineering Science, Osaka University, and Mathematical Statistics Team, RIKEN Center for Advanced Intelligence Project.

Proceedings of the 2017 Conference on Empirical Methods in Natural Language Processing, pages 767–772
Copenhagen, Denmark, September 7–11, 2017.

2015; Nakazawa et al., 2016).

However, there are some problems for these supervised word segmentation as a preprocessing step of a word embedding pipeline. First, they require language-specific manually annotated resources such as word dictionaries and segmented corpora. Since these manually annotated resources are typically unavailable for domain-specific corpora (e.g. Twitter or Weibo corpora that contain many neologisms and informal words), we have to create manually annotated resources if we need. Second, they cannot take advantage of word occurrence frequencies in a corpus. Even though a certain proper noun (e.g. "老人と海" (*The Old Man and the Sea*)) occurs frequently in a corpus, word segmenters will continue to split the proper noun erroneously (e.g. "老人/と/海" (a old man / and / a sea)) if it is not registered in the word dictionary. Because of segmentation errors incurred by these problems, the downstream word embedding model cannot learn vector representation of proper nouns, neologisms, and informal words.

In this paper, in order to learn word vectors from a raw text corpus while avoiding the above problems, we propose a new word segmentation-free pipeline for word embedding, referred to as *segmentation-free word embedding (sembei)*. Our framework first enumerates all possible segmentations (referred to as a *frequent n-gram lattice*) based on character n-grams that frequently occurred in the raw corpus, and then learns n-gram vectors from co-occurrence frequencies over the frequent n-gram lattice. Using the general idea of segmentation-free word embedding, we can extend existing word embedding models. Specifically, in this paper, we propose a segmentation-free version of the widely used skip-gram model with negative sampling (SGNS) (Mikolov et al., 2013), which we refer to as *SGNS-sembei*.

Although the frequent character n-grams necessarily include many non-words (i.e. n-grams that are not words), remarkably, our results show that nearest neighbor search works well for frequent words and even proper nouns (e.g. nearest neighbors of n-gram "ドイツ" (Germany) are "中国" (China), "イギリス" (United Kingdom), etc.). This observation suggests that we can use the proposed method for automatic acquisition of synonyms from large raw text corpora.

We conduct experiments on a noun category prediction task on several corpora and observe that our method outperforms the conventional approaches that use word segmenters. Fig. 1 shows a t-SNE projection of vector representation of Japanese nouns which is learned from only a raw Twitter corpus. We can see that the proposed method can learn vector representation of these nouns, and the learnt representation achieves good separation based on their categories.

2 Related Work

There are some representation models that do not rely on any segmenters. Dhingra et al. (2016) proposed a character-based RNN model for vector representation of tweets, and Schütze (2017) proposed a new text embedding method that learns n-gram vectors from the corpus that segmented randomly and then constructs text embeddings by summing up the n-gram vectors. In the field of representation learning for biological sequences (e.g. DNA and RNA), Asgari and Mofrad (2015) applied the skip-gram model (Mikolov et al., 2013) to fixed length fragments of biological sequences. These methods mainly aim at learning vector representation of texts or biological sequences instead of words or fragments of sequences. On the other hand, in this paper, we focus on learning vector representation of words from a raw corpus of unsegmented languages.

3 Conventional Approaches to Word Embeddings

Word embedding is also commonly used in NLP for unsegmented languages (Prettenhofer and Stein, 2010; Funaki and Nakayama, 2015; Ishiwatari et al., 2015). In these studies, they usually segment a raw corpus into words using a word segmenter or a morphological analyzer, and then feed the segmented corpus to word embedding models (e.g. the skip-gram model (Mikolov et al., 2013) or the GloVe (Pennington et al., 2014)) as in the case of space-delimited languages. The flowchart of the above process is shown in the left part of Fig. 2.

3.1 The original SGNS

The original skip-gram model with negative sampling (Mikolov et al., 2013) (we refer to it as *the original SGNS*) learns vector representation of words $\boldsymbol{v}_w$ and their contexts $\tilde{\boldsymbol{v}}_c$ that minimize the

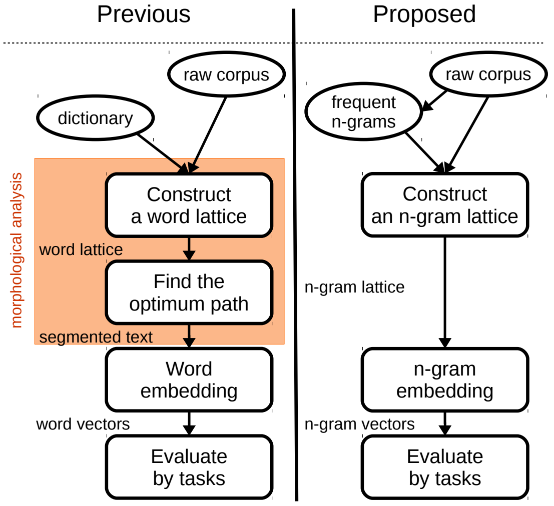

Figure 2: Flowcharts of previous and proposed pipelines. Morphological analyzers are in charge of the shaded part. Our main idea is to replace a word dictionary with a set of frequent character n-grams, and omit the indentification of the optimum path.

following objective function:

$$\underset{\{\boldsymbol{v}_w\}\cup\{\tilde{\boldsymbol{v}}_c\}}{\text{maximize}} \sum_{(w,c)\in\mathcal{D}} \log\sigma(\boldsymbol{v}_w^\top\tilde{\boldsymbol{v}}_c) + \sum_{(w,c)\in\mathcal{D}'} \log\sigma(-\boldsymbol{v}_w^\top\tilde{\boldsymbol{v}}_c) \tag{1}$$

where $\sigma(x) := (1+e^{-x})^{-1}$, $\mathcal{D}$ is a multiset (bag) of positive samples (i.e. co-occurred pairs in the corpus), and $\mathcal{D}'$ is a multiset of negative samples. This objective function is maximized using stochastic gradient descent (SGD).

4 Segmentation-Free Word Embeddings

In this section, we first introduce the general idea of *segmentation-free word embeddings* (*sembei*), and then propose a segmentation-free version of the SGNS.

While conventional word embedding approaches learn word vectors from segmented corpora that provided by word segmenters, our approach learns n-gram vectors from raw corpora, as in the right part of Fig. 2. In order to learn n-gram vectors from a raw corpus of unsegmented languages, we first construct a *frequent n-gram lattice*, which represents all possible segmentations based on frequent character n-grams of the corpus, in the same way as the construction of word lattices used in morphological analysis. Then, we learn n-gram vectors using co-occurrence statistics over the frequent n-gram lattice instead of segmented corpora as in conventional approaches.

4.1 Segmentation-Free Version of the SGNS

Here, we introduce a segmentation-free version of SGNS, referred to as *SGNS-sembei*, as an application of the idea of segmentation-free word embedding. Our method simply optimizes the original SGNS's objective function (1) with the slight modification: changing the definition of the multiset of positive samples $\mathcal{D}$.

In SGNS-sembei, $\mathcal{D}$ is redefined as the multiset of character n-gram pairs (w, c) where w and c occur adjacently in the corpus (i.e. w and c are connected in the frequent n-gram lattice). In addition, to discriminate co-occurrence with different order in the frequent n-gram lattice, we define contextual words with their relative positions to the center word as the same way as Ling et al. (2015) did.

We also redefine the multiset of negative samples $\mathcal{D}'$ using $\mathcal{D}$ in the same way as the original SGNS, and then optimize the objective function (1) using SGD.

Table 1: Examples of labels of entities (in Japanese, and in English for reference) and its categories extracted from Wikidata.

label (ja)	label (en)	category
ドイツ	Germany	country

5 Experiment

In this section, we evaluate our method by the noun category prediction task on Twitter, Weibo, and Wikipedia corpora.

The C++ implementation of the proposed method is available on GitHub[1].

5.1 Settings

We used four raw text corpora: Wikipedia (Japanese), Wikipedia (Chinese), Twitter (Japanese), and Weibo (Chinese). The Wikipedia corpora consist of only a part of the Wikipedia

[1] https://github.com/oshikiri/w2v-sembei

Table 2: Micro F-scores (higher is better) and coverages [%] (in parentheses, higher is better).

	dictionary		Japanese		Chinese	
	default	Wikidata	Wikipedia	Twitter	Wikipedia	Weibo
SGNS	✓		0.896 (34)	0.761 (46)	0.889 (86)	0.766 (88)
SGNS	✓	✓	0.945 (98)	0.867 (96)	**0.891** (94)	0.765 (93)
SGNS-sembei			**0.949** (**100**)	**0.870** (**100**)	**0.891** (**100**)	**0.811** (**100**)

dumps[2] (dated on February 20th, 2017), whose HTML tags are removed. The Weiboscope corpus (Chau et al., 2013) consists of 226,841,122 posts mainly in Chinese, and we use only a part of it. The Twitter corpus consists of 17,316,968 Japanese tweets that were collected from October 26th, 2016 until November 22nd, 2016 via the Twitter Streaming API. We removed hashtags, users' id, and URL from Twitter and Weibo corpora. We extracted about 1,460k frequent n-grams[3] as the *frequent character n-grams* for our proposed method.

We extracted the noun-category pairs from the Wikidata (Vrandečić and Krötzsch, 2014) (We used the dump dated January 9th, 2017) as follows. We first extracted Wikidata entities whose headwords are also in the 1,460k frequent n-grams, and then extracted the Wikidata entities whose "`instance of`" properties are any of the predetermined category set[4], and then collected names and their categories of the entities. Examples of the extracted noun-category pairs are shown in Table 1.

We randomly split the noun-category pairs into a train (60%) and a test (40%) set. We trained linear C-SVM classifiers (Hastie et al., 2009) with the train set to predict categories from vector representation of the nouns. We performed a grid search over $(C, \text{classifier}) \in \{0.5, 1, 5, 10, 50, 100\} \times \{\text{one-vs-one}, \text{one-vs-rest}\}$ of linear SVM using the train set for each vector representation, and reported the best scores on the test set.

5.2 Baseline Systems

We compared SGNS-sembei with the conventional approaches that use the original SGNS and word segmenters. To segment the raw corpora, we used the MeCab (Kudo et al., 2004) for Japanese corpora and the Stanford Word Segmenter (Tseng et al., 2005) for Chinese corpora with their default dictionaries[5]. And we ignored the words that occur less than 5 times. We also ran these baseline systems in an ideal setting: running the word segmenters with the default dictionaries and additional dictionaries that consist of the nouns extracted in § 5.1.

We performed a grid search over $(h, t, n_{\text{neg}}) \in \{5, 8, 10\} \times \{10^{-5}, 10^{-4}, 10^{-3}\} \times \{3, 10, 25\}$ where h is the size of context window, t is the sampling threshold, and n_{neg} is the number of negative samples.

5.3 Results

In both the original SGNS and SGNS-sembei, we fixed the dimensionality of vector representation to 200 and the number of iterations to 5 in both baseline and our method. In SGNS-sembei, we used the number of negative samples $n_{\text{neg}} = 10$, size of context window $h = 1$, initial learning rate $\alpha_{\text{init}} = 0.01$.

The resulting micro F-scores and the coverages (i.e. the percentages of the noun-category pairs whose nouns' vector representation exists) are shown in Table 2, and the t-SNE (Maaten and Hinton, 2008) projections of Japanese nouns vectors learned from the Twitter corpus are shown in Fig. 1. We observed that our proposed method outperforms the conventional approaches that use word segmenters. Furthermore, the coverages of our method were higher than those of the SGNS with the default dictionary (especially in Japanese) and competitive to those of the SGNS with the default dictionary and Wikidata (which is an ideal

[2] We used {ja,zh}wiki-20170220-pages-articles1.xml in `https://dumps.wikimedia.org`

[3] In this experiment, we defined the frequent n-grams as the union of the top-k_n frequent n-grams, where n and k_n are the pre-specified numbers. And we used $n = 8$, $(k_1, \ldots, k_8) = (10000, 300000, 300000, 300000, 200000, 200000, 100000, 50000)$ for Japanese corpora, and $n = 7$, $(k_1, \ldots, k_7) = (10000, 400000, 400000, 300000, 200000, 100000, 50000)$ for Chinese corpora

[4] {country, profession, ship, railway station, food, chemical compound, prefecture of Japan, manga, human } for Japanese, and {country, profession, television series, business enterprise, city, chemical compound, taxon, human} for Chinese

[5] We use `mecab-ipadic v2.7.0` for the MeCab and `dict-chris6.ser.gz` for the Stanford Word Segmenter.

setting) even though our method does not require any manually annotated resources. We can also see that the learnt representation achieves good separation based on their categories as in Fig. 1. Nearest neighbor search using Twitter and Weibo corpora was also performed as preliminary experiments, and surprisingly, it worked well for frequent words as in Table. 3.

Table 3: Results of nearest neighbor search for frequent words

Language	Query	3-Nearest Neighbors
Japanese	ドイツ (Germany)	中国 (China), イギリス (UK), ポーランド (Poland)
	酸素 (oxygen)	水素 (hydrogen), 鉄分 (iron), 二酸化炭素 (carbon dioxide)
Chinese	德国 (Germany)	美国 (USA), 英国 (UK), 法国 (France)
	羽毛球 (badminton)	台球 (billiards), 网球 (tennis), 乒乓球 (pingpong)

6 Conclusion

We proposed segmentation-free word embedding for unsegmented languages. Although our method does not rely on any manually annotated resources, experimental results of the noun category prediction task on several corpora showed that our method outperforms conventional approaches that rely on manually annotated resources.

As an anonymous reviewer suggested, a possible direction of future work is to leverage another word segmentation approach which uses linguistic features, such as the Stanford Word Segmenter (Tseng et al., 2005) with k-best segmentations.

Acknowledgments

I would like to thank Hidetoshi Shimodaira, Thong Pham, Kazuki Fukui, and anonymous reviewers for their helpful suggestions. This work was partially supported by grants from Japan Society for the Promotion of Science KAKENHI (JP16H02789) to HS.

From Textbooks to Knowledge: A Case Study in Harvesting Axiomatic Knowledge from Textbooks to Solve Geometry Problems

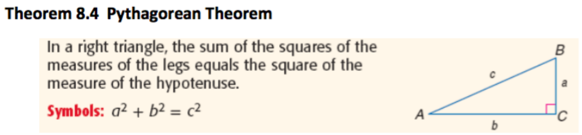
Abstract

Textbooks are rich sources of knowledge. Harvesting knowledge from textbooks is a key challenge in many educational applications. In this paper, we present an approach to obtain axiomatic knowledge of geometry in the form of horn-clause rules from math textbooks. The approach uses rich contextual and typographical features extracted from the textbooks. It also leverages the redundancy and shared ordering of axioms across multiple textbooks to accurately harvest axioms. These axioms are then parsed into horn-clause rules that are used to improve the state-of-the-art in solving geometry problems.

1 Introduction

Recently, researchers have proposed standardized tests as "drivers for progress in AI" (Clark and Etzioni, 2016). There is a growing body of work in solving standardized tests such as reading comprehensions (Richardson et al., 2013; Sachan et al., 2015, inter alia), science question answering (Schoenick et al., 2016; Sachan et al., 2016, inter alia), algebra word problems (Kushman et al., 2014, inter alia), geometry problems (Seo et al., 2015), pre-university entrance exams (Fujita et al., 2014), etc. A major challenge in building these solvers is the lack of subject knowledge. For example, geometry tests require knowledge of geometry axioms and pre-university exams require knowledge of laws of physics, chemistry, etc.

In this paper, we present an automatic approach that can (a) harvest such subject knowledge from textbooks, and (b) parse the extracted knowledge to structured programs that the solvers can use. Unlike information extraction systems trained on domains such as web documents (Chang et al., 2003; Etzioni et al., 2004, inter alia), learning an information extraction system that can extract axiomatic knowledge from textbooks is challenging because of the small amount of in-domain labeled data available for these tasks. We tackle this challenge by (a) leveraging the *redundancy* and *shared ordering* of axiom mentions across multiple textbooks[1], and (b) utilizing rich contextual and typographical features[2] from textbooks to effectively extract and parse axioms. Finally, we also provide an approach to parse the extracted axiom mentions from various textbooks and reconcile them to achieve the best program for each axiom.



Theorem 8.4 Pythagorean Theorem

In a right triangle, the sum of the squares of the measures of the legs equals the square of the measure of the hypotenuse.

Symbols: $a^2 + b^2 = c^2$

Figure 1: An excerpt of a textbook from our dataset that introduces the Pythagoras theorem. The textbook has a lot of typographical features that can be used to harvest this theorem: The textbook explicitly labels it as a "theorem"; there is a colored bounding box around it; an equation writes down the rule and there is a supporting figure. Our models leverages such rich contextual and typographical information (when available) to accurately harvest axioms and then parses them to horn-clause rules. The horn-clause rule derived by our approach for the Pythagoras theorem is: $isTriangle(ABC) \wedge perpendicular(AC, BC) \implies BC^2 + AC^2 = AB^2$.

As a case study, we use our approach to harvest axiomatic knowledge of geometry from math textbooks, and use this knowledge to improve the state-of-the-art system for solving SAT style geometry problems. Seo et al. (2015) recently presented *GEOS*, an automated end-to-end system that solves SAT style geometry questions such as the one shown in Figure 2. *GEOS* derives a logical expression that represents the meaning of the

[1] The same axiom can be potentially mentioned in a number of textbooks in different ways. All textbooks typically introduce axioms in roughly the same order – for example, pythagorous theorem would typically be introduced after introducing the notion of a right angled triangle.

[2] Textbooks contain rich context and typographical information (see Figure 1 for an illustrative example). We use this rich information as features in our model.

Figure 2: An example SAT style geometry problem with the question text, corresponding diagram and (optionally) answer candidates. Below: A logical expression that represents the meaning of the text description and the diagram in the problem. *GEOS* derives a weighted logical expression where each predicates also carries a weighted score but we do not show them here for clarity.

text description and the diagram (also shown in Figure 2), and then solves the geometry question by checking the satisfiablity of the derived logical expression. While this solver has its basis in coordinate geometry and indeed works, it has some key issues: *GEOS* requires an explicit mapping of each predicate into a set of constraints over point coordinates[3]. These constraints can be non-trivial to write, requiring significant manual engineering. As a result, *GEOS*'s constraint set is incomplete and it cannot solve a number of SAT style geometry questions. Furthermore, this solver is not interpretable. As our user studies show, it is not natural for a student to understand the solution of these geometry questions in terms of satisfiability of constraints over coordinates. A more natural way for students to understand and reason about these questions is through deductive reasoning using axioms of geometry[4].

We use our model to extract and parse axiomatic knowledge from a novel dataset of 20 publicly available math textbooks. We use this structured axiomatic knowledge to build a new axiomatic solver that performs logical inference to solve geometry problems. Our axiomatic solver outperforms *GEOS* on all existing test sets introduced in Seo et al. (2015) as well as a new test set of geometry questions collected from these textbooks. We also performed user studies on a number of school students studying geometry who found that our axiomatic solver is more *interpretable* and *useful* compared to *GEOS*.

2 Background: GEOS

Our work reuses *GEOS* to parse the question text and diagram into its formal problem description as shown in Figure 2. *GEOS* parses the question text and the diagram to a formal problem description. *GEOS* uses a logical formula, a first-order logic expression that includes known numbers or geometrical entities (e.g. 4 cm) as constants, unknown numbers or geometrical entities (e.g. O) as variables, geometric or arithmetic relations (e.g. *isLine*, *isTriangle*) as predicates and properties of geometrical entities (e.g. *measure*, *liesOn*) as functions.

This is done by learning a set of relations that potentially correspond to the question text (or the diagram) along with a confidence score. For diagram parsing, *GEOS* uses a publicly available diagram parser for geometry problems (Seo et al., 2014). For text parsing, *GEOS* takes a multi-stage approach, which maps words or phrases in the text to their corresponding concepts, and then identifies relations between identified concepts. Given this formal problem description, *GEOS* use a numerical method to check the satisfiablity of literals by defining a relaxed indicator function for each literal. These indicator functions are manually engineered for every predicate. Since this is a cumbersome process, *GEOS* has an incomplete mapping of literals to indicator functions.

3 Set up for the Axiomatic Solver

In this work, we replace the numerical solver of *GEOS* with an axiomatic solver. We extract axiomatic knowledge from textbooks and parse them into horn clause rules. Then we build an axiomatic solver that performs logical inference with these horn clause rules and the formal problem description. A sample logical program (in prolog notation) that solves the problem in Figure 2 is given in Figure 3. The logical program has a set of declarations from the *GEOS* text and diagram parsers which describe the problem specification

[3] For example, the predicate *isPerpendicular*(AB, CD) is mapped to the constraint $\frac{y_B - y_A}{x_B - x_A} \times \frac{y_D - y_C}{x_D - x_C} = -1$.

[4] For example, the deductive reasoning required to solve the question in Figure 2 is: (1) Use the axiom that the sum of interior angles of a triangle is 180°and the fact that ∠AMO is 90°to conclude that ∠MOA is 60°. (2) △MOA ∼ △MOB (using a similar triangle axiom) and then, ∠MOB = ∠MOA = 60°(using the axiom that corresponding angles of similar triangles are equal). (3) Use angle sum rule to conclude that ∠AOB = ∠MOB + ∠MOA = 120°. (4) Use the axiom that the angle subtended by an arc of a circle at the centre is double the angle subtended by it at any point on the circle to conclude that ∠ADB = 0.5×∠AOB = 60°.

Figure 3: A sample logical program (in prolog style) that solves the problem in Figure 2. The program consists of a set of data structure declarations that correspond to types in the prolog program, a set of declarations from the diagram and text parse and a subset of the geometry axioms written as horn clause rules. The axioms are used as the underlying theory with the aforementioned declarations to yield the solution upon logical inference. Normalized confidence weights from the diagram, text and axiom parses are used as probabilities. For readers understanding, we list the axioms in the order (1 to 7) they are used to solve the problem. However, this ordering is not required. Other (less probable) declarations and axiom rules are not shown here for clarity but they can be assumed to be present.

and the parsed horn clause rules describe the underlying theory. Normalized confidence scores from question text, diagram and axiom parsing models are used as probabilities in the program. Next, we describe how we harvest structured axiomatic knowledge from textbooks.

4 Harvesting Axiomatic Knowledge

We present a structured prediction model that identifies axioms in textbooks and then parses them. Since harvesting axioms from a single textbook is a very hard problem, we use multiple textbooks and leverage the redundancy of information to accurately extract and parse axioms. We first define a joint model that identifies axiom mentions in each textbook and aligns repeated mentions of the same axiom across textbooks. Then, given a set of axioms (with possibly, multiple mentions of each axiom), we define a parsing model that maps each axiom to a horn clause rule by utilizing the various mentions of the axiom.

Given a set of textbooks $\mathcal{B}$ in machine readable form (XML in our experiments), we extract chapters relevant for geometry in each of them to obtain a sequence of sentences (with associated typographical information) from each textbook. Let $\mathbf{S}_b = \{s_0^{(b)}, s_1^{(b)}, \ldots s_{|\mathbf{S}_b|}^{(b)}\}$ denote the sequence of sentences in textbook b. $|\mathbf{S}_b|$ denotes the number of sentences in textbook b.

4.1 Axiom Identification and Alignment

We decompose the problem of extracting axioms from textbooks into two tractable sub-problems: (a) identification of axiom mentions in each textbook using a sequence labeling approach, and (b) aligning repeated mentions of the same axiom across textbooks. Then, we combine the learned models for these sub-problems into a joint optimization framework that simultaneously learns to identify and align axiom mentions. Joint modeling of the axiom identification and alignment is necessary as both sub-problems can help each other.

4.1.1 Axiom Identification

Linear-chain CRF formulation (Lafferty et al., 2001) can be used for the subproblem of axiom identification. Given $\{\mathbf{S}_b | b \in \mathcal{B}\}$, the model labels each sentence $s_i^{(b)}$ as **B**efore, **I**nside or **O**utside an axiom. Hereon, a contiguous block of sentences labeled $\mathbf{B}$ or $\mathbf{I}$ will be considered as an axiom mention. Let $\mathcal{T} = \{\mathbf{B}, \mathbf{I}, \mathbf{O}\}$ denote the tag set. Let $y_i^{(b)}$ be the tag assigned to $s_i^{(b)}$ and $\mathbf{Y}_b$ be the tag sequence assigned to $\mathbf{S}_b$. The CRF defines:

$$p(\mathbf{Y}_b|\mathbf{S}_b;\boldsymbol{\theta}) \propto \prod_{k=1}^{|\mathbf{S}_b|} \exp\left(\sum_{i,j\in\mathcal{T}} \boldsymbol{\theta}_{ij}^T \mathbf{f}_{ij}(y_{k-1}^{(b)}, y_k^{(b)}, \mathcal{S}_b)\right)$$

We find the parameters $\boldsymbol{\theta}$ using maximum-likelihood estimation with L2 regularization:

$$\boldsymbol{\theta}^* = \arg\max_{\boldsymbol{\theta}} \sum_{b\in\mathcal{B}} \log p(\mathbf{Y}_b|\mathbf{S}_b;\boldsymbol{\theta}) - \lambda||\boldsymbol{\theta}||_2^2$$

We use L-BFGS to optimize the objective and Viterbi decoding for inference.

Features: Features f look at a pair of adjacent tags $y_{k-1}^{(b)}$, $y_k^{(b)}$, the input sequence $\mathbf{S}_b$, and where we are in the sequence. The features (listed in Table 1) include various content based features encoding various notions of similarity between pairs of sentences as well as various typographical features such as whether the sentences are annotated as an axiom (or theorem or corollary) in the textbook, contain equations, diagrams, text that is bold or italicized, are in the same node of the xml hierarchy, are contained in a bounding box, etc.

Some extracted axiom mentions contain pointers to a diagram eg. “Figure 2.1”. We consider the diagram to be a part of the axiom mention.

4.1.2 Axiom Alignment

Next, we leverage the redundancy of information and the relatively fixed ordering of axioms in various textbooks by aligning various mentions of the same axiom across textbooks and introducing structural constraints on the alignment.

Content	Sentence Overlap	Semantic Textual Similarity between the current and next sentence. We include features that compute the proportion of common unigrams and geometry entities (constants, predicates and functions) across the two sentences. This feature is conjoined with the tag assigned to the current and next sentence.
	Geometry entities	No. of geometry entities (normalized by the number of tokens) in this sentence. This feature is conjoined with the tag assigned to the current sentence.
	Intra-sentence semantics	Indicator that the current sentence contains any one of the following words: *hence*, *if*, *equal*, *twice*, *proportion*, *ratio*, *product*. This feature is conjoined with the tag assigned to the current sentence.
Typography	Axiom, Theorem, Corollary Mention	(a) The current (or previous) sentence is mentioned as an Axiom, Theorem or Corollary e.g. *Similar Triangle Theorem* or *Corollary 2.1*. (b) The section or subsection in the textbook containing the current (or previous) sentence mentions an Axiom, Theorem or Corollary. This feature is conjoined with the tag assigned to the current (and previous) sentence.
	Eqn. Template	The current (or next) sentence contains an equation eg. $PA \times PB = PT^2$. This feature is conjoined with the tag assigned to the current (and next) sentence.
	Assoc. Diagram	The current sentence contains a pointer to a figure eg. “Figure 2.1”. This feature is conjoined with the tag assigned to the current sentence.
	RST edge	Indicator for the RST relation between the current and next sentence. This feature is conjoined with the tag assigned to the current and next sentence.
	Bold/Underline	The sentence (or previous) sentence contains text that is in bold font or underlined. Conjoined with the tag assigned to the current (and previous) sentence.
	XML structure	Indicator that the current and previous sentence are in the same node of the XML hierarchy. Conjoined with the tag assigned to the current and previous sentence.
	Bounding box	Indicator that the current and previous sentence are bounded by a bounding box in the textbook. Conjoined with the tag assigned to the current and previous sentence.

Table 1: Feature set for our axiom identification model. The features are based on content and typography.

Let $\mathbf{A}_b = \left(A_1^{(b)}, A_2^{(b)}, \ldots, A_{|\mathbf{A}_b|}^{(b)}\right)$ be the axiom mentions extracted from textbook b. Let $\mathbf{A}$ denote the collection of axiom mentions extracted from all textbooks. We assume a global ordering of axioms $\mathbf{A}^* = (A_1^*, A_2^*, \ldots, A_U^*)$ where U is some pre-defined upper bound on the total number of axioms in geometry. Then, we emphasize that the axiom mentions extracted from each textbooks (roughly) follow this ordering. Let $Z_{ij}^{(b)}$ be a random variable that denotes if axiom $A_i^{(b)}$ extracted from book b refers to the global axiom A_j^*. We introduce a log-linear model that factorizes over alignment pairs:

$$P(\mathbf{Z}|\mathbf{A};\boldsymbol{\phi}) = \frac{1}{Z(\mathbf{A};\boldsymbol{\phi})} \times$$
$$\exp\left(\sum_{\substack{b_1,b_2\in\mathcal{B}\\ b_1\neq b_2}} \sum_{1\leq k\leq U} \sum_{\substack{1\leq i\leq|\mathbf{A}_{b_1}|\\ 1\leq j\leq|\mathbf{A}_{b_2}|}} Z_{ik}^{(b_1)} Z_{jk}^{(b_2)} \boldsymbol{\phi}^T \mathbf{g}(A_i^{(b_1)}, A_j^{(b_2)})\right)$$

Here, $Z(\mathbf{A};\boldsymbol{\phi})$ is the partition function of the log-linear model. $\mathbf{g}$ denotes the feature function described later. We introduce the following constraints on the alignment structure:

C1: An axiom appears in one book at-most once

C2: An axiom refers to exactly one theorem in the global ordering

C3: Ordering Constraint: If i^{th} axiom in a book refers to the j^{th} axiom in the global ordering then no axiom succeeding the i^{th} axiom can refer to a global axiom preceding j.

Learning with Hard Constraints: We find the optimal parameters $\boldsymbol{\phi}$ using maximum-likelihood estimation with L2 regularization:

$$\boldsymbol{\phi}^* = \arg\max_{\boldsymbol{\phi}} \log P(\mathbf{Z}|\mathbf{A};\boldsymbol{\phi}) - \mu||\boldsymbol{\phi}||_2^2$$

We use L-BFGS to optimize the objective. To compute feature expectations appearing in the gradient of the objective, we use a Gibbs sampler. The sampling equations for Z_{ik}^b are:

$$P(Z_{ik}^{(b)}|rest) \propto \exp\left(T_b(i,k)\right) \quad (1)$$
$$T_b(i,k) = Z_{ik}^{(b)} \sum_{\substack{b'\in\mathcal{B}\\ b'\neq b}} \sum_{1\leq j\leq|A_{b'}|} Z_{jk}^{(b')} \boldsymbol{\phi}^T \mathbf{g}(A_i^{(b)}, A_j^{(b')})$$

Note that the constraints $C1\ldots3$ define the feasible space of alignments. Our sampler always samples the next $Z_{ik}^{(b)}$ in this feasible space.

Learning with Soft Constraints: We might want to treat some constraints, in particular, the ordering constraints $C3$ as soft constraints. We can write down the constraint $C3$ using the alignment variables:

$$Z_{ij}^{(b)} \leq 1 - Z_{kl}^{(b)}$$
$$\forall\ 1 \leq i < k \leq |\mathbf{A}_b|, 1 \leq l < j \leq U$$
$$\forall\ b \in \mathcal{B}$$

To model these constraints as soft constraints, we penalize the model for violating these constraints. Let the penalty for violating the above constraint be $\exp\left(\nu \max\left(0, 1 - Z_{ij}^{(b)} - Z_{kl}^{(b)}\right)\right)$. We introduce a new regularization term: $\mathbf{R}(\mathbf{Z}) = \sum_{\substack{1\leq i<k\leq|\mathbf{A}_b|\\ 1\leq l<j\leq U\\ b\in\mathcal{B}}} \exp\left(\nu \max\left(0, 1 - Z_{ij}^{(b)} - Z_{kl}^{(b)}\right)\right)$. Here ν is a hyper-parameter to tune the cost of violating a constraint. We write down the following regularized objective:

$$\boldsymbol{\phi}^* = \arg\max_{\boldsymbol{\phi}} \log P(\mathbf{Z}|\mathbf{A};\boldsymbol{\phi}) - \mathbf{R}(\mathbf{Z}) - \mu||\boldsymbol{\phi}||_2^2$$

We use L-BFGS to find the optimal parameters $\boldsymbol{\phi}*$. We perform Gibbs sampling to compute feature expectations. The sampling equation for $Z_{ik}^{(b)}$ is similar (eq 1), but:

$$T_b(i,k) = \sum_{\substack{b'\in\mathcal{B}\\ b'\neq b}} \sum_{1\leq j\leq|A_{b'}|} Z_{ik}^{(b)} Z_{jk}^{(b')} \boldsymbol{\phi}^T \mathbf{g}(A_i^{(b)}, A_j^{(b')})$$

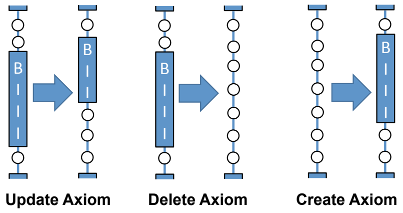

Figure 4: An illustration of the three operations to sample axiom blocks.

$$+\nu \sum_{\substack{b'\in\mathcal{B}\\ b'\neq b}} \sum_{i<j\leq|A_{b'}|} \sum_{1\leq l<k} \left(1 - Z_{ik}^{(b)} - Z_{jl}^{(b')}\right)$$
$$+\nu \sum_{\substack{b'\in\mathcal{B}\\ b'\neq b}} \sum_{1\leq j<i|} \sum_{k<l\leq U} \left(1 - Z_{ik}^{(b)} - Z_{jl}^{(b')}\right)$$

Features: Now, we describe the features g. These too include content based features encoding various notions of similarity between pairs of axiom mentions as well as various typographical features. The features are listed in Table 2.

4.1.3 Joint Identification and Alignment

Joint modeling of axiom identification and alignment components is useful as both problems potentially help each other. Let $Y_{ij}^{(b)}$ denote that the sentence $s_i^{(b)}$ from book b has tag j. We reuse the definitions of the alignment variables $Z_{ij}^{(b)}$ as before. We further define $Z_{i0}^{(b)}$ such that it denotes that the i^{th} axiom in textbook b is not aligned to any global axiom. We again define a log-linear model with factors that score axiom identification and axiom alignments.

$$p(\mathbf{Y},\mathbf{Z}|\{\mathbf{S}_b\};\boldsymbol{\theta},\boldsymbol{\phi}) \propto f_{AI}(\mathbf{Y}|\{\mathbf{S}_b\};\boldsymbol{\theta}) \times f_{AA}(\mathbf{Z}|\mathbf{Y},\{\mathbf{S}_b\};\boldsymbol{\phi})$$

Here, the factors:

$$f_{AI} = \exp(\sum_{b\in\mathcal{B}} \sum_{k=1}^{|\mathbf{S}_b|} \sum_{i,j\in\mathcal{T}} Y_{k-1i}^{(b)} Y_{kj}^{(b)} \boldsymbol{\theta}_{ij}^T \mathbf{f}_{ij}(i,j,\mathcal{S}_b))$$
$$f_{AA} = \exp(\sum_{\substack{b_1,b_2\in\mathcal{B}\\ b_1\neq b_2}} \sum_{1\leq k\leq U} \sum_{\substack{1\leq i\leq|\mathbf{A}_{b_1}|\\ 1\leq j\leq|\mathbf{A}_{b_2}|}} Z_{ik}^{(b_1)} Z_{jk}^{(b_2)} \boldsymbol{\phi}^T \mathbf{g}(A_i^{(b_1)}, A_j^{(b_2)}))$$

We write down the model constraints below:
C1': Every sentence has a unique label
C2' Tag O cannot be followed by tag I
C3' Consistency between Y's and Z's i.e. axiom boundaries defined by Y's and Z's must agree.
C4' = C3.

We use L-BFGS for learning. To compute feature expectations, we use a Metropolis Hastings sampler that samples $\mathbf{Y}'s$ and $\mathbf{Z}'s$ alternatively. Sampling for $\mathbf{Z}'s$ reduces to Gibbs sampling and the sampling equations are as same as before (Section 4.1.2). For better mixing, we sample $\mathbf{Y}$ in blocks. Consider blocks of $\mathbf{Y}$'s which denote axiom boundaries at time stamp t , we define three operations to sample axiom blocks at the next time stamp. The operations (shown in Figure 4) are:

Update axiom: The axiom boundary can be shrunk, expanded or moved. The new axiom, however, cannot overlap with other axioms.
Delete axiom: The axiom can be deleted by labeling all its sentences as O.
Introduce axiom: Given a contiguous sequence of sentences labeled O, a new axiom can be introduced.

Note that these three operations define an ergodic Markov chain. We use the axiom identification part of the model as the proposal:

$$Q(\bar{\mathbf{Y}}|\mathbf{Y}) \propto \exp\left(\sum_{b\in\mathcal{B}} \sum_{k=1}^{|\mathbf{S}_b|} \sum_{i,j\in\mathcal{T}} \bar{Y}_{k-1i}^{(b)} \bar{Y}_{kj}^{(b)} \boldsymbol{\theta}_{ij}^T \mathbf{f}_{ij}(i,j,\mathcal{S}_b)\right)$$

Hence, the acceptance ratio only depends on the alignment part of the model: $R(\bar{\mathbf{Y}}|\mathbf{Y}) = \min\left(1, \frac{U(\bar{\mathbf{Y}})}{U(\mathbf{Y})}\right)$ where $U(\mathbf{Y}) = f_{AA}$. We again have two variants, where we model the ordering constraints (C4$'$) as soft or hard constraints.

4.2 Axiom Parsing

After harvesting axioms, we build a parser for these axioms that maps raw axioms to horn clause rules. The axiom harvesting step provides us a multi-set of axiom extractions. Let $\mathcal{A} = \{\mathbf{A}_1, \mathbf{A}_2, \ldots, \mathbf{A}_{|\mathcal{A}|}\}$ represent the multi-set where each axiom $\mathbf{A}_i$ is mentioned at least once.

First, we describe a base parser that parses axiom mentions to horn clause rules. Then, we utilize the redundancy of axiom extractions from various sources (textbooks) to improve our parser.

4.2.1 Base Axiomatic Parser

Our base parser identifies the *premise* and *conclusion* portions of each axiom and then uses *GEOS*'s text parser to parse the two portions into a logical formula. Then, the two logical formulas are put together to form horn clause rules.

Axiom mentions (for example, the Pythagoras theorem mention in Figure 1) are often accompanied by equations or diagrams. When the mention has an equation, we simply treat the equation as the *conclusion* and the rest of the mention as the *premise*. When the axiom has an associated diagram, we always include the diagram in the *premise*. We learn a model to predict the split of the axiom text into two parts forming the *premise* and the *conclusion* spans. Then, the *GEOS* parser maps the *premise* and *conclusion* spans to *premise* and *conclusion* logical formulas, respectively.

Let Z_s represent the split that demarcates the *premise* and *conclusion* spans. We score the ax-

Unigram, Bigram, Dependency and Entity Overlap	Real valued features that compute the proportion of common unigrams, bigrams, dependencies and geometry entities (constants, predicates and functions) across the two axioms. When comparing geometric entities, we include geometric entities derived from the associated diagrams when available.
Longest Common Subsequence	Real valued feature that computes the length of longest common sub-sequence of words between two axiom mentions normalized by the total number of words in the two mentions.
Number of sentences	Real valued feature that computes the absolute difference in the number of sentences in the two mentions.
Alignment Scores	We use an off-the-shelf monolingual word aligner – *JACANA* (Yao et al., 2013) pretrained on PPDB – and compute alignment score between axiom mentions as the feature.
MT Metrics	We use two common MT evaluation metrics *METEOR* (Denkowski and Lavie, 2010) and *MAXSIM* (Chan and Ng, 2008), and use the evaluation scores as features. While *METEOR* computes n-gram overlaps controlling on precision and recall, *MAXSIM* performs bipartite graph matching and maps each word in one axiom to at most one word in the other.
Summarization Metrics	We also use *Rouge-S* (Lin, 2004), a text summarization metric, and use the evaluation score as a feature. *Rouge-S* is based on skip-grams.
Equation Template	Indicator feature that matches templates of equations detected in the axiom mentions.
Image Caption	Proportion of common unigrams in the image captions of the diagrams associated with the axiom mentions. If both mentions do not have associated diagrams, this feature doesn't fire.
XML structure	Indicator matching the current (and parent) node of axiom mentions in respective XML hierarchies.

Table 2: Feature set for our axiom alignment model. The features are based on content, structure and typography.

iom split as a log-linear model: $p(Z_s|a;\mathbf{w}) \propto \exp\left(\mathbf{w}^T\mathbf{h}(a, Z_s)\right)$. Here, $\mathbf{h}$ are feature functions described later. We found that in most cases (>95%), the premise and conclusion are contiguous spans in the axiom mention where the left span corresponds to the *premise* and the right span corresponds to the *conclusion*. Hence, we search over the space of contiguous spans to infer Z_s. We use L-BGFGS for learning.

Features: We list the features $\mathbf{h}$ in Table 3. The features are defined over candidate spans forming the text split, are strongly inspired from rhetorical structure theory (Mann and Thompson, 1988) and previous works on discourse parsing (Marcu, 2000; Soricut and Marcu, 2003). Given a beam of *Premise* and *Conclusion* splits, we use the *GEOS* parser to get *Premise* and *Conclusion* logical formulas for each split in the beam and obtain a beam of axiom parses for each axiom in each textbook.

4.2.2 Multi-source Axiomatic Parser

Now, we describe a multi-source parser that utilizes the redundancy of axiom extractions from various sources (textbooks). Given a beam of 10-best parses for each axiom from each source, we use a number of heuristics to determine the best parse for the axiom:

1. Majority Voting: For each axiom, pick the parse that occurs most frequently across beams.

2. Average Score: Pick the parse that has the highest average parse score (only counting top 5 parses for each source), for each axiom.

3. Learn Source Confidence: Learn a set of weights $\{\mu_1, \mu_2, \ldots, \mu_S\}$, one for each source and then picks the parse that has the highest average weighted parse score for each axiom.

4. Predicate Score: Instead of selecting from one of the top parses across various sources, treat each axiom parse as a bag of premise predicates and a bag of conclusion predicates. Then, pick a subset of premise and conclusion predicates for the final parse using average scoring with thresholding.

5 Experiments

Datasets: We use a collection of grade 6-10 Indian high school math textbooks by four publishers/authors – *NCERT*, *R S Aggarwal*, *R D Sharma* and *M L Aggarwal* – a total of $5 \times 4 = 20$ textbooks to validate our model. Millions of students in India study geometry from these books every year and these books are readily available online. We manually marked chapters relevant for geometry in these books and then parsed them using Adobe Acrobat's *pdf2xml* parser. Then, we annotated geometry axioms, alignments and parses for grade 6, 7 and 8 textbooks by the four publishers/authors. We use grade 6, 7 and 8 textbook annotations for development, training, and testing, respectively. All the hyper-parameters in all the models are tuned on the development set using grid search.

GEOS used 13 types of entities and 94 functions and predicates. We add some more entities, functions and predicates to cover other more complex concepts in geometry not covered in *GEOS*. Thus, we obtain a final set of 19 entity types and 115 functions and predicates for our parsing model. We use Stanford CoreNLP (Manning et al., 2014) for feature generation. We use two datasets for evaluating our system: (a) practice and official SAT style geometry questions used in *GEOS*, and (b) an additional dataset of geometry questions collected from the aforementioned textbooks. This dataset consists of a total of 1406 SAT style questions across grades 6-10, and is approximately 7.5 times the size of the dataset used in *GEOS*. We split the dataset into training (350 questions),

Discourse Markers	Discourse markers (connectives, cue-words or cue-phrases, etc) have been shown to give good indications on discourse structure (Marcu, 2000). We build a list of discourse markers using the training set, considering the first and last tokens of each span, culled to top 100 by frequency. We use these 100 discourse markers as features. We repeat the same procedure by using part-of-speech (POS) instead of words and use them as features.
Punctuation	Punctuation at the segment border is an excellent cue. We include indicator features whether there is a punctuation at the segment border.
Text Organization	Indicator that the two text spans are part of the same (a) sentence, (b) paragraph.
XML Structure	Indicator that the two spans are in the same node in the XML hierarchy. Conjoined with the indicator feature that the two spans are part of the same paragraph.
RST Parse	We use an off-the-shelf RST parser (Feng and Hirst, 2014) and include an indicator feature that the segmentation matches the parse segmentation. We also include the RST label as a feature.
Span Lengths	The distribution of the two text spans is typically dependent on their lengths. We use the ratio of the length of the two spans as an additional feature.
Soricut and Marcu Segmenter	Soricut and Marcu (2003) (section 3.1) presented a statistical model for deciding elementary discourse unit boundaries. We use the probability given by this model retrained on our training set as feature. This feature uses both lexical and syntactic information.
Head / Common Ancestor/ Attachment Node	Head node is the word with the highest occurrence as a lexical head in the lexicalized tree among all the words in the text span. The attachment node is the parent of the head node. We have features for the head words of the left and right spans, the common ancestor (if any), the attachment node and the conjunction of the two head node words. We repeat these features with part-of-speech (POS) instead of words.
Syntax	Distance to (a) root (b) common ancestor for the nodes spanning the respective spans. We use these distances, and the difference in the distances as features.
Dominance	*Dominance* (Soricut and Marcu, 2003) is a key idea in discourse which looks at syntax trees and studies sub-trees for each span to infer a logical nesting order between the two. We use the dominance relationship is a feature. See Soricut and Marcu (2003) for details.
Span Similarity	Proportion of (a) words (b) geometry relations (c) relation-arguments shared by the two spans.
No. of Relations	Number of geometry relations represented in the two spans. We use the Lexicon Map from GEOS to compute the number of expressed geometry relations.
Relative Position	Relative position of the two lexical heads and the text split in sentence.

Table 3: Feature set for our axiom parsing model.

	Strict Comp.			Relaxed Comp.		
	P	**R**	**F**	**P**	**R**	**F**
Identification	64.3	69.3	66.7	84.3	87.9	86.1
Joint-Hard	68.0	68.1	68.0	85.4	87.1	86.2
Joint-Soft	69.7	71.1	**70.4**	86.9	88.4	**87.6**

Table 4: Test set Precision, Recall and F-measure scores for axiom identification when performed alone and when performed jointly with axiom alignment. We show results for both strict as well as relaxed comparison modes. For the joint model, we show results when we model ordering constraints as hard or soft constraints.

	P	**R**	**F**	**NMI**
Alignment	71.8	74.8	73.3	0.60
Joint-Hard	75.0	76.4	75.7	0.65
Joint-Soft	79.3	81.4	**80.3**	**0.69**

Table 5: Test set Precision, Recall, F-measure and NMI scores for axiom alignment when performed alone and when performed jointly with axiom identification. For the joint model, we show results when we model ordering constraints as hard or soft constraints.

development (150 questions) and test (906 questions) with equal proportion of grade 6-10 questions. We annotated the 500 training and development questions with ground-truth logical forms. We use the training set to train another version of *GEOS* with expanded set of entity types, functions and predicates. We call this system *GEOS++*.

Results: We first evaluate the axiom identification, alignment and parsing models individually.

For axiom identification, we compare the results of automatic identification with gold axiom identifications and compute the precision, recall and F-measure on the test set. We use strict as well as relaxed comparison. In strict comparison mode the automatically identified mentions and gold mentions must match exactly to get credit, whereas, in the relaxed comparison mode only a majority (>50%) of sentences in the automatically identified mentions and gold mentions must match to get credit. Table 4 shows the results of axiom identification where we clearly see improvements in performance when we jointly model axiom identification and alignment. This is due to the fact that both the components reinforce each other. We also observe that modeling the ordering constraints as soft constraints leads to better performance than modeling them as hard constraints. This is because the ordering of presentation of axioms is generally (yet not always) consistent across textbooks.

To evaluate axiom alignment, we first view it as a series of decisions, one for each pair of axiom mentions and compute precision, recall and F-score by comparing automatic decisions with gold decisions. Then, we also use a standard clustering metric, Normalized Mutual Information (NMI) (Strehl and Ghosh, 2002) to measure the quality of axiom mention clustering. Table 5 shows the results on the test set when gold axiom identifications are used. We observe improvements in axiom alignment performance too when we jointly model axiom identification and alignment jointly both in terms of F-score as well as NMI. Modeling ordering constraints as soft constraints again leads to better performance than modeling them as hard constraints in terms of both metrics.

To evaluate axiom parsing, we compute precision, recall and F-score in (a) deriving literals in axiom parses, as well as for (b) the final axiom parses on our test set. Table 6 shows the re-

		Literals			Full Parse		
		P	R	F	P	R	F
	GEOS	86.7	70.9	78.0	64.2	56.6	60.2
GEOS++	Single Src.	91.6	75.3	82.6	68.8	60.4	64.3
	Maj. Voting	90.2	78.5	83.9	70.0	63.3	66.5
	Avg. Score	90.8	79.6	84.9	71.7	66.4	69.0
	Src. Confid.	91.0	79.9	85.1	73.3	68.1	70.6
	Pred. Score	92.8	82.8	**87.5**	76.6	70.1	**73.2**

Table 6: Test set Precision, Recall and F-measure scores for axiom parsing. These scores are computed over literals derived in axiom parses or full axiom parses. We show results for the old *GEOS* system, for the improved *GEOS++* system with expanded entity types, functions and predicates, and for the multi-source parsers presented in this paper.

	Practice	Official	Textbook
GEOS	61	49	32
Our System	**64**	**55**	**51**
Oracle	80	78	72

Table 7: Scores for solving geometry questions on the SAT practice and official datasets and a dataset of questions from the 20 textbooks. We use SATs grading scheme that rewards a correct answer with a score of 1.0 and penalizes a wrong answer with a negative score of 0.25. *Oracle* uses gold axioms but automatic text and diagram interpretation in our logical solver. All differences between *GEOS* and our system are significant (p¡0.05 using the two-tailed paired t-test).

	Interpretability		Usefulness	
	GEOS	*O.S.*	*GEOS*	*O.S.*
Grade 6	2.7	**2.9**	2.9	**3.2**
Grade 7	3.0	**3.7**	3.3	**3.6**
Grade 8	2.7	**3.5**	3.1	**3.5**
Grade 9	2.4	**3.3**	3.0	**3.7**
Grade 10	2.8	**3.1**	3.2	**3.8**
Overall	2.7	**3.3**	3.1	**3.6**

Table 8: User study ratings for *GEOS* and our system (O.S.) by students in grade 6-10. Ten students in each grade were asked to rate the two systems on a scale of 1-5 on two facets: 'interpretability' and 'usefulness'. Each cell shows the mean rating computed over ten students in that grade for that facet.

sults of axiom parsing for *GEOS* (trained on the training set) as well as various versions of our best performing system (*GEOS*++ with our axiomatic solver) with various heuristics for multi-source parsing. The results show that our system (single source) performs better than *GEOS* as it is trained with the expanded set of entity types, functions and predicates. The results also show that the choice of heuristic is important for the multi-source parser – though all the heuristics lead to improvements over the single source parser. The average score heuristic that chooses the parse with the highest average score across sources performs better than majority voting which chooses the best parse based on a voting heuristic. Learning the confidence of every source and using a weighted average is an even better heuristic. Finally, predicate scoring which chooses the parse by scoring predicates on the premise and conclusion sides performs the best leading to 87.5 F1 score (when computed over parse literals) and 73.2 F1 score (when computed on the full parse). The high F1 score for axiom parsing on the test set shows that our approach works well and we can accurately harvest axiomatic knowledge from textbooks.

Finally, we use the extracted horn clause rules in our axiomatic solver for solving geometry problems. For this, we over-generate a set of horn clause rules by generating 3 horn clause parses for each axiom and use them as the underlying theory in prolog programs such as the one shown in Figure 3. We use weighted logical expressions for the question description and the diagram derived from *GEOS*++ as declarations, and the (normalized) score of the parsing model multiplied by the score of the joint axiom identification and alignment model as weights for the rules. Table 7 shows the results for our best end-to-end system and compares it to *GEOS* on the practice and official SAT dataset from Seo et al. (2015) as well as questions from the 20 textbooks. On all the three datasets, our system outperforms *GEOS*. Especially on the dataset from the 20 textbooks (which is indeed a harder dataset and includes more problems which require complex reasoning based on geometry), *GEOS* doesn't perform very well whereas our system still achieves a good score. *Oracle* shows the performance of our system when gold axioms (written down by an expert) are used along with automatic text and diagram interpretations in *GEOS*++. This shows that there is scope for further improvement in our approach.

Interpretability: Students around the world solve geometry problems through rigorous deduction whereas the numerical solver in *GEOS* does not provide such interpretability. One of the key benefits of our axiomatic solver is that it provides an easy-to-understand student-friendly deductive solution to geometry problems.

To test the interpretability of our axiomatic solver, we asked 50 grade 6-10 students (10 students in each grade) to use *GEOS* and our system (*GEOS*++ with our axiomatic solver) as a web-based assistive tool while learning geometry. They were each asked to rate how 'interpretable' and 'useful' the two systems were on a scale of 1-5. Table 8 shows the mean rating by students in each grade on the two facets. We can observe that students of each grade found our system to be more interpretable as well as more useful to them than *GEOS*. This study lends support to our claims about the need of an interpretable deductive solver for geometry problems.

6 Related Work

Solving Geometry Problems: While the problem of using computers to solve geometry questions is old (Feigenbaum and Feldman, 1963; Schattschneider and King, 1997; Davis, 2006), NLP and computer vision techniques were first used to solve geometry problems in Seo et al. (2015). While Seo et al. (2014) only aligned geometric shapes with their textual mentions, Seo et al. (2015) also extracted geometric relations and built *GEOS*, the first automated system to solve SAT style geometry questions. *GEOS* used a coordinate geometry based solution by translating each predicate into a set of manually written constraints. A boolean satisfiability problem posed with these constraints was used to solve the multiple-choice question. *GEOS* had two key issues: (a) it needed access to answer choices which may not always be available for such problems, and (b) it lacked the deductive geometric reasoning used by students to solve these problems. Our axiomatic solver mitigates these issues by performing deductive reasoning using axiomatic knowledge extracted from textbooks.

Information Extraction from Textbooks: Our model builds upon ideas from Information extraction (IE), which is the task of automatically extracting structured information from unstructured and/or semi-structured documents. While there has been a lot of work in IE on domains such as web documents (Chang et al., 2003; Etzioni et al., 2004; Cafarella et al., 2005; Chang et al., 2006; Banko et al., 2007; Etzioni et al., 2008; Mitchell et al., 2015) and scientific publication data (Shah et al., 2003; Peng and McCallum, 2006; Saleem and Latif, 2012), work on IE from educational material is much more sparse. Most of the research in IE from educational material deals with extracting simple educational concepts (Shah et al., 2003; Canisius and Sporleder, 2007; Yang et al., 2015; Wang et al., 2015; Liang et al., 2015; Wu et al., 2015; Liu et al., 2016b; Wang et al., 2016) or binary relational tuples (Balasubramanian et al., 2002; Clark et al., 2012; Dalvi et al., 2016) using existing IE techniques. On the other hand, our approach extracts axioms and parses them to horn clause rules. This is much more challenging. Raw application of rule mining or sequence labeling techniques used to extract information from web documents and scientific publications to educational material usually leads to poor results as the amount of redundancy in educational material is lower and the amount of labeled data is sparse. Our approach tackles these issues by making judicious use of typographical information, the redundancy of information and ordering constraints to improve the harvesting and parsing of axioms. This has not been attempted in previous work.

Language to Programs: After harvesting axioms from textbooks, we also present an approach to parse the axiom mentions to horn clause rules. This work is related to a large body of work on semantic parsing (Zelle and Mooney, 1993, 1996; Kate et al., 2005; Zettlemoyer and Collins, 2012, inter alia). Semantic parsers typically map natural language to formal programs such as database queries (Liang et al., 2011; Berant et al., 2013; Yaghmazadeh et al., 2017, inter alia), commands to robots (Shimizu and Haas, 2009; Matuszek et al., 2010; Chen and Mooney, 2011, inter alia), or even general purpose programs (Lei et al., 2013; Ling et al., 2016; Yin and Neubig, 2017; Ling et al., 2017). More specifically, Liu et al. (2016a) and Quirk et al. (2015) learn “If-Then” and “If-This-Then-That” rules, respectively. In theory, these works can be adapted to parse axiom mentions to horn-clause rules. However, this would require a large amount of supervision which would be expensive to obtain. We mitigated this issue by using redundant axiom mention extractions from multiple textbooks and then combining the parses obtained from various textbooks to achieve a better final parse for each axiom.

7 Conclusion

We presented an approach to harvest structured axiomatic knowledge from math textbooks. Our approach uses rich features based on context and typography, the redundancy of axiomatic knowledge and shared ordering constraints across multiple textbooks to accurately extract and parse axiomatic knowledge to horn clause rules. We used the parsed axiomatic knowledge to improve the best previously published automatic approach to solve geometry problems. A user-study conducted on a number of school students studying geometry found our approach to be more interpretable and useful than its predecessor. While this paper focused on harvesting geometry axioms from textbooks as a case study, it can be extended to obtain valuable structured knowledge from textbooks in areas such as science, engineering and finance.

Abstract

We present RACE, a new dataset for benchmark evaluation of methods in the reading comprehension task. Collected from the English exams for middle and high school Chinese students in the age range between 12 to 18, RACE consists of near 28,000 passages and near 100,000 questions generated by human experts (English instructors), and covers a variety of topics which are carefully designed for evaluating the students' ability in understanding and reasoning. In particular, the proportion of questions that requires reasoning is much larger in RACE than that in other benchmark datasets for reading comprehension, and there is a significant gap between the performance of the state-of-the-art models (43%) and the ceiling human performance (95%). We hope this new dataset can serve as a valuable resource for research and evaluation in machine comprehension. The dataset is freely available at http://www.cs.cmu.edu/~glai1/data/race/ and the code is available at https://github.com/qizhex/RACE_AR_baselines

1 Introduction

Constructing an intelligence agent capable of understanding text as people is the major challenge of NLP research. With recent advances in deep learning techniques, it seems possible to achieve human-level performance in certain language understanding tasks, and a surge of effort has been devoted to the machine comprehension task where people aim to construct a system with the ability to answer questions related to a document that it has to comprehend (Chen et al., 2016; Kadlec et al., 2016; Dhingra et al., 2016; Yang et al., 2017).

Towards this goal, several large-scale datasets (Rajpurkar et al., 2016; Onishi et al., 2016; Hill et al., 2015; Trischler et al., 2016; Hermann et al., 2015) have been proposed, which allow researchers to train deep learning systems and obtain results comparable to the human performance. While having a suitable dataset is crucial for evaluating the system's true ability in reading comprehension, the existing datasets suffer several critical limitations. Firstly, in all datasets, the candidate options are directly extracted from the context (as a single entity or a text span), which leads to the fact that lots of questions can be solved trivially via word-based search and context-matching without deeper reasoning; this constrains the types of questions as well. Secondly, answers and questions of most datasets are either crowd-sourced or automatically-generated, bringing a significant amount of noises in the datasets and limits the ceiling performance by domain experts, such as 82% for Childrens Book Test and 84% for Who-did-What. Yet another issue in existing datasets is that the topic coverages are often biased due to the specific ways that the data were initially collected, making it hard to evaluate the ability of systems in text comprehension over a broader range of topics.

To address the aforementioned limitations, we constructed a new dataset by collecting a large set of questions, answers and associated passages in the English exams for middle-school and high-school Chinese students within the 12–18 age range. Those exams were designed by domain experts (instructors) for evaluating the reading comprehension ability of students, with ensured quality and broad topic coverage. Furthermore, the answers by machines or by humans can be objectively graded for evaluation

and comparison using the same evaluation metrics. Although efforts have been made with a similar motivation, including the MCTest dataset created by (Richardson et al., 2013) (containing 500 passages and 2000 questions) and several others (Peñas et al., 2014; Rodrigo et al., 2015; Khashabi et al., 2016; Shibuki et al., 2014), the usefulness of those datasets is significantly restricted due to their small sizes, especially not suitable for training powerful deep neural networks whose success relies on the availability of relatively large training sets.

Our new dataset, namely RACE, consists of 27,933 passages and 97,687 questions. After reading each passage, each student is asked to answer several questions where each question is provided with four candidate answers – only one of them is correct . Unlike existing datasets, both the questions and candidate answers in RACE are not restricted to be the text spans in the original passage; instead, they can be described in any words. A sample from our dataset is presented in Table 1.

Our latter analysis shows that correctly answering a large portion of questions in RACE requires the ability of reasoning, the most important feature as a machine comprehension dataset (Chen et al., 2016). RACE also offers two important subdivisions of the reasoning types in its questions, namely passage summarization and attitude analysis, which have not been introduced by the any of the existing large-scale datasets to our knowledge.

In addition, compared to other existing datasets where passages are either domain-specific or of a single fixed style (namely news stories for CNN/-Daily Mail, NEWSQA and Who-did-What, fiction stories for Children's Book Test and Book Test, and Wikipedia articles for SQUAD), passages in RACE almost cover all types of human articles, such as news, stories, ads, biography, philosophy, etc., in a variety of styles. This comprehensiveness of topic/style coverage makes RACE a desirable resource for evaluating the reading comprehension ability of machine learning systems in general.

The advantages of our proposed dataset over existing large datasets in machine reading comprehension can be summarized as follows:

- All questions and candidate options are generated by human experts, which are intentionally designed to test human agent's ability in reading comprehension. This makes RACE a relatively accurate indicator for reflecting the text comprehension ability of machine learning systems under human judge.
- The questions are substantially more difficult than those in existing datasets, in terms of the large portion of questions involving reasoning. At the meantime, it is also sufficiently large to support the training of deep learning models.
- Unlike existing large-scale datasets, candidate options in RACE are human generated sentences which may not appear in the original passage. This makes the task more challenging and allows a rich type of questions such as passage summarization and attitude analysis.
- Broad coverage in various domains and writing styles: a desirable property for evaluating generic (in contrast to domain/style-specific) comprehension ability of learning models.

2 Related Work

In this section, we briefly outline existing datasets for the machine reading comprehension task, including their strengths and weaknesses.

2.1 MCTest

MCTest (Richardson et al., 2013) is a popular dataset for question answering in the same format as RACE, where each question is associated with four candidate answers with a single correct answer. Although questions in MCTest are of high-quality ensured by careful examinations through crowdsourcing, it contains only 500 stores and 2000 questions, which substantially restricts its usage in training advanced machine comprehension models. Moreover, while MCTest is designed for 7 years old children, RACE is constructed for middle and high school students at 12–18 years old hence is more complicated and requires stronger reasoning skills. In other words, RACE can be viewed as a larger and more difficult version of the MCTest dataset.

2.2 Cloze-style datasets

The past few years have witnessed several large-scale cloze-style datasets (Hermann et al., 2015; Hill et al., 2015; Bajgar et al., 2016; Onishi et al., 2016), whose questions are formulated by obliterating a word or an entity in a sentence.

Passage:

In a small village in England about 150 years ago, a mail coach was standing on the street. It didn't come to that village often. People had to pay a lot to get a letter. The person who sent the letter didn't have to pay the postage, while the receiver had to.
"Here's a letter for Miss Alice Brown," said the mailman.
" I'm Alice Brown," a girl of about 18 said in a low voice.
Alice looked at the envelope for a minute, and then handed it back to the mailman.
"I'm sorry I can't take it, I don't have enough money to pay it", she said.
A gentleman standing around were very sorry for her. Then he came up and paid the postage for her.
When the gentleman gave the letter to her, she said with a smile, " Thank you very much, This letter is from Tom. I'm going to marry him. He went to London to look for work. I've waited a long time for this letter, but now I don't need it, there is nothing in it."
"Really? How do you know that?" the gentleman said in surprise.
"He told me that he would put some signs on the envelope. Look, sir, this cross in the corner means that he is well and this circle means he has found work. That's good news."
The gentleman was Sir Rowland Hill. He didn't forgot Alice and her letter.
"The postage to be paid by the receiver has to be changed," he said to himself and had a good plan.
"The postage has to be much lower, what about a penny? And the person who sends the letter pays the postage. He has to buy a stamp and put it on the envelope." he said . The government accepted his plan. Then the first stamp was put out in 1840. It was called the "Penny Black". It had a picture of the Queen on it.

Questions:

1): The first postage stamp was made _.
A. in England B. in America C. by Alice D. in 1910

2): The girl handed the letter back to the mailman because _ .
A. she didn't know whose letter it was
B. she had no money to pay the postage
C. she received the letter but she didn't want to open it
D. she had already known what was written in the letter

3): We can know from Alice's words that _ .
A. Tom had told her what the signs meant before leaving
B. Alice was clever and could guess the meaning of the signs
C. Alice had put the signs on the envelope herself
D. Tom had put the signs as Alice had told him to

4): The idea of using stamps was thought of by _ .
A. the government
B. Sir Rowland Hill
C. Alice Brown
D. Tom

5): From the passage we know the high postage made _ .
A. people never send each other letters
B. lovers almost lose every touch with each other
C. people try their best to avoid paying it
D. receivers refuse to pay the coming letters

Answer: ADABC

Table 1: Sample reading comprehension problems from our dataset.

CNN/Daily Mail (Hermann et al., 2015) are the largest machine comprehension datasets with 1.4M questions. However, both require limited reasoning ability (Chen et al., 2016). In fact, the best machine performance obtained by researchers (Chen et al., 2016; Dhingra et al., 2016) is close to human's performance on CNN/Daily Mail.

Childrens Book Test (CBT) (Hill et al., 2015) and Book Test (BT) (Bajgar et al., 2016) are constructed in a similar manner. Each passage in CBT consist of 20 contiguous sentences extracted from children's books and the next (21st) sentence is used to make the question. The main difference between the two datasets is the size of BT being 60 times larger. Machine comprehension models have also matched human performance on CBT (Bajgar et al., 2016).

Who Did What (WDW) (Onishi et al., 2016) is yet another cloze-style dataset constructed from the LDC English Gigaword newswire corpus. The authors generate passages and questions by picking two news articles describing the same event, using one as the passage and the other as the question.

High noise is inevitable in cloze-style datasets due to their automatic generation process, which is reflected in the human performance on these datasets: 82% for CBT and 84% for WDW.

2.3 Datasets with Span-based Answers

In datasets such as SQUAD (Rajpurkar et al., 2016), NEWSQA (Trischler et al., 2016) and MS MARCO (Nguyen et al., 2016), the answer to each question is in the form of a text span in the article. Articles of SQUAD, NEWSQA and MS MARCO come from Wikipedia, CNN news and the Bing search engine respectively. The answer to a certain question may not be unique and could be multiple spans. Instead of evaluating the accuracy, researchers need to use F1 score, BLEU (Papineni et al., 2002) or ROUGE (Lin and Hovy, 2003) as metrics, which measure the overlap between the prediction and ground truth answers since the questions come without candidate spans.

Datasets with span-based answers are challenging as the space of possible spans is usually large. However, restricting answers to be text spans in the context passage may be unrealistic and more importantly, may not be intuitive even for humans, indicated by the suffered human performance of 80.3% on SQUAD (or 65% claimed by Trischler et al. (2016)) and 46.5% on NEWSQA. In other words, the format of span-based answers may not necessarily be a good examination of reading comprehension of machines whose aim is to approach the comprehension ability of *humans*.

2.4 Datasets from Examinations

There have been several datasets extracted from examinations, aiming at evaluating systems under the same conditions as how humans are evaluated in schools. E.g., the AI2 Elementary School Science Questions dataset (Khashabi et al., 2016) contains 1080 questions for students in elementary schools; NTCIR QA Lab (Shibuki et al., 2014) evaluates systems by the task of solving real-world university entrance exam questions; The Entrance Exams task at CLEF QA Track (Peñas et al., 2014; Rodrigo et al., 2015) evaluates the system's reading comprehension ability. However, data provided in these existing tasks are far from sufficient for the training of advanced data-driven machine reading models, partially due to the expensive data generation process by human experts.

To the best of our knowledge, RACE is the first *large-scale* dataset of this type, where questions are created based on exams designed to evaluate human performance in reading comprehension.

3 Data Analysis

In this section, we study the nature of questions covered in RACE at a detailed level. Specifically, we present the dataset statistics in Section 3.1, and then analyze different reasoning/question types in RACE in the remaining subsections.

3.1 Dataset Statistics

As mentioned in section 1, RACE is collected from English examinations designed for 12–15 year-old middle school students, and 15–18 year-old high school students in China. To distinguish the two subgroups with drastic difficulty gap, RACE-M denotes the middle school examinations and RACE-H denotes high school examinations. We split 5% data as the development set and 5% as the test set for RACE-M and RACE-H respectively. The number of samples in each set is shown in Table 2. The statistics for RACE-M and RACE-H is summarized in Table 3. We can find that the length of the passages and the vocabulary size in the RACE-H are much larger than that of the RACE-M, an evidence of the higher difficulty of high school examinations.

However, notice that since the articles and questions are selected and designed to test Chinese students learning English as a foreign language, the vocabulary size and the complexity of the language constructs are simpler than news articles and Wikipedia articles in other QA datasets.

3.2 Reasoning Types of the Questions

To get a comprehensive picture about the reasoning difficulty requirement of RACE, we conduct human annotations of questions types. Following Chen et al. (2016); Trischler et al. (2016), we stratify the questions into five classes as follows with ascending order of difficulty:

- Word matching: The question exactly matches a span in the article. The answer is self-evident.

- Paraphrasing: The question is entailed or paraphrased by exactly one sentence in the passage. The answer can be extracted within the sentence.

- Single-sentence reasoning: The answer could be inferred from a single sentence of the article by recognizing incomplete information or conceptual overlap.

- Multi-sentence reasoning: The answer must be inferred from synthesizing information distributed across multiple sentences.

- Insufficient/Ambiguous: The question has no answer or the answer is not unique based on the given passage.

We refer readers to (Chen et al., 2016; Trischler et al., 2016) for examples of each category.

To obtain the proportion of different question types, we sample 100 passages from RACE (50 from RACE-M and 50 from RACE-H), all of which have 5 questions hence there are 500 questions in total. We put the passages on Amazon Mechanical Turk[1], and a Hit is generated by a passage

[1] https://www.mturk.com/mturk/welcome

Dataset	RACE-M			RACE-H			RACE			
Subset	Train	Dev	Test	Train	Dev	Test	Train	Dev	Test	All
# passages	6,409	368	362	18,728	1,021	1,045	25,137	1,389	1,407	27,933
# questions	25,421	1,436	1,436	62,445	3,451	3,498	87,866	4,887	4,934	97,687

Table 2: The separation of the training, development and test sets of RACE-M,RACE-H and RACE

Dataset	RACE-M	RACE-H	RACE
Passage Len	231.1	353.1	321.9
Question Len	9.0	10.4	10.0
Option Len	3.9	5.8	5.3
Vocab size	32,811	125,120	136,629

Table 3: Statistics of RACE where Len denotes length and Vocab denotes Vocabulary.

with 5 questions. Each question is labeled by two crowdworkers. We require the turkers to both answer the questions and label the reasoning type. We pay \$0.70 and \$1.00 per passage in RACE-M and RACE-H respectively, and restrict the access to master turkers only. Finally, we get 1000 labels for the 500 questions.

The statistics about the reasoning type is summarized in Table 4. The higher difficulty level of RACE is justified by its higher ratio of reasoning questions in comparison to CNN, SQUAD and NEWSQA. Specifically, 59.2% questions of RACE are either in the category of single-sentence reasoning or in the category of multi-sentence reasoning, while the ratio is 21%, 20.5% and 33.9% for CNN, SQUAD and NEWSQA respectively. Also notice that the ratio of word matching questions on RACE is only 15.8%, the lowest among several categories. In addition, questions in RACE-H are more complex than questions in RACE-M since RACE-M has more word matching questions and fewer reasoning questions.

3.3 Subdividing Reasoning Types

To better understand our dataset and facilitate future research, we list the subdivisions of questions under the reasoning category. We find the most frequent reasoning subdivisions include: detail reasoning, whole-picture understanding, passage summarization, attitude analysis and world knowledge. One question may fall into multiple divisions. Definition of these subdivisions and their associated examples are as follows:

1. Detail reasoning: to answer the question, the agent should be clear about the details of the passage. The answer appears in the passage but it cannot be found by simply matching the question with the passage. For example, Question 1 in the sample passage falls into this category.

2. Whole-picture reasoning: the agent needs to understand the whole picture of the story to obtain the correct answer. For example, to answer the Question 2 in the sample passage, the agent is required to comprehend the entire story.

3. Passage summarization: The question requires the agent to select the best summarization of the passage among four candidate summarizations. A typical question of this type is "The main idea of this passage is __.". An example question can be found in Appendix A.1.

4. Attitude analysis: The question asks about the opinions/attitudes of the author or a character in the story towards somebody or something, e.g.,

- *Evidence*: "...Many people optimistically thought industry awards for better equipment would stimulate the production of quieter appliances. It was even suggested that noise from building sites could be alleviated ..."
- *Question*: What was the author's attitude towards the industry awards for quieter?
- *Options*: A.suspicious B.positive C.enthusiastic D.indifferent

5. World knowledge: Certain external knowledge is needed. Most frequent questions under this category involve simple arithmetic.

- *Evidence*: "The park is open from 8 am to 5 pm."
- *Question*: The park is open for __ hours a day.
- *Options*: A.eight B.nine C.ten D.eleven

To the best of our knowledge, questions like passage summarization and attitude analysis have not been introduced by any of the existing large-scale machine comprehension datasets. Both are crucial components in evaluating humans' reading comprehension abilities.

Dataset	RACE-M	RACE-H	RACE	CNN	SQUAD	NEWSQA
Word Matching	29.4%	11.3%	15.8%	13.0%†	39.8%*	32.7%*
Paraphrasing	14.8%	20.6%	19.2%	41.0%†	34.3%*	27.0%*

Table 4: Statistic information about Reasoning type in different datasets. * denotes the numbers coming from (Trischler et al., 2016) based on 1000 samples per dataset, and numbers with † come from (Chen et al., 2016).

4 Collection Methodology

We collected the raw data from three large free public websites[2][3][4] in China[5], where the reading comprehension problems are extracted from English examinations designed by teachers in China. The data before cleaning contains 137,918 passages and 519,878 questions in total, where there are 38,159 passages with 156,782 questions in the middle school group, and 99,759 passages with 363,096 questions in the high school group.

The following filtering steps are conducted to clean the raw data. Firstly, we remove all problems and questions that do not have the same format as our problem setting, e.g., a question would be removed if the number of its options is not four. Secondly, we filter all articles and questions that are not self-contained based on the text information, i.e. we remove the articles and questions containing images or tables. We also remove all questions containing keywords "underlined" or "paragraph", since it is difficult to reproduce the effect of underlines and the paragraph segment information. Thirdly, we remove all duplicated articles.

On one of the websites (xkw.com), the answers are stored as images. We used two standard OCR programs tesseract [6] and ABBYY FineReader [7] to process the images. We remove all the answers that two software disagree. The OCR task is easy since we only need to recognize printed alphabet A, B, C, D with a standard font. Finally, we get the cleaned dataset RACE, with 27,933 passages and 97,687 questions.

5 Experiments

In this section, we compare the performance of several state-of-the-art reading comprehension models with human performance. We use accuracy as the metric to evaluate different models.

5.1 Methods for Comparison

Sliding Window Algorithm Firstly, we build the rule-based baseline introduced by Richardson et al. (2013). It chooses the answer having the highest matching score. Specifically, it first concatenates the question and the answer and then calculates the TF-IDF style matching score between the concatenated sentence with every window (a span of text) of the article. The window size is decided by the model performance in the training and dev sets.

Stanford Attentive Reader Stanford Attentive Reader (Stanford AR) (Chen et al., 2016) is a strong model that achieves state-of-the-art results on CNN/Daily Mail. Moreover, the authors claim that their model has nearly reached the ceiling performance on these two datasets.

Suppose that the triple of passage, question and options is denoted by $(p, q, o_{1,\cdots,4})$. We first employ bidirectional GRUs to encode p and q respectively into $h_1^p, h_2^p, \dots, h_n^p$ and h^q. Then we summarize the most relevant part of the passage into s^p with an attention model. Following Chen et al. (2016), we adopt a bilinear attention form. Specifically,

$$\begin{aligned} \alpha_i &= \text{Softmax}_i((h_i^p)^T W_1 h^q) \\ s^p &= \sum_i \alpha_i h_i^p \end{aligned} \tag{1}$$

Similarly, we use bidirectional GRUs to encode option o_i into a vector h^{o_i}. Finally, we compute the matching score between the i-th option $(i = 1, \cdots, 4)$ and the summarized passage using

a bilinear attention. We pass the scores through softmax to get a probability distribution. Specifically, the probability of option i being the right answer is calculated as

$$p_i = \text{Softmax}_i(h^{o_i} W_2 s^d) \tag{2}$$

Gated-Attention Reader Gated AR (Dhingra et al., 2016) is the state-of-the-art model on multiple datasets. To build query-specific representations of tokens in the document, it employs an attention mechanism to model multiplicative interactions between the query embedding and the document representation. With a multi-hop architecture, GA also enables a model to scan the document and the question iteratively for multiple passes. In other words, the multi-hop structure makes it possible for the reader to refine token representations iteratively and the attention mechanism find the most relevant part of the document. We refer readers to (Dhingra et al., 2016) for more details.

After obtaining a query specific document representation s^d, we use the same method as bilinear operation listed in Equation 2 to get the output.

Note that our implementation slightly differs from the original GA reader. Specifically, the Attention Sum layer is not applied at the final layer and no character-level embeddings are used.

Implementation Details We follow Chen et al. (2016) in our experiment settings. The vocabulary size is set to $50k$. We choose word embedding size $d = 100$ and use the 100-dimensional Glove word embedding (Pennington et al., 2014) as embedding initialization. GRU weights are initialized from Gaussian distribution $\mathcal{N}(0, 0.1)$. Other parameters are initialized from a uniform distribution on $(-0.01, 0.01)$. The hidden dimensionality is set to 128 and the number of layers is set to one for both Stanford AR and GA. We use vanilla stochastic gradient descent (SGD) to train our models. We apply dropout on word embeddings and the gradient is clipped when the norm of the gradient is larger than 10. We use a grid search on validation set to choose the learning rate within $\{0.05, 0.1, 0.3, 0.5\}$ and dropout rate within $\{0.2, 0.5, 0.7\}$. The highest accuracy on validation set is obtained by setting learning rate to 0.1 for Stanford AR and 0.3 for GA and dropout rate to 0.5. The data of RACE-M and RACE-H is used together to train our model and testing is performed separately.

5.2 Human Evaluation

As described in section 3.2, a randomly sampled subset of test set has been labeled by Amazon Turkers, which contains 500 questions with half from RACE-H and with the other half from RACE-M. The turkers' performance is 85% for RACE-M and 70% for RACE-H. However, it is hard to guarantee that every turker performs the survey carefully, given the difficult and long passages of high school problems. Therefore, to obtain the ceiling human performance on RACE, we manually labeled the proportion of valid questions. A question is valid if it is unambiguous and has a correct answer. We found that 94.5% of the data is valid, which sets the ceiling human performance. Similarly, the ceiling performance on RACE-M and RACE-H is 95.4% and 94.2% respectively.

5.3 Main Results

We compare models' and human ceiling performance on datasets which have the same evaluation metric with RACE. The compared datasets include RACE, MCTest, CNN/Daily Mail (CNN and DM), CBT and WDW. On CBT, we report performance on two subsets where the missing token is either a common noun (CBT-C) or name entity (CBT-N) since the language models have already reached human-level performance on other types (Hill et al., 2015). The comparison is shown in Table 5.

Performance of Sliding Window We first compare MCTest with RACE using Sliding Window, where it is unable to train Stanford AR and Gated AR on MCTest's limited training data. Sliding Window achieves an accuracy of 51.5% on MCTest while only 37.3% on RACE, meaning that to answer the questions of RACE requires more reasoning than MCTest.

The performance of sliding window on RACE is not directly comparable with CBT and WDW since CBT has ten candidate answers for each question and WDW has an average of three. Instead, we evaluate the performance improvement of sliding window on the random baseline. Larger improvement indicates more questions solvable by simple matching. On RACE, Sliding Window is 28.6% better than the random baseline, while the improvement is 58.5%, 92.2% and 50% for CBT-N, CBT-C and WDW.

The accuracy on RACE-M (37.3%) and RACE-H (30.4%) indicates that the middle school questions are simpler based on the matching algorithm.

Performance of Neural Models We further compare the difficulty of different datasets by state-of-the-art neural models' performance. A lower performance means that more problems are unsolvable by machines. The Stanford AR and Gated AR achieve an accuracy of only 43.3% and 44.1% on RACE while their accuracy is much higher on CNN/Daily Mail, Childrens Book Test and Who-Did-What. It justifies the fact that, among current large-scale machine comprehension datasets, RACE is the most challenging one.

Human Ceiling Performance The human performance is 94.5% which shows our data is quite clean compared to other large-scale machine comprehension datasets. Since we cannot enforce every turker do the test cautiously, the result shows a gap between turkers' performance and human performance. Reasonably, problems in the high school group with longer passages and more complex questions lead to more significant divergence. Nevertheless, the start-of-the-art models still have a large room to be improved to reach turkers' performance. The performance gap is 41% for the middle school problems and 25% for the high school problems. What's more, The performance of Stanford AR and GA is only less than a half of the ceiling human performance, which indicates that to match the humans' reading comprehension ability, we still have a long way to go.

5.4 Reason Types Analysis

We evaluate human and models on different types of questions, shown in Figure 1. Turkers do the best on word matching problems while doing the worst on reasoning problems. Sliding window performs better on word matching than problems needing reasoning or paraphrasing. Surprisingly, Stanford AR does not have a stronger performance on the word matching category than reasoning categories. A possible reason is that the proportion of data in reasoning categories is larger than that of data. Also, the candidate answers of simple matching questions may share similar word embeddings. For example, if the question is about color, it is difficult to distinguish candidate answers, "green", "red", "blue" and "yellow", in the embedding vector space. The similar performance on different categories also explains the reason that the performance of the neural models is close in the middle and high school groups in Table 5.

6 Conclusion

We introduce a large, high-quality dataset for reading comprehension that is carefully designed to examine human ability on this task. Some desirable properties of RACE include the broad coverage of domains/styles and the richness in the question format. Most importantly, it requires substantially more reasoning to do well on RACE than on other datasets, as there is a significant gap between the performance of state-of-the-art machine comprehension models and that of the human. We hope this dataset will stimulate the development of more advanced machine comprehension models.

Beyond Sentential Semantic Parsing: Tackling the Math SAT with a Cascade of Tree Transducers

Mark Hopkins, Cristian Petrescu-Prahova, Roie Levin,

Allen Institute for Artificial Intelligence
Seattle, WA
{markh,cristipp,roiel,rlebras,alvaroh,vidurj}@allenai.org

Abstract

We present an approach for answering questions that span multiple sentences and exhibit sophisticated cross-sentence anaphoric phenomena, evaluating on a rich source of such questions – the math portion of the Scholastic Aptitude Test (SAT). By using a tree transducer cascade as its basic architecture, our system (called EUCLID) propagates uncertainty from multiple sources (e.g. coreference resolution or verb interpretation) until it can be confidently resolved. Experiments show the first-ever results (43% recall and 91% precision) on SAT algebra word problems. We also apply EUCLID to the public Dolphin algebra question set, and improve the state-of-the-art F_1-score from 73.9% to 77.0%.

1 Introduction

Math word problems pose questions that are challenging for current question answering (QA) systems to solve. Consider the following question originating from a study guide for the Math SAT[1]:

> **Example 1:** Suppose $3x + y = 15$, where x is a positive integer. What is the difference between the largest possible value of y and the smallest possible value of x, assuming that y is also a positive integer?

The correct response is 11; however its relationship with the other numbers in the question (3 and 15) is oblique and not easily mapped to an operator tree or equation template. This encourages us to build a semantic parser that produces an explicit representation of what the question is asking, if we want to make quantitative progress on the question set. However, while it is not hard to formalize the semantics:

$$X \times Y = \{(x, y) \mid 3x + y = 15, x, y \in \mathbb{Z}^+\}$$
$$X = \{x \mid (x, y) \in X \times Y\}$$
$$Y = \{y \mid (x, y) \in X \times Y\}$$
$$\textbf{solve: } \max Y - \min X$$

it is not clear how to devise a compositional transformation from the original question to the formal semantics, since the meaning is dispersed throughout the discourse, such that neither the maximization nor the minimization can be locally derived from some subtree of the syntactic structure.

Moreover, SAT questions quickly reach the limits of preprocessing tools like anaphora resolution:

> **Example 2:** $\langle r, s, t\rangle$ In the sequence above, if each term after the first is x more than the previous term, what is the average of r, s, and t in terms of r and x?

Understanding this question requires a nuanced resolution of *each term after the first* to the subsequence $\langle s, t\rangle$, a coreference resolution beyond the grasp of the current state of the art.

Generally speaking, question discourse (with its complex cross-sentence semantics and anaphora) has not been a major focus of QA research. In this paper, we use math SAT questions to develop an approach to handling question discourse. Our parser uses an intermediate semantic language that allows complex semantics (like those of Example 1) to be compositionally constructed from a multi-sentence question passage (Section 5.1). By architecting our semantic parser as a cascade of nondeterministic tree transducers (Gécseg and Steinby, 1997), we can propagate uncertainty until it can be

[1] The Math SAT is a standardized exam administered to college-bound high school students in the United States.

Proceedings of the 2017 Conference on Empirical Methods in Natural Language Processing, pages 795–804

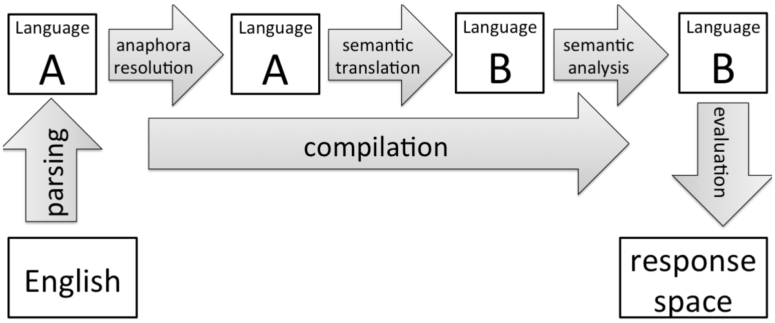

Figure 1: High-level view of EUCLID's architecture.

confidently resolved – sometimes as late as during program interpretation (Section 6). The integrated approach also allows us to handle novel classes of anaphoric phenomena by framing anaphora resolution as an operation on a parse forest decorated with implicits (Section 5.2).

Ultimately we produce an end-to-end system (called EUCLID) that achieves 43% recall and 91% precision on SAT closed-vocabulary algebra questions, a subset (described in more detail in the next section) that constitutes approximately 45% of a typical math SAT. We also achieve state-of-the-art results on the publicly released Dolphin question set (Shi et al., 2015), a set of more than 1500 algebra questions released by Microsoft Research. Finally, we provide a look at our early progress on extending the system to tackle the math SAT in its entirety.

2 Anatomy of a Math SAT

To assess our semantic parser, we compiled three question sets. Two question sets were created from sample SAT exams found in study guides (published by Kaplan and McGraw-Hill). We used the Kaplan set (12 exams, 648 total questions) for training/development and the McGraw-Hill set (13 exams[2], 686 total questions) for devtest. We reserved official practice exams (8 exams, 396 total questions) released by the College Board for final testing. We did not subselect questions from the exams, rather we used them in their entirety.[3] We encoded mathematical formatting using LATEX.

During the compilation of these questions, they were split into 4 broad categories:

1. **Algebra (closed vocabulary)** (e.g. Examples 1 and 2) **:** Algebra questions drawn from a limited mathematical vocabulary.
2. **Algebra (open vocabulary)** (e.g. "At a basketball tournament involving 8 teams, each team played 4 games with each of the other teams. How many games were played at this tournament?") **:** Algebra questions drawn from an open-ended vocabulary.
3. **Geometry:** Geometry questions, typically involving a diagram.
4. **Other** A catch-all for questions that do not fall neatly into the above categories.

In this paper, we focus our attention on closed-vocabulary algebra, which constitutes approximately 45% of the questions.

3 Related Work

Most of the recent work on math questions has focused on open-vocabulary algebra problems, also known as math story problems. Benchmark datasets include Alg514 (Kushman et al., 2014), AI2 (Hosseini et al., 2014), Illinois and Commoncore (Roy and Roth, 2015), and DRAW (Upadhyay and Chang, 2016). A common property of these datasets is that they have been curated such that any given question can be solved by a limited-depth operator tree (AI2, Illinois, Commoncore) or a limited set of equation templates (Alg514 and DRAW). Because of this, it is feasible to use discriminative approaches (Kushman et al., 2014; Hosseini et al., 2014; Roy and Roth, 2015; Zhou et al., 2015; Koncel-Kedziorski et al., 2015; Mitra and Baral, 2016) that extract the quantities, featurize the question, and then perform a weighted search over the space of instantiated operator trees or equation templates. However it is not clear how one can extend these discriminative techniques to

[2] 12 full exams + 1 PSAT

[3] One exception: we exclude the "comparison"-style questions (discontinued in 2005) from pre-2005 exams.

handle the complex semantics found in Examples 1 and 2.

Very recently, (Matsuzaki et al., 2017) published a paper about their semantic parsing approach to pre-university math problems (harvested from Japanese exams rather than the Math SAT). It is challenging to do a direct comparison, since they report results only on the Japanese-language exams. They report end-to-end system results of 11% recall and 50% precision.

(Shi et al., 2015) harvested a fairly diverse set of closed-vocabulary algebra problems (called Dolphin) from the web and provided the first results on that dataset. Here, we demonstrate how to handle the more complex discourse semantics and anaphoric phenomena found in Math SAT questions, and establish a new state-of-the-art result on the Dolphin benchmark.

4 System Overview

Figure 1 shows a high-level view of our QA system. We will give a general overview in this section, and then explore more advanced concepts and examples in the subsequent section.

4.1 Intermediate Languages

Our QA system has two basic languages that mediate the transformation from the question passage to the answer: a syntactic language $\mathcal{A}$ and a semantic language $\mathcal{B}$.

Syntactic language $\mathcal{A}$ has a constituent-style syntax convenient[4] for the tree transducers in our cascade. In Figure 2, we show an example. We have three basic node types: *clauses*, *entities* (these correspond to noun phrases), and *details* (these correspond to adjectival and adverbial modifiers). Each node has a table of *fields* (key-value pairs) that store child relationships and auxiliary information like tense and number. For brevity, this additional structure is omitted from Figure 2, but a more explicit visualization can be found in Figure 4 (top).

A program in semantic language $\mathcal{B}$ is a set of constraint declarations. For instance, the question from Figure 2 ("Let $m+3 < 15$. If m is a positive integer, what is the sum of all values of m?") compiles to the semantic program in Figure 3. When

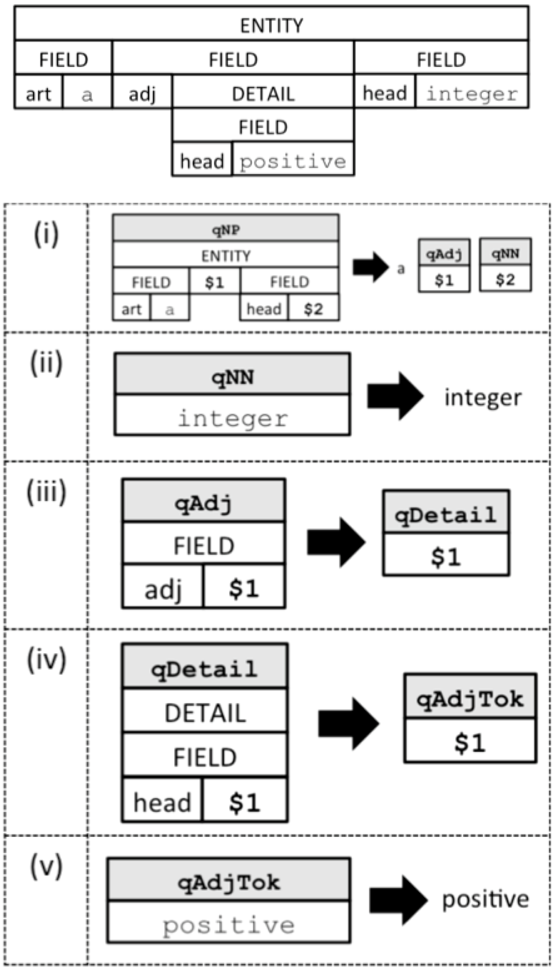

Figure 4: Example XTOPs transducer rules (bottom) used to derive a syntactic parse from the noun phrase "a positive integer" (via backward application of the transducer).

the form of the tree is unimportant, it will be convenient to use a more legible LISP-style format, e.g.

$(< (+\ m\ 3)\ 15)$
$(>\ m\ 0)$
$(\text{int}\ m)$
$(\text{proto}\ m\ M)$
$(=\ ?q\ (\text{sum}\ M))$

Every constraint in this program should be easily understandable, except for (proto m M), which loosely means that M is the set of all possible values of m. In Section 5.1, we discuss the proto directive in more detail.

[4] We experimented with adopting an existing syntax, like the Penn Treebank Syntax or the Stanford Dependency Syntax, but it turned out to be easier to develop the syntax in parallel with the needs of our system. Having said that, it is not intended to be wildly different from those formalisms.

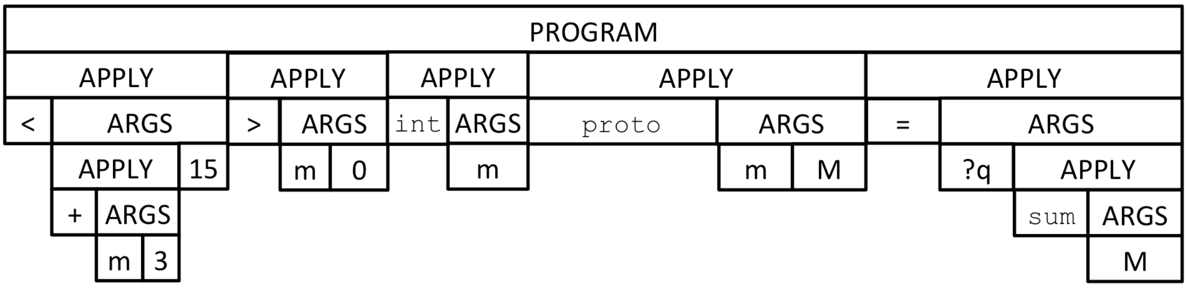

Figure 3: Example semantic program for the question "Let $m + 3 < 15$. If m is a positive integer, what is the sum of all values of m?"

4.2 Syntactic Parsing

The first stage of our QA system parses the question passage into language $\mathcal{A}$[5]. We implemented the parser as the backward application of an extended top-down tree-to-string (XTOPs) transducer[6].

We refer the reader to (Maletti et al., 2009) for a theoretical presentation of XTOPs, and instead give a brief intuitive presentation of the device. An XTOPs transducer defines a top-down transformation from a tree language to a string language, via a set of stateful rewrite rules. For instance, rules (i) through (v) of Figure 4 can generate the string "a positive integer" from the $\mathcal{A}$-tree pictured at the top of the figure, given start state **qNP**.

Given an XTOPs transducer M, we can parse string s through *backward application* of the transducer, i.e. compute the set of trees $M^{-1}(s)$ that could have generated string s from the start state. Efficient backward application of XTOPs transducers is supported by packages like Tiburon (May and Knight, 2006).

Our XTOPs transducer has approximately 140 states and 550 engineered rules (approximately 200 of these rules are used for parsing formal mathematics and a subset of LaTeX). Most lexical rules are automatically generated on-the-fly from WordNet (Miller, 1995).

4.3 Compilation

We then compile the parses of the question passage, by running them forward through a cascade of bottom-up tree transducers (Engelfriet, 1975). Again we refer the reader to the literature (Maletti, 2011, 2014) for a theoretical presentation of bottom-up tree transducers, and use Figure 5 to provide intuition about the device. A bottom-up tree transducer defines a transformation from a tree language to a (possibly different) tree language, via a set of stateful bottom-up rewrite rules.

In Figure 5, we show how this transformation works in the context of the semantic translation step, which uses a multi bottom-up transducer (MBOT) to map our syntactic language $\mathcal{A}$ into our

[5] Recall: language $\mathcal{A}$ is the syntactic language described in the previous section. An example is shown in Figure 2.

[6] We chose to implement the parsing step by engineering a transducer rather than using an off-the-shelf statistical parser. While we tried to retrofit a parser – e.g. as done by (Seo et al., 2015) – to serve our needs, it turned out to be somewhat more robust (and relatively simple) to engineer our own.

semantic language $\mathcal{B}$. There is a single state (indicated by a gray shaded rectangle) that has two children: (i) a *return value*, and (ii) a set of *side-effect* statements.

The first rule application transforms "all values of m" into a *return value* of M (a new variable introduced to indicate the set of all values of variable m) and a *side-effect* (proto m M), indicating that M equals the set of all possible values of m. The second rule application transforms "the sum of M" into a *return value* of (sum M), and propagates upward the accumulated side-effects.

We implemented all three compilation steps from Figure 1 (anaphora resolution, semantic translation, and semantic analysis) as the forward application of a bottom-up tree transducer. Anaphora resolution resolves any nodes that refer to other nodes in the tree. Semantic translation translates syntactic language $\mathcal{A}$ into semantic language $\mathcal{B}$. Semantic analysis type-checks the trees for internal consistency.

4.4 Interpretation

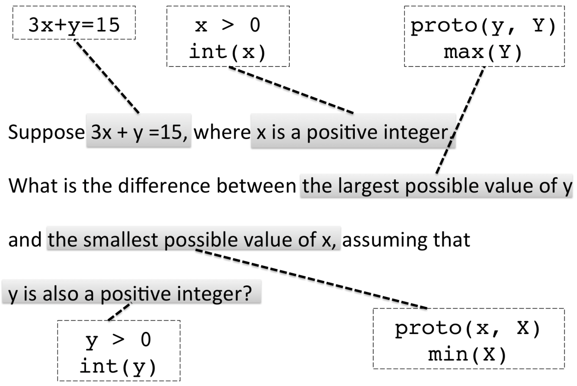
Finally, each derived $\mathcal{B}$-tree is sent to an evaluator to obtain an answer. Our main evaluator is a wrapped version of Z3 (de Moura and Bjorner, 2008), a widely used Satisfiability Modulo Theories (SMT) solver. If it does not find an answer, we fall back to a numeric optimization solver similar to one used by (Seo et al., 2015).

5 Spotlights

Having provided a bird's eye view in the last section, we now spotlight some key details of our QA system.

5.1 Spotlight: Complex Aggregations

A core challenge of semantic parsing is how best to read complex semantic phenomena from a syntactic representation. Two such phenomena are superlatives and counting. GeoQuery (Zelle and Mooney, 1996) has examples[7] of these, as does[8] WebQuestions (Berant et al., 2013). Unfortunately, it is not clear how existing strategies for dealing with aggregative constructs (e.g. (Liang et al., 2011)) can be extended to the more complex multi-sentence questions found on the SATs. For instance, the basic semantics of Example 1 (enumerated in Section 1) is dispersed throughout the question passage, such that neither the maximization nor the minimization can be locally derived from some subtree of the dependency structure.



3x+y=15
x > 0
int(x)
proto(y, Y)
max(Y)
Suppose 3x + y =15, where x is a positive integer.
What is the difference between the largest possible value of y
and the smallest possible value of x, assuming that
y is also a positive integer?
y > 0
int(y)
proto(x, X)
min(X)

Figure 6: Understanding complex aggregations by decomposing them into order-independent atoms.

To deal with this challenge, we designed our semantic language $\mathcal{B}$ to decompose the semantics of aggregative constructs into order-independent atoms. Consider the following restatement of the semantics of Example 1:

$$\begin{gathered}\mathsf{proto}(\dot{x}, X)\\ \mathsf{proto}(\dot{y}, Y)\\ 3\dot{x} + \dot{y} = 15\\ \dot{x} > 0\\ \dot{y} > 0\\ \dot{x} \in \mathbb{Z}\\ \dot{y} \in \mathbb{Z}\\ \textbf{solve:}\ \max Y - \min X\end{gathered}$$

where $\mathsf{proto}(\dot{z}, Z)$ designates that a variable $\dot{z}$ should be treated as the prototype variable of a statement in set-builder notation, i.e. $Z = \{\dot{z} \mid ...\}$. We treat any other statement featuring prototype variable $\dot{z}$ as a constraint appearing on the right side of the set-builder statement. If there are multiple prototype statements, they are grouped into a single set-builder statement (as occurs with $\dot{x}$ and $\dot{y}$ in our example).

The power of this decomposition is that it can be reconstructed piecemeal from an arbitrarily complex passage. The atomic statements can be interpreted locally in an arbitrary order, as in Figure 6, then synthesized into set-builder notation during evaluation.

[7] e.g. "What is the capital of the state that borders the most states?"

[8] e.g. "How many pets did John F. Kennedy own?"

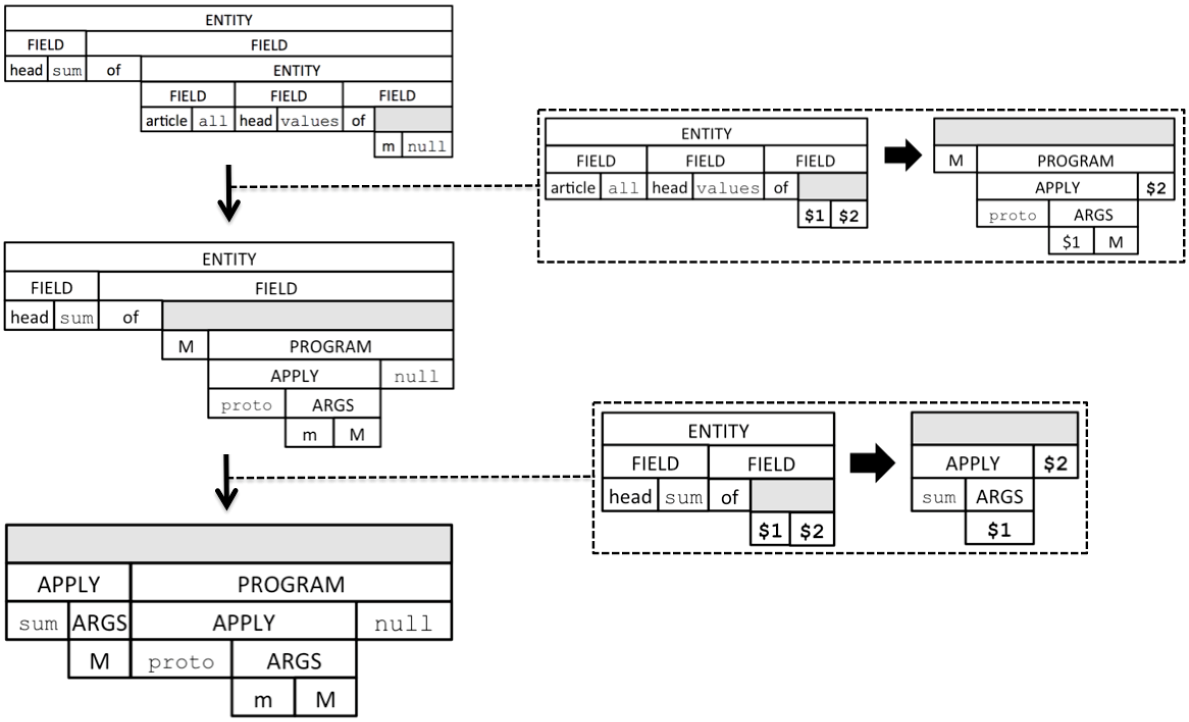


Figure 5: Example semantic translation using an MBOT.

5.2 Spotlight: Complex Anaphoric Phenomena

The anaphora resolution task (Ge et al., 1998) is typically defined at the lexical level. For instance, in the sentence "c is equal to its square," a traditional evaluation like the CoNLL-2011 Shared Task (Pradhan et al., 2011) would ask whether the string "its" is aligned to the string "c". These evaluations also assume that both the reference and the referent (a.k.a. antecedent) are contiguous strings in the text.

Math SAT problems exhibit a host of new challenges that fall outside traditionally studied definitions of anaphora resolution:

- **One-to-many coreference**[9] *(One integer is 5 more than another. What is the sum of the numbers?)*: "The numbers" refers to two discontiguous strings: "one integer" and "another".

- **Implicit set reference** *(Two numbers sum to 5. If the first is 2, what is the second?)*: "The second" implies a latent set that needs to be resolved (to "two numbers") in order to understand the sentence. This phenomenon is shown in Figure 7.

- **Implicit clausal reference** *(If 7 is divided by 3, what is the remainder?)*: "The remainder" implies a latent clause that needs to be resolved (to "7 is divided by 3") in order to understand the sentence.

We address this broader class of anaphora by a two-pass process:

1. First, we introduce implicit sets and clauses when appropriate. For instance, implicit sets are introduced for superlative and ordinal constructions, while implicit clauses are introduced for functional nouns like "remainder." In Figure 7, these implicits are depicted as bracketed phrases (i.e. [of a set]).

2. Anaphora resolution then proceeds as a bottom-up tree-labeling process, shown in Figure 7. For each subtree, a resolution function ρ partially maps subtree entities to subtree nodes. Note that ancestors can overwrite the resolutions of their descendants. This occurs in the second example of Figure 7, where the implicit set E7 is initially resolved to implicit set E4, but is later resolved to the entity E1 ("two numbers") once it comes into scope.

In our initial system, the resolution function ρ was

[9] A recent ACL paper (Vala et al., 2016) has provided a preliminary treatment of this phenomenon.

engineered heuristically. We later replaced this with a learned version (by using our system to generate training data). Due to space considerations, details are omitted.

6 Results with the Unweighted Nondeterministic Cascade

In the basic cascade from Section 4, the number of trees passed from module to module can expand, but it can also contract (for instance, in the semantic translation step, there can be multiple ways of translating a parse, or none at all). This allows the QA system to disambiguate question passages by eliminating parses for which there is no consistent semantics. On the subset of the Kaplan questions for which at least one parse exists, the average number of trees after the parsing step is 7.5. The average number of trees after the semantic analysis step goes down to only 2.4. At that point, obviously we need to choose some priority in which to feed these finalized programs to the evaluation module. Using a simple heuristic (process smaller programs first), we obtain 70.2% recall and 95.8% precision on the Kaplan closed-vocabulary algebra questions[10].

This high precision can be partially attributed to the fact that most SAT questions are multiple-choice (thus we can sequentially evaluate the finalized programs until we find a viable answer). We do not have that luxury on the Dolphin dataset, a set of direct-answer algebra questions curated by Microsoft Research (split into a development set of 374 questions and a test set of 1504 questions). On the subset of the development questions for which at least one parse exists (90.3% of the questions), the average number of trees after the parsing step is 4.3. The average number of trees after the semantic analysis step goes down to 1.5. Our basic system obtains 66.3% recall on the development questions. Naturally the precision is not as high as on the multiple choice questions, but surprisingly we still obtain 85.5% precision, even with an unweighted cascade.

7 Introducing a Parse Ranker

Most of this precision loss is due to legitimate parse ambiguity that cannot be resolved through semantic interpretability alone. Rather, the disambiguation requires some additional pragmatic convention. Consider the example: "When the reciprocal of three times a number is subtracted from the reciprocal of the number, the result is one sixth. Find the number." By interpreting "the reciprocal of three" as $\frac{1}{3}$, the meaning of this question becomes "When $\frac{1}{3}$ times a number is subtracted from the reciprocal of the number, the result is one sixth. Find the number." This is not however the most human-intuitive interpretation of the question. Somehow the system must identify the pragmatic cues that cause humans to disprefer this interpretation.

To identify these cues, we insert a *parse ranking module* between the parsing module and the anaphora resolution module (see Figure 1 for a reminder of the system components). The goal of the parse ranker is to associate a lower cost to "more intuitive" interpretations when there are multiple plausible syntactic interpretations. The

[10] Recall and precision numbers are computed over the entire set of questions, regardless of whether they have a valid parse.

	recall	prec.	F1
Kaplan (non-blind)	70.2	95.8	81.0
McGraw-Hill (blind)	41.0	91.8	56.7
Official (blind)	43.1	90.8	58.5

Table 1: Results on the closed-vocabulary algebra subsets of our Math SAT question sets.

rest of the cascade propagates these costs. Similar to existing work, e.g. (Charniak and Johnson, 2005), we implement the cost function as an L_1-regularized logistic regression model.

Adding the trained parse ranker module improves performance on the Dolphin development set to 75.7% recall and 97.3% precision (from 66.3% recall and 85.5% precision).

8 Final Results

Results from our final system are shown in Table 1 (for the closed-vocabulary algebra subsets of our math SAT question sets) and Table 2 (for the Dolphin question sets). EUCLID generalizes reasonably well to the blind SAT questions, achieving approximately 60% of the system's recall on the training questions, at a precision of approximately 91%. To give a sense of the extent of the generalization from training to test, Table 3 offers a couple of correctly answered questions from the blind[11] McGraw-Hill set, plus their closest analog in the training questions (by edit distance). The performance on the blind test sets (including all questions, not just closed-vocabulary algebra) corresponds to an SAT score of approximately 350 (out of 800). A random-guessing baseline has an expected score of 200.

Table 4 provides a failure analysis on the McGraw-Hill data, categorizing a sample of 50 questions. Half of the questions failed to have a valid parse. Roughly a quarter of the questions had at least one valid parse, but none of these resulted in a semantic program. 18% of the questions compiled into at least one semantic program, but none of these produced an answer when fed to the interpreter. 8% of the questions compiled into a semantic form that produced an incorrect answer.

failed to produce an answer from any semantic program	18%
produced an incorrect answer	8%

Table 4: Error analysis on the blind McGraw-Hill set, surveying the first point of failure for a sample of 50 incorrectly answered questions.

Besides the Math SAT datasets, EUCLID also has state-of-the-art performance on the public Dolphin question set, achieving an absolute recall improvement[12] of nearly 5% with a small loss in precision. This raises the state-of-the-art F_1-score on this data set from 73.9% to 77.0%.

[11] Apart from harvesting a sample of correctly answered questions for this analysis, the McGraw-Hill set was kept completely blind. The official set was left completely untouched.

[12] This improvement is statistically significant with a P-value < 0.01.

Table 5: Snapshot of early progress across several subgenres of the Math SAT. In our early stages, we are hillclimbing on the hosseini datasets from (Hosseini et al., 2014), which are simpler than the open-vocabulary algebra questions from the Math SAT.

9 Towards a Broad-Coverage SAT solver

This paper reports on the first steps of a longer-term initiative to build a unified system that can pass the math SAT. We have made some preliminary forays into extending the system to handle the more complex subdomains described in Section 2, namely open-vocabulary algebra and geometry. Key research challenges presented by these new domains are:

- **Mapping into richer semantic languages:** The math story problems of open-vocabulary algebra require languages that reason about state change and can introduce assumptions not explicitly represented in the text.
- **Robustly synthesizing diagram and text information:** For geometry questions, we are building on key early work in this area performed by (Seo et al., 2014, 2015).
- **Extending the system in a scalable way:** Writing new transducer rules for each new domain is not a sustainable way to extend our system. We are exploring how to use natural language to "program" our system, e.g. by automatically inducing transducer rules for paraphrase text.

A snapshot of our current progress is shown in Table 5.

10 Discussion

In the process of creating a QA system for math SAT questions, this project has yielded several general strategies for beyond-sentential semantic parsing. For instance:

- One can modularize the parser as a cascade of tree transducers, allowing uncertainty about anaphora resolution and lexical interpretation to be propagated until it can be confidently resolved, sometimes as late as program interpretation (see Section 6).
- One can atomize complex semantic phenomena (e.g. aggregrative constructs) into small order-independent pieces. This allows a simpler transformation from a syntactic form, because these atoms can be locally recognized, incrementally composed, and globally reconstituted into a structured semantics (see Section 5.1).
- One can reframe bread-and-butter NLP tasks (e.g. anaphora resolution) to fit better within (and take advantage of) the context of the transducer cascade (see Section 5.2)

An important focus of this paper has been issues of representation, namely how to develop intermediate structured languages that facilitate the automatic transformation of question discourse into a response. Because we can use the resulting QA system to generate gold intermediate trees for any correctly answered question in our dataset, one way to view this work is as a data annotation project. One distinguishing advantage is that our intermediate languages come with a "proof of usefulness." They are not designed based on speculative utility – rather, they have already proven useful in the context of a functioning QA system.

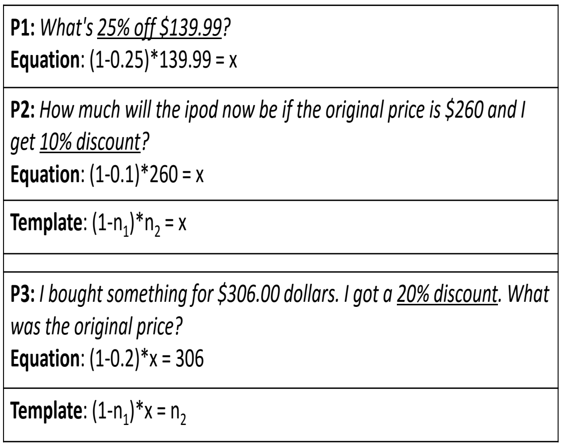
Abstract

This paper presents a novel template-based method to solve math word problems. This method learns the mappings between math concept phrases in math word problems and their math expressions from training data. For each equation template, we automatically construct a rich template sketch by aggregating information from various problems with the same template. Our approach is implemented in a two-stage system. It first retrieves a few relevant equation system templates and aligns numbers in math word problems to those templates for candidate equation generation. It then does a fine-grained inference to obtain the final answer. Experiment results show that our method achieves an accuracy of 28.4% on the linear Dolphin18K benchmark, which is 10% (54% relative) higher than previous state-of-the-art systems while achieving an accuracy increase of 12% (59% relative) on the TS6 benchmark subset.

1 Introduction

The research topic of automatically solving math word problems dates back to the 1960s (Bobrow, 1964a,b; Charniak, 1968). Recently many systems have been proposed to these types of problems (Kushman et al., 2014; Hosseini et al., 2014; Koncel-Kedziorski et al., 2015; Zhou et al., 2015; Roy and Roth, 2015; Shi et al., 2015; Upadhyay et al., 2016; Mitra and Baral, 2016). On a recent evaluation conducted by Huang et al. (2016), current state-of-the-art systems only achieved an 18.3% accuracy on their published dataset Dolphin18K. Their results indicate that math word problem solving is a very challenging task.

To solve a math word problem, a system needs to understand natural language text to extract information from the problem as local context. Also, it should provide an external knowledge base, including commonsense knowledge (e.g. *"a chicken has two legs"*) and mathematical knowledge (e.g. *"the perimeter of a rectangle = 2 * length + 2 * width"*). The system can then perform reasoning based on the above two resources to generate an answer.



P1: *What's 25% off $139.99?*
Equation: (1-0.25)*139.99 = x

P2: *How much will the ipod now be if the original price is $260 and I get 10% discount?*
Equation: (1-0.1)*260 = x

Template: $(1-n_1)*n_2 = x$

P3: *I bought something for $306.00 dollars. I got a 20% discount. What was the original price?*
Equation: (1-0.2)*x = 306

Template: $(1-n_1)*x = n_2$

Figure 1: Math Word Problem Examples.

In this paper, we focus on the acquisition of mathematical knowledge, or deriving math concepts from natural language. Consider the first two problems $P1$ and $P2$ in Figure 1. The math concept in the problems tells you to take away a percentage from one and get the resulting percentage of a total. Using mathematical language, it can be formulated as $(1-n_1)*n_2$, where n_1, n_2 are quantities. In this example, we can derive the concept of subtraction from the text "*[NUM] % off*" and "*[NUM] % discount*".

Acquisition of mathematical knowledge is non-trivial. Initial statistical approaches (Hosseini et al., 2014; Roy and Roth, 2015; Koncel-Kedziorski et al., 2015) derive math concepts based on observations from their dataset of specific types of problems, e.g. problems with one single equation. For example, Hosseini et al. (2014) assumes verbs and only verbs embed math concepts and map them to addition/subtraction. Roy and Roth (2015); Koncel-Kedziorski et al. (2015) assume there is only one unknown variable in the problem and cannot derive math concepts involving constants or more than one unknown variables, such as "*the product of two unknown numbers*".

Template-based approaches (Kushman et al., 2014; Zhou et al., 2015; Upadhyay et al., 2016), on the other hand, leverage the built-in composition structure of equation system templates to formulate all types of math concepts seen in training data, such as $(1 - n_1) * n_2 = x$ in Figure 1. However, they suffer from two major shortcomings. First, the math concepts they learned, which is expressed as an entire template, fails to capture a lot of useful information with sparse training instances. We argue that it would be more expressive if the math concept is learned in a finer granularity. Second, their learning processes rely heavily on lexical and syntactic features, such as the dependency path between two slots in a template. When applied to a large-scale dataset, they create a huge and sparse feature space and it is unclear how these template-related features would contribute.

To alleviate the sparseness problem of math concept learning and better utilize templates, we propose a novel approach to capture rich information contained in templates, including textual expressions that imply math concepts. We parse the template into a tree structure and define "template fragment" as any subtree with at least one operator and two operands. We learn fine-grained mappings between textual expressions and template fragments, based on longest common substring. For example, given the three problems in Figure 1, we can map "*[NUM] %* off" and "*[NUM] %* discount" to $1 - n_1$, and "*[NUM] %* off *[NUM]*" to $(1 - n_1) * n_2 = x$. In this way, we can decompose the templates and learn math concepts in a finer grain. Furthermore, we observe that problems of the same template share some common properties. By aggregating problems of the same template and capturing these properties, we automatically construct a sketch for each template in the training data.

Our approach is implemented in a two-stage system. We first retrieve a few relevant templates in the training data. This narrows our search space to focus only on those templates that are likely to be relevant. Then we align numbers in the problem to those few returned templates, and do fine-grained inference to obtain the final answer. We show that the textural expressions and template sketch we propose are effective for both stages. In addition, our system significantly reduces the hypothesis space of candidate equations compared to previous systems, which benefits the learning process and inference at scale.

We evaluate our system on the benchmark dataset provided by Huang et al. (2016). Experiments show that our system outperforms two state-of-the-art baselines with a more than 10% absolute (54% relative) accuracy increase in the linear benchmark and a more than 20% absolute (71% relative) accuracy increase for the dataset with a template size greater than or equal to 6.

In the remaining parts of this paper, we introduce related work in Section 2, describe template sketch and textual expression learning in Section 3, present our two-stage system in Section 4, summarize experiment setup and results in Section 5, and conclude this paper in Section 6.

2 Related Work

Automatic math word problem solving methods (Bobrow, 1964a,b; Charniak, 1968, 1969; Briars and Larkin, 1984; Fletcher, 1985; Dellarosa, 1986; Bakman, 2007; Yuhui et al., 2010) developed before 2008 are mostly rule-based. They accept limited well-format input sentences and map them into certain structures by pattern matching. They usually focus on problems with simple math operations such as addition or subtraction. Please see Mukherjee and Garain (2008) for a summary.

In recent years, symbolic and statistical methods have been explored by various researchers. In the symbolic approach, systems transform math word problems to structured representations. Bakman (2007) maps math problems to predefined schema with a table of textual formulas and changing verbs. Liguda and Pfeiffer (2012) uses augmented semantic networks to represent math problems. Shi et al. (2015) parses math problems to their pre-defined semantic language. However, these methods are only effective in their designated math problem categories and are not scalable to other categories. For example, the method used by Shi et al. (2015) works extremely well for solving number word problems but not others.

In the statistical machine learning approach, Hosseini et al. (2014) solves addition and subtraction problems by extracting quantities as states and derive math concepts from verbs in the training data. Kushman et al. (2014) and Zhou et al. (2015) generalize equations attached to problems with variable slots and number slots. They learn a probabilistic model for finding the best solution equation. Upadhyay et al. (2016) follows their approach and leverage math word problems without equation annotation as external resources. Seo et al. (2015) solves a set of SAT geometry questions with text and diagram provided. Koncel-Kedziorski et al. (2015) and Roy and Roth (2015) target math problems that can be solved by one single linear equation. They map quantities and words to candidate equation trees and select the best tree using a statistical learning model. Mitra and Baral (2016) considers addition and subtraction problems in three basic problem types: “Change”, “Part Whole” and “Comparison”. They manually design different features for each type, which is difficult to expand to more types.

In summary, previous methods can achieve high accuracy in limited math problem categories, (i.e. (Kushman et al., 2014; Shi et al., 2015)), but do not scale or perform well in datasets containing various math problem types as in Huang et al. (2016), as their designed features are becoming sparse. Their process of acquiring mathematical knowledge is either sparse or based on certain assumptions of specific problem types. To alleviate this problem, we introduce our template sketch construction and fine-grained expressions learning in the next section.

3 Template Sketch Construction

A template sketch contains template information. We define three categories of information for the sketch shown in this section. Next we describe how we construct a template sketch, via aggregation of rich information from training problems. We group problems of the same template in training set as one cluster and collect information. See Figure 2 for the outline of our template sketch construction.

3.1 Definition

Template: It is first introduced in Kushman et al. (2014). It is a unique form of an equation system. For example, given an equation system as follows:

$$\begin{gathered} 2 \cdot x_1 + 4 \cdot x_2 = 34 \\ x_1 + 4 = x_2 \end{gathered}$$

This equation system is a solution for a specific math word problem. We replace the numbers with four number slots $\{n_1, n_2, n_3, n_4\}$ and generalize the equations to the following template:

$$\begin{gathered} n_1 \cdot x_1 + n_2 \cdot x_2 = n_3 \\ x_1 + n_4 = x_2 \end{gathered}$$

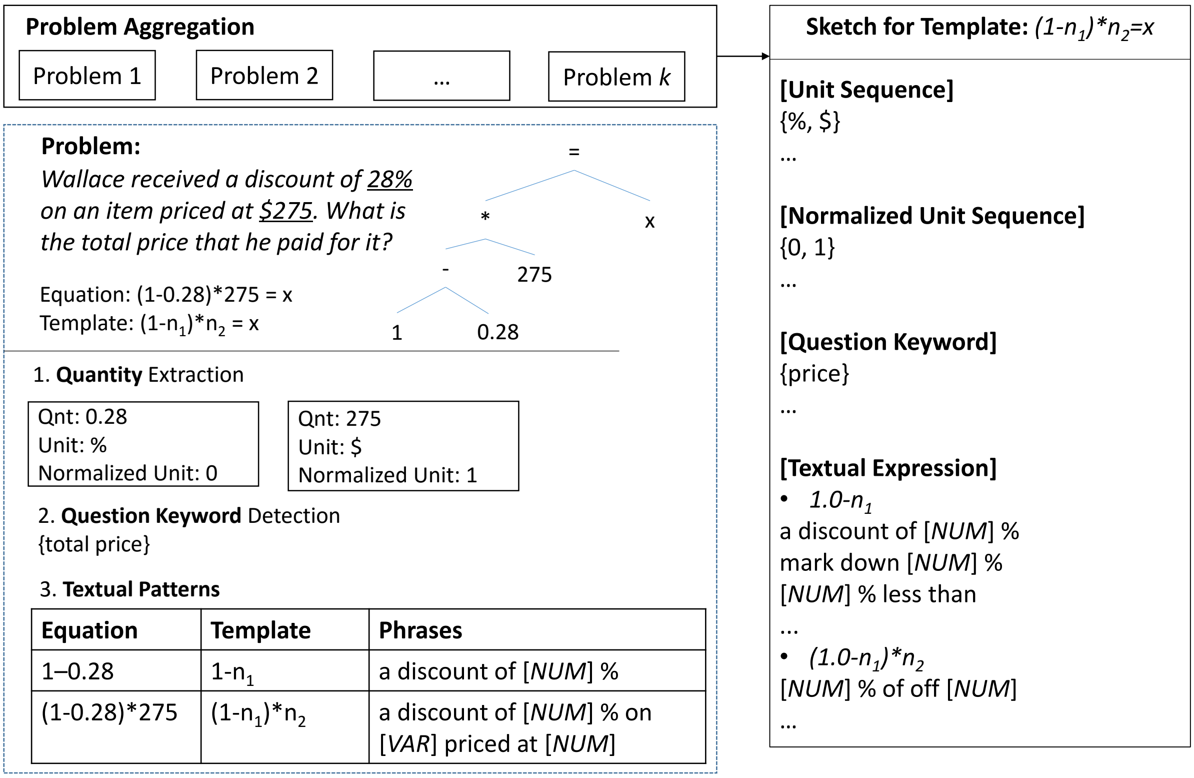
Alignment: We align numbers in the math problem with the number slots of a template. For the first math problem in Figure 1 with its corresponding template $(1 - n_1) * n_2 = x$, there are two numbers 0.25 and 139.99 to align with two number slots n_1 and n_2, which results in two different alignments.

Kushman et al. (2014) aligns nouns to variable slots $\{x_1, x_2, ...\}$ which leads to a huge hypothesis space and does not perform as well as the number slot alignment only method proposed later by (Zhou et al., 2015). Therefore, we only consider number slot alignment in this paper.

3.2 Textual Expressions

For template fragments, there are usually some textual expressions. For example, “n_1 % off” and “n_1 % discount” are both mapped to the template fragment $1 - n_1$.

We employ a statistical framework to automatically mine textual expressions for template fragments from a training dataset. First we parse the equation to a hierarchical tree. In a bottom-up approach, we obtain each possible subtree as a template fragment t_k, which associates with at least one number slot. For each t_k, we use the numbers to anchor the number-related phrases in the problem, replace numbers with“*[NUM]*” and noun phrases with “*[VAR]*”, and cluster the phrases $P = \{p_1, p_2, \cdots\}$ with the same t_k across all data given all training problems. Then we compute the longest common substring lcs^k_{ij} between pairs p_i and p_j and calculate tf-idf score of lcs^k_{ij}. We keep the lcs^k_{ij} with scores above certain empirically determined threshold as the textual expressions.



Equation	Template	Phrases
1–0.28	$1\text{-}n_1$	a discount of [*NUM*] %
(1-0.28)*275	$(1\text{-}n_1)*n_2$	a discount of [*NUM*] % on [*VAR*] priced at [*NUM*]

Figure 2: Template Sketch Construction.

3.3 Slot Type

Number slots in templates have their own type of constraints. For example, in the template $(1-n_1)*n_2 = x$, usually n_1 represents a percentage quantity and n_2 is the quantity of an object.

We model slot types with quantity units, and find the direct governing noun phrase as its 'owner'. For the problem in Figure 2, we extract quantity unit sequence as $\{\%, \$\}$, normalized unit sequence as $\{0, 1\}$ (because % and $ are of different quantity types), and quantity owners as {discount, item}. The slot type information provides important clues to choose the correct template and alignment.

3.4 Question Keyword

Question keyword decides which template we use. Given the following problem setting: "A rectangle has a width of 5cm and a length of 10cm.", we can ask either Q1:"What is the *area* of the rectangle?" or Q2: "What is the *difference* between width and length?". The question keywords *area* and *difference* help our system to decide if is should apply template $n_1 * n_2 = x$ for Q1 and apply template $n_1 - n_2 = x$ for Q2.

We first detect the question sentence (containing keywords "what","how","figure out"...). Then we extract the question keyword on the dependency tree with simple rules that we observed in the dev set (e.g. retrieving nouns with "$attr - nsubj$" dependency relation with keyword "what"). Please note that we favor recall over precision of our detected question keywords since they are used as features instead of hard constrains on template decision. Simple rule-based extraction can already satisfy our need for detecting question keywords in math problems.

4 Two-Stage System

In this section, we describe our two-stage system for solving math problems, including template retrieval and alignment ranking. We show how to apply textual expressions and template sketch to our system.

4.1 Template Retrieval

We use an efficient retrieval module to first narrow our search space and focus only on templates that are likely to be relevant. Let χ denote the set of test problems, and $T = \{t_1, t_2, \ldots, t_j\}$ as the template set in the training data. For each test problem x_i, our goal is to select the correct template

t_j. We define the conditional probability of selecting a template given a problem as follows:

$$p(t_j|x_i;\nu_t) = \frac{\exp(\nu_t \cdot f(x_i, t_j))}{\sum_{t'_j \in T} \exp(\nu_t \cdot f(x_i, t'_j))}$$

where ν_t is the model parameter and $f(x_i, t_j)$ is the feature vector. We apply the Ranking SVM (Herbrich et al., 2000) to minimize a regularized margin-based pairwise loss. We then have the following objective function:

$$\frac{1}{2}\|\nu_t\|^2 + C\sum_i l(\nu_t^T f(x_i, t_j)^+ - \nu_t^T f(x_i, t_l)^-)$$

where superscript "+" indicates the correct instance and "-" indicates the false ones. We use the loss function $l(t) = max(0, 1-t)^2$.

To construct the vector $f(x_i, t_j)$ for template t_j, we use the three categories in the template sketch shown in Table 1. Let $Q(t_j)$ represent the cluster of training problems with template t_j.

Textual Features
Contains textual expressions in each template fragments?
Average Word Overlap with $Q(t_j)$
Max Word Overlap with $Q(t_j)$
Quantity Features
Unit sequence in $Q(t_j)$
Normalized unit sequence in $Q(t_j)$
Question Features
Is Question keyword in $Q(t_j)$

Table 1: Features for template retrieval.

At the phrase level, as we have mined different expressions in 3.2 for slots in templates, we can extract the phrases related to each number or number pair in a test problem and match them with expressions. For example, given a test problem to match template $(1 - n_1) * n_2 = x$ in Figure 2, we have two groups of patterns to match, corresponding to $1.0 - n_1$ and $(1.0 - n_1) * n_2$ respectively.

Quantity types in a problem are important. We use the unit type sequences and normalized unit type sequence for describing number slot types in a template. In addition, if a number unit type cannot differentiate each number slot, we will make use of number "owner" as defined in subsection 3.3. For example, in the sentence "The width is 3cm and the length is 5cm", we extract two quantities with unit type sequence {cm, cm}; and owner {width, length}.

In addition, we consider question keywords for templates. For example, if the question keyword is "difference", then $x + n_1 = n_2$ will have a higher probability of being selected than $x = n_1 * n_2$.

We observe that in some cases, one word difference can lead to two different templates. To consider cases in which some templates are very similar (e.g. $x + n_1 = n_2$ and $n_1 + n_2 = x$, part/whole unknown), we retrieve the top ranked N (N=3) templates as candidates for alignment in the next stage.

4.2 Alignment Ranking

For each top N templates from the previous stage, we generate possible alignments $A = \{a_1, a_2, \ldots, a_m\}$ as the candidate equation system for the test problem x_i. We train a ranking model to choose the alignment with the highest probability $p(a_k|x_i, t_j; \nu_a)$, where ν_a is the model parameter vector.

$$p(a_k) = \frac{\exp(\nu_a \cdot f(x_i, a_k))}{\sum_{a'_k \in A} \exp(\nu_{a'} \cdot f(x_i, a'_k))}$$

We use the same ranking model as in template selection stage and the objective function is changed to:

$$\frac{1}{2}\|\nu_a\|^2 + C\sum_i l(\nu_a^T f(x_i, a_k)^+ - \nu_a^T f(x_i, a_l)^-)$$

We design more fine-grained features for each number slot to formulate the alignment feature vector $f(x_i, a_k)$. It contains the following features in Table 2.

Textual Features
Match textual expressions in template fragment aligned to each number slot (pair)
Quantity Features
Aligned unit sequence in $Q(t_j)$
Aligned normalized unit sequence in $Q(t_j)$
Relationship with noun phrase
Optimal number 1 or 2 is used?
Solution Features
Is integer solution?
Is positive solution?

Table 2: Features for alignment ranking.

At the textual level, we want to capture textual expressions describing each number slot. For example, in the template $(1 - n_1) * n_2 = x$, we have mined patterns of $1 - n_1$ in 3.2, such as "a discount of n_1 %", "mark down n_1 %", etc. Given the problem in Figure 2 as the test problem, alignment (**1-0.28**) $* 275 = x$ matches textual expressions, while (**1-275**) $* 0.28 = x$ does not.

For quantity features, we use the alignment-ordered unit sequence. For the problem in Figure 2 mapping to template $(1 - n_1) * n_2 = x$, we have two different alignments: $\{n_1$:0.28, n_2:275$\}$, $\{n_1$:275,n_2:0.28$\}$. Their aligned unit sequences are $\{$%, \$$\}$ and $\{$\$,%$\}$ respectively. We also use the relations of quantities with noun phrases to differentiate number slot interaction with unknown variable slots and number slots, such as $n_1 * x$ and $n_1 * n_2$.

Some templates have numerical solution properties while others do not. For example, template $x_1 = (n_1 - n_2)/(n_3 - n_4)$ would be less likely to have any strong indication of integer solution properties. We count the percentage of integer/positive solutions from the corresponding problems as the probability that this template prefers an integer/positive solution.

4.3 Model Discussion

Our method has two main differences from previous template-based methods (Kushman et al., 2014; Zhou et al., 2015; Upadhyay et al., 2016).

First, previous methods implicitly model mapping from problem text to templates. We learn fine-grained textual expressions mapped to template fragments; and explicitly model the property of templates with template sketches. Second, previous methods align numbers for all templates in a training set, while we only examine the N most probable templates. This significantly reduces the equation candidate search space. Given a problem in which m numbers align with a template of n number slots, the number of possible equation candidates would be A_m^n. The search space grows linearly with the number of templates in the training data. Suppose $m = 5$, $n = 4$ and we have 1000 templates, the total space would be $(5 * 4 * 3 * 2) * 1000 = 120,000$ for one problem in Zhou et al. (2015), and will be much larger if it considers unknown variable alignment as in (Kushman et al., 2014).

5 Experiments

Settings As demonstrated in Huang et al. (2016), previous datasets for math problems are limited in both scale and diversity. We conduct our experiment on their dataset Dolphin18K. We use the linear subset, containing 10,644 problems in total. We use two baseline systems for comparison: (1) ZDC (Zhou et al., 2015) is a statistical learning method that is an improved version of KAZB (Kushman et al., 2014)[1]. (2) SIM (Huang et al., 2016) is a simple similarity based method. We do not compare other systems because they only solve one specific type of problem, e.g. Hosseini et al. (2014) only handle addition/subtraction problems and Koncel-Kedziorski et al. (2015) aim to solve problems with one single linear equation. Experiments are conducted using 5-fold cross-validation with 80% problems randomly selected as training data and the remaining 20% for testing. We report the solution accuracy.

5.1 Overall Evaluation Results

Table 3 shows the overall performance of different systems. In the table, the size of a template is the number of problems corresponding to a template. For example, for templates with a size 100 or larger, their problem counts add up to 1,807.

Template Size	problems	ZDC (%)	SIM (%)	Ours (%)
>=100	1807	34.2	29.7	64.5
>=50	4281	31.1	27.2	39.3
>=20	5392	29.4	25.8	36.9
>=10	6216	25.3	24.6	35.7
>=6	6827	21.7	20.2	**34.6**
>=5	7081	21.6	20.1	34.3
>=4	7262	21.1	19.8	33.8
>=3	7466	20.7	19.7	33.2
>=2	8229	20.6	20.3	32.2
>=1	10644	17.9	18.4	**28.4**

Table 3: Overall evaluation results.

From the table, we observe that our model consistently achieves better performance than the baselines on all template sizes. As the template size becomes larger, all three systems achieve better performance. When template size equals 6 (TS6, as a de-facto template size constrain adopted in ZDC), our model achieve an absolute increase of over 12% (59% relative). This demonstrates the effectiveness of our proposed method.

[1] We ignore KAZB because it does not complete running on the dataset in three days

When including long tail problems with a template size less than 2, performance of all three systems drop significantly. This is because the templates of these problems are not seen in the training set, and thus are difficult to solve using these template-based methods. Still, we have at least 10% absolute (54% relative) accuracy increase on the whole test set compared to the two baselines. Previous template-based methods require templates size larger than 6 in the data as constraints. From the result, we can see that our method relaxes the template size constraint and matches more problems with less frequent templates.

5.2 Accuracy per Template

Here we investigate the performance of different templates. In Table 4, we sample some dominant templates and report their accuracies. For our model, we report both template retrieval accuracy and final solution accuracy.

As we can see, our method performs better than the baselines for most dominant templates. Performance of the dominant templates can reach an accuracy level of 60%. This proves that our template sketch and textual expressions are effective in capturing rich template information.

To our surprise, some templates tend to perform better than others even with smaller template sizes. For example, $x_1 = n_1 - n_2$, which represents the subtraction problem, has 63 problems but performs not as well as $x_1 = (n_1 - n_2)/(n_3 - n_4)$ which has 48 problems. We look into their corresponding problems and find out that $x_1 = n_1 - n_2$ are applied to more themes in natural language than $x_1 = (n_1 - n_2)/(n_3 - n_4)$, which are almost about the theme of "coordinate slope".

In our model, there is a gap between template retrieval accuracy and final solution accuracy, which means that although we select the correct template candidates for the problem, the alignment model cannot rank the equations correctly.

5.3 Two-Stage Evaluation

Next, we evaluate the performance of our two-stage system. Accuracy of template retrieval and alignment ranking is shown in Table 5.

For template retrieval accuracy, Hit@N means the correct template for a problem is included in the top N list returned by our model. We estimate the best achievable performance by using oracle template retrieval. The result is **47.1%** (Hit@ALL), which means 47.1% of the templates exist more than once in the problem set. Please note that our template retrieval evaluation may be underestimated, since in some cases, a test problem can be solved by different templates.

We then use the top N templates as input for both our alignment ranking and ZDC. From the table, we have the following observations: (1) Hit@3 performs better compared to Hit@1 for both systems. This confirms our claim that some templates are similar and we need to incorporate more fine-grained features to differentiate in the alignment step; (2) It obtains the highest accuracy when $N = 3$ and decreases when N gets larger. Both systems get benefits from our template retrieval which helps retrieve relevant templates and reduce the hypothesis space of equations; (3) Given the same N templates input, our alignment ranking achieves better performance than ZDC. This implies that our features are more indicative.

5.4 Feature Ablation

This section describes our feature ablation study.

Template Retrieval In Table 6, we conduct three configurations against our model (FULL). Each ablated configuration corresponds to one category of our template sketch. From the table, we can see that all three categories of features contribute to system performance. We remove QUANTITY results in the worse performance comparing to the FULL model.

Alignment Ranking In Table 7, N means to select the top N templates in the previous stage for alignment. The column "Correct Template" represents how well the alignment model can perform given the correct template input for alignment. Our alignment model (FULL) performs the best compared to the three ablated settings, which confirms the effectiveness of template properties.

5.5 Error Analysis

We have observed that template-based methods have difficulty solving problems with small template sizes, especially for cases that have a single problem instance (i.e. template size = 1). We sample 100 problems in which our system makes mistakes in the dev set of Dolphin18K and summarize them in Table 8.

Quantity Type The types of quantities are difficult to determined. For the example problem in

				Ours	
Template	problems	ZDC (%)	SIM (%)	Template retrieval Acc (%)	Final Acc (%)
$n_1 * x_1 = n_2$	548	26.3	23.9	87.0	58.7
$n_1/x_1 = n_2/n_3$	453	21.4	29.8	94.1	61.5
$x_1 = n_1 * n_2$	403	23.6	28.0	78.9	63.4
$n_1 * x_1 + n_2 * x_2 = n_3;$ $x_1 + x_2 = n_4$	300	86.3	69.7	94.9	85.8
$x_1 = n_1 * n_2 * n_3$	103	22.3	32.0	67.0	55.0
$x_1 + x2 = n_1$ $x1 - x_2 = n2$	80	39.7	48.8	79.4	65.1
$x_1 = n_1 - n_2$	63	11.7	15.9	50.7	23.4
$x_1 = (n_1 - n_2)/(n_3 - n_4)$	48	14.9	18.8	95.7	89.4

Table 4: Accuracy Per Template. Template retrieval acc reports percent of templates appears in one of the top 3 templates returned by our method.

Hit@N	1	2	3	4	5	10	20	50	ALL
Template retrieval Acc (%)	17.5	22.4	26.3	27.2	28.0	30.2	32.7	35.2	47.1
Final Acc (%)	24.9	27.6	**28.4**	27.9	27.4	25.3	22.3	22.1	20.1
ZDC (%)	19.5	20.1	20.1	19.9	19.8	19.1	18.9	18.6	17.9

Table 5: Results of template retrieval and final accuracy with different top N templates retrieved.

Model	Hit @1 (%)	Hit @3 (%)	Hit @10 (%)
FULL	17.5	26.3	30.2
-TEXTUAL	14.1	24.7	28.4
-QUANTITY	11.4	23.4	25.9
-QUESTION	16.9	25.4	29.8

Table 6: Feature ablation of template retrieval.

Model	Correct Template (%)	N= 1 (%)	N= 3 (%)
FULL	34.5	24.9	28.4
-TEXTUAL	31.9	22.2	25.1
-QUANTITY	29.2	20.9	23.3
-SOLUTION	26.3	18.7	21.2

Table 7: Feature ablation of alignment ranking.

the table, if we can detect “24 male” is the same as “men”, the problem can be solved.

Relation/State Detection If we can identify the changed states or mathematical relations between variables, we can solve this category of problems. In the example problem, it is important to understand that “commission is taken out” is my money state.

External Knowledge This requires specific mathematical models, such as permutation and combination, or commonsense knowledge, e.g. a dice has 6 sides.

Equation Decomposition The limitation of template-based approaches is that they require test problems belonging to one of the templates seen in training. Thus, for problems corresponding to template sizes less than 2, we can decompose templates into smaller units and conduct learning more precisely. We then need to generate the equations, which is also a challenge.

6 Conclusion and Future Work

In this paper, we propose a novel approach to solving math word problems with rich information of templates. We learn mappings between textual expressions and template fragments. Furthermore, we automatically construct sketches for each template. We implement a two-stage system, including template retrieval and alignment ranking. Experiments show that our method performs signifi-

Category	Math Problem
Quantity Type (10%)	The ratio of **women** to **men** in a certain club is 3 to 2. If there are 24 **male** club members, then how many female club members are there?
Relation/State Detection (12%)	If I am selling something for $25,000 and **a 7% commission is taken out**, how much money will I **be left** with?
External Knowledge (23%)	Find the probability that total score is 10 or more given at least one dice show 6 if 2 dice red & blue thrown?
Equation Decomposition (55%)	The average weight of A, B and C is 45 kg. If the average weight of A and B is 40 kg and that of B and C is 43 kg, the weight of B is?

Table 8: Error Categorization.

cantly better than two state-of-the-art systems.

Based on our error analysis, we plan to improve our model by detecting quantity types more accurately, learning relations and incorporating commonsense knowledge. For long tail problems with a template size less 2, we want to utilize the fine-grained expressions we have learned and decompose equations for learning. Then we can reason with small equation units to generate a final equation in testing. We would like to leverage semantic parsing and transform math problems to a more structured representation. Additionally, we plan to apply our findings to generating math problem.

Abstract

Deep neural networks for machine comprehension typically utilizes only word or character embeddings without explicitly taking advantage of structured linguistic information such as constituency trees and dependency trees. In this paper, we propose *structural embedding of syntactic trees* (SEST), an algorithm framework to utilize structured information and encode them into vector representations that can boost the performance of algorithms for the machine comprehension. We evaluate our approach using a state-of-the-art neural attention model on the SQuAD dataset. Experimental results demonstrate that our model can accurately identify the syntactic boundaries of the sentences and extract answers that are syntactically coherent over the baseline methods.

1 Introduction

Reading comprehension such as SQuAD (Rajpurkar et al., 2016) or NewsQA (Trischler et al., 2016) requires identifying a span from a given context, which is an extension to the traditional question answering task, aiming at responding questions posed by human with natural language (Nyberg et al., 2002; Ferrucci et al., 2010; Liu, 2017; Yang, 2017). Many works have been proposed to leverage deep neural networks for such question answering tasks, most of which involve learning the query-aware context representations (Dhingra et al., 2016; Seo et al., 2017; Wang and Jiang, 2016; Xiong et al., 2017). Although deep learning based methods demonstrated great potentials for question answering, none them take syntactic information of the sentences such as *constituency tree* and *dependency tree* into consideration. Such techniques have been proven to be useful in many natural language understanding tasks in the past and illustrated noticeable improvements such as the work by (Rajpurkar et al., 2016). In this paper, we adopt similar ideas but apply them to a neural attention model for question answering.

The constituency tree (Manning et al., 1999) of a sentence defines internal nodes and terminal nodes to represent phrase structure grammars and the actual words. Figure 1 illustrates the constituency tree of the sentence "the architect or engineer acts as the project coordinator". Here, "the architect or engineer" and "the project coordinator" are labeled as noun phrases ("NP"), which is critical for answering the question below. Here, the question asks for the name of certain occupation that can be best answered using an noun phrase. Utilizing the know ledge of a constituency relations, we can reduce the size of the candidate space and help the algorithm to identify the correct answer.

> *Whose role is to design the works, prepare the specifications and produce construction drawings, administer the contract, tender the works, and manage the works from inception to completion?*

On the other hand, a dependency tree (Manning et al., 1999) is constructed based on the dependency structure of a sentence. Figure 2 displays the dependency tree for sentence

> *The Annual Conference, roughly the equivalent of a diocese in the Anglican Communion and the Roman Catholic Church or a synod in some Lutheran denominations such as the Evangelical Lutheran Church in America, is the basic unit of organization within the UMC.*

Proceedings of the 2017 Conference on Empirical Methods in Natural Language Processing, pages 815–824
Copenhagen, Denmark, September 7–11, 2017.

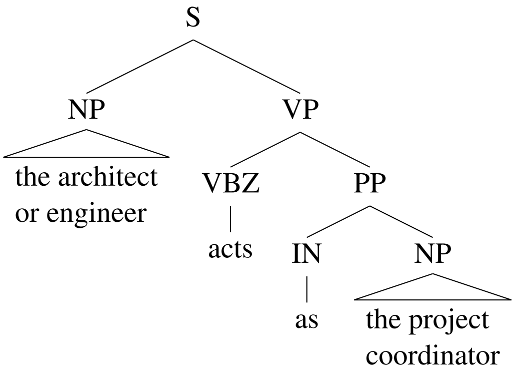

Figure 1: The constituency tree of context "the architect or engineer acts as the project coordinator"

"The Annual Conference" being the subject of "the basic unit of organization within the UMC" provides a critical clue for the model to skip over a large chunk of the text when answering the question "What is the basic unit of organization within the UMC". As we show in the analysis section, adding dependency information dramatically helps identify dependency structures within the sentence, which is otherwise difficult to learn.

In this paper, we propose Structural Embedding of Syntactic Trees (SEST) that encode syntactic information structured by constituency tree and dependency tree into neural attention models for the question answering task. Experimental results on SQuAD dataset illustrates that the syntactic information helps the model to choose the answers that are both succinct and grammatically coherent, which boosted the performance on both qualitative studies and numerical results. Our focus is to show adding structural embedding can improve baseline models, rather than directly compare to published SQuAD results. Although the methods proposed in the paper are demonstrated using syntactic trees, we note that similar approaches can be used to encode other types of tree structured information such as knowledge graphs and ontology relations.

2 Methodology

The general framework of our model is illustrated in Figure 3. Here the input of the model is the embedding of the context and question while the output is two indices *begin* and *end* which indicate the begin and end indices of the answer in the context space.

The input of the model contains two parts: the word/character model and the syntactic model. The shaded portion of our model in Figure 3 represents the encoded syntactic information of both context and question that are fed into the model. To gain an insight of how the encoding works, consider a sentence which syntactic tree consists of four nodes $(o1, o2, o3, o4)$. A specific word is represented to be a sequence of nodes from its leave all the way to the root. We cover how this process work in detail in Section 3.1.1 and 3.1.2. Another input that will be fed into deep learning model is the embedding information for words and characters respectively. There are many ways to convert words in a sentence into a high-dimensional embedding. We choose GloVe (Pennington et al., 2014b) to obtain a pre-trained and fixed vector for each word. Instead of using a fixed embedding, we use Convolutional Neural Networks (CNN) to model character level embedding, which values can be changed during training (Kim, 2014). To integrate both embeddings into the deep neural model, we feed the concatenation of them for the question and the context to be the input of the model.

The inputs are processed in the embedding layer to form more abstract representations. Here we choose a multi-layer bi-directional Long Short Term Memory (LSTM) (Hochreiter and Schmidhuber, 1997) to obtain more abstract representations for words in the contexts and questions.

After that, we employ an attention layer to fuse information from both the contexts and the questions. Various matching mechanisms using attentions have been extensively studied for machine comprehension tasks (Xiong et al., 2017; Seo et al., 2017; Wang et al., 2016; Wang and Jiang, 2016). We use the Bi-directional Attention flow model (Seo et al., 2017) which performs context-to-question and question-to-context attentions in both directions. The context-to-question attention signifies which question words are most relevant to each context word. For each context word, the attention weight is first computed by a softmax function with question words, and the attention vector of each context word is then computed by a weighted sum of the question words' embeddings obtained from the embedding layer. The question-to-context attention summarizes a context vector by performing a soft attention with context words given the question. We then represent each context word as the concatenation of the embedding vector obtained from the embedding layer, the atten-

tion vector obtained from the context-to-question attention and the context vector obtained from the question-to-context attention. We then feed the concatenated vectors to a stacked bi-directional LSTM with two layers to obtain the final representations of context words. We note that our proposed structural embedding of syntactic trees can be easily applied to any attention approaches mentioned above.

For the machine comprehension task in this paper, the answer to the question is a phrase in the context. In the output layer, we use two softmax functions over the output of the attention layer to predict the begin and end indices of the phrase in the context.

3 Structural Embedding of Syntactic Tree

We detail the procedures of two alternative implementation of our methods: the Structural Embedding of Constituency Trees model (SECT) and the Structural Embedding of Dependency Trees model (SEDT). We assume that the syntactic information has already been generated in the preprocessing step using tools such as the Stanford CoreNLP (Manning et al., 2014).

3.1 Syntactic Sequence Extraction

We first extract a *syntactic collection* $\mathcal{C}(p)$ for each word p, which consists of a set of nodes $\{o_1, o_2, \ldots, o_{d-1}, o_d\}$ in the syntactic parse tree $\mathcal{T}$. Each node o_i can be a word, a grammatical category (e.g., part-of-speech tagging), or a dependency link label, depending on the type of syntactic tree we use. To construct syntactic embeddings, the first thing we need to do is to define a specific *processing order* $\mathcal{A}$ over the syntactic collection $\mathcal{C}(p)$, in which way we can extract a *syntactic sequence* $\mathcal{S}(p)$ for the word p.

3.1.1 Structural Embedding of Constituency Trees (SECT)

The constituency tree is a syntactic parse tree constructed by phrase structure grammars (Manning et al., 1999), which defines the way to hierarchically construct a sentence from words in a bottom-up manner based on constituency relations. Words in the contexts or the questions are represented by leaf nodes in the constituency tree while the non-terminal nodes are labeled by categories of the grammar. Non-terminal nodes summarize the grammatical function of the sub-tree. Figure 1 shows an example of the constituency tree with "the architect or engineer" being annotated as a noun phrase (NP).

A path originating from the leaf node to the root node captures the syntactic information in the constituency tree in a hierarchical way. The higher the node is, the longer span of words the sub-tree of this node covers. Hence, to extract the syntactic sequence $\mathcal{S}(p)$ for a leaf node p, it is reasonable to define the processing order $\mathcal{A}(p)$ from the leaf p all the way to its root. For example, the syntactic sequence for the phrase "the project coordinator" in Figure 1 is detected as (NP, PP, VP, S). In practice, we usually take the last hidden units of Bi-directional encoding mechanisms such as Bi-directional LSTM to represent the sequence state, as is indicated in Figure 4 (a). We set a window size to limit the amount of information that is used in our models. For example, if we choose the window size as 2, then the syntactic sequence becomes (NP, PP). This process is introduced for both performance and memory utilization consideration, which is discussed in detail in Section 4.5.

In addition, a non-terminal node at a particular position in the syntactic sequence defines the begin and end indices of a phrase in the context. By measuring the similarity between syntactic se-

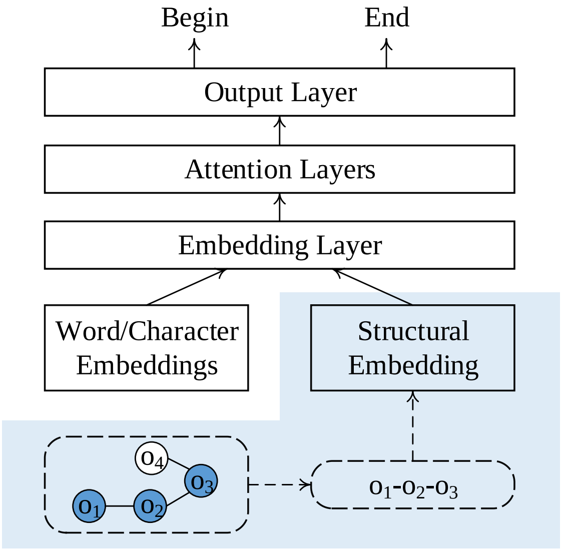

Figure 3: Model Framework. The neural network for training and testing is built by components with solid lines, which includes the embedding layer, attention layer, and output layer. The shaded area highlights the part of the framework that involves syntactic information. Components with dashed lines is an example to illustrate how syntactic information is decoded. Here a sentence is decomposed into a syntactic tree with four nodes and the syntactic information for a specific word is recorded as the path from its position in the syntactic tree to the root, i.e. (o_1, o_2, o_3) in this case.

quences $\mathcal{S}(p)$ extracted for each word p of both the question and the context, we are able to locate the boundaries of the answer span. This is done in the attention layer shown in Figure 3.

3.1.2 Structural Embedding of Dependency Trees (SEDT)

The dependency tree is a syntactic tree constructed by dependency grammars (Manning et al., 1999), which defines the way to connect words by directed links that represent dependencies. A dependency link is able to capture both long and short distance dependencies of words. Relations on links vary in their functions and are labeled with different categories. For example, in the dependency tree plotted in Figure 2, the link from "unit" to "Conference" indicates that the target node is a nominal subject (i.e. NSUBJ) of the source node.

The syntactic collection $\mathcal{C}(p)$ for dependency tree is defined as p's children, each represented by its word embedding concatenated with a vector that uniquely identifies the dependency label. The processing order $\mathcal{A}(p)$ for dependency tree is then defined to be the dependent's original order in the sentence.

Take the word "unit" as an example, we encode the dependency sub-tree using a Bi-directional LSTM, as indicated in Figure 4 (b). In such as a sub-tree, since children are directly linked to the root, they are position according to the original sequence in the sentence. Similar to the syntactic encoding of C-Tree, we take the last hidden states as its embedding.

Similar to SECT, we use a window of size l to limit the amount of syntactic information for the learning models by choosing only the l-nearest dependents, which is again reported in Section 4.5.

3.2 Syntactic Sequence Encoding

Similar to previous work (Cho et al., 2014; Kim, 2014), we use a neural network to encode a variable-length syntactic sequence into a fixed-length vector representation. The encoder can be a Recurrent Neural Network (RNN) or a Convolutional Neural Network (CNN) that learns a structural embedding for each node such that embedding of nodes under similar syntactic trees are close in their embedding space.

We can use a Bi-directional LSTM as our RNN encoder, where the hidden state $\mathbf{v}_t^p$ is updated according to Eq. 1. Here $\mathbf{x}_t^p$ is the t^{th} node in the syntactic sequence of the word p, which is a vector that uniquely identifies each syntactic node. We obtain the structural embedding of the given word p, $\mathbf{v}_{\text{Bi-LSTM}}^p = \mathbf{v}_T^p$ to be the final hidden state.

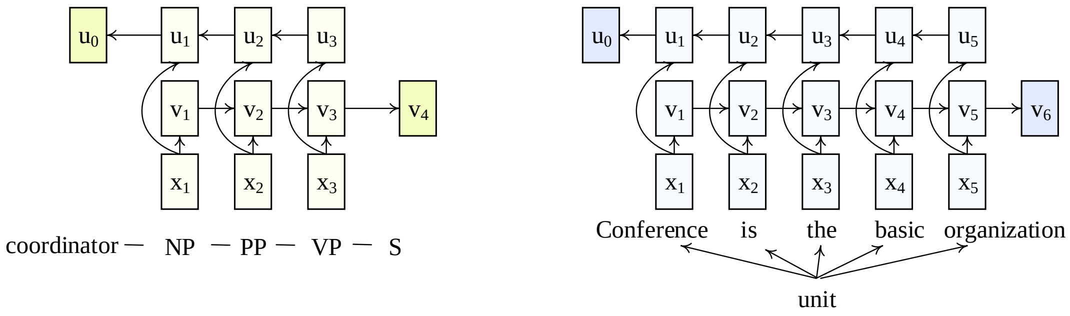
$$\mathbf{v}_t^p = \text{Bi-LSTM}(\mathbf{v}_{t-1}^p, \mathbf{x}_t^p) \tag{1}$$

Alternatively, we can also use CNN to obtain embeddings from a sequence of syntactic nodes. We denote l as the length of the filter of the CNN encoder. We define $\mathbf{x}_{i:i+l}^p$ as the concatenation of the vectors from $\mathbf{x}_i^p$ to $\mathbf{x}_{i+l-1}^p$ within the filter. The i^{th} element in the j^{th} feature map can be obtained in Eq. 2. Finally we obtain the structural embedding of the given word p by $\mathbf{v}_{\text{CNN}}^p$ in Eq. 3.

$$\mathbf{c}_{i,j}^p = f(\mathbf{w}_j \cdot \mathbf{x}_{i:i+l-1} + b_j) \tag{2}$$

$$\mathbf{v}_{\text{CNN}}^p = \max_{row}(\mathbf{c}^p) \tag{3}$$

where $\mathbf{w}_j$ and b_j are the weight and bias of the j^{th} filter respectively, f is a non-linear activation function and $\max_{row}(\cdot)$ takes the maximum value along rows in a matrix.



(a) A SECT example

(b) A SEDT example

Figure 4: Two examples are used to illustrate how the syntactic information is encoded for SECT and SEDT respectively. Take Bi-directional LSTM as examples, where $\mathbf{x}$ is a vector such as word embedding, $\mathbf{v}$ and $\mathbf{u}$ are the outputs of the forward and backward LSTMs respectively. For SECT, we encode the syntactic sequence (NP, PP, VP) for the word "coordinator" in Figure 1. We use fixed vectors for syntactic tags (e.g., NP, PP and VP), initialized with multivariate normal distribution. The final representation for the target word "coordinator" can be represented as the concatenation $[\mathbf{Ew}; \mathbf{u}_0; \mathbf{v}_4]$, where $\mathbf{Ew}$ is the word embedding for "coordinator" that is 100 dimensions in our experiments and each of the encoded vector $\mathbf{u}$ and $\mathbf{v}$ can be 30 dimensional. For SEDT, we encode the word "unit" in Figure 2 with its dependent nodes including "Conference", "is", "the", "basic", "organization", ordered by their positions in the original sentence. Each word is represented with its word embedding. Similar to SECT, the final representation is the concatenation $[\mathbf{Ew}; \mathbf{u}_0; \mathbf{v}_6]$, which will be sent to the input layer of a neural network.

4 Experiments

We conducted systematic experiments on the SQuAD dataset (Rajpurkar et al., 2016). We compared our methods against Bi-Directional Attention Flow (BiDAF), as well as the SEST models described in Section 3.

4.1 Preprocessing

A couple of preprocessing steps is performed to ensure that the deep neural models get the correct input. We segmented context and questions into sentences by using NLTK's Punkt sentence segmenter[1]. Words in the sentences were then converted into symbols by using PTB Tokenizer[2]. Syntactic information including POS tags and syntactic trees were acquired by Stanford CoreNLP utilities (Manning et al., 2014). For the parser, we collected constituent relations and dependency relations for each word by using tree annotation and enhanced dependencies annotation respectively. To generate syntactic sequence, we removed sequences whose first node is a punctuation ("$", ":", "#", ".", " " ", " " ", ","). To use dependency labels, we removed all the subcategories (e.g., "nmod:poss" ⇒ "nmod").

4.2 Experiment Setting

We run our experiments on a machine that contains a single GTX 1080 GPU with 8GB VRAM. All of the models being compared have the same settings on character embedding and word embedding. As introduced in Section 2, we use a variable character embedding with a fixed pre-trained word embedding to serve as part of the input into the model. The character embedding is implemented using CNN with a one-dimensional layer consists of 100 units with a channel size of 5. It has an input depth of 8. The max length of SQuAD is 16 which means there are a maximum 16 words in a sentence. The fixed word embedding has a dimension of 100, which is provided by the GloVe data set (Pennington et al., 2014a). The settings for syntactic embedding are slightly different for each model. The BiDAF model does not deal with syntactic information. The POS model contains syntactic information with 39 different POS tags that serve as both input and output. For SECT and SEDT the input of the model has a size of 8 with 30 units to be output. Both of them has a maximum length size that is set to be 10 and 20 respectively, which values will be further discussed in Section 4.5. They also have two different ways to encode the syntactic information as indi-

[1] http://www.nltk.org/api/nltk.tokenize.html

[2] http://nlp.stanford.edu/software/tokenizer.shtml

cated in Section 3: LSTM and CNN. We apply the same sets of parameters when we experiment them with the two models. We report the results on the SQuAD development set and the blind test set.

4.3 Predictive Performance

We first compared the performance of single models between the baseline approach BiDAF and the proposed SEST approaches, including SEPOS, SECT-LSTM, SECT-CNN, SEDT-LSTM, and SEDT-CNN, on the development dataset of SQuAD. For each model, we conducted 5 different single experiments and evaluated them using two metrics: "Exact match" (EM), which calculates the ratio of questions that are answered correctly by strict string comparison, and the F1 score, which calculates the harmonic mean of the precision and recall between predicted answers and ground true answers at the character level. As shown in Table 1, we reported the maximum, the mean, and the standard deviation of EM and F1 scores across all single runs for each approach, and highlighted the best model using bold font. SECT-LSTM is the second best method, which confirms the predictive powers of different types of syntactic information. We could see that SEDT-LSTM model outperforms the baseline method and other proposed methods in terms of both EM and F1. Another observation is that our propose models achieve higher relative improvements in EM scores than F1 scores over the baseline methods, providing the evidence that syntactic information can accurately locate the boundaries of the answer.

Moreover, we found that both SECT-LSTM and SEDT-LSTM have better performance than their CNN counterparts, which suggests that LSTM can more effectively preserve the syntactic information. As a result, we conducted further analysis of only SECT-LSTM and SEDT-LSTM models in the subsequent subsections and drop the suffix "-LSTM" for abbreviation. We built an ensemble model from the 5 single models for the baseline method BiDAF and our proposed methods SEPOS, SECT-LSTM, and SEDT-LSTM. The ensemble model choose the answer with the highest sum of confidence scores among the 5 single models for each question. We compared these models on both the development set and official test set and reported the results in Table 2. We found that the models have higher performance on the test set than the development set, which coincides with the previous results on the same data set (Seo et al., 2017; Xiong et al., 2017).

4.4 Contribution of Syntactic Sequence

To take a closer look at how syntactic sequences affect the performance, we removed the character/word embedding from our model seen in Figure 3 and conducted experiments based on the syntactic input alone. In particular, we are interested in two aspects related to syntactic sequences: First, the ability to predict answers of questions of syntactic sequences compared to complete random sequences. Second, the amount of impacts brought by our proposed ordering introduced in Section 3.1.1 and Section 3.1.2 compared to random ordering.

We compared the performance of the models using syntactic information along in their original order (i.e. SECT-Only and SEDT-Only) against their counterparts with the same syntactic tree nodes but with randomly shuffled order (i.e. SECT-Random-Order and SEDT-Random-Order) as well as the baselines with randomly generated tree nodes (i.e. SECT-Random and SEDT-Random). Here we choose the length of window size to be 10. The predictive results in terms of EM and F1 metrics are reported in Table 3. From the table we see that both the ordering and the contents of the syntactic tree are important for the models to work properly: constituency and dependency trees achieved over 20% boost on performance compared to the randomly generated ones and our proposed ordering also out-performed the random ordering. It also worth mentioning that the ordering of dependency trees seems to have less impact on the performance compared to that of the constituency trees. This is because sequences extracted from constituency trees contain hierarchical information, which ordering will affect the output of the model significantly. However, sequences extracted from dependency trees are all children nodes, which are often interchangeable and don't seem to be affected by ordering much.

4.5 Window Size Analysis

As we have mentioned in the earlier sections, limiting the window size is an important technique to prevent excessive usage on VRAM. In practice, we found that limiting the window size also benefits the performance of our models. In Table 4 we compared the predictive performance of SECT

Method	Single				Ensemble	
	EM		F1		EM	F1
	Max	Mean (±SD)	Max	Mean (±SD)

Method	Len	EM	F1
SECT	1	65.58 (± 2.58)	75.31 (± 2.39)
	5	65.74 (± 3.77)	75.48 (± 3.39)
	10	**67.51 (± 0.34)**	**77.14 (± 0.39)**
	Max	67.48 (± 0.33)	77.09 (± 0.45)
SEDT	1	66.23 (± 2.5)	73.85 (± 2.22)
	10	**67.39 (± 0.09)**	**76.93 (± 0.21)**

Table 4: Performance means and standard deviations of different window sizes on the development set.

and SEDT models by varying the length of their window sizes from 1 to maximum on the development set. In general the results illustrate that performances of the models increase with the length of the window. However, we found that for SECT model, its mean performance reached the peak while standard deviations narrowed when window size reaches 10. We also observed that larger window size does not generate predictive results that is as good as the one with window size set to 10. This suggests that there exists an optimal window size for the constituency tree. One possible explanation is increasing the window size leads to the increase in the number of syntactic nodes in the extracted syntactic sequence. Although subtrees might be similar between context and question, it is very unlikely that the complete trees are the same. Because of that, allowing the syntactic sequence to extend beyond the certain heights will introduce unnecessary noise into the learned representation, which will compromise the performance of the models. Similar conclusion holds for the SEDT model, which has an improved performance and decreased variance with the window size is set to 10. We did not perform experiments with window size beyond 10 for SEDT since it will consume VRAM that exceeds the capacity of our computing device.

4.6 Overlapping Analysis

To further understand the performance benefits of incorporating syntactic information into the question answering problem, we can take a look at the questions on which models disagree. Figure 5 is the Venn Diagram on the questions that have been corrected identified by SECT, SEDT and the baseline BiDAF model. Here we see that the vast

Table 6: Questions that are correctly answered by SEDT but not BiDAF

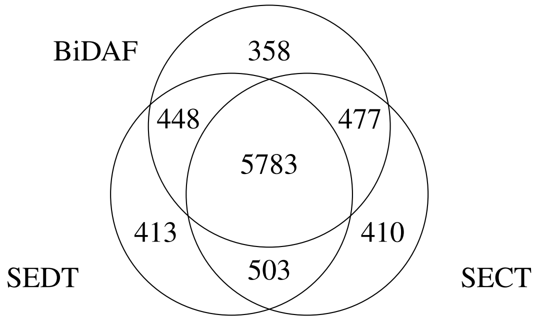

Figure 5: Venn Diagram on the number of correct answers predicted by BiDAF, SECT and SEDT

majority of the correctly answered questions are shared across all three models. The rest of them indicates questions that models disagree and are distributed fairly evenly.

To understand the types of the questions that syntactic models can do better, we extracted three questions that were correctly answered by SECT and SEDT but not the baseline model. In Table 5, all of the three questions are "Wh-questions" and expect the answer of a noun phrase (NP). Without knowing the syntactic information, BiDAF answered questions with unnecessary structures such as verb phrases (vp) (e.g. "acts as $\cdots$ ", "represented $\cdots$ ") or prepositional phrases (pp) (e.g. "in $\cdots$ ") in addition to NPs (e.g. "the architect engineer", "uncertainty" and "powerful high frequency currents") that normal human would answer. For that reason, answers provided by BiDAF failed the exact match although its answers are semantically equivalent to the ones provided by SECT. Having incorporated constituency information provided an huge advantage in inferring the answers that are most natural for a human.

The advantages of using the dependency tree in our model can be illustrated using the questions in Table 6. Here again we listed the ones that are correctly identified by SEDT but not BiDAF. As we can see that the answer provided by BiDAF for first question broke the parenthesis incorrectly, this problem that can be easily solved by utilizing dependency information. In the second example, BiDAF failed to identify the dependency structures between "50%" and the keyword being asked "wheat", which resulted in an incorrect answer that has nothing to do with the question. SEDT, on the other hand, answered the question correctly. In the third question, the key to the answer is to correctly identify the subject of question phrase "is the basic unit of organization". Using the dependency tree as illustrated in Figure 2, SEDT is able to identify the subject phrase correctly, namely "The Annual Conference". However, BiDAF failed to anwer the question correctly and selected a noun phrase as the answer.

5 Related Work

Reading Comprehension. Reading comprehension is a challenging task in NLP research. Since the release of the SQuAD data set, many works have been done to construct models on this massive question answering data set. Rajpurkar et. al. are among the first authors to explore the SQuAD. They used logistic regression with pos tagging information (Rajpurkar et al., 2016) and provided a strong baseline for all subsequent models. A steep improvement was given by the RaSoR model (Lee et al., 2016) which utilized recurrent neural networks to consider all possible subphrases of the context and evaluated them one by one. To avoid comparing all possible candidates and to improve the performance, Match-LSTM (Wang and Jiang, 2016) was proposed by using a pointer network (Vinyals et al., 2015) to extract the answer span from the context. The same idea was taken to the BiDAF (Seo et al., 2017) model by introducing a bi-directional attention mechanism. Despite the above-mentioned strong models for the machine comprehension task, none of them considers syntactic information into their prediction models.

Representations of Texts and Words. One of the main issues in reading comprehension is to identify the latent representations of texts and words (Cui et al., 2016; Lee et al., 2016; Wang et al., 2016; Xiong et al., 2017; Yu et al., 2016). Many pre-trained libraries such as word2vec (Mikolov et al., 2013) and Glove (Pennington et al., 2014a) have been widely used to map words into a high dimensional embedding space. Another approach is to generate embeddings by using neural networks models such as Character Embedding (Kim, 2014) and Tree-LSTM (Tai et al., 2015). One thing that worth mentioning is that although Tree-LSTM does utilize syntactic information, it targets at the phrases or sentences level embedding other than the word level embedding we have discussed in this paper. Many machine comprehension models include both pre-trained embeddings and variable embeddings that can be changed through a training stage (Seo et al., 2017).

6 Conclusion

In this paper, we proposed methods to embed syntactic information into the deep neural models to improve the accuracy of our model in the machine comprehension task. We formally defined our SEST framework and proposed two instances to it: the structural embedding of constituency trees (SECT) and the structural embedding of dependency trees (SEDT). Experimental results on SQuAD data set showed that our proposed approaches outperform the state-of-the-art BiDAF model, proving that the proposed embeddings play a significant part in correctly identifying answers for the machine comprehension task. In particular, we found that our model can perform especially well on exact match metrics, which requires syntactic information to accurately locate the boundaries of the answers. Similar approaches can be used to encode other tree structures such as knowledge graphs and ontology relations.

This work opened several potential new lines of research: 1) In the experiments of our paper we utilized the BiDAF model to retrieve answers from the context. Since there are no structures in the BiDAF models to specifically optimize for syntactic information, an attention mechanism that is designed for to utilize syntactic information should be studied. 2) Another direction of research is to incorporate SEST with deeper neural networks such as VD-CNN (Conneau et al., 2017) to improve learning capacity for syntactic embedding. 3) Tree structured information such as knowledge graphs and ontology structure should be studied and improve question answering tasks using similar techniques to the ones proposed in the paper.

Abstract

Humans interpret texts with respect to some background information, or *world knowledge*, and we would like to develop automatic reading comprehension systems that can do the same. In this paper, we introduce a task and several models to drive progress towards this goal. In particular, we propose the task of *rare entity prediction*: given a web document with several entities removed, models are tasked with predicting the correct missing entities conditioned on the document context and the lexical resources. This task is challenging due to the diversity of language styles and the extremely large number of rare entities. We propose two recurrent neural network architectures which make use of external knowledge in the form of entity descriptions. Our experiments show that our hierarchical LSTM model performs significantly better at the rare entity prediction task than those that do not make use of external resources.

1 Introduction

Reading comprehension is the ability to process some text and understand its contents, in order to form some beliefs about the world. The starting point of this paper is the fact that world knowledge plays a crucial role in human reading comprehension and language understanding. Work in the psychology of reading literature has demonstrated this point, for example by showing that readers are better able to recall the contents of a story when it describes a counter-intuitive but plausible sequence of events, rather than a bizarre or a highly predictable one (Barrett and Nyhof, 2001). This point is also central to work in the Schankian tradition of scripts (Schank and Abelson, 1977).

Despite the importance of world knowledge, previous data sets and tasks for reading comprehension have targeted other aspects of the reading comprehension problem, at times explicitly attempting to factor out its influence. In the Daily Mail/CNN dataset (Hermann et al., 2015), named entities such *Clarkson* and *Top Gear* are replaced by anonymized entity tokens like *ent212*. The Children's Book Test focuses on the role of context and memory (Hill et al., 2016a), and the fictional genre makes it difficult to connect the entities in the stories to real-world knowledge about those entities.

As a result, language models have proved to be a highly competitive solution to these tasks. Chen et al. (2016) showed that their attention-based LSTM model achieves state-of-the-art results on the Daily Mail/CNN data set. In fact, their analysis shows that more than half of the questions can be answered by exact word matching and sentence-level paraphrase detection, and that many of the remaining errors are difficult to solve exactly because the entity anonymization procedure removes necessary world knowledge.

In this paper, we propose a novel task called *rare entity prediction*, which places the use of external knowledge at its core, with the following key features. First, our task is similar in flavour to the Children's Book and other language modeling tasks, in that the goal of the models is to predict missing elements in text. However, our task involves predicting missing named entities, rather than missing words. Second, the number of unique named entities in the data set is very large, roughly on par with the number of documents. As such, there are very few instances per named entity for systems to train on. Instead, they must rely on external knowledge sources such as Freebase (Bollacker et al., 2008) in order to make inferences

about the likely entities that fit the context.

For our task, we use a significantly enhanced version of the Wikilinks dataset (Singh et al., 2012), with entity descriptions extracted from Freebase serving as the lexical resources, which we call the *Wikilinks Rare Entity Prediction* dataset. An example from the Wikilinks Entity Prediction dataset is shown in Table 1.

We also introduce several recurrent neural network-based models for this task which take in entity descriptions of candidate entities. Our first model, DOUBENC, combines information derived from two encoders: one for the text passage being read, and one for the entity description. Our second model, HIERENC, is an extension which considers information from a document-level context, in addition to the local sentential context. We show that language modeling baselines that do not consider entity descriptions are unable to achieve good performance on the task. RNN-based models that are trained to leverage external knowledge perform much better; in particular, HIERENC achieves a 17% increase in accuracy over the language model baseline.

2 Related Work

Related to our work is the task of *entity prediction*, also called *link prediction* or *knowledge base completion*, in the context of multi-relational data. Multi-relational datasets like WordNet (Miller, 1995) and Freebase (Bollacker et al., 2008) consist of entity-relation *triples* of the form (head, relation, tail). In entity prediction, either the head or tail entity is removed, and the model has to predict the missing entity. Recent efforts have integrated different sources of knowledge, for example combining distributional and relational semantics for building word embeddings (Fried and Duh, 2015; Long et al., 2016). While this task requires understanding and predicting associations between entities, it does not require contextual reasoning with text passages, which is crucial in rare entity prediction.

Rare entity prediction is also clearly distinct from tasks such as entity tagging and recognition (Ritter et al., 2011), as models are provided with the actual name of the entity in question, and only have to match the entity with related concepts and tags. It is more closely related to the machine reading literature from e.g. Etzioni et al. (2006); however, the authors define machine reading as primarily unsupervised, whereas our task is supervised.

A similar supervised reading comprehension task was proposed by Hermann et al. (2015) using news articles from CNN and the Daily Mail. Given an article, models are tasked with filling in blanks of one-sentence summaries of the article. The original dataset was found to have a low ceiling for machine improvement (Chen et al., 2016); thus, alternative datasets have been proposed that consist of more difficult questions (Trischler et al., 2016; Rajpurkar et al., 2016). A dataset with a similar task was also proposed by Hill et al. (2016a), where models must answer questions about short children's stories. While these tasks require the understanding of unstructured natural language, they do not require integration with external knowledge sources.

Hill et al. (2016b) proposed a method of combining distributional semantics with an external knowledge source in the form of dictionary definitions. The purpose of their model is to obtain more accurate word and phrase embeddings by combining lexical and phrasal semantics, and they achieve fairly good performance on reverse dictionaries and crossword puzzle solving tasks.

Perhaps the most related approach to our work is the one developed by Ahn et al. (2016). The authors propose a WikiFacts dataset where Wikipedia descriptions are aligned with Freebase facts. While they also aim to integrate external knowledge with unstructured natural language, their task differs from ours in that it is primarily a language modeling problem.

More recently, Bahdanau et al. (2017) investigated a similar approach to generate embeddings for out-of-vocabulary words from their definitions and applied it to a number of different tasks. However, their method mainly focuses on modeling generic concepts and is evaluated on tasks that do not require the understanding of world knowledge specifically. Our work, on the other hand, shows the effectiveness of incorporating external descriptions for modeling real-world named entities and is evaluated on a task that explicitly requires the understanding of such external knowledge.

3 Rare Entity Prediction

3.1 The *Wikilinks* Dataset

The *Wikilinks* dataset (Singh et al., 2012) is a large dataset originally designed for cross-document coreference resolution, the task of grouping entity mentions from a set of documents into clusters that represent a single entity. The dataset consists of a list of non-Wikipedia web pages (discovered using the Google search index) that contain hyperlinks to Wikipedia, such as random blog posts or news articles. Every token with a hyperlink to Wikipedia is then marked and considered an entity mention in the dataset. Each entity mention is also linked back to a knowledge base through their corresponding Freebase IDs

In order to ensure the hyperlinks refer to the correct Wikipedia pages, additional filtering is conducted to ensure that either (1) at least one token in the hyperlink (or *anchor*) matches a token in the title of the Wikipedia page, or (2) the anchor text matches exactly an anchor from the Wikipedia page text, which can be considered an alias of the page. As many near-duplicate copies of Wikipedia pages can be found online, any web pages where more than 70% of the sentences match those from their linked Wikipedia pages are discarded.

3.2 The *Wikilinks Rare Entity Prediction* Dataset

We use a significantly pre-processed and augmented version of the *Wikilinks* dataset for the purpose of entity prediction, which we call the *Wikilinks Rare Entity Prediction* dataset. In particular, we parse the HTML texts of the web pages and extract their page contents to form our corpus. Entity mentions with hyperlinks to Wikipedia are marked and replaced by a special token (**blank**), serving as the placeholder for missing entities that we would like the models to predict. The correct missing entity $\tilde{e}$ is preserved as a target. Additionally, we extract the lexical definitions of all entities that are marked in the corpus from Freebase using their Freebase IDs, which are available for all entities in the *Wikilinks* dataset. These lexical definitions will serve as the external knowledge to our models.

Number of documents	269,469
Average # blanks *per* doc	3.69
Average # candidates *per* doc	3.35
Number of unique entities	245,116
# entities with $n <= 5$	207,435 (**84.6%**)
# entities with $n <= 10$	227,481 (**92.8%**)
# entities with $n <= 20$	238,025 (**97.1%**)

Table 2: Statistics for the augmented version of the *Wikilinks* dataset, where n represents the entity frequency in the corpus. Web documents with more than 10 blanks to fill are filtered out for computational reasons.

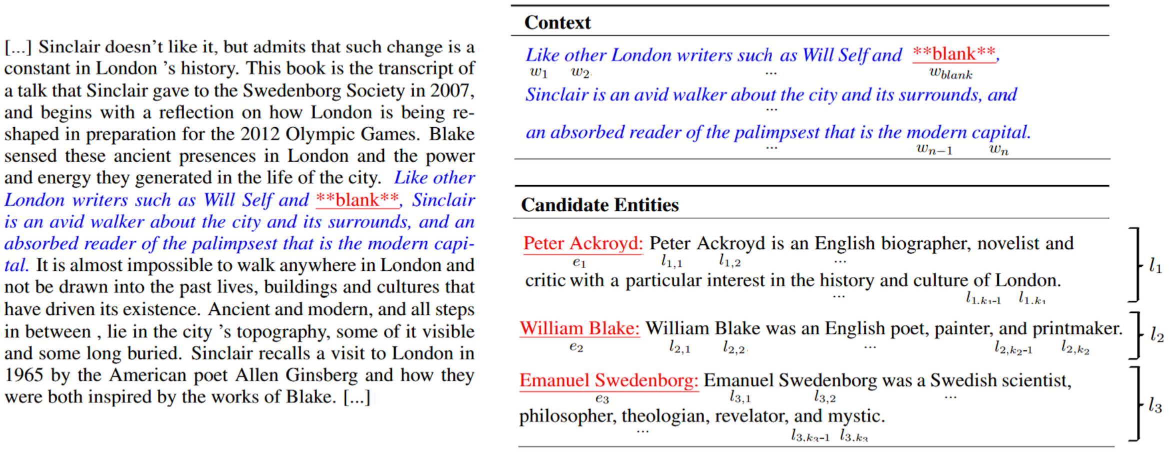
Table 2 shows some basic statistics of a subset of the corpus used in our experiments. As we can see, unlike the Children's Book dataset, which has 50k candidate entities for almost 700k context and query pairs (Hill et al., 2016a), the number of unique entities found in our dataset has the same order of magnitude as the number of documents available.

Moreover, the majority of entities appears a relatively small number of times, with 92.8% observed less than or equal to 10 times across the entire corpus. This suggests that models that only rely on the surrounding context information may not be able to correctly predict the missing entities. This further motivates us to incorporate additional information into the decision process to improve the performance. In the experiments section, we show that the external entity descriptions are indeed necessary to achieve better results.

3.3 Task Definition[1]

Here we formalize the task definition of the entity prediction problem. Given a document $\mathcal{D}$ in

[1] On notation: we use A to denote sequences, $\mathcal{A}$ to denote sets, a to denote words / entities, $\mathbf{a}$ to denote vectors, A to denote matrices.



[...] Sinclair doesn't like it, but admits that such change is a constant in London 's history. This book is the transcript of a talk that Sinclair gave to the Swedenborg Society in 2007, and begins with a reflection on how London is being reshaped in preparation for the 2012 Olympic Games. Blake sensed these ancient presences in London and the power and energy they generated in the life of the city. *Like other London writers such as Will Self and* **blank**, *Sinclair is an avid walker about the city and its surrounds, and an absorbed reader of the palimpsest that is the modern capital.* It is almost impossible to walk anywhere in London and not be drawn into the past lives, buildings and cultures that have driven its existence. Ancient and modern, and all steps in between , lie in the city 's topography, some of it visible and some long buried. Sinclair recalls a visit to London in 1965 by the American poet Allen Ginsberg and how they were both inspired by the works of Blake. [...]

Context

Like other London writers such as Will Self and **blank**, *Sinclair is an avid walker about the city and its surrounds, and an absorbed reader of the palimpsest that is the modern capital.*

Candidate Entities

Peter Ackroyd: Peter Ackroyd is an English biographer, novelist and critic with a particular interest in the history and culture of London.

William Blake: William Blake was an English poet, painter, and printmaker.

Emanuel Swedenborg: Emanuel Swedenborg was a Swedish scientist, philosopher, theologian, revelator, and mystic.

Figure 1: An example from the *Wikilinks Rare Entity Prediction* dataset. Shown is a paragraph from the dataset, along with the context (in blue italics) and the missing entity (in red underline). We also visually show the notation that we use for the remainder of this paper. The correct answer here is Peter Ackroyd.

the corpus, we split it into an ordered list of contexts $\mathcal{C} = \{\mathsf{C}_1, ..., \mathsf{C}_n\}$ where each context C_i $(1 \leq i \leq n)$ is a word sequence $(w_1, ..., w_m)$ where the special token **blank** is found. Let $\mathcal{E}$ be the set of candidate entities. For each missing entity, we want the model to select the correct entity $\tilde{e} \in \mathcal{E}$ to fill the blank slot. In our problem setting, the model also has access to the lexical resource $\mathcal{L} = \{\mathsf{L}_e \mid e \in \mathcal{E}\}$ where $\mathsf{L}_e = (l_{e_1}, ..., l_{e_k})$ is the lexical definition of entity e extracted from the knowledge base. Thus, the task of the model is to predict the correct missing entities for each empty slot in $\mathcal{D}$.

There are several possible ways to specify the candidate set $\mathcal{E}$. For instance, we could define $\mathcal{E}$ so that it includes all entities found in the corpus. However, given the extremely large amount of unique entities found in the dataset, this would render the task difficult to solve from both a practical and computational perspective. We present a simpler version of the task where $\mathcal{E}$ is the set of entities that are present in the document $\mathcal{D}$. Note that we can make the task arbitrarily more difficult by randomly sampling other entities from the entity vocabulary and adding them to candidate set.

We show an example from the *Wikilinks Entity Prediction* dataset in Figure 1, along with a visual guide to the notation from this section.

4 Model Architectures

In this section, we present two models that use the lexical definitions of entities to solve the proposed rare entity prediction problem. The basic building blocks of our models are recurrent neural networks (RNN) with long short-term memory (LSTM) units (Hochreiter and Schmidhuber, 1997). An RNN is a neural network with feedback connections that allows information from the past to be encoded in the hidden layer representation, thus is ideal for modeling sequential data (Dietterich, 2002) and most language related problems.

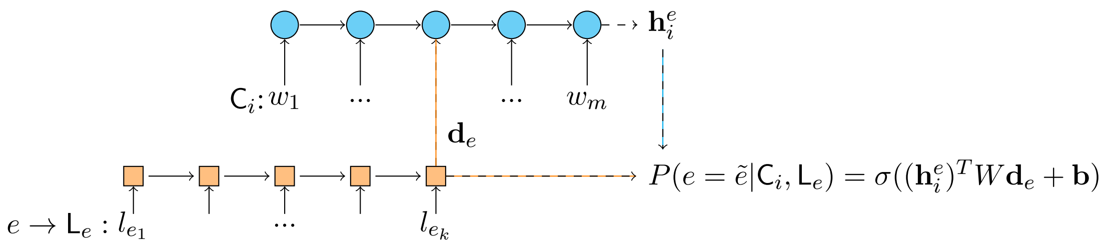
LSTMs are an extension of RNNs which include a memory cell $\mathbf{c}_t$ alongside their hidden state representation $\mathbf{h}_t$. Reads and writes to the memory cell are controlled by a set of three gates that allow the model to either keep or discard information from the past and update their state with the current input. This allows LSTMs to model potentially longer dependencies and at the same time mitigate the vanishing and exploding gradient problems, which are quite common among regular RNNs (Bengio et al., 1994). In our experiments, we use LSTMs augmented with peephole connections (Gers et al., 2002).

We denote the output (i.e. the last hidden state) of an RNN f operating on a sequence S as $f(\mathsf{S})$, and subscript the t-th hidden state as $f_t(\mathsf{S})$.

4.1 Double Encoder (DoubEnc)

This model uses two jointly trained recurrent models, a lexical encoder $g(.)$ and a context encoder $f(.)$, and a logistic predictor P (see Figure 2).

The lexical encoder converts the definition of an entity into a vector embedding, while the context encoder repeats the same process for a given context to obtain its context embedding. These two embeddings are then used by P to predict if the



$\mathbf{h}_i^e$
C_i: w_1
...
...
w_m
$\mathbf{d}_e$
$P(e = \tilde{e}|\mathsf{C}_i, \mathsf{L}_e) = \sigma((\mathbf{h}_i^e)^T W \mathbf{d}_e + \mathbf{b})$
$e \rightarrow \mathsf{L}_e : l_{e_1}$
...
l_{e_k}

Figure 2: Our double encoder architecture. Each entity e has an associated lexical definition $\mathsf{L}_e = (l_{e_1}, l_{e_2}, ..., l_{e_k})$, which is fed through the lexical encoder g (orange squares) to provide an encoding $\mathbf{d}_e$. This definition embedding is then fed as the *blank* input token of context C_i to the context encoder f (blue circles), which provides a context embedding $\mathbf{h}_i^e$.

given entity-context pair is correct. Additionally, the blank in the context sentence is replaced by the encoded definition embedding to provide more information to f.

For an entity e in the candidate set $\mathcal{E}$ of document $\mathcal{D}$, we retrieve its corresponding lexical definition L_e, itself a sequence of words, to compute its encoding $g(\mathsf{L}_e) \equiv \mathbf{d}_e$.

For a given context C_i, we replace the embedding of the blank token with $\mathbf{d}_e$. Thus $\mathsf{C}_i = (w_1, ..., w_{blank}, ..., w_m)$ becomes $\mathsf{C}_i^e = (w_1, ..., \mathbf{d}_e, ..., w_m)$[2]. We then compute the context embedding of the new C_i^e, $f(\mathsf{C}_i^e) \equiv \mathbf{h}_i^e$.

After getting $\mathbf{h}_i^e$ and $\mathbf{d}_e$, we wish to compute the probability of candidate e being the correct entity $\tilde{e}$ missing in context C_i. This probability is the output of the predictor:

$$P(e = \tilde{e}|\mathsf{C}_i, \mathsf{L}_e) = \sigma((\mathbf{h}_i^e)^T W \mathbf{d}_e + \mathbf{b})$$

where σ is the sigmoid function, W and $\mathbf{b}$ are model parameters.

The cross term $(\mathbf{h}_i^e)^T W \mathbf{d}_e$ is a dot product between $\mathbf{h}_i^e$ and $\mathbf{d}_e$ that weighs the dimensions differently based on the learned parameters W. Similar prediction methods have been used successfully for question answering (Bordes et al., 2014; Yu et al., 2014) and dialogue response retrieval (Lowe et al., 2015).

We also experimented with only feeding $\mathbf{h}_i^e$ to the predictor, without the cross term, and found this slows down training the lexical encoder. While $\mathbf{h}_i^e$ is a function of $\mathbf{d}_e$, using $\mathbf{d}_e$ in the cross term $(\mathbf{h}_i^e)^T W \mathbf{d}_e$ provides a much shorter gradient path from the loss to the lexical encoder through $\mathbf{d}_e$, thus allowing both modules to learn at the same pace.

Given a context, the model outputs a probability for each entity $e \in \mathcal{E}$. Entities in the candidate set are then ranked against each other according to their predicted probabilities. The entity with the highest probability is considered as the most plausible answer for the missing entity in the current context. We consider the model to make an error if that entity is not $\tilde{e}$.

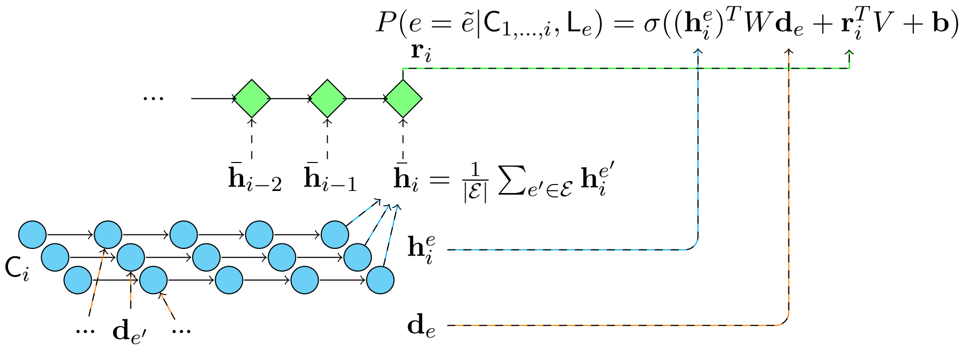
4.2 Hierarchical Double Encoder (HierEnc)

The double encoder architecture mentioned above considers each context independently. However, since each document consists of a sequence of contexts, the knowledge carried by other contexts in $\mathcal{C}$ could also provide useful information for the decision process of C_i. To that end, we propose a hierarchical model structure by adding a LSTM network r, which we call the temporal network (see Figure 3), on top of the double encoder architecture. Since a document is a sequence of C_is, each *time step* of this network consists of one such context, and thus is indexed with i.

Since we already have a context encoder f, we reuse the output of $f(\mathsf{C}_i^e)$ as the input of r at time step i. More specifically, we combine the embeddings generated by f into a single one via averaging: $\bar{\mathbf{h}}_i = \frac{1}{|\mathcal{E}|} \sum_{e' \in \mathcal{E}} \mathbf{h}_i^{e'}$, which then serves as the input to the temporal network for context C_i. Note that alternatively, one could aggregate information about the past predictions through other means like policies or soft attention. However, this would introduce extra complexities to the learning process. As such, we use averaging to that end.

Finally, at each time step i, the temporal network outputs an embedding $r_i(\mathsf{C}_1, ..., \mathsf{C}_n) \equiv \mathbf{r}_i$. We use this temporal embedding to predict the probability of the context-entity pair with a

[2] We mix the word / vector notation here since each word w is replaced by its corresponding word embedding vector.



$P(e = \tilde{e}|\mathsf{C}_{1,\ldots,i}, \mathsf{L}_e) = \sigma((\mathbf{h}_i^e)^T W \mathbf{d}_e + \mathbf{r}_i^T V + \mathbf{b})$
$\mathbf{r}_i$
...
$\bar{\mathbf{h}}_{i-2}$
$\bar{\mathbf{h}}_{i-1}$
$\bar{\mathbf{h}}_i = \frac{1}{|\mathcal{E}|} \sum_{e' \in \mathcal{E}} \mathbf{h}_i^{e'}$
$\mathbf{h}_i^e$
C_i
... $\mathbf{d}_{e'}$ ...
$\mathbf{d}_e$

Figure 3: Our hierarchical encoder architecture. Each entity e is encoded as $\mathbf{d}_e$, at each time step, $\mathbf{h}_i^e$ is computed for each e. $\bar{\mathbf{h}}_i$ is the average encoding, which is fed as input to the temporal network r (green diamonds). The temporal network produces $\mathbf{r}_i$, which is used to compute $P(e = \tilde{e}|\mathsf{C}_{1,\ldots,i}, \mathsf{L}_e)$.

slightly altered logistic predictor:

$$P(e = \tilde{e}|\mathsf{C}_{1,\ldots,i}, \mathsf{L}_e) = \sigma((\mathbf{h}_i^e)^T W \mathbf{d}_e + \mathbf{r}_i^T V + \mathbf{b})$$

where W, V and $\mathbf{b}$ are model parameters. The entities in candidate set are again ranked against each other based on their probabilities.

5 Experiments

5.1 Setup

We randomly partition the data into training, validation and test sets. The training set consists of approximately 80% of the total documents, the validation and test sets comprise about 10% each.

In our experiments, the context windows are defined as the sentences where the special ***blank*** tokens are found; the lexical definitions for each entity are the first sentences of their Freebase descriptions. We experimented with different configurations of defining contexts and entity definitions, such as expanding the context windows by including sentences that come before and after the one where blank is found, as well as taking more than one sentence out of the entity description. However, results on validation set show that increasing the context window size and the definition size had very little impact on accuracies, but drastically increased the training time of all models. We thus chose to use only the immediate sentence of the context and the first sentence of the entity description.

To train our models, we use the correct missing entity for each blank as the positive example and all other entities in the candidate set as the negative examples, which we found to be more beneficial empirically than using only a subset of rest of the candidate set. During the testing phase, we present each entity in the candidate set to our models and record the probabilities output by the models. The entity with the highest probability is chosen as the model prediction. For all gradient-based methods, including both baseline models and our proposed models, the learning objective is to minimize the binary cross-entropy of the training data.

We measure the performance on our entity prediction task using the *accuracy*; that is, the number of correct entity predictions made by the model divided by the total number of predictions. This is equivalent to the metric of Recall@1 that is often used in information retrieval.

5.2 Baselines

In order to demonstrate the effects of using lexical resources as external knowledge for solving the task, we present three sets of baselines: one set of simple baselines (RANDOM and FREQENT), one LSTM-based model that only relies on the contexts and does not utilize the definitions (CONTENC), and another set of models that do make use of the entity definitions but in a simplistic fashion (TF-IDF + COS and AVGEMB + COS).

RANDOM For each context in a given document, this baseline simply selects an entity from the candidate set uniformly at random as its prediction.

FREQENT Under this baseline, we rank all entities in the candidate set by the number of times that they appear in the document. For each blank in the document, we always choose the entity with the highest frequency in that document as the prediction. Note that this baseline has access to extra information compared to the other models, in particular the total number of times each entity appears in the document.

ContEnc Instead of using their definitions, entities are treated as regular tokens in vocabulary. Thus for a particular entity e, the context sequence $\mathsf{C}_i = (w_1, ..., w_{blank}, ..., w_m)$ becomes $(w_1, ..., w_e, ..., w_m)$. We feed the sequence C_i into the context encoder and as usual take the last hidden state as the context embedding $\mathbf{h}_i^e$. Thus given C_i and $e \in E$, the probability of e being the correct missing entity is:

$$P(e = \tilde{e}|\mathsf{C}_i) = \sigma((h_i^e)^T W + \mathbf{b})$$

where again σ is the sigmoid function, W and $\mathbf{b}$ are model parameters. This model is essentially a language model baseline, that does not make use of the external a priori knowledge.

Tf-Idf + cos This method takes the term frequency-inverse document frequency (TF-IDF) vectors of the context and the entity definition as their corresponding embeddings. The aggregations of contexts and definitions are treated as their own corpora, and two separate TF-IDF transformers are fitted. Candidate entities are ranked by the *cosine similarity* between their definition vectors and the context vector. The entity with the highest cosine similarity score is chosen as the prediction.

AvgEmb + cos This baseline computes the context embedding by taking the *average* of some pre-trained word embeddings. The entities' embeddings are computed in the same way. In our experiments, we choose to use the published *GloVe* (Pennington et al., 2014) pre-trained word embeddings. Same as above, the prediction is made by considering the cosine similarity between the context embedding and the entity embeddings.

5.3 Hyperparameters

For the ContEnc baseline, we choose 300 as the size of hidden state for the encoder. For the DoubEnc and the HierEnc models, the size of hidden state for both the context encoder and the lexical encoder is set to 300. An RNN with 200 LSTM units is used as the temporal network in the hierarchical case. All three models are trained with stochastic gradient descent with Adam (Kingma and Ba, 2015) as our optimizer, with learning rates of 10^{-3} used for ContEnc and 10^{-4} used for DoubEnc as well as HierEnc. Models with the best performance on validation set are saved and used to test on test set.

Model	Accuracy Valid	Accuracy Test
Fixed Baselines		
Random	29.4%	30.1%
FreqEnt	32.9%	33.1%
Without External Knowledge		
ContEnc	39.3%	39.6%
With External Knowledge		
Tf-Idf + cos	29.2%	30.0%
AvgEmb + cos	35.5%	35.9%
DoubEnc	54.7%	54.0%
HierEnc	**57.3%**	**56.6%**

Table 3: Empirical results on *Wikilinks Entity Prediction* dataset for proposed baselines and models.

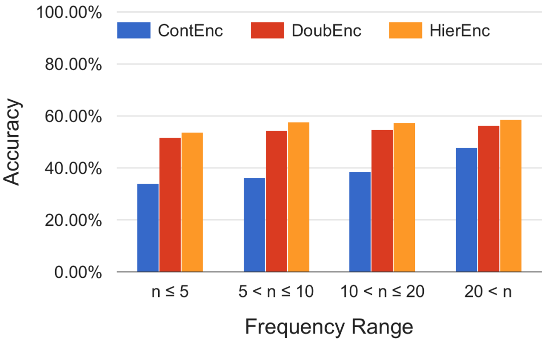


Figure 4: Accuracies of ContEnc, DoubEnc, and HierEnc on test set, for different frequency ranges; n is entity frequency in the entire corpus.

5.4 Results

Empirical results are shown in Table 3. We test our proposed model architectures (detailed in Section 4), along with baselines described in Section 5.2.

It is clear from Table 3 that models that only use contextual knowledge give relatively poor performance compared to the ones that utilize lexical resources. The large discrepancy between the context encoder and the double encoder shows that lexical resources play a crucial role in solving the task. The best result is achieved by the hierarchical double encoder, which confirms that knowing about previous contexts is indeed beneficial to the prediction at the current time step.

We performed statistical significance tests on the predictions from ContEnc, compared to the predictions made by DoubEnc and HierEnc respectively. Both tests yielded $p < 10^{-5}$. We also computed the p-value between DoubEnc and Hi-

Context & Prediction
[...] We heard from Audrey Bomse, who is with the Free Gaza movement. She was in ______, Cyprus. [...]
ContEnc: Istanbul   HierEnc: Larnaca
Candidate Set
Istanbul: Istanbul is the most populous city in Turkey, and the country's economic, cultural, and historical center.
Larnaca: Larnaca is a city on the southern coast of Cyprus and the capital of eponymous district.
Ben Macintyre: Ben Macintyre is a British author, historian, reviewer and columnist writing for The Times newspaper.
(Other candidate entities......)

Table 4: An example from the test set, with the predictions made by ContEnc and HierEnc; HierEnc was able to successfully predict the correct missing entity, *Larnaca*.

erEnc, with $p \approx 0.003$. This suggests that the performance improvement achieved by the hierarchical model is statistically significant.

6 Discussion

Figure 4 provides a performance breakdown of test accuracies over various entity frequencies for ContEnc, DoubEnc, and HierEnc. As we can see, the biggest performance gap between the baseline and our two proposed models occurs when $n \leq 5$; as entity frequencies increase, the accuracy of ContEnc also increases. This confirms the value and necessity of lexical resources, especially when entities appear extremely infrequently. We also see that HierEnc outperforms DoubEnc consistently over all frequency ranges. This suggests that by propagating information from the past through temporal network, the hierarchical model is able to reason beyond the local context, thus achieve higher accuracies.

Table 4 shows an example found in the test set, along with the predictions from ContEnc and HierEnc. Even though the context encoder baseline was able to identify that the missing entity should be a city, it incorrectly predicted *Istanbul*. This is likely because *Istanbul* appears 86 times in the dataset, whereas *Larnaca* appears only twice in the test set, *and not at all in the training set*. It seems that, although the context encoder was able to derive a strong association between Istanbul and Middle Eastern geolocations, such knowledge was not learned for Larnaca because of the lack of examples. Conversely, the hierarchical double encoder was able to take both the context and the external knowledge into account and successfully predicted the correct missing city.

One interesting observation is the margin of difference in accuracy between the context encoder and the embedding average baseline. The context encoder, which is a relatively sophisticated context-only model, only slightly outperforms the simple embedding average baseline that has no learning component. This suggests that the entity definitions are valuable in solving such tasks even when it is used in a rather simplistic way.

As we discussed in Section 5.1, we found in initial experiments that using a large context window size (including sentences before and after the sentence where blank token is found) does not have any significant positive impact on the results. This may imply that words that are most informative about the missing entity in the blank are generally found in vicinity of the blank. It is also likely that more sophisticated models will be able to use the surrounding context information more effectively, leading to greater performance increases.

7 Conclusions

In this paper, we examined the use of external knowledge in the form of lexical resources to solve reading comprehension problems. Specifically, we propose the problem of rare entity prediction. In our *Wikilinks Rare Entity Prediction* dataset, the majority of the entities have very low frequencies across the entire corpus; thus, models that solely rely on co-occurrence statistics tend to under-perform. We show that models leveraging the Freebase descriptions achieve large performance gains, particularly when this information is incorporated intelligently as in our double encoder-based models.

For future work, we plan to examine the effects of other knowledge sources. In this paper, we use entity definitions as the source of external knowledge. However, Freebase also contains other types of valuable information, such as relational information between entities. Thus, one potential direction for future work would be to incorporate both relational information and lexical definitions.

We have demonstrated the crucial role that external knowledge plays in solving tasks with many rare entities. We believe that incorporating external knowledge into other systems, such as dialogue agents, should also see similar positive results. We plan to explore the idea of external knowledge integration further in future research.

Abstract

We develop a technique for transfer learning in machine comprehension (MC) using a novel two-stage synthesis network (SynNet). Given a high-performing MC model in one domain, our technique aims to answer questions about documents in another domain, where we use no labeled data of question-answer pairs. Using the proposed SynNet with a pretrained model on the SQuAD dataset, we achieve an F1 measure of 46.6% on the challenging NewsQA dataset, approaching performance of in-domain models (F1 measure of 50.0%) and outperforming the out-of-domain baseline by 7.6%, without use of provided annotations.[1]

1 Introduction

Machine comprehension (MC), the ability to answer questions over a provided context paragraph, is a key task in natural language processing. The rise of high-quality, large-scale human-annotated datasets for this task (Rajpurkar et al., 2016; Trischler et al., 2016) has allowed for the training of data-intensive but expressive models such as deep neural networks (Wang et al., 2016; Xiong et al., 2017; Seo et al., 2017). Moreover, these datasets have the attractive quality that the answer is a short snippet of text within the paragraph, which narrows the search space of possible answer spans.

However, many of these models rely on large amounts of human-labeled data for training. Yet data collection is a time-consuming and expensive task. Moreover, direct application of a MC model trained on one domain to answer questions over paragraphs from another domain may suffer performance degradation.

While understudied, the ability to transfer a MC model to multiple domains is of great practical importance. For instance, the ability to quickly use a MC model trained on Wikipedia to bootstrap a question-answering system over customer support manuals or news articles, where there is no labeled data, can unlock a great number of practical applications.

In this paper, we address this problem in MC through a two-stage synthesis network (SynNet). The SynNet generates synthetic question-answer pairs over paragraphs in a new domain that are then used in place of human-generated annotations to finetune a MC model trained on the original domain.

The idea of generating synthetic data to augment insufficient training data has been explored before. For example, for the target task of translation, Sennrich et al. (2016) present a method to generate synthetic translations given real sentences to refine an existing machine translation system.

However, unlike machine translation, for tasks like MC, we need to synthesize both the question and answers given the context paragraph. Moreover, while the question is a syntactically fluent natural language sentence, the answer is mostly a salient semantic concept in the paragraph, e.g., a named entity, an action, or a number, which is often a single word or short phrase.[2] Since the answer has a very different linguistic structure compared to the question, it may be more appropri-

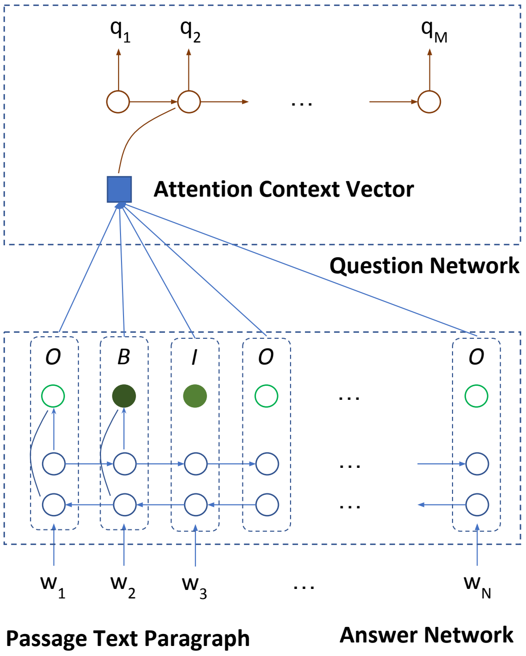

Figure 1: Illustration of the two-stage SynNet. The SynNet is trained to synthesize the answer and the question, given the paragraph. The first stage of the model, an answer synthesis module, uses a bi-directional LSTM to predict IOB tags on the input paragraph, which mark out key semantic concepts that are likely answers. The second stage, a question synthesis module, uses a uni-directional LSTM to generate the question, while attending on embeddings of the words in the paragraph and IOB ids. Although multiple spans in the paragraph could be identified as potential answers, we pick one span when generating the question.

ate to view answers and questions as two different types of data. Hence, the synthesis of a (question, answer) tuple is needed.

In our approach, we decompose the process of generating question-answer pairs into two steps, answer generation conditioned on the paragraph, and question generation conditioned on the paragraph and answer. We generate the answer first because answers are usually key semantic concepts, while questions can be viewed as a full sentence composed to inquire the concept.

Using the proposed SynNet, we are able to outperform a strong baseline of directly applying a high-performing MC model trained on another domain. For example, when we apply our algorithm using a pretrained model on the Stanford Question-Answering Dataset (SQuAD) (Rajpurkar et al., 2016), which consists of Wikipedia articles, to answer questions on the NewsQA dataset (Trischler et al., 2016), which consists of CNN/Daily Mail articles, we improve the performance of the SQuAD baseline from 39.0% to 46.6% F1 and approach results of previously published work of Trischler et al. (2016) (50.0% F1), without use of labeled data in the new domain. Moreover, an error analysis reveals that we achieve higher accuracy over the baseline on all common question types.

2 Related Work

2.1 Question Answering

Question answering is an active area in natural language processing with ongoing research in many directions (Berant et al., 2013; Hill et al., 2015; Golub and He, 2016; Chen et al., 2016; Hermann et al., 2015). Machine comprehension, a form of extractive question answering where the answer is a snippet or multiple snippets of text within a context paragraph, has recently attracted a lot of attention in the community. The rise of large-scale human annotated datasets with over 100,000 realistic question-answer pairs such as SQuAD (Rajpurkar et al., 2016), NewsQA (Trischler et al., 2016), and MSMARCO (Nguyen et al., 2016), has led to a large number of successful deep learning models (Lee et al., 2016; Seo et al., 2017; Xiong et al., 2017; Dhingra et al., 2017; Wang and Jiang, 2016).

2.2 Semi-Supervised Learning

Semi-supervised learning has a long history (c.f. Chapelle et al. (2009) for an overview), and has been applied to many tasks in natural language processing such as dependency parsing (Koo et al., 2008), sentiment analysis (Yang et al., 2015),machine translation (Sennrich et al., 2016), and semantic parsing (Berant and Liang, 2014; Wang et al., 2015; Jia and Liang, 2016). Recent work generated synthetic annotations on unsupervised data to boost the performance of both reading comprehension and visual question answering models (Yang et al., 2017; Ren et al., 2015), but on domains with some form of annotated data. There has also been work on generating high-quality questions (Yuan et al., 2017; Serban et al., 2016; Labutov et al., 2015), but not how to best use them to train a model. In contrast, we use the two-stage SynNet to generate data tuples to directly boost performance of a model on a domain with no annotations.

2.3 Transfer Learning

Transfer learning (Pan and Yang, 2010) has been successfully applied to numerous domains in machine learning, such as machine translation (Zoph et al., 2016), computer vision, (Sharif Razavian et al., 2014), and speech recognition (Doulaty et al., 2015). Specifically, object recognition models trained on the large-scale ImageNet challenge (Russakovsky et al., 2015) have proven to be excellent feature extractors for diverse tasks such as image captioning (i.e., Lu et al. (2017); Fang et al. (2015); Karpathy and Fei-Fei (2015)) and visual question answering (i.e., Zhou et al. (2015); Xu and Saenko (2016); Fukui et al. (2016); Yang et al. (2016)), among others. In a similar fashion, we use a model pretrained on the SQuAD dataset as a generic feature extractor to bootstrap a QA system on NewsQA.

3 The Transfer Learning Task for MC

We formalize the task of machine comprehension below. Our MC model takes as input a tokenized question $q = \{q_0, q_1, ...q_n\}$, a context paragraph $p = \{p_0, p_1, ...p_n\}$, where q_i, p_i are words, and learns a function $f(p, q) \mapsto \{a_{start}, a_{end}\}$ where a_{start} and a_{end} are pointer indices into paragraph p, i.e., the answer $a = p_{a_{start}}...p_{a_{end}}$.

Given a collection of labeled paragraph, question, answer triples $\{p, q, a\}_{i=1}^{n}$ from a particular domain s, i.e., Wikipedia articles, we can learn a MC model $f_s(p, q)$ that is able to answer questions in that domain.

However, when applying the model trained in one domain to answer questions in another, the performance may degrade. On the other hand, labeling data to train a model in the new domain is expensive and time-consuming.

In this paper, we propose the task of transferring a MC system $f_s(p, q)$ that is trained in a source domain to answer questions over another target domain, t. In the target domain t, we are given an unlabeled set $p_t = \{p\}_{i=1}^{k}$ of k paragraphs. During test time, we are given an unseen set of paragraphs, p^*, in the target domain, over which we would like to answer questions.

4 The Model

4.1 Two-Stage SynNet

To bootstrap our model f_s we use a SynNet (Figure 1), which consists of answer synthesis and question synthesis modules, to generate data on p_t. Our SynNet learns the conditional probability of generating answer $a = \{a_{start}, a_{end}\}$ and question $q = \{q_1, ...q_n\}$ given paragraph p, $P(q, a|p)$. We decompose the joint probability distribution $P(q, a|p)$ into a conditional probability distribution $P(q|p, a)P(a|p)$, where we first generate the answer a, followed by generating the question q conditioned on the answer and paragraph.

4.1.1 Answer Synthesis Module

In our answer synthesis module we train a simple IOB tagger to predict whether each word in the paragraph is part of an answer or not.

More formally, given a set of words in a paragraph $p = \{p_1...p_n\}$, our IOB tagging model learns the conditional probability of labels $y_1...y_n$, where $y_1 \in \text{IOB}_{\text{START}}, \text{IOB}_{\text{MID}}, \text{IOB}_{\text{END}}$ if a word p_i is marked as an answer by the annotator in our train set, NONE otherwise.

We use a bi-directional Long-Short Term Memory Network (Bi-LSTM) (Hochreiter and Schmidhuber, 1997) for tagging. Specifically, we project each word $p_i \mapsto p_i^*$ into a continuous vector space via pretrained GloVe embeddings (Pennington et al., 2014). We then run a Bi-LSTM over the word embeddings $p_1^*, ...p_n^*$ to produce a context-dependent word representation $h_1, ...h_n$, which we feed into two fully connected layers followed by a softmax to produce our tag likelihoods for each word.

We select all consecutive spans where $y \neq$ NONE produced by the tagger as our candidate answer chunks, which we feed into our question synthesis module for question generation.

4.1.2 Question Synthesis Module

Our question synthesis module learns the conditional probability of generating question $q = \{q_1, ...q_n\}$ given answer $a = a_{start}, a_{end}$ and paragraph $p = p_1...p_n$, $P(q_1, ...q_n|p_1...p_n, a_{start}, a_{end})$. We decompose the joint probability distribution of generating all the question words $q_1, ...q_n$ into generating the question one word at a time, i.e. $\prod_{i=1}^{n} P(q_i|p, a, q_{1...i-1})$.

The model is similar to an encoder-decoder network with attention (Bahdanau et al., 2014), which computes the conditional probability $P(q_i|p_1...p_n, a_{start}, a_{end}, q_{1...i-1})$. We run a Bi-LSTM over the paragraph to produce context-dependent word representations $h = \{h_1, ...h_n\}$. To model where the answer is in the paragraph, similar to Yang et al. (2017), we insert answer information by appending a zero/one feature to the paragraph word embeddings. Then, at each time step i, a decoder network attends to both h and the previously generated question token q_{i-1} to produce a hidden representation r_i. Since paragraphs may often have named entities and rare words not present during training, we incorporate a copy mechanism into our models (Gu et al., 2016).

We use an architecture motivated by latent predictor networks (Ling et al., 2016) to force the model to learn when to copy vs. directly predict the word, without direct supervision of what action to choose. Specifically, at every time step i, two latent predictors generate the probability of generating word w_i, a pointer network C_p (Vinyals et al., 2015) which can copy a word from the context paragraph, and a vocabulary predictor V_p which directly generates a probability distribution of choosing a word w_i from a predefined vocabulary. The likelihood of choosing predictor k at time step i is proportional to $w_k r_i$, and the likelihood of predicting question token q_i is given by $q_i^* = p^v l^v(w_i) + (1 - p^v) l^c(w_i)$, where v represents the vocabulary predictor and c represents the copy predictor, and $l(w_i)$ is the likelihood of the word given by the predictor.[3] For training, since no direct supervision is given as to which predictor to choose, we minimize the cross entropy loss of producing the correct question tokens $\sum_{j=1}^{n} -log(q_j^*)$ by marginalizing out latent variables using a variant of the forward-backward algorithm (see Ling et al. (2016) for full details).

During inference, to generate a question $q_1 ... q_n$, we use greedy decoding in the following manner. At time step i, we select the most likely predictor (C_p or V_p), followed by the most likely word q_i given the predictor. We feed the predicted word as input at the next timestep back into the decoder until we predict the end symbol, END, after which we stop decoding.

4.2 Machine Comprehension Model

Our machine comprehension model $f(p, q) \mapsto a$ learns the conditional likelihood of predicting answer pointers $a = \{a_{start}, a_{end}\}$ given paragraph p and question q, $P(a|p, q)$. In our experiments we use the open-source Bi-directional Attention Flow (BiDAF) network (Seo et al., 2017)[4] since it is one of the best-performing models on the SQuAD dataset,[5] although we note that our algorithm for data synthesis can be used with any MC model.

Algorithm 1: Training Algorithm

   domain $t$. For every batch sampled from $x_t$,
   sample $k$ batches from $x_s$;
```

4.3 Algorithm Overview

Having given an overview of our SynNet and a brief overview of the MC model we describe our training procedure, which is illustrated in Algorithm 1.

4.4 Training

Our approach for transfer learning consists of several training steps. First, given a series of labeled examples $x_s = \{p_s, q_s, a_s\}_{i=1}^{n}$ from domain s, paragraphs $p_{j=1}^{m}$ from domain t, and pretrained MC model $f_s(p, q)$, we train the SynNet g_s to maximize the likelihood of the question-answer pairs in s.

Second, we fix our SynNet g_s and we sample $x_t = \{p_t, q_t, a_t\}_{i=1}^{k}$ question-answer pairs on the paragraphs in domain t. Several examples of generated questions can be found in Table 1.

We then transfer the MC model originally learned on the source domain to the target domain t using SGD on the synthetic data. However, since the synthetic data is usually noisy, we alternatively train the MC model with mini-batches from x_s and x_t, which we call *data-regularization*. Every k batches from x, we sample 1 batch of synthetic data from x', where k is a hyper-parameter, which we set to 4. Letting the model encounter many examples from source domain s serves to regularize

[3] Since we only have two predictors, $p^c = 1 - p^v$

the distribution of the synthetic data in the target domain with real data from s. We checkpoint finetuned model f_s^* every i mini-batches, $i = 1000$ in our experiments, and save a copy of the model at each checkpoint.

At test time, to generate an answer, we feed paragraph $p = \{p_0, p_1, ...p_n\}$ and question q through our finetuned MC model $f^*(p, q)$ to get $P(p_i = a_{start})$, $P(p_i = a_{end})$ for all $i \in 1...n$. We then use dynamic programming (Seo et al., 2017) to find the optimal answer span $\{a_{start}, a_{end}\}$. To improve the stability of using our model for inference, we average the predicted answer likelihoods from model copies at different checkpoints prior to running the dynamic programming algorithm.

5 Experimental Setup

We summarize the datasets we use in our experiments, parameters for our model architectures, and training details.

The SQuAD dataset consists of approximately 100,000 question-answer pairs on Wikipedia, 87,600 of which are used for training, 10,570 for development, and an unknown number in a hidden test set. The NewsQA dataset consists of 92,549 train, 5,166 development and 5,165 test questions on CNN/Daily Mail news articles. Both the domain type (i.e., news) and question types differ between the two datasets. For example, an analysis of a randomly generated sample of 1,000 questions from both NewsQA and SQuAD (Trischler et al., 2016) reveals that approximately 74.1% of questions in SQuAD require word matching or paraphrasing to retrieve the answer, as opposed to 59.7% in NewsQA. As our test metrics, we report two numbers, exact match (EM) and F1 score.

We train a BIDAF model on the SQuAD train dataset and use a two-stage SynNet to finetune it on the NewsQA train dataset.

We initialize word-embeddings for the BIDAF model, answer synthesis module, and question synthesis module with 300-dimensional-GloVe vectors (Pennington et al., 2014) trained on the 840 Billion Words Common Crawl corpus. We set all embeddings of unknown word tokens to zero.

For both the answer synthesis and question synthesis module, we use a vocabulary of size 110,179. We use LSTMs with hidden states of size 150 for the answer module vs. those of size 100 for the question module since the answer module is less memory intensive than the question module.

We train both the answer and question module with Adam (Kingma and Ba, 2015) and a learning rate of 1e-2. We train a BIDAF model with the default hyperparameters provided in the open-source repository. To stop training of the question synthesis module, after each epoch, we monitor both the loss as well as the quality of questions generated on the SQuAD development set. To stop training of the answer synthesis module, we similarly monitor predictions on the SQuAD development set.

To train the question synthesis module, we only use the questions provided in the SQuAD train set. However, to train the answer synthesis module, we further augment the human-annotated labels of each paragraph with tags from a simple NER system[6] because labels of answers provided in the train set are underspecified, i.e., many words in the paragraph that could be potential answers are not labeled. Therefore, we assume any named entities could also be potential answers of certain questions, in addition to the answers explicitly labeled by annotators.

To generate question-answer pairs on the NewsQA train set using the SynNet, we first run every paragraph through our answer synthesis module. We then randomly sample up to 30 candidate answers extracted by our module, which we feed into the question synthesis module. This results in 250,000 synthetic question-answer pairs that we can use to finetune our MC model.

6 Experimental Results

We report the main results on the NewsQA test set (Table 2), report brief results on SQuAD (Table 3), conduct ablation studies (Table 4), and conduct an error analysis.

6.1 Results

We compare to the best previously published work, which trains BARB (Trischler et al., 2016) and Match-LSTM (Wang and Jiang, 2016) architectures, and a BIDAF model we train on NewsQA. Directly applying a BIDAF model trained on SQuAD to predict on NewsQA leads to poor performance with an F1 measure of 39.0%, 13.2% lower than one trained on labeled NewsQA data. Using the 2-stage SynNet already leads to a slight boost in performance (F1 measure of 44.3%), which implies that having exposure to the new domain via question-answer pairs provides important signal for the model during training. When we augment the answers from our answer synthesis module with those from a generic NER system to produce questions, we have an additional 2.3% performance boost. Finally, when we ensemble with the original model, we boost the EM further by 0.2%. Our final system achieves an F1 measure of 46.6%, approaching previously published results of 50.0%. The results demonstrate that using the proposed architecture and training procedure, we can transfer a MC model from one domain to another, without use of annotated data.

We also evaluate the SynNet on the NewsQA-to-SQuAD direction. We directly apply the best setting from the other direction and report the result in Table 3. The SynNet improves over the baseline by 1.6% in EM and 0.7% in F1. Limited by space, we leave out ablation studies in this direction.

6.2 Ablation Studies

To better understand how various components in our training procedure and model impact overall performance we conduct several ablation studies, as summarized in Table 4.

6.2.1 Answer Synthesis

We experiment with using the answer chunks given in the train set, A_{oracle}, to generate synthetic questions, versus those from an NER system, A_{ner}. Results in Table 4(A) show that using human-annotated answers to generate questions leads to a significant performance boost over using answers from an answer generation module. This supports the hypothesis that the answers humans choose to generate questions for provide important linguistic cues for finetuning the machine comprehension model.

6.2.2 Question Synthesis

To see how copying impacts performance, we explore using the entire paragraph to generate the question vs. only the two sentences before and one sentence after the answer span and report results in Table 4(B). On the NewsQA train set, synthetic questions that use 2 sentences contain an average of 3.0 context words within 10 words to the left and right of the answer chunk, those that use the entire context have 2.1 context words, and human generated questions only have 1.7 words. Training with generated questions that have a large amount of overlap with words close to the answer span (i.e., those that use 2-sentences vs. entire context for generation) leads to models that perform worse, especially with synthetic answer spans and no data regularization (35.6% F1 vs. 34.3% F1). One possible reason is that, according to analysis in Trischler et al. (2016), significantly more questions in the NewsQA dataset re-

Method	System	EM	F1
Transfer Learning	M_{sq} (baseline)	24.9	39.0
	M_{sq} + A_{gen} + Q_{gen}	30.6	44.3
	M_{sq} + A_{gen} + A_{ner} + Q_{gen}	32.8	46.6
	M_{sq} + A_{gen} + A_{ner} + Q_{gen} + M^*_{sq}	**33.0**	**46.6**
Supervised Learning	Barb-LSTM on NewsQA (Trischler et al., 2016)	34.9	50.0
	Match-LSTM on NewsQA (Trischler et al., 2016)	34.1	48.2
	BIDAF on NewsQA	37.1	52.3
	BIDAF on SQuAD finetuned on NewsQA	37.3	52.2

Table 2: **Main Results**. Exact match (EM) and span F1 scores on the NewsQA test set of a BIDAF model finetuned with our SynNet. M_{sq} refers to a baseline BIDAF model trained on SQuAD, A_{gen}, Q_{gen} refers to using answers generated from our SynNet respectively to finetune the model on NewsQA, A_{ner} refers to using answers extracted from a standard NER system to generate questions. M^*_{sq} refers to using the baseline SQUAD model in the ensemble.

System	EM	F1
M_{newsqa}	46.3	60.8
M_{newsqa} + S_{net}	47.9	61.5

Table 3: **NewsQA to SQuAD**. Exact match (EM) and span F1 results on SQuAD development set of a NewsQA BIDAF model baseline vs. one finetuned on SQuAD using the data generated by a 2-stage SynNet (S_{net}).

quire paraphrase, inference, and synthesis as opposed to word-matching.

6.2.3 Model Finetuning

To see how the quantity of synthetic questions encountered during training impacts performance, we use $k = \{0, 2, 4\}$ mini-batches from SQuAD for every synthetic mini-batch from NewsQA to finetune our model, and average the prediction of 4 checkpointed models during testing. As we see from the results, letting the model to encounter data from human annotations, although from another domain, serves as a key form of data-regularization, yielding consistent improvement as k increases. We hypothesize this is because the data distribution of machine-generated questions is different than human-annotated ones; our batching scheme provides a simple way to prevent overfitting to this distribution.

A)	EM	F1	B)	EM	F1
k=0	27.2	40.5	2s + A_{ner}	22.8	36.1
k=2	29.8	43.9	all + A_{ner}	27.2	40.5
k=4	30.4	44.3	2s + A_{oracle}	31.3	45.2
			all + A_{oracle}	32.5	46.8

Table 4: **Ablation Studies**. Exact match (EM) and span F1 results on NewsQA test set of a BIDAF model finetuned with a 2-stage SynNet. In study A, we vary k, the number of mini-batches from SQuAD for every batch in NewsQA. In study B, we set $k = 0$, and vary the answer type and how much of the paragraph we use for question synthesis. $2 - sent$ refers to using two sentences before answer span, while all refers to using the entire paragraph. A_{ner} refers to using an NER system and A_{or} refers to using the human-annotated answers to generate questions.

6.3 Error Analysis

In this section we provide a qualitative analysis of some of our components to help guide further research in this task.

6.3.1 Answer Synthesis

We randomly sample and present a paragraph with answers extracted by our answer synthesis module (Tables 5 and 6). Although the module appears to have high precision, i.e., it picks up entities such as the "Atlantic Paranormal Society", it misses clear entities such as "David Schrader", which suggests training a system with full NER/POS tags as la-

They are ghost hunters , or , as they prefer to be called , paranormal investigators . “ Ghost-Hunters ”, which airs a special live show at **7 p.m. Halloween night ,** is helping lift the stigma once attached to paranormal investigators . The show has become so popular that the group featured in each episode – **Atlantic Paranormal Society** - has spawned imitators across **United States** and affiliates in **countries** . TAPS , as the “ **Hunters”** group is informally known , even has its own “ **Reality Radio”** show , magazine , lecture tours , T-shirts – and groupies . “ **Hunters”** has made creepy cool , says David Schrader , a paranormal investigator and co-host of “ **Radio** ”, a radio show that investigates paranormal activity.

Table 5: Sample predictions from our answer synthesis module.

What is Oklahoma’s unemployment rate until Oklahoma City ?
What was the manager of the Oklahoma City agency ?
How many companies are in Oklahoma City ?
How many workers may Oklahoma have as fair hold ?
Who said the bureau has already hired civilians to choose
What was the average hour manager of Oklahoma City ?
How much would Oklahoma have a year to be held
What year did Oklahoma ’s census build job industry ?

Table 6: Predictions from the question synthesis module on a subset of a paragraph.

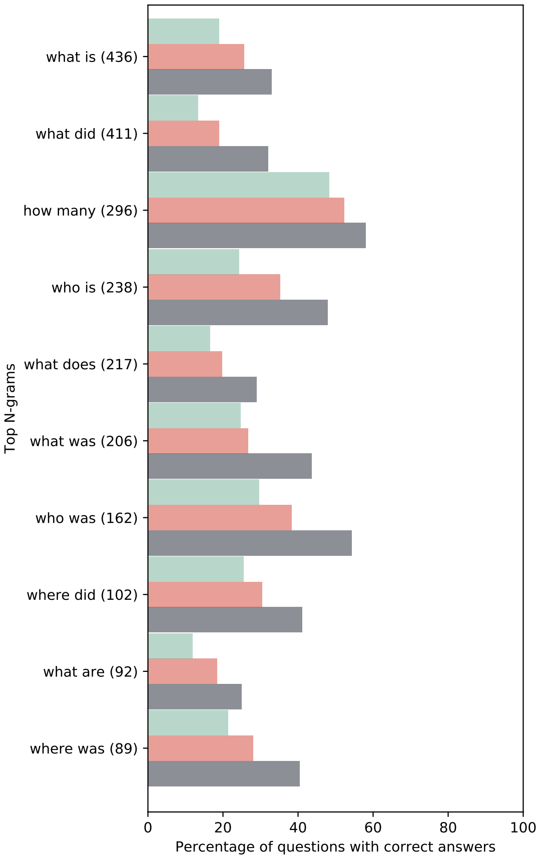

Figure 2: NewsQA accuracy of baseline BIDAF model trained on SQuAD (light green), vs. model finetuned with our method (red) vs. one trained from scratch on NewsQA (dark grey).

bels would yield better results, and also explains why augmenting synthetic data generated by SynNet with such tags leads to improved performance.

6.3.2 Question Synthesis

We randomly sample synthetic questions generated by our module and present our results in Table 6. Due to the copy mechanism, our module has the tendency to directly use many words from the paragraph, especially common entities, such as “Oklahoma” in the example. Thus, one way to generate higher-quality questions may be to introduce a cost function that promotes diversity during decoding, especially within a single paragraph. In turn, this would expose the RC model to a larger variety of training examples in the new domain, which can lead to better performance.

6.3.3 Machine Comprehension Model

We examine the performance over various question types of a finetuned BIDAF on NewsQA vs. one trained on NewsQA vs. one trained on SQuAD (Figure 2). Finetuning with SynNet improves performance over all question types given, with the largest performance boost on location and person-identification questions. Similarly, models trained on synthetic questions tend to approach in-domain performance on numeric and person-identification questions, but still struggle with questions that require higher-order reasoning, i.e. those starting with “what was” or “what did”. Designing a question generator that explicitly requires such reasoning may be one way to further bridge the gap in performance.

7 Conclusion

We introduce a two-stage SynNet for the task of transfer learning for machine comprehension, a task which is both challenging and of practical importance. With our network and a simple training algorithm where we generate synthetic question-answer pairs on the target domain, we are able to generalize a MC model from one domain to another with no annotated data. We present strong results on the NewsQA test set, improving performance of a baseline BIDAF model by over 7.6% F1. Through ablation studies and error analysis, we provide insights into our methodology on the

SynNet and MC models that can help guide further research in this task.

Deep Neural Solver for Math Word Problems

Yan Wang   Xiaojiang Liu   Shuming Shi
Tencent AI Lab
{brandenwang, kieranliu, shumingshi}@tencent.com

Abstract

This paper presents a deep neural solver to automatically solve math word problems. In contrast to previous statistical learning approaches, we directly translate math word problems to equation templates using a recurrent neural network (RNN) model, without sophisticated feature engineering. We further design a hybrid model that combines the RNN model and a similarity-based retrieval model to achieve additional performance improvement. Experiments conducted on a large dataset show that the RNN model and the hybrid model significantly outperform state-of-the-art statistical learning methods for math word problem solving.

1 Introduction

Developing computer models to automatically solve math word problems has been an interest of NLP researchers since 1963 Feigenbaum et al. (1963); Bobrow (1964); Briars and Larkin (1984); Fletcher (1985). Recently, machine learning techniques Kushman et al. (2014); Amnueypornsakul and Bhat (2014); Zhou et al. (2015); Mitra and Baral (2016) and semantic parsing methods Shi et al. (2015); Koncel-Kedziorski et al. (2015) are proposed to tackle this problem and promising results are reported on some datasets. Although progress has been made in this task, performance of state-of-the-art techniques is still quite low on large datasets having diverse problem types Huang et al. (2016).

Problem: Dan have 2 pens, Jessica have 4 pens. How many pens do they have in total ? **Equation**: x = 4+2
Solution: 6

Table 1: A math word problem

A typical math word problems are shown in Table 1. The reader is asked to infer how many pens Dan and Jessica have, based on constraints provided. Given the success of deep neural networks (DNN) on many NLP tasks (like POS tagging, syntactic parsing, and machine translation), it may be interesting to study whether DNN could also help math word problem solving. In this paper, we propose a recurrent neural network (RNN) model for automatic math word problem solving. It is a sequence to sequence (seq2seq) model that transforms natural language sentences in math word problems to mathematical equations. Experiments conducted on a large dataset show that the RNN model significantly outperforms state-of-the-art statistical learning approaches.

Since it has been demonstrated Huang et al. (2016) that a simple similarity based method performs as well as more sophisticated statistical learning approaches on large datasets, we implement a similarity-based retrieval model and compare with our seq2seq model. We observe that although seq2seq performs better on average, the retrieval model is able to correctly solve many problems for which RNN generates wrong results. We also find that the accuracy of the retrieval model positively correlate with the maximal similarity score between the target problem and the problems in training data: the larger the similarity score, the higher the average accuracy is.

Inspired by these observations, we design a hybrid model which combines the seq2seq model and the retrieval model. In the hybrid model, the retrieval model is chosen if the maximal similarity score returned by the retrieval model is larger than a threshold, otherwise the seq2seq model is selected to solve the problem. Experiments on our

Proceedings of the 2017 Conference on Empirical Methods in Natural Language Processing, pages 845–854
Copenhagen, Denmark, September 7–11, 2017.

dataset show that, by introducing the hybrid model, the accuracy increases from 58.1% to 64.7%.

Our contributions are as follows:

1) To the best of our knowledge, this is the first work of using DNN technology for automatic math word problem solving.

2) We propose a hybrid model where a seq2seq model and a similarity-based retrieval model are combined to achieve further performance improvement.

3) A large dataset is constructed for facilitating the study of automatic math problem solving.[1]

The remaining part of this paper is organized as follows: After analyzing related work in Section 2, we formalize the problem and introduce our dataset in Section 3. We present our RNN-based seq2seq model in Section 4, and the hybrid model in Section 5. Then experimental results are shown and analyzed in Section 6. Finally we conclude the paper in Section 7.

2 Related work

2.1 Math Word Problems Solving

Previous work on automatic math word problem solving falls into two categories: symbolic approaches and statistical learning approaches.

In 1964, STUDENT Bobrow (1964) handles algebraic problems by two steps: first, they transform natural language sentences into kernel sentences using a small set of transformation patterns. Then the kernel sentences are transformed to mathematical expressions by pattern matching. A similar approach is also used to solve English rate problems Charniak (1968, 1969). Liguda and Pfeiffer Liguda and Pfeiffer (2012) propose modeling math word problems with augmented semantic networks. In addition, Addition/subtraction problems are studied most Briars and Larkin (1984); Dellarosa (1986); Bakman (2007); Yuhui et al. (2010); Roy et al. (2015).

In 2015, Shi et.al Shi et al. (2015) propose a system SigmaDolphin which automatically solves math word problems by semantic parsing and reasoning. In the same year, Koncel et.al Koncel-Kedziorski et al. (2015) also formalizes the problem of solving multi-sentence algebraic word problems as that of generating and scoring equation trees.

Since 2014, statistical learning based approaches are proposed to solve the math word problems. Hosseini et al. Hosseini et al. (2014) deal with the open-domain aspect of algebraic word problems by learning verb categorization from training data. Kushman et al. Kushman et al. (2014) proposed a equation template system to solve a wide range of algebra word problems. Zhou et al. Zhou et al. (2015) further extends this method by adopting the max-margin objective, which results in higher accuracy and lower time cost. In addition, Roy and Roth Roy et al. (2015); Roy and Roth (2016) tries to handle arithmetic problems with multiple steps and operations without depending on additional annotations or predefined templates. Mitra et al. Mitra and Baral (2016) presents a novel method to learn to use formulas to solve simple addition-subtraction arithmetic problems.

As reported in 2016 Huang et al. (2016), state-of-the-art approaches have extremely low performance on a big and highly diverse data set (18,000+ problems). In contrast to these approaches, we study the feasibility of applying deep learning to the task of math word problem solving.

2.2 Sequence to Sequence (seq2seq) Learning

With the framework of seq2seq learning Sutskever et al. (2014); Wiseman and Rush (2016), recent advances in neural machine translation (NMT) Bahdanau et al. (2014); Cho et al. (2014) and neural responding machine (NRM) Shang et al. (2015) have demonstrated the power of recurrent neural networks (RNNs) at capturing and translating natural language semantics. The NMT and NRM models are purely data-driven and directly learn to converse from end-to-end conversational corpora.

Recently, the task of translating natural language queries into regular expressions is explored by using a seq2seq model Locascio et al. (2016), which achieves a performance gain of 19.6% over previous state-of-the-art models. To our knowledge, we are the first to apply seq2seq model to the task of math word problem solving.

3 Problem Formulation and Dataset

3.1 Problem Formulation

A math word problem P is a word sequence W_p and contains a set of variables $V_p = \{v_1, \dots, v_m, x_1, \dots, x_k\}$ where $v_1, \dots, v_m$ are known numbers in P and $x_1, \dots, x_k$ are variables

[1] We plan to make the dataset publicly available when the paper is published

Problem: Dan have 5 pens and 3 pencils, Jessica have 4 more pens and 2 less pencils than him. How many pens and pencils do Jessica have in total?
Equation: x = 5 + 4 +3 -2
Solution: 10

Table 2: A math word problem

whose values are unknown. A problem P can be solved by a mathematical equation E_p formed by V_p and mathematical operators.

In math word problems, different equations may belong to a same equation template. For example, equation $x = (9 * 3) + 7$ and equation $x = (4 * 5) + 2$ share the same equation template $x = (n_1 * n_2) + n_3$. To decrease the diversity of equations, we map each equation to an equation template T_p through a number mapping M_p. The number mapping process can be defined as:

Definition 1 *Number mapping: For a problem P with m known numbers, a number mapping M_p maps the numbers in problem P to a list of number tokens $\{n_1, \ldots, n_m\}$ by their order in the problem text.*

Definition 2 *Equation template: A general form of equations. For a problem P with equation E_p and number mapping M_p, its equation template is obtained by mapping numbers in E_p to a list of number tokens $\{n_1, \ldots, n_m\}$ according to M_p.*

Take the problem in Table 2 as an example, first we can obtain a number mapping from the problem:

$$M : \{n_1 = 5; \quad n_2 = 3; \quad n_3 = 4; \quad n_4 = 2; \}$$

and then the given equation can be expressed as an equation template:

$$x = n_1 + n_3 + n_2 - n_4$$

After number mapping, the problem in Table 2 can be mapped to:

"Dan have n_1 pens and n_2 pencils, Jessica have n_3 more pens and n_4 less pencils than him. How many pens and pencils do Jessica have in total?"

We solve math word problems by generating equation templates through a seq2seq model. The input of the seq2seq model is the sequence W_P after number mapping, and the output is an equation template T_P. The equation E_P can be obtained by applying the corresponding number mapping M_P to T_P.

3.2 Constructing a Large Dataset

Most public datasets for automatic math word problem solving are quite small and contains limited types of problems. The most frequently used Alg514 (Kushman et al., 2014) dataset contains only 514 linear algebra problems with 28 equation templates. There are 1,000 problems in the newly constructed DRAW-1K (Shyam and Ming-Wei, 2017) dataset. Dophin1878 (Shi et al., 2015) includes 1,878 number word problems. An exception is the Dolphin18K dataset (Huang et al., 2016) which contains 18,000+ problems. However, this dataset has not been made publicly available so far.

Since DNN-based approaches typically need large training data, we have to build a large dataset of labeled math word problems. We crawl over 60,000 Chinese math word problems from a couple of online education web sites. All of them are real math word problems for elementary school students. We focus on one-unknown-variable linear math word problems in this paper. For other problem types, we would like to leave as future work. Please pay attention that the solutions to the problems are in natural language, and we have to extract equation systems and structured answers from the solution text. We implement a rule-based extraction method for this purpose, which achieves very high precision and medium recall. That is, most equations and structured answers extracted by our method are correct, and many problems are dropped from the dataset. As a result, we get dataset Math23k which contains 23,161 problems labeled with structured equations and answers. Please refer to Table 3 for some statistics of the dataset and a comparison with other public datasets.

4 Deep Neural Solver

In this section, we propose a *RNN-based seq2seq model* to translate problem text to math equations. Since not all numbers in problem text may be useful for solving the problem, we propose, in Section 4.2, a *significant number identification* model to distinguish whether a number in a problem should appear in the corresponding equations.

4.1 RNN based Seq2seq Model

Figure 1 shows our RNN-based seq2seq model for transforming problem text to a math equation, using the problem in Table 2 as an example. The in-

dataset	# problems	# templates	# sentences	# words	problem types

Number mapping: {n1=5, n2=3, n3=4, n4=2}
Problem: Dan have 5 pens and 3 pencils, Jessica have 4 more pens and 2 less pencils than him. How many pens and pencils do Jessica have in total?

Figure 1: The seq2seq model

put sequence W is the problem after number mapping:

"Dan have n_1 pens and n_2 pencils, Jessica have n_3 more pens and n_4 less pencils than him. How many pens and pencils do Jessica have in total?"

The output sequence $R = \{r_1, \ldots, r_s\}$ is the equation template:

$$x = n_1 + n_3 + n_2 - n_4$$

The gated recurrent units (GRU) (Chung et al., 2014) and long short-memory (LSTM) (Hochreiter and Schmidhuber, 1997) cells are used for encoding and decoding, respectively. The reason why we use GRU as the encoder instead of LSTM is that the GRU has less parameters and less likely to be overfitted on small dataset. Four fundamental operational stages of GRU are as follows:

$$\begin{aligned}
z_t &= \sigma(W^{(z)} x_t + U^z h_{t-1}) && \text{(Update gate)}\\
r_t &= \sigma(W^{(r)} x_t + U^r h_{t-1}) && \text{(Reset gate)}\\
\hat{h_t} &= tanh(r_t \odot U h_{t-1} + W x_t) && \text{(New memory)}\\
h_t &= (1 - z_t) \odot \hat{h_t} + z_t \odot h_{t-1} && \text{(Hidden state)}
\end{aligned} \tag{1}$$

where σ represents the sigmoid function and $\odot$ is an element-wise multiplication. The input x_t is a word w_t along with previously generated character r_{t-1} . The variables U and W are weight matrices for each gate.

The fundamental operational stages of LSTM are as follows:

$$\begin{aligned}
i_t &= \sigma(W^{(i)} x_t + U^i h_{t-1}) && \text{(Input gate)}\\
f_t &= \sigma(W^{(f)} x_t + U^f h_{t-1}) && \text{(Forget gate)}\\
o_t &= \sigma(W^{(o)} x_t + U^o h_{t-1}) && \text{(Output gate)}\\
\tilde{c}_t &= tanh(W^{(c)} x_t + U^{(c)} h_{t-1}) && \text{(New memory)}\\
c_t &= f_t \odot \tilde{c}_{t-1} + i_t \odot \tilde{c}_t && \text{(Final memory)}\\
h_t &= o_t \odot tanh(c_t) && \text{(Hidden state)}
\end{aligned} \tag{2}$$

where the input x_t is a word w_t along with previously generated character r_{t-1} .

Then, we redesigned the activation function of the seq2seq model, which is different from vanilla seq2seq models. If we directly generate equation templates by a softmax function, some incorrect equations may be generated, such as: "$x = n_1 + + * n_2$" and "$x = (n_1 * n_2$". To ensure that the output equations are mathematically correct, we need to find out which characters are illegal according to previously generated characters. This is done by five predefined rules like:

- Rule 1: If r_{t-1} in $\{+, -, *, /\}$, then r_t will not in $\{+, -, *, /,), =\}$;
- Rule 2: If r_{t-1} is a number, then r_t will not be a number and not in $\{(, =\}$;

- Rule 3: If r_{t-1} is "=", then r_t will not in $\{+, -, *, /, =,)\}$;
- Rule 4: If r_{t-1} is "(", then r_t will not in $\{(,), +, -, *, /, =\}$;
- Rule 5: If r_{t-1} is ")", then r_t will not be a number and not in $\{(,)\}$;

A binary vector ρ_t can be generated depends on r_{t-1} and these rules. Each position in ρ_t is corresponding to a character in the output vocabulary, where "1" represents that the character is mathematically correct, and "0" indicates mathematically incorrect. Thus, the output probability distribution at each time-step t can be calculated as:

$$P(\hat{r_t}|h_t) = \frac{\rho_t \odot e^{h_t^T W^s}}{\sum \rho_t \odot e^{h_t^T W^s}} \tag{3}$$

where h_t is the output of LSTM decoder, and W^s is the weight matrix. The probability of mathematically incorrect characters will be 0.

Our model is five layers deep, with a word embedding layer, a two-layer GRU as encoder and a two-layer LSTM as decoder. Both the encoder and decoder contain 512 nodes. We perform standard dropout during training (Srivastava et al., 2014) after GRU and LSTM layer with dropout probability equal to 0.5. We train for 80 epochs, utilizing a mini-batch size of 256 and a learning-rate of 0.01.

4.2 Significant Number Identification (SNI)

In a math word problem, not all numbers appear in the equation for solving the problem. An example is shown in Table 4, where the number *"1"* in *"1 day, 1 girl"* and number *"2"* in *"She has 2 types of"* should not be used in equation construction. We say a number is *significant* if the number should be included in the equation to the problem; otherwise it is *insignificant*. For the problem in Table 4, significant numbers are 9, 3, and 5, while 1 and 2 are insignificant numbers. Identifying significant and insignificant numbers are important for constructing correct equations. For this purpose, we build a LSTM-based binary classification model to determine whether a number in a piece of problem text is significant.

The training data for SNI model are extracted from the math word problems. Each number and its context in problems is a training instance of SNI. An instance will be labelled"True" if the number is *significant*, otherwise it will be labelled "False". The structure of SNI model is shown in Figure 2. By using single layer LSTMs with 128 nodes and a symmetric window of length 3, our model achieves 99.1% accuracy. Table 4 is an example of number mapping with and without SNI.

Problem: 1 day, 1 girl was organizing her book case making sure each of the shelves had exactly 9 books on it. She has 2 types of books - mystery books and picture books. If she had 3 shelves of mystery books and 5 shelves of picture books, how many books did she have in total?
Number mapping: $n_1 = 1; n_2 = 1; n_3 = 9;$ $n_4 = 2; n_5 = 3; n_6 = 5$
Equation template: $x = n_5 * n_3 + n_6 * n_3$
Number mapping with SNI: $n_1 = 9; n_2 = 3; n_3 = 5$
Equation template with SNI: $x = n_2 * n_1 + n_3 * n_1$
Problem after number mapping and SNI: 1 day, 1 girl was organizing her book case making sure each of the shelves had exactly n_1 books on it. She has 2 types of books -mystery books and picture books. If she had n_2 shelves of mystery books and n_3 shelves of picture books, how many books did she have in total?

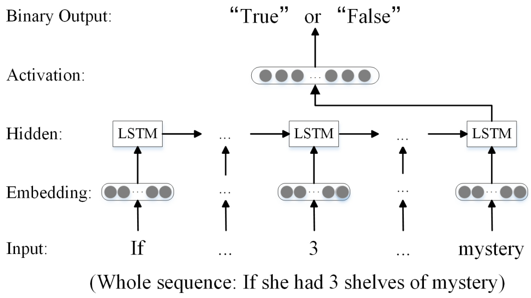

Figure 2: The significant number identification model

5 Hybrid Model

To compare the performance of our deep neural solver and traditional statistical learning methods, we implement a similarity-based retrieval model (refer to Section 5.1 for more details).

The Venn diagram in Figure 3 shows the relationship between the problems solved by the re-

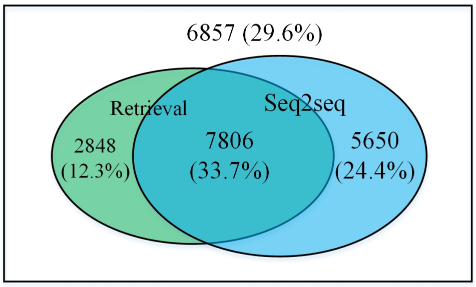

Figure 3: **Green area**: problems correctly solved by the retrieval model; **Blue area**: problems correctly solved by the seq2seq model; **Overlapped area**: problems correctly solved by both models; **White area**: problems that both models fail to solve

trieval model and those solved by the seq2seq model. We can see that although seq2seq performs better on average, the retrieval model is able to correctly solve many problems that seq2seq cannot solve. If we can combine the two models properly to build a hybrid model, more problems may get solved.

In this section, we first give some details about the retrieval model in Section 5.1, then the hybrid model is introduced in Section 5.2.

5.1 Retrieval Model

The retrieval model solves problems by calculating the lexical similarity between the testing problem and each problem in the training data, and then the equation template of the most similar problem is applied to the testing problem. Each problem is modeled as a vector of word TF-IDF scores $W = [w_{1,d}, w_{2,d}, \ldots, w_{N,d}]^T$, where

$$w_{t,d} = tf_{t,d} * \frac{|D|}{|d \in D | t \in d|} \tag{4}$$

and $tf_{t,d}$ is the word frequency of word t in problem d; $|D|$ is the total number of problems in dataset; $|d \in D | t \in d|$ is the number of documents containing the word t.

The similarity between the testing problem P_T and another problem Q can be calculated by the Jaccard similarity between their corresponding vectors:

$$J(P_T, Q) = \frac{|P_T \cap Q|}{|P_T \cup Q|} = \frac{|P_T \cap Q|}{|P_T| + |Q| - |P_T \cap Q|} \tag{5}$$

The retrieval model will choose training problem Q_1 that have the maximal similarity with P_T and use the equation template T of Q_1 as the template of problem P_T.

An important and interesting observation about the retrieval model is the relation between the maximal similarity and solution accuracy. Figure 4 shows the results of only considering the problems for those the maximal similarity returned by retrieval model is above a threshold θ (in other words, we skip a problem if its corresponding maximal similarity is below the threshold). It is clear that the larger the similarity score, the higher the average accuracy is. In our hybrid model, we make use of this property to combine the seq2seq model and the retrieval model.

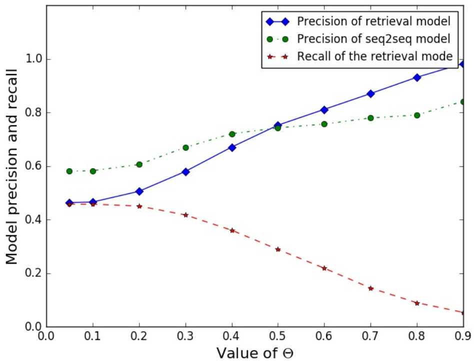

Figure 4: Precision and recall of the retrieval model, and the precision of the seq2seq model w.r.t. different similarity threshold (θ) values

5.2 Hybrid Model

Our hybrid model combines the retrieval model and the seq2seq model by setting a hyper-parameter θ as the threshold of similarity. In algorithm 1, if the Jaccard similarity between testing problem P_T and the retrieved problem Q_1 is higher than θ, the model will choose the equation template T of Q_1 as the equation template of problem P_T. Otherwise an equation template will be generated by a seq2seq model. As shown in Figure 4, the retrieval model has a higher precision than the seq2seq model when we set a high threshold.

6 Experiments

In this section, we conduct experiments on two datasets to examine the performance of the proposed models. Our main experimental result is to show a significant improvement over the baseline

Algorithm 1 Hybrid model

```
Input: $Q$: problems in training data;
       $P_T$: testing problem;
       $\theta$: pre-defined threshold of similarity
Output: Problem solution
Get equation templates and number mappings for training problems $Q$ and testing problem $P_T$.
Number identification: identify significant numbers
Retrieval:
choose problem $Q_1$ from $Q$ that has the maximal Jaccard similarity with $P_T$
if $J(P_T, Q_1) > \theta$ then
    Apply the retrieval model: select equation template $T$ of $Q_1$
else
    Apply the seq2seq model: $T = seq2seq(P_T)$
end if
Applying number mappings of $P_T$ to $T$ and calculating final solution
```

method on the proposed Math23K dataset. We further show that the baseline method cannot solve problems with new equation templates. In contrast, the proposed seq2seq model is quite robust on problems with new equation templates (refer to Table 7).

6.1 Experimental Setup

Datasets: As introduced in Section 3.2, we collected a dataset called Math23K which contains 23161 math word problems labeled with equation templates and answers. All these problems are linear algebra questions with only one variable. There are 2187 equation templates in the dataset. In addition, we also evaluate our method on a public dataset Alg514 (Kushman et al., 2014).

Baseline: We compare our proposed methods with two baselines. The first baseline is the retrieval model introduced in Section 5.1. The second one is ZDC (Zhou et al., 2015), which is an improved version of KAZB (Kushman et al., 2014). It maps a problem to one equation template defined in the training set by reasoning across problem sentences. It reports an accuracy of 79.7% on the Alg514 dataset. The Stanford parser is adopted in ZDC to parse all math word problems to Stanford coreNLP output formats. [2]

6.2 Experimental Results

Each approach is evaluated on each dataset via 5-fold cross-validation: In each run, 4 folds are used for training and 1 fold is used for testing. Evaluation results are summarized in Table 5. First, to test the effectiveness of *significant number identification* (SNI), model performance before and after the application of SNI are compared. Then, the performance of the hybrid model, seq2seq model, and retrieval model are examined on two datasets respectively.

To check whether the performance improvements are significant enough, we conduct statistical significance study upon pairs of methods. Table 6 shows the results of sign test, where the symbol $>$ indicates that the method in the row significantly (with p value < 0.05) improves the performance of the method in the column, and the symbol $\gg$ indicates that the performance improvement is extremely significant (with p value < 0.01).

Several observations can be made from the re-

[2] We also try to run KAZB on our dataset, but fail on our workstation (2 12-core E5-2650 CPU, 128G RAM, 4 K80 GPUs) due to large memory consumption.

sults. First, the seq2seq model significantly outperforms state-of-the-art statistical learning methods (ZDC and the retrieval model). Second, by combining the retrieval model and the seq2seq model using a simple mechanism, our hybrid model achieves significant performance gain with respect to the seq2seq model. Third, the SNI module can effectively improve model accuracy. The accuracy of the hybrid model and seq2seq model gains approximately 4% increase after number identification. Please pay attention that on the small dataset of Alg514, the seq2seq model behaves much worse than others. This is not surprising, because deep neural networks typically need large training data.

Figure 5 shows the performance of different models on various scales of training data. As expected, the seq2seq model performs very well on big datasets, but poorly on small datasets.

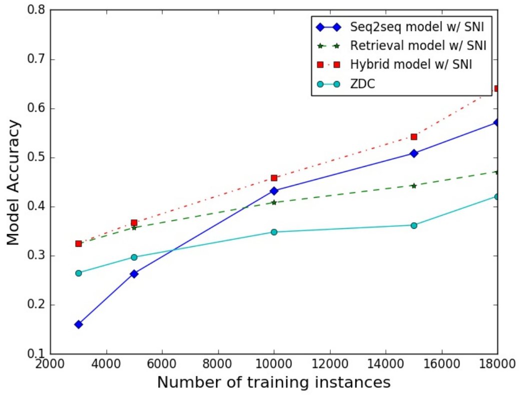

Figure 5: Performance of different models versus the size of training set

Ability to Generate New Equation Templates: please note that many problems in Math23K can be solved using the same equation template. For example, a problem which corresponds to the equation $x = (9 * 3) + 7$ and a different problem that maps to $x = (4 * 5) + 2$ share the same equation template.

One nice property of the seq2seq model is its ability of generating new equation templates. Most previous statistical learning methods (with a few exceptions) for math word problem solving are only able to select an equation template from those in the training data. In other words, they cannot generate new templates. To test the performance of the seq2seq model in generating new templates, we make a new split of our dataset between training data and test data, to ensure that the training data and the test data do not share overlapped templates. As a result, we get a training set with 19, 024 problems and 1, 802 equation templates, and a testing set with 4, 137 problems and 315 equation templates.

	Math23K
ZDC	15.1%
Retrieval model w/o SNI	26.1%
Retrieval model w/ NI	29.2%
Seq2seq model w/o SNI	40.3%
Seq2seq model w/ SNI	**47.5%**
Hybrid model w/o SNI	40.3%
Hybrid model w/ SNI	**47.7%**

Table 7: Experimental results of non-overlapping templates between training data and test data

Experimental results on the new training set and test set are shown is shown in Table 7. By comparing Table 5 and Table 7, it is clear that the gap between the seq2seq model and the baselines becomes larger in the new settings. It is because the seq2seq model can effectively generate new equation templates for new problems, instead of selecting equation templates from the training set.

Although ZDC and the retrieval model cannot generate new templates, their accuracy is not zero in the new settings. That is because one problem can be solved by multiple equation templates: Although one problem is labeled with template T_1 in the test set, it may also be solved by another template T_2 in the training set.

6.3 Discussion

Compare to most previous statistical learning methods for math problem solving, our proposed seq2seq model and hybrid model have the following advantages: 1) They have higher accuracy on large training data. On the Math23K dataset, the hybrid model achieves at least 22% higher accuracy than the baselines. 2) They have the ability of generating new templates (i.e., templates that are not in the training data. 3) They do not rely on sophisticated feature engineering.

7 Conclusion

We have proposed an RNN-based seq2seq model to automatically solve math word problems. This model directly transforms problem text to a math equation template. This is the first work of applying deep learning technologies to math word problem solving. In addition, we have designed a hybrid model which combines the seq2seq model and a retrieval model to further improve performance. A large dataset has been constructed for model training and empirical evaluation. Experimental results show that both the seq2seq model and the hybrid model significantly outperform state-of-the-art statistical learning methods in math word problem solving.

The output of our seq2seq model is a single equation containing one unknown variable. Therefore our approach is only applicable to the problems whose solution involves one linear equation of one unknown variable. As future work, we plan to extend our model to be able to generate equation systems and nonlinear equations.

Abstract

Community-driven Question Answering (CQA) systems such as Yahoo! Answers have become valuable sources of reusable information. CQA retrieval enables usage of historical CQA archives to solve new questions posed by users. This task has received much recent attention, with methods building upon literature from translation models, topic models, and deep learning. In this paper, we devise a CQA retrieval technique, *LASER-QA*, that embeds question-answer pairs within a unified latent space preserving the local neighborhood structure of question and answer spaces. The idea is that such a space mirrors semantic similarity among questions as well as answers, thereby enabling high quality retrieval. Through an empirical analysis on various real-world QA datasets, we illustrate the improved effectiveness of LASER-QA over state-of-the-art methods.

1 Introduction

Community-based Question Answering (CQA) services such as Yahoo! Answers[1], Quora[2], StackOverflow[3], and Baidu Zhidao[4] have become a dependable source of knowledge to solve common user problems. These allow a user to post queries such as *how* and *why* questions that seek descriptive solutions and opinions as answers. Over time, these services build up a large archive of question-answer knowledge that may be leveraged to solve new user questions. The CQA retrieval problem, that has received much recent attention, is about addressing this opportunity. CQA retrieval methods focus on finding historical archived knowledge (questions, answers or QA pairs) that are relevant to a newly posed user question. The central technical challenge that differentiates CQA retrieval from other general purpose IR tasks is that of the need to address the lexical gap (aka *lexical chasm*) in QA archives. Lexical chasm means that text fragments in questions (e.g., *disk full*) may lead to semantically correlated content in answers (e.g.,*format*). This QA-correlation is different from semantic relatedness such as *synonymy* and *antonymy*; in the above example, the correlation is due to *disk full* issues often leading to solution involving disk *format*ing. Explicit correlation modelling, using statistical translation models, have met with much success in CQA retrieval.

Table 1: Example CQA Pairs

#	QA	Cause
1	**Q:** My internet connection is not working, my router shows the "Internet" led blinking in red.	Router Authentication Issue
	A: Please go to the router login page and re-login with broadband credentials; click "connect" and you should be on the internet.	
2	**Q:** My internet connection is not working, only the power led is lit in the router.	Router Loose Connection
	A: Can you check whether the broadband cable is plugged in. Maybe, the broadband cable is not connected properly.	

In this paper, we take a neighborhood preserving learning approach, and learn a unified representation for QA pairs in an abstract *latent space*. Consider two example CQA pairs from a technical support forum presented in Table 1; the intuitive causes listed alongside are external to the dataset. Though the questions are reasonably similar lexically, they pertain to very different issues

as illustrated by the wide disparity in the answers posed to them. We model QA-pairs in a unified space that preserves the similarity neighborhood in question and answer spaces. In this example, the wide divergence in answer-space similarity neighborhoods between the two QAs would pull them apart, so they live in different parts of the latent space, reflecting the dissimilarity between their causes. Thus, our contribution in this paper is a neighborhood-preserving method for CQA retrieval, LASER-QA, expanding to **LA**tent-**S**pace **E**mbedding for **R**retrieval in **QA** archives.

2 Related Work

The three main CQA retrieval tasks target retrieving (a) related past questions (Zhou et al., 2015), (b) potentially usable past answers (Shtok et al., 2012), and (c) past question-answer pairs (Xue et al., 2008). Techniques for CQA typically use one of: (i) statistical translation models, (ii) topic models and (iii) neural networks. A fourth class target exploiting metadata such as question categories and author data, or domain-specific syntactic information, and are not as applicable in the absence of such information.

In the interest of keeping this section focused on retrieval, we do not cover other tasks that have been addressed for CQA, such as QA-pair discovery (Deepak and Visweswariah, 2014), clustering (Deepak, 2016) and auxiliary IR tasks such as query suggestions (Deepak et al., 2013).

2.1 Translation Model based Techniques

Translation models (Brown et al., 1990) take parallel corpora, collections of document pairs expressing the same thing in different natural languages, and learn correlations between words/phrases; for example, $p(f|e)$ quantifies the probability of an english word *e* getting translated to a french word *f* in an English-French translation system. Though question-answer pairs do not semantically qualify as parallel corpora, usage of translation models treating them so(Xue et al., 2008) have led to retrieval accuracy improvements. Simplistically, a high probability for $p(format|disk)$ leads to retrieval models boosting the score of a answer containing the word *format* to respond to a user query involving a *disk* problem. Later methods have improved upon them by phrase-level (Zhou et al., 2011) and entity-level (Singh, 2012) modelling as well as by unimportant word removal (Lee et al., 2008) and differential treatment of concepts (Park and Croft, 2015). Recent work has even explored using a different language (e.g., Chinese) to enrich questions (Zhang et al., 2015).

2.2 Topic Model based Techniques

Topic models (Blei et al., 2003) have been used to retrieve topically similar questions (Cai et al., 2011) with usage of the solution side leading to further improvements (Ji et al., 2012). They have been combined with language modeling whereby question and answer parts are modeled to have been generated from *paired* latent topics, but in ”question and answer languages” (Zhang et al., 2014). We will use such paired topic modelling, called TBLM, as a baseline in our experimental study.

2.3 Topic+Translation Models

Hybrid methods build upon topic and translation models by interpolating the separate scorings. Due to the usage of a combination of multiple types of parameterized models, the results of such ”pipeline methods” have been observed to be hard to reproduce (Qiu et al., 2013).We use a recent hybrid scoring method, called TopicTRLM (Zhou et al., 2015), as a baseline in our experimental study.

2.4 Deep Learning Methods

Neural networks such as DBNs (Wang et al., 2011; Hu et al., 2013) and more sophisticated neural pipelines (Shen et al., 2015) have been explored for CQA retrieval. A recent work (Nakov et al., 2016a) trains a neural network to discriminate between good and bad comments for a question. Using neural networks for retrieval within question datasets (not involving answers) has also been a subject of recent interest (e.g., (Bogdanova et al., 2015; Das et al., 2016)). The most recent method for generic QA-pair processing, which we will call as AENN (Zhou et al., 2016), trains separate autoencoders for question and answer corpora, and induces correlatedness of intermediate representations in a fine-tuning step. In our empirical analysis, we will use the AENN approach from (Zhou et al., 2016) as a baseline.

2.5 Auxiliary-information based Methods

This category of methods target to exploit specific kinds of auxiliary information that are potentially available with CQA data. Techniques have considered usage of question categories (Cao et al., 2009; Zhou et al., 2014), the split between question title and description (Qiu et al., 2013), and assumptions of the question syntax (Duan et al., 2008). While such information is available in many systems, QA information from systems such as forums and chat-based customer support sometimes have very little information other than just QA-pairs. We target a general scenario where such metadata is not expected as a pre-requisite, as in the case of most techniques from other categories.

3 Problem Statement

Let $\mathcal{D} = \{(\boldsymbol{q}_1, \boldsymbol{a}_1), \dots, (\boldsymbol{q}_n, \boldsymbol{a}_n)\}$ be QA pairs from a CQA archive where answer $\boldsymbol{a}_i$ is associated with question $\boldsymbol{q}_i$; for cases involving multiple answers for a question, the question would be replicated for each answer. For a new question $\boldsymbol{q}$, the CQA retrieval problem is about devising a scoring function $f(\boldsymbol{q}, (\boldsymbol{q}_i, \boldsymbol{a}_i))$ that quantifies the relevance of each $(\boldsymbol{q}_i, \boldsymbol{a}_i)$ pair from $\mathcal{D}$ to the new question $\boldsymbol{q}$. Having devised a scoring function, retrieval is trivially accomplished by choosing an ordered set of top-t QA pairs from $\mathcal{D}$ in accordance with their $f(\cdot, \cdot)$ scores.

3.1 Evaluation

In the datasets that we use, we have labels indicating which QAs are related/relevant to a particular question. Thus, the quality of the scoring function can be evaluated using traditional information retrieval metrics (Robertson and Zaragoza, 2007) such as Precision, MAP, MRR, and NDCG when measured against such labellings. In addition, we will use one more metric, namely **Success Rate**, *the fraction of questions for which at least one related question is ranked among the top-t*, in evaluation.

4 LASER-QA: The Proposed Technique

Our method, LASER-QA, embeds QA pairs in $\mathcal{D}$, within a unified space of desired dimensionality.

$$\{(\boldsymbol{q}_1, \boldsymbol{a}_1), \dots, (\boldsymbol{q}_n, \boldsymbol{a}_n)\} \xrightarrow{LASER-QA} \{\boldsymbol{u}_1, \dots, \boldsymbol{u}_n\}$$

where, $\boldsymbol{u}_i \in \mathbb{R}^d$ is a vector space embedding in the latent space $\mathbb{R}^d$. As we will illustrate, LASER-QA targets to preserve the local similarity structures in the question and answer spaces within the unified embedding. Having built the embedding of QA pairs, cosine similarity between vectors in $\mathbb{R}^d$ is used for scoring:

$$f(\boldsymbol{q}, (\boldsymbol{q}_i, \boldsymbol{a}_i)) = \frac{\boldsymbol{u}^\top \boldsymbol{u}_i}{\|\boldsymbol{u}\| \|\boldsymbol{u}_i\|}, \tag{1}$$

where, $\boldsymbol{u} \in \mathbb{R}^d$ is the embedding of the new question $\boldsymbol{q}$; we will outline the embedding of single questions into $\mathbb{R}^d$ in a later section.

Our motivation behind LASER-QA stems from the idea of Local Linear Embedding (LLE) (Saul and Roweis, 2000); further, the choice of local neighborhood preservation is motivated by pervasive usage of local neighbors (i.e., k-NN retrieval) in case-based reasoning frameworks (De Mantaras et al., 2005) that seek to reuse structured problem-solution data.

4.1 Data Representation

We use the *tf-idf* vector representation for each question (denoted as $\boldsymbol{x}_i$) and each answer ($\boldsymbol{y}_i$) in $\mathcal{D}$. The *tf-idf* vectors are in $\mathbb{R}^D$ where D denotes the size of the vocabulary. The question and answer tf-idf vectors are arranged as columns to form matrices $\boldsymbol{X}$ and $\boldsymbol{Y}$, both of size $D \times n$. Recall, the *latent space* would be a Euclidean space of dimension d, and typically, we have $d < D$. Our method is intentionally designed to not rely on the specifics of the representation used, and thus can make use of any vector representation of text data. Note that our latent space embeddings in $\mathbb{R}^d$ are evidently unrelated to distributional text embeddings (e.g., (Mikolov et al., 2013)) and are complementary in that such embeddings could be used as an alternative input representation for $\boldsymbol{x}_i$ and $\boldsymbol{y}_i$.

4.2 Regularized Reconstruction Coefficients

For any question $\boldsymbol{x}_i$, let $\mathcal{N}_k(\boldsymbol{x}_i)$ denote the set of top-k nearest questions to the question $\boldsymbol{x}_i$, proximity assessed using cosine similarity of vectors in $\mathbb{R}^D$; analogously, $\mathcal{N}_k(\boldsymbol{y}_i)$ denotes the top-k nearest answers to $\boldsymbol{y}_i$. Much like the representation, the similarity measure may also be replaced as appropriate. Inspired by LLE (Saul and Roweis, 2000), we model the local neighborhood geometry around $\boldsymbol{x}_i$ using *reconstruction coefficient* w_{ij}^q for each question $\boldsymbol{x}_j \in \mathcal{N}_k(\boldsymbol{x}_i)$. We intend to learn the co-efficients such that $\boldsymbol{x}_i$ may be reconstructed well as a linear combination of the neighbors using the co-efficients. Thus, these co-efficients are computed by minimizing, for every question

$\boldsymbol{x}_i$, the *regularized reconstruction penalty (RRP)* given below:

$$\text{RRP}(\boldsymbol{x}_i) = \frac{1}{2}\left\|\boldsymbol{x}_i - \sum_{\boldsymbol{x}_j \in \mathcal{N}_k(\boldsymbol{x}_i)} w_{ij}^q \boldsymbol{x}_j\right\|^2 + \frac{\lambda}{2}\sum_{\boldsymbol{x}_j \in \mathcal{N}_k(\boldsymbol{x}_i)} \left(w_{ij}^q\right)^2 \tag{2}$$

The first term denotes the approximation error in reconstructing $\boldsymbol{x}_i$ as a linear combination of its k nearest neighbors using weights w_{ij}^q. The second term is an L2 regularization term weighted with a non-negative hyperparameter λ, which we set to 0.01 in our experiments. We replaced the sum-to-one constraint in (Saul and Roweis, 2000) by L2 regularization since the former produces large swings in magnitude on either sides of 0.0 (note co-efficients are not constrained to be non-negative) on high-dimensional spaces such as our tf-idf space, leading to stability concerns.

By explicitly assigning $w_{ij}^q = 0 \; \forall \boldsymbol{x}_j \notin \mathcal{N}_k(\boldsymbol{x}_i)$, we rewrite the above problem as:

$$\begin{aligned} \min_{\boldsymbol{w}_i^q} \; & \frac{1}{2}\boldsymbol{w}_i^{q\top}\left(\boldsymbol{X}^\top\boldsymbol{X} + \lambda\boldsymbol{I}\right)\boldsymbol{w}_i^q - \\ & \boldsymbol{w}_i^{q\top}\boldsymbol{X}^\top\boldsymbol{x}_i + \frac{1}{2}\boldsymbol{x}_i^\top\boldsymbol{x}_i \\ & \text{subject to } \; w_{ij}^q = 0 \; \forall j \notin \mathcal{N}_k(\boldsymbol{x}_i) \end{aligned} \tag{3}$$

where $\boldsymbol{I}$ is an $n \times n$ identity matrix and $\boldsymbol{w}_i^q$ is a column vector of size n comprising reconstruction coefficients vector for $\boldsymbol{x}_i$. It can be shown that the nonzero entries of the optimal coefficient vector is:

$$(\boldsymbol{X}_i^\top\boldsymbol{X}_i + \lambda\boldsymbol{I}_k)^{-1}\boldsymbol{X}_i^\top\boldsymbol{x}_i \tag{4}$$

where $\boldsymbol{I}_k$ is an identity matrix of the size k and matrix $\boldsymbol{X}_i$ is a $D \times k$ matrix obtained from the matrix $\boldsymbol{X}$ by retaining only those columns which are neighbors of $\boldsymbol{x}_i$. Note, the above matrix inverse is well-defined since the matrix is *positive definite* by construction. Once we find these optimal coefficient vectors for all questions (answers), we stack them together column-wise and obtain a matrix, $\boldsymbol{W}^q$ ($\boldsymbol{W}^a$) of size $n \times n$, called the reconstruction coefficient matrix for questions (answers). These two matrices $\boldsymbol{W}^q$ and $\boldsymbol{W}^a$ capture the local geometry of the questions and answers in the QA-archive $\mathcal{D}$.

4.3 Embedding into Latent Space $\mathbb{R}^d$

In this step, we use the $\boldsymbol{W}^q$ and $\boldsymbol{W}^a$ matrices to do the transformation of the QA pairs, the $(\boldsymbol{x}_i, \boldsymbol{y}_i)$s to $\boldsymbol{u}_i$s. Building upon LLE, we develop a scheme to preserve the local neighborhood structure around $\boldsymbol{x}_i$ and $\boldsymbol{y}_i$ in learning the $\boldsymbol{u}_i$.

$$\begin{aligned} \min_{\boldsymbol{U}} \; & \alpha\sum_{i=1}^{n}\|\boldsymbol{u}_i\text{-}\boldsymbol{U}\boldsymbol{w}_i^q\|^2 + (1\text{-}\alpha)\sum_{i=1}^{n}\|\boldsymbol{u}_i\text{-}\boldsymbol{U}\boldsymbol{w}_i^a\|^2 \\ & \text{subject to: } \sum_{i=1}^{n}\boldsymbol{u}_i = 0 \\ & \qquad\qquad \boldsymbol{U}\boldsymbol{U}^\top = (n\text{-}1)\boldsymbol{I}_d \end{aligned} \tag{5}$$

where, $\boldsymbol{U}$ is a $d \times n$ matrix whose i^{th} column is equal to $\boldsymbol{u}_i$. $\alpha \in [0, 1]$ is a weighting parameter that allows to trade-off between question and answer spaces. At $\alpha = 1$, the embedding $\boldsymbol{u}_i$ will try to maximally align with question $\boldsymbol{x}_i$ and vice versa. Our constraints, like the analogous ones in LLE, ensure origin-centered mean solutions and avoid degenerate solutions, respectively (Pang et al., 2005). The first constraint is soft in that any optimal solution disregarding the constraint can be shifted to ensure origin-centering.

Towards capturing the optimal solution for Eq. 5, we define three $n \times n$ symmetric matrices,

$$\boldsymbol{Q} = (\boldsymbol{I} - \boldsymbol{W}^q)(\boldsymbol{I} - \boldsymbol{W}^q)^\top \tag{6}$$

$$\boldsymbol{A} = (\boldsymbol{I} - \boldsymbol{W}^a)(\boldsymbol{I} - \boldsymbol{W}^a)^\top \tag{7}$$

$$\boldsymbol{Z} = \alpha\boldsymbol{Q} + (1 - \alpha)\boldsymbol{P}, \; \alpha \in [0, 1] \tag{8}$$

Theorem 1. *If the eigenvalues of the matrix $\boldsymbol{Z}$ are arranged in the descending order and the eigenvectors corresponding to the last d eigenvalues are denoted by $\{\boldsymbol{v}_1, \boldsymbol{v}_2, \ldots, \boldsymbol{v}_d\}$, then, the optimal solution for Eq. (5), denoted by $\boldsymbol{U}^*$ is:*

$$\boldsymbol{U}^* = \begin{pmatrix} \boldsymbol{v}_1^\top \\ \boldsymbol{v}_2^\top \\ \cdots \\ \boldsymbol{v}_d^\top \end{pmatrix} \tag{9}$$

Further, origin centering is achieved by the following transformation:

$$\boldsymbol{U}^*_{centered} = \boldsymbol{U}^* - \boldsymbol{U}^*\boldsymbol{e}\boldsymbol{e}^\top \tag{10}$$

where $\mathbf{e}$ *is a a vector of all* $1'$*s.*

Proof: First, observe that the objective function of Eq. (5) can be rewritten in a compact form:

$$\alpha \left\| \boldsymbol{U} - \boldsymbol{U}\boldsymbol{W}^q \right\|_F^2 + (1-\alpha) \left\| \boldsymbol{U} - \boldsymbol{U}\boldsymbol{W}^a \right\|_F^2 \quad (11)$$

where, $\| \cdot \|_F$ denotes the Frobenius norm. Now, keeping the first constraint aside, we fold in the second constraint using Lagrange multipliers yielding the following Lagrangian $L(\boldsymbol{U}, \boldsymbol{\Lambda})$.

$$L(\boldsymbol{U}, \boldsymbol{\Lambda}) = \alpha \left\| \boldsymbol{U}\text{-}\boldsymbol{U}\boldsymbol{W}^q \right\|_F^2 + (1\text{-}\alpha) \left\| \boldsymbol{U}\text{-}\boldsymbol{U}\boldsymbol{W}^a \right\|_F^2 \\ + \boldsymbol{e}^\top \left(\boldsymbol{\Lambda} \circ \left(\boldsymbol{U}\boldsymbol{U}^\top\text{-}(n\text{-}1)\boldsymbol{I}_d \right) \right) \boldsymbol{e} \quad (12)$$

where $\boldsymbol{e}$ is an all 1's vector. In this Lagrangian,

- Matrix $\boldsymbol{\Lambda}$ is a $d \times d$ symmetric matrix denoting the Lagrange multipliers for the second constraint. Note, the last term is a compact representation of $d^2/2$ equality constraints.
- The symbol $\circ$ denotes the Hadamard products (element wise product) of two matrices.

For any matrix $\boldsymbol{M}$, we have $\|\boldsymbol{M}\|_F^2 = \text{Tr}(\boldsymbol{M}\boldsymbol{M}^\top)$ where Tr(.) is the trace. Thus, we can rewrite the first two terms of Eq.(12) as:

$$\alpha \,\text{Tr}\left((\boldsymbol{U} - \boldsymbol{U}\boldsymbol{W}^q)(\boldsymbol{U} - \boldsymbol{U}\boldsymbol{W}^q)^\top \right) + \\ (1-\alpha)\,\text{Tr}\left((\boldsymbol{U} - \boldsymbol{U}\boldsymbol{W}^a)(\boldsymbol{U} - \boldsymbol{U}\boldsymbol{W}^a)^\top \right)$$

A slight re-arrangement yields:

$$\alpha \,\text{Tr}\left(\boldsymbol{U}(\boldsymbol{I} - \boldsymbol{W}^q)(\boldsymbol{I} - \boldsymbol{W}^q)^\top \boldsymbol{U}^\top \right) + \\ (1-\alpha)\,\text{Tr}\left(\boldsymbol{U}(\boldsymbol{I} - \boldsymbol{W}^a)(\boldsymbol{I} - \boldsymbol{W}^a)^\top \boldsymbol{U}^\top \right)$$

The Q and A space components are now separated out into the first and second terms. We now simplify the notation using Eq. (6) and (7) to:

$$L(\boldsymbol{U}, \boldsymbol{\Lambda}) = \alpha \,\text{Tr}\left(\boldsymbol{U}\boldsymbol{Q}\boldsymbol{U}^\top \right) + (1\text{-}\alpha)\,\text{Tr}\left(\boldsymbol{U}\boldsymbol{A}\boldsymbol{U}^\top \right) \\ + \boldsymbol{e}^\top \left(\boldsymbol{\Lambda} \circ \left(\boldsymbol{U}\boldsymbol{U}^\top\text{-}(n\text{-}1)\boldsymbol{I}_d \right) \right) \boldsymbol{e}$$

Recall the following for any matrices $\boldsymbol{A}, \boldsymbol{B}$, & $\boldsymbol{C}$.

1. $\boldsymbol{A} \circ (\boldsymbol{B} - \boldsymbol{C}) = (\boldsymbol{A} \circ \boldsymbol{B}) - (\boldsymbol{A} \circ \boldsymbol{C})$
2. $\boldsymbol{e}^\top (\boldsymbol{A} \circ \boldsymbol{B})\, \boldsymbol{e} = \text{Tr}(\boldsymbol{A}\boldsymbol{B}^\top) = \text{Tr}(\boldsymbol{A}^\top \boldsymbol{B})$

This allows us to rewrite Eq. (13) as:

$$L(\boldsymbol{U}, \boldsymbol{\Lambda}) = \text{Tr}\left(\alpha \boldsymbol{U}\boldsymbol{Q}\boldsymbol{U}^\top + (1-\alpha)\boldsymbol{U}\boldsymbol{A}\boldsymbol{U}^\top \right. \\ \left. + \boldsymbol{\Lambda}\boldsymbol{U}\boldsymbol{U}^\top - (n-1)\boldsymbol{\Lambda} \right) \quad (13)$$

To find an optimal $\boldsymbol{U}$, we differentiate $L(\boldsymbol{U}, \boldsymbol{\Lambda})$ w.r.t $\boldsymbol{U}$ and equate to zero. This leads to:

$$\frac{\partial L(\boldsymbol{U}, \boldsymbol{\Lambda})}{\partial \boldsymbol{U}} = 2\alpha \boldsymbol{U}\boldsymbol{Q} + 2(1-\alpha)\boldsymbol{U}\boldsymbol{A} + 2\boldsymbol{\Lambda}\boldsymbol{U} = 0$$

The above follows from standard matrix properties (Petersen and Pedersen, 2012). Re-arranging:

$$(\alpha \boldsymbol{Q} + (1-\alpha)\boldsymbol{A})\, \boldsymbol{U}^\top = -\boldsymbol{U}^\top \boldsymbol{\Lambda} \quad (14)$$

One possible solution of the above equation could be constructed in the following manner.

1. Let $\boldsymbol{Z} = \alpha \boldsymbol{Q} + (1-\alpha)\boldsymbol{A}$
2. Compute the Eigen decomposition of $\boldsymbol{Z}$
3. Find the lowest (i.e., bottom) d Eigen values, and take the corresponding Eigen vectors.
4. Form a matrix $\boldsymbol{U}$ by stacking the selected Eigen vectors row-wise.

While any subset of d eigenvectors (and their eigenvalues) would be a solution for Eq. (14), we would take the bottom d eigenvectors for minimizing the objective; this is so since the objective becomes $\text{Tr}(-\boldsymbol{\Lambda})$ when Eq. (14) holds. The matrix constructed above is the optimal $\boldsymbol{U}^*$ in Eq. (9). This completes the proof. ■

The first constraint in Eq.(5) is then applied to centre the vectors around the origin using Eq.(10).

4.4 Embedding a new Question in $\mathbb{R}^d$

To use the historical $\boldsymbol{u}_i$ vectors to retrieve historical QAs against a new question (vector) $\boldsymbol{q}$, we need to embed the latter in the same space $\mathbb{R}^d$. This is achieved using the same structure as applied in forming the embedding; we start with identifying, from $\mathcal{D}$, the k-nearest questions to $\boldsymbol{q}$. The reconstruction co-efficient vector $\boldsymbol{w}^q$ is then learnt using Eq. (2). Finally, we obtain the embedding $\boldsymbol{u}$ for $\boldsymbol{x}$ as a $\boldsymbol{w}^q$-weighted linear combination of the $\mathbb{R}^d$ embeddings corresponding to the k-nearest neighbors. This is captured in steps 9-11 in Algorithm 1 given in the next section.

```
Algorithm 1: LASER-QA Algorithm
input   : $\mathcal{D} = \{(\boldsymbol{q}_1, \boldsymbol{a}_1), \ldots, (\boldsymbol{q}_n, \boldsymbol{a}_n)\}$
          (CQA corpus) & query $\boldsymbol{q}$
output  : Top-$t$ relevant QA pairs from $\mathcal{D}$
Offline Phase
1  Use appropriate data representation to form
     vector-pairs $(\boldsymbol{x}_i, \boldsymbol{y}_i)$ for every QA $(\boldsymbol{q}_i, \boldsymbol{a}_i)$;
2  Compute the reconstruction coefficient
     matrices $\boldsymbol{W}^q$ and $\boldsymbol{W}^a$ (Ref. Section 4.2);
3  $\boldsymbol{Q} \leftarrow (\boldsymbol{I} - \boldsymbol{W}^q)(\boldsymbol{I} - \boldsymbol{W}^q)^\top$;
4  $\boldsymbol{A} \leftarrow (\boldsymbol{I} - \boldsymbol{W}^a)(\boldsymbol{I} - \boldsymbol{W}^a)^\top$;
5  $\boldsymbol{Z} \leftarrow \alpha \boldsymbol{Q} + (1 - \alpha)\boldsymbol{A}$;
6  $\{\boldsymbol{v}_1, \boldsymbol{v}_2, \ldots, \boldsymbol{v}_d\} \leftarrow$ Bottom $d$ eigenvectors of
     matrix $\boldsymbol{Z}$;
7  $\boldsymbol{U}^* \leftarrow \begin{pmatrix} \boldsymbol{v}_1^\top \\ \boldsymbol{v}_2^\top \\ \cdots \\ \boldsymbol{v}_d^\top \end{pmatrix}$;
8  $\boldsymbol{U}^*_{\text{centered}} = \boldsymbol{U}^* - \boldsymbol{U}^* \boldsymbol{e}\boldsymbol{e}^\top$;
Query-time (Online) Phase
9  $\boldsymbol{x} \leftarrow$ Vector representation of the query $\boldsymbol{q}$;
10 $\boldsymbol{w}_x \leftarrow$ Vector of size $n$ capturing the
     reconstruction coefficients for $\boldsymbol{x}$;
11 $\boldsymbol{u} \leftarrow \boldsymbol{U}^*_{\text{centered}} \boldsymbol{w}_x$;
12 Output top-$t$ QA pairs based by computing
     the following scores
     $$f(\boldsymbol{q}, (\boldsymbol{q}_i, \boldsymbol{a}_i)) = \frac{\boldsymbol{u}^\top \boldsymbol{u}_i}{\|\boldsymbol{u}\| \|\boldsymbol{u}_i\|}$$
```

4.5 LASER-QA Algorithm

The details of the LASER-QA technique from the previous sections are summarized in Algorithm 1, with the offline (Steps 1-8) and query-time phase (Steps 9-12) clearly demarcated. It may be noted that, LASER-QA, being an optimization-based method, preserves Q/A-space local neighborhoods on a best-effort basis and does not offer guarantees on the fraction of local neighbors preserved from either spaces in the $\mathbb{R}^d$ embedding.

4.5.1 Generalizability of LASER-QA

LASER-QA can be easily extended to incorporate other kinds of information that might be available along with QA pairs such as images, votes (e.g., Blurtit[5], Quora and Yahoo! Answers) tags (Quora), categories (answers.com[6] and Yahoo! Answers) or comments (Quora and Blurtit). Consider data in the form of triplets $(\boldsymbol{q}_i, \boldsymbol{a}_i, \boldsymbol{m}_i)$ where $\boldsymbol{m}_i$ represents the extra information. The $\boldsymbol{m}_i$ vectors are subjected to the same form of processing as $\boldsymbol{q}_i$ and $\boldsymbol{a}_i$ vectors, leading to the $\boldsymbol{W}^m$ and $\boldsymbol{M}$ matrices. Line 5 in Algorithm 1 would then change to:

$$\boldsymbol{Z} \leftarrow \alpha_q \boldsymbol{Q} + \alpha_a \boldsymbol{A} + \alpha_m \boldsymbol{M} \tag{15}$$

where the different αs denote interpolation weights that need to be set appropriately. The remainder of the LASER-QA steps remain identical to Algorithm 1. It may be noted that α_m could be set to a low value if the utility of the extra information is deemed to be low.

4.5.2 Scalability of LASER-QA

We now analyze the scalability of LASER-QA, separately analysing the (a) one-time offline phase, and (b) query-time phase.

Offline Phase: This is a one-time operation at the system design time, involving matrix multiplications followed by eigen-decomposition. Our matrices being sparse, multiplications are fast and worst-case quadratic[7] in n. The Eigendecomposition is $\mathcal{O}(n^3)$, but being a fundamental matrix operation, very efficient implementations exist (especially for symmetric matrices such as ours) with sub-second response times for n of the order of thousands (in packages such as Eigen[8] and LAPACK[9]), trendlines illustrating that Eigendecompositions with even n of the order of millions are easy. The embeddings of all vectors are then indexed using conventional multi-dimensional indexes and/or locality sensitive hashing to aid querying.

Online/Query-time Phase: This encompasses (a) an IR query to find the k most similar questions, (b) solving for the k reconstruction co-efficients in Eq. 4 and forming the embedding, and (c) simply querying for top-t nearest neighbors over indexes built at design-time. The main query-time overhead (vis-a-vis conventional information retrieval) is the additional query over the multi-dimensional index; this construction ensures fast sub-linear response times for the online phase.

Scalability against other methods: In contrast to LASER-QA, it is notable that the baselines

[5] http://www.blurtit.com/

[6] http://www.answers.com/

[7] https://goo.gl/RQ1m0V

[8] https://goo.gl/phMJv9

[9] https://goo.gl/rJjBY6 (Fig 3.1)

employ expensive query-time operations; specifically, it is unclear as to how query-time retrieval using Eq.4 in the TBLM paper (Zhang et al., 2014) and Eq.1 in Topic-TRLM paper (Zhou et al., 2015) could be completed in sub-linear time.

5 Experimental Evaluation

5.1 Datasets and Experimental Setup

Datasets: We use two recent datasets in our evaluation, CQADupStack (Hoogeveen et al., 2015) and SemEval2016-Task3 (Nakov et al., 2016b). The former has a manually labelled set of *related* questions to every question, whereas the latter has relevance labels associated with answers (appearing as *comments*); these labellings make automated evaluation possible. Among the 12 subsets in CQADupStack, owing to scalability issues of the AENN baseline, we choose the three smaller subsets from CQADupStack, namely *webmasters* (1299 QAs), *android* (2193), and *gis* (3726) for a full comparative evaluation. Each of these are split into two halves, with one portion used for the training (that is, learning the statistical model such as LASER-QA, translation model, etc.) and the other one used for the testing (the 50:50 split ensures a sizeable test set). The *related* labellings are used only for evaluation purposes; however, since only training pairs are retrieved within this setup, *related* labellings across QAs in the testing set would be missed, artificially lowering the recall of all the methods in our evaluation. In a recent analysis (Hoogeveen et al., 2016), CQADupStack authors quantify the incompleteness of labeling in the dataset. Such issues further artificially reduce retrieval accuracies as estimated from our automated evaluation. The SemEval2016 dataset, on the other hand, has an implicit test-train split. We use the subset of the data categorized under *Qatar Living Lounge*, the largest category (which is 27% of the full dataset), for our experiments. All 'comments' that are labelled relevant to the associated question are paired together as QA-pairs to form a training set of 1366 pairs, with the test questions from the dataset used as is.

Baselines: As detailed in Section 2, we compare against three baselines (a) TBLM (Zhang et al., 2014) (topic model approach), (b) Topic-TRLM (Zhou et al., 2015) (topic+translation models), and (b) AENN (Zhou et al., 2016) (deep learning). TBLM requires an *answer quality signal* that we set to unity. We use author-recommended parameter settings for TBLM and TopicTRLM. Since AENN learns a latent space representation (though a separate one for questions and answers unlike LASER-QA), the evaluation w.r.t LASER-QA is a direct comparison of the quality of the respective latent spaces. The AENN method requires training triplets, i.e., [question, answer, other answer]; we populate the *other answer* part using the answer of a related question. This gives AENN an advantage as it uses relations among training pairs that are unavailable to other methods. For AENN, quality measures peaked around 2000 (for *webmasters* and *gis*) and 3000 (for *android* and *SemEval2016*) for latent space dimensionality; our results are from such settings.

LASER-QA Parameters: We set $k = 15$ and $\alpha = 0.8$, the latter ensuring that the question space is given more importance. We always set d to the number of eigen vectors in $\boldsymbol{Z}$, equalling $|\mathcal{D}|$. We will separately study LASER-QA trends against parameter variations as well.

Evaluation Metrics: We use Precision, Success Rate (SR) (Ref. Sec 3), MAP and NDCG (Robertson and Zaragoza, 2007) for our evaluation. Precision simply measures the fraction of related documents among the top-t that were retrieved. Due to this rank-agnostic construction, precision is unable to incentivize for putting the relevant results at the top of the result instead of deeper down. In contrast, MAP and NDCG are rank-aware metrics. MAP[10] computes the average of precisions computed at rank positions where a relevant result is returned. NDCG is another rank-aware metric[11] that discounts the appearance of the revelant result based on it's rank in the result set. We assess statistical significance using randomization tests (Smucker et al., 2007).

5.2 Evaluation Results and Insights

Table 2 summarizes the comparative evaluation across varying t (best results boldfaced). The following observations are notable:

- LASER-QA outperforms the other methods across datasets. This is followed by Topic-TRLM, TBLM and then AENN.

- LASER-QA's margin is highest at (small) values of t that are typical of scenarios involving human perusal of results. As t in-

Table 3: LASER-QA Results (Boldfacing and Statistical Significance indications from comparison with TopicTRLM and TBLM) over Larger Categories in CQADupStack

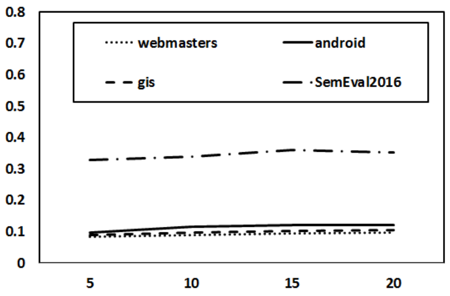

Figure 1: NDCG (Y-axis) v/s. k

creases way beyond the training neighborhood size (i.e., 15), LASER-QA is seen to deteriorate gracefully (as expected).

- LASER-QA performance peaks on rank-aware metrics such as MAP and NDCG (even at $t = 50$), indicating it's high effectiveness in producing relevant results at the top.

These observations underline the effectiveness of LASER-QA as a CQA retrieval method. It may be noted that LASER-QA uses compact representations ($d < 2000$), as compared to vocabulary space representations that are typically ≥ 5000.

Trends at High t: The performance trends at high values of t are explained by the usage of the local neighborhood (of size k) in LASER-QA latent space learning. Going down the result list much beyond k reveals expected, but graceful, decline in accuracy. For automated processing scenarios that necessitate large t, a correspondingly high k may be used in learning. It is notable that LASER-QA's focus on local neighborhood manifests as enhanced accuracy at the top of the result set.

LASER-QA Analysis on Larger CQADupStack Datasets: Owing to scalability issues of AENN that disallows a full evaluation over larger categories in CQADupStack, we present LASER-QA results over them in Table 3 to illustrate the consistency in trends. Boldfacing and statistical significance have the same semantics as earlier, with the comparison performed against only TopicTRLM and TBLM.

5.3 LASER-QA Parameter Analysis

We now analyze the NDCG trends (NDCG being the most popular IR metric) across LASER-QA parameters, i.e., k, α and d, varying each one separately keeping the default choice for others.

- **Varying k:** Figure 1 plots NDCG against values of k from $\{5, 10, 15, 20\}$. As may be seen, the accuracy is seen to improve with increasing k in the lower ranges, while sat-

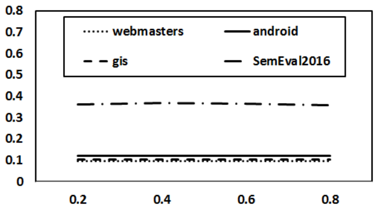

Figure 2: NDCG (Y-axis) v/s varying values of α

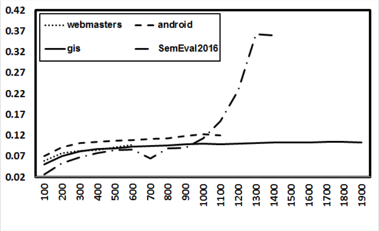

Figure 3: NDCG (Y-axis) v/s varying values of d

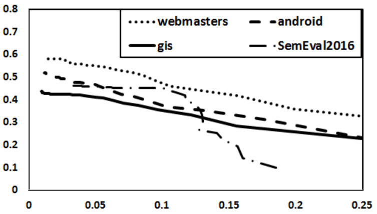

Figure 4: Precision (Y-axis) v/s Recall (X-axis)

urating beyond 15. The trends are seen to be similar across datasets.

- **Varying α:** The retrieval accuracies were seen to be stable across a wide range of values of α such as illustrated in Figure 2. This shows that LASER-QA is not very sensitive to α.

- **Varying d:** The size of the latent space, d, forms a critical parameter for LASER-QA. Given the LASER-QA construction, this space is limited by the number of eigenvectors in the matrix $\boldsymbol{Z}$ which is $n \times n$. This means, d is limited above by n, the size of the training dataset. Table 3 plots the accuracies with varying values of d, with the upper end different for different datasets due to the dependence on the training dataset size. The plots indicate that the performance improves steadily with increasing values of d. The performance saturates beyond 400 for the topically coherent CQADupStack datasets. The *Qatar Living Lounge* category in SemEval2016, unlike the CQADupStack categories, is more diverse discussing issues ranging from massage centres to immigration. Thus, LASER-QA is able to make use of much more dimensions to model the complexity involved.

To summarize, LASER-QA is not very sensitive to α and is best run with $k \geq 15$ and values of $d \approx n$.

Finally, the precision-recall curve with varying values of t is presented in Figure 4. As may be observed, LASER-QA exhibits a gradual degradation of precision with increasing t correlated with a corresponding improvement in recall. The diversity in the SemEval2016 dataset manifests as a sharper precision drop at high t, as the result set starts to transcend sub-topic boundaries.

6 Conclusions

We considered the problem of CQA retrieval – the task of retrieving relevant historical QA pairs in response to a new question. We formulated a method that builds upon the ideas from local linear embedding to use collective corpus level information across historical QA pairs to embed them in a latent space. In contrast to the mainstream paradigm in literature, we do not explicitly model lexical correlations; instead, we learn an embedding of QA pairs in a way that the local neighborhood in question and answer spaces are preserved. LASER-QA provides a single-model based solution in lieu of learning separate models (e.g., topic and translation models) which are then interpolated to a final scoring; the latter approach has been observed to have reproducilibility issues (Qiu et al., 2013). We analyzed our method empirically against state of the art methods from across families of CQA retrieval methods that use topic models, translation models and deep learning. Our empirical results confirm that the LASER-QA method significantly outperforms the baselines on all IR metrics of interest, underlining the effectiveness of our modelling.
Future Work: A study on the correlation between the kNNs in the LASER-QA embedded space and the original Question and Answer spaces would provide insights into the extent of correlation between manifolds in the original spaces. Further, we would like to see how LASER-QA generalizes to beyond text; one immediate scenario of interest is to explore how pictures and multimedia within QAs may be leveraged within LASER-QA.

Abstract

This paper presents how to generate questions from given passages using neural networks, where large scale QA pairs are automatically crawled and processed from Community-QA website, and used as training data. The contribution of the paper is 2-fold: First, two types of question generation approaches are proposed, one is a retrieval-based method using convolution neural network (CNN), the other is a generation-based method using recurrent neural network (RNN); Second, we show how to leverage the generated questions to improve existing question answering systems. We evaluate our question generation method for the answer sentence selection task on three benchmark datasets, including SQuAD, MS MARCO, and WikiQA. Experimental results show that, by using generated questions as an extra signal, significant QA improvement can be achieved.

1 Introduction

Question Answering (or QA) is one of the core problems for AI, and consists of several typical tasks, i.e. community-based QA (Qiu and Huang, 2015), knowledge-based QA (Berant et al., 2013), text-based QA (Yu et al., 2014), and reading comprehension (Rajpurkar et al., 2016). Most of current QA systems, e.g. (Berant and Liang, 2014), (Qiu and Huang, 2015), (Xiong et al., 2017), (Yin and Schtze, 2017), need labeled QA pairs as training data. Although labeling efforts have been made, such as WebQuestions dataset (Berant et al., 2013) and SimpleQuestions dataset (Bordes et al., 2015) for knowledge-based QA, WikiQA dataset (Yang et al., 2015) for text-based QA, SQuAD dataset (Rajpurkar et al., 2016) and MS MARCO dataset (Nguyen et al., 2016) for reading comprehension, these datasets are still with limited sizes, as labeling is very expensive.

Motivated by this, we explore how to generate questions from given passages using neural networks, with three expected goals: (1) the training data should need few or no human efforts and reflect commonly-asked question intentions; (2) the questions are generated based on natural language passages, and should have good quality; (3) the generated questions should be helpful to QA tasks.

To achieve the 1^{st} goal, we propose to acquire large scale high-quality training data from Community-QA (CQA) website. The motivation of using CQA website for training data collection is that, such websites (e.g., YahooAnswers, Quora, etc.) contain large scale QA pairs generated by real users, and these questions reflect the most common user intentions, and therefore are useful to search, QA, and chatbot scenarios.

To achieve the 2^{nd} goal, we explore two ways to generate questions for a given passage, one is a retrieval-based method using convolution neural network (CNN), the other is a generation-based method using recurrent neural network (RNN). We evaluate the generation quality by BLEU score (Papineni et al., 2002) and human annotations, and discuss their pros and cons in Section 9.

To achieve the 3^{rd} goal, we integrate our question generation approach into an end-to-end QA task, i.e., answer sentence selection, and evaluate its impact on three popular benchmark datasets, SQuAD, MS MARCO, and WikiQA. Experimental results show that, the generated questions can improve the QA quality on all these three datasets.

2 Question Generation

Formally, given a passage S, question generation (**QG**) engine generates a set of questions $\{Q_i\}$,

Proceedings of the 2017 Conference on Empirical Methods in Natural Language Processing, pages 866–874
Copenhagen, Denmark, September 7–11, 2017.

where each generated $\mathcal{Q}_i$ can be answered by $\mathcal{S}$. There are four components in our QG engine:

1. *Question Pattern Mining*, which extracts the frequently-asked question patterns from large scale CQA questions, without any human annotation effort;
2. *Question Pattern Prediction*, which predicts top-N question patterns $\mathcal{Q}_p^1, ..., \mathcal{Q}_p^N$ given $\mathcal{S}$, by a retrieval-based method or a generation-based method. Therefore, "*Prediction*" has two different meanings here: in retrieval-based method, it means to rank existing question patterns and select the highest ranked ones, while in generation-based method, it means to generate question patterns based on $\mathcal{S}$ in a sequence-to-sequence manner, each of which could be a totally new question pattern beyond the existing question pattern set;
3. *Question Topic Selection*, which selects a phrase $\mathcal{Q}_t$ from $\mathcal{S}$ as the question topic, based on a predicted question pattern $\mathcal{Q}_p$. $\mathcal{Q}_t$ will be filled into $\mathcal{Q}_p$ to form a complete question;
4. *Question Ranking*, which ranks all generated questions by a set of features. Here, multiple questions with different intentions could be generated, as $\mathcal{S}$ could contain multiple facts.

3 Question Pattern Mining

A question pattern (or **QP**) is defined as a word sequence $\mathcal{Q}_p = \{w_1, w_2, ..., w_L\}$. Each QP should contain one and only one special word "#" as the placeholder, and all the other $L-1$ words are terminal words. For example, "*who founded # ?*" is a question pattern, and "#" denotes the placeholder, which could be an organization name. We generate questions only using *frequently-asked* question patterns, where "frequently-asked" denotes that each question pattern should be extracted from a large scale question set more than T times, where T denotes a pre-defined threshold.

In this paper, a question cluster (or **QC**) based approach is proposed to mine frequently-asked question patterns from large scale CQA questions.

First, a set of question clusters is collected from CQA webpages, and each question cluster consists of questions that are grouped as related questions[1] by the CQA website. For example, when the query "*what is the population of nyc*" is issued to YahooAnswers[2], the returned page contains a list of related questions including "*population of nyc*", "*nyc population*", "*nyc census*", and etc.

Second, for each question cluster $\mathcal{QC} = \{\mathcal{Q}_1, ..., \mathcal{Q}_K\}$, we enumerate all valid continuous n-grams, each of which should contain at least one content word and its order should be equal or less then 7, as question topic candidates $\{\mathcal{Q}_t^1, ..., \mathcal{Q}_t^M\}$. We then assign an importance score $Impts(\cdot)$ to each question topic candidate $\mathcal{Q}_t^m$:

$$Impts(\mathcal{Q}_t^m) = \sum_{\mathcal{Q}_k \in \mathcal{QC}} \delta(\mathcal{Q}_t^m, \mathcal{Q}_k) \cdot |\mathcal{Q}_t^m|$$

$\mathcal{Q}_t^m$ denotes the m^{th} question topic candidate, $\delta(\mathcal{Q}_t^m, \mathcal{Q}_k)$ equals to 1 when $\mathcal{Q}_t^m$ occurs in $\mathcal{Q}_k$, and 0 otherwise, $|\mathcal{Q}_t^m|$ denotes $\mathcal{Q}_t^m$'s word count, which boosts longer question topic candidates.

For each $\mathcal{QC}$, we select $\mathcal{Q}_t$ with the highest importance score as the question topic, and remove it from each question to form a question pattern. We call each removed question topic as a **historical question topic** of its corresponding question pattern. If $\mathcal{Q}_t$ doesn't exist in a question, ignore it.

Mining question patterns based on question clusters is motivated by the observation that, all questions within a QC tend to ask questions about an identical "*question topic*" (e.g., *nyc* in the above example) from different aspects, or the same aspect but using different expressions. Thus, we can leverage the consensus information among questions to detect the boundary of the question topic: *the more times an n-gram occurs in different questions within a question cluster, the more likely it is the question topic of the current question cluster*.

Although the question pattern mining approach described above is simple, it works surprisingly well. Table 1 shows statistics of question patterns mined from YahooAnswers, and Figure 1 gives examples of frequently-asked question patterns with their corresponding historical question topics. We have two interesting observations:

1. Most frequently-asked question patterns (frequency >=10,000) are with high quality, and reflect the most common user intentions;
2. Most historical question topics extracted are entities. This is achieved without using any prior semantic knowledge base or dictionary.

[1] Usually, each question page of a CQA website contains a field that shows a list of related questions.

4 Question Pattern Prediction

Given a passage $\mathcal{S}$, question pattern prediction predicts $\mathcal{S}$'s most related question patterns, and then use them to generate questions. For example, given $\mathcal{S}$ as "*Tesla Motors is an American automaker and energy storage company co-founded by Elon Musk, Martin Eberhard, Marc Tarpenning, JB Straubel and Ian Wright, and is based in Palo Alto.*", two question patterns can be derived from $\mathcal{S}$, including: (1) *who founded # ?*, which can be inferred by the context around "*co-founded by*", and (2) *where is # located ?*, which can be inferred by the context around "*is based in*". Based on these two question patterns, we can generate two questions, "*who founded Tesla Motors ?*" and "*where is Tesla Motors located ?*" respectively.

4.1 Training Data Construction

We collect QA pairs from YahooAnswers. For each QA pair $< \mathcal{Q}, A >$, if (1) $\mathcal{Q}$ can be matched by a frequently-asked question pattern $\mathcal{Q}_p$, and (2) the matched question topic $\mathcal{Q}_t$ of $\mathcal{Q}$ based on $\mathcal{Q}_p$ exists in A, then we create a training instance as $< A, \mathcal{Q}_p, \mathcal{Q}_t >$. $\mathcal{Q}_t \in A$ makes sure that the question topic occurs in both $\mathcal{Q}$ and A. If the matched question topic only exists in $\mathcal{Q}$, we just discard it. By doing so, we collect a total of 1,984,401 training instances as training data for QP prediction.

Two neural network-based question pattern prediction approaches are explored in this paper:

- *Retrieval-based QP Prediction*, which considers QP prediction as a ranking task;
- *Generation-based QP Prediction*, which considers QP prediction as a generation task.

4.2 Retrieval-based QP Prediction

The retrieval-based QP prediction is done based on an attention-based convolution neural network. It takes a passage and a question pattern as input, and outputs their corresponding vector representations. We denote each input pair as $\langle \mathcal{S}, \mathcal{Q}_p \rangle$, where $\mathcal{S}$ is a passage, and $\mathcal{Q}_p$ is a question pattern.

In the input layer, given an input pair $\langle \mathcal{S}, \mathcal{Q}_p \rangle$, an attention matrix $\mathcal{A}tt \in \Re^{|\mathcal{S}| \times |\mathcal{Q}_p|}$ is generated by pre-trained word embeddings of $\mathcal{S}$ and $\mathcal{Q}_p$, where each element $\mathcal{A}tt_{i,j} \in \mathcal{A}$tt is computed as:

$$\mathcal{A}tt_{i,j} = cosine(v_i^{\mathcal{S}}, v_j^{\mathcal{Q}_p})$$

where $v_i^{\mathcal{S}}$ (or $v_j^{\mathcal{Q}_p}$) denotes the embedding vector of the i^{th} (or j^{th}) word in $\mathcal{S}$ (or $\mathcal{Q}_p$).

Then, column-wise and row-wise max-pooling are applied to $\mathcal{A}tt$ to generate two attention vectors $V^{\mathcal{S}} \in \Re^{|\mathcal{S}|}$ and $V^{\mathcal{Q}_p} \in \Re^{|\mathcal{Q}_p|}$, where the k^{th} elements of $V^{\mathcal{S}}$ and $V^{\mathcal{Q}_p}$ are computed as:

$$V_k^{\mathcal{S}} = \max_{1<l<|\mathcal{Q}_p|} \{\mathcal{A}tt_{k,l}\} \; and \; V_k^{\mathcal{Q}_p} = \max_{1<l<|\mathcal{S}|} \{\mathcal{A}tt_{l,k}\}$$

$V_k^{\mathcal{S}}$ (or $V_k^{\mathcal{Q}_p}$) can be interpreted as the *attention score* of the k^{th} word in $\mathcal{S}$ (or $\mathcal{Q}_p$) with regard to all words in $\mathcal{Q}_p$ (or $\mathcal{S}$).

Next, two *attention distributions* $D^{\mathcal{S}} \in \Re^{|\mathcal{S}|}$ and $D^{\mathcal{Q}_p} \in \Re^{|\mathcal{Q}_p|}$ are generated for $\mathcal{S}$ and $\mathcal{Q}_p$ based on $V^{\mathcal{S}}$ and $V^{\mathcal{Q}_p}$ respectively, where the k^{th} elements of $D^{\mathcal{S}}$ and $D^{\mathcal{Q}_p}$ are computed as:

$$D_k^{\mathcal{S}} = \frac{e^{V_k^{\mathcal{S}}}}{\sum_{l=1}^{|\mathcal{S}|} e^{V_l^{\mathcal{S}}}} \; and \; D_k^{\mathcal{S}\mathcal{Y}} = \frac{e^{V_k^{\mathcal{Q}_p}}}{\sum_{l=1}^{|\mathcal{Q}_p|} e^{V_l^{\mathcal{Q}_p}}}$$

$D_k^{\mathcal{S}x}$ (or $D_k^{\mathcal{S}y}$) can be interpreted as the *normalized attention score* of the k^{th} word in $\mathcal{S}$ (or $\mathcal{Q}_p$) with regard to all words in $\mathcal{Q}_p$ (or $\mathcal{S}$).

Last, we update each pre-trained word embedding $v_k^{\mathcal{S}}$ (or $v_k^{\mathcal{Q}_p}$) to $\hat{v}_k^{\mathcal{S}}$ (or $\hat{v}_k^{\mathcal{Q}_p}$), by multiplying every value in $v_k^{\mathcal{S}}$ (or $v_k^{\mathcal{Q}_p}$) with $D_k^{\mathcal{S}}$ (or $D_k^{\mathcal{Q}_p}$). The underlying intuition of updating pre-trained word embeddings is to *re-weight the importance of each word in $\mathcal{S}$ (or $\mathcal{Q}_p$) based on $\mathcal{Q}_p$ (or $\mathcal{S}$), instead of treating them in an equal manner*.

In the convolution layer, we first derive an input matrix $Z_{\mathcal{S}} = \{l_1, ..., l_{|\mathcal{S}|}\}$, where l_t is the concatenation of a sequence of $m = 2d - 1$[3] updated word embeddings $[\hat{v}_{t-d}^{\mathcal{S}}, ..., \hat{v}_t^{\mathcal{S}}, ..., \hat{v}_{t+d}^{\mathcal{S}}]$, centralized in the t^{th} word in $\mathcal{S}$. Then, the convolution layer performs sliding window-based feature extraction to project each vector representation $l_t \in Z_{\mathcal{S}}$ to a contextual feature vector $h_t^{\mathcal{S}}$:

$$h_t^{\mathcal{S}} = tanh(W_c \cdot l_t)$$

where W_c is the convolution matrix, $tanh(x) = \frac{1-e^{-2x}}{1+e^{-2x}}$ is the activation function. The same operation is performed to $\mathcal{Q}_p$ as well.

In the pooling layer, we aggregate local features extracted by the convolution layer from $\mathcal{S}$, and form a sentence-level global feature vector with a fixed size independent of the length of the input sentence. Here, *max-pooling* is used to force the network to retain the most useful local features by $l_p^{\mathcal{S}} = [v_1^{\mathcal{S}}, ..., v_K^{\mathcal{S}}]$, where:

$$v_i^{\mathcal{S}} = \max_{t=1,...,|\mathcal{S}|} \{h_t^{\mathcal{S}}(i)\}$$

$h_t^{\mathcal{S}}(i)$ denotes the i^{th} value in the vector $h_t^{\mathcal{S}}$. The same operation are performed to $\mathcal{Q}_p$ as well.

In the output layer, one more non-linear transformation is applied to $l_p^{\mathcal{S}}$:

$$y(\mathcal{S}) = tanh(W_s \cdot l_p^{\mathcal{S}})$$

W_s is the semantic projection matrix, $y(\mathcal{S})$ is the final sentence embedding of $\mathcal{S}$. The same operation is performed to $\mathcal{Q}_p$ to obtain $y(\mathcal{Q}_p)$.

We train model parameters W_c and W_s by minimizing the following ranking loss function:

$$\mathcal{L} = \max\{0, M - cosine(y(\mathcal{S}), y(\mathcal{Q}_p)) \\ + cosine(y(\mathcal{S}), y(\mathcal{Q}_p^-))\}$$

where M is a constant, $\mathcal{Q}_p^-$ is a negative instance.

4.3 Generation-based QP Prediction

The generation-based QP prediction is done based on an sequence-to-sequence BiGRU (Bahdanau et al., 2015) that is commonly used in the neural machine translation field.

The encoder reads a word sequence of an input passage $\mathcal{S} = (x_1, ..., x_{|\mathcal{S}|})$, and the decoder predicts a word sequence of an output question pattern $\mathcal{Q}_p = (y_1, ..., y_{|\mathcal{Q}t|})$. The probability of generating a question pattern $\mathcal{Q}_p$ is computed as:

$$p(\mathcal{Q}_p) = \prod_{i=1}^{|\mathcal{Q}_p|} p(y_i | y_1, ..., y_{i-1}, c_i)$$

where each conditional probability is defined as:

$$p(y_i | y_1, ..., y_{i-1}, c_i) = g(y_{i-1}, s_i, c_i)$$

$g(\cdot)$ denotes a nonlinear function that outputs the probability of generating y_i. s_i denotes the hidden state of time t in decoder, which is computed as:

$$s_i = (1 - z_i) \circ s_{i-1} + z_i \circ \tilde{s}_i$$

where

$$\tilde{s}_i = \tanh(WE_{y_{i-1}} + U[r_i \circ s_{i-1}] + Cc_i)$$

$$z_i = \delta(W_z E_{y_{i-1}} + U_z s_{i-1} + C_z c_i)$$

$$r_i = \delta(W_r E_{y_{i-1}} + U_r s_{i-1} + C_r c_i)$$

$\delta(\cdot)$ is the sigmoid function, $\circ$ represents element-wise multiplication, $E_w \in \Re^{m \times 1}$ denotes the word embedding of a word w, W, W_z, $W_r \in \Re^{n \times m}$, U, U_z, $U_r \in \Re^{n \times n}$, and C, C_z, $C_r \in \Re^{n \times 2n}$ are weights. c_i denotes the context vector, which is computed as:

$$c_i = \sum_{j=1}^{|\mathcal{S}|} \alpha_{ij} h_j$$

where

$$\alpha_{ij} = \frac{exp(e_{ij})}{\sum_{k=1}^{|\mathcal{S}|} exp(e_{ik})}$$

$$e_{ij} = v_a^T \tanh(W_a s_{i-1} + U_a h_j)$$

$v_a \in \Re^{n'}$, $W_a \in \Re^{n' \times n}$, and $U_a \in \Re^{n' \times 2n}$ are weights. h_j denotes the j^{th} hidden state from encoder, which is the concatenation of the forward hidden state $\overrightarrow{h}_j$ and the back forward state $\overleftarrow{h}_j$.

[3] In this paper, m is set to 3.

For training, stochastic gradient descent (SGD) algorithm is used, and Adadelta (Zeiler, 2012) is used to adapt the learning rate of each parameter. Given a batch of $D = \{< \mathcal{S}, \mathcal{Q}_p >\}_{i=1}^{M}$ pairs with size M instances, the objective function is to minimize the negative log-likelihood:

$$\mathcal{L} = -\frac{1}{M} \sum_{<\mathcal{S},\mathcal{Q}_p>} \sum_{t=1}^{T} log(p(y_t|y_{<t}, \mathcal{S}))$$

For prediction, beam search is used to output the top-N question pattern predictions.

Retrieval-based approach can only find existing question patterns for each passage, but it makes sure that each question pattern comes from real questions and is in a good grammatical form; Generation-based approach, on the other hand, can generate totally new question patterns beyond existing question pattern set. We will compare both of them in the experimental part (Section 8).

5 Question Topic Selection

Given a passage $\mathcal{S}$ and a predicted question pattern $\mathcal{Q}_p$, question topic selection selects an n-gram (or a phrase) $\mathcal{Q}_t$ from $\mathcal{S}$, which can be then filled into $\mathcal{Q}_p$ to form a complete question. Since we have two question pattern prediction methods, we have two ways to select the question topic $\mathcal{Q}_t$ as well.

For $\mathcal{Q}_p$ from retrieval-based method, two types of prior knowledge are used to extract question topic candidates from $\mathcal{S}$, including:

- Entities as question topic candidates, which are detected based on Freebase[4] entities;
- Noun phrases as question topic candidates, which are detected based on the Stanford parser (Klein and Manning, 2003).

Once a question topic candidate $\mathcal{Q}_t$ is extracted from $\mathcal{S}$, we then measure how $\mathcal{Q}_t$ can fit $\mathcal{Q}_p$ by:

$$s(\mathcal{Q}_t, \mathcal{Q}_p) = \frac{1}{N} \cdot \sum_k \#(\mathcal{Q}_p^{t_k}) \cdot dist(v_{\mathcal{Q}_t}, v_{\mathcal{Q}_p^{t_k}})$$

$s(\mathcal{Q}_t, \mathcal{Q}_p)$ denotes the confidence that $\mathcal{Q}_t$ can be filled into $\mathcal{Q}_p$ to generate a reasonable question. $\mathcal{Q}_p^{t_k}$ denotes the k^{th} historical question topic of $\mathcal{Q}_p$. $\#(\mathcal{Q}_p^{t_k})$ denotes the number of times that $\mathcal{Q}_p^{t_k}$ is extracted from different question clusters to generate $\mathcal{Q}_p$. v_p denotes the question topic embedding of p, which is computed as the average of word embeddings in p. $dist(\cdot)$ denotes the cosine distance between two question topic embeddings. $N = \sum_k \#(\mathcal{Q}_p^{t_k})$ denotes the total number of historical question topics of $\mathcal{Q}_p$. The basic principle of the above equation is that, *the historical question topics of a given question pattern can help on measuring how possible a question topic candidate can be filled into this question pattern to form a reasonable question.* For example, as most historical question topics of "*who founded # ?*" are organization names, then it is very unlikely a date or a film name is suitable for this question pattern to generate a reasonable question.

For $\mathcal{Q}_p$ from generation-based method, suppose the placeholder # is the i^{th} word in $\mathcal{Q}_p$, then we select the j^{th} word $w_j \in \mathcal{S}$ as the question topic, which satisfies the following constraint:

$$w_j = \arg\max_{w_{j'} \in \mathcal{S}} \alpha_{ij'} = \arg\max_{w_{j'} \in \mathcal{S}} \frac{exp(e_{ij'})}{\sum_{k=1}^{|\mathcal{S}|} exp(e_{ik})}$$

This question topic selection strategy leverages the attention scores between $\mathcal{S}$ and $\mathcal{Q}_p$, and can be considered as a *COPY* mechanism.

6 Question Ranking

Given a predicted question pattern $\mathcal{Q}_p$ and a selected question topic $\mathcal{Q}_t$ of an input passage $\mathcal{S}$, a complete question $\mathcal{Q}$ can be simply generated by replacing $\#$ in $\mathcal{Q}_p$ with $\mathcal{Q}_t$. We use a set of features to rank generated question candidates:

- *question pattern prediction score*, which is the prediction score by either retrieval-based approach or generation-based approach;
- *question topic selection score*, for retrieval-based approach, this score is computed as $s(\mathcal{Q}_t, \mathcal{Q}_p)$, while for generation-based approach, this score is the attention score;
- *QA matching score*, which measures relevance between generated question $\mathcal{Q}$ and $\mathcal{S}$.
- *word overlap between* $\mathcal{Q}$ and $\mathcal{S}$, which counts number of words that co-occur in $\mathcal{Q}$ and $\mathcal{S}$;
- *question pattern frequency*, which equals to the extraction frequency of $\mathcal{Q}_p$, if $\mathcal{Q}$ is generated from or matched by $\mathcal{Q}_p$, and 0 otherwise.

All features are combined by a linear model as:

$$p(\mathcal{Q}|\mathcal{S}) = \sum_i \lambda_i \cdot h_i(\mathcal{Q}, \mathcal{S}, \mathcal{Q}_p, \mathcal{Q}_t)$$

[4] https://developers.google.com/freebase/

where $h_i(\mathcal{Q}, \mathcal{S}, \mathcal{Q}_p, \mathcal{Q}_t)$ is one of the features described above, and λ_i is the corresponding weight.

7 Question Generation for QA

This section describes how question generation can improve existing QA systems. There are several types of QA systems, i.e. knowledge-based QA, community-based QA, text-based QA, etc, and in this paper, we focus on text-based QA task (a.k.a. answer sentence selection), which aims to select one or multiple answer sentences from a text given an input question. We select this task as it can be considered as a dual task of QG.

A typical answer sentence selection method, such as (Yin et al., 2016; Santos et al., 2016; Miller et al., 2016; Tymoshenko et al., 2016), computes the relevance score between input question $\mathcal{Q}$ and each answer candidate $\mathcal{A}$, and selects the one with the highest relevance score as the final answer:

$$\widehat{\mathcal{A}} = \arg\max_{\mathcal{A}} P(\mathcal{A}|\mathcal{Q})$$

Motivated by Dual Learning (He et al., 2016), we integrate question generation into answer ranking procedure, by changing the above formula to:

$$\widehat{\mathcal{A}} = \arg\max_{\mathcal{A}}\{P(\mathcal{A}|\mathcal{Q}) + \lambda \cdot QQ(\mathcal{Q}, \mathcal{Q}^{gen}_{max})\}$$

λ is hyper-parameter, and in order to compute $QQ(\mathcal{Q}, \mathcal{Q}^{gen}_{max})$, we generate top-10 questions $\{\mathcal{Q}^{gen}_1, ..., \mathcal{Q}^{gen}_{10}\}$ for current answer candidate $\mathcal{A}$, and then compute the *question-to-generated question* matching score $QQ(\mathcal{Q}, \mathcal{Q}^{gen}_{max})$, by computing the similarity between input question $\mathcal{Q}$ and generated questions $\{\mathcal{Q}^{gen}_1, ..., \mathcal{Q}^{gen}_{10}\}$ as:

$$QQ(\mathcal{Q}, \mathcal{Q}^{gen}_{max}) = \arg\max_{i=1,...,10} sim(\mathcal{Q}, \mathcal{Q}^{gen}_i) \cdot p(\mathcal{Q}^{gen}_i)$$

$sim(\mathcal{Q}, \mathcal{Q}^{gen}_i)$ is the similarity between the input question $\mathcal{Q}$ and the i^{th} generated question $\mathcal{Q}^{gen}_i$, and computed as the cosine distance between averaged word embedding of $\mathcal{Q}$ and averaged word embedding of $\mathcal{Q}^{gen}_i$, $p(\mathcal{Q}^{gen}_i)$ denotes the posterior probability that is computed based on the generation score of each generated question:

$$p(\mathcal{Q}^{gen}_i) = \frac{p(\mathcal{Q}^{gen}_i|\mathcal{A})}{\sum_{i'=1}^{10} p(\mathcal{Q}^{gen}_{i'}|\mathcal{A})}$$

$p(\mathcal{Q}^{gen}_i|\mathcal{A})$ is output by the question generation model described in Section 6. The underlying motivation is that, *the questions generated from correct answers are more likely to be similar to labeled questions than questions generated from wrong answers*.

8 Related Work

Yao et al. (2012) proposed a semantic-based question generation approach, which first parses the input sentence into its corresponding Minimal Recursion Semantics (MRS) representation, and then generates a question guided by the English Resource Grammar that includes a large scale hand-crafted lexicon and grammar rules.

Labutov et al. (2015) proposed an 'ontology-crowd-relevance' method for question generation. First, Freebase types and Wikipedia session names are used as semantic tags to understand texts. Question are then generated based on question templates that are aligned with types/session names and labeled by crowdsourcing. All generated questions are ranked by a relevance model.

Chali and Hasan (2015) proposed a topic-to-question method, which uses about 350 general-purpose rules to transform the semantic-role labeled sentences into corresponding questions.

Serban et al. (2016) used the encoder-decoder framework to generate 30M QA pairs, but their inputs are knowledge triples, instead of passages.

Song and Zhao (2016) proposed a question generation method using question template seeds and used search engine to do question expansion.

Du et al. (2017) proposed a neural question generation method using a vanilla sequence-to-sequence RNN model, which is most-related to our work. But this method is still based on labeled dataset, and tried RNN only.

Comparing to all these related work mentioned above, our question generation approach has two uniqueness: (1) all question patterns, that are used as training data for question generation, are automatically extracted from a large scale CQA question set without any crowdsourcing effort. Such question patterns reflect the most common user intentions, and therefore are useful to search, QA, and chatbot engines; (2) it is also the first time question generation is integrated and evaluated in an end-to-end QA task directly, and shows significant improvements.

9 Experiment

9.1 Dataset

As described in Section 4.1, we collect $1,984,401$ $< A, \mathcal{Q}_p, \mathcal{Q}_t >$ pairs from YahooAnswers, and use them as the training set of the question pattern prediction model. We re-use the dev sets and test sets of SQuAD, MS MARCO, and WikiQA, to evaluate the quality of generated questions. The dataset statistics are in Table 2.

	# of QA Pairs
training set	1,984,401
dev set (SQuAD)	26,442
test set (SQuAD)	26,604
dev set (MS MARCO)	39,510
test set (MS MARCO)	42,850
dev set (WikiQA)	2,733
test set (WikiQA)	6,165

Table 2: Dataset Statistics.

Besides, an answer sentence selection model (Yin et al., 2016) is trained based on the 1,984,401 QA pairs from the training set as well, and used to compute the QA matching score for question ranking, as we described in Section 6. Feature weights for question ranking are optimized on dev set.

9.2 Evaluation on Question Generation

We first perform a vanilla sequence-to-sequence method (Du et al., 2017) using the original training sets of these three datasets, and show QG results in Table 3, where BLEU 4 score is used as the metric.

BLEU 4	Seq2Seq-QG
SQuAD	12.28
MS MARCO	10.46
WikiQA	2.04

Table 3: QG results using original training sets.

We then evaluate the quality of the generated questions based on auto-extracted training set. For each passage in the test set, we generate two top-1 questions based on retrieval-based method and generation-based method respectively, and then compare them with labeled questions using *BLEU 4* as the metric. Results are listed in Table 4.

BLEU 4	R-QG	G-QG
SQuAD (crawled)	9.87	12.39
MS MARCO (crawled)	9.86	11.46
WikiQA (crawled)	11.38	13.57

Table 4: QG results using auto-extracted training set, where **R-QG** denotes results from Retrieval-based QG method, **G-QG** denotes results from Generation-based QG method.

From Table 3 and 4 we can see two findings: (1) Comparing to QG results based on original labeled training sets, G-QG achieves comparable or better results. We think this is due to two facts: first, the size of the automatically constructed training set is much larger than the labeled training sets, and second, as the QA pairs from CQA websites are generated by real users, the quality is good. (2) Generation-based QG performs better than Retrieval-based QG. By analyzing outputs we find that, for question pattern prediction, both retrieval-based and generation-based methods perform similarly. However, Generation-based QG performs better than Retrieval-based QG on question topic selection. This could be caused by the fact that, in Generation-based QG, question topic selection is based on the attention mechanism, which is optimized together with question pattern prediction in an end-to-end way; while in Retrieval-based QG, question topic selection is a separate task, and based on the similarity between each question topic candidate and historical question topics of a given question pattern. The embedding of each question topic is pre-trained, which is not directly related to the question generation task. So such method cannot handle unseen question topics very well. Another disadvantage of Retrieval-based QG is that, each time, we have to compute the similarity between the input passage and each question pattern. When question pattern size is large, the computation is very expensive.

In order to better understand the question generation quality, we manually check a set of sampled outputs, and list the main errors in Figure 2:

- *Multi-Fact Error* (40%). Most input passages include more than one fact. For such a question, it is reasonable to generate different questions from different aspects, all of which can be answered by the input passage. For each passage in QAGen, we only label one question as ground truth. In the future, we will extend QAGen to be a more comprehensive dataset, by labeling multiple questions to each passage for more reasonable evaluation;

- *Paraphrase Error* (30%). The same question can be expressed by different ways. Labeling more paraphrased questions for a passage can alleviate this issue as well;

- *Question Topic Selection Error* (15%). This error is caused by selecting either a total-

ly wrong question topic, or a partially right question topic. In the future, we plan to develop an independent question topic selection model for the question generation task.

9.3 Evaluation on QA

As described in Section 7, we combine question generation into QA system for answer sentence selection task, and do evaluation on SQuAD, MS MARCO, and WikiQA. Evaluation results are shown in Table 5, 6, and 7, where **QA** denotes the result of our in-house implementation of a retrieval-based answer selection approach (DocChat) proposed by (Yan et al., 2016), **QA+QG** denotes result by combining question-to-generated question matching score with DocChat score.

QA+QG	0.7742	0.7893	0.6624

Table 7: Impact of QG on WikiQA.

The improvement on MS MARCO dataset is most significant. We think it due to the fact that, the questions from MS MARCO dataset are from Bing search log, which are generated naturally by real users. This is similar to the questions coming for CQA websites; while questions from the other datasets are labeled by crowd-sourcing.

In order to explain these improvements, two datasets, *WikiQG+* and *WikiQG-*, are built from WikiQA test set: given each document and its labeled question, we pair the question with its CORRECT answer sentence as a QA pair and add it to WikiQG+; we also pair the same question with a randomly selected WRONG answer sentence as a QA pair and add it to WikiQG-. Then, we generate questions for passages in WikiQG+ and WikiQG- respectively, and compare them with labeled questions. The BLEU 4 score is **0.2031** on WikiQG+, and 0.1301 on WikiQG-, which indicates that the questions generated from correct answers are more likely to be similar to labeled questions than questions generated from wrong answers.

10 Conslusion

This paper presents a neural question generation method that is based on training data collected from CQA questions. We integrate the QA pair generation task into an end-to-end QA task, and show significant improvements, which indicates that, QA task and QG are dual tasks that can boost each other. In the future, we will explore more ways to leverage QG for QA task.

Abstract

Question answering (QA) systems are sensitive to the many different ways natural language expresses the same information need. In this paper we turn to paraphrases as a means of capturing this knowledge and present a general framework which learns felicitous paraphrases for various QA tasks. Our method is trained end-to-end using question-answer pairs as a supervision signal. A question and its paraphrases serve as input to a neural scoring model which assigns higher weights to linguistic expressions most likely to yield correct answers. We evaluate our approach on QA over Freebase and answer sentence selection. Experimental results on three datasets show that our framework consistently improves performance, achieving competitive results despite the use of simple QA models.

1 Introduction

Enabling computers to automatically answer questions posed in natural language on any domain or topic has been the focus of much research in recent years. Question answering (QA) is challenging due to the many different ways natural language expresses the same information need. As a result, small variations in semantically equivalent questions, may yield different answers. For example, a hypothetical QA system must recognize that the questions "*who created microsoft*" and "*who started microsoft*" have the same meaning and that they both convey the `founder` relation in order to retrieve the correct answer from a knowledge base.

Given the great variety of surface forms for semantically equivalent expressions, it should come as no surprise that previous work has investigated the use of paraphrases in relation to question answering. There have been three main strands of research. The first one applies paraphrasing to match natural language and logical forms in the context of semantic parsing. Berant and Liang (2014) use a template-based method to heuristically generate canonical text descriptions for candidate logical forms, and then compute paraphrase scores between the generated texts and input questions in order to rank the logical forms. Another strand of work uses paraphrases in the context of neural question answering models (Bordes et al., 2014a,b; Dong et al., 2015). These models are typically trained on question-answer pairs, and employ question paraphrases in a multi-task learning framework in an attempt to encourage the neural networks to output similar vector representations for the paraphrases.

The third strand of research uses paraphrases more directly. The idea is to paraphrase the question and then submit the rewritten version to a QA module. Various resources have been used to produce question paraphrases, such as rule-based machine translation (Duboue and Chu-Carroll, 2006), lexical and phrasal rules from the Paraphrase Database (Narayan et al., 2016), as well as rules mined from Wiktionary (Chen et al., 2016) and large-scale paraphrase corpora (Fader et al., 2013). A common problem with the generated paraphrases is that they often contain inappropriate candidates. Hence, treating all paraphrases as equally felicitous and using them to answer the question could degrade performance. To remedy this, a scoring model is often employed, however independently of the QA system used to find the answer (Duboue and Chu-Carroll, 2006; Narayan et al., 2016). Problematically, the separate paraphrase models used in previous work do not fully utilize the supervision signal from the training data, and as such cannot be properly tuned

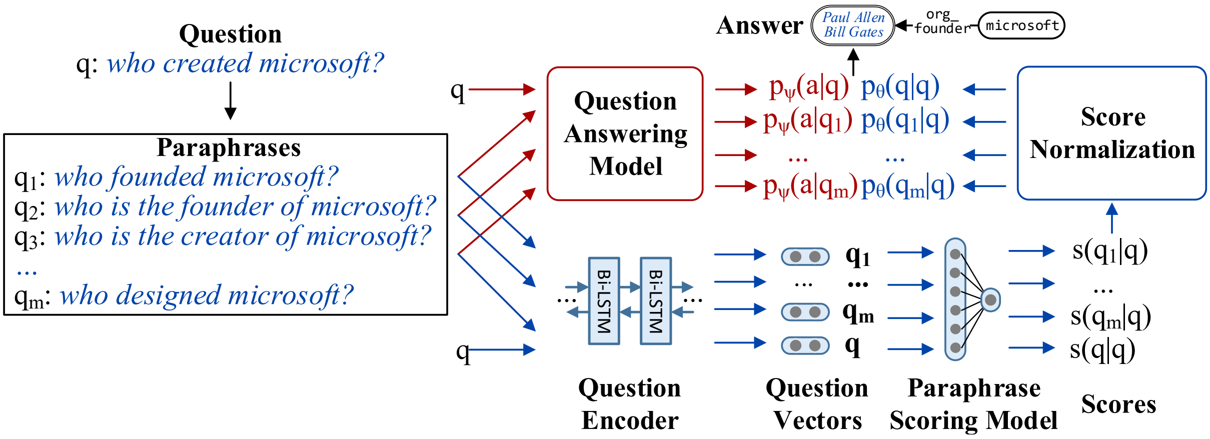

Figure 1: We use three different methods to generate candidate paraphrases for input q. The question and its paraphrases are fed into a neural model which scores how suitable they are. The scores are normalized and used to weight the results of the question answering model. The entire system is trained end-to-end using question-answer pairs as a supervision signal.

to the question answering tasks at hand. Based on the large variety of possible transformations that can generate paraphrases, it seems likely that the kinds of paraphrases that are useful would depend on the QA application of interest (Bhagat and Hovy, 2013). Fader et al. (2014) use features that are defined over the original question and its rewrites to score paraphrases. Examples include the pointwise mutual information of the rewrite rule, the paraphrase's score according to a language model, and POS tag features. In the context of semantic parsing, Chen et al. (2016) also use the ID of the rewrite rule as a feature. However, most of these features are not informative enough to model the quality of question paraphrases, or cannot easily generalize to unseen rewrite rules.

In this paper, we present a general framework for learning paraphrases for question answering tasks. Given a natural language question, our model estimates a probability distribution over candidate answers. We first generate paraphrases for the question, which can be obtained by one or several paraphrasing systems. A neural scoring model predicts the quality of the generated paraphrases, while learning to assign higher weights to those which are more likely to yield correct answers. The paraphrases and the original question are fed into a QA model that predicts a distribution over answers given the question. The entire system is trained end-to-end using question-answer pairs as a supervision signal. The framework is flexible, it does not rely on specific paraphrase or QA models. In fact, this plug-and-play functionality allows to learn specific paraphrases for different QA tasks and to explore the merits of different paraphrasing models for different applications.

We evaluate our approach on QA over Freebase and text-based answer sentence selection. We employ a range of paraphrase models based on the Paraphrase Database (PPDB; Pavlick et al. 2015), neural machine translation (Mallinson et al., 2016), and rules mined from the WikiAnswers corpus (Fader et al., 2014). Results on three datasets show that our framework consistently improves performance; it achieves state-of-the-art results on GraphQuestions and competitive performance on two additional benchmark datasets using simple QA models.

2 Problem Formulation

Let q denote a natural language question, and a its answer. Our aim is to estimate $p\,(a|q)$, the conditional probability of candidate answers given the question. We decompose $p\,(a|q)$ as:

$$p\,(a|q) = \sum_{q' \in H_q \cup \{q\}} \underbrace{p_\psi\,(a|q')}_{\text{QA Model}} \; \underbrace{p_\theta\,(q'|q)}_{\text{Paraphrase Model}} \qquad (1)$$

where H_q is the set of paraphrases for question q, ψ are the parameters of a QA model, and θ are the parameters of a paraphrase scoring model.

As shown in Figure 1, we first generate candidate paraphrases H_q for question q. Then, a neural scoring model predicts the quality of the generated paraphrases, and assigns higher weights to the paraphrases which are more likely to obtain

Input: what be the zip code of the largest car manufacturer	
what be the zip code of the largest vehicle manufacturer	PPDB
what be the zip code of the largest car producer	PPDB
what be the postal code of the biggest automobile manufacturer	NMT
what be the postcode of the biggest car manufacturer	NMT
what be the largest car manufacturer 's postal code	Rule
zip code of the largest car manufacturer	Rule

Table 1: Paraphrases obtained for an input question from different models (PPDB, NMT, Rule). Words are lowercased and stemmed.

the correct answers. These paraphrases and the original question simultaneously serve as input to a QA model that predicts a distribution over answers for a given question. Finally, the results of these two models are fused to predict the answer. In the following we will explain how $p\left(q'|q\right)$ and $p\left(a|q'\right)$ are estimated.

2.1 Paraphrase Generation

As shown in Equation (1), the term $p\left(a|q\right)$ is the sum over q and its paraphrases H_q. Ideally, we would generate all the paraphrases of q. However, since this set could quickly become intractable, we restrict the number of candidate paraphrases to a manageable size. In order to increase the coverage and diversity of paraphrases, we employ three methods based on: (1) lexical and phrasal rules from the Paraphrase Database (Pavlick et al., 2015); (2) neural machine translation models (Sutskever et al., 2014; Bahdanau et al., 2015); and (3) paraphrase rules mined from clusters of related questions (Fader et al., 2014). We briefly describe these models below, however, there is nothing inherent in our framework that is specific to these, any other paraphrase generator could be used instead.

2.1.1 PPDB-based Generation

Bilingual pivoting (Bannard and Callison-Burch, 2005) is one of the most well-known approaches to paraphrasing; it uses bilingual parallel corpora to learn paraphrases based on techniques from phrase-based statistical machine translation (SMT, Koehn et al. 2003). The intuition is that two English strings that translate to the same foreign string can be assumed to have the same meaning. The method first extracts a bilingual phrase table and then obtains English paraphrases by pivoting through foreign language phrases.

Drawing inspiration from syntax-based SMT, Callison-Burch (2008) and Ganitkevitch et al. (2011) extended this idea to syntactic paraphrases, leading to the creation of PPDB (Ganitkevitch et al., 2013), a large-scale paraphrase database containing over a billion of paraphrase pairs in 24 different languages. Pavlick et al. (2015) further used a supervised model to automatically label paraphrase pairs with entailment relationships based on natural logic (MacCartney, 2009). In our work, we employ bidirectionally entailing rules from PPDB. Specifically, we focus on lexical (single word) and phrasal (multiword) rules which we use to paraphrase questions by replacing words and phrases in them. An example is shown in Table 1 where we substitute *car* with *vehicle* and *manufacturer* with *producer*.

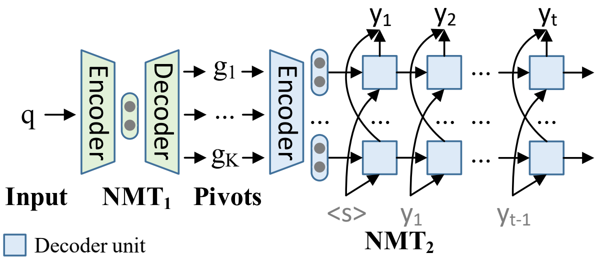

Figure 2: Overview of NMT-based paraphrase generation. NMT$_1$ (green) translates question q into pivots $g_1 \ldots g_K$ which are then back-translated by NMT$_2$ (blue) where K decoders jointly predict tokens at each time step, rather than only conditioning on one pivot and independently predicting outputs.

2.1.2 NMT-based Generation

Mallinson et al. (2016) revisit bilingual pivoting in the context of neural machine translation (NMT, Sutskever et al. 2014; Bahdanau et al. 2015) and present a paraphrasing model based on neural networks. At its core, NMT is trained end-to-end to maximize the conditional probability of a correct translation given a source sentence, using a bilingual corpus. Paraphrases can be obtained by translating an English string into a foreign language and then back-translating it into English. NMT-based pivoting models offer advantages over conventional methods such as the ability to learn continuous representations and to consider wider context while paraphrasing.

In our work, we select German as our pivot following Mallinson et al. (2016) who show that it outperforms other languages in a wide range of paraphrasing experiments, and pretrain two NMT systems, English-to-German (EN-DE) and

Source	Target
the average size of __	what be __ average size
__ be locate on which continent	what continent be __ a part of
language speak in __	what be the official language of __
what be the money in __	what currency do __ use

Table 2: Examples of rules used in the rule-based paraphrase generator.

German-to-English (DE-EN). A naive implementation would translate a question to a German string and then back-translate it to English. However, using only one pivot can lead to inaccuracies as it places too much faith on a single translation which may be wrong. Instead, we translate from multiple pivot sentences (Mallinson et al., 2016). As shown in Figure 2, question q is translated to K-best German pivots, $\mathcal{G}_q = \{g_1, \ldots, g_K\}$. The probability of generating paraphrase $q' = y_1 \ldots y_{|q'|}$ is decomposed as:

$$\begin{aligned} p\left(q' | \mathcal{G}_q\right) &= \prod_{t=1}^{|q'|} p\left(y_t | y_{<t}, \mathcal{G}_q\right) \\ &= \prod_{t=1}^{|q'|} \sum_{k=1}^{K} p\left(g_k | q\right) p\left(y_t | y_{<t}, g_k\right) \end{aligned} \tag{2}$$

where $y_{<t} = y_1, \ldots, y_{t-1}$, and $|q'|$ is the length of q'. Probabilities $p\left(g_k|q\right)$ and $p\left(y_t|y_{<t}, g_k\right)$ are computed by the EN-DE and DE-EN models, respectively. We use beam search to decode tokens by conditioning on multiple pivoting sentences. The results with the best decoding scores are considered candidate paraphrases. Examples of NMT paraphrases are shown in Table 1.

Compared to PPDB, NMT-based paraphrases are syntax-agnostic, operating on the surface level without knowledge of any underlying grammar. Furthermore, paraphrase rules are captured implicitly and cannot be easily extracted, e.g., from a phrase table. As mentioned earlier, the NMT-based approach has the potential of performing major rewrites as paraphrases are generated while considering wider contextual information, whereas PPDB paraphrases are more local, and mainly handle lexical variation.

2.1.3 Rule-Based Generation

Our third paraphrase generation approach uses rules mined from the WikiAnswers corpus (Fader et al., 2014) which contains more than 30 million question clusters labeled as paraphrases by WikiAnswers[1] users. This corpus is a large resource (the average cluster size is 25), but is relatively noisy due to its collaborative nature – 45% of question pairs are merely related rather than genuine paraphrases. We therefore followed the method proposed in (Fader et al., 2013) to harvest paraphrase rules from the corpus. We first extracted question templates (i.e., questions with at most one wild-card) that appear in at least ten clusters. Any two templates co-occurring (more than five times) in the same cluster and with the same arguments were deemed paraphrases. Table 2 shows examples of rules extracted from the corpus. During paraphrase generation, we consider substrings of the input question as arguments, and match them with the mined template pairs. For example, the stemmed input question in Table 1 can be paraphrased using the rules ("*what be the zip code of __*", "*what be __ 's postal code*") and ("*what be the zip code of __*", "*zip code of __*"). If no exact match is found, we perform fuzzy matching by ignoring stop words in the question and templates.

2.2 Paraphrase Scoring

Recall from Equation (1) that $p_\theta\left(q'|q\right)$ scores the generated paraphrases $q' \in H_q \cup \{q\}$. We estimate $p_\theta\left(q'|q\right)$ using neural networks given their successful application to paraphrase identification tasks (Socher et al., 2011; Yin and Schütze, 2015; He et al., 2015). Specifically, the input question and its paraphrases are encoded as vectors. Then, we employ a neural network to obtain the score $s\left(q'|q\right)$ which after normalization becomes the probability $p_\theta\left(q'|q\right)$.

Encoding Let $q = q_1 \ldots q_{|q|}$ denote an input question. Every word is initially mapped to a d-dimensional vector. In other words, vector $\mathbf{q}_t$ is computed via $\mathbf{q}_t = \mathbf{W}_q \mathbf{e}\left(q_t\right)$, where $\mathbf{W}_q \in \mathbb{R}^{d \times |\mathcal{V}|}$ is a word embedding matrix, $|\mathcal{V}|$ is the vocabulary size, and $\mathbf{e}\left(q_t\right)$ is a one-hot vector. Next, we use a bi-directional recurrent neural network with long short-term memory units (LSTM, Hochreiter and Schmidhuber 1997) as the question encoder, which is shared by the input questions and their paraphrases. The encoder recursively processes tokens one by one, and uses the encoded vectors to represent questions. We compute the hidden vectors at the t-th time step via:

[1] wiki.answers.com

$$\begin{aligned}\overrightarrow{\mathbf{h}}_t &= \text{LSTM}\left(\overrightarrow{\mathbf{h}}_{t-1}, \mathbf{q}_t\right), t = 1, \ldots, |q| \\ \overleftarrow{\mathbf{h}}_t &= \text{LSTM}\left(\overleftarrow{\mathbf{h}}_{t+1}, \mathbf{q}_t\right), t = |q|, \ldots, 1\end{aligned} \tag{3}$$

where $\overrightarrow{\mathbf{h}}_t, \overleftarrow{\mathbf{h}}_t \in \mathbb{R}^n$. In this work we follow the LSTM function described in Pham et al. (2014). The representation of q is obtained by:

$$\mathbf{q} = \left[\overrightarrow{\mathbf{h}}_{|q|}, \overleftarrow{\mathbf{h}}_1\right] \tag{4}$$

where $[\cdot, \cdot]$ denotes concatenation, and $\mathbf{q} \in \mathbb{R}^{2n}$.

Scoring After obtaining vector representations for q and q', we compute the score $s(q'|q)$ via:

$$s(q'|q) = \mathbf{w}_s \cdot [\mathbf{q}, \mathbf{q}', \mathbf{q} \odot \mathbf{q}'] + b_s \tag{5}$$

where $\mathbf{w}_s \in \mathbb{R}^{6n}$ is a parameter vector, $[\cdot, \cdot, \cdot]$ denotes concatenation, $\odot$ is element-wise multiplication, and b_s is the bias. Alternative ways to compute $s(q'|q)$ such as dot product or with a bilinear term were not empirically better than Equation (5) and we omit them from further discussion.

Normalization For paraphrases $q' \in H_q \cup \{q\}$, the probability $p_\theta(q'|q)$ is computed via:

$$p_\theta(q'|q) = \frac{\exp\{s(q'|q)\}}{\sum_{r \in H_q \cup \{q\}} \exp\{s(r|q)\}} \tag{6}$$

where the paraphrase scores are normalized over the set $H_q \cup \{q\}$.

2.3 QA Models

The framework defined in Equation (1) is relatively flexible with respect to the QA model being employed as long as it can predict $p_\psi(a|q')$. We illustrate this by performing experiments across different tasks and describe below the models used for these tasks.

Knowledge Base QA In our first task we use the Freebase knowledge base to answer questions. Query graphs for the questions typically contain more than one predicate. For example, to answer the question "*who is the ceo of microsoft in 2008*", we need to use one relation to query "*ceo of microsoft*" and another relation for the constraint "*in 2008*". For this task, we employ the SIMPLEGRAPH model described in Reddy et al. (2016, 2017), and follow their training protocol and feature design. In brief, their method uses rules to convert questions to ungrounded logical forms, which are subsequently matched against Freebase subgraphs. The QA model learns from question-answer pairs: it extracts features for pairs of questions and Freebase subgraphs, and uses a logistic regression classifier to predict the probability that a candidate answer is correct. We perform entity linking using the Freebasee/KG API on the original question (Reddy et al., 2016, 2017), and generate candidate Freebase subgraphs. The QA model estimates how likely it is for a subgraph to yield the correct answer.

Answer Sentence Selection Given a question and a collection of relevant sentences, the goal of this task is to select sentences which contain an answer to the question. The assumption is that correct answer sentences have high semantic similarity to the questions (Yu et al., 2014; Yang et al., 2015; Miao et al., 2016). We use two bidirectional recurrent neural networks (BILSTM) to separately encode questions and answer sentences to vectors (Equation (4)). Similarity scores are computed as shown in Equation (5), and then squashed to $(0, 1)$ by a sigmoid function in order to predict $p_\psi(a|q')$.

2.4 Training and Inference

We use a log-likelihood objective for training, which maximizes the likelihood of the correct answer given a question:

$$\text{maximize} \sum_{(q,a) \in \mathcal{D}} \log p(a|q) \tag{7}$$

where $\mathcal{D}$ is the set of all question-answer training pairs, and $p(a|q)$ is computed as shown in Equation (1). For the knowledge base QA task, we predict how likely it is that a subgraph obtains the correct answer, and the answers of some candidate subgraphs are partially correct. So, we use the binary cross entropy between the candidate subgraph's F1 score and the prediction as the objective function. The RMSProp algorithm (Tieleman and Hinton, 2012) is employed to solve this non-convex optimization problem. Moreover, dropout is used for regularizing the recurrent neural networks (Pham et al., 2014).

At test time, we generate paraphrases for the question q, and then predict the answer by:

$$\hat{a} = \arg\max_{a' \in \mathcal{C}_q} p(a'|q) \tag{8}$$

where $\mathcal{C}_q$ is the set of candidate answers, and $p(a'|q)$ is computed as shown in Equation (1).

3 Experiments

We compared our model which we call PARA4QA (as shorthand for learning to paraphrase for question answering) against multiple previous systems on three datasets. In the following we introduce these datasets, provide implementation details for our model, describe the systems used for comparison, and present our results.

3.1 Datasets

Our model was trained on three datasets, representative of different types of QA tasks. The first two datasets focus on question answering over a structured knowledge base, whereas the third one is specific to answer sentence selection.

WEBQUESTIONS This dataset (Berant et al., 2013) contains $3,778$ training instances and $2,032$ test instances. Questions were collected by querying the Google Suggest API. A breadth-first search beginning with *wh-* was conducted and the answers were crowd-sourced using Freebase as the backend knowledge base.

GRAPHQUESTIONS The dataset (Su et al., 2016) contains $5,166$ question-answer pairs (evenly split into a training and a test set). It was created by asking crowd workers to paraphrase 500 Freebase graph queries in natural language.

WIKIQA This dataset (Yang et al., 2015) has $3,047$ questions sampled from Bing query logs. The questions are associated with $29,258$ candidate answer sentences, $1,473$ of which contain the correct answers to the questions.

3.2 Implementation Details

Paraphrase Generation Candidate paraphrases were stemmed (Minnen et al., 2001) and lowercased. We discarded duplicate or trivial paraphrases which only rewrite stop words or punctuation. For the NMT model, we followed the implementation[2] and settings described in Mallinson et al. (2016), and used English↔German as the language pair. The system was trained on data released as part of the WMT15 shared translation task (4.2 million sentence pairs). We also had access to back-translated monolingual training data (Sennrich et al., 2016a). Rare words were split into subword units (Sennrich et al., 2016b) to handle out-of-vocabulary words in questions. We used the top 15 decoding results as candidate paraphrases. We used the S size package of PPDB 2.0 (Pavlick et al., 2015) for high precision. At most 10 candidate paraphrases were considered. We mined paraphrase rules from WikiAnswers (Fader et al., 2014) as described in Section 2.1.3. The extracted rules were ranked using the pointwise mutual information between template pairs in the WikiAnswers corpus. The top 10 candidate paraphrases were used.

Training For the paraphrase scoring model, we used GloVe (Pennington et al., 2014) vectors[3] pretrained on Wikipedia 2014 and Gigaword 5 to initialize the word embedding matrix. We kept this matrix fixed across datasets. Out-of-vocabulary words were replaced with a special unknown symbol. We also augmented questions with start-of- and end-of-sequence symbols. Word vectors for these special symbols were updated during training. Model hyperparameters were validated on the development set. The dimensions of hidden vectors and word embeddings were selected from $\{50, 100, 200\}$ and $\{100, 200\}$, respectively. The dropout rate was selected from $\{0.2, 0.3, 0.4\}$. The BILSTM for the answer sentence selection QA model used the same hyperparameters. Parameters were randomly initialized from a uniform distribution $\mathcal{U}(-0.08, 0.08)$. The learning rate and decay rate of RMSProp were 0.01 and 0.95, respectively. The batch size was set to 150. To alleviate the exploding gradient problem (Pascanu et al., 2013), the gradient norm was clipped to 5. Early stopping was used to determine the number of epochs.

3.3 Paraphrase Statistics

Table 3 presents descriptive statistics on the paraphrases generated by the various systems across datasets (training set). As can be seen, the average paraphrase length is similar to the average length of the original questions. The NMT method generates more paraphrases and has wider coverage, while the average number and coverage of the other two methods varies per dataset. As a way of quantifying the extent to which rewriting takes place, we report BLEU (Papineni et al., 2002) and TER (Snover et al., 2006) scores between the original questions and their paraphrases. The NMT

TER (%)	39.18	14.87	38.59	45.38	19.94	43.44	46.10	17.20	48.59

Table 3: Statistics of generated paraphrases across datasets (training set). avg($|q|$): average question length; avg($|q'|$): average paraphrase length; avg($\#q'$): average number of paraphrases; coverage: the proportion of questions that have at least one candidate paraphrase.

method and the rules extracted from WikiAnswers tend to paraphrase more (i.e., have lower BLEU and higher TER scores) compared to PPDB.

3.4 Comparison Systems

We compared our framework to previous work and several ablation models which either do not use paraphrases or paraphrase scoring, or are not jointly trained.

The first baseline only uses the base QA models described in Section 2.3 (SimpleGraph and BiLSTM). The second baseline (AvgPara) does not take advantage of paraphrase scoring. The paraphrases for a given question are used while the QA model's results are directly averaged to predict the answers. The third baseline (DataAugment) employs paraphrases for data augmentation during training. Specifically, we use the question, its paraphrases, and the correct answer to automatically generate new training samples.

In the fourth baseline (SepPara), the paraphrase scoring model is separately trained on paraphrase classification data, without taking question-answer pairs into account. In the experiments, we used the Quora question paraphrase dataset[4] which contains question pairs and labels indicating whether they constitute paraphrases or not. We removed questions with more than 25 tokens and sub-sampled to balance the dataset. We used 90% of the resulting 275K examples for training, and the remaining for development. The paraphrase score $s(q'|q)$ (Equation (5)) was wrapped by a sigmoid function to predict the probability of a question pair being a paraphrase. A binary cross-entropy loss was used as the objective. The classification accuracy on the dev set was 80.6%.

Method	Average F1 (%)	
	GraphQ	WebQ
Sempre (Berant et al., 2013)	10.8	35.7
Jacana (Yao and Van Durme, 2014)	5.1	33.0
ParaSemp (Berant and Liang, 2014)	12.8	39.9
SubGraph (Bordes et al., 2014a)	-	40.4
MCCNN (Dong et al., 2015)	-	40.8
Yao15 (Yao, 2015)	-	44.3
AgendaIL (Berant and Liang, 2015)	-	49.7
STAGG (Yih et al., 2015)	-	48.4 (52.5)
MCNN (Xu et al., 2016)	-	47.0 (53.3)
TypeRerank (Yavuz et al., 2016)	-	**51.6** (52.6)
BiLayered (Narayan et al., 2016)	-	47.2
UDepLambda (Reddy et al., 2017)	**17.6**	49.5
SimpleGraph (baseline)	15.9	48.5
AvgPara	16.1	48.8
SepPara	18.4	49.6
DataAugment	16.3	48.7
Para4QA	**20.4**	**50.7**
−NMT	18.5	49.5
−PPDB	19.5	50.4
−Rule	19.4	49.1

Table 4: Model performance on GraphQuestions and WebQuestions. Results with additional task-specific resources are shown in parentheses. The base QA model is SimpleGraph. Best results in each group are shown in **bold**.

Finally, in order to assess the individual contribution of different paraphrasing resources, we compared the Para4QA model against versions of itself with one paraphrase generator removed (−NMT/−PPDB/−Rule).

3.5 Results

We first discuss the performance of Para4QA on GraphQuestions and WebQuestions. The first block in Table 4 shows a variety of systems previously described in the literature using average F1 as the evaluation metric (Berant et al., 2013). Among these, ParaSemp, SubGraph, MCCNN, and BiLayered utilize paraphrasing resources. The second block compares Para4QA against various related baselines (see Section 3.4). SimpleGraph results on WebQuestions and GraphQuestions are taken from Reddy et al. (2016) and Reddy et al. (2017), respectively.

Overall, we observe that Para4QA outperforms baselines which either do not employ paraphrases (SimpleGraph) or paraphrase scoring (AvgPara, DataAugment), or are not jointly trained (SepPara). On GraphQuestions, our model Para4QA outperforms the previous state of the art by a wide margin. Ablation experiments with one of the paraphrase generators removed

Table 5: Model performance on WIKIQA. +CNT: word matching features introduced in Yang et al. (2015). The base QA model is BILSTM. Best results in each group are shown in **bold**.

show that performance drops most when the NMT paraphrases are not used on GRAPHQUESTIONS, whereas on WEBQUESTIONS removal of the rule-based generator hurts performance most. One reason is that the rule-based method has higher coverage on WEBQUESTIONS than on GRAPHQUESTIONS (see Table 3).

Results on WIKIQA are shown in Table 5. We report MAP and MMR which evaluate the relative ranks of correct answers among the candidate sentences for a question. Again, we observe that PARA4QA outperforms related baselines (see BILSTM, DATAAUGMENT, AVGPARA, and SEPPARA). Ablation experiments show that performance drops most when NMT paraphrases are removed. When word matching features are used (see +CNT in the third block), PARA4QA reaches state of the art performance.

Examples of paraphrases and their probabilities $p_\theta(q'|q)$ (see Equation (6)) learned by PARA4QA are shown in Table 6. The two examples are taken from the development set of GRAPHQUESTIONS and WEBQUESTIONS, respectively. We also show the Freebase relations used to query the correct answers. In the first example, the original question cannot yield the correct answer because of the mismatch between the question and the knowledge base. The paraphrase contains "*role*" in place of "*sort of part*", increasing the chance of overlap between the question and the predicate words. The second question contains an informal expression "*play 4*", which confuses the QA model. The paraphrase model generates "*play for*" and predicts a high paraphrase score for it. More generally, we observe that the model tends to give higher probabilities $p_\theta(q'|q)$ to paraphrases biased towards delivering appropriate answers.

Examples	$p_\theta(q'\|q)$
(music.concert_performance.performance_role)	
what sort of part do queen play in concert	0.0659
what role do queen play in concert	0.0847
what be the role play by the queen in concert	0.0687
what role do queen play during concert	0.0670
what part do queen play in concert	0.0664
which role do queen play in concert concert	0.0652
(sports.sports_team_roster.team)	
what team do shaq play 4	0.2687
what team do shaq play for	0.2783
which team do shaq play with	0.0671
which team do shaq play out	0.0655
which team have you play shaq	0.0650
what team have we play shaq	0.0497

Table 6: Questions and their top-five paraphrases with probabilities learned by the model. The Freebase relations used to query the correct answers are shown in brackets. The original question is underlined. Questions with incorrect predictions are in *red*.

We also analyzed which structures were mostly paraphrased within a question. We manually inspected 50 (randomly sampled) questions from the development portion of each dataset, and their three top scoring paraphrases (Equation (5)). We grouped the most commonly paraphrased structures into the following categories: a) question words, i.e., wh-words and and "*how*"; b) question focus structures, i.e., cue words or cue phrases for an answer with a specific entity type (Yao and Van Durme, 2014); c) verbs or noun phrases indicating the relation between the question topic entity and the answer; and d) structures requiring aggregation or imposing additional constraints the answer must satisfy (Yih et al., 2015). In the example "*which year did Avatar release in UK*", the question word is "*which*", the question focus is "*year*", the verb is "*release*", and "*in UK*" constrains the answer to a specific location.

Figure 3 shows the degree to which different types of structures are paraphrased. As can be seen, most rewrites affect Relation Verb, especially on WEBQUESTIONS. Question Focus, Relation NP, and Constraint & Aggregation are more

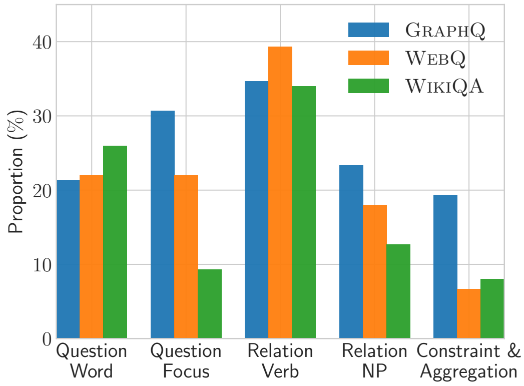

Figure 3: Proportion of linguistic phenomena subject to paraphrasing within a question.

Method	Average F1 (%)	
	Simple	Complex
SimpleGraph	20.9	12.2
Para4QA	**27.4** (+6.5)	**16.0** (+3.8)

Table 7: We group GraphQuestions into simple and complex questions and report model performance in each split. Best results in each group are shown in **bold**. The values in brackets are absolute improvements of average F1 scores.

often rewritten in GraphQuestions compared to the other datasets.

Finally, we examined how our method fares on simple versus complex questions. We performed this analysis on GraphQuestions as it contains a larger proportion of complex questions. We consider questions that contain a single relation as simple. Complex questions have multiple relations or require aggregation. Table 7 shows how our model performs in each group. We observe improvements for both types of questions, with the impact on simple questions being more pronounced. This is not entirely surprising as it is easier to generate paraphrases and predict the paraphrase scores for simpler questions.

4 Conclusions

In this work we proposed a general framework for learning paraphrases for question answering. Paraphrase scoring and QA models are trained end-to-end on question-answer pairs, which results in learning paraphrases with a purpose. The framework is not tied to a specific paraphrase generator or QA system. In fact it allows to incorporate several paraphrasing modules, and can serve as a testbed for exploring their coverage and rewriting capabilities. Experimental results on three datasets show that our method improves performance across tasks. There are several directions for future work. The framework can be used for other natural language processing tasks which are sensitive to the variation of input (e.g., textual entailment or summarization). We would also like to explore more advanced paraphrase scoring models (Parikh et al., 2016; Wang and Jiang, 2016) as well as additional paraphrase generators since improvements in the diversity and the quality of paraphrases could also enhance QA performance.

Temporal Information Extraction for Question Answering Using Syntactic Dependencies in an LSTM-based Architecture

Yuanliang Meng, Anna Rumshisky, Alexey Romanov

Abstract

In this paper, we propose to use a set of simple, uniform in architecture LSTM-based models to recover different kinds of temporal relations from text. Using the shortest dependency path between entities as input, the same architecture is implemented to extract intra-sentence, cross-sentence, and document creation time relations. A "double-checking" technique reverses entity pairs in classification, boosting the recall of positive cases and reducing misclassifications between opposite classes. An efficient pruning algorithm resolves conflicts globally. Evaluated on QA-TempEval (SemEval2015 Task 5), our proposed technique outperforms state-of-the-art methods by a large margin. We also conduct intrinsic evaluation and post state-of-the-art results on Timebank-Dense.

1 Introduction

Recovering temporal information from text is essential to many text processing tasks that require deep language understanding, such as answering questions about the timeline of events or automatically producing text summaries. This work presents intermediate results of an effort to build a temporal reasoning framework with contemporary deep learning techniques.

Until recently, there has been remarkably few attempts to evaluate temporal information extraction (TemporalIE) methods in context of downstream applications that require reasoning over the temporal representation. One recent effort to conduct such evaluation was SemEval2015 Task 5, a.k.a. QA-TempEval (Llorens et al., 2015a), which used question answering (QA) as the target application. QA-TempEval evaluated systems producing TimeML (Pustejovsky et al., 2003) annotation based on how well their output could be used in QA. We believe that application-based evaluation of TemporalIE should eventually completely replace the intrinsic evaluation if we are to make progress, and therefore we evaluated our techniques mainly using QA-TempEval setup.

Despite the recent advances produced by multi-layer neural network architectures in a variety of areas, the research community is still struggling to make neural architectures work for linguistic tasks that require long-distance dependencies (such as discourse parsing or coreference resolution). Our goal was to see if a relatively simple architecture with minimal capacity for retaining information was able to incorporate the information required to identify temporal relations in text.

Specifically, we use several simple LSTM-based components to recover ordering relations between temporally relevant entities (events and temporal expressions). These components are fairly uniform in their architecture, relying on dependency relations recovered with a very small number of mature, widely available processing tools, and require minimal engineering otherwise. To our knowledge, this is the first attempt to apply such simplified techniques to the TemporalIE task, and we demonstrate this streamlined architecture is able to outperform state-of-the-art results on a temporal QA task with a large margin.

In order to demonstrate generalizability of our proposed architecture, we also evaluate it intrinsically using TimeBank-Dense[1] (Chambers et al., 2014). TimeBank-Dense annotation aims to approximate a complete temporal relation graph by including all intra-sentential relations, all relations between adjacent sentences, and all relations with document creation time. Although our system

Proceedings of the 2017 Conference on Empirical Methods in Natural Language Processing, pages 887–896
Copenhagen, Denmark, September 7–11, 2017.

was not optimized for such a paradigm, and this data is quite different in terms of both the annotation scheme and the evaluation method, we obtain state-of-the-art results on this corpus as well.

2 Related Work

A multitude of TemporalIE systems have been developed over the past decade both in response to the series of shared tasks organized by the community (Verhagen et al., 2007, 2010; UzZaman et al., 2012; Sun et al., 2013; Bethard et al., 2015; Llorens et al., 2015b; Minard et al., 2015) and in standalone efforts (Chambers et al., 2014; Mirza, 2016).

The best methods used by TemporalIE systems to date tend to rely on highly engineered task-specific models using traditional statistical learning, typically used in succession (Sun et al., 2013; Chambers et al., 2014). For example, in a recent QA-TempEval shared task, the participants routinely used a series of classifiers (such as support vector machine (SVM) or hidden Markov chain SVM) or hybrid methods combining hand crafted rules and SVM, as was used by the top system in that challenge (Mirza and Minard, 2015). While our method also relies on decomposing the temporal relation extraction task into subtasks, we use essentially the same simple LSTM-based architecture for different components, that consume a highly simplified representation of the input.

Although there has not been much work applying deep learning techniques to TemporalIE, some relevant work has been done on a similar (but typically more local) task of relation extraction. Convolutional neural networks (Zeng et al., 2014) and recurrent neural networks both have been used for argument relation classification and similar tasks (Zhang and Wang, 2015; Xu et al., 2015; Vu et al., 2016). We take inspiration from some of this work, including specifically the approach proposed by Xu et al. (2015) which uses syntactic dependencies.

3 Dataset

We used QA-TempEval (SemEval 2015 Task 5)[2] data and evaluation methods in our experiments. The training set contains 276 annotated TimeML files, mostly news articles from major agencies or Wikinews from late 1990s to early 2000s. This data contains annotations for events, temporal expressions (referred to as TIMEXes), and temporal relations (referred to as TLINKs). The test set contains unannotated files in three genres: 10 news articles composed in 2014, 10 Wikipedia articles about world history, and 8 blogs entries from early 2000s.

In QA-TempEval, evaluation is done via a QA toolkit which contains yes/no questions about temporal relations between two events or an event and a temporal expression. QA evaluation is not available for most of the training data except for 25 files, for which 79 questions are available. We used used this subset of the training data for validation. The test set contains unannotated files, so QA is the only way to measure the performance. The total of 294 questions is available for the test data, see Table 6.

We also use TimeBank-Dense dataset, which contains a subset of the documents in QA-TempEval. In TimeBank-Dense, all entity pairs in the same sentence or in consecutive sentences are labeled. If there is no information about the relation between two entities, it is labeled as “vague”. We follow the experimental setup in (Chambers et al., 2014), which splits the corpus into training/validation/test sets of 22, 5, and 9 documents, respectively.

4 TIMEX and Event Extraction

The first task in our TemporalIE pipeline (TEA) is to identify time expressions (TIMEXes) and events in text. We utilized the HeidelTime package (Strötgen and Gertz, 2013) to identify TIMEXes. We trained a neural network model to identify event mentions. Contrary to common practice in TemporalIE, our models do not rely on event attributes, and thus we did not attempt to identify them.

Feature	Explanation
is_main_verb	whether the token is the main verb of a sentence
is_predicate	whether the token is the predicate of a phrase
is_verb	whether the token is a verb
is_noun	whether the token is a noun

Table 1: Token features for event extraction

We perform tokenization, part-of-speech tagging, and dependency parsing using NewsReader (Agerri et al., 2014). Every token is represented with a set of features derived from preprocessing. Syntactic dependencies are not used for event extraction, but are used later in the pipeline for

[2] http://alt.qcri.org/semeval2015/task5/

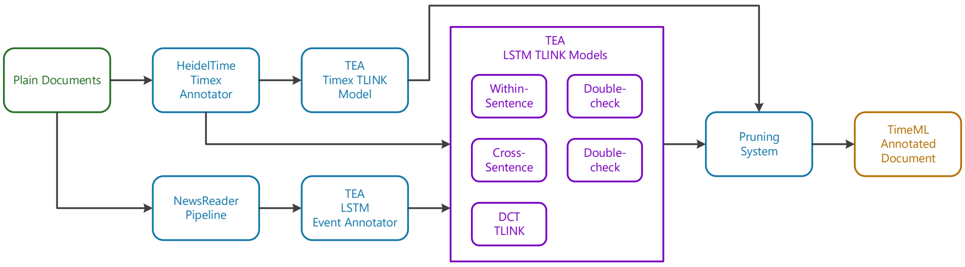

Figure 1: System overview for our temporal extraction annotator (TEA) system

TLINK classification. The features used to identify events are listed in Table 1.

The event extraction model uses long short-term memory (LSTM) (Hochreiter and Schmidhuber, 1997), an RNN architecture well-suited for sequential data. The extraction model has two components, as shown on the right of Figure 2. One component is an LSTM layer which takes word embeddings as input. The other component takes 4 token-level features as input. These components produce hidden representations which are concatenated, and fed into an output layer which performs binary classification. For each token, we use four tokens on each side to represent the surrounding context. The resulting sequence of nine word embeddings is then used as input to an LSTM layer. If a word is near the edge of a sentence, zero padding is applied. We only use the token-level features of the target token, and ignore those from the context words. The 4 features are all binary, as shown in Table 1. Since the vast majority of event mentions in the training data are single words, we only mark single words as event mentions.

5 TLINK Classification

Our temporal relation (TLINK) classifier consists of four components: an LSTM-based model for intra-sentence entity relations, an LSTM-based model for cross-sentence relations, another LSTM-based model for relations with document creation time, and a rule-based component for TIMEX pairs. The four models perform TLINK classifications independently, and the combined results are fed into a pruning module to remove the conflicting TLINKs. The three LSTM-based components use the same streamlined architecture over token sequences recovered from shortest dependency paths between entity pairs.

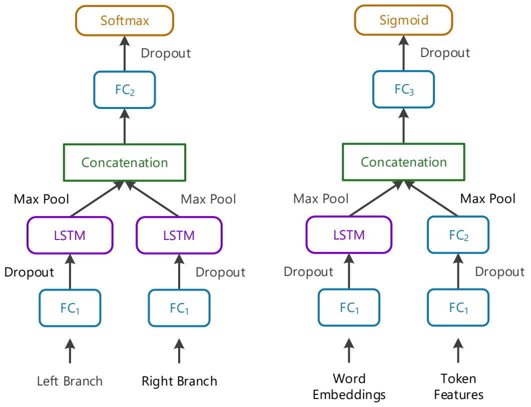

Figure 2: Model architecture. Left: intra-sentence and cross-sentence model. Right: Event extraction model.

5.1 Intra-Sentence Model

A TLINK extraction model should be able to learn the patterns that correspond to specific temporal relations, such as specific temporal prepositional phrases and clauses with temporal conjunctions. This suggests such models may benefit from encoding syntactic relations, rather than linear sequences of lexical items.

We use the shortest path between entities in a dependency tree to capture the essential context. Using the NewsReader pipeline, we identify the shortest path, and use the word embeddings for all tokens in the path as input to a neural network. Similar to previous work in relation extraction (Xu et al., 2015), we use two branches, where the left branch processes the path from the source entity to the least common ancestor (LCA), and the right branch processes the path from the target entity to the LCA. However, our TLINK extraction model uses only word embeddings as input, not POS tags, grammatical relations themselves, or WordNet hypernyms.

For example, for the sentence “Their marriage ended before the war”, given an event pair (*marriage*, *war*), the left branch of the model will receive the sequence (*marriage, ended*), while the right branch will receive (*war, before, ended*). The LSTM layer processes the appropriate sequence of word embeddings in each branch. This is followed by a separate max pooling layer for each branch, so for each LSTM unit, the maximum value over the time steps is used, not the final step value. During the early stages of model design, we observed that this max pooling approach (also used in Xu et al. (2015)) resulted in a slight improvement in performance. Finally, the results from the max pooling layers of both branches are concatenated and fed to a hidden layer, followed by a softmax to yield a probability distribution over the classes. The model architecture is shown in Figure 2 (left). We also augment the training data by flipping every pair, i.e. if $(e_1, e_2) \rightarrow$ BEFORE, $(e_2, e_1) \rightarrow$ AFTER is also included.

5.2 Cross-Sentence Model

TLINKs between the entities in consecutive sentences can often be identified without any external context or prior knowledge. For example, the order of events may be indicated by discourse connectives, or the events may follow natural order, potentially encoded in their word embeddings.

To recover such relations, we use a model similar to the one used for intra-sentence relations, as described in Section5.1. Since there is no common root between entities in different sentences, we use the path between an entity and the sentence root to construct input data. A sentence root is often the main verb, or a conjunction.

5.3 Relations to DCT

The document creation time (DCT) naturally serves as the "current time". In this section, we discuss how to identify temporal relations between an event and DCT. The assumption here is that an event mention and its local context can often suffice for DCT TLINKs. For example, English has inflected verbs for tense in finite clauses, and uses auxiliaries to express aspects.

The model we use is again similar to the one in Section5.2. Although one branch would suffice in this case, we use two branches in our implementation. One branch processes the path from a given entity to the sentence root, and the other branch processes the same path in reverse, from the root to the entity.

5.4 Relations between TIMEXes

Time expressions explicitly signify a time point or an interval of time. Without the TIMEX entities serving as "hubs", many events would be isolated from each other. We use rule-based techniques to identify temporal relations between TIMEX pairs that have been identified and normalized by HeidelTime. The relation between the DCT and other time expressions is just a special case of TIMEX-to-TIMEX TLINK and is handled with rules as well.

DATE value	**Calculation**	**Representation**

2017-08-04	START = $2017 + 7/12 + 3/365$
	$= 2017.591$
	END = START
		(2017.591, 2017.591)

2017-SU
(Summer 2017)
	START = $2017 + 5/12 = 2017.416$
	END = $2017 + 8/12 = 2017.666$
		(2017.416, 2017.666)

Table 2: Examples of DATE values and their tuple representations

In the present implementation, we focus on the DATE class of TIMEX tags, which is prevalent in the newswire text. The TIME class tags which contain more information are converted to DATE. Every DATE value is mapped to a tuple of real values (*start*, *end*). The "value" attribute of TIMEX tags follows the ISO-8601 standard, so the mapping is straightforward. Table 2 provides some examples. We set the minimum time interval to be a day. Practically, such a treatment suffices for our data. After mapping DATE values to tuples of real numbers, we can define 5 relations between TIMEX entities $T_1 = (start_1, end_1)$ and $T_2 = (start_2, end_2)$ as follows:

$$T_1 \times T_2 \rightarrow \begin{cases} \text{BEFORE} & \text{if } end_1 < start_2 \\ \text{AFTER} & \text{if } start_1 > end_2 \\ \text{INCLUDES} & \text{if } start_1 < start_2 \\ & \text{ and } end_1 > end_2 \\ \text{IS\_INCLUDED} & \text{if } start_1 > start_2 \\ & \text{ and } end_1 < end_2 \\ \text{SIMULTANEOUS} & \text{if } start_1 = start_2 \\ & \text{ and } end_1 = end_2 \end{cases} \tag{1}$$

The TLINKs from training data contain more types of relations than the five described in Equation 1. However relations such as IBEFORE ("immediately before"), IAFTER("immediately after") and IDENTITY are only used on event pairs, not TIMEX pairs. The QA system also does not target questions on TIMEX pairs. The purpose here is to use the TIMEX relations to link the otherwise isolated events.

6 Double-checking

A major difficulty we have is that the TLINKs for intra-sentence, cross-sentence, and DCT relations in the training data are not comprehensive. Often, the temporal relation between two entities is clear, but the training data provides no TLINK annotation. We downsampled the NO-LINK class in training in order to address both the class imbalance and the fact that TimeML-style annotation is de-facto sparse, with only a fraction of positive instances annotated.

In addition to that, we introduce a technique to boost the recall of positive classes (not NO-LINK) and to reduce the misclassification between the opposite classes. Since entity pairs are always classified in both orders, if both orders produce a TLINK relation, rather than NO-LINK, we adopt the label with a higher probability score, as assigned by the softmax classifier. We call this technique "double-checking". It serves to reduce the errors that are fundamentally harmful (e.g. BEFORE misclassified as AFTER, and vice versa). We also allow a positive class to have the "veto power" against NO-LINK class. For instance, if our model predicts $(e_1, e_2) \rightarrow$ AFTER but NO-LINK reversely, we adopt the former.

NO-LINK ratio	Recall	Recall	BEFORE	AFTER
	BEFORE	AFTER	as AFTER	as BEFORE
0.5	0.451	0.445	0.075	0.092
0.1	0.643	0.666	0.145	0.159
0.1 + double-check	0.721	0.721	0.125	0.125

Table 3: Effects of downsampling and double-checking on intra-sentence results. 0.5 NO-LINK ratio means that NO-LINKs are downsampled to a half of the number of all positive instances combined. BEFORE as AFTER shows the fraction of BEFORE misclassified as AFTER, and vice versa.

Table 3 shows the effects of double-checking and downsampling the NO-LINK cases on the intra-sentence model. Double-checking technique not only further boosts recall, but also reduces the misclassification between the opposite classes.

7 Pruning TLINKs

The four TLINK classification models in Section 5 deal with different kinds of TLINKs, so their output does not overlap. Nevertheless temporal relations are transitive in nature, so the deduced relations from given TLINKs can be in conflict.

Most conflicts arise from two types of relations, namely BEFORE/AFTER and INCLUDES/IS_INCLUDED. Naturally, we can convert TLINKs of opposite relations and put them all together. If we use a directed graph to represent the BEFORE relations between all entities, it should be acyclic. Sun (2014) proposed a strategy that "prefers the edges that can be inferred by other edges in the graph and remove the ones that are least so". Another strategy is to use the results from separate classifiers or "sieves" to rank TLINKs according to their confidence (Mani et al., 2007; Chambers et al., 2014). High-ranking results overwrite low-ranking ones.

We follow the same idea of purging the weak TLINKs. Given a directed graph, our approach is to remove the edges to break cycles, so that the sum of weights from the removed edges is minimal. This problem is actually an extension of the minimum feedback arc set problem and is NP-hard (Karp, 1972). We therefore adopt a heuristic-based approach, applied separately to the graphs induced by BEFORE/AFTER and INCLUDES/IS_INCLUDED relations.[3] The softmax layer provides a probability score for each relation class, which represents the strength of a link. TLINKs between TIMEX pairs are generated by rules, so we assume them to be reliable and assign them a score of 1. Although INCLUDES/IS_INCLUDED edges can generate conflicts in a BEFORE/AFTER graph as well, we currently do not resolve such conflicts because they are relatively rare. We also do not use SIMULTANEOUS/IDENTITY relations to merge nodes, because we found that it leads to very unstable results.

For a given relation (e.g., BEFORE), we incrementally build a directed graph with all edges representing that relation. We first initialize the graph with TIMEX-to-TIMEX relations. Event vertices are then added to this graph in a random order. For each event, we add all edges associated with it. If this creates a cycle, the edges are removed one by one until there is no cycle, keeping track of the sum of the scores associated with removed edges. We choose the order in which the edges are removed to minimize that value.[4] The algorithm is shown above.

In practice, the vertices do not have a high de-

[3] We found that ENDS and BEGINS TLINKs are too infrequent to warrant a separate treatment.

[4] By removing an edge, we mean resetting the relation to NO-LINK. Another possibility may be to set the relation associated with the edge to the one with the second highest probability score, however this may create additional cycles.

```
$X \leftarrow$ EVENTS;
$V \leftarrow$ TIMEXes;
$E \leftarrow$ TIMEX pairs;
Initialize $G \leftarrow < V, E >$;
for $x \in X$ do
    $V' \leftarrow V + \{x\}$;
    $C \leftarrow \{(x,v) \cup (v,x) | v \in V\}$ ;
    $E' \leftarrow E \cup C$ ;
    $G' \leftarrow < V', E' >$ ;
    if $cycle\_exists(G')$ then
        for $C_i \in \pi(C)$ do
            $score_i = 0$;
            while $C_i \neq \phi$ & $cycle\_exists(G \cup C_i)$
              do
                $c \leftarrow C_i.pop()$;
                $score_i += weight(c)$;
            end
        end
    end
    $G \leftarrow G \cup C_i$ s.t. $i = argmin(score_i)$;
end
```

Algorithm 1: Algorithm to prune edges. $\pi(C)$ denotes some permutations of C, where C is a list of weighted edges.

gree for a given relation, so permuting the candidates $N \times (N-1)$ times (i.e., not fully), where N is the number of candidates, produces only a negligible slowdown. We also make sure to try the greedy approach, dropping the edges with the smallest weights first.

8 Model Settings

In this section, we describe the model settings used in our experiments. All models requiring word embeddings use 300-dimensional word2vec vectors trained on Google News corpus (3 billion running words).[5] Our models are written in Keras on top of Theano.

TIMEX and Event Annotation The LSTM layer of the event extraction model contains 128 LSTM units. The hidden layer on top of that has 30 neurons. The input layer corresponding to the 4 token features is connected with a hidden layer with 3 neurons. The combined hidden layer is then connected with a single-neuron output layer. We set a dropout rate 0.5 on input layer, and another drop out rate 0.5 on the hidden layer before output.

As mentioned earlier, we do not attempt to tag event attributes. Since the vast majority of tokens are outside of event mention boundaries, we set higher weights for the positive class. In order to answer questions about temporal relations, it is not particularly harmful to introduce spurious events, but missing an event makes it impossible to answer any question related to it. Therefore we intentionally boost the recall while sacrificing precision. Table 4 shows the performance of our event extraction, as well as the performance of HeidelTime TIMEX tagging. For events, partial overlap of mention boundaries is considered an error.

Annotation	Prec	Rec	F1
TIMEX	0.838	0.850	0.844
Event	0.729	0.963	0.830

Table 4: TIMEX and event evaluation on validation set.

Intra-Sentence Model We identify 12 classes of temporal relations, plus a NO-LINK class. For training, we downsampled NO-LINK class to 10% of the number of positive instances. Our system does not attempt to resolve coreference. For the purpose of identifying temporal relations, SIMULTANEOUS and IDENTITY links capture the same relation of simultaneity, which allowed us to combine them. The LSTM layer of the intra-sentence model contains 256 LSTM units on each branch. The hidden layer on top of that has 100 neurons. We set a dropout rate 0.6 on input layer, and another drop out rate 0.5 on the hidden layer before output.

Cross-Sentence Model The training and evaluation procedures are very similar to what we did for intra-sentence models, and the hyperparameters for the neural networks are the same. Now the vast majority of entity pairs have no TLINKs explicitly marked in training data. Unlike the intra-sentence scenario, however, a NO-LINK label is truly adequate in most cases. We found that downsampling NO-LINK instances to match the number of all positive instances (ratio=1) yields desirable results. Since positive instances are very sparse in both the training and validation data, the ratio should not be too low, so as not to risk overfitting.

DCT Model We use the same hyperparameters for the DCT model as for the intra-sentence and cross-sentence models. Again, the training files do not sufficiently annotate TLINKs with DCT even if the relations are clear, so there are many false negatives. We downsample the NO-LINK instances so that they are 4 times the number of positive instances.

Table 5: QA results on validation data. There are **79** questions in total. The 4 systems on the top of the table are provided with the toolkit. The systems starting with "human-" are annotated by human experts. TEA-final utilizes both double-check and pruning. TEA-flat uses the flat context. TEA-Dense is trained on TimeBank-Dense.

9 Experiments

In this section, we first describe the model selection experiments on QA-TempEval validation data, selectively highlighting results of interest. We then present the results obtained with the optimized model on the QA-TempEval task and on TimeBank-Dense.

9.1 Model Selection Experiments

As mentioned before, "gold" TLINKs are sparse, so we cannot merely rely on the F1 scores on validation data to do model selection. Instead, we used the QA toolkit. The toolkit contains 79 yes-no questions about temporal relations between entities in the validation data. Originally, only 6 questions have "no" as the correct answer, and 1 question is listed as "unknown". After investigating the questions and answers, however, we found some errors and typos[6]. After fixing the errors, there are 7 no-questions and 72 yes-questions in total. All evaluations are performed on the fixed data.

The evaluation tool draws answers from the annotations only. If an entity (event or TIMEX) involved in a question is not annotated, or the TLINK cannot be found, the question will then be counted as not answered. There is no way for participants to give an answer directly, other than delivering the annotations. The program generates Timegraphs to infer relations from the annotated TLINKs. As a result, relations without explicit TLINK labels can still be used if they can be inferred from the annotations. The QA toolkit uses the following evaluation measures:

$$\text{coverage} = \frac{\#\text{answered}}{\#\text{questions}},\ \text{precision} = \frac{\#\text{correct}}{\#\text{answered}}$$

$$\text{recall} = \frac{\#\text{correct}}{\#\text{questions}},\ \text{f1} = \frac{2\times\text{precision}\times\text{recall}}{\text{precision}+\text{recall}}$$

Table 5 shows the results produced by different models on the validation data. The results of the four systems above the first horizontal line are provided by the task organizer. Among them, the top two use annotations provided by human experts. As we can see, the precision is very high, both above 0.90. Our models cannot reach that precision. In spite of the lower precision, automated systems can have much higher coverages i.e. answer a lot more questions.

As a starting point, we evaluated the validation files in their original form, and the results are shown as "orig. validation data" of Table 5. The precision was good, but with very low coverage. This supports our claim that the TLINKs provided by the training/validation files are not complete. We also tried using the event and TIMEX tags from the validation data, but performing TLINK classification with our system. As shown with "orig. tags TEA tlinks" in the table, now the coverage rises to 64 (or 0.81), and the overall F1 score reaches 0.52. The TEA-initial system uses our own annotators. The performance is similar, with a slight improvement in precision. This result shows our event and TIMEX tags work well, and are not inferior to the ones provided by the training data.

The double-checking technique boosts the coverage a lot, probably because we allow positive results to veto NO-LINKs. Combining double-checking with the pruning technique yields the best results, with F1 score 0.58, answering 42 out of 79 questions correctly.

In order to validate the choice of the dependency path-based context, we also experimented with a conventional flat context window, using the same hyperparameters. Every entity is represented by a 11-word window, with the entity mention in the middle. If two entities are near each other, their windows are cut short before reaching the other entity. Using the flat context instead of dependency paths yields a much weaker performance.

[6] Question 24 from XIE19980821.0077.tml should be answered with "yes", but the answer key contains a typo "is". Question 34 from APW19980219.0476.tml has BEFORE that should be replaced with AFTER. Question 29 from XIE19980821.0077.tml has "unknown" in the answer key, but after reading the article, we believe the correct answer is "no".

This confirms our hypothesis that syntactic dependencies represent temporal relations better than word windows. However, it should be noted that we did not separately optimize the models for the flat context setting. The large performance drop we saw from switching to flat context did not warrant performing a separate parameter search.

We also wanted to check whether a comprehensive annotation of TLINKs in the training data can improve model performance on the QA task. We therefore trained our model on TimeBank-Dense data and evaluated it with QA (see the TEA-Dense line in Table 5). Interestingly, the performance is nearly as good as our top model, although TimeBank-Dense only uses five major classes of relations. For one thing, it shows that our system may perform equally after being trained on sparsely labeled data and on densely labeled data, judged from the QA evaluation tool. If this is true, excessively annotated data may not be necessary in some tasks.

Table 6: Test data statistics. Adapted from Table 1 in Llorens et al. (2015a).

9.2 QA-TempEval Experiments

We use the QA toolkit provided by the QA-TempEval organizers to evaluate our system on the test data. The documents in test data are not annotated at all, so the event tags, TIMEX tags, and TLINKs are all created by our system.

Table 6 shows the the statistics of test data. As we can see, the vast majority of the questions in the test set should be answered with *yes*. Generally speaking, it is much more difficult to validate a specific relation (answer *yes*) than to reject it (answer *no*) when we have as many as 12 types of relations in addition to the vague NO-LINK class. **dist-** means questions involving entities that are in the same sentence or in consecutive sentences. **dist+** means the entities are farther away.

The QA-TempEval task organizers used two evaluation methods. The first method is exactly the same as the one we used on validation data. The second method used a so-called Time Expression Reasoner (TREFL) to add relations between TIMEXes, and evaluated the augmented results. The goal of such an extra run is to "analyze how a general time expression reasoner could improve results". Our model already includes a component to handle TIMEX relations, so we will compare our results with other systems' in both methods.

Table 7: QA evaluation on test data without TREFL

The results are shown in Table 7. We give the results for the hlt-fbk systems that were submitted by the top team. Among them, hlt-fbk-ev2-trel2 was the overall winner of TempEval task in 2015. ClearTK, CAEVO, TIPSEMB and TIPSem were some off-the-shelf systems provided by the task organizers for reference. These systems were not optimized for the task (Llorens et al., 2015a).

For news and Wikipedia genres, our system outperforms all other systems by a large margin. For blogs genre, however, the advantage of our system is unclear. Recall that our training set contains news articles only. While the trained model works well on Wikipedia dataset too, blog dataset is fundamentally different in the following ways: (1) each blog article is very short, (2) the style of writing in blogs is much more informal, with non-standard spelling and punctuation, and (3) blogs

All Genres (294 questions)

system	prec	rec	f1	% awd	# corr
hlt-fbk-ev2-trel2	0.49	0.30	0.37	62	89
hlt-fbk-ev2-trel2-TREFL	0.51	0.34	0.40	**67**	99
TEA	**0.59**	**0.39**	**0.47**	66	**114**
TEA-TREFL	0.58	0.38	0.46	66	111

Table 8: Test results over all genres.

are written in first person, and the content is usually personal stories and feelings.

Interestingly, the comparison between different hlt-fbk submissions suggests that resolving event coreference (implemented by hlt-fbk-ev2-trel2) substantially improves system performance for the news and Wikipedia genres. However, although our system does not attempt to handle event coreference explicitly, it easily outperforms the hlt-fbk-ev2-trel2 system in the genres where coreference seems to matter the most.

Evaluation with TREFL The extra evaluation with TREFL has a post-processing step that adds TLINKs between TIMEX entities. Our model already employs such a strategy, so this post-processing does not help. In fact, it drags down the scores a little. Table 8 summarizes the results over all genres before and after applying TREFL. For comparison, we include the top 2015 system, hlt-fbk-ev2-trel2. As we can see, TEA generally shows substantially higher scores.

9.3 TimeBank-Dense Experiments

We trained and evaluated the same system on TimeBank-Dense to see how it performs on a similar task with a different set of labels and another method of evaluation. In this experiment, we used the event and TIMEX tags from test data, as Mirza and Tonelli (2016).

Since all the NO-LINK (vague) relations are labeled, downsampling was not necessary. We did use double-checking in the final conflict resolution, but without giving positive cases the veto power over NO-LINK. Because NO-LINK relations dominate, especially for cross-sentence pairs, we set class weights to be inversely proportional to the class frequencies during training. We also reduced input batch size to counteract class imbalance.

We ran two sets of experiments. One used the uniform configurations for all the neural network models, similar to our experiments with QA-TempEval. The other tuned the hyperparameters for each component model (number of neurons, dropout rates, and early stop) separately.

system	ClearTK	NavyT	CAEVO	CATENA	TEA-Dense	
					uniform	tuned
F1	0.447	0.453	0.507	0.511	0.505	0.519

Table 9: TEA results on TimeBank-Dense. ClearTK, NavyT, and CAEVO are systems from Chambers et al. (2014). CATENA is from Mirza and Tonelli (2016)

The results from TimeBank-Dense are shown in Talble 9. Even though TimeBank-Dense has a very different methodology for both annotation and evaluation, our “out-of-the-box” model which uses uniform configurations across different components obtains F1 0.505, compared to the best F1 of 0.511 in previous work. Our best result of 0.519 is obtained by tuning hyperparameters on intra-sentence, cross-sentence, and DCT models independently.

For the QA-TempEval task, we intentionally tagged a lot of events, and let the pruning algorithm resolve potential conflicts. In the TimeBank-Dense experiment, however, we only used the provided event tags, which are sparser than what we have in QA-TempEval. The system may have lost some leverage that way.

10 Conclusion

We have proposed a new method for extraction of temporal relations which takes a relatively simple LSTM-based architecture, using shortest dependency paths as input, and re-deploys it in a set of subtasks needed for extraction of temporal relations from text. We also introduce two techniques that leverage confidence scores produced by different system components to substantially improve the results of TLINK classification: (1) a “double-checking” technique which reverses pairs in classification, thus boosting the recall of positives and reducing misclassifications among opposite classes and (2) an efficient pruning algorithm to resolve TLINK conflicts. In a QA-based evaluation, our proposed method outperforms state-of-the-art methods by a large margin. We also obtain state-of-the art results in an intrinsic evaluation on a very different TimeBank-Dense dataset, proving generalizability of the proposed model.

Ranking Kernels for Structures and Embeddings: A Hybrid Preference and Classification Model

Abstract

Recent work has shown that Tree Kernels (TKs) and Convolutional Neural Networks (CNNs) obtain the state of the art in answer sentence reranking. Additionally, their combination used in Support Vector Machines (SVMs) is promising as it can exploit both the syntactic patterns captured by TKs and the embeddings learned by CNNs. However, the embeddings are constructed according to a classification function, which is not directly exploitable in the preference ranking algorithm of SVMs. In this work, we propose a new hybrid approach combining preference ranking applied to TKs and pointwise ranking applied to CNNs. We show that our approach produces better results on two well-known and rather different datasets: WikiQA for answer sentence selection and SemEval cQA for comment selection in Community Question Answering.

1 Introduction

Recent work on learning to rank (L2R) has shown that deep learning and kernel methods are two very effective approaches, given their ability of engineering features. In particular, in question answering (QA), Convolutional Neural Networks (CNN), e.g., (Severyn and Moschitti, 2015; Miao et al., 2016; Yin et al., 2016) can automatically learn the representation of question and answer passage (Q/AP) in terms of word embeddings and their non-linear transformations. These are then used by the other layers of the network to measure Q/AP relatedness. In contrast, Convolution Tree Kernels (CTK) can be applied to relational structures built on top of syntactic/semantic structures derived from Q/AP text (Tymoshenko et al., 2016a). CNNs as well as CTKs can achieve the state of the art in ranking APs or also questions. Considering their complementary approach for generating features, studying ways to combine them is very promising. In (Tymoshenko et al., 2016a), we investigated the idea of extracting layers from CNNs and using them in a kernel function to be further combined with CTKs in a composite reranking kernel. This was used in an SVM^{Rank} (Joachims, 2002) model, which obtained a significant improvement over the individual methods. However, the simple use of CNN layers as vectors in a preference ranking approach is intutively not optimal since such layers are basically learnt in a classification model, thus they are not optimized for SVM^{Rank}.

In this work, we further compare and investigate different ways of combining CTKs and CNNs in reranking settings. In particular, we follow the intuition that as CNNs learn the embeddings in a classification setting they should be used in the same way for building the reranking kernel, i.e., we need to use the embeddings in a pointwise reranking fashion. Therefore, we propose a hybrid preference-pointwise kernel, which consists in (i) a standard reranking kernel based on CTKs applied to the Q/AP structural representations; and (ii) a classification kernel based on the embeddings learned by neural networks. The intuition about the hybrid models is to add CNN layer vectors, not their difference, to the preference CTK. That is, CNN layers are still used as they were used in a classification setting whereas CTKs follow the standard SVM^{Rank} approach.

We tested our proposed models on the answer sentence selection benchmark, WikiQA (Yang et al., 2015), and the benchmark from cQA SemEval-2016 Task 3.A[1] corpus. We show that

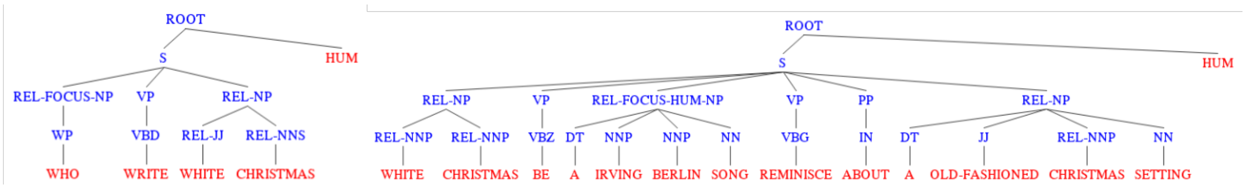

Figure 1: Shallow chunk-based tree representation of a question in the Q/AP pair: Q: *"Who wrote white Christmas?"*, AP: *"White Christmas is an Irving Berlin song"*.

the proposed hybrid kernel consistently outperforms standard reranking models in all settings.

2 Answer Sentence/Comment Selection

We focus on two question answering subtasks: answer sentence selection task (AST) and the comment selection task from cQA.

AST consists in selecting correct answer sentences (i.e., an AP composed of only one sentence) for a question Q from a set of candidate sentences, $S = \{s_1, ..., s_N\}$. In factoid question answering, Q typically asks for an entity or a fact, e.g., time location and date. S is typically a result of so-called *primary search*, a result of fast-recall/low-precision search for potential answer candidates. For example, it could be a set of candidate APs returned when running a search engine over a large corpus using Q as a search query. Many such APs are typically not pertinent to the original question, thus automatic approaches for selecting those useful are very valuable.

cQA proposes a task similar to AST, where Q is a question asked by a user in a web forum and S are the potential answers to the question posted as comments by other users. Again, many comments in a cQA thread do not contain an answer to the original question, thus raising the need for automatic comment selection.

The crucial features for both tasks capture information about the relations between Q and an AP. Manual feature engineering can provide competitive results (Nicosia et al., 2015), however, it requires significant human expertise in the specific domain and is time-consuming. Thus, machine learning methods for automatic feature engineering are extremely valuable.

3 CTK and CNN models

Our baselines are the standalone CTK and CNN models originally proposed in (Severyn et al., 2013; Severyn and Moschitti, 2015) and further advanced in (Tymoshenko et al., 2016a,b). The following subsections provide a brief overview of these models.

3.1 CTK structures

The CTK models are applied to syntactic structural representations of Q and AP. We used shallow chunk-based and constituency tree representations in AST (Tymoshenko et al., 2016a) and cQA (Tymoshenko et al., 2016b), respectively. We follow the tree construction algorithms provided in the work above. Due to the space restrictions, we present only high-level details below.

A shallow chunk-based representations of a text contains lemma nodes at leaf level and their part-of-speech (POS) tag nodes at the preterminal level. The latter are further grouped under the chunk and sentence nodes.

A constituency tree representation is an ordinary constituency parse tree. In all representations, we mark lemmas that occur in both Q and AP by prepending the **REL** tag to the labels of the corresponding preterminal nodes and their parents.

Moreover, in the AST setting, often question and focus classification information is used (Li and Roth, 2002), thus we enrich our representation with the question class and focus information, when is available.

Additionally, we mark AP chunks containing named entities that match the expected answer type of the question by prepending *REL-FOCUS-<QC>* to them. Here, the $< QC >$ placeholder is substituted with the actual question class. Fig. 1 illustrates a shallow chunk-based syntactic structure enriched with relational tags.

3.2 Convolutional Neural Networks

A number of NN-based models have been proposed in the research line of answer selection (Hu et al., 2014; Yu et al., 2014). Here, we employ

task3/

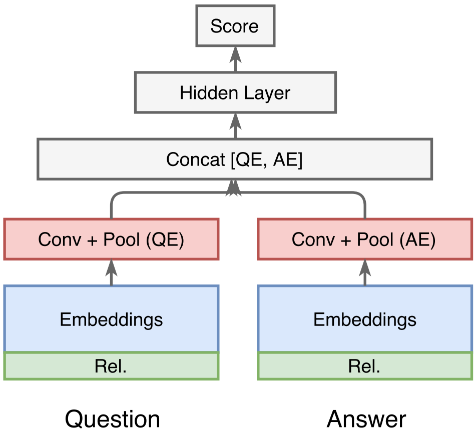

Figure 2: CNN architecture to compute the similarity between question and answer.

the NN model described in (Tymoshenko et al., 2016a) and depicted in Fig. 2. It includes two main components (i) two sentence encoders that map input documents i into fixed size m-dimensional vectors x_{s_i}, and (ii) a feed forward NN that computes the similarity between the two sentences in the input.

We use a sentence model built with a convolution operation followed by a k-max pooling layer with $k = 1$. The sentence vectors, x_{s_i}, are concatenated together and given in input to standard NN layers, which are constituted by a non-linear hidden layer and a sigmoid output layer. The sentence encoder, $x_{s_i} = f(s_i)$ outputs a fixed-size vector representation of the input sentence s_i (we will refer to $f(s_i)$ as question embedding, QE, and answer embedding, AE, respectively).

Additionally, we encode the relational information between Q and AP, by injecting relation features into the network. In particular, we associate each word w of the input sentences with a *word overlap* binary feature indicating if w is shared by both Q and AP.

4 Hybrid learning to rank model

We represent a Q/AP pair as $p = (q, a, \vec{x})$, where q and a are the structural representations of Q and AP (as described in Sec. 3), and $\vec{x}$ is a feature vector that incorporates the features characterizing the Q/AP pair (e.g., similarity features between Q and AP or their embeddings learned by an NN).

Reranking kernel. This kernel captures differences between two Q/AP pairs, p_1 and p_2, and predicts which pair should be ranked higher, i.e., in which pair, AP has higher probability to provide a correct answer to Q. In the reranking setting, a training/classification instance is a pair of Q/AP pairs, $\langle p_1 = (q, a_1, \vec{x}_1), \quad p_2 = (q, a_2, \vec{x}_2)\rangle$. The instance is positive if p_1 is ranked higher than p_2, and negative otherwise. One approach for producing training data is to form pairs both using $\langle p_1, p_2\rangle$ and $\langle p_2, p_1\rangle$, thus generating both positive and negative examples.

However, since these are clearly redundant as formed by the same members, it is more efficient training with a reduced set of examples such that members are not swapped. Algorithm 1 describes how we generate a more compact set of positive (E_+) and negative (E_-) training examples for a specific Q.

Given a pair of examples, $\langle p_1, p_2\rangle$ and $\langle p'_1, p'_2\rangle$, we used the following preference kernel (Shen and Joshi, 2003):

$$\begin{aligned} R_K(\langle p_1, p_2\rangle, \langle p'_1, p'_2\rangle) = K(p_1, p'_1) + \\ +K(p_2, p'_2) - K(p_1, p'_2) - K(p_2, p'_1), \end{aligned} \tag{1}$$

which is equivalent to the dot product between vector subtractions, i.e., $\big(\phi(p_1) - \phi(p_2)\big) \cdot \big(\phi(p'_1) - \phi(p'_2)\big)$, used in preference reranking, where ϕ is a feature map. Additionally, we indicate (i) with R_{TK} the preference kernel using TKs applied to q and a trees, i.e., $TK(p_i, p_j) = TK(q_i, q_j) + TK(a_i, a_j)$; and (ii) with R_V, the preference kernel applied to vectors, i.e., $V(p_i, p_j) = V(\vec{x}_i, \vec{x}_j)$. Our final reranking kernel is:

$$\begin{aligned} RK(\langle p_1, p_2\rangle, \langle p'_1, p'_2\rangle) = R_{TK}(\langle p_1, p_2\rangle, \langle p'_1, p'_2\rangle) + \\ +R_V(\langle p_1, p_2\rangle, \langle p'_1, p'_2\rangle) \end{aligned} \tag{2}$$

Now, if we substitute the explicit form for R_V, we have:

$$\begin{aligned} RK(\langle p_1, p_2\rangle, \langle p'_1, p'_2\rangle) = R_{TK}(\langle p_1, p_2\rangle, \langle p'_1, p'_2\rangle) + \\ +V(p_1, p'_1) + V(p_2, p'_2) - V(p_1, p'_2) - V(p_2, p'_1) \end{aligned}$$

Since our vectors are internal network layers in order to not lose important information with differences (operated by R_V), we only keep $V(p_1, p'_1)$ (or equivalently $V(p_2, p'_2)$), i.e.,

$$\begin{aligned} RK(\langle p_1, p_2\rangle, \langle p'_1, p'_2\rangle) = R_{TK}(\langle p_1, p_2\rangle, \langle p'_1, p'_2\rangle) + \\ V(p_1, p'_1) \end{aligned} \tag{3}$$

Note that our approach also works when using Alg. 1.

Algorithm 1 Generating training data for reranking

```
Require: $S_{q+}, S_{q-}$ - $(q, a, \vec{x})$-triplets for correct and wrong
    answer sentences per question Q
$E_+ \leftarrow \emptyset$, $E_- \leftarrow \emptyset$, $flip \leftarrow$ true
for all $s_+ \in S_{q+}$ do
    for all $s_- \in S_{q-}$ do
        if $flip$ == true then
            $E_+ \leftarrow E_+ \cup (s_+, s_-)$
            $flip \leftarrow$ false
        else
            $E_- \leftarrow E_- \cup (s_-, s_+)$
            $flip \leftarrow$ true
return $E_+, E_-$
```

5 Experiments

In our experiments, we compare various methods of combining CTKs and CNNs, using standard and our hybrid reranking kernels. The software for reproducing our experimental results is available at https://github.com/iKernels/RelTextRank.

5.1 Experimental setup

WikiQA, sentence selection dataset: this was created for open domain QA. Table 1 provides the statistics regarding this dataset. Following Yang et al. (2015), we discard questions that have either only correct or only incorrect answers.

cQA, SemEval-2016 dataset: we used the English data from Task 3, Subtask A[2]. We can exactly compare with the state of the art in SemEval. It contains questions collected from the *Qatar Living forum*[3] and the first ten comments per question manually annotated. The train, dev. and test sets contain 1790, 244 and 327 questions, respectively.

Text Preprocessing: we used the Illinois chunker (Punyakanok and Roth, 2001) and the Stanford CoreNLP (Manning et al., 2014) toolkit, v3.6.0. When experimenting with SemEval-2016, we perform preprocessing as in (Tymoshenko et al., 2016a), e.g., we truncate all the comments to 2000 symbols and sentences to 70 words.

CTKs: we trained our models with SVM-Light-TK[4] using the partial tree kernel (PTK) and the subset tree kernel (STK). We use PTK for WikiQA and STK for SemEval as suggested in our previous work (Tymoshenko et al., 2016a) with default parameters and the polynomial kernel (P) of degree 3 on all feature vectors, which are embeddings learned as described in Section 3.2.

Dataset	Q	AP	Q with AP
WikiQA-train	2,118	20,360	873
WikiQA-test	633	6,165	243
WikiQA-dev	296	2,733	126

Table 1: WikiQA statistics.

Neural Network (CNN) setup: we used the same setup and parameters as (Tymoshenko et al., 2016a): we pre-initialize the word embeddings with skipgram embedding of dimensionality 50 trained on the English Wikipedia dump (Mikolov et al., 2013). We used a single non-linear hidden layer (with hyperbolic tangent activation, Tanh), whose size is equal to the size of the previous layer, i.e., the join layer. The network is trained using SGD with shuffled mini-batches using the Rmsprop update rule (Tieleman and Hinton, 2012). The model is trained until the validation loss stops improving. The size of the sentences embedding (QE and AE) and of the join layer is set as 200.

QA metrics: we report our results in terms of Mean Average Precision (MAP), Mean Reciprocal Rank (MRR) and P@1.

5.2 Ranking with trees and embeddings

We evaluate the combination techniques proposed in Sec. 4 on the SemEval-2016 and WikiQA development (DEV) and test (TEST) sets. Additionally, to have more reliable results, it is standard practice to apply n-fold cross-validation. However, we cannot do this on the training (TRAIN) sets, since the embeddings learned in Sec. 3.2 are trained on TRAIN by construction, and therefore cross-validation on TRAIN would exhibit unrealistically high performance. Thus, we employed the following disjoint *Cross Validation* approach: we train 5 models as in traditional 5-fold cross-validation on TRAIN. Then, we merged WikiQA DEV and TEST sets, split the resulting set into 5 subsets, and use *i*-th subset to test the model trained in *i*-th fold (*i*=1,..,5).

Table 2 reports the performance of the models. Here, Rank corresponds to the traditional reranking model described by Eq. 2 in Sec. 4. Hybrid refers to our new reranking/classification kernels described by Eq. 3. V means that the model uses a kernel applied to the embedding feature vectors only. T specifies that the model employs struc-

Table 2: Experimental results on WikiQA and SemEval-2016 Task 3.A corpora

tural representations with a tree kernel. Finally, V+T means that both embedding feature vectors and trees are used.

The experiments show that: in general, a standalone model with CTKs applied to the syntactic structures (*Rank:T*) outperforms the standalone feature-based models using embeddings as feature vectors (V).

Then, the straightforward combination of tree and polynomial kernels applied to the syntactic structural representations and embeddings (*Rank: T+V*) does not improve over the *Rank: T* model.

At the same time, the Hybrid model consistently outperforms all the other models in all possible experimental configurations, thus confirming our hypothesis that the classification setting is more appropriate when using embeddings as feature vectors in the kernel-based ranking models.

Additionally, for reference, we report the performance of the CNN we used to obtain the embeddings. It is consistently outperformed by the Hybrid model on all the datasets.

Finally, in the last four lines of Tab. 2, we report the performance of the state-of-the-art models from previous work, measured on exactly the same experimental settings we used.

Here *Rank':T+V* is our model described in (Tymoshenko et al., 2016a), based on the traditional reranking model. Our updated version obtains comparable performance on WikiQA-DEV and slightly lower performance on WikiQA-TEST (probably, just due to differences in preprocessing after we updated our pre-processing pipelines).

ABCNN (Yin et al., 2016) is another state-of-the-art system based on advanced attention-based convolutional networks. All our models involving CTKs outperform it.

KeLP (#1) (Filice et al., 2016) and ConvKN (#2) (Barrón-Cedeño et al., 2016) are the two top-performing SemEval 2016, Task 3.A competition systems (Nakov et al., 2016). ConvKN (#2) is an earlier version of our approach, which also employs CTKs and embeddings. Both KeLP and ConvKN (i) employ cQA-domain-specific hand-crafted features, which also consider the thread-level information, while in this work, we do not use manually engineered features; (ii) they employ PTK, which is capable of learning more powerful features than SST, but it is more computationally complex; (iii) KeLP system parameters were optimized in cross-validation on the training set, while, in this work, we perform no parameter optimization. Nevertheless, the performance of our *Hybrid:T+V* models on SemEval TEST is comparable to that of ConvKN (#2).

6 Conclusion

In this paper, we have studied and compared state-of-the-art feature engineering approaches, namely CTKs and CNNs, on two different QA tasks, AST and cQA. We investigated the ways of combining the two approaches into a single model and proposed a hybrid reranking-classification kernel for combining the structural representations and embeddings learned by CNNs.

We have shown that the combination of CTKs and CNNs with a hybrid kernel in the reranking setting outperforms the state of the art on AST and is comparable to the state of the art in cQA. In particular, in cQA, a combination of CTKs and CNNs performs comparably to the systems using domain specific features that were manually engineered.

Recovering Question Answering Errors via Query Revision

Semih Yavuz and **Izzeddin Gur** and **Yu Su** and **Xifeng Yan**
Department of Computer Science, University of California, Santa Barbara
{syavuz,izzeddingur,ysu,xyan}@cs.ucsb.edu

Abstract

The existing factoid QA systems often lack a post-inspection component that can help models recover from their own mistakes. In this work, we propose to cross-check the corresponding KB relations behind the predicted answers and identify potential inconsistencies. Instead of developing a new model that accepts evidences collected from these relations, we choose to plug them back to the original questions directly and check if the revised question makes sense or not. A bidirectional LSTM is applied to encode revised questions. We develop a scoring mechanism over the revised question encodings to refine the predictions of a base QA system. This approach can improve the F_1 score of STAGG (Yih et al., 2015), one of the leading QA systems, from 52.5% to 53.9% on WEBQUESTIONS data.

1 Introduction

With the recent advances in building large scale knowledge bases (KB) like Freebase (Bollacker et al., 2008), DBpedia (Auer et al., 2007), and YAGO (Suchanek et al., 2007) that contain the world's factual information, KB-based question answering receives attention of research efforts in this area. Traditional semantic parsing is one of the most promising approaches that tackles this problem by mapping questions onto logical forms using logical languages CCG (Kwiatkowski et al., 2013; Reddy et al., 2014; Choi et al., 2015; Reddy et al., 2016), DCS (Berant et al., 2013; Berant and Liang, 2014, 2015), or directly query graphs (Yih et al., 2015) with predicates closely related to KB schema. Recently, neural network based models have been applied to question answering (Bordes et al., 2015; Yih et al., 2015; Xu et al., 2016a,b).

Refinement Candidate
Predicted Candidate

Figure 1: Sketch of our approach. Elements in solid round rectangles are KB relation labels. Relation on the left is correct, but the base QA system predicts the one on the right. Dotted rectangles represent **revised questions** with relation labels plugged in. The left revised question looks semantically closer to the original question and itself is more consistent. Hence, it shall be ranked higher than the right one.

While these approaches yielded successful results, they often lack a post-inspection component that can help models recover from their own mistakes. Table 1 shows the potential improvement we can achieve if such a component exists. Can we leverage textual evidences related to the predicted answers to recover from a prediction error? In this work, we show it is possible.

Our strategy is to cross-check the corresponding KB relations behind the predicted answers and identify potential inconsistencies. As an intermediate step, we define **question revision** as a tailored transformation of the original question using textual evidences collected from these relations in a knowledge base, and check if the revised questions make sense or not. Figure 1 illustrates the idea over an example question "*what did Mary Wollstonecraft fight for ?*" Obviously, "*what [area of activism] did [activist] fight for ?*" looks more consistent over "*what [profession] did [person] fight for ?*" We shall build a model that prefers the former one. This model shall be specialized for comparing the revised questions and checking which one makes better sense, not for answering the revised questions. This strategy differentiates

our work from many existing QA studies.

Given a question, we first create its revisions with respect to candidate KB relations. We encode question revisions using a bidirectional LSTM. A scoring mechanism over these encodings is jointly trained with LSTM parameters with the objective that the question revised by a correct KB relation has higher score than that of other candidate KB relations by a certain confidence margin. We evaluate our method using STAGG (Yih et al., 2015) as the base question answering system. Our approach is able to improve the F_1 performance of STAGG (Yih et al., 2015) from 52.5% to 53.9% on a benchmark dataset WEBQUESTIONS (Berant et al., 2013). Certainly, one can develop specialized LSTMs that directly accommodate text evidences without revising questions. We have modified QA-LSTM and ATTENTIVE-LSTM (Tan et al., 2016) accordingly (See Section 4). However, so far the performance is not as good as the question revision approach.

2 Question Revisions

We formalize three kinds of question revisions, namely entity-centric, answer-centric, and relation-centric that revise the question with respect to evidences from topic entity type, answer type, and relation description. As illustrated in Figure 2, we design revisions to capture generalizations at different granularities while preserving the question structure.

Let s_r (e.g., `Activist`) and o_r (e.g., `ActivismIssue`) denote the subject and object types of a KB relation r (e.g., `AreaOfActivism`), respectively. Let α (`type.object.name`) denote a function returning the textual description of a KB element (e.g., relation, entity, or type). Assuming that a candidate answer set is retrieved by executing a KB relation r from a topic entity in question, we can uniquely identify the types of topic entity and answer for the hypothesis by s_r and o_r, respectively. It is also possible that a chain of relations $r = r_1 r_2 \dots r_k$ is used to retrieve an answer set from a topic entity. When $k = 2$, by abuse of notation, we define $s_{r_1 r_2} = s_{r_1}$, $o_{r_1 r_2} = o_{r_2}$, and $\alpha(r_1 r_2) = concat(\alpha(r_1), \alpha(r_2))$.

Expressivity

Figure 2: Illustration of different question revision strategies on the running example w.r.t KB relation `activism.activist.area_of_activism`.

Let $m : (q, r) \mapsto q'$ denote a mapping from a given question $q = [w_1, w_2, \dots, w_L]$ and a KB relation r to revised question q'. We denote the index span of wh-words (e.g., "what") and topic entity (e.g., "Mary Wollstonecraft") in question q by $[i_s, i_e]$ and $[j_s, j_e]$, respectively.

Entity-Centric (EC). Entity-centric question revision aims a generalization at the entity level. We construct it by replacing topic entity tokens with its type. For the running example, it becomes "*what did [activist] fight for*". Formally, $m_{EC}(q, r) = [w_{[1:j_s-1]}; \alpha(s_r); w_{[j_e+1:L]}]$.

Answer-Centric (AC). It is constructed by augmenting the wh-words of entity-centric question revision with the answer type. The running example is revised to "*[what activism issue] did [activist] fight for*". We formally define it as $m_{AC}(q, r) = [w'_{[1:i_e]}; \alpha(o_r); w'_{[i_e+1:L']}]$, where w'_i's are the tokens of entity-centric question revision $m_{EC}(q, r)$ of length L' with $[i_s, i_e]$ still denoting the index span of wh-words in w'.

Relation-Centric (RC). Here we augment the wh-words with the relation description instead of answer type. This form of question revision has the most expressive power in distinguishing between the KB relations in question context, but it can suffer more from the training data sparsity. For the running example, it maps to "*[what area of activism] did [activist] fight for*". Formally, it is defined as $m_{RC}(q, r) = [w'_{[1:i_e]}; \alpha(r); w'_{[i_e+1:L']}]$.

3 Model

3.1 Task Formulation

Given a question q, we first run an existing QA system to answer q. Suppose it returns r as the top predicted relation and r' is a candidate relation that is ranked lower. Our objective is to decide if there is a need to replace r with r'. We formulate this task as finding a scoring function $s : (q, r) \to \mathbb{R}$ and a confidence margin threshold $t \in \mathbb{R}_{>0}$ such that the function

$$replace(r, r', q) = \begin{cases} 1, \text{if } s(q, r') - s(q, r) \geq t \\ 0, \text{otherwise} \end{cases} \quad (1)$$

makes the replacement decision.

3.2 Encoding Question Revisions

Let $q' = (w'_1, w'_2, \ldots, w'_l)$ denote a question revision. We first encode all the words into a d-dimensional vector space using an embedding matrix. Let $\mathbf{e}_i$ denote the embedding of word w'_i. To obtain the contextual embeddings for words, we use bi-directional LSTM

$$\overrightarrow{\mathbf{h}}_i = LSTM_{fwd}(\overrightarrow{\mathbf{h}}_{i-1}, \mathbf{e}_i) \quad (2)$$

$$\overleftarrow{\mathbf{h}}_i = LSTM_{bwd}(\overleftarrow{\mathbf{h}}_{i+1}, \mathbf{e}_i) \quad (3)$$

with $\overrightarrow{\mathbf{h}}_0 = \mathbf{0}$ and $\overleftarrow{\mathbf{h}}_{l+1} = \mathbf{0}$. We combine forward and backward contextual embeddings by $\mathbf{h}_i = \mathbf{concat}(\overrightarrow{\mathbf{h}}_i, \overleftarrow{\mathbf{h}}_i)$. We then generate the final encoding of revised question q' by $\mathbf{enc}(q') = \mathbf{concat}(\mathbf{h}_1, \mathbf{h}_l)$.

3.3 Training Objective

Score Function. Given a question revision mapping m, a question q, and a relation r, our scoring function is defined as $s(q, r) = \boldsymbol{w}^T \mathbf{enc}(m(q, r))$ where $\boldsymbol{w}$ is a model parameter that is jointly learnt with the LSTM parameters.

Loss Function. Let $\mathcal{T} = \{(q, a_q)\}$ denote a set of training questions paired with their true answer set. Let $U(q)$ denote the set of all candidate KB relations for question q. Let $f(q, r)$ denote the F_1 value of an answer set obtained by relation r when compared to a_q. For each candidate relation $r \in U(q)$ with a positive F_1 value, we define

$$N(q, r) = \{r' \in U(q) : f(q, r) > f(q, r')\} \quad (4)$$

as the set of its negative relations for question q. Similar to a hinge-loss in (Bordes et al., 2014), we define the objective function $J(\boldsymbol{\theta}, \boldsymbol{w}, \boldsymbol{E})$ as

$$\sum_{(q,r,r')} max(0, \delta_\lambda(q, r, r') - s(q, r) + s(q, r')) \quad (5)$$

where the sum is taken over all valid $\{(q, r, r')\}$ triplets and the penalty margin is defined as $\delta_\lambda(q, r, r') = \lambda(f(q, r) - f(q, r'))$.

We use this loss function because: i) it allows us to exploit partially correct answers via F_1 scores, and ii) training with it updates the model parameters towards putting a large margin between the scores of correct (r) and incorrect (r') relations, which is naturally aligned with our prediction refinement objective defined in Equation 1.

4 Alternative Solutions

Our approach directly integrates additional textual evidences with the question itself, which can be processed by any sequence oriented model, and benefit from its future updates without significant modification. However, we could also design models taking these textual evidences into specific consideration, without even appealing to question revision. We have explored this option and tried two methods that closely follow QA-LSTM and ATTENTIVE-LSTM (Tan et al., 2016). The latter model achieves the state-of-the-art for passage-level question answer matching. Unlike our approach, they encode questions and evidences for candidate answers in parallel, and measure the semantic similarity between them using *cosine* distance. The effectiveness of these architectures has been shown in other studies (Neculoiu et al., 2016; Hermann et al., 2015; Chen et al., 2016; Mueller and Thyagarajan, 2016) as well.

We adopt these models in our setting as follows: (1) Textual evidences $\alpha(s_r)$ (equiv. of **EC** revision), $\alpha(o_r)$ (equiv. of **AC** revision) or $\alpha(r)$ (equiv. of **RC** revision) of a candidate KB relation r is used in place of a candidate answer a in the original model, (2) We replace the entity mention with a universal #entity# token as in (Yih et al., 2015) because individual entities are rare and uninformative for semantic similarity, (3) We train the score function $sim(q, r)$ using the objective defined in Eq. 5. Further details of the alternative solutions can be found in Appendix A.

5 Experiments

Datasets. For evaluation, we use the WEBQUESTIONS (Berant et al., 2013), a benchmark dataset for QA on Freebase. It contains 5,810 questions whose answers are annotated from Freebase using Amazon Mechanical Turk. We also use SIMPLEQUESTIONS (Bordes et al., 2015), a collection of 108,442 question/Freebase-fact pairs, for training data augmentation in some of our experiments, which is denoted by **+SimpleQ.** in results.

Table 3: $\mathbf{F_1}$ performance of variants of our model QuesRev and alternative solutions on base QA system STAGG.

Training Data Preparation. WebQuestions only provides question-answer pairs along with annotated topic entities. We generate candidates $U(q)$ for each question q by retrieving 1-hop and 2-hop KB relations r from annotated topic entity e in Freebase. For each relation r, we query $(e, r, ?)$ against Freebase and retrieve the candidate answers r_a. Then, we compute $f(q, r)$ by comparing the answer set r_a with the annotated answers.

5.1 Implementation Details

Word embeddings are initialized with pretrained GloVe (Pennington et al., 2014) vectors[1], and updated during the training. We take the dimension of word embeddings and the size of LSTM hidden layer equal and experiment with values in $\{50, 100, 200, 300\}$. We apply dropout regularization on both input and output of LSTM encoder with probability 0.5. We hand tuned penalty margin scalar λ as 1. The model parameters are optimized using Adam (Kingma and Ba, 2015) with batch size of 32. We implemented our models in *tensorflow* (Abadi et al., 2016).

To refine predictions r of a base QA system, we take its second top ranked prediction as the refinement candidate r', and employ $replace(r, r', q)$ in Eq. 1. Confidence margin threshold t is tuned by grid search on the training data after the score function is trained. QuesRev-**AC** + **RC** model is obtained by a linear combination of QuesRev-**AC** and QuesRev-**RC**, which is formally defined in Appendix B. To evaluate the alternative solutions for prediction refinement, we apply the same decision mechanism in Eq. 1 with the trained $sim(q, r)$ in Section 4 as the score function.

We use a dictionary[2] to identify wh-words in a question. We find topic entity spans using Stanford NER tagger (Manning et al., 2014). If there are multiple matches, we use the first matching span for both.

5.2 Results

Table 2 presents the main result of our prediction refinement model using STAGG's results. Our approach improves the performance of a strong base QA system by 1.4% and achieves 53.9% in F_1 measure, which is slightly better than the state-of-the-art KB-QA system (Xu et al., 2016a). However, it is important to note here that Xu et al. (2016a) uses DBPedia knowledge base in addition to Freebase and the Wikipedia corpus that we do not utilize. Moreover, applying our approach on the STAGG predictions reranked by (Yavuz et al., 2016), referred as STAGG-Rank in Table 2, leads to a further improvement over a strong ensemble baseline. These suggest that our system captures orthogonal signals to the ones exploited in the base QA models. Improvements of QuesRev over both STAGG and STAGG-Rank are statistically significant.

In Table 3, we present variants of our approach. We observe that **AC** model yields to best refinement results when trained only on WebQuestions data (e.g., **WebQ.** column). This empirical observation is intuitively expected because it has more generalization power than **RC**, which might make **AC** more robust to the training data sparsity. This intuition is further justified by observing that augmenting the training data with SimpleQuestions improves the performance of **RC** model most as it has more expressive power.

Although both QA-LSTM and Attentive-LSTM lead to successful prediction refinements on STAGG, question revision approach consistently outperforms both of the alternative solutions. This suggests that our way of incorporating the new textual evidences by naturally blending them in

Table 4: Example predictions of STAGG (Yih et al., 2015) and replacements proposed by variants of QUESREV, followed by their corresponding question revisions. The colors *red* and *blue* indicate wrong and correct, respectively. Domain names of KB relations are dropped for brevity.

the question context leads to a better mechanism for checking the consistency of KB relations with the question. It is possible to argue that part of the improvements of refinement models over STAGG in Table 3 may be due to model ensembling. However, the performance gap between QUESREV and the alternative solutions enables us to isolate this effect for query revision approach.

6 Related Work

One of the promising approaches for KB-QA is semantic parsing, which uses logical language CCG (Kwiatkowski et al., 2013; Reddy et al., 2014; Choi et al., 2015) or DCS (Berant et al., 2013) for finding the right grounding of the natural language on knowledge base. Another major line of work (Bordes et al., 2014; Yih et al., 2015; Xu et al., 2016b) exploit vector space embedding approach to directly measure the semantic similarity between questions and candidate answer subgraphs in KB. In this work, we propose a post-inspection step that can help existing KB-QA systems recover from answer prediction errors.

Our work is conceptually related to traditional query expansion, a well-explored technique (Qiu and Frei, 1993; Mitra et al., 1998; Navigli and Velardi, 2003; Riezler et al., 2007; Fang, 2008; Sordoni et al., 2014; Diaz et al., 2016) in information retrieval area. The intuition behind query expansion is to reformulate the original query to improve retrieval performance. Our approach revises questions using candidate answers already retrieved by a base QA system. Revised questions are then used for reasoning about the corresponding predictions themselves, not for retrieving more candidates. Hence, it is specialized rather as a reasoning component than a retrieval one.

Hypothesis generation steps in (Téllez-Valero et al., 2008) and (Trischler et al., 2016) are related to our question revision process. However, hypotheses in these approaches need to be further compared against supporting paragraphs for reasoning. This limits the applicability of them in KB-QA setting due to lack of supporting texts. Our approach modifies the appropriate parts of the question using different KB evidences behind candidate answers that are more informative and generalizable. This enables us to make reasoning about candidate predictions directly via revised questions without relying on any supporting texts.

7 Conclusion

We present a prediction refinement approach for question answering over knowledge bases. We introduce question revision as a tailored augmentation of the question via various textual evidences from KB relations. We exploit revised questions as a way to reexamine the consistency of candidate KB relations with the question itself. We show that our method improves the quality of answers produced by STAGG on the WEBQUESTIONS dataset.

A Implementation details of alternative solutions

Following (Tan et al., 2016), we use the same bidirectional LSTM for both questions and textual evidences. For the attentive model, we apply the attention mechanism on the question side because our objective is to match textual evidences to the question context unlike the original model. We use average pooling for both models and compute the *general* attention via a bilinear term that has been shown effective in (Luong et al., 2015).

For the model and training parameters, we follow the strategy described in Section 5.1 with a difference that λ is tuned to be 0.2 in this setting. This intuitively makes sense because the score $sim(q, r)$ is in $[-1, 1]$.

To clarify the question and answer sides for the alternative models, we provide concrete examples in Table 5 for the running example.

Question Side	Answer Side	Model Name
what did #entity# fight for	activist	ALT.-(equiv **EC**)
what did #entity# fight for	activism issue	ALT.-(equiv **AC**)
what did #entity# fight for	area of activism	ALT.-(equiv **RC**)

Table 5: Question (q) and answer (a) sides used for alternative (e.g., ALT.) solutions QA-LSTM and ATTENTIVE-LSTM.

B Combining multiple question revision strategies

We also performed experiments combining multiple question revisions that may potentially capture complementary signals. To this end, let $s_1, \ldots, s_k$ be the trained scoring functions with question revisions constructed by $m_1, \ldots, m_k$, we define $s(q, r) = \sum_{i=1}^{k} \gamma_i s_i(q, r)$ where $\gamma \in \mathbb{R}^k$ is a weight vector that is trained using the same objective defined in Equation 5. This strategy is used to obtain **AC+RC** model reported in experimental results by combining **AC** and **RC** for $k = 2$.

An empirical study on the effectiveness of images in Multimodal Neural Machine Translation

Jean-Benoit Delbrouck and **Stéphane Dupont**
TCTS Lab, University of Mons, Belgium
{jean-benoit.delbrouck, stephane.dupont}@umons.ac.be

Abstract

In state-of-the-art Neural Machine Translation (NMT), an attention mechanism is used during decoding to enhance the translation. At every step, the decoder uses this mechanism to focus on different parts of the source sentence to gather the most useful information before outputting its target word. Recently, the effectiveness of the attention mechanism has also been explored for multimodal tasks, where it becomes possible to focus both on sentence parts and image regions that they describe. In this paper, we compare several attention mechanism on the multimodal translation task (English, image → German) and evaluate the ability of the model to make use of images to improve translation. We surpass state-of-the-art scores on the Multi30k data set, we nevertheless identify and report different misbehavior of the machine while translating.

1 Introduction

In machine translation, neural networks have attracted a lot of research attention. Recently, the attention-based encoder-decoder framework (Sutskever et al., 2014; Bahdanau et al., 2014) has been largely adopted. In this approach, Recurrent Neural Networks (RNNs) map source sequences of words to target sequences. The attention mechanism is learned to focus on different parts of the input sentence while decoding. Attention mechanisms have shown to work with other modalities too, like images, where their are able to learn to attend the salient parts of an image, for instance when generating text captions (Xu et al., 2015). For such applications, Convolutional Neural Networks (CNNs) such as Deep Residual (He et al., 2016) have shown to work best to represent images.

Multimodal models of texts and images empower new applications such as visual question answering or multimodal caption translation. Also, the grounding of multiple modalities against each other may enable the model to have a better understanding of each modality individually, such as in natural language understanding applications.

In the field of Machine Translation (MT), the efficient integration of multimodal information still remains a challenging task. It requires combining diverse modality vector representations with each other. These vector representations, also called context vectors, are computed in order the capture the most relevant information in a modality to output the best translation of a sentence.

To investigate the effectiveness of information obtained from images, a multimodal machine translation shared task (Specia et al., 2016) has been addressed to the MT community[1]. The best results of NMT model were those of Huang et al. (2016) who used LSTM fed with global visual features or multiple regional visual features followed by rescoring. Recently, Calixto et al. (2017) proposed a doubly-attentive decoder that outperformed this baseline with less data and without rescoring.

Our paper is structured as follows. In section 2, we briefly describe our NMT model as well as the conditional GRU activation used in the decoder. We also explain how multi-modalities can be implemented within this framework. In the following sections (3 and 4), we detail three attention mechanisms and explain how we tweak them to work as well as possible with images. Finally, we report and analyze our results in section 5 then conclude in section 6.

2 Neural Machine Translation

In this section, we detail the neural machine translation architecture by Bahdanau et al. (2014), implemented as an attention-based encoder-decoder framework with recurrent neural networks (§2.1). We follow by explaining the conditional GRU layer (§2.2) - the gating mechanism we chose for our RNN - and how the model can be ported to a multimodal version (§2.3).

2.1 Text-based NMT

Given a source sentence $X = (x_1, x_2, \ldots, x_M)$, the neural network directly models the conditional probability $p(Y|X)$ of its translation $Y = (y_1, y_2, \ldots, y_N)$. The network consists of one encoder and one decoder with one attention mechanism. The encoder computes a representation C for each source sentence and a decoder generates one target word at a time and by decomposing the following conditional probability :

$$\log p(Y|X) = \sum_{t=1}^{n} \log p(y_t|y < t, C) \qquad (1)$$

Each source word x_i and target word y_i are a column index of the embedding matrix $\boldsymbol{E}_X$ and $\boldsymbol{E}_Y$. The encoder is a bi-directional RNN with Gated Recurrent Unit (GRU) layers (Chung et al., 2014; Cho et al., 2014), where a forward RNN $\overrightarrow{\Psi}_{\text{enc}}$ reads the input sequence as it is ordered (from x_1 to x_M) and calculates a sequence of forward hidden states $(\overrightarrow{\boldsymbol{h}}_1, \overrightarrow{\boldsymbol{h}}_2, \ldots, \overrightarrow{\boldsymbol{h}}_M)$. A backward RNN $\overleftarrow{\Psi}_{\text{enc}}$ reads the sequence in the reverse order (from x_M to x_1), resulting in a sequence of backward hidden states $(\overleftarrow{\boldsymbol{h}}_M, \overleftarrow{\boldsymbol{h}}_{M-1}, \ldots, \overleftarrow{\boldsymbol{h}}_1)$. We obtain an annotation for each word x_i by concatenating the forward and backward hidden state $\boldsymbol{h}_t = [\overrightarrow{\boldsymbol{h}}_t; \overleftarrow{\boldsymbol{h}}_t]$. Each annotation $\boldsymbol{h}_t$ contains the summaries of both the preceding words and the following words. The representation C for each source sentence is the sequence of annotations $C = (\boldsymbol{h}_1, \boldsymbol{h}_2, \ldots, \boldsymbol{h}_M)$.

The decoder is an RNN that uses a conditional GRU (cGRU, more details in §2.2) with an attention mechanism to generate a word y_t at each time-step t. The cGRU uses it's previous hidden state $\boldsymbol{s}_{t-1}$, the whole sequence of source annotations C and the previously decoded symbol y_{t-1} in order to update it's hidden state $\boldsymbol{s}_t$:

$$\mathbf{s}_t = \text{cGRU}\left(\mathbf{s}_{t-1}, y_{t-1}, C\right) \qquad (2)$$

In the process, the cGRU also computes a time-dependent context vector $\boldsymbol{c}_t$. Both $\boldsymbol{s}_t$ and $\boldsymbol{c}_t$ are further used to decode the next symbol. We use a deep output layer (Pascanu et al., 2014) to compute a vocabulary-sized vector :

$$\boldsymbol{o}_t = \boldsymbol{L}_o \tanh(\boldsymbol{L}_s s_t + \boldsymbol{L}_c \boldsymbol{c}_t + \boldsymbol{L}_w \boldsymbol{E}_Y[y_{t-1}]) \qquad (3)$$

where $\boldsymbol{L}_o$, $\boldsymbol{L}_s$, $\boldsymbol{L}_c$, $\boldsymbol{L}_w$ are model parameters. We can parameterize the probability of decoding each word y_t as:

$$p(y_t|y_{t-1}, \boldsymbol{s}_t, \boldsymbol{c}_t) = \text{Softmax}(\boldsymbol{o}_t) \qquad (4)$$

The initial state of the decoder $\boldsymbol{s}_0$ at time-step $t = 0$ is initialized by the following equation :

$$\boldsymbol{s}_0 = f_{\text{init}}(\boldsymbol{h}_M) \qquad (5)$$

where f_{init} is a feedforward network with one hidden layer.

2.2 Conditional GRU

The conditional GRU [2] consists of two stacked GRU activations called REC_1 and REC_2 and an attention mechanism f_{att} in between (called ATT in the footnote paper). At each time-step t, REC1 firstly computes a hidden state proposal $\boldsymbol{s}'_t$ based on the previous hidden state $\boldsymbol{s}_{t-1}$ and the previously emitted word y_{t-1}:

$$\begin{aligned}
\boldsymbol{z}'_t &= \sigma\left(\boldsymbol{W}'_z \boldsymbol{E}_Y[y_{t-1}] + \boldsymbol{U}'_z \boldsymbol{s}_{t-1}\right) \\
\boldsymbol{r}'_t &= \sigma\left(\boldsymbol{W}'_r \boldsymbol{E}_Y[y_{t-1}] + \boldsymbol{U}'_r \boldsymbol{s}_{t-1}\right) \\
\underline{\boldsymbol{s}}'_t &= \tanh\left(\boldsymbol{W}' \boldsymbol{E}_Y[y_{t-1}] + \boldsymbol{r}'_t \odot (\boldsymbol{U}' \boldsymbol{s}_{t-1})\right) \\
\boldsymbol{s}'_t &= (1 - \boldsymbol{z}'_t) \odot \underline{\boldsymbol{s}}'_t + \boldsymbol{z}'_t \odot \boldsymbol{s}_{t-1} \qquad (6)
\end{aligned}$$

Then, the attention mechanism computes c_t over the source sentence using the annotations sequence C and the intermediate hidden state proposal $\boldsymbol{s}'_t$:

$$\boldsymbol{c}_t = f_{\text{att}}\left(\text{C}, \boldsymbol{s}'_t\right) \qquad (7)$$

Finally, the second recurrent cell REC_2, computes the hidden state $\boldsymbol{s}_t$ of the cGRU by looking at the intermediate representation $\boldsymbol{s}'_t$ and context vector $\boldsymbol{c}_t$:

$$\begin{aligned}
\boldsymbol{z}_t &= \sigma\left(\boldsymbol{W}_z \boldsymbol{c}_t + \boldsymbol{U}_z \boldsymbol{s}'_t\right) \\
\boldsymbol{r}_t &= \sigma\left(\boldsymbol{W}_r \boldsymbol{c}_t + \boldsymbol{U}_r \boldsymbol{s}'_t\right) \\
\underline{\boldsymbol{s}}_t &= \tanh\left(\boldsymbol{W} \boldsymbol{c}_t + \boldsymbol{r}_t \odot (\boldsymbol{U} \boldsymbol{s}'_t)\right) \\
\boldsymbol{s}_t &= (1 - \boldsymbol{z}_t) \odot \underline{\boldsymbol{s}}_t + \boldsymbol{z}_t \odot \boldsymbol{s}'_t \qquad (8)
\end{aligned}$$

2.3 Multimodal NMT

Recently, Calixto et al. (2017) proposed a doubly attentive decoder (referred as the ”MNMT” model in the author’s paper) which can be seen as an expansion of the attention-based NMT model proposed in the previous section. Given a sequence of second a modality annotations $I = (\boldsymbol{a}_1, \boldsymbol{a}_2, \ldots, \boldsymbol{a}_L)$, we also compute a new context vector based on the same intermediate hidden state proposal $\boldsymbol{s}'_t$:

$$\boldsymbol{i}_t = f'_{\text{att}}\left(\text{I}, \boldsymbol{s}'_t\right) \tag{9}$$

This new time-dependent context vector is an additional input to a modified version of REC2 which now computes the final hidden state $\boldsymbol{s}_t$ using the intermediate hidden state proposal $\boldsymbol{s}'_t$ and both time-dependent context vectors $\boldsymbol{c}_t$ and $\boldsymbol{i}_t$:

$$\begin{aligned}
\boldsymbol{z}_t &= \sigma\left(\boldsymbol{W}_z \boldsymbol{c}_t + \boldsymbol{W}_z \boldsymbol{i}_t + \boldsymbol{U}_z \boldsymbol{s}'_t\right) \\
\boldsymbol{r}_t &= \sigma\left(\boldsymbol{W}_r \boldsymbol{c}_t + \boldsymbol{W}_r \boldsymbol{i}_t + \boldsymbol{U}_r \boldsymbol{s}'_t\right) \\
\underline{\boldsymbol{s}}_t &= \tanh\left(\boldsymbol{W} \boldsymbol{c}_t + \boldsymbol{W} \boldsymbol{i}_t + \boldsymbol{r}_t \odot \left(\boldsymbol{U} \boldsymbol{s}'_t\right)\right) \\
\boldsymbol{s}_t &= (1 - \boldsymbol{z}_t) \odot \underline{\boldsymbol{s}}_t + \boldsymbol{z}_t \odot \boldsymbol{s}'_t
\end{aligned} \tag{10}$$

The probabilities for the next target word (from equation 3) also takes into account the new context vector $\boldsymbol{i}_t$:

$$\boldsymbol{L}_o \tanh(\boldsymbol{L}_s \boldsymbol{s}_t + \boldsymbol{L}_c \boldsymbol{c}_t + \boldsymbol{L}_i \boldsymbol{i}_t + \boldsymbol{L}_w \boldsymbol{E}_Y [y_{t-1}]) \tag{11}$$

where $\boldsymbol{L}_i$ is a new trainable parameter.

In the field of multimodal NMT, the second modality is usually an image computed into feature maps with the help of a CNN. The annotations $a_1, a_2, \ldots, a_L$ are spatial features (i.e. each annotation represents features for a specific region in the image) . We follow the same protocol for our experiments and describe it in section 5.

3 Attention-based Models

We evaluate three models of the image attention mechanism f'_{att} of equation 7. They have in common the fact that at each time step t of the decoding phase, all approaches first take as input the annotation sequence I to derive a time-dependent context vector that contain relevant information in the image to help predict the current target word y_t. Even though these models differ in how the time-dependent context vector is derived, they share the same subsequent steps. For each mechanism, we propose two hand-picked illustrations showing where the attention is placed in an image.

3.1 Soft attention

Soft attention has firstly been used for syntactic constituency parsing by Vinyals et al. (2015) but has been widely used for translation tasks ever since. One should note that it slightly differs from Bahdanau et al. (2014) where their attention takes as input the previous decoder hidden state instead of the current (intermediate) one as shown in equation 7. This mechanism has also been successfully investigated for the task of image description generation (Xu et al., 2015) where a model generates an image’s description in natural language. It has been used in multimodal translation as well (Calixto et al., 2017), for which it constitutes a state-of-the-art.

The idea of the soft attentional model is to consider all the annotations when deriving the context vector $\boldsymbol{i}_t$. It consists of a single feed-forward network used to compute an expected alignment $\boldsymbol{e}_t$ between modality annotation $\boldsymbol{a}_l$ and the target word to be emitted at the current time step t. The inputs are the modality annotations and the intermediate representation of REC1 $\boldsymbol{s}'_t$:

$$\boldsymbol{e}_{t,l} = \boldsymbol{v}^T \tanh(\boldsymbol{U}_a \boldsymbol{s}'_t + \boldsymbol{W}_a \boldsymbol{a}_l) \tag{12}$$

The vector $\boldsymbol{e}_t$ has length L and its l-th item contains a score of how much attention should be put on the l-th annotation in order to output the best word at time t. We compute normalized scores to create an attention mask $\boldsymbol{\alpha}_t$ over annotations:

$$\boldsymbol{\alpha}_{t,i} = \frac{\exp(\boldsymbol{e}_{t,i})}{\sum_{j=1}^{L} \exp(\boldsymbol{e}_{t,j})} \tag{13}$$

$$\boldsymbol{i}_t = \sum_{i=1}^{L} \boldsymbol{\alpha}_{t,i} \boldsymbol{a}_i \tag{14}$$

Finally, the modality time-dependent context vector $\boldsymbol{i}_t$ is computed as a weighted sum over the annotation vectors (equation 14). In the above expressions, $\boldsymbol{v}^T$, $\boldsymbol{U}_a$ and $\boldsymbol{W}_a$ are trained parameters.

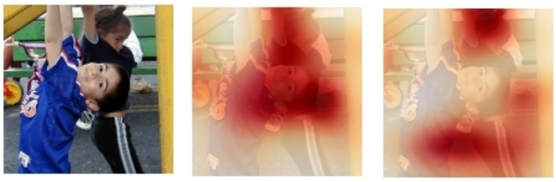

Figure 1: Die beiden Kinder spielen auf dem Spielplatz .

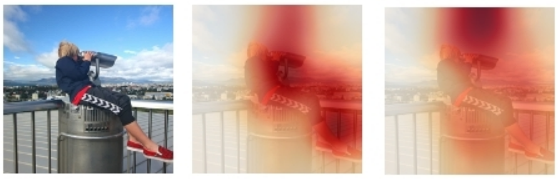

Figure 2: Ein Junge sitzt auf und blickt aus einem Mikroskop .

3.2 Hard Stochastic attention

This model is a stochastic and sampling-based process where, at every timestep t, we are making a hard choice to attend only one annotation. This corresponds to one spatial location in the image. Hard attention has previously been used in the context of object recognition (Mnih et al., 2014; Ba et al., 2015) and later extended to image description generation (Xu et al., 2015). In the context of multimodal NMT, we can follow Xu et al. (2015) because both our models involve the same process on images.

The mechanism f'_{att} is now a function that returns a sampled intermediate latent variables $\gamma_{t,i}$ based upon a multinouilli distribution parameterized by $\boldsymbol{\alpha}$:

$$\gamma_t \sim \text{Multinoulli}(\{\boldsymbol{\alpha}_{1,\ldots,L}\}) \tag{15}$$

where $\gamma_{t,i}$ an indicator one-hot variable which is set to 1 if the i-th annotation (out of L) is the one used to compute the context vector $\boldsymbol{i}_t$:

$$p(\gamma_{t,i} = 1|\boldsymbol{\gamma} < t, I) = \boldsymbol{\alpha}_{t,i} \tag{16}$$

$$\boldsymbol{i}_t = \sum_{i=1}^{L} \gamma_{t,i} \boldsymbol{a}_i \tag{17}$$

Context vector $\boldsymbol{i}_t$ is now seen as the random variable of this distribution. We define the variational lower bound $\mathcal{L}(\gamma)$ on the marginal log evidence $\log p(y|I)$ of observing the target sentence y given modality annotations I.

$$\begin{aligned}\mathcal{L}(\gamma) &= \sum_{\gamma} p(\gamma|I) \log p(y|\gamma, I) \\ &\leq \log \sum_{\gamma} p(\gamma|I) p(y|\gamma, I) \\ &= \log p(y|I)\end{aligned} \tag{18}$$

The learning rules can be derived by taking derivatives of the above variational free energy $\mathcal{L}(\gamma)$ with respect to the model parameter $\boldsymbol{W}$:

$$\frac{\partial \mathcal{L}}{\partial \boldsymbol{W}} = \sum_{\gamma} p(\gamma|I) \Bigg[\frac{\partial \log p(y|\gamma, I)}{\partial \boldsymbol{W}} + \log p(y|\gamma, I) \frac{\partial \log p(\gamma|I)}{\partial \boldsymbol{W}} \Bigg] \tag{19}$$

In order to propagate a gradient through this process, the summation in equation 19 can then be approximated using Monte Carlo based sampling defined by equation 16:

$$\frac{\partial \mathcal{L}}{\partial \boldsymbol{W}} \approx \frac{1}{N} \sum_{n=1}^{N} \Bigg[\frac{\partial \log p(y|\tilde{\gamma}^n, I)}{\partial \boldsymbol{W}} + \log p(y|\tilde{\gamma}^n, I) \frac{\partial \log p(\tilde{\gamma}^n|I)}{\partial \boldsymbol{W}} \Bigg] \tag{20}$$

To reduce variance of the estimator in equation 20, we use a moving average baseline estimated as an accumulated sum of the previous log likelihoods with exponential decay upon seeing the k-th mini-batch:

$$b_k = 0.9 \times b_{k-1} + 0.1 \times \log p(y|\tilde{\gamma}_k, I) \tag{21}$$

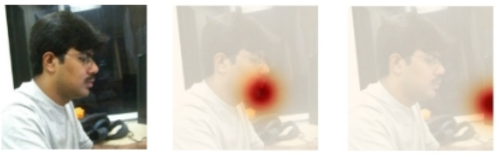

Figure 3: Ein Mann sitzt neben einem Computerbildschirm .

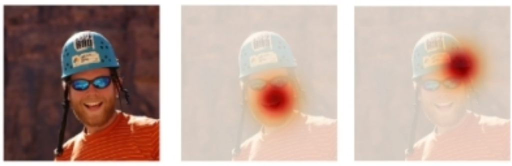

Figure 4: Ein Mann in einem orangefarbenen Hemd und mit Helm .

3.3 Local Attention

In this section, we propose a local attentional mechanism that chooses to focus only on a small subset of the image annotations. Local Attention has been used for text-based translation (Luong et al., 2015) and is inspired by the selective attention model of Gregor et al. (2015) for image generation. Their approach allows the model to select an image patch of varying location and zoom. Local attention uses instead the same ”zoom” for all target positions and still achieved good performance. This model can be seen as a trade-off between the soft and hard attentional models. The model picks one patch in the annotation sequence (one spatial location) and selectively focuses on a small window of context around it. Even though an image can't be seen as a temporal sequence, we still hope that the model finds points of interest and selects the useful information around it. This approach has an advantage of being differentiable whereas the stochastic attention requires more complicated techniques such as variance reduction and reinforcement learning to train as shown in section 3.2. The soft attention has the drawback to attend the whole image which can be difficult to learn, especially because the number of annotations L is usually large (presumably to keep a significant spatial granularity).

More formally, at every decoding step t, the model first generates an aligned position p_t. Context vector $\boldsymbol{i}_t$ is derived as a weighted sum over the annotations within the window $[p_t - N; p_t + N]$ where N is a fixed model parameter chosen empirically[3]. These selected annotations correspond to a squared region in the attention maps around p_t. The attention mask $\boldsymbol{\alpha}_t$ is of size $2N + 1$. The model predicts p_t as an aligned position in the annotation sequence (referred as Predictive alignment (local-m) in the author's paper) according to the following equation:

$$p_t = S \cdot \text{sigmoid}(\boldsymbol{v}^T \tanh(\boldsymbol{U}_a \boldsymbol{s}'_t)) \tag{22}$$

where $\boldsymbol{v}^T$ and $\boldsymbol{U}_a$ are both trainable model parameters and S is the annotation sequence length $|I|$. Because of the sigmoid, $p_t \in [0, S]$. We use equation 12 and 13 respectively to compute the expected alignment vector $\boldsymbol{e}_t$ and the attention mask $\boldsymbol{\alpha}_t$. In addition, a Gaussian distribution centered around p_t is placed on the alphas in order to favor annotations near p_t:

$$\boldsymbol{\alpha}_{t,i} = \boldsymbol{\alpha}_{t,i} \exp\left(-\frac{(i - p_t)^2}{2\sigma^2}\right) \tag{23}$$

where standard deviation $\sigma = \frac{D}{2}$. We obtain context vector $\boldsymbol{i}_t$ by following equation 14.

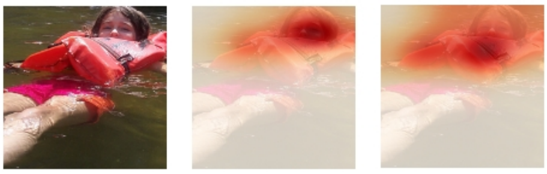

Figure 5: Ein Mädchen mit einer Schwimmweste schwimmt im Wasser .

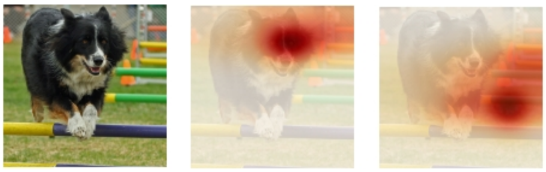

Figure 6: Ein kleiner schwarzer Hund springt über Hindernisse .

4 Image attention optimization

Three optimizations can be added to the attention mechanism regarding the image modality. All lead to a better use of the image by the model and improved the translation scores overall.

At every decoding step t, we compute a gating scalar $\boldsymbol{\beta}_t \in [0, 1]$ according to the previous decoder state $\boldsymbol{s}_{t-1}$:

$$\boldsymbol{\beta}_t = \sigma(\boldsymbol{W}_\beta \boldsymbol{s}_{t-1} + \boldsymbol{b}_\beta) \tag{24}$$

It is then used to compute the time-dependent image context vector :

$$\boldsymbol{i}_t = \boldsymbol{\beta}_t \sum_{l=1}^{L} \boldsymbol{\alpha}_{t,l} \boldsymbol{a}_l \tag{25}$$

Xu et al. (2015) empirically found it to put more emphasis on the objects in the image descriptions generated with their model.

We also double the output size of trainable parameters $\boldsymbol{U}_a$, $\boldsymbol{W}_a$ and $\boldsymbol{v}^T$ in equation 12 when it comes to compute the expected annotations over the image annotation sequence. More

[3] We pick $N = |\boldsymbol{a}_i|/4 = 49$

formally, given the image annotation sequence $I = (\boldsymbol{a}_1, \boldsymbol{a}_2, \ldots, \boldsymbol{a}_L), \boldsymbol{a}_i \in \mathbb{R}^D$, the three matrices are of size $D \times 2D$, $D \times 2D$ and $2D \times 1$ respectively. We noticed a better coverage of the objects in the image by the alpha weights.

Lastly, we use a grounding attention inspired by Delbrouck and Dupont (2017). The mechanism merge each spatial location $\boldsymbol{a}_i$ in the annotation sequence I with the initial decoder state $\boldsymbol{s}_0$ obtained in equation 5 with non-linearity :

$$I' = (f(\boldsymbol{a}_1 + \boldsymbol{s}_0), f(\boldsymbol{a}_2 + \boldsymbol{s}_0), \ldots, f(\boldsymbol{a}_L + \boldsymbol{s}_0)) \tag{26}$$

where f is $\tanh$ function. The new annotations go through a L2 normalization layer followed by two 1×1 convolutional layers (of size $D \to 512, 512 \to 1$ respectively) to obtain $L \times 1$ weights, one for each spatial location. We normalize the weights with a softmax to obtain a soft attention map $\boldsymbol{\alpha}$. Each annotation $\boldsymbol{a}_i$ is then weighted according to its corresponding $\boldsymbol{\alpha}_i$:

$$I = (\boldsymbol{\alpha}_1 \boldsymbol{a}_1, \boldsymbol{\alpha}_2 \boldsymbol{a}_2, \ldots, \boldsymbol{\alpha}_L \boldsymbol{a}_L) \tag{27}$$

This method can be seen as the removal of unnecessary information in the image annotations according to the source sentence. This attention is used on top of the others - before decoding - and is referred as ”grounded image” in Table 1.

5 Experiments

For this experiments on Multimodal Machine Translation, we used the Multi30K dataset (Elliott et al., 2016) which is an extended version of the Flickr30K Entities. For each image, one of the English descriptions was selected and manually translated into German by a professional translator. As training and development data, 29,000 and 1,014 triples are used respectively. A test set of size 1000 is used for metrics evaluation.

5.1 Training and model details

All our models are build on top of the nematus framework (Sennrich et al., 2017). The encoder is a bidirectional RNN with GRU, one 1024D single-layer forward and one 1024D single-layer backward RNN. Word embeddings for source and target language are of 620D and trained jointly with the model. Word embeddings and other non-recurrent matrices are initialized by sampling from a Gaussian $\mathcal{N}(0, 0.01^2)$, recurrent matrices are random orthogonal and bias vectors are all initialized to zero.

To create the image annotations used by our decoder, we used a ResNet-50 pre-trained on ImageNet and extracted the features of size $14 \times 14 \times 1024$ at its res4f layer (He et al., 2016). In our experiments, our decoder operates on the flattened 196×1024 (i.e $L \times D$). We also apply dropout with a probability of 0.5 on the embeddings, on the hidden states in the bidirectional RNN in the encoder as well as in the decoder. In the decoder, we also apply dropout on the text annotations $\boldsymbol{h}_i$, the image features $\boldsymbol{a}_i$, on both modality context vector and on all components of the deep output layer before the readout operation. We apply dropout using one same mask in all time steps (Gal and Ghahramani, 2016).

We also normalize and tokenize English and German descriptions using the Moses tokenizer scripts (Koehn et al., 2007). We use the byte pair encoding algorithm on the train set to convert space-separated tokens into subwords (Sennrich et al., 2016), reducing our vocabulary size to 9226 and 14957 words for English and German respectively.

All variants of our attention model were trained with ADADELTA (Zeiler, 2012), with mini-batches of size 80 for our monomodal (text-only) NMT model and 40 for our multimodal NMT. We apply early stopping for model selection based on BLEU4 : training is halted if no improvement on the development set is observed for more than 20 epochs. We use the metrics BLEU4 (Papineni et al., 2002), METEOR (Denkowski and Lavie, 2014) and TER (Snover et al., 2006) to evaluate the quality of our models' translations.

5.2 Quantitative results

We notice a nice overall progress over Calixto et al. (2017) multimodal baseline, especially when using the stochastic attention. With improvements of +1.51 BLEU and -2.2 TER on both precision-oriented metrics, the model shows a strong similarity of the n-grams of our candidate translations with respect to the references. The more recall-oriented metrics METEOR scores

Model	**Test Scores**					
	BLEU↑		METEOR↑		TER↓	
Monomodal (text only)						
Caglayan et al. (2016)	32.50		49.2			
Calixto et al. (2017)	33.70		52.3		46.7	
NMT	34.11	↑ +0.41	52.4	↑ +0.1	46.2	↓ -0.5
Multimodal						
Caglayan et al. (2016)	27.82		45.0		-	
Huang et al. (2016)	36.50		54.1		-	
Calixto et al. (2017)	36.50		55.0		43.7	
Soft attention	37.10	↑ +0.60	54.8	↓ -0.2	42.8	↓ -0.9
Local attention	37.55	↑ +1.05	54.8	↓ -0.2	42.4	↓ -1.3
Stochastic attention	38.01	↑ +1.51	55.4	↑ +0.4	41.5	↓ -2.2
Soft attention + grounded image	37.62	↑ +1.12	55.3	↑ +0.3	41.8	↓ -1.9
Stochastic attention + grounded image	38.17	↑ +1.67	55.4	↑ +0.4	41.5	↓ -2.2

Table 1: Results on the 1000 test triples of the Multi30K dataset. We pick Calixto et al. (2017) scores as baseline and report our results accordingly (green for improvement and red for deterioration). In each of our experiments, Soft attention is used for text. The comparison is hence with respect to the attention mechanism used for the image modality.

are roughly the same across our models which is expected because all attention mechanisms share the same subsequent step at every time-step t, i.e. taking into account the attention weights of previous time-step $t - 1$ in order to compute the new intermediate hidden state proposal and therefore the new context vector i_t. Again, the largest improvement is given by the hard stochastic attention mechanism (+0.4 METEOR): because it is modeled as a decision process according to the previous choices, this may reinforce the idea of recall. We also remark interesting improvements when using the grounded mechanism, especially for the soft attention. The soft attention may benefit more of the grounded image because of the wide range of spatial locations it looks at, especially compared to the stochastic attention. This motivates us to dig into more complex grounding techniques in order to give the machine a deeper understanding of the modalities.

Note that even though our baseline NMT model is basically the same as Calixto et al. (2017), our experiments results are slightly better. This is probably due to the different use of dropout and subwords. We also compared our results to Caglayan et al. (2016) because our multimodal models are nearly identical with the major exception of the gating scalar (cfr. section 4). This motivated some of our qualitative analysis and hesitation towards the current architecture in the next section.

5.3 Qualitative results

For space-saving and ergonomic reasons, we only discuss about the hard stochastic and soft attention, the latter being a generalization of the local attention.

As we can see in Figure 7, the soft attention model is looking roughly at the same region of the image for every decoding step t. Because the words "*hund*"(dog), "*wald*"(forest) or "*weg*"(way) in left image are objects, they benefit from a high gating scalar. As a matter of fact, the attention mechanism has learned to detect the objects within a scene (at every time-step, whichever word we are decoding as shown in the right image) and the gating scalar has learned to decide whether or not we have to look at the picture (or more accurately whether or not we are translating an object). Without this scalar, the translation scores undergo a massive drop (as seen in Caglayan et al. (2016)) which means that the attention mechanisms don't really understand the more complex relationships between objects, what is really happening in the scene. Surprisingly, the

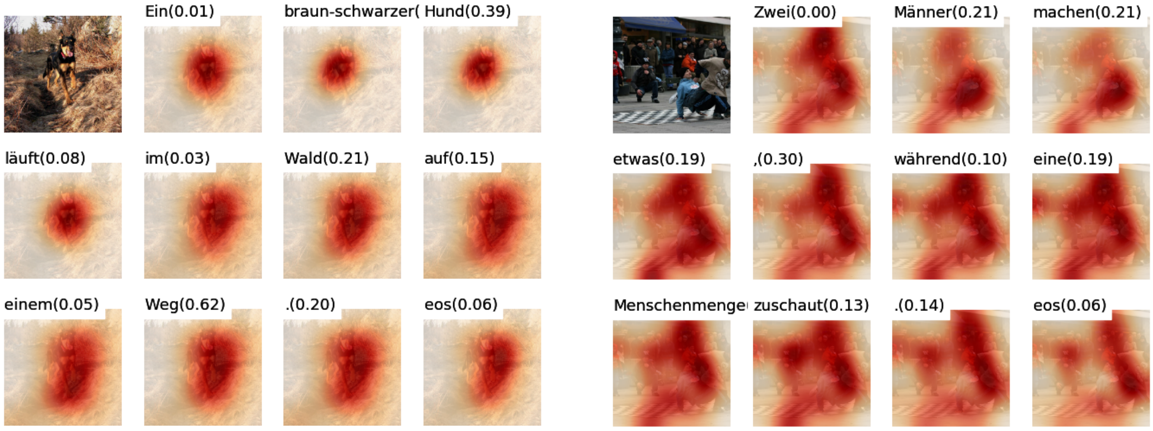

Figure 7: Representative figures of the soft-attention behavior discussed in §5.3

gating scalar happens to be really low in the stochastic attention mechanism: a significant amount of sentences don't have a summed gating scalar ≥ 0.10. The model totally discards the image in the translation process.

It is also worth to mention that we use a ResNet trained on 1.28 million images for a classification tasks. The features used by the attention mechanism are strongly object-oriented and the machine could miss important information for a multimodal translation task. We believe that the robust architecture of both encoders $\{\overleftarrow{\Psi}_{\text{enc}}, \overrightarrow{\Psi}_{\text{enc}}\}$ combined with a GRU layer and word-embeddings took care of the right translation for relationships between objects and time-dependencies. Yet, we noticed a common misbehavior for all our multimodal models: if the attention loose track of the objects in the picture and ”gets lost”, the model still takes it into account and somehow overrides the information brought by the text-based annotations. The translation is then totally mislead. We illustrate with an example:

Source:	A child claps while riding on a woman 's shoulders .
GT:	Ein Kind sitzt auf den Schultern einer Frau und klatscht .
Mono:	Ein Kind sitzt auf den Schultern einer Frau und schläft .
Soft:	Ein Kind , das sich auf der Schultern eines Frau reitet , fährt auf den Schultern .
Hard:	Ein Kind in der Haltung , während er auf den Schultern einer Frau fährt .

The monomodal translation has a sentence-level BLEU of 82.16 whilst the soft attention and hard stochastic attention scores are of 16.82 and 34.45 respectively. Figure 8 shows the attention maps for both mechanism. Nevertheless, one has to concede that the use of images indubitably helps the translation as shown in the score tabular.

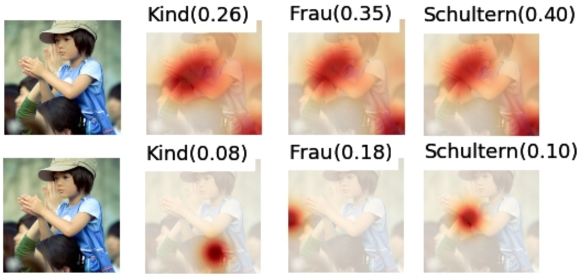

Figure 8: Wrong detection for both Soft attention (top) and Hard stochastic attention (bottom)

6 Conclusion and future work

We have tried different attention mechanism and tweaks for the image modality. We showed improvements and encouraging results overall on the Flickr30K Entities dataset. Even though we identified some flaws of the current attention mechanisms, we can conclude pretty safely that images are an helpful resource for the machine in a translation task. We are looking forward to try out richer and more suitable features for multimodal translation (ie. dense captioning features). Another interesting approach would be to use visually grounded word embeddings to capture visual notions of semantic relatedness.

Sound-Word2Vec: Learning Word Representations Grounded in Sounds

Ashwin Vijayakumar[1], **Ramakrishna Vedantam**[2] and **Devi Parikh**[1]

Abstract

To be able to interact better with humans, it is crucial for machines to understand sound – a primary modality of human perception. Previous works have used sound to learn embeddings for improved generic semantic similarity assessment. In this work, we treat sound as a first-class citizen, studying downstream 6textual tasks which require aural grounding. To this end, we propose *sound-word2vec* – a new embedding scheme that learns specialized word embeddings grounded in sounds. For example, we learn that two seemingly (semantically) unrelated concepts, like *leaves* and *paper* are similar due to the similar *rustling* sounds they make. Our embeddings prove useful in textual tasks requiring aural reasoning like text-based sound retrieval and discovering Foley sound effects (used in movies). Moreover, our embedding space captures interesting dependencies between words and onomatopoeia and outperforms prior work on aurally-relevant word relatedness datasets such as AMEN and ASLex.

1 Introduction

Sound and vision are the dominant perceptual signals, while language helps us communicate complex experiences via rich abstractions. For example, a novel can stimulate us to mentally construct the image of the scene despite having never physically perceived it. Indeed, language has evolved to contain numerous constructs that help depict visual concepts. For example, we can easily form the picture of a *white, furry* cat with *blue* eyes via. a description of the cat in terms of its visual attributes (Lampert et al., 2009; Parikh and Grauman, 2011).

Need for Onomatopoeia. However, how would one describe the auditory instantiation of cats? While a first thought might be to use audio descriptors like *loud*, *shrill*, *husky etc*. as mid-level constructs or "attributes", arguably, it is difficult to precisely convey and comprehend sound through such language. Indeed, Wake and Asahi (1998) find that humans first communicate sounds using "onomatopoeia" – words that are suggestive of the phonetics of sounds while having no explicit meaning *e.g. meow, tic-toc*. When asked for further explanation of sounds, humans provide descriptions of potential sound sources or impressions created by the sound (*pleasant, annoying,* etc.)

Need for Grounding in Sound. While onomatopoeic words exist for commonly found concepts, a vast majority of concepts are not as perceptually striking or sufficiently frequent for us to come up with dedicated words describing their sounds. Even worse, some sounds, say, musical instruments, might be difficult to mimic using speech. Thus, for a large number of concepts there seems to be a gap between sound and its counterpart in language (Sundaram and Narayanan, 2006). This becomes problematic in specific situations where we want to talk about the heavy tail of concepts and their sounds, or while describing a particular sound we want to create as an effect (say in movies). To alleviate this, a common literary strategy is to provide metaphors to more relatable exemplars. For example, when we say, "He thundered angrily", we compare the person's angry speech to the sound of thunder to convey the seriousness of the situation. However, without this grounding in sound, thunder and anger both appear to be seemingly unrelated concepts in terms of semantics.

Contributions. In this work, we learn embeddings to bridge the gap between sound and its counterpart in language. We follow a retrofitting strategy, capturing similarity in sounds associated with words, while using distributional semantics (from word2vec) to provide smoothness to the embeddings. Note that we are not interested in capturing phonetic similarity, but the grounding in sound of the concept associated with the word (say "rustling" of leaves and paper.) We demonstrate the effectiveness of our embeddings on three downstream tasks that require reasoning about related aural cues:

1. Text-based sound retrieval – Given a textual query describing the sound and a database containing sounds and associated textual tags, we retrieve sound samples by matching text (Sec. 5.1)
2. Foley Sound Discovery – Given a short phrase that outlines the technique of producing Foley sounds[1], we discover other relevant words (objects or actions) which can produce similar sound effects (Sec. 5.2)
3. Aurally-relevant word relatedness assessment on AMEN and ASLex (Kiela and Clark, 2015) (Sec. 5.3)

We also qualitatively compare with word2vec to highlight the unique notions of word relatedness captured by imposing auditory grounding.

2 Related Work

Audio and Word Embeddings. Multiple works in the recent past (Bruni et al., 2014; Lazaridou et al., 2015; Lopopolo and van Miltenburg, 2015; Kiela and Clark, 2015; Kottur et al., 2016) have explored using perceptual modalities like vision and sound to learn language embeddings. While Lopopolo and van Miltenburg (2015) show preliminary results on using sound to learn distributional representations, Kiela and Clark (2015) build on ideas from Bruni et al. (2014) to learn word embeddings that respect both linguistic and auditory relationships by optimizing a joint objective. Further, they propose various fusion strategies to combine knowledge from both the modalities. Instead, we "specialize" embeddings to exclusively respect relationships defined by sounds, while initializing with word2vec embeddings for smoothness. Similar to previous findings (Melamud et al., 2016), we observe that our specialized embeddings outperform language-only as well as other multi-modal embeddings in the downstream tasks of interest.

In an orthogonal and interesting direction, other recent works (Chung et al., 2016; He et al., 2016; Settle and Livescu, 2016) learn word representations based on similarity in their pronunciation and not the sounds associated with them. In other words, phonetically similar words that have near identical pronunciations are brought closer in the embedding space (*e.g.*, *flower* and *flour*).

Sundaram and Narayanan (2006) study the applicability of onomatopoeia to obtain semantically meaningful representations of audio. Using a novel word-similarity metric and principal component analysis, they find representations for sounds and cluster them in this derived space to reason about similarities. In contrast, we are interested in learning word representations that respect aural-similarity. More importantly, our approach learns word representations for in a data-driven manner without having to first map the sound or its tags to corresponding onomatopoeic words.

Multimodal Learning with Surrogate Supervision. Kottur et al. (2016) and Owens et al. (2016) use a surrogate modality to induce supervision to learn representations for a desired modality. While the former learns word embeddings grounded in cartoon images, the latter learns visual features grounded in sound. In contrast, we use sound as the surrogate modality to supervise representation learning for words.

3 Datasets

Freesound. We use the freesound database (Font et al., 2013), also used in prior work (Kiela and Clark, 2015; Lopopolo and van Miltenburg, 2015) to learn the proposed sound-word2vec embeddings. Freesound is a freely available, collaborative dataset consisting of user uploaded sounds permitting reuse. All uploaded sounds have human descriptions in the form of tags and captions in natural language. The tags contain a broad set of relevant topics for a sound (*e.g.*, *ambience, electronic, birds, city, reverb*) and

[1] Foley sounds are sound effects (typically ambient sounds) that are added to movies in the post-production stage to make actions or situations appear more realistic. These sounds are generally created using easily available proxy objects that mimic the sound of the true situation being depicted. For example, sound of breaking celery sticks is used to create the effect of breaking bones.

captions describing the content of the sound, in addition to details pertaining to audio quality. For the text-based sound retrieval task, we use a subset of 234,120 sounds from this database and divide it into training (80%), validation (10%) and testing splits (10%). Further, for foley sound discovery, we aggregate descriptions of foley sound production provided by sound engineers (epicsound, accessed 23-Jan-2017; Singer, accessed 23-Jan-2017) to create a list of 30 foley sound pairs, which forms our ground truth for the task. For example, the description to produce a foley "driving on gravel" sound is to record the "crunching sound of plastic or polyethene bags".

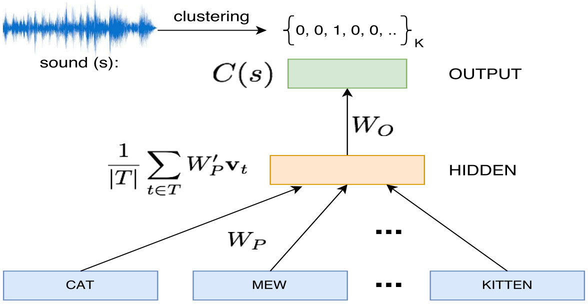
AMEN and ASLex. AMEN and ASLex (Kiela and Clark, 2015) are subsets of the standard MEN (Bruni et al., 2014) and SimLex (Hill et al., 2015) word similarity datasets consisting of word-pairs that "can be associated with a distinctive associated sound". We evaluate on this dataset for completeness to benchmark our approach against previous work. However, we are primarily interested in the slightly different problem of relating words with similar auditory instantions that may or may not be semantically related as opposed to relating semantically similar words that can be associated with some common auditory signal.

4 Approach

We use the Freesound database to construct a dataset of tuples $\{s, T\}$, where s is a sound and T is the set of associated user-provided tags. We then aim to learn an embedding space for the tags that respects auditory grounding using sound information as cross-modal context – similar to word2vec (Mikolov et al., 2013) that uses neighboring words as context / supervision. We now explain our approach in detail.

Audio Features and Clustering. We represent each sound s by a feature vector consisting of the mean and variance of the following audio descriptors that are readily available as part of Freesound database:

- Mel-Frequency Cepstral Co-efficients: This feature represents the short-term power spectrum of an audio and closely approximates the response of the human auditory system – computed as given in (Ganchev et al., 2005).
- Spectral Contrast: It is the magnitude difference in the peaks and valleys of the spectrum – computed according to (Akkermans et al., 2009).



sound (s):
clustering
$\{0, 0, 1, 0, 0, ..\}_K$
$C(s)$
OUTPUT
W_O
$\frac{1}{|T|}\sum_{t \in T} W'_P \mathbf{v}_t$
HIDDEN
W_P
...
CAT
MEW
...
KITTEN

Figure 1: The model used to learn the proposed sound-word2vec embeddings. The projection matrix W_P containing that is used as the sound-word2vec embedding is learned by training the model to accurately predict the cluster assignment of the sound.

- Dissonance: It measures the perceptual roughness of the sound (Plomp and Levelt, 1965).
- Zero-crossing Rate: It is the percentage of sign changes between consecutive signal values and is indicative of noise content.
- Spectral Spread: This feature is the concatenation of the k-order moments of the spectrum, where $k \in \{0, 1, 2, 3, 4\}$.
- Pitch Salience: This feature helps discriminate between musical and non-musical tones. While, pure tones and unpitched sounds have values near 0, musical sounds containing harmonics have higher values (Ricard, 2004).

We then use K-Means algorithm to cluster the sounds in this feature space to assign each sound to a cluster $C(s) \in \{1, \ldots K\}$. We set K to 30 by evaluating the performance of the embeddings on text-based audio-retrieval on the held out validation set. Note that the clustering is only performed once, prior to representation learning described below.

Representation Learning. We represent each tag $t \in T$ using a $|\mathcal{V}|$ dimensional one-hot encoding denoted by $\mathbf{v}_t$, where $\mathcal{V}$ is the set of all unique tags in the training set (the size of our dictionary). This one-hot vector $\mathbf{v}_t$ is projected into a D-dimensional vector space via $W_P \in \mathbb{R}^{|\mathcal{V}| \times D}$, the *projection matrix*. This projection matrix computes the representation for each word in $\mathcal{V}$. The idea of our approach is to use W_P to accurately predict cluster assignments (for sounds associated with words), which enforces grounding in sound. For each data-point, we obtain the summary of the tags T, by averaging the projections of all tags in the set as $\frac{1}{|T|}\sum_{t \in T} W'_P \mathbf{v}_t$. We then transform the so obtained summary representation via a linear layer (with parameters W_O) and pass the output through the softmax function to obtain a distribution, $p(c|T)$ over the K sound clusters. We perform maximum-likelihood training for the correct cluster assignment $C(s)$[2], optimizing for parameters W_P and W_O:

$$\max_{W_P, W_O} \log P(c = C(s)|T) \tag{1}$$

We use SGD with momentum to optimize this objective which essentially is the cross-entropy between cluster assignments and $p(c|T)$. We set D to 300 to be consistent with the publicly available word2vec embeddings.

Initialization. We initialize W_P with word2vec embeddings (Mikolov et al., 2013) trained on the Google news corpus dataset with ∼3M words. We fine-tune on a subset of 9578 tags which are present in both Freesound as well as Google news corpus datasets, which is 55.68% of the original tags in the Freesound dataset. This helps us remove noisy tags unrelated to the content of the sound.

In addition to enlarging the vocabulary, the pre-training helps induce smoothness in the sound-word2vec embeddings – allowing us to transfer semantics learnt from sounds to words that were not present as tags in the Freesound database. Indeed, we find that word2vec pre-training helps improve performance (Sec. 5.3). Our use of language embeddings as an initialization to fine-tune (specialize) from, as opposed to formulating a joint objective with language and audio context (Kiela and Clark, 2015) is driven by the fact that we are interested in embeddings for words grounded in sounds, and not better generic word similarity.

5 Results

Ablations. In addition to the language-only baseline word2vec (Mikolov et al., 2013), we compare against tag-word2vec – that predicts a tag using other tags of the sound as context, inspired by (Font et al., 2014). We also report results with a randomly initialized projection matrix (sound-word2vec(r) to evaluate the effectiveness of pre-training with word2vec.

Prior work. We compare against previous works Lopopolo and van Miltenburg (2015) and Kiela and Clark (2015). While the former uses a standard bag of words and SVD pipeline to arrive at distributional representations for words, the latter trains under a joint objective that respects both linguistic and auditory similarity. We use the openly available implementation for Lopopolo and van Miltenburg (2015) and re-implement Kiela and Clark (2015) and train them on our dataset for a fair comparison of the methods. In addition, we show a comparison to word-vectors released by (Kiela and Clark, 2015) in the supplementary material. All approaches use an embedding size of 300 for consistency.

5.1 Text-based Sound Retrieval

Given a textual description of a sound as query, we compare it with tags associated with sounds in the database to retrieve the sound with the closest matching tags. Note that this is a purely textual task, albeit one that needs awareness of sound. In a sense, this task exactly captures what we want our model to be able to do – bridge the semantic gap between language and sound. We use the training split (Sec. 3) to learn the sound-word2vec vectors, validation to pick the number of clusters (K), and report results on the test split. For retrieval, we represent sounds by averaging the learnt embeddings for the associated tags. We embed the caption provided for the sound (in the Freesound database) in a similar manner, and use it as the query. We then rank sounds based on the cosine similarity between the tag and query representations for retrieval. We evaluate using standard retrieval metrics – `Recall@{1,10,50,100}`. Note that the entire testing set (≈10k sounds) is present in the retrieval pool. So, `recall@100` corresponds to obtaining the correct result in the top 1% of the search results, which is a relatively stringent evaluation criterion.

Results. Table. 1 shows that our sound-word2vec embeddings outperform the baselines. We see that specializing the embeddings for sound using our two-stage training outperforms prior work(Kiela and Clark (2015) and Lopopolo and van Miltenburg (2015)), which did not do specialization. Among our approaches, tag-word2vec performs second best – this is intuitive since the tag distributions implicitly capture auditory relatedness (a sound may have tags *cat* and *meow*), while word2vec and sound-word2vec(r) have the lowest performance.

[2] We also tried to regress directly to sound features instead of clustering, but found that it had poor performance.

Embedding	Recall			
	@1	@10	@50	@100
word2vec	6.47±0.00	14.25±0.05	21.72±0.12	26.03±0.22
tag-word2vec	6.95±0.02	15.10±0.03	22.43±0.09	27.21±0.24
sound-word2vec(r)	6.49±0.00	14.98±0.03	21.96±0.11	26.43±0.20
(Lopopolo and van Miltenburg, 2015)	6.48±0.02	15.09±0.05	21.82±0.13	26.89±0.23
(Kiela and Clark, 2015)	6.52±0.01	15.21±0.03	21.92±0.08	27.74±0.21
sound-word2vec	**7.11**±0.02	**15.88**±0.04	**23.14**±0.09	**28.67**±0.17

Table 1: Text-based sound retrieval (*higher* is better). We find that our sound-word2vec model outperforms all baselines.

Embedding	Spearman Correlation ρ_s	
	AMEN	ASLex
(Lopopolo and van Miltenburg, 2015)	0.410±0.09	0.237±0.04
(Kiela and Clark, 2015)	0.648±0.08	0.366±0.11
sound-word2vec	**0.674**±0.05	**0.391**±0.06

Table 2: Comparison to state of the art AMEN and ASLex datasets (Kiela and Clark, 2015) (*higher* is better). Our approach performs better than Kiela and Clark (2015).

5.2 Foley Sound Discovery

In this task, we evaluate how well embeddings identify matching pairs of target sounds (*flapping bird wings*) and descriptions of Foley sound production techniques (*rubbing a pair of gloves*). Intuitively, one expects sound-aware word embeddings to do better at this task than sound-agnostic ones. We setup a ranking task by constructing a set of original Foley sound pairs and decoy pairs formed by pairing the target description with every word from the vocabulary. We rank using cosine similarity between the average word-vectors in each member of the pair. A good embedding is one in which the original Foley sound pair has the lowest rank. We use the mean rank of the Foley sound in the dataset for evaluation. We transfer the embeddings from Sec. 5.1 to this task, without additional training.

Results. We find that Sound-word2vec performs the best with a mean rank of 34.6 compared to other baselines tag-word2vec (38.9), sound-word2vec(r) (114.3) and word2vec (189.45). As observed previously, the second best performing approach is tag-word2vec. Lopopolo and van Miltenburg (2015) and Kiela and Clark (2015) perform worse than tag-word2vec with a mean rank of 48.4 and 42.1 respectively. Note that random chance gets a rank of $(|\mathcal{V}| + 1)/2 = 4789.5$.

word	word2vec	sound-word2vec
apple	apples, pear, fruit berry, pears, strawberry	bite, snack, chips chew, munch, carton
wood	lumber, timber, softwoods, hardwoods, cedar, birch	wooden, snap, knock, smack, whack, snapping
bones	skull, femur, skeletons, thighbone, pelvis, molar	eggshell, carrot, arm blood, polystyrene, crunch
glass	hand-blown, glassware, tumbler, Plexiglass, wine-glass, bottle	shattered, ceramic, smash clink, beer, spoon
Onomatopoeic query words		
boom	booms, booming, bubble, craze, downturn, upswing	bomb, bang, explosion bombing, exploding, ecstatic
jingle	song, commercial, catchy-tune, ditty, slogan, anthem	magic, tinkle, nails bells, key, doorbell
slam	slams, piledriver, uranage spinkick, hiptoss, hit	shut, lock, opening closing, latch, door
quack	charlatan, quackery, crackpot homeopaths, concoctions, snake-oil	duck, snort, calling chirp, tweet, oink

Table 3: We show nearest neighbors in both word2vec and sound-word2vec spaces for eight words ('regular' words, top half and onomatopoeic words, bottom half).

5.3 Evaluation on AMEN and ASLex

AMEN and ASLex (Kiela and Clark, 2015) are subsets of the MEN and SimLex-999 datasets for word relatedness grounded in sound. From Table 2, we can see that our embeddings outperform (Kiela and Clark, 2015) on both AMEN and ASLex. These datasets were curated by annotating concepts related by sound; however we observe that relatedness is often confounded. For example, *(river, water), (automobile, car)* are marked as aurally related however they do not stand out as aurally-related examples as they are already semantically related. In contrast, we are interested in how onomatopoeic words relate to regular words (Table 3), which we study by explicit grounding in sound. Thus while we show competitive performance on this dataset, it might not be best suited for studying the benefits of our approach.

6 Discussion and Conclusion

We show nearest neighbors in both sound-word2vec and word2vec space (Table 3) to qualitatively demonstrate the unique dependencies captured due to auditory grounding. While word2vec maps a word (say, *apple*) to other semantically similar words (other fruits), similar 'sounding' words (*chips*) or onomatopoeia (*munch*) are closer in our embedding space. Moreover, onomatopoeic words (say, *boom* and *slam*) are mapped to relevant objects (*explosion* and *door*). Interestingly, parts (*e.g.*, *lock, latch*) and actions (*closing*) are also closer to the onomatopoeic query – exhibiting an understanding of the auditory scene.

Conclusion. In this work we introduce a novel word embedding scheme that respects auditory grounding. We show that our embeddings provide strong performance on text-based sound retrieval, Foley sound discovery along with intuitive nearest neighbors for onomatopoeia that are tasks in text requiring auditory reasoning. We hope our work motivates further efforts on understanding and relating onomatopoeia words to "regular" words.

Acknowledgements. We thank the Freesound team and Frederic Font in particular for helping us with the Freesound API. We also thank Khushi Gupta and Stefan Lee for fruitful discussions. Abstract

In this paper, we make a simple observation that questions about images often contain *premises* – objects and relationships implied by the question – and that reasoning about premises can help Visual Question Answering (VQA) models respond more intelligently to irrelevant or previously unseen questions.

When presented with a question that is irrelevant to an image, state-of-the-art VQA models will still answer purely based on learned language biases, resulting in nonsensical or even misleading answers. We note that a visual question is irrelevant to an image if at least one of its premises is false (*i.e.* not depicted in the image). We leverage this observation to construct a dataset for Question Relevance Prediction and Explanation (QRPE) by searching for false premises. We train novel question relevance detection models and show that models that reason about premises consistently outperform models that do not.

We also find that forcing standard VQA models to reason about premises during training can lead to improvements on tasks requiring compositional reasoning.

1 Introduction

The task of providing natural language answers to free-form questions about an image – *i.e.* Visual Question Answering (VQA) – has received substantial attention in the past few years (Malinowski and Fritz, 2014; Antol et al., 2015; Malinowski et al., 2015; Zitnick et al., 2016; Kim et al., 2016; Wu et al., 2016; Lu et al., 2016; Andreas et al., 2016; Lu et al., 2017) and has quickly become a popular problem area. Despite significant progress on VQA benchmarks (Antol et al., 2015), current models still present a number of unintelligent and problematic tendencies.

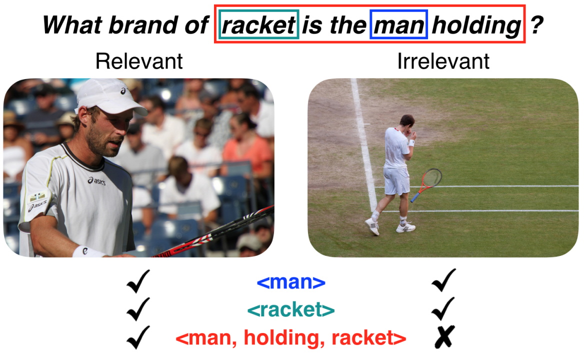

Figure 1: Questions asked about images often contain *'premises'* that imply visual semantics. From the above question, we can infer that a relevant image must contain a man, a racket, and that the man must be holding the racket. We extract these premises from visually grounded questions and use them to construct a new dataset and models for question relevance prediction. We also find that augmenting standard VQA training with simple premise-based questions results in improvements on tasks requiring compositional reasoning.

When faced with questions that are irrelevant or not applicable for an image, current 'forced choice' models will still produce an answer. For example, given an image of a dog and a query "*What color is the bird?*", standard VQA models might answer "*Red*" confidently, based solely on language biases in the training set (*i.e.* an overabundance of the word "red"). In these cases, the predicted answers are senseless at best and misleading at worst, with either case posing serious problems for real-world applications. Like Ray et al. (2016), we argue that practical VQA systems must be able to identify and explain irrelevant questions. For instance, a more intelligent VQA model with this capability might answer "*There is no bird in the image*" for this example.

Premises. In this paper, we show that question *premises* - *i.e.* objects and relationships implied by a question - can enable VQA models to respond more intelligently to irrelevant or previously unseen questions. We develop a premise extraction pipeline based on SPICE (Anderson et al., 2016) and demonstrate how these premises can be used to improve modern VQA models in the face of irrelevant or previously unseen questions.

Concretely, we define premises as facts implied by the language of questions, for example the question *"What brand of racket is the man holding?"* shown in Fig. 1 implies the existence of a man, a racket, and that the man is holding the racket. For visually grounded questions (*i.e.* those asked about a particular image) these premises imply visual qualities, including the presence of objects as well as their attributes and relationships.

Broadly speaking, we explore the usefulness of premises in two settings – when visual questions are known to be relevant to the images they are asked on (*e.g.* in the VQA dataset) and in real-life situations where such an assumption cannot be made (*e.g.* when generated by visually impaired users). In the former case, we show that knowing that a question is relevant allows us to perform data augmentation by creating additional simple question-answer pairs using the premises of source questions. In the latter case, we show that explicitly reasoning about premises provides an effective and interpretable way of determining whether a question is relevant to an image.

Irrelevant Question Detection. We consider a question to be relevant to an image if all of the question's premises apply to the corresponding image, that is to say all objects, attributes, and interactions implied by the question are depicted in the image. We refer to premises that apply for a given image as true premises and those that do not apply as false premises. In order to train and evaluate models for this task, we curate a new irrelevant question detection dataset which we call the Question Relevance Prediction and Explanation (QRPE) dataset. QRPE is automatically curated from annotations already present in existing datasets, requiring no additional labeling.

We collect the QRPE dataset by taking each image-question pair in the VQA dataset (Antol et al., 2015) and finding the most visually similar other image for which exactly one of the question premises is false. In this way, we collect tuples consisting of two images, a question, and a premise where the question is relevant for one image and not for the other due to the premise being false.

For context, the only other existing irrelevant question detection dataset (Ray et al., 2016) collected irrelevant question-image pairs by human verification of random pairs. In comparison, QRPE is substantially larger, balanced between irrelevant and relevant examples, and presents a considerably more difficult task due to the closeness of the image pairs both visually and with respect to question premises.

We train novel models for irrelevant question detection on the QRPE dataset and compare to existing methods. In these experiments, we show that models that explicitly reason about question premises consistently outperform baseline models that do not.

VQA Data Augmentation. Finally, we also introduce an approach to generate simple, templated question-answer pairs about elementary concepts from premises of complex training questions. In initial experiments, we show that adding these simple question-answer pairs to VQA training data can improve performance on tasks requiring compositional reasoning. These simple questions improve training by bringing implicit training concepts "to the surface", *i.e.* introducing direct supervision of important implicit concepts by transforming them to simple training pairs.

2 Related Work

Visual Question Answering: Starting from simple bag-of-word and CNN+LSTM models (Antol et al., 2015), VQA architectures have seen considerable innovation. Many top-performing models integrate attention mechanisms (over the image, the question, or both) to focus on important structures (Fukui et al., 2016; Lu et al., 2016, 2017), and some have been designed with compositionality in mind (Andreas et al., 2016; Hendricks et al., 2016). However, improving compositionality or performance through data augmentation remains a largely unstudied area.

Some other recent work has developed models which produce natural language explanations for their outputs (Park et al., 2016; Wang et al., 2016), but there has not been work on generating explanations for irrelevant questions or false premises.

Question Relevance: Most related to our work is that of Ray et al. (2016), which introduced the task of irrelevant question detection for VQA. To evaluate on this task, they created the Visual True and False Question (VTFQ) dataset by pairing VQA questions with random VQA images and having human annotators verify whether or not the question was relevant. As a result, many of the irrelevant image-question pairs exhibit a complete mismatch of image and question content. Our Question Relevance Prediction and Explanation (QRPE) dataset on the other hand is collected such that irrelevant images for each question closely resemble the source image both visually and semantically. We also provide premise-level annotations which can be used to develop models that not only decide whether a question is relevant, but also provide explanations for *why* that is the case.

Semantic Tuple Extraction: Extracting structured facts in the form of semantic tuples from text is a well studied problem (Schuster et al., 2015; Anderson et al., 2016; Elhoseiny et al., 2016); however, recent work has begun extending these techniques to visual domains (Xu et al., 2017; Johnson et al., 2015). Additionally, the Visual Genome (Krishna et al., 2016) dataset contains dense image annotations for objects and their attributes and relationships. However, we are the first to consider these facts to reason about question relevancy and compositionality in VQA.

3 Extracting Premises of a Question

In Section 1, we introduced the concept of premises and how they can be used. We now formalize this concept and explain how premises can be extracted from questions.

We define question premises as facts implied about an image from a question asked about it, which we represent as tuples. Returning to our running example question *"What brand of racket is the man holding?"*, we can express these premises as the tuples '<*man*>', '<*racket*>', and '<*man, holding, racket*>' respectively. We categorize these tuples into three groups based on their complexity. First-order premises representing the presence of objects ('<*man*>', '<*cat*>', '<*sky*>'), second-order premises capturing the attributes of objects ('<*man, tall*>', '<*car, moving*>'), and third-order premises containing interactions between objects (*e.g.* '<*man, kicking, ball*>', '<*cat, above, car*>').

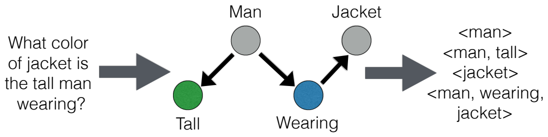

Figure 2: **Premise Extraction Pipeline.** Objects (gray), attributes (green), and relations (blue) scene graph nodes are converted into 1st, 2nd, and 3rd order premises respectively.

Premise Extraction: To extract premises from questions, we use the semantic tuple extraction pipeline used in the SPICE metric (Anderson et al., 2016). Originally defined as a metric for image captioning, SPICE transforms a sentence into a scene graph using the Stanford Scene Graph Parser (Schuster et al., 2015) and then extracts semantic tuples from this representation. Fig. 2 shows this process for a sample question. The question is represented as a graph of objects, attributes, and relationships from which first, second, and third order premises are extracted respectively. As this pipeline was originally designed for descriptive captions rather than questions, we found a number of minor modifications helpful in extracting quality question premises, including disabling pronoun resolution, verb lemmatization and METEOR-based Synset matching. We will release our premise extraction code publicly to encourage reproducibility.

While this extraction process typically produces high quality premise tuples, there are some sources of noise which must be filtered out. The SPICE process occasionally produces duplicate nodes or object nodes not linked to nouns in the question, which we filter out. We also remove premises containing words like photo, image, *etc.* that refer to the image rather than its content.

A more nuanced source of erroneous premises comes from the ambiguity in existential questions, *i.e.* those about the existence of certain image content. For example, while the question *"Is the little girl moving?"* contains the premise '<*girl, little*>', it is unclear without the answer whether '<*girl, moving*>' is also a premise. Similarly, for the question *"How many giraffes are in the image?"*, '<*giraffe, many*>' cannot be considered a premise as there may be 0 giraffes in the image. To avoid introducing false premises, we filter out existential and counting questions.

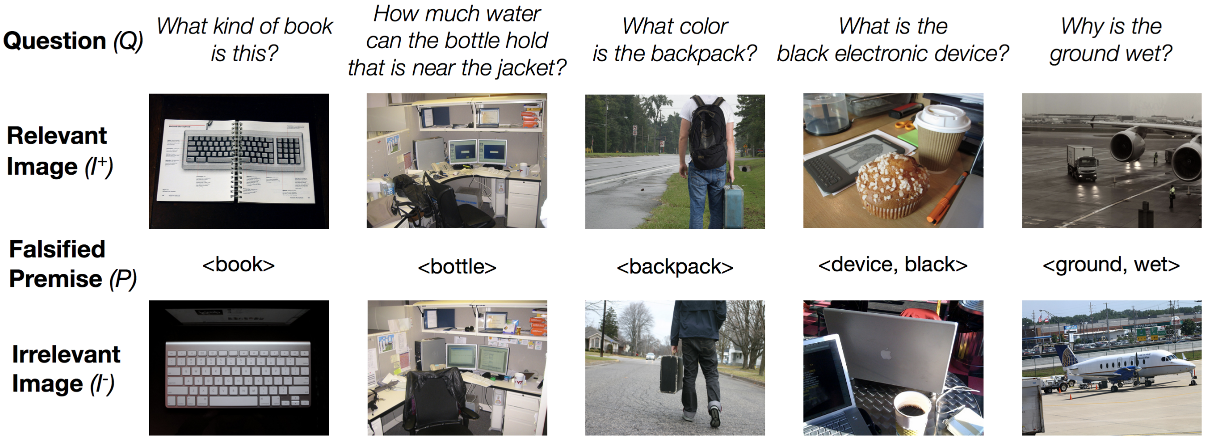

Figure 3: **Some Examples from QRPE Dataset.** For a given question Q and a relevant image I^+, we find an irrelevant image I^- for which exactly one premise P of the question is false. If there are multiple such candidates, we select the candidate most visually most similar to I^+. As can be seen from these examples, the QRPE dataset is very challenging, with only minor visual and semantic differences separating the relevant and irrelevant images.

4 Question Relevance Prediction and Explanation (QRPE) Dataset

As discussed in Section 1, modern VQA models fail to differentiate between relevant and irrelevant questions, answering either with confidence. This behavior is detrimental to the real world application of VQA systems. In this section, we curate a new dataset for question relevance in VQA which we call the Question Relevance Prediction and Explanation (QRPE) dataset. We plan to release QRPE publicly to help future efforts.

In order to train and evaluate models for irrelevant question detection, we would like to create a dataset of tuples (I^+, Q, P, I^-) comprised of a natural language question Q, an image I^+ for which Q is relevant, and an image I^- for which Q is irrelevant because premise P is false. While it is not required to collect both a relevant and irrelevant image for each question, we argue that doing so is a simple way to balance the dataset and it ensures that biases against rarer questions (which would be irrelevant for most images) cannot be exploited to inflate performance.

We base our dataset on the existing VQA corpus (Antol et al., 2015), taking the human-generated (and therefore relevant) image-question pairs from VQA as I^+ and Q. As previously discussed, we can define the relevancy of a question in terms of the validity of its premises for an image, so we extract premises from each question Q and must find a suitable irrelevant image I^-. However, there are certainly many images for which one or more of Q's premises are false and an important design decision is then how to select I^- from this set.

To ensure our dataset is as realistic and challenging as possible, we consider irrelevant images which only have a single false question premise under Q which we denote P. For example, the question *"Is the big red dog old?"* could be matched with an image containing a big, white dog or a small red dog, but not a small white dog. In this way, we ensure that image content is semantically appropriate for the question topic but not quite relevant. Additionally, this provides each irrelevant image with an explanation for why the question does not apply.

Furthermore, we sort this subset of irrelevant image by their visual distance to the source image I^+ based on image encodings from a VGGNet (Simonyan and Zisserman, 2014) pretrained on ImageNet (Russakovsky et al., 2012). This ensures that the relevant and irrelevant images are visually similar and act as difficult examples.

A major difficulty with our proposed data collection process is how to verify whether a premise if true or false for any given image in order to identify irrelevant images. We detail dataset construction and our approach for this problem in the following section.

4.1 Dataset Construction

We curate our QRPE dataset automatically from existing annotations in COCO (Lin et al., 2014) and Visual Genome (Krishna et al., 2016). COCO is a set of over 300,000 images annotated with object segmentations and presence information for 80 classes as well as text descriptions of image content. Visual Genome builds on this dataset, providing more detailed object, attribute, and rela-

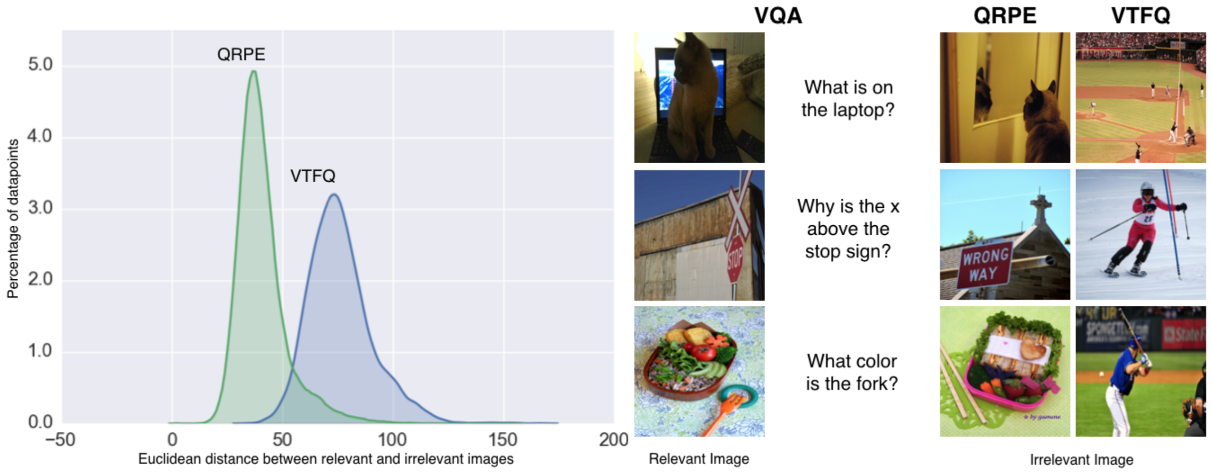

Figure 4: **A comparison of the QRPE and VTFQ Datasets.** On the left, we plot the Euclidean distance between VGGNet-fc7 features extracted from each relevant-irrelevant image pair for each dataset. Note that VTFQ has significantly higher visual distances. On the right, we show some qualitative examples of irrelevant images for questions that occur in both datasets. VTFQ images are significantly less related to the source image and question than in our dataset.

tionship annotations for over 100,000 COCO images. We make use of these data sources to extract first and second order premises from VQA questions which are also based on COCO images.

For first order premises (*i.e.* existential premises), we consider only the 80 classes present in COCO (Lin et al., 2014). As VQA and COCO share the same images, we can easily determine if a first order premise is true or false for a candidate irrelevant image simply by checking for the absence of the appropriate class annotation.

For second order premises (*i.e.* attributed objects), we rely on Visual Genome (Krishna et al., 2016) annotations for object and attribute labels. Unlike in COCO, the lack of a particular object label in an image for Visual Genome does not necessarily indicate that the object is not present, both due to annotation noise and the use of multiple synonyms for objects by human labelers. As a consequence, we restrict the set of candidate irrelevant images to those which contain a matching object to the question premise but a different attribute. Without further restriction, the selected irrelevant attributes do not tend to be mutually exclusive with the source attribute (*i.e.* matching '<*dog, old*>' and '<*dog, red*>'). To correct this and ensure a false premise, we further restrict the set to attributes which are antonyms (*e.g.* '<*young*>' for source attribute '<*old*>') or taxonomic sister terms (*e.g.* '<*green*>' for source attribute '<*red*>') of the original premise attribute. We also experimented with third order premises; however, the lack of a corresponding sense of mutual exclusion for verbs and the sparsity of <object, relationship, object> premises made finding non-trivial irrelevant images difficult.

To recap, our data collection approach is to take each image-question pair in the VQA dataset and extract its first and second order question premises. For each premise, we find all images which lack only this premise and rank them by their visual distance. The closest of these is kept as the irrelevant image for each image-question pair.

4.2 Exploring the Dataset

Fig. 3 shows sample (I^+, Q, P, I^-) tuples from our dataset. These examples illustrate the difficulty of our dataset. For instance, the images in the second column differ only by the presence of the water bottle and images in the fourth column are differentiated by the color of the devices. Both of these are fine details of the image content.

The QRPE dataset contains 53,911 (I^+, Q, P, I^-) tuples generated from as many premises. In total, it contains 1530 unique premises and 28,853 unique questions. Among the 53,911 premises, 3876 are second-order, attributed object premises while the remaining 50,035 are first-order object/scene premises. We divide our dataset into two parts – a training set with 35,486 tuples that are generated from the VQA training set and a validation set with 18,425 tuples generated from the VQA validation set.

Manual Validation. We also manually validated 1000 randomly selected (I^+, Q, P, I^-) tuples from our dataset. We noted that 99.10% of the premises P were valid (*i.e.* implied by the question) in I^+ and 97.3% were false for the negative image I^-. This demonstrates the high reliability of our automated annotation pipeline.

4.3 Comparison to VTFQ

We contrast our approach to the VTFQ dataset of Ray et al. (2016). As discussed prior, VTFQ was collected by selecting a random question and image from the VQA set and asking human annotators to report if the question was relevant, producing a pair. This approach results in irrelevant image-question pairs that are unambiguously unrelated, with the visual content of the image having nothing at all to do with the question or its source image from VQA.

To quantify this effect and compare to QRPE, we pair each irrelevant image-question pair (I^-, Q) from VTFQ with a relevant image from the VQA dataset. Specifically, we find the nearest neighbor question Q^{nn} in the VQA dataset to Q based on an average of the word2vec (Mikolov et al., 2013) embedding of each word, and select the image on which Q^{nn} was asked as I^+ to form (I^+, Q, P, I^-) tuples like in our proposed dataset.

In Fig. 4, we present a quantitative and qualitative comparison of the two datasets based on these tuples. On the left side of the figure, we plot the distributions of Euclidean distance between the fc7 features of each (I^+, I^-) pair in both datasets. We find that the mean distance in the VTFQ dataset is nearly twice that of our QRPE dataset, indicating that irrelevant images in VTFQ are less visually related to source images though we do note the distribution of distances in both datasets is long tailed.

On the right side of Fig. 4, we also provide qualitative examples of questions that occur in both datasets. The example on the last row is perhaps most striking. The source question is asking the color of a fork and the relevant image shows an overhead view of a meal with an orange fork set nearby. The irrelevant image in QRPE is a similar image of food, but with chopsticks! Conversely, the image from VTFQ is a man playing baseball.

5 Question Relevance Detection

In this section, we introduce a simple baseline for irrelevant question detection on the QRPE dataset and demonstrate that explicitly reasoning about premises improves performance for both our new model and existing methods. More formally, we consider the binary classification task of predicting if a question Q_i from an image-question pair (I_i, Q_i) is relevant to image I_i.

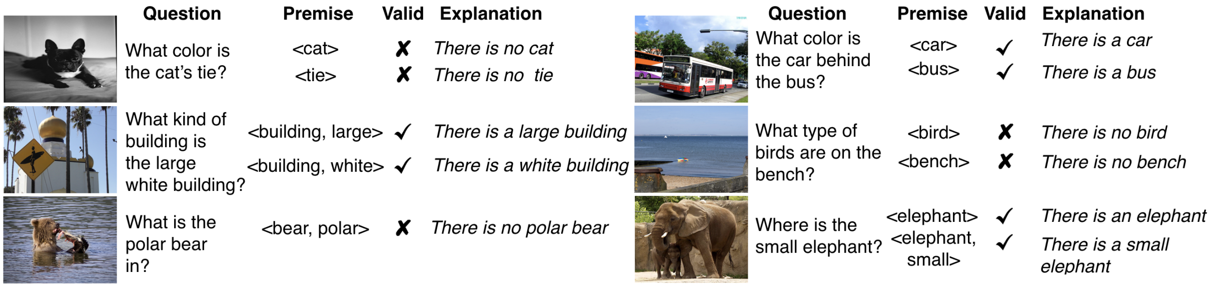
A Simple Premise-Aware Model. Like the standard VQA task, question relevance detection also requires making a prediction based on an encoded image and question. With this in mind, we begin with a straight-forward approach based on the Deeper LSTM VQA model architecture of Antol et al. (2015). This model encodes the image I via a VGGNet and the question Q with an LSTM over one-hot word encodings. The concatenation of these embeddings are input to a multi-layer perceptron. We fine-tune this model for the binary question relevance detection task starting from a model pretrained on the VQA task. We denote this model as `VQA-Bin`.

We extend the `VQA-Bin` model to explicitly reason about premises. We extract first and second order premises from the question Q and encode them as two concatenated one-hot vectors. We add an additional LSTM to encode the premises and concatenate this added feature to the image and question feature. We refer to this premise-aware model as `VQA-Bin-Premise`.

Attention Models. We also extend the attention based Hierarchical Co-Attention VQA model of Lu et al. (2016) for the task of question relevance in a way similar to Deeper LSTM model. We call this model `HieCoAtt-Bin`. The corresponding premise-aware model is referred to as `HieCoAtt-Bin-Prem`.

Existing Methods. We compare our approaches with the best performing model of Ray et al. (2016). This model (which we denote `QC-Sim`) uses a pretrained captioning model to automatically provide natural language image descriptions and reasons about relevance based on a learned similarity between the question and image caption.

Specifically, the approach uses NeuralTalk2 (Karpathy and Li, 2015) trained on the MS COCO dataset (Lin et al., 2014) to generate a caption for each image. Both the caption and question are



Question	Premise	Valid	Explanation
What color is the cat's tie?	<cat> <tie>	✗ ✗	*There is no cat* *There is no tie*
What kind of building is the large white building?	<building, large> <building, white>	✓ ✓	*There is a large building* *There is a white building*
What is the polar bear in?	<bear, polar>	✗	*There is no polar bear*

Question	Premise	Valid	Explanation
What color is the car behind the bus?	<car> <bus>	✓ ✓	*There is a car* *There is a bus*
What type of birds are on the bench?	<bird> <bench>	✗ ✗	*There is no bird* *There is no bench*
Where is the small elephant?	<elephant> <elephant, small>	✓ ✓	*There is an elephant* *There is a small elephant*

Figure 5: **Question relevance explanation:** We provide selected examples of predictions from the False Premise Detection model (`FPD`) on the QRPE test set. Reasoning about premises presents the opportunity to produce natural language statements indicating *why* a question is irrelevant to an image, by pointing to the premise that is invalid.

Models	Overall	First Order	Second Order
VQA-Bin	66.50	67.36	53.00
VQA-Bin-Prem	66.77	67.04	54.38
HieCoAtt-Bin	70.74	71.35	**61.54**
HieCoAtt-Bin-Prem	73.34	73.97	60.35
QC-Sim	74.35	75.82	55.12
PC-Sim	75.05	76.47	56.04
QPC-Sim	**75.31**	**76.67**	55.95

Table 1: Accuracy of Question Relevance models on the QRPE test set. We find that premise-aware models consistently outperform alternative models.

embedded as a fixed length vector through an encoding LSTM (with words being represented as word2vec (Mikolov et al., 2013) vectors). These question and caption embeddings are concatenated and fed to a multilayer perceptron to predict relevance. We consider two additional versions of this approach that consider only premise-caption similarity (`PC-Sim`) and question-premise-caption similarities (`QPC-Sim`).

Results. We train each model on the QRPE train split and report results on the test set in Table 1. As the dataset is balanced in the label space, random accuracy stands at 50%. We find that the simple `VQA-Bin` model achieves 66.5% accuracy while the attention based model `HieCoAtt-Bin` attains 70.74% accuracy. Surprisingly, the caption-similarity based `QC-Sim` model significantly outperforms these baseline, obtaining an accuracy of 74.35% while only reasoning about relevancy from textual descriptions of images. We note that the caption similarity based approaches use a large amount of outside data during pretraining of the captioning model and the word2vec embeddings, which may have contributed to the effectiveness of these methods.

Most interestingly, we find that the addition of extracted premise representations consistently improves performance of base models. `VQA-Bin-Prem`, `HieCoAtt-Bin-Prem`, `PC-Sim`, and `QPC-Sim` outperform their no-premise information counterparts, with `QPC-Sim` being the overall best performing approach at 75.31% accuracy. This is especially interesting given that the models *already* have access to the question from which the premises were extracted. This result seems to imply there is value in explicitly isolating premises from sentence grammar.

We further divide our test set into two splits consisting of (Q, I) pairs created by either falsifying first-order and second-order premises. We find that all our models perform significantly better on the first-order split. We hypothesize that the significant diversity in visual representations of attributed objects and comparatively fewer examples for each type makes it more difficult to learn subtle differences for second-order premises.

5.1 Question Relevance Explanation

In addition to identifying whether a question is irrelevant to an image, being able to indicate *why* carries significant real-world utility. From an interpretability perspective, reporting which premise is false is more informative than simply answering the question in the negative, as it can help to correct the questioner's misconception regarding the scene. We propose to generate such explanations by identifying the particular question premise(s) that do not apply to an image.

By construction, irrelevant images in the QRPE dataset are picked on the basis of negating a single premise – we now use our dataset to train models to detect false premises, and use the premises classified as irrelevant to generate templated natural language explanations.

Fig. 5 illustrates the task setup for false premise detection. Given a question-image pair, say *"What color is the cat's tie?"*, the objective is to identify which (if any) question premises are not grounded in the image, in this case both <*cat*> and <*tie*>. Alternatively, for the question *"What* *kind of building is the large white building?"*, both premises <*building, large*> and <*building, white*> are true premises grounded in the image.

We train a simple false premise detection model for this task. Our model is a multilayer perceptron that takes one-hot encodings of premises and VGGNet (Simonyan and Zisserman, 2014) image features as input to predict whether the premise is grounded in the image or not. We trained our false premise detection model (`FPD`) model on all premises in the QRPE dataset.

Our `FPD` model achieves an accuracy of 61.12% on the QRPE dataset. In Fig. 5, we present qualitative results of our premise classification and explanation pipeline. For the question *"What color is the cat's tie?"*, the model correctly recognizes 'cat' and 'tie' as false premises, and we generate statements in natural language indicating the same. Thus, determining question relevance by reasoning about each premise presents the opportunity to generate simple explanations that can provide valuable feedback to the questioner, and help improve model trust.

6 Premise-Based Visual Question Answering Data Augmentation

In this section, we develop a premise-based data augmentation scheme for VQA that generates simple, templated questions based on premises present in complex visually-grounded questions from the VQA (training) dataset.

Using the pipeline presented in Section 3, we extract premises from questions in the VQA dataset and apply a simple templated question generation strategy to transform premises into question and answer pairs. Note that because the source questions come from sighted humans about an image, we do not need to filter out binary or counting questions in order to avoid false premises as in Section 3. We do however filter based on SPICE similarity between the generated and source questions to avoid generating duplicates.

We design templates for each type of premise – first-order (*e.g.* '<*man*>' – *"Is there a man?" Yes*), second-order (*e.g.* '<*man, walking*>' – *"What is the man doing?" Walking*, and '<*car, red*>' – *"What is the color of the car?" Red*), and third-order ('<*man, holding, racket*>' – *"What is the man holding?" Racket*, *"Who is holding the racket?" Man*). This process transforms implicit premise concepts which previously had to be learned as part of understanding more complex questions into simple, explicit training examples that can be directly supervised.

Training Data	Other	Number	Yes	No	Total
Source	123,817	29,698	57217	35842	246,574
Premise	137,483	1,850	387,941	0	527,274

Table 2: Answer type distribution of source and premise questions on the Compositional VQA train set.

Fig. 6 shows sample premise questions produced from source VQA questions using our pipeline. We note that the distribution of premise questions varies drastically from the source VQA distribution (see Table 2).

We evaluate multiple models with and without premise augmentation on two splits of the VQA dataset - the standard split and the compositional split of Agrawal et al. (2017). The compositional split is specifically designed to test a model's ability to generalize to unseen/rarely seen combinations of concepts at test time.

Augmentation Strategies. We evaluate the Deeper LSTM model of Lu et al. (2015) on the standard and compositional splits with two augmentation strategies - `All` which includes the entire set of premise questions and `Top-1k-A` which includes only questions with answers in the top 1000 most common VQA answers. The results are listed in Table 3. We find minor improvement of 0.34% on the standard split under `Top-1k-A` premise question augmentation. On the compositional split, we observe a 1.16% gain with `Top-1k-A` augmentation over no augmentation. In this setting, explicitly reasoning about objects and attributes seen in the questions seems to help the model disentangle objects from their common characteristics.

Other Models. To check the general effectiveness of our approach, we further evaluate `Top-1k-A` augmentation for three additional VQA models on the compositional split. We find inconsistent improvements for these more advanced models with some improving while others see reductions in accuracy when adding premises.

7 Conclusions and Future Work

In this paper, we made the simple observation that questions about images often contain premises implied by the question and that reasoning about premises can help VQA models respond more in-

What player number is about to swing at the ball? Is there a player number? Yes Is there a ball in the image? Yes Is there a number in the image? Yes	**Why is the man looking at the lady?** Who is looking at the lady? Man Is there a lady in the image? Yes Is there a man in the image? Yes	**How many people are wearing safety jackets?** Can you see people in the image? Yes What are the people wearing? Jacket Who is wearing the jacket? People
What is the child sitting on? What is the child doing? Sitting Is there a child in the image? Yes	**Where is the pink hat?** What is the color of hat? Pink Is there a hat in the image? Yes	**What is the item called that the cat is looking at?** Is there a cat in the image? Yes Is there an item in the image? Yes

telligently to irrelevant or novel questions.

We develop a system for automatically extracting these question premises. Using these premises, we automatically created a novel dataset for Question Relevance Prediction and Explanation (QRPE) which consists of 53,911 question, relevant image, and irrelevant image triplets. We also train novel question relevance prediction models and show that models that take advantage of premise information outperform models that do not. Furthermore, we demonstrated that questions generated from premises may be an effective data augmentation technique for VQA tasks that require compositional reasoning.

Integrating Question Relevance Prediction and Explanation (QRPE) models with existing VQA systems would form a natural extension to our approach. In this setting, the relevance prediction model would determine the applicability of a question to an image, and select an appropriate path of action. If the question is classified as relevant, the VQA model would generate a prediction; otherwise, a question relevance explanation model would provide a natural language sentence indicating which premise(s) are not valid for the image. Such systems would be a step in the direction of making VQA systems move beyond academic settings to real-world environments.

Abstract

Existing image captioning models do not generalize well to out-of-domain images containing novel scenes or objects. This limitation severely hinders the use of these models in real world applications dealing with images in the wild. We address this problem using a flexible approach that enables existing deep captioning architectures to take advantage of image taggers at test time, without re-training. Our method uses constrained beam search to force the inclusion of selected tag words in the output, and fixed, pretrained word embeddings to facilitate vocabulary expansion to previously unseen tag words. Using this approach we achieve state of the art results for out-of-domain captioning on MSCOCO (and improved results for in-domain captioning). Perhaps surprisingly, our results significantly outperform approaches that incorporate the same tag predictions into the learning algorithm. We also show that we can significantly improve the quality of generated ImageNet captions by leveraging ground-truth labels.

1 Introduction

Automatic image captioning is a fundamental task that couples visual and linguistic learning. Recently, models incorporating recurrent neural networks (RNNs) have demonstrated promising results on this challenging task (Vinyals et al., 2015; Fang et al., 2015; Devlin et al., 2015), leveraging new benchmark datasets such as the MSCOCO dataset (Lin et al., 2014). However, these datasets are generally only concerned with a relatively small number of objects and interactions. Unsurprisingly, models trained on these datasets do not generalize well to out-of-domain images containing novel scenes or objects (Tran et al., 2016). This limitation severely hinders the use of these models in real world applications dealing with images in the wild.

Figure 1: We successfully caption images containing previously unseen objects by incorporating semantic attributes (i.e., image tags) during RNN decoding. Actual example from Section 4.2.

Although available image-caption training data is limited, many image collections are augmented with ground-truth text fragments such as semantic attributes (i.e., image tags) or object annotations. Even if these annotations do not exist, they can be generated using (potentially task specific) image taggers (Chen et al., 2013; Zhang et al., 2016) or object detectors (Ren et al., 2015; Krause et al., 2016), which are easier to scale to new concepts. In this paper our goal is to incorporate text fragments such as these during caption generation, to improve the quality of resulting captions. This goal poses two key challenges. First, RNNs are generally opaque, and difficult to influence at test time. Second, text fragments may include words

Proceedings of the 2017 Conference on Empirical Methods in Natural Language Processing, pages 936–945
Copenhagen, Denmark, September 7–11, 2017. ©2017 Association for Computational Linguistics

that are not present in the RNN vocabulary.

As illustrated in Figure 1, we address the first challenge (guidance) by using *constrained beam search* to guarantee the inclusion of selected words or phrases in the output of an RNN, while leaving the model free to determine the syntax and additional details. Constrained beam search is an approximate search algorithm capable of enforcing any constraints over resulting output sequences that can be expressed in a finite-state machine. With regard to the second challenge (vocabulary), empirically we demonstrate that an RNN can successfully generalize from similar words if both the input and output layers are fixed with pretrained word embeddings and then expanded as required.

To evaluate our approach, we use a held-out version of the MSCOCO dataset. Leveraging image tag predictions from an existing model (Hendricks et al., 2016) as constraints, we demonstrate state of the art performance for out-of-domain image captioning, while simultaneously improving the performance of the base model on in-domain data. Perhaps surprisingly, our results significantly outperform approaches that incorporate the same tag predictions into the learning algorithm (Hendricks et al., 2016; Venugopalan et al., 2016). Furthermore, we attempt the extremely challenging task of captioning the ImageNet classification dataset (Russakovsky et al., 2015). Human evaluations indicate that by leveraging ground truth image labels as constraints, the proportion of captions meeting or exceeding human quality increases from 11% to 22%. To facilitate future research we release our code and data from the project page[1].

2 Related Work

While various approaches to image caption generation have been considered, a large body of recent work is dedicated to neural network approaches (Donahue et al., 2015; Mao et al., 2015; Karpathy and Fei-Fei, 2015; Vinyals et al., 2015; Devlin et al., 2015). These approaches typically use a pretrained Convolutional Neural Network (CNN) image encoder, combined with a Recurrent Neural Network (RNN) decoder trained to predict the next output word, conditioned on previous words and the image. In each case the decoding process remains the same—captions are generated by searching over output sequences greedily or with beam search.

Recently, several works have proposed models intended to describe images containing objects for which no caption training data exists (out-of-domain captioning). The Deep Compositional Captioner (DCC) (Hendricks et al., 2016) uses a CNN image tagger to predict words that are relevant to an image, combined with an RNN language model to estimate probabilities over word sequences. The tagger and language models are pretrained separately, then fine-tuned jointly using the available image-caption data.

Building on the DCC approach, the Novel Object Captioner (NOC) (Venugopalan et al., 2016) is contemporary work with ours that also uses pretrained word embeddings in both the input and output layers of the language model. Another recent work (Tran et al., 2016) combines specialized celebrity and landmark detectors into a captioning system. More generally, the effectiveness of incorporating semantic attributes (i.e., image tags) into caption model training for in-domain data has been established by several works (Fang et al., 2015; Wu et al., 2016; Elliot and de Vries, 2015).

Overall, our work differs fundamentally from these approaches as we do not attempt to introduce semantic attributes, image tags or other text fragments into the learning algorithm. Instead, we incorporate text fragments during model decoding. To the best of our knowledge we are the first to consider this more loosely-coupled approach to out-of-domain image captioning, which allows the model to take advantage of information not available at training time, and avoids the need to retrain the captioning model if the source of text fragments is changed.

More broadly, the problem of generating high probability output sequences using finite-state machinery has been previously explored in the context of poetry generation using RNNs (Ghazvininejad et al., 2016) and machine translation using n-gram language models (Allauzen et al., 2014).

3 Approach

In this section we describe the constrained beam search algorithm, the base captioning model used in experiments, and our approach to expanding the model vocabulary with pretrained word embeddings.

[1] www.panderson.me/constrained-beam-search

3.1 Constrained Beam Search

Beam search (Koehn, 2010) is an approximate search algorithm that is widely used to decode output sequences from Recurrent Neural Networks (RNNs). We briefly describe the RNN decoding problem, before introducing constrained beam search, a multiple-beam search algorithm that enforces constraints in the sequence generation process.

Let $\boldsymbol{y}_t = (y_1, ..., y_t)$ denote an output sequence of length t containing words or other tokens from vocabulary V. Given an RNN modeling a probability distribution over such sequences, the RNN decoding problem is to find the output sequence with the maximum log-probability, where the log probability of any partial sequence $\boldsymbol{y}_t$ is typically given by $\sum_{j=1}^{t} \log p(y_j \mid y_1, ..., y_{j-1})$.

As it is computationally infeasible to solve this problem, beam search finds an approximate solution by maintaining a beam B_t containing only the b most likely partial sequences at each decoding time step t, where b is known as the beam size. At each time step t, the beam B_t is updated by retaining the b most likely sequences in the candidate set E_t generated by considering all possible next word extensions:

$$E_t = \big\{(\boldsymbol{y}_{t-1}, w) \mid \boldsymbol{y}_{t-1} \in B_{t-1}, w \in V\big\} \qquad (1)$$

To decode output sequences under constraints, a naive approach might impose the constraints on sequences produced at the end of beam search. However, if the constraints are non-trivial (i.e. only satisfied by relatively low probability output sequences) it is likely that an infeasibly large beam would be required in order to produce sequences that satisfy the constraints. Alternatively, imposing the constraints on partial sequences generated by Equation 1 is also unacceptable, as this would require that constraints be satisfied at every step during decoding—which may be impossible.

To fix ideas, suppose that we wish to generate sequences containing at least one word from each constraint set C1 = {‘chair’, ‘chairs’} and C2 = {‘desk’, ‘table’}. Note that it is possible to *recognize* sequences satisfying these constraints using the finite-state machine (FSM) illustrated in Figure 2, with start state s_0 and accepting state s_3. More generally, any set of constraints that can be represented with a regular expression can also be expressed as an FSM (either deterministic or non-deterministic) that recognizes sequences satisfying those constraints (Sipser, 2012).

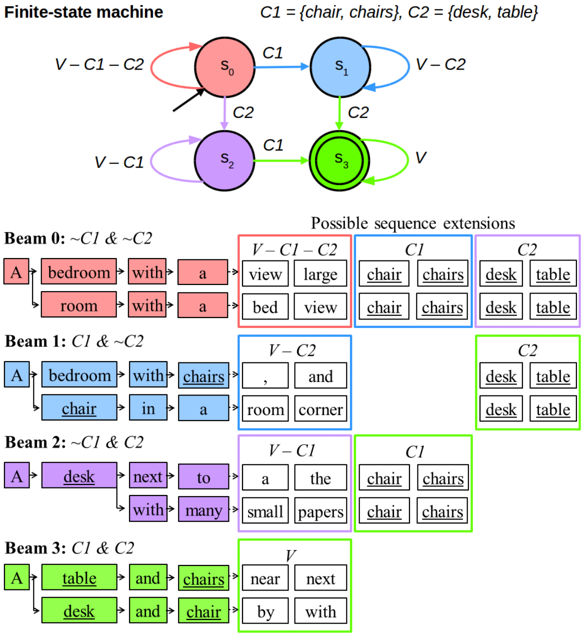

Figure 2: Example of constrained beam search decoding. Each output sequence must include the words ‘chair’ or ‘chairs’, and ‘desk’ or ‘table’ from vocabulary V. A finite-state machine (FSM) that recognizes valid sequences is illustrated at top. Each state in the FSM corresponds to a beam in the search algorithm (bottom). FSM state transitions determine the destination beam for each possible sequence extension. Valid sequences are found in Beam 3, corresponding to FSM accepting state s_3.

Since RNN output sequences are generated from left-to-right, to *generate* constrained sequences, we take an FSM that recognizes sequences satisfying the required constraints, and use the following multiple-beam decoding algorithm. For each state $s \in S$ in the FSM, a corresponding search beam B^s is maintained. As in beam search, each B^s is a set containing at most b output sequences, where b is the beam size. At each time step, each beam B^s_t is updated by retaining the b most likely sequences in its candidate set E^s_t given by:

$$E^s_t = \bigcup_{s' \in S} \big\{(\boldsymbol{y}_{t-1}, w) \mid \boldsymbol{y}_{t-1} \in B^{s'}_{t-1}, w \in V, \\ \delta(s', w) = s\big\} \qquad (2)$$

where $\delta : S \times V \mapsto S$ is the FSM state-transition function that maps states and words to states. As specified by Equation 2, the FSM state-transition function determines the appropriate candidate set for each possible extension of a partial sequence. This ensures that sequences in accepting states must satisfy all constraints as they have been recognized by the FSM during the decoding process.

Initialization is performed by inserting an empty sequence into the beam associated with the start state s_0, so $B_0^0 := \{\epsilon\}$ and $B_0^{i \neq 0} := \emptyset$. The algorithm terminates when an accepting state contains a completed sequence (e.g., containing an end marker) with higher log probability than all incomplete sequences. In the example contained in Figure 2, on termination captions in Beam 0 will not contain any words from C1 or C2, captions in Beam 1 will contain a word from C1 but not C2, captions in Beam 2 will contain a word from C2 but not C1, and captions in Beam 3 will contain a word from both C1 and C2.

3.1.1 Implementation Details

In our experiments we use two types of constraints. The first type of constraint consists of a conjunction of disjunctions $C = D_1, ..., D_m$, where each $D_i = w_{i,1}, ..., w_{i,n_i}$ and $w_{i,j} \in V$. Similarly to the example in Figure 2, a partial caption $\boldsymbol{y}_t$ satisfies constraint C iff for each $D_i \in C$, there exists a $w_{i,j} \in D_i$ such that $w_{i,j} \in \boldsymbol{y}_t$. This type of constraint is used for the experiments in Section 4.2, in order to allow the captioning model freedom to choose word forms. For each image tag, disjunctive sets are formed by using WordNet (Fellbaum, 1998) to map the tag to the set of words in V that share the same lemma.

The use of WordNet lemmas adds minimal complexity to the algorithm, as the number of FSM states, and hence the number of search beams, is not increased by adding disjunctions. Nevertheless, we note that the algorithm maintains one beam for each of the 2^m subsets of disjunctive constraints D_i. In practice $m \leq 4$ is sufficient for the captioning task, and with these values our GPU constrained beam search implementation based on Caffe (Jia et al., 2014) generates 40k captions for MSCOCO in well under an hour.

The second type of constraint consists of a subsequence that must appear in the generated caption. This type of constraint is necessary for the experiments in Section 4.3, because WordNet synsets often contain phrases containing multiple words. In this case, the number of FSM states, and the number of search beams, is linear in the length of the subsequence (the number of states is equal to number of words in a phrase plus one).

3.2 Captioning Model

Our approach to out-of-domain image captioning could be applied to any existing CNN-RNN captioning model that can be decoding using beam search, e.g., (Donahue et al., 2015; Mao et al., 2015; Karpathy and Fei-Fei, 2015; Vinyals et al., 2015; Devlin et al., 2015). However, for empirical evaluation we use the Long-term Recurrent Convolutional Network (Donahue et al., 2015) (LRCN) as our base model. The LRCN consists of a CNN visual feature extractor followed by two LSTM layers (Hochreiter and Schmidhuber, 1997), each with 1,000 hidden units. The model is factored such that the bottom LSTM layer receives only language input, consisting of the embedded previous word. At test time the previous word is the predicted model output, but during training the ground-truth preceding word is used. The top LSTM layer receives the output of the bottom LSTM layer, as well as a per-timestep static copy of the CNN features extracted from the input image.

The feed-forward operation and hidden state update of each LSTM layer in this model can be summarized as follows. Assuming N hidden units within each LSTM layer, the N-dimensional input gate i_t, forget gate f_t, output gate o_t, and input modulation gate g_t at timestep t are updated as:

$$i_t = \text{sigm}\left(W_{xi}x_t + W_{hi}h_{t-1} + b_i\right) \tag{3}$$

$$f_t = \text{sigm}\left(W_{xf}x_t + W_{hf}h_{t-1} + b_f\right) \tag{4}$$

$$o_t = \text{sigm}\left(W_{xo}x_t + W_{ho}h_{t-1} + b_o\right) \tag{5}$$

$$g_t = \tanh\left(W_{xc}x_t + W_{hc}h_{t-1} + b_c\right) \tag{6}$$

where $x_t \in \mathbb{R}^K$ is the input vector, $h_t \in \mathbb{R}^N$ is the LSTM output, W's and b's are learned weights and biases, and $\text{sigm}(\cdot)$ and $\tanh(\cdot)$ are the sigmoid and hyperbolic tangent functions, respectively, applied element-wise. The above gates control the memory cell activation vector $c_t \in \mathbb{R}^N$ and output $h_t \in \mathbb{R}^N$ of the LSTM as follows:

$$c_t = f_t \odot c_{t-1} + i_t \odot g_t \tag{7}$$

$$h_t = o_t \odot \tanh\left(c_t\right) \tag{8}$$

where $\odot$ represents element-wise multiplication.

Using superscripts to represent the LSTM layer index, the input vector for the bottom LSTM is an encoding of the previous word, given by:

$$x_t^1 = W_e \Pi_t \tag{9}$$

where W_e is a word embedding matrix, and Π_t is a one-hot column vector identifying the input word at timestep t. The top LSTM input vector comprises the concatenated output of the bottom LSTM and the CNN feature descriptor of the image I, given by:

$$x_t^2 = (h_t^1, \mathrm{CNN}_\theta(I)) \tag{10}$$

For the CNN component of the model, we evaluate using the 16-layer VGG (Simonyan and Zisserman, 2015) model and the 50-layer Residual Net (He et al., 2016), pretrained on ILSVRC-2012 (Russakovsky et al., 2015) in both cases. Unlike Donahue et. al. (2015), we do not fix the CNN weights during initial training, as we find that performance improves if all training is conducted end-to-end. In training, we use only very basic data augmentation. All images are resized to 256 × 256 pixels and the model is trained on random 224 × 224 crops and horizontal flips using stochastic gradient descent (SGD) with hand-tuned learning rates.

3.3 Vocabulary Expansion

In the out-of-domain scenario, text fragments used as constraints may contain words that are not actually present in the captioning model's vocabulary. To tackle this issue, we leverage pretrained word embeddings, specifically the 300 dimension GloVe (Pennington et al., 2014) embeddings trained on 42B tokens of external text corpora. These embeddings are introduced at both the word input and word output layers of the captioning model and fixed throughout training. Concretely, the ith column of the W_e input embedding matrix is initialized with the GloVe vector associated with vocabulary word i. This entails reducing the dimension of the original LRCN input embedding from 1,000 to 300. The model output is then:

$$v_t = \tanh\left(W_v h_t^2 + b_v\right) \tag{11}$$

$$p(y_t \mid y_{t-1}, ..., y_1, I) = \mathrm{softmax}\left(W_e^T v_t\right) \tag{12}$$

where v_t represents the top LSTM output projected to 300 dimensions, W_e^T contains GloVe embeddings as row vectors, and $p(y_t \mid y_{t-1}, ..., y_1, I)$ represents the normalized probability distribution over the predicted output word y_t at timestep t, given the previous output words and the image. The model is trained with the conventional softmax cross-entropy loss function, and learns to predict v_t vectors that have a high dot-product similarity with the GloVe embedding of the correct output word.

Given these modifications — which could be applied to other similar captioning models — the process of expanding the model's vocabulary at test time is straightforward. To introduce an additional vocabulary word, the GloVe embedding for the new word is simply concatenated with W_e as an additional column, increasing the dimension of both Π_t and p_t by one. In total there are 1.9M words in our selected GloVe embedding, which for practical purposes represents an open vocabulary. Since GloVe embeddings capture semantic and syntactic similarities (Pennington et al., 2014), intuitively the captioning model will generalize from similar words in order to understand how the new word can be used.

4 Experiments

4.1 Microsoft COCO Dataset

The MSCOCO 2014 captions dataset (Lin et al., 2014) contains 123,293 images, split into a 82,783 image training set and a 40,504 image validation set. Each image is labeled with five human-annotated captions.

In our experiments we follow standard practice and perform only minimal text pre-processing, converting all sentences to lower case and tokenizing on white space. It is common practice to filter vocabulary words that occur less than five times in the training set. However, since our model does not learn word embeddings, vocabulary filtering is not necessary. Avoiding filtering increases our vocabulary from around 8,800 words to 21,689, allowing the model to potentially extract a useful training signal even from rare words and spelling mistakes (which are generally close to the correctly spelled word in embedding space). In all experiments we use a beam size of 5, and we also enforce the constraint that a single word cannot be predicted twice in a row.

4.2 Out-of-Domain Image Captioning

To evaluate the ability of our approach to perform out-of-domain image captioning, we replicate an existing experimental design (Hendricks et al., 2016) using MSCOCO. Following this ap-

		Out-of-Domain Test Data				In-Domain Test Data		
Model	CNN	SPICE	METEOR	CIDEr	F1	SPICE	METEOR	CIDEr
DCC (Hendricks et al., 2016)	VGG-16	13.4	21.0	59.1	39.8	15.9	23.0	77.2

Table 1: Evaluation of captions generated using constrained beam search with 1 – 4 predicted image tags used as constraints (Base+T1 – 4). Our approach significantly outperforms both the DCC and NOC models, despite reusing the image tag predictions of the DCC model. Importantly, performance on in-domain data is not degraded but can also improve.

Model	bottle	bus	couch	microwave	pizza	racket	suitcase	zebra	Avg
DCC (Hendricks et al., 2016)	4.6	29.8	45.9	28.1	64.6	52.2	13.2	79.9	39.8
NOC (Venugopalan et al., 2016)	**17.8**	**68.8**	25.6	24.7	69.3	**68.1**	39.9	**89.0**	49.1
Base+T4	16.3	67.8	**48.2**	**29.7**	**77.2**	57.1	**49.9**	85.7	**54.0**

Table 2: F1 scores for mentions of objects not seen during caption training. Our approach (Base+T4) reuses the top 4 image tag predictions from the DCC model but generates higher F1 scores by interpreting tag predictions as constraints. All results based on use of the VGG-16 CNN.

proach, all images with captions that mention one of eight selected objects (or their synonyms) are excluded from the image caption training set. This reduces the size of the caption training set from 82,783 images to 70,194 images. However, the complete caption training set is tokenized as a bag of words per image, and made available as image tag training data. As such, the selected objects are unseen in the image caption training data, but not the image tag training data. The excluded objects, selected by Hendricks et. al. (2016) from the 80 main object categories in MSCOCO, are: 'bottle', 'bus', 'couch', 'microwave', 'pizza', 'racket', 'suitcase' and 'zebra'.

For validation and testing on this task, we use the same splits as in prior work (Hendricks et al., 2016; Venugopalan et al., 2016), with half of the original MSCOCO validation set used for validation, and half for testing. We use the validation set to determine hyperparameters and for early-stopping, and report all results on the test set. For evaluation the test set is split into in-domain and out-of-domain subsets, with the out-of-domain designation given to any test image that contains a mention of an excluded object in at least one reference caption.

To evaluate generated caption quality, we use the SPICE (Anderson et al., 2016) metric, which has been shown to correlate well with human judgment on the MSCOCO dataset, as well as the METEOR (Denkowski and Lavie, 2014) and CIDEr (Vedantam et al., 2015) metrics. For consistency with previously reported results, scores on out-of-domain test data are macro-averaged across the eight excluded object classes. To improve the comparability of CIDEr scores, the inverse document frequency statistics used by this metric are determined across the entire test set,

Base: A woman is playing tennis on a tennis court. **Tags:** tennis, player, ball, racket. **Base+T4:** A tennis player swinging a racket at a ball.

Base: A man standing next to a yellow train. **Tags:** bus, yellow, next, street. **Base+T4:** A man standing next to a yellow bus on the street.

Base: A close up of a cow on a dirt ground. **Tags:** zebra, zoo, enclosure, standing. **Base+T4:** A zebra standing in front of a zoo enclosure.

Base: A dog is sitting in front of a tv. **Tags:** dog, head, television, cat. **Base+T4:** A dog with a cat on its head watching television.

Base: A group of people playing a game of tennis. **Tags:** pink, tennis, crowd, ball. **Base+T4:** A crowd of people standing around a pink tennis ball.

Figure 3: Examples of out-of-domain captions generated on MSCOCO using the base model (Base), and the base model constrained to include four predicted image tags (Base+T4). Words never seen in training captions are underlined. The bottom row contains some failure cases.

rather than within subsets. On out-of-domain test data, we also report the F1 metric for mentions of excluded objects. To calculate the F1 metric, the model is considered to have predicted condition positive if the generated caption contains at least one mention of the excluded object, and negative otherwise. The ground truth is considered to be positive for an image if the excluded object in question is mentioned in any of the reference captions, and negative otherwise.

As illustrated in Table 1, on the out-of-domain test data, our base model trained only with image captions (Base) receives an F1 score of 0, as it is incapable of mentioned objects that do not appear in the training captions. In terms of SPICE, METEOR and CIDEr scores, our base model performs slightly worse than the DCC model on out-of-domain data, but significantly better on in-domain data. This may suggest that the DCC model achieves improvements in out-of-domain performance at the expense of in-domain scores (in-domain scores for the NOC model were not available at the time of submission).

Results marked with '+' in Table 1 indicate that our base model has been decoded with constraints in the form of predicted image tags. However, for the fairest comparison, and because re-using existing image taggers at test time is one of the motivations for this work, we did not train an image tagger from scratch. Instead, in results T1–4 we use the top 1–4 tag predictions respectively from the VGG-16 CNN-based image tagger used in the DCC model. This model was trained by the authors to predict 471 MSCOCO visual concepts including adjectives, verbs and nouns. Examples of generated captions, including failure cases, are presented in Figure 3.
