As indicated in Table 1, using similar model capacity, the constrained beam search approach with predicted tags significantly outperforms prior work in terms SPICE, METEOR and CIDEr scores, across both out-of-domain and in-domain test data, utilizing varying numbers of tag predictions. Overall these results suggest that, perhaps surprisingly, it may be better to incorporate image tags into captioning models during decoding rather than during training. It also appears that, while introducing image tags improves performance on both out-of-domain and in-domain evaluations, it is beneficial to introduce more tag constraints when the test data is likely to contain previously unseen objects. This reflects the trading-off of influence between the image tags and the captioning model. For example, we noted that when using two tag constraints, 36% of generated captions were identical to the base model, but when using four tags this proportion dropped to only 3%.

To establish performance upper bounds, we train the base model on the complete MSCOCO training set (Base All Data). We also evaluate captions generated using our approach combined with an 'oracle' image tagger consisting of the top 3 ground-truth image tags (T3*). These were determined by selecting the 3 most frequently mentioned words in the reference captions for each test image (after eliminating stop words). The very high scores recorded for this approach may motivate the use of more powerful image taggers in future work. Finally, replacing VGG-16 with the more powerful ResNet-50 (He et al., 2016) CNN leads to modest improvements as indicated in the lower half of Table 1.

Evaluating F1 scores for object mentions (see Table 2), we note that while our approach outperforms prior work when four image tags are used, a significant increase in this score should not be expected as the underlying image tagger is the same.

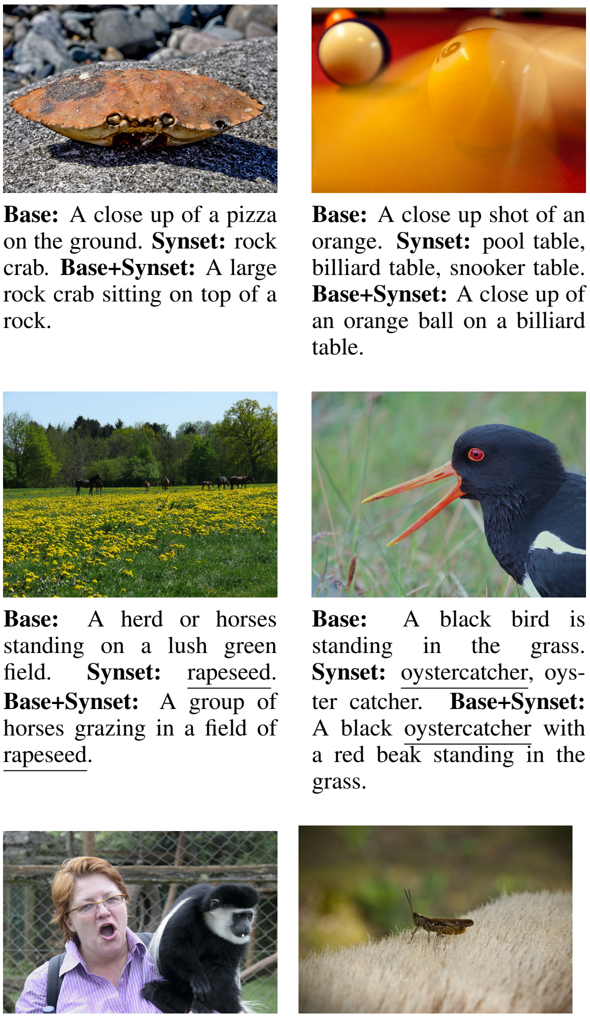
4.3 Captioning ImageNet

Consistent with our observation that many image collections contain useful annotations, and that we should seek to use this information, in this section we caption a 5,000 image subset of the ImageNet (Russakovsky et al., 2015) ILSVRC 2012 classification dataset for assessment. The dataset contains 1.2M images classified into 1,000 object categories, from which we randomly select five images from each category.

For this task we use the ResNet-50 (He et al., 2016) CNN, and train the base model on a combined training set containing 155k images comprised of the MSCOCO (Chen et al., 2015) training and validation datasets, and the full Flickr 30k (Young et al., 2014) captions dataset. We use constrained beam search and vocabulary expansion to ensure that each generated caption includes a phrase from the WordNet (Fellbaum, 1998) synset representing the ground-truth image category. For synsets that contain multiple entries, we run constrained beam search separately for each phrase and select the predicted caption with the highest log probability overall.

Note that even with the use of ground-truth object labels, the ImageNet captioning task remains extremely challenging as ImageNet contains a wide variety of classes, many of which are not evenly remotely represented in the available image-caption training datasets. Nevertheless, the injection of the ground-truth label frequently improves the overall structure of the caption over the base model in multiple ways. Examples of generated captions, including failure cases, are presented in Figure 4.

As the ImageNet dataset contains no existing caption annotations, following the human-evaluation protocol established for the MSCOCO 2015 Captioning Challenge (Chen et al., 2015), we used Amazon Mechanical Turk (AMT) to collect a human-generated caption for each sample image.



Base: A close up of a pizza on the ground. **Synset:** rock crab. **Base+Synset:** A large rock crab sitting on top of a rock.

Base: A close up shot of an orange. **Synset:** pool table, billiard table, snooker table. **Base+Synset:** A close up of an orange ball on a billiard table.

Base: A herd or horses standing on a lush green field. **Synset:** rapeseed. **Base+Synset:** A group of horses grazing in a field of rapeseed.

Base: A black bird is standing in the grass. **Synset:** oystercatcher, oyster catcher. **Base+Synset:** A black oystercatcher with a red beak standing in the grass.

Base: A man and a woman standing next to each other. **Synset:** colobus, colobus monkey. **Base+Synset:** Two colobus standing next to each other near a fence.

Base: A bird standing on top of a grass covered field. **Synset:** cricket. **Base+Synset:** A bird standing on top of a cricket field.

Figure 4: Examples of ImageNet captions generated by the base model (Base), and by the base model constrained to include the ground-truth synset (Base+Synset). Words never seen in the MSCOCO / Flickr 30k caption training set are underlined. The bottom row contains some failure cases.

For each of the 5,000 samples images, three human evaluators were then asked to compare the caption generated using our approach with the human-generated caption (Base+Syn v. Human). Using a smaller sample of 1,000 images, we also collected evaluations comparing our approach to the base model (Base+Syn v. Base), and comparing the base model with human-generated captions (Base v. Human). We used only US-based AMT

	Better	Equally Good	Equally Poor	Worse
Base v. Human	0.05	0.06	0.04	0.86
Base+Syn v. Human	0.12	0.10	0.05	0.73
Base+Syn v. Base	0.39	0.06	0.42	0.13

Table 3: In human evaluations our approach leveraging ground-truth synset labels (Base+Syn) improves significantly over the base model (Base) in both direct comparison and in comparison to human-generated captions.

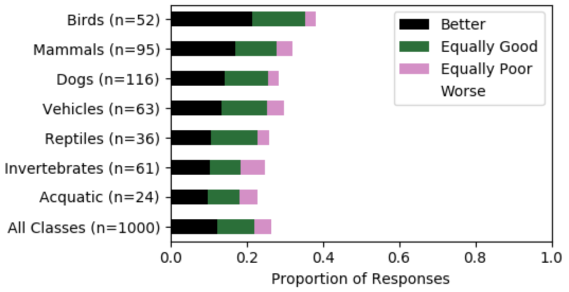


Figure 5: AMT evaluations of generated (Base+Syn) ImageNet captions versus human captions, by super-category.

workers, screened according to their performance on previous tasks. For both tasks, the user interface and question phrasing was identical to the MSCOCO collection process. The results of these evaluations are summarized in Table 3.

Overall, Base+Syn captions were judged to be equally good or better than human-generated captions in 22% of pairwise evaluations (12% 'better', 10% 'equally good'), and equally poor or worse than human-generated captions in the remaining 78% of evaluations. Although still a long way from human performance, this is a significant improvement over the base model with only 11% of captions judged to be equally good or better than human. For context, using the identical evaluation protocol, the top scoring model in the MSCOCO Captioning Challenge (evaluating on in-domain data) received 11% 'better', and 17% 'equally good' evaluations.

To better understand performance across synsets, in Figure 5 we cluster some class labels into super-categories using the WordNet hierarchy, noting particularly strong performances in super-categories that have some representation in the caption training data — such as birds, mammals and dogs. These promising results suggest that fine-grained object labels can be successfully integrated with a general purpose captioning model using our approach.

5 Conclusion and Future Research

We investigate *constrained beam search*, an approximate search algorithm capable of enforcing any constraints over resulting output sequences that can be expressed in a finite-state machine. Applying this approach to out-of-domain image captioning on a held-out MSCOCO dataset, we leverage image tag predictions to achieve state of the art results. We also show that we can significantly improve the quality of generated ImageNet captions by using the ground-truth labels.

In future work we hope to use more powerful image taggers, and to consider the use of constrained beam search within an expectation-maximization (EM) algorithm for learning better captioning models from weakly supervised data.

Abstract

In this paper, we investigate large-scale zero-shot activity recognition by modeling the visual and linguistic attributes of action verbs. For example, the verb "salute" has several properties, such as being a light movement, a social act, and short in duration. We use these attributes as the internal mapping between visual and textual representations to reason about a previously unseen action. In contrast to much prior work that assumes access to gold standard attributes for zero-shot classes and focuses primarily on object attributes, our model uniquely learns to infer action attributes from dictionary definitions and distributed word representations. Experimental results confirm that action attributes inferred from language can provide a predictive signal for zero-shot prediction of previously unseen activities.

1 Introduction

We study the problem of inferring action verb attributes based on how the word is defined and used in context. For example, given a verb such as "swig" shown in Figure 1, we want to infer various properties of actions such as *motion dynamics* (moderate movement), *social dynamics* (solitary act), *body parts* involved (face, arms, hands), and *duration* (less than 1 minute) that are generally true for the range of actions that can be denoted by the verb "swig".

Our ultimate goal is to improve *zero-shot learning* of activities in computer vision: predicting a previously unseen activity by integrating background knowledge about the conceptual properties of actions. For example, a computer vision system may have seen images of "drink" activities during training, but not "swig". Ideally, the system should infer the likely visual characteristics of "swig" using world knowledge implicitly available in dictionary definitions and word embeddings.

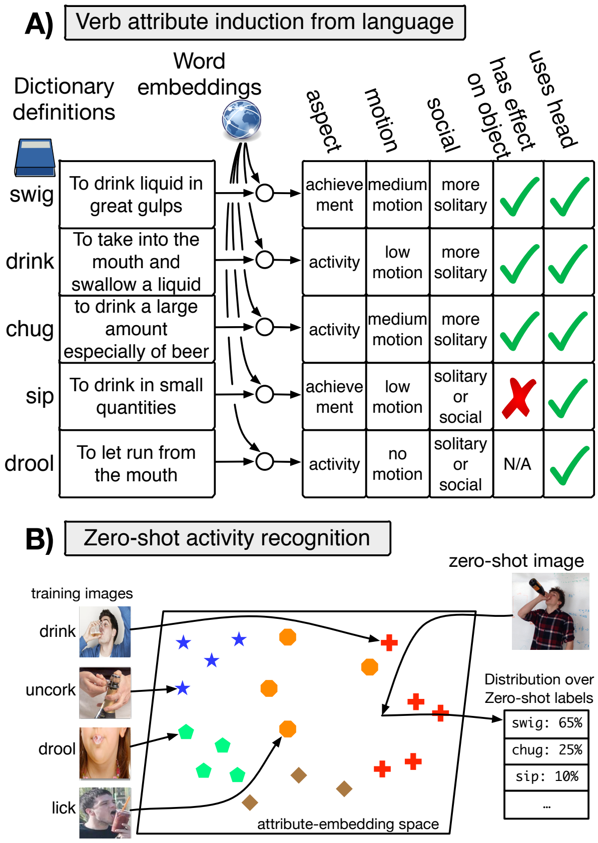

Figure 1: An overview of our task. Our goal is twofold. **A:** we seek to use use distributed word embeddings in tandem with dictionary definitions to obtain a high level understanding of verbs. **B:** we seek to use these predicted attributes to allow a classifier to recognize a broader set of activities than what was seen in training time.

However, most existing literature on zero-shot learning has focused on object recognition with only a few notable exceptions (see Related Work

Proceedings of the 2017 Conference on Empirical Methods in Natural Language Processing, pages 946–958
Copenhagen, Denmark, September 7–11, 2017. ©2017 Association for Computational Linguistics

in Section 8). There are two critical reasons: *object attributes*, such as color, shape, and texture, are conceptually straightforward to enumerate. In addition, they have distinct visual patterns which are robust for current vision systems to recognize. In contrast, *activity attributes* are more difficult to conceptualize as they involve varying levels of abstractness, which are also more challenging for computer vision as they have less distinct visual patterns. Noting this difficulty, Antol et al. (2014) instead employ cartoon illustrations as intermediate mappings for zero-shot dyadic activity recognition. We present a complementary approach: that of tackling the abstractness of verb attributes directly. We develop and use a corpus of verb attributes, using linguistic theories on verb semantics (e.g., aspectual verb classes of Vendler (1957)) and also drawing inspiration from studies on linguistic categorization of verbs and their properties (Friedrich and Palmer, 2014; Siegel and McKeown, 2000).

In sum, we present the first study aiming to recover general action attributes for a diverse collection of verbs, and probe their predictive power for zero-shot activity recognition on the recently introduced imSitu dataset (Yatskar et al., 2016). Empirical results show that action attributes inferred from language can help classifying previously unseen activities and suggest several avenues for future research on this challenging task. We publicly share our dataset and code for future research.[1]

2 Action Verb Attributes

We consider seven different groups of action verb attributes. They are motivated in part by potential relevance for visual zero-shot inference, and in part by classical literature on linguistic theories on verb semantics. The attribute groups are summarized below.[2] Each attribute group consists of a set of attributes, which sums to $K = 24$ distinct attributes annotated over the verbs.[3]

[1] Aspectual Classes We include the aspectual verb classes of Vendler (1957):

- *state*: a verb that does not describe a changing situation (e.g. “have”, “be”)
- *achievement*: a verb that can be *completed* in a short period of time (e.g. “open”, “jump”)
- *accomplishment*: a verb with a sense of completion over a longer period of time (e.g. “climb”)
- *activity*: a verb without a clear sense of completion (e.g. “swim”, “walk”, “talk”)

[2] Temporal Duration This attribute group relates to the aspectual classes above, but provides additional estimation of typical time duration with four categories. We categorize verbs by best-matching temporal units: seconds, minutes, hours, or days, with an additional option for verbs with unclear duration (e.g., “provide”).

[3] Motion Dynamics This attribute group focuses on the energy level of motion dynamics in four categories: no motion (“sleep”), low motion (“smile”), medium (“walk”), or high (“run”). We add an additional option for verbs whose motion level depends highly on context, such as ‘finish.’

[4] Social Dynamics This attribute group focuses on the likely social dynamics, in particular, whether the action is usually performed as a solitary act, a social act, or either. This is graded on a 5-part scale from least social (-2) to either $(+0)$ to most social $(+2)$

[5] Transitivity This attribute group focuses on whether the verb can take an object, or be used without. This gives the model a sense of the implied action dynamics of the verb between the agent and the world. We record three variables: whether or not the verb is naturally transitive on a person (“I hug her” is natural), on a thing (“I eat it”), and whether the verb is intransitive (“I run”).

[6] Effects on Arguments This attribute group focuses on the effects of actions on agents and other arguments. For each of the possible transitivities of the verb, we annotate whether or not it involves *location change* (“travel”), *world change* (“spill”), *agent or object change* (“cry”) , or *no visible change* (“ponder”).

[7] Body Involvements This attribute group specifies prominent body parts involved in carrying out the action. For example, “open” typically involves “hands” and “arms” when used in a physical sense. We use five categories: head, arms, torso, legs, and other body parts.

[1] Available at http://github.com/rowanz/verb-attributes

[2] The full list is available in the supplemental section.

[3] Several of our attributes are categorical; if converted to binary attributes, we would have 40 attributes in total.

Action Attributes and Contextual Variations In general, contextual variations of action attributes are common, especially for frequently used verbs that describe everyday physical activities. For example, while "open" typically involves "hands", there are exceptions, e.g. "open one's eyes". In this work, we focus on stereotypical or prominent characteristics across a range of actions that can be denoted using the same verb. Thus, three investigation points of our work include: (1) crowd-sourcing experiments to estimate the distribution of human judgments on the prominent characteristics of everyday physical action verbs, (2) the feasibility of learning models for inferring the prominent characteristics of the everyday action verbs despite the potential noise in the human annotation, and (3) their predictive power in zero-shot action recognition despite the potential noise from contextual variations of action attributes. As we will see in Section 7, our study confirms the usefulness of studying action attributes and motivates the future study in this direction.

Relevance to Linguistic Theories The key idea in our work that action verbs project certain expectations about their influence on their arguments, their pre- and post-conditions, and their implications on social dynamics, etc., relates to the original Frame theories of Baker et al. (1998a). The study of action verb attributes are also closely related to formal studies on verb categorization based on the characteristics of the actions or states that a verb typically associates to (Levin, 1993), and cognitive linguistics literature that focus on causal structure and force dynamics of verb meanings (Croft, 2012).

3 Learning Verb Attributes from Language

In this section we present our models for learning verb attributes from language. We consider two complementary types of language-based input: dictionary definitions and word embeddings. The approach based on dictionary definitions resembles how people acquire the meaning of a new word from a dictionary lookup, while the approach based on word embeddings resembles how people acquire the meaning of words in context.

Overview This task follows the standard supervised learning approach where the goal is to predict K attributes per word in the vocabulary $\mathcal{V}$. Let $x_v \in \mathcal{X}$ represent the input representation of a word $v \in \mathcal{V}$. For instance, x_v could denote a word embedding, or a definition looked up from a dictionary (modeled as a list of tokens). Our goal is to produce a model $f : \mathcal{X} \to \mathbb{R}^d$ that maps the input to a representation of dimension d. Modeling options include using pretrained word embeddings, as in Section 3.1, or using a sequential model to encode a dictionary, as in Section 3.2.

Then, the estimated probability distribution over attribute k is given by:

$$\hat{y}_{v,k} = \sigma(\mathbf{W}^{(k)} f(x_v)). \qquad (1)$$

If the attribute is binary, then $\mathbf{W}^{(k)}$ is a vector of dimension d and σ is the sigmoid function. Otherwise, $\mathbf{W}^{(k)}$ is of shape $d_k \times d$, where d_k is the dimension of attribute k, and σ is the softmax function. Let the vocabulary $\mathcal{V}$ be partitioned into sets $\mathcal{V}_{train}$ and $\mathcal{V}_{test}$; then, we train by minimizing the cross-entropy loss over $\mathcal{V}_{train}$ and report attribute-level accuracy over words in $\mathcal{V}_{test}$.

Connection to Learning Object Attributes This problem has been studied before for zero-shot object recognition, but there are several key differences. Al-Halah et al. (2016) build the 'Class-Attribute Association Prediction' model (CAAP) that classifies the attributes of an object class from its name. They apply it on the Animals with Attributes dataset, a dataset containing 50 animal classes, each described by 85 attributes (Lampert et al., 2014). Importantly, these attributes are concrete details with semantically meaningful names such as "has horns" and "is furry". The CAAP model takes advantage of this, consisting of a tensor factorization model initialized by the word embeddings of the object class names as well as the attribute names. On the other hand, *verb attributes* such as the ones we outline in Section 2, are technical linguistic terms. Since word embeddings principally capture common word senses, they are unsuited for verb attributes. Thus, we evaluate two versions of CAAP as a baseline: one where the model is preinitialized with GloVe embeddings (Pennington et al., 2014) for the attribute names (CAAP-pretrained), and one where the model is learned from random initialization (CAAP-learned).

3.1 Learning from Distributed Embeddings

One way of producing attributes is from distributed word embeddings such as word2vec

(Mikolov et al., 2013). Intuitively, we expect similar verbs to have similar distributions of nearby nouns and adverbs, which can greatly help us in zero-shot prediction. In our experiments, we use 300-dimensional GloVe vectors trained on 840B tokens of web data (Pennington et al., 2014). We use logistic regression to predict each attribute, as we found that extra hidden layers did not improve performance. Thus, we let $f^{emb}(x_v) = \mathbf{w}_v$, the GloVe embedding of v, and use Equation 1 to get the distribution over labels.

We additionally experiment with retrofitted embeddings, in which embeddings are mapped in accordance with a lexical resource. Following the approach of Faruqui et al. (2015), we retrofit embeddings using WordNet (Miller, 1995), Paraphrase-DB (Ganitkevitch et al., 2013), and FrameNet (Baker et al., 1998b).

3.2 Learning from Dictionary Definitions

We additionally propose a model that learns the attribute-grounded meaning of verbs through dictionary definitions. This is similar in spirit to the task of using a dictionary to predict word embeddings (Hill et al., 2016).

BGRU encoder Our first model involves a Bidirectional Gated Recurrent Unit (BGRU) encoder (Cho et al., 2014). Let $x_{v,1:T}$ be a definition for verb v, with T tokens. To encode the input, we pass it through the GRU equation:

$$\vec{\mathbf{h}}_t = \text{GRU}(x_{v,t}, \vec{\mathbf{h}}_{t-1}). \qquad (2)$$

Let $\overleftarrow{\mathbf{h}}_1$ denote the output of a GRU applied on the reversed input $x_{v,T:1}$. Then, the BGRU encoder is the concatenation $f^{bgru} = \vec{\mathbf{h}}_T \| \overleftarrow{\mathbf{h}}_1$.

Bag-of-words encoder Additionally, we try two common flavors of a Bag-of-Words model. In the standard case, we first construct a vocabulary of 5000 words by frequency on the dictionary definitions. Then, $f^{bow}(x_v)$ represents the one-hot encoding $f^{bow}(x_v)_i = [i \in x_v]$, in other words, whether word i appears in definiton x_v for verb v.

Additionally, we try out a Neural Bag-of-Words model where the word embeddings in a definition are averaged (Iyyer et al., 2015). This is $f^{nbow}(x_{v,1:T}) = \frac{1}{|T|}\sum_{t=1}^{T} f^{emb}(x_{v,t})$.

Dealing with multiple definitions per verb One potential pitfall with using dictionary definitions is that there are often many defnitions associated with each verb. This creates a dataset bias since polysemic verbs are seen more often. Additionally, dictionary definitions tend to be sorted by relevance, thus lowering the quality of the data if all definitions are weighted equally during training. To counteract this, we randomly oversample the definitions at training time so that each verb has the same number of definitions.[4] At test time, we use the first-occurring (and thus generally most relevant) definition per verb.

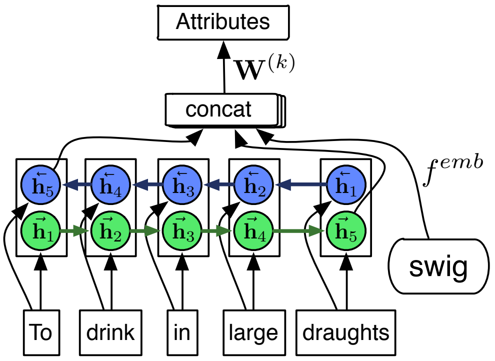

Figure 2: Overview of our combined dictionary + embedding to attribute model. Our encoding is the concatenation of a Bidirectional GRU of a definition and the word embedding for that word. The encoding is then mapped to the space of attributes using parameters $\mathbf{W}^{(k)}$.

3.3 Combining Dictionary and Embedding representations

We hypothesize that the two modalities of the dictionary and distributional embeddings are complementary. Therefore, we propose an early fusion (concatenation) of both categories. Figure 2 describes the GRU + embedding model – in other words, $f^{BGRU+emb} = f^{BGRU} \| f^{emb}$. This can likewise be done with any choice of definition encoder and word embedding.

4 Zero-Shot Activity Recognition

4.1 Verb Attributes as Latent Mappings

Given learned attributes for a collection of activities, we would like to evaluate their performance at describing these activities from real world images in a zero-shot setting. Thus, we consider several models that classify an image's label by pivoting through an attribute representation.

[4] For the (neural) bag of words models, we also tried concatenating the definitions together per verb and then doing the encoding. However, we found that this gave worse results.

Overview A formal description of the task is at follows. Let the space of labels be $\mathcal{V}$, partitioned into $\mathcal{V}_{train}$ and $\mathcal{V}_{test}$. Let $z_v \in \mathcal{Z}$ represent an image with label $v \in \mathcal{V}$; our goal is to correctly predict this label amongst verbs $v \in \mathcal{V}_{test}$ at test time, despite never seeing any images with labels in $\mathcal{V}_{test}$ during training.

Generalization will be done through a lookup table $\mathbf{A}$, with known attributes for each $v \in \mathcal{V}$. Formally, for each attribute k we define it as:

$$\mathbf{A}^{(k)}_{v',i} = \begin{cases} 1 & \text{if attribute } k \text{ for verb } v' \text{ is } i \\ -1 & \text{otherwise} \end{cases} \tag{3}$$

For binary attributes, we need only one entry per verb, making $\mathbf{A}^{(k)}$ a single column vector. Let our image encoder be represented by the map $g : \mathcal{Z} \to \mathbb{R}^d$. We then use the linear map in Equation 1 to produce the log-probability distribution over each attribute k. The distribution over labels is then:

$$P(\cdot|z_v) = \underset{v'}{\text{softmax}} \left(\sum_k \mathbf{A}^{(k)} \mathbf{W}^{(k)} g(z_v) \right) \tag{4}$$

where $\mathbf{W}^{(k)}$ is a learned parameter that maps the image encoder to the attribute representation. We then train our model by minimizing the cross-entropy loss over the training verbs $\mathcal{V}_{train}$.

Convolutional Neural Network (CNN) Encoder Our image encoder is a CNN with the Resnet-152 architecture (He et al., 2016). We use weights pretrained on ImageNet (Deng et al., 2009) and perform additional pretraining on ImSitu using the classes $\mathcal{V}_{train}$. After this, we remove the top layer and set $g(x_v)$ to be the 2048-dimensional image representation from the network.

4.1.1 Connection to other attribute models

Our model is similar to those of Akata et al. (2013) and Romera-Paredes and Torr (2015) in that we predict the attributes indirectly and train the model through the class labels.[5] It differs from several other zeroshot models, such as Lampert et al. (2014)'s Direct Attribute Prediction (DAP) model, in that DAP is trained by maximizing the probability of predicting each attribute and then multiplies the probabilities at test time. Our use of joint training allows the recognition model to directly optimize class-discrimination rather than attribute-level accuracy.

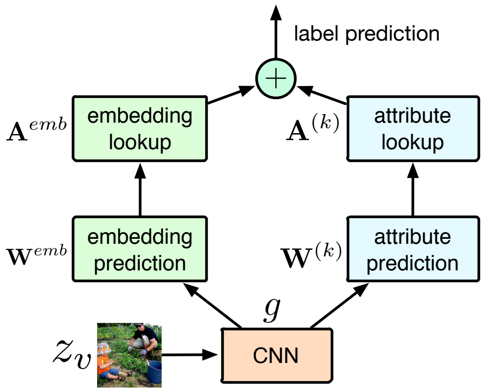

Figure 3: Our proposed model for combining attribute-based zero-shot learning and word-embedding based transfer learning. The embedding and attribute lookup layers are used to predict a distribution of labels over $\mathcal{V}_{train}$ during training and $\mathcal{V}_{test}$ during testing.

4.2 Verb Embeddings as Latent Mappings

An additional method of doing zero-shot image classification is by using word embeddings directly. Frome et al. (2013) build DeVISE, a model for zero-shot learning on ImageNet object recognition where the objective is for the image model to predict a class's word embedding directly. DeVISE is trained by minimizing

$$\sum_{v' \in \mathcal{V}_{train} \setminus \{v\}} \max\{0, .1 + (\mathbf{w}_{v'} - \mathbf{w}_v)\mathbf{W}^{emb} g(z_v)\}$$

for each image z_v. We compare against a version of this model with fixed GloVe embeddings $\mathbf{w}$.

Additionally, we employ a variant of our model using only word embeddings. The equation is the same as Equation 4, except using the matrix $\mathbf{A}^{emb}$ as a matrix of word embeddings: i.e., for each label v we consider, we have $\mathbf{A}^{emb}_v = \mathbf{w}_v$.

4.3 Joint prediction from Attributes and Embeddings

To combine the representation power of the attribute and embedding models, we build an ensemble combining both models. This is done by adding the logits before the softmax is applied:

$$\underset{v'}{\text{softmax}} \left(\sum_k \mathbf{A}^{(k)} \mathbf{W}^{(k)} g(z_v) + \mathbf{A}^{emb} \mathbf{W}^{emb} g(z_v) \right)$$

A diagram is shown in Figure 3. We find that during optimization, this model can easily overfit, presumably by excessive coadaption of the embedding and attribute components. To solve this,

[5] Unlike these models, however, we utilize (some) categorical attributes and optimize using cross-entropy.

we train the model to minimize the cross entropy of three sources independently: the attributes only, the embeddings only, and the sum, weighting each equally.

Incorporating predicted and gold attributes We additionally experiment with an ensemble of our model, combining predicted and gold attributes of $\mathcal{V}_{test}$. This allows the model to hedge against cases where a verb attribute might have several possible correct answers. A single model is trained; at test time, we multiply the class level probabilities $P(\cdot|z_v)$ of each together to get the final predictions.

5 Actions and Attributes Dataset

To evaluate our hypotheses on action attributes and zero-shot learning, we constructed a dataset using crowd-sourcing experiments. The *Actions and Attributes* dataset consists of annotations for 1710 verb templates, each consisting of a verb and an optional particle (e.g. “put” or “put *up*”).

We selected all verbs from the ImSitu corpus, consisting of images representing verbs from many categories (Yatskar et al., 2016), then extended the set using the MPII movie visual description dataset and ScriptBase datasets, (Rohrbach et al., 2015; Gorinski and Lapata, 2015). We used the spaCy dependency parser (Honnibal and Johnson, 2015) to extract the verb template for each sentence, and collected annotations on Mechanical Turk to filter out nonliteral and abstract verbs. Turkers annotated this filtered set of templates using the attributes described in Section 2. In total, 1203 distinct verbs are included. The templates are split randomly by verb; out of 1710 total templates, we save 1313 for training, 81 for validation, and 316 for testing.

To provide signal for classifying these verbs, we collected dictionary definitions for each verb using the Wordnik API,[6] including only senses that are explicitly labeled “verb.” This leaves us with 23,636 definitions, an average of 13.8 per verb.

6 Experimental Setup

BGRU pretaining We pretrain the BGRU model on the Dictionary Challenge, a collection of 800,000 word-definition pairs obtained from Wordnik and Wikipedia articles (Hill et al., 2016); the objective is to obtain a word’s embedding given one of its definitions. For the BGRU model, we use an internal dimension of 300, and embed the words to a size 300 representation. The vocabulary size is set to 30,000 (including all verbs for which we have definitions). During pretraining, we keep the architecture the same, except a different 300-dimensional final layer is used to predict the GloVe embeddings.

Following Hill et al. (2016), we use a ranking loss. Let $\hat{\mathbf{w}} = \mathbf{W}^{emb} f(x)$ be the predicted word embeddings for each definition x of a word in the dictionary (not necessarily a verb). Let $\mathbf{w}$ be the word’s embedding, and $\widetilde{\mathbf{w}}$ be the embedding of a random dictionary word. The loss is then given by:

$$L = \max\{0, .1 - \cos(\mathbf{w}, \hat{\mathbf{w}}) + \cos(\mathbf{w}, \widetilde{\mathbf{w}})\}$$

After pretraining the model on the Dictionary Challenge, we fine-tune the attribute weights $\mathbf{W}^{(k)}$ using the cross-entropy over Equation 1.

Zero-shot with the imSitu dataset We build our image-to-verb model on the newly introduced imSitu dataset, which contains a diverse collection of images depicting one of 504 verbs. The images represent a variety of different semantic role labels (Yatskar et al., 2016). Figure 4 shows examples from the dataset. We apply our attribute split to the dataset and are left with 379 training classes, 29 validation classes, and 96 test classes.

Zero-shot activity recognition baselines We compare against several additional baseline models for learning from attributes and embeddings. Romera-Paredes and Torr (2015) propose “Embarassingly Simple Zero-shot Learning” (ESZL), a linear model that directly predicts class labels through attributes and incorporates several types of regularization. We compare against a variant of Lampert et al. (2014)’s DAP model discussed in Section 4.1.1. We additionally compare against DeVISE (Frome et al., 2013), as mentioned in Section 4.2. We use a Resnet-152 CNN finetuned on the imSitu $\mathcal{V}_{train}$ classes as the visual features for these baselines (the same as discussed in Section 4.1).

Additional implementation details are provided in the Appendix.

Table 1: Results on the text-to-attributes task. All values reported are accuracies (in %). For attributes where multiple labels can be selected, the accuracy is averaged over all instances (e.g., the accuracy of "Body" is given by the average of accuracies from correctly predicting Head, Torso, etc.). As such, we report two ways of averaging the results: microaveraging (where the accuracy is the average of accuracies on the underlying labels) and macroaveraging (where the accuracy is averaged together from the groups).

7 Experimental Results

7.1 Predicting Action Attributes from Text

Our results for action attribute prediction from text are given in Table 1. Several examples are given in the supplemental section in Table 3. Our results on the text-to-attributes challenge confirm that it is a challenging task for two reasons. First, there is noise associated with the attributes: many verb attributes are hard to annotate given that verb meanings can change in context.[7] Second, there is a lack of training data inherent to the problem: there are not many common verbs in English, and it can be difficult to crowdsource annotations for rare ones. Third, any system must compete with strong frequency-based baselines, as attributes are generally sparse. Moreover, we suspect that were more attributes collected (so as to cover more obscure patterns), the sparsity would only increase.

Despite this, we report strong baseline results on this problem, particularly with our embedding based models. The performance gap between embedding- and definition-based models can possibly be explained by the fact that the word embeddings are trained on a very large corpus of real-world *examples* of the verb, while the definition is only a single high-level representation meant to be understood by someone who already speaks that language. For instance, it is likely difficult for the definition-based model to infer whether a verb is transitive or not (Transi.), since definitions might assume commonsense knowledge about the underlying concepts the verb represents. The strong performance of embedding models is further enhanced by using retrofitted word embeddings, suggesting an avenue for improvement on language grounding through better representation of linguistic corpora.

We additionally see that both joint dictionary-embedding models outperform the dictionary-only models overall. In particular, the BGRU+GloVe model performs especially well at determining the aspect and motion attributes of verbs, particularly relative to the baseline. The strong performance of the BGRU+GloVe model indicates that there is some signal that is missing from the distributional embeddings that can be recovered from the dictionary definition. We thus use the predictions of this model for zero-shot image recognition.

Based on error analysis, we found that one common mode of failure is where contextual knowledge is required. To give an example, the embedding based model labels "shop" as a likely solitary action. This is possibly because there are a lack of similar verbs in $\mathcal{V}_{train}$; by random chance, "buy" is also in the test set. We see that this can be partially mitigated by the dictionary, as evidenced by the fact that the dictionary-based models label "shop" as in between social and solitary. Still, it is a difficult task to infer that people like to "visit stores in search of merchandise" together.

7.2 Zero-shot Action Recognition

Our results for verb prediction from images are given in Table 2. Despite the difficulty of predicting the correct label over 96 unseen choices,

[7] As such, our attributes have a median Krippendorff Alpha of $\alpha = .359$.

	Attributes used			$v \in \mathcal{V}_{test}$	
Model	atts(P)	atts(G)	GloVe	top-1	top-5
Random				1.04	5.20
DeVISE			✓	16.50	37.56
ESZL		✓		3.60	14.81
	✓			3.27	13.21
DAP		✓		3.35	16.69
	✓			4.33	17.56
Ours		✓		4.79	19.98
	✓			7.04	22.19
	✓	✓		7.71	24.90
			✓	17.60	39.29
		✓	✓	18.10	41.46
	✓		✓	16.75	40.44
	✓	✓	✓	**18.15**	**42.17**

Table 2: Results on the image-to-verb task. atts(P) refers to attributes predicted from the BGRU+GloVe model described in Section 3, atts(G) to gold attributes, and GloVe to GloVe vectors. The accuracies reported are amongst the 96 unseen labels of $\mathcal{V}_{test}$.

our models show predictive power. Although our attribute models do not outperform our embedding models and DeVISE alone, we note that our joint attribute and embedding model scores the best overall, reaching 18.10% in top-1 and 41.46% in top-5 accuracy when using gold attribute annotations for the zero-shot verbs. This result is possibly surprising given the small number of attributes ($K = 24$) in total, of which most tend to be sparse (as can be seen from the baseline performance in Table 1). We thus hypothesize that collecting more activity attributes would further improve performance.

We also note the success in performing zero-shot learning with predicted attributes. Perhaps paradoxically, our attribute-only models (along with DAP) perform better in both accuracy metrics when given predicted attributes at test time, as opposed to gold attributes. Further, we get an extra boost by ensembling predictions of our model when given two sets of attributes at test time, giving us the best results overall at 18.15% top-1 accuracy and 42.17% top-5. Interestingly, better performance with predicted attributes is also reported by Al-Halah et al. (2016): predicting the attributes with their CAAP model and then running the DAP model on these predicted attributes outperforms the use of gold attributes at test time. It is somewhat unclear why this is the case - possibly, there is some bias in the attribute labeling, which the attribute predictor can correct for.

In addition to quantitative results, we show some zero-shot examples in Figure 4. The examples show inherent difficulty of zero-shot action recognition. Incorrect predictions are often reasonably related to the situation ("rub" vs "dye") but picking the correct target verb based on attribute-based inference is still a challenging task.

Although our results appear promising, we argue that our model still fails to represent much of the semantic information about each image class. In particular, our model is prone to *hubness*: the overprediction of a limited set of labels at test time: those that closely match signatures of examples in the training set. This problem has previously been observed with the use of word embeddings for zero-shot learning (Marco and Georgiana, 2015) and can be seen in our examples (for instance, the over-prediction of "buy"). Unfortunately, we were unable to mitigate this problem in a way that also led to better quantitative results (for instance, by using a ranking loss as in DeVISE (Frome et al., 2013)). We thus leave resolving the hubness problem in zero-shot activity recognition as a question for future work.

8 Related Work

Learning attributes from embeddings Rubinstein et al. (2015) seek to predict McRae et al. (2005)'s feature norms from word embeddings of concrete nouns. Likewise, the CAAP model of Al-Halah et al. (2016) predicts the object attributes of concrete nouns for use in zero-shot learning. In contrast, we predict verb attributes. A related task is that of improving word embeddings using multimodal data and linguistic resources (Faruqui et al., 2015; Silberer et al., 2013; Vendrov et al., 2016). Our work runs orthogonal to this, as we focus on word attributes as a tool for a zero-shot activity recognition pipeline.

Zero-shot learning with objects Though distinct, our work is related to zero-shot learning of objects in computer vision. There are several datasets (Nilsback and Zisserman, 2008; Welinder et al., 2010) and models developed on this task (Romera-Paredes and Torr (2015); Lampert et al. (2014); Mukherjee and Hospedales (2016); Farhadi et al. (2010)). In addition,

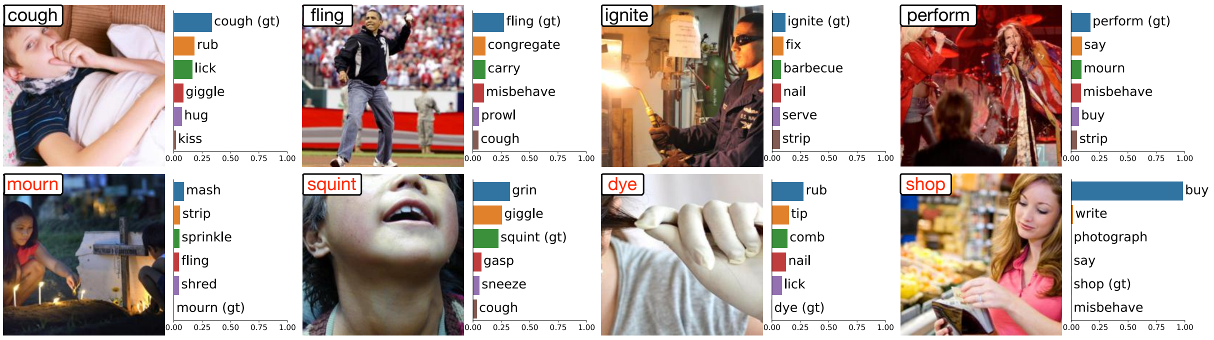

Figure 4: Predictions on unseen classes from our attribute+embedding model with gold attributes. The top and bottom rows show successful and failure cases respectively. The bars to the right of each image represent a probability distribution, showing the ground truth class and the top 5 scoring incorrect classes.

Ba et al. (2015) augment existing datasets with descriptive Wikipedia articles so as to learn novel objects from descriptive text. As illustrated in Section 1, action attributes pose unique challenges compared to object attributes, thus models developed for zero-shot object recognition are not as effective for zero-shot action recognition, as has been empirically shown in Section 7.

Zero-shot activity recognition In prior work, zero-shot activity recognition has been studied on video datasets, each containing a selection of concrete physical actions. The MIXED action dataset, itself a combination of three action recognition datasets, has 2910 labeled videos with 21 actions, each described by 34 action attributes (Liu et al., 2011). These action attributes are concrete binary attributes corresponding to low-level physical movements, for instance, “arm only motion,” “leg: up-forward motion.” By using word embeddings instead of attributes, Xu et al. (2017) study video activity recognition on a variety of action datasets, albeit in the transductive setting wherein access to the test labels is provided during training. In comparison with our work on imSitu (Yatskar et al., 2016), these video datasets lack broad coverage of verb-level classes (and for some, sufficient data points per class).

The abstractness of broad-coverage activity labels makes the problem much more difficult to study with attributes. To get around this, Antol et al. (2014) present a synthetic dataset of cartoon characters performing dyadic actions, and use these cartoon illustrations as internal mappings for zero-shot recognition of dyadic actions in real-world images. We investigate an alternative approach by using linguistically informed verb attributes for activity recognition.

9 Future work / Conclusion

Several possibilities remain open for future work. First, more attributes could be collected and evaluated, possibly integrating other linguistic theories about verbs, with more accurate modeling of context. Second, while our experiments use attributes as a pivot between language and vision domains, the effects of this could be explored more in future work. In particular, since our experiments show that unsupervised word embeddings significantly help performance, it might be desirable to learn data-driven attributes in an end-to-end fashion directly from a large corpus or from dictionary definitions. Third, future research on action attributes should ideally include videos to better capture attributes that require temporal signals.

Overall, however, our work presents a strong early step towards zero-shot activity recognition, a relatively less studied task that poses several unique challenges over zero-shot object recognition. We introduce new action attributes motivated by linguistic theories and demonstrate their empirical use for reasoning about previously unseen activities.

A Supplemental

Implementation details

Our CNN and BGRU models are built in PyTorch[8]. All of our one-layer neural network models are built in Scikit-learn (Pedregosa et al., 2011) using the provided LogisticRegression class (using one-versus-rest if appropriate). Our neural models use the Adam optimizer (Kingma and Ba, 2014), though we weak the default hyperparameters somewhat.

Recall that our dictionary definition model is a bidirectional GRU with a hidden size of 300, with a vocabulary size of 30,000. After pretraining on the Dictionary Challenge, we freeze the word embeddings and apply a dropout rate of 50% before the final hidden layer. We found that such an aggressive dropout rate was necessary due to the small size of the training set. During pretraining, we used a learning rate of 10^{-4}, a batch size of 64, and set the Adam parameter ϵ to the default $1e^{-8}$. During finetuning, we set $\epsilon = 1.0$ and the batch size to 32. In general, we found that setting too low of an ϵ during finetuning caused our zero-shot models to update parameters too aggressively during the first couple of updates, leading to poor results.

For our CNN models, we pretrained the Resnet 152 (initialized with imagenet weights) on the

[8] pytorch.org

training classes of the imSitu dataset, using a learning rate of 10^{-4} and $\epsilon = 10^{-8}$. During finetuning, we dropped the learning rate to 10^{-5} and set $\epsilon = 10^{-1}$. We also froze all parameters except for the final resnet block, and the linear attribute and embedding weights. We also found L2 regularization quite important in reducing overfitting, and we applied regularization at a weight of 10^{-4} to all trainable parameters.

Full list of attributes

The following is a full list of the attributes. In addition to the attributes presented here, we also crowdsourced attributes for the emotion content of each verb (e.g., happiness, sadness, anger, and surprise). However, we found these annotations to be skewed towards "no emotion", since most verbs do not strongly associate with a specific emotion. Thus, we omit them in our experiments.

(1) Aspectual Classes: one attribute with 5 values:

- (a) State
- (b) Achievement
- (c) Accomplishment
- (d) Activity
- (e) Unclear without context

(2) Temporal Duration: one attribute with 5 values:

- (a) Atemporal
- (b) On the order of seconds
- (c) On the order of hours
- (d) On the order of days

(3) Motion Dynamics: One attribute with 5 values:

- (a) unclear without context
- (b) No motion
- (c) Low motion
- (d) Medium motion
- (e) High motion

(4) Social Dynamics: One attribute with 5 values:

- (a) solitary
- (b) likely solitary
- (c) solitary or social
- (d) likely social
- (e) social

(5) Transitivity: Three binary attributes:

- (a) Intransitive: 1 if the verb can be used intransitively, 0 otherwise
- (b) Transitive (person): 1 if the verb can be used in the form "<someone>", 0 otherwise
- (c) Transitive (object): 1 if the verb can be used in the form "<verb> something", 0 otherwise

Deriving continous grounded meaning representations from referentially structured multimodal contexts

Abstract

Corpora of referring expressions paired with their visual referents are a good source for learning word meanings directly grounded in visual representations. Here, we explore additional ways of extracting from them word representations linked to multi-modal context: through expressions that refer to the *same* object, and through expressions that refer to *different* objects in the *same scene*. We show that continuous meaning representations derived from these contexts capture complementary aspects of similarity, even if not outperforming textual embeddings trained on very large amounts of raw text when tested on standard similarity benchmarks. We propose a new task for evaluating grounded meaning representations—detection of potentially co-referential phrases—and show that it requires precise denotational representations of attribute meanings, which our method provides.

1 Introduction

Various routes for linking language to extra-linguistic context have been explored in recent years. A lot of research has looked at integrating visual representations, either directly (Matuszek et al., 2012; Krishnamurthy and Kollar, 2013; Yu et al., 2016; Schlangen et al., 2016) or through mapping into a multi-modal distributional space (Feng and Lapata, 2010; Bruni et al., 2012; Kiela and Bottou, 2014; Lazaridou et al., 2015). Young et al. (2014) have explored a less direct link, by representing the extension of phrasal expressions as sets of images, and deriving from this a precise notion of denotational similarity. In very recent work, Cocos and Callison-Burch (2017) use spatial context from geo-located tweets to induce word embeddings that capture situational similarity between lexical items.

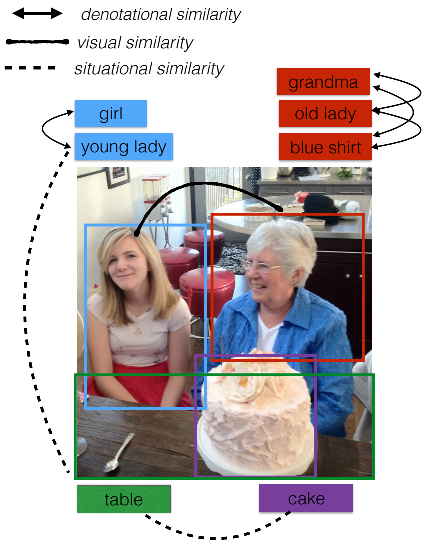

Figure 1: Dimensions of context in referential, visually grounded language, and similarity relations that can be derived from it, image from MsCoco (Lin et al., 2014))

In this paper, we explore an approach that combines aspects of several of these paths. Starting point is the observation that corpora of exophoric referring expressions provide richly structured contexts that go beyond just linking individual expressions with their denotations. As an example consider the scene in Figure 1 depicting several referents and corresponding referring expressions produced by different speakers. This scene provides a learner not only with an example of a referent for the word *lady*, it also provides the information that *lady* can co-refer with *girl*, and that its denotations can spatially / situationally co-occur with those of *table* and *cake*. From these types of information we infer word embeddings, following the method from Levy and Goldberg (2014) for training embeddings on arbi-

Copenhagen, Denmark, September 7–11, 2017.

trary non-linear context, and we show that these capture complementary aspects of word similarity that purely textual induction methods conflate. We also show that these representations handle a more directly referential similarity task better.

2 Word Embeddings from Multi-Modal Referential Contexts

We base our study on the REFERIT and REFCOCO corpus (Kazemzadeh et al., 2014; Yu et al., 2016) building upon image collections by (Grubinger et al., 2006) and (Lin et al., 2014); for the latter, we also use referring expressions collected by Mao et al. (2015). This corpus gives us visual scenes containing sets of objects, $s = o_1, \ldots, o_n$. Each object is associated with a set of referring expressions $r_1, \ldots, r_m$; and we use a standard method (a ConvNet) for providing a visual representation vis_i for it. Each referring expression, in turn, is defined as a linear sequence of words $r_i = w_1 \ldots w_k$. In the following, we structure this context into four dimensions—visual, textual, situational and denotational—which we use to derive different word embeddings.

2.1 Textual Context (TXT)

We learn standard distributional word embeddings from our corpus, ignoring extra-linguistic context. We train a skip-gram model (Mikolov et al., 2013) with negative sampling with window width 5, 300 dimensions. For comparison, we also use the textual word embeddings provided by Baroni et al. (2014), trained on a much larger web corpus (5-word context window, 10 negative samples, 400 dimensions). We distinguish the two textual embeddings using the subscripts TXT$_{ref}$, TXT$_{web}$.

2.2 Visual Grounding (VIS)

Given a set of referring expressions containing the word w and their corresponding referent $(o_j, r_j), w \in r_j$, we can derive a visual context for the word w by averaging over the visual representations of its referents vis_j, as proposed for instance by Kiela and Bottou (2014). The visual context of a word can be seen as a 'visual prototype'. We derive representations of our visual inputs with a convolutional neural network, "GoogLeNet" (Szegedy et al., 2015), that was trained on data from the ImageNet corpus (Deng et al., 2009), and extract the final fully-connected layer before the classification layer, to give us a 1024 dimensional representation of the region. Following (Schlangen et al., 2016), we also add 7 features that encode information about the region relative to the image, the full representation hence is a vector of 1031 features. Each word is then represented as the average over its visual vectors.

2.3 Situational Grounding (SIT)

We also train word embeddings (dim. 300) that predict words paired with their situational context, following the method by Levy and Goldberg (2014). This captures similarities between words occurring for different objects in the same scene, e.g. *cake* in the context of *table* in Figure 1. Given a pair of referring expressions $(r_i, o_i), (r_j, o_j), o_i \neq o_j$, r_i and r_j are co-situational expressions. Thus, for a word $w_i \in r_i$, we consider all words $w_j \in r_j$ as its situational context. In practice, we compute situational contexts only for the head nouns of each referring expression, as we expect situational similarities to be useful for capturing similarities between nouns.

2.4 Denotational Grounding (DEN)

As our data typically records multiple co-referential expressions for an object (3 expressions on average in the REFCOCO data), we define the denotational context based on sets of expressions referring to the same object $(r_1, o_i) \ldots (r_n, o_i)$. For a word $w_i \in r_i$, we consider all words w_{j_l} (with $w_{j_l} \in r_j$) as denotational context, where r_j and r_i refer to the same object. When two words occur in a denotational context, we have strong evidence that they are semantically compatible, i.e. can refer to the same objects as *girl* and *lady* in Figure 1 do. Similar to our training procedure for situational embeddings, we now learn 300-dimensional word embeddings that predict occurrences of a word based on co-referential contexts, pairing each word with all words from referring expressions describing the same object.

3 Word Similarity and Relatedness

We now have four different continuous representations for words; in the following, we evaluate them for how well they predict semantic relations.

Similarity We evaluate on some similarity data sets, reporting Spearman ρ correlations between human ratings and cosine similarities for word vectors. We use the MEN (Bruni et al., 2012) and

Silberer and Lapata (2014)'s data with semantic (SemSim) and visual similarity (VisSim) ratings.

Compatibility As generic semantic similarity judgements are known to be "fuzzy" (Faruqui et al., 2016), we also evaluate on Kruszewski and Baroni (2015)'s benchmark on semantic compatibility. They define two words as being *semantically compatible* "if they can potentially refer to the same thing". We expect our denotational and visual embeddings to be highly useful for this task. We report unsupervised results obtained from cosine similarities between word embeddings.

Hypernym Directionality We adopt an evaluation procedure by Kiela et al. (2015b) on hypernym pairs in the BLESS data set (Baroni and Lenci, 2011). Given a general (e.g. 'animal') and a concrete noun (e.g. 'dog') that stand in the hypernym relation, the task is to identify the noun that is more general. Lazaridou et al. (2015) found that the generality or concreteness of a noun's meaning is reflected in the entropy of its embedding, and we adopt that measure for our purposes. Thus, we compute entropies of our word embeddings and report accuracies corresponding to the proportion of noun pairs where the entropy of the more general noun is higher than the more concrete noun.

Vocabulary We intersect the vocabularies covered by the different embeddings, which amounts to 1960 words in total. We restrict evaluation to the corresponding word pairs in the above data sets, coverage is reported in Table 1.

Results As shown in Table 1, the performance of embeddings learned on referring expression corpora are generally below state-of-the-art distributional vectors trained on large web corpora. However, some interesting tendencies can be observed by comparing embeddings learned from different context dimensions. Denotational embeddings in isolation provide a precise representation of meaning that outperforms the other types of embeddings on semantic similarity judgements in MEN and SemSim, and detects hypernym directionality most accurately. An interesting exception is the compatibility data set where visual embeddings clearly outperform textual and denotational embeddings. Situational embeddings perform less well than textual and denotational embeddings but, interestingly, are similar in performance to visual embeddings on semantic similarity, suggesting that visual and situational similarity seem to be equally important aspects of general semantic similarity. Concatenation of denotational and textual embeddings yields the best results for correlations with human similarity judgements. This is expected as denotational similarity is probably too restricted for generic semantic similarity. We experimented with further embedding combinations, but only the fusion of the textual and denotational dimension outperformed the embeddings obtained from a particular grounding dimension.

Table 2: Model correlations

Table 2 shows correlations on cosine similarities on all word pairs from MEN, SemSim, VisSim and Compatibility between our word embeddings. This further corroborates the finding that different dimensions of grounding lead to complementary notions of similarity. In particular, correlation between visual and situational embeddings is relatively low, as compared to more fuzzy textual embeddings which correlate well with denotational embeddings. For a qualitative analysis, more examples are shown in Appendix A.

Qualitative Discussion Table 3 illustrates similarities learned from different grounding dimensions by means of some qualitative examples. Whereas denotational and visual embeddings rank semantically compatible words on top (e.g. *grass-grassy*), situational embeddings clearly focus more on topical similarity (*grass-clouds*). Given these examples, the finding that visual embeddings outperform denotational embeddings on the semantic compatibility task (see Table 1) seems rather contradictory. A preliminary error analysis suggests that the compatibility ratings that humans provide 'out of context' in a rating task differ

to some extent from referential choices in our corpus. As an example, in the compatibility data set, the words *pigeon* and *mother* are rated as being equally similar to *animal*. However, in our corpus of referring expressions, *mother* is never used to refer to animal entities and our denotational embeddings predict them to be highly dissimilar, whereas visual embeddings are slightly more robust in this case.

More generally, textual embeddings learned from referring expressions captures a much more fuzzy and generic notion of similarity than denotational, visual or situational embeddings, e.g. *grass* is similar to *shrubs* and to *sand* in the textual space. This fuzziness has been found for word embeddings trained on large amounts of raw text as well (Faruqui et al., 2016).

4 Approximate Co-Reference Detection

Another important testbed for models of lexical meaning is their ability to capture semantic inference, with textual entailment as a well-known paradigm: here the task is to predict whether a textual hypothesis h can be inferred from a given premise p (Dagan et al., 2006). Young et al. (2014) have proposed a less strict variant of this called "approximate textual entailment". The main idea is that premise and hypothesis candidates can be automatically extracted from a corpus of captioned images. Given a set of captions known to describe the same image and an hypothesis, the task is to determine whether the hypothesis can describe the same image as the premise.

Inspired by this approach, we use the multimodal corpus of referring expressions to set up a new task for evaluating word embeddings, which consists of capturing approximate inferential relations between referring expressions. Thus, in our case, the hypothesis and the premise are expressions referring to objects, and the task is to determine whether they could (potentially) refer to the same object. Note that this is also similar to the notion of semantic compatibility proposed by Kruszewski and Baroni (2015), but extended to phrasal expressions. We can automatically extract positive and negative pairs from the data (see Section 2) by looking at pairs of expressions referring to objects in the same image and distinguishing **coreferential expressions** referring to the same entity (e.g. *grandma* - *old lady*), and **non-coreferential expressions** referring to different entities, e.g. *old lady* - *young lady*. In contrast to the majority of existing similarity and relatedness benchmarks which are centered around nouns, this task requires precise meaning representations for attribute-like words (e.g. *left-right*, *old-young*) which occur frequently in our data and which are frequently used to distinguish between objects occurring in the same situation. In particular, as the scenes in our data sets contain many objects of the same category (e.g. in the REFCOCO data), the distinction can often not be made by looking at the noun only, e.g. for classifying '*old* lady' - '*young* lady' as non-coreferential.

We call this task *approximate* coreference detection as the premise and hypothesis might describe complementary aspects of the same object such that the distinction cannot be made perfectly without the original perceptual context. For instance, in some cases, *lady in blue* and *young lady* might denote the same referent, in others not (see Figure 1). Thus, we note that the upper bound for automatic (or human) performance in this task is clearly not 100%. In future work, we plan to combine this with a reference resolution system that grounds the expressions in a given image.

Data and Set-up Given an image with several objects and a set of expressions referring to these, we compute the set of expression pairs P for that image. This set now divides into positive instances, i.e. expressions that both refer to the same object in the image, and negative instances, i.e. expressions that describe distinct entities in the scene. As this gives us a lot of data, we adopt a supervised learning approach for modeling the task of approximate co-reference detection. Thus, we use our embeddings to extract a range of similarity measures between the expression pairs and feed these metrics as features into a classifier, trained to predict whether two phrases co-refer. This set-up is largely similar to Young et al. (2014)'s evaluation setting for approximate textual entailment.

Similarity Measures Given a pair P of expressions $r_i = w_{i_1} \dots w_{i_n}, r_j = w_{j_1} \dots w_{j_m}$, we extract pairwise cosine similarities between the embeddings $cos(w_{i_x}, w_{j_y})$, using average $(\sum_{(w_i,w_j)\in P} cos(w_i, w_j) \times \frac{1}{|P|})$, maximum $(\max_{(w_i,w_j)\in P} cos(w_i, w_j))$ and minimum distance $(\min_{(w_i,w_j)\in P} cos(w_i, w_j))$ as features for classification. Furthermore, we restrict the words in each expression such that they are disjunct sets excluding words that occur in both expressions, $w_i \neq w_j, \forall(w_i, w_j) \in P$. We extract the same average, maximum and minimum distance measures on these lexically disjunct expressions. Finally, we compose word embeddings for each expressions via addition ($r_i = w_{i_1} + \dots + w_{i_n}$) and add the cosine between the composed embeddings ($cos(r_i, r_j)$) to our list of features. Here, we compare textual, visual and denotational embeddings, as our situational embeddings only cover nouns.

Training From REFERIT, we extract 161K training and 18K test pairs, dividing into 66% non-coreferential and 34% coreferential expressions. We re-train our embeddings on the training portions of this data. We only consider non-coreferential expressions that refer to objects of the same type, according to their label annotated in the data set. From REFCOCO, we extract 300k pairs from the training set and 95k pairs from the test set, dividing into roughly 70% non-coreferential and 30% coreferential expressions. We randomly sample these pairs, the overall number of possible pairs in REFCOCO exceeds 2 million. We train a binary logistic regression classifier on each corpus, given the similarity measures extracted for each word embedding.

Results We report accuracies on co-referential expression detection in Table 4, on REFERIT and REFCOCO. Similarities derived from denotational embeddings clearly outperform the other classifiers on both data sets, including state-of-the-art textual embeddings learned on a much larger web corpus. On REFCOCO, only denotational embeddings lead to a clear improvement over the majority baseline. While the low performance of standard distributional embeddings is rather expected on this task (see previous findings on e.g. predicting antonyms (Nguyen et al., 2016)), the clear advange of denotational over visual embeddings is noteworthy. Whereas visual grounding is relatively effective for modeling compatibility between nouns (see Table 1), it does not seem to capture attribute meaning accurately as illustrated in Table 5. Here, the average of all visual objects referred to as e.g. *small* seems to be rather noisy and lead to high similarity with rather random words (*directly*) whereas denotational embeddings model accurate compatibility relations between e.g. *small-smaller*.

5 Conclusion

Whereas it is notoriously difficult to tailor or specialise distributional meaning representations inferred from text to particular aspects of semantic relatedness (Kiela et al., 2015a; Nguyen et al., 2016; Rimell et al., 2017), this work has shown that a multi-modal corpus of referring expressions can be used to derive a range of continuous meaning representations grounded in different aspects of context, capturing different notions of similarity. As compared to visual embeddings used in previous works, we found that denotational embeddings are particularly useful for detecting semantic relations. Other, recently proposed tasks related to modeling word association (Vulić et al., 2017), commonsense knowledge (Vedantam et al., 2015) or child-directed input (Lazaridou et al., 2016) provide interesting testbeds for future work.

Hierarchically-Attentive RNN for Album Summarization and Storytelling

Licheng Yu and **Mohit Bansal** and **Tamara L. Berg**
UNC Chapel Hill
{licheng, mbansal, tlberg}@cs.unc.edu

Abstract

We address the problem of end-to-end visual storytelling. Given a photo album, our model first selects the most representative (summary) photos, and then composes a natural language story for the album. For this task, we make use of the Visual Storytelling dataset and a model composed of three hierarchically-attentive Recurrent Neural Nets (RNNs) to: encode the album photos, select representative (summary) photos, and compose the story. Automatic and human evaluations show our model achieves better performance on selection, generation, and retrieval than baselines.

1 Introduction

Since we first developed language, humans have always told stories. Fashioning a good story is an act of creativity and developing algorithms to replicate this has been a long running challenge. Adding pictures as input can provide information for guiding story construction by offering visual illustrations of the storyline. In the related task of image captioning, most methods try to generate descriptions only for individual images or for short videos depicting a single activity. Very recently, datasets have been introduced that extend this task to longer temporal sequences such as movies or photo albums (Rohrbach et al., 2016; Pan et al., 2016; Lu and Grauman, 2013; Huang et al., 2016).

The type of data we consider in this paper provides input illustrations for story generation in the form of photo albums, sampled over a few minutes to a few days of time. For this type of data, generating textual descriptions involves telling a temporally consistent story about the depicted visual information, where stories must be coherent and take into account the temporal context of the images. Applications of this include constructing visual and textual summaries of albums, or even enabling search through personal photo collections to find photos of life events.

Previous visual storytelling works can be classified into two types, vision-based and language-based, where image or language stories are constructed respectively. Among the vision-based approaches, unsupervised learning is commonly applied: e.g., (Sigurdsson et al., 2016) learns the latent temporal dynamics given a large amount of albums, and (Kim and Xing, 2014) formulate the photo selection as a sparse time-varying directed graph. However, these visual summaries tend to be difficult to evaluate and selected photos may not agree with human selections. For language-based approaches, a sequence of natural language sentences are generated to describe a set of photos. To drive this work (Park and Kim, 2015) collected a dataset mined from Blog Posts. However, this kind of data often contains contextual information or loosely related language. A more direct dataset was recently released (Huang et al., 2016), where multi-sentence stories are collected describing photo albums via Amazon Mechanical Turk.

In this paper, we make use of the Visual Storytelling Dataset (Huang et al., 2016). While the authors provide a seq2seq baseline, they only deal with the task of generating stories given 5-representative (summary) photos hand-selected by people from an album. Instead, we focus on the more challenging and realistic problem of end-to-end generation of stories from entire albums. This requires us to either generate a story from all of the album's photos or to learn selection mechanisms to identify representative photos and then generate stories from those summary photos. We evaluate each type of approach.

Ultimately, we propose a model of hierarchically-attentive recurrent neural nets,

Proceedings of the 2017 Conference on Empirical Methods in Natural Language Processing, pages 966–971
Copenhagen, Denmark, September 7–11, 2017. ©2017 Association for Computational Linguistics

consisting of three RNN stages. The first RNN encodes the whole album context and each photo's content, the second RNN provides weights for photo selection, and the third RNN takes the weighted representation and decodes to the resulting sentences. Note that during training, we are only given the full input albums and the output stories, and our model needs to learn the summary photo selections latently.

We show that our model achieves better performance over baselines under both automatic metrics and human evaluations. As a side product, we show that the latent photo selection also reasonably mimics human selections. Additionally, we propose an album retrieval task that can reliably pick the correct photo album given a sequence of sentences, and find that our model also outperforms the baselines on this task.

2 Related work

Recent years have witnessed an explosion of interest in vision and language tasks, reviewed below.

Visual Captioning: Most recent approaches to image captioning (Vinyals et al., 2015b; Xu et al., 2015) have used CNN-LSTM structures to generate descriptions. For captioning video or movie content (Venugopalan et al., 2015; Pan et al., 2016), sequence-to-sequence models are widely applied, where the first sequence encodes video frames and the second sequence decodes the description. Attention techniques (Xu et al., 2015; Yu et al., 2016; Yao et al., 2015) are commonly incorporated for both tasks to localize salient temporal or spatial information.

Video Summarization: Similar to documentation summarization (Rush et al., 2015; Cheng and Lapata, 2016; Mei et al., 2016; Woodsend and Lapata, 2010) which extracts key sentences and words, video summarization selects key frames or shots. While some approaches use unsupervised learning (Lu and Grauman, 2013; Khosla et al., 2013) or intuitive criteria to pick salient frames, recent models learn from human-created summaries (Gygli et al., 2015; Zhang et al., 2016b,a; Gong et al., 2014). Recently, to better exploit semantics, (Choi et al., 2017) proposed textually customized summaries.

Visual Storytelling: Visual storytelling tries to tell a coherent visual or textual story about an image set. Previous works include storyline graph modeling (Kim and Xing, 2014), unsupervised mining (Sigurdsson et al., 2016), blog-photo alignment (Kim et al., 2015), and language retelling (Huang et al., 2016; Park and Kim, 2015). While (Park and Kim, 2015) collects data by mining Blog Posts, (Huang et al., 2016) collects stories using Mechanical Turk, providing more directly relevant stories.

3 Model

Our model (Fig. 1) is composed of three modules: Album Encoder, Photo Selector, and Story Generator, jointly learned during training.

3.1 Album Encoder

Given an album $A = \{a_1, a_2, ..., a_n\}$, composed of a set of photos, we use a bi-directional RNN to encode the local album context for each photo. We first extract the 2048-dimensional visual representation $f_i \in R^k$ for each photo using ResNet101 (He et al., 2016), then a bi-directional RNN is applied to encode the full album. Following (Huang et al., 2016), we choose a Gated Recurrent Unit (GRU) as the RNN unit to encode the photo sequence. The sequence output at each time step encodes the local album context for each photo (from both directions). Fused with the visual representation followed by ReLU, our final photo representation is (top module in Fig. 1):

$$\begin{aligned} f_i &= \text{ResNet}(a_i) \\ \vec{h}_i &= \overrightarrow{\text{GRU}}_{album}(f_i, \vec{h}_{i-1}) \\ \overleftarrow{h}_i &= \overleftarrow{\text{GRU}}_{album}(f_i, \overleftarrow{h}_{i+1}) \\ v_i &= \text{ReLU}([\vec{h}_i, \overleftarrow{h}_i] + f_i). \end{aligned}$$

3.2 Photo Selector

The Photo Selector (illustrated in the middle yellow part of Fig. 1) identifies representative photos to summarize an album's content. As discussed, we do not assume that we are given the ground-truth album summaries during training, instead regarding selection as a latent variable in the end-to-end learning. Inspired by Pointer Networks (Vinyals et al., 2015a), we use another GRU-RNN to perform this task [1].

Given the album representation $V^{n \times k}$, the photo selector outputs probabilities $p_t \in R^n$ (likelihood of selection as t-th summary image) for all photos using soft attention.

$$\begin{aligned} \bar{h}_t &= \text{GRU}_{select}(p_{t-1}, \bar{h}_{t-1}), \\ p(y_{a_i}(t) = 1) &= \sigma(\text{MLP}([\bar{h}_t, v_i])), \end{aligned}$$

[1] While the pointer network requires grounding labels, we regard the labels as latent variables

Figure 1: Model: the *album encoder* is a bi-directional GRU-RNN that encodes all album photos; the *photo selector* computes the probability of each photo being the tth album-summary photo; and finally, the *story generator* outputs a sequence of sentences that combine to tell a story for the album.

At each summarization step, t, the GRU takes the previous p_{t-1} and previous hidden state as input, and outputs the next hidden state $\bar{h}_t$. $\bar{h}_t$ is fused with each photo representation v_i to compute the i^{th} photo's attention $p_t^i = p(y_{a_i}(t) = 1)$. At test time, we simply pick the photo with the highest probability to be the summary photo at step t.

3.3 Story Generator

To generate an album's story, given the album representation matrix V and photo summary probabilities p_t from the first two modules, we compute the visual summary representation $g_t \in R^k$ (for the t-th summary step). This is a weighted sum of the album representations, i.e., $g_t = p_t^T V$. Each of these 5 g_t embeddings (for $t = 1$ to 5) is then used to decode 1 of the 5 story sentences respectively, as shown in the blue part of Fig. 1.

Given a story $S = \{s_t\}$, where s_t is t-th summary sentence. Following Donahue et al. (2015), the l-th word probability of the t-th sentence is:

$$\begin{aligned} w_{t,l-1} &= W_e s_{t,l-1}, \\ \tilde{h}_{t,l} &= \text{GRU}_{story}(w_{t,l-1}, g_t, \tilde{h}_{t,l-1}), \\ p(s_{t,l}) &= \text{softmax}(\text{MLP}(\tilde{h}_{t,l})), \end{aligned} \tag{1}$$

where W_e is the word embedding. The GRU takes the joint input of visual summarization g_t, the previous word embedding $w_{t,l}$, and the previous hidden state, then outputs the next hidden state. The generation loss is then the sum of the negative log likelihoods of the correct words: $L_{gen}(S) = -\sum_{t=1}^{T} \sum_{l=1}^{L_t} \log p_{t,l}(s_{t,l})$.

To further exploit the notion of temporal coherence in a story, we add an order-preserving constraint to order the sequence of sentences within a story (related to the story-sorting idea in Agrawal et al. (2016)). For each story S we randomly shuffle its 5 sentences to generate negative story instances S'. We then apply a max-margin ranking loss to encourage correctly-ordered stories: $L_{rank}(S, S') = \max(0, m - \log p(S') + \log p(S))$. The final loss is then a combination of the generation and ranking losses:

$$L = L_{gen}(S) + \lambda L_{rank}(S, S'). \tag{2}$$

4 Experiments

We use the Visual Storytelling Dataset (Huang et al., 2016), consisting of 10,000 albums with 200,000 photos. Each album contains 10-50 photos taken within a 48-hour span with two annotations: 1) 2 album summarizations, each with 5 selected representative photos, and 2) 5 stories describing the selected photos.

4.1 Story Generation

This task is to generate a 5-sentence story describing an album. We compare our model with two sequence-to-sequence baselines: 1) an encoder-decoder model (enc-dec), where the sequence of album photos is encoded and the last hidden state is fed into the decoder for story generation, 2) an encoder-attention-decoder model (Xu et al., 2015) (enc-attn-dec) with weights computed using a soft-attention mechanism. At each decoding time step, a weighted sum of hidden states from the encoder is decoded. For fair comparison, we

	beam size=3			
	Bleu3	Rouge	Meteor	CIDEr
enc-dec	19.58	29.23	33.02	4.65
enc-attn-dec	19.73	28.94	32.98	4.96
h-attn	20.53	29.82	33.81	6.84
h-attn-rank	**20.78**	**29.82**	**33.94**	**7.38**
h-(gd)attn-rank	21.02	29.53	34.12	7.51

Table 1: Story generation evaluation.

enc-dec (29.50%)	h-attn-rank (70.50%)
enc-attn-dec (30.75%)	h-attn-rank (69.25%)
h-attn-rank (30.50%)	gd-truth (69.50%)

Table 2: Human evaluation showing how often people prefer one model over the other.

use the same album representation (Sec. 3.1) for the baselines.

We test two variants of our model trained with and without ranking regularization by controlling λ in our loss function, denoted as h-attn (without ranking), and h-attn-rank (with ranking). Evaluations of each model are shown in Table 1. The h-attn outperforms both baselines, and h-attn-rank achieves the best performance for all metrics. Note, we use beam-search with beam size=3 during generation for a reasonable performance-speed trade-off (we observe similar improvement trends with beam size = 1).[2] To test performance under optimal image selection, we use one of the two ground-truth human-selected 5-photo-sets as an oracle to hard-code the photo selection, denoted as h-(gd)attn-rank. This achieves only a slightly higher Meteor compared to our end-to-end model.

Additionally, we also run human evaluations in a forced-choice task where people choose between stories generated by different methods. For this evaluation, we select 400 albums, each evaluated by 3 Turkers. Results are shown in Table 2. Experiments find significant preference for our model over both baselines. As a simple Turing test, we also compare our results with human written stories (last row of Table 2), indicating room for improvement of methods.

4.2 Album Summarization

We evaluate the precision and recall of our generated summaries (output by the photo selector) compared to human selections (the combined set of both human-selected 5-photo stories). For comparison, we evaluate enc-attn-dec on the same task by aggregating predicted attention and selecting the 5 photos with highest accumulated attention. Additionally, we also run DPP-based video summarization (Kulesza et al., 2012) using the same album features. Our models have higher performance compared to baselines as shown in Table 3 (though DPP also achieves strong results, indicating that there is still room to improve the pointer network).

	precision	recall
DPP	43.75%	27.41%
enc-attn-dec	38.53%	24.25%
h-attn	42.85%	27.10%
h-attn-rank	**45.51%**	**28.77%**

Table 3: Album summarization evaluation.

	R@1	R@5	R@10	MedR
enc-dec	10.70%	29.30%	41.40%	14.5
enc-attn-dec	11.60%	33.00%	45.50%	11.0
h-attn	18.30%	**44.50%**	**57.60%**	**6.0**
h-attn-rank	**18.40%**	43.30%	55.50%	7.0

Table 4: 1000 album retrieval evaluation.

4.3 Output Example Analysis

Fig. 2 shows several output examples for both summarization and story generation, comparing our model to the baseline and ground-truth. More examples are provided in the supplementary.

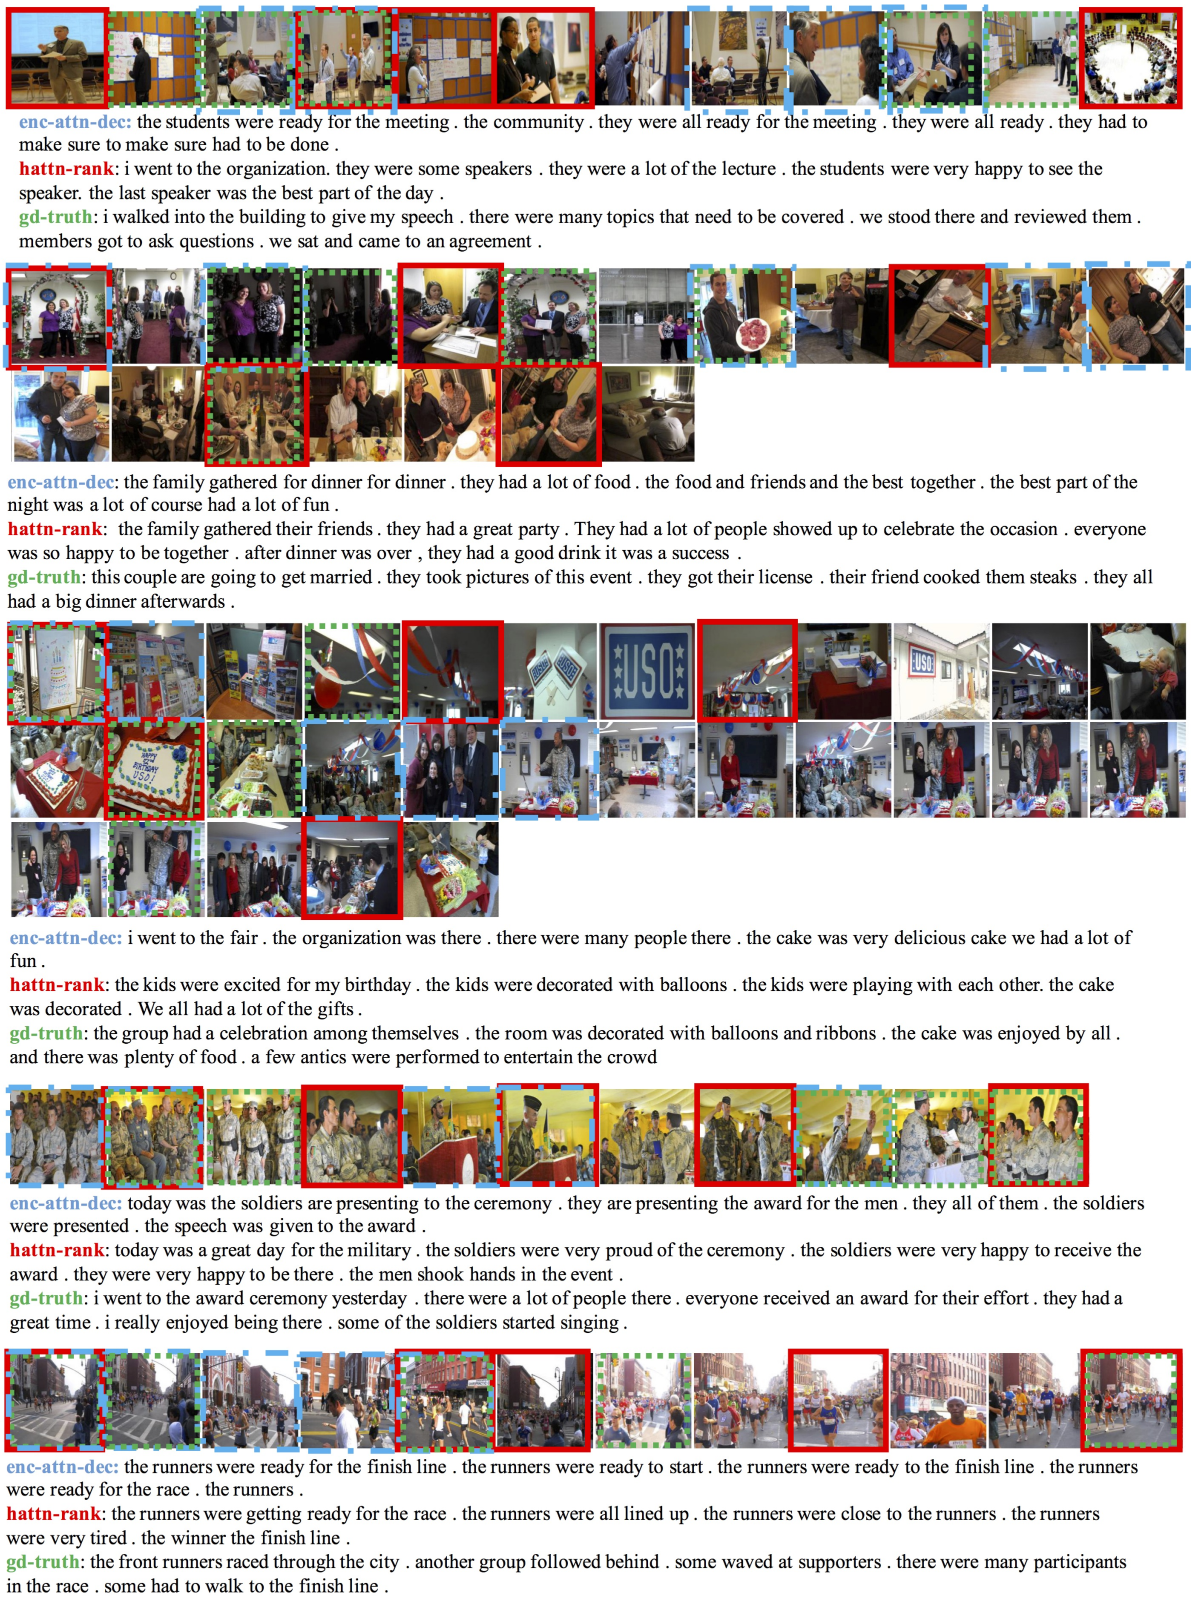
4.4 Album Retrieval

Given a human-written story, we introduce a task to retrieve the album described by that story. We randomly select 1000 albums and one ground-truth story from each for evaluation. Using the generation loss, we compute the likelihood of each album A_m given the query story S and retrieve the album with the highest generation likelihood, $A = \text{argmax}_{A_m} p(S|A_m)$. We use Recall@k and Median Rank for evaluation. As shown in Table 4), we find that our models outperform the baselines, but the ranking term in Eqn.2 does not improve performance significantly.

5 Conclusion

Our proposed hierarchically-attentive RNN based models for end-to-end visual storytelling can jointly summarize and generate relevant stories from full input photo albums effectively. Automatic and human evaluations show that our method outperforms strong sequence-to-sequence

[2] We also compute the p-value of Meteor on 100K samples via the bootstrap test (Efron and Tibshirani, 1994), as Meteor has better agreement with human judgments than Bleu/Rouge (Huang et al., 2016). Our h-attn-rank model has strong statistical significance ($p = 0.01$) over the enc-dec and enc-attn-dec models (and is similar to the h-attn model).



enc-attn-dec: the students were ready for the meeting . the community . they were all ready for the meeting . they were all ready . they had to make sure to make sure had to be done .

hattn-rank: i went to the organization. they were some speakers . they were a lot of the lecture . the students were very happy to see the speaker. the last speaker was the best part of the day .

Abstract

Sports channel video portals offer an exciting domain for research on multimodal, multilingual analysis. We present methods addressing the problem of automatic video highlight prediction based on joint visual features and textual analysis of the real-world audience discourse with complex slang, in both English and traditional Chinese. We present a novel dataset based on League of Legends championships recorded from North American and Taiwanese Twitch.tv channels (will be released for further research), and demonstrate strong results on these using multimodal, character-level CNN-RNN model architectures.

1 Introduction

On-line eSports events provide a new setting for observing large-scale social interaction focused on a visual story that evolves over time—a video game. While watching sporting competitions has been a major source of entertainment for millennia, and is a significant part of today's culture, eSports brings this to a new level on several fronts. One is the global reach, the same games are played around the world and across cultures by speakers of several languages. Another is the scale of on-line text-based discourse during matches that is public and amendable to analysis. One of the most popular games, League of Legends, drew 43 million views for the 2016 world series final matches (broadcast in 18 languages) and a peak concurrent viewership of 14.7 million[1]. Finally, players interact through what they see on screen while fans (and researchers) can see *exactly* the same views.

This paper builds on the wealth of interaction around eSports to develop predictive models for match video highlights based on the audience's online chat discourse as well as the visual recordings of matches themselves. ESports journalists and fans create highlight videos of important moments in matches. Using these as ground truth, we explore automatic prediction of highlights via multimodal CNN+RNN models for multiple languages. Appealingly this task is *natural*, as the community already produces the ground truth and is global, allowing multilingual multimodal grounding.

Highlight prediction is about capturing the exciting moments in a specific video (a game match in this case), and depends on the context, the state of play, and the players. This task of predicting the exciting moments is hence different from summarizing the entire match into a story summary. Hence, highlight prediction can benefit from the available real-time text commentary from fans, which is valuable in exposing more abstract background context, that may not be accessible with

Proceedings of the 2017 Conference on Empirical Methods in Natural Language Processing, pages 972–978
Copenhagen, Denmark, September 7–11, 2017.

computer vision techniques that can easily identify some aspects of the state of play. As an example, computer vision may not understand why Michael Jordan's dunk is a highlight over that of another player, but concurrent fan commentary might reveal this.

We collect our dataset from Twitch.tv, one of the live-streaming platforms that integrates comments (see Fig. 1), and the largest live-streaming platform for video games. We record matches of the game League of Legends (LOL), one of the largest eSports game in two subsets, 1) the spring season of the North American League of Legends Championship Series (NALCS), and 2) the League of Legends Master Series (LMS) hosted in Taiwan/Macau/HongKong, with chat comments in English and traditional Chinese respectively. We use the community created highlights to label each frame of a match as highlight or not.

In addition to our new dataset, we present several experiments with multilingual character-based models, deep-learning based vision models either per-frame or tied together with a video-sequence LSTM-RNN, and combinations of language and vision models. Our results indicate that while *surprisingly* the visual models generally outperform language-based models, we can still build reasonably useful language models that help disambiguate difficult cases for vision models, and that combining the two sources is the most effective model (across multiple languages).

2 Related Work

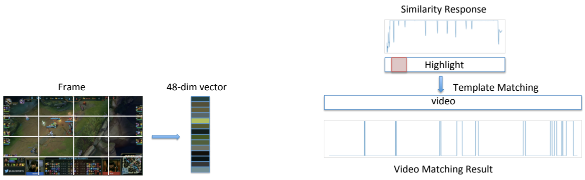
We briefly discuss a small sample of the related work on language and vision datasets, summarization, and highlight prediction. There has been a surge of vision and language datasets focusing on captions over the last few years, (Rashtchian et al., 2010; Ordonez et al., 2011; Lin et al., 2014), followed by efforts to focus on more specific parts of images (Krishna et al., 2016), or referring expressions (Kazemzadeh et al., 2014), or on the broader context (Huang et al., 2016). For video, similar efforts have collected descriptions (Chen and Dolan, 2011), while others use existing descriptive video service (DVS) sources (Rohrbach et al., 2015; Torabi et al., 2015). Beyond descriptions, other datasets use questions to relate images and language (Antol et al., 2015; Yu et al., 2015). This approach is extended to movies in Tapaswi et al. (2016).

The related problem of visually summarizing videos (as opposed to finding the highlights) has produced datasets of holiday and sports events with multiple users making summary videos (Gygli et al., 2014) and multiple users selecting summary key-frames (de Avila et al., 2011) from short videos. For language-based summarization, *Extractive models* (Filippova and Altun, 2013; Filippova et al., 2015) generate summaries by selecting important sentences and then assembling these, while *Abstractive models* (Chopra et al., 2016; Mei et al., 2016; Nallapati et al., 2016; See et al., 2017) generate/rewrite the summaries from scratch.

Closer to our setting, there has been work on highlight prediction in football (soccer) and basketball based on audio of broadcasts (Cheng and Hsu, 2006) (Wang et al., 2004) where commentators may have an outsized impact or visual features (Bertini et al., 2005). In the spirit of our study, there has been work looking at tweets during sporting events (Hsieh et al., 2012), but the tweets are not as immediate or as well aligned with the games as the eSports comments. More closely related to our work, Song (2016) collects videos for Heroes of the Storm, League of Legends, and Dota2 on online broadcasting websites of around 327 hours total. They also provide highlight labeling annotated by four annotators. Our method, on the other hand, has a similar scale of data, but we use existing highlights, and we also employ textual *audience* chat commentary, thus providing a new resource and task for Language and Vision research. In summary, we present the first language-vision dataset for video highlighting that contains audience reactions in chat format, in multiple languages. The community produced ground truth provides labels for each frame and can be used for supervised learning. The language side of this new dataset presents interesting challenges related to real-world Internet-style slang.

3 Data Collection

Our dataset covers 218 videos from NALCS and 103 from LMS for a total of 321 videos from week 1 to week 9 in 2017 spring series from each tournament. Each week there are 10 matches for NALCS and 6 matches for LMS. Matches are best of 3, so consist of two games or three games. The first and third games are used for training. The second games in the first 4 weeks are used as valida-



(a) Feature vector of frame

(b) Template Matching

Figure 2: Highlight Labeling: (a) The feature representation of each frame is calculated by averaging each color channel in each subregion. (b) After template matching, the top bar shows the maximum of similarity matching of each frame in the highlight and the bottom bar is the labeling result of the video.

tion and the remainder of second games are used as test. Table 1 lists the numbers of videos in train, validation, and test subsets.

Dataset	Train	Val	Testing	Total
NALCS	128	40	50	218
LMS	57	18	28	103

Table 1: Dataset statistics (number of videos).

Each game's video ranges from 30 to 50 minutes in length which contains image and chat data linked to the specific timestamp of the game. The average number of chats per video is 7490 with a standard deviation of 4922. The high value of standard deviation is mostly due to the fact that NALCS simultaneously broadcasts matches in two different channels (nalcs1[2] and nalcs2[3]) which often leads to the majority of users watching the channel with a relatively more popular team causing an imbalance in the number of chats. If we only consider LMS which broadcasts with a single channel, the average number of chats are 7210 with standard deviation of 2719. The number of viewers for each game averages about 21526, and the number of unique users who type in chat is on average 2185, i.e., roughly 10% of the viewers.

Highlight Labeling For each game, we collected community generated highlights ranging from 5 minutes to 7 minutes in length. For the purpose of consistency within our data, we collected the highlights from a single Youtube channel, Onivia,[4] which provided highlights for both championship tournaments in a consistent arrangement. We expect such consistency will aid our model to better pick up characteristics for determining highlights. We next need to align the position of the frames from the highlight video to frames in the full game video. For this, we adopted a template matching approach. For each frame in the video and the highlight, we divide it into 16 regions of 4 by 4 and use the average value of each color channel in each region as the feature. The feature representation of each frame ends up as a 48-dim vector as shown in Figure 2a. For each frame in the highlight, we can find the most similar frame in the video by calculating distance between these two vectors. However, matching a single frame to another suffers from noise. Therefore, we alternatively concatenate the following frames to form a window and use template matching to find the best matching location in the video. We found out that when the window size is 60 frames, it gives consistent and high quality results. For each frame, the result contains not only the best matching score but also the location of that match in the video.[5] Figure 2b illustrates this matching process.

4 Model

In this section, we explain the proposed models and components. We first describe the notation and definition of the problem, plus the evaluation metric used. Next, we explain our vision model V-CNN-LSTM and language model L-Char-LSTM. Finally, we describe the joint multimodal model lv-LSTM.

Problem Definition Our basic task is to determine if a frame of the full input video should be labeled as being part of the output highlight or not. To simplify our notation, we use $X = \{x_1, x_2, ..., x_t\}$ to denote a sequence of features for frames. Chats are expressed as $C = \{(c_1, ts_1), ..., (c_n, ts_n)\}$. where each chat c comes with a timestamp ts. Methods take the image features and/or chats and predict labels for the frames, $Y = \{y_1, y_2, ..., y_t\}$.

Evaluation Metric: We refer to the set of frames with positive ground truth label as S_{gt} and the set

[2] https://www.twitch.tv/nalcs1

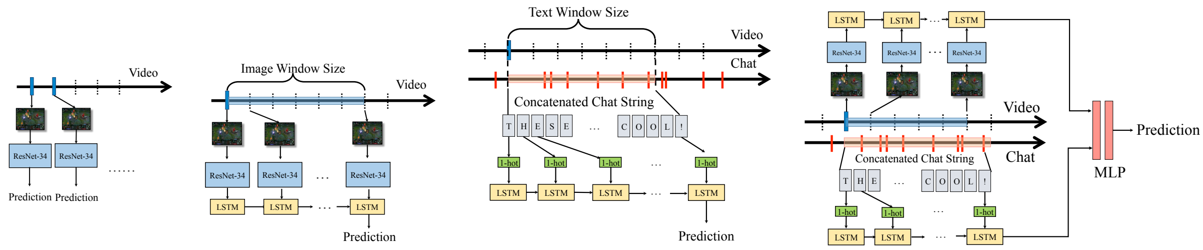
[4] https://www.youtube.com/channel/UCPhab209KEicqPJFAk9IZEA

[5] When the window contains a moment of clip transition in highlights, the best matching score appears low. This is used to separate all clips in the highlight. Then we can use the starting and end locations of each clip to label the video.



(a) V-CNN (b) V-CNN-LSTM (c) L-Char-LSTM (d) Full model : lv-LSTM

Figure 3: Network architecture of proposed models.

of predicted frames with a positive label as S_{pred}. Following (Gygli et al., 2014; Song et al., 2015), we use the harmonic mean F-score in Eq.2 widely used in video summarization task for evaluation:

$$P = \frac{S_{gt} \cap S_{pred}}{|S_{pred}|}, \quad R = \frac{S_{gt} \cap S_{pred}}{|S_{gt}|} \qquad (1)$$

$$F = \frac{2PR}{P + R} \times 100\% \qquad (2)$$

V-CNN We use the ResNet-34 model (He et al., 2016) to represent frames, motivated by its strong results on the ImageNet Challenge (Russakovsky et al., 2015). Our naive V-CNN model (Figure 3a) uses features from the pre-trained version of this network [6] directly to make prediction at each frame (which are resized to 224x224).

V-CNN-LSTM In order to exploit visual video information sequentially over time, we use a memory-based LSTM-RNN on top of the image features, so as to model long-term dependencies. All of our videos are 30FPS. As the difference between consecutive frames is usually minor, we run prediction every 10th frame during evaluation and interpolate predictions between these frames. During training, due to the GPU memory constraints, we unfold the LSTM cell 16 times. Therefore the image window size is around 5-seconds (16 samples every 10th frame from 30fps video). The hidden state from the last cell is used as the V-CNN-LSTM feature. This process is shown in Figure 3b.

L-Word-LSTM and L-Char-LSTM Next, we discuss our language-based models using the audience chat text. Word-level LSTM-RNN models (Sutskever et al., 2014) are a common approach to embedding sentences. Unfortunately, this does not fit our Internet-slang style language with irregularities, “mispelled” words (hapy, happppppy), emojis (^_^), abbreviations (LOL), marks (?!?!?!?!), or onomatopoeic cases (e.g., 4 which sounds like yes in traditional Chinese). People may type variant length of 4, e.g.,, 4444444 to express their remarks.

Therefore, alternatively, we model the audience chat with a character-level LSTM-RNN model (Graves, 2013). Characters of the language, Chinese, English, or Emojis, are expanded to multiple ASCII characters according to the two-character Unicode or other representations used on the chat servers. We encode a 1-hot vector for each ASCII input character. For each frame we use all chats that occur in the next W_t seconds which are called text window size to form the input for L-Char-LSTM. We concatenate all the chats in a window, separating them by a special stop character, and then fed to a 3-layer L-Char-LSTM model.[7] This model is shown in Figure 3c. Following the setting in Sec. 5, we evaluate the text window size from 5 seconds to 9 seconds, and got the following accuracies:32.1%, 29.6%, 41.5%, 28.2%, 34.4%. We achieved best results with text window size as 7 seconds, and used this in rest of the experiments.

Joint lv-LSTM Model Our final lv-LSTM model combines the best vision and language models: V-CNN-LSTM and L-Char-LSTM. For the vision and language models, we can extract features F_v and F_l from V-CNN-LSTN and L-Char-LSTM, respectively. Then we concatenate F_v and F_l, and feed it into a 2-layer MLP. The completed model is shown in Figure 3d. We expect there is room to improve this approach, by using more involved representations, e.g., Bilinear Pooling (Fukui et al., 2016), Memory Networks (Xiong et al., 2016), and Attention Models (Lu et al., 2016); this is future work.

[6] https://github.com/pytorch/pytorch

[7] The number of these stop characters is then an encoding of the number of chats in the window. Therefore, the L-Char-LSTM could learn to use this #chats information, if it is a useful feature. Also, some content has been deleted by Twitch.tv or the channel itself due to the usage of improper words. We use symbol ”\n” to replace such cases.

Method	Data	UF	P	R	F
L-Char-LSTM	C	100%	0.11	0.99	19.6
L-Char-LSTM	C	last 25%	0.35	0.51	41.5
L-Word-LSTM	C	last 25%	0.10	0.99	19.2
V-CNN	V	100%	0.40	0.93	56.2
V-CNN	V	last 25%	0.57	0.74	64.0
V-CNN-LSTM	V	last 25%	0.58	0.82	68.3
lv-LSTM	C+V	last 25%	0.77	0.72	**74.8**

Table 2: Ablation Study: Effects of various models. **C**:Chat, **V**:Video, **UF**: % of frames Used in highlight clips as positive training examples; **P**: Precision, **R**: Recall, **F**: F-score.

5 Experiments and Results

Training Details In development and ablation studies, we use train and val splits of the data from NALCS to evaluate models in Section 3. For the final results, models are retrained on the combination of train and val data (following major vision benchmarks e.g. PASCAL-VOC and COCO), and performance is measured on the test set. We separate the highlight prediction to three different tasks based on using different input data: videos, chats, and videos+chats. The details of dataset split are in Section 3. Our code is implemented in PyTorch.

To deal with the large number of frames total, we sample only 5k positive and 5k negative examples in each epoch. We use batch size of 32 and run 60 epochs in all experiments. Weight decay is 10^{-4} and learning rate is set as 10^{-2} in the first 20 epochs and 10^{-3} after that. Cross entropy loss is used. Highlights are generated by fans and consist of clips. We match each clip to when it happened in the full match and call this the highlight clip (non-overlapping). The action of interest (kill, objective control, etc.) often happens in the later part of a highlight clip, while the clip contains some additional context before that action that may help set the stage. For some of our experimental settings (Table 2), we used a heuristic of only including the last 25% frames in every highlight clip as positive training examples. During evaluation, we used all frames in the highlight clip.

Ablation Study Table 2 shows the performance of each module separately on the dev set. For the basic L-Char-LSTM and V-CNN models, using only the last 25% of frames in highlight clips in training works best. In order to evaluate the performance of L-Char-LSTM model, we also train a Word-LSTM model by tokenizing all the chats and only considering the words that appeared more than 10 times, which results in 10019 words. We use this vocabulary to encode the words to 1-hot vectors. The L-Char-LSTM outperforms L-Word-LSTM by 22.3%.

Method	Data	NALCS	LMS
L-Char-LSTM	chat	43.2	39.7
V-CNN-LSTM	video	72.2	69.2
lv-LSTM	chat+video	**74.7**	**70.0**

Table 3: Test Results on the NALCS (English) and LMS (Traditional Chinese) datasets.

Test Results Test results are shown in Table 3. Somewhat surprisingly, the vision only model is more accurate than the language only model, despite the real-time nature of the comment stream. This is perhaps due to the visual form of the game, where highlight events may have similar animations. However, including language with vision in the lv-LSTM model significantly improves over vision alone, as the comments may exhibit additional contextual information. Comparing results between ablation and the final test, it seems more data contributes to higher accuracy. This effect is more apparent in the vision models, perhaps due to complexity. Moreover, L-Char-LSTM performs better in English compared to traditional Chinese. From the numbers given in Section 3, variation in the number of chats in NALCS was much higher than LMS, which one may expect to have a critical effect in the language model. However, our results seem to suggest that the L-Char-LSTM model can pickup other factors of the chat data (e.g. content) instead of just counting the number of chats. We expect a different language model more suitable for the traditional Chinese language should be able to improve the results for the LMS data.

6 Conclusion

We presented a new dataset and multimodal methods for highlight prediction, based on visual cues and textual audience chat reactions in multiple languages. We hope our new dataset can encourage further multilingual, multimodal research.

Reinforced Video Captioning with Entailment Rewards

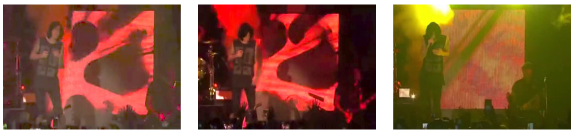
Ramakanth Pasunuru and **Mohit Bansal**
UNC Chapel Hill
{ram, mbansal}@cs.unc.edu

Abstract

Sequence-to-sequence models have shown promising improvements on the temporal task of video captioning, but they optimize word-level cross-entropy loss during training. First, using policy gradient and mixed-loss methods for reinforcement learning, we directly optimize sentence-level task-based metrics (as rewards), achieving significant improvements over the baseline, based on both automatic metrics and human evaluation on multiple datasets. Next, we propose a novel entailment-enhanced reward (CIDEnt) that corrects phrase-matching based metrics (such as CIDEr) to only allow for logically-implied partial matches and avoid contradictions, achieving further significant improvements over the CIDEr-reward model. Overall, our CIDEnt-reward model achieves the new state-of-the-art on the MSR-VTT dataset.

1 Introduction

The task of video captioning (Fig. 1) is an important next step to image captioning, with additional modeling of temporal knowledge and action sequences, and has several applications in online content search, assisting the visually-impaired, etc. Advancements in neural sequence-to-sequence learning has shown promising improvements on this task, based on encoder-decoder, attention, and hierarchical models (Venugopalan et al., 2015a; Pan et al., 2016a). However, these models are still trained using a word-level cross-entropy loss, which does not correlate well with the sentence-level metrics that the task is finally evaluated on (e.g., CIDEr, BLEU). Moreover, these models suffer from exposure bias (Ranzato et al., 2016), which occurs when a model is only exposed to the training data distribution, instead of its own predictions. First, using a sequence-level training, policy gradient approach (Ranzato et al., 2016), we allow video captioning models to directly optimize these non-differentiable metrics, as rewards in a reinforcement learning paradigm. We also address the exposure bias issue by using a mixed-loss (Paulus et al., 2017; Wu et al., 2016), i.e., combining the cross-entropy and reward-based losses, which also helps maintain output fluency.



Ground truth: A band is performing a song.
A rock concert performance by a band.
Baseline-XE: A person is playing a video game.
CIDEr-RL: A band is playing a video game.
CIDEnt-RL: A band is performing a song.

Figure 1: A correctly-predicted video caption generated by our CIDEnt-reward model.

Next, we introduce a novel entailment-corrected reward that checks for logically-directed partial matches. Current reinforcement-based text generation works use traditional phrase-matching metrics (e.g., CIDEr, BLEU) as their reward function. However, these metrics use *undirected* n-gram matching of the machine-generated caption with the ground-truth caption, and hence fail to capture its *directed logical correctness*. Therefore, they still give high scores to even those generated captions that contain a single but critical wrong word (e.g., negation, unrelated action or object), because all the other words still match with the ground truth. We introduce CIDEnt, which penalizes the phrase-matching metric (CIDEr) based reward, when the entailment score is low. This ensures that a generated caption gets a high re-

Proceedings of the 2017 Conference on Empirical Methods in Natural Language Processing, pages 979–985

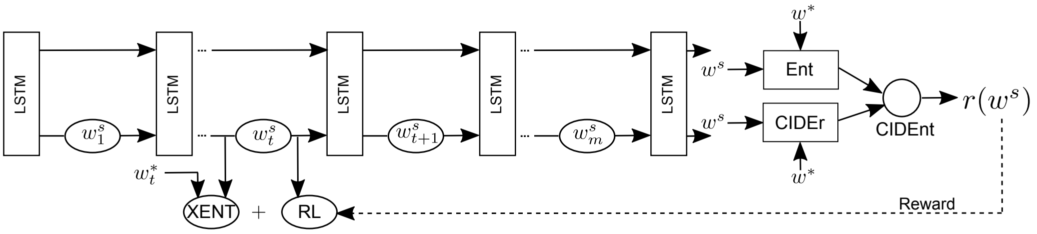

Figure 2: Reinforced (mixed-loss) video captioning using entailment-corrected CIDEr score as reward.

ward only when it is a directed match with (i.e., it is logically implied by) the ground truth caption, hence avoiding contradictory or unrelated information (e.g., see Fig. 1). Empirically, we show that first the CIDEr-reward model achieves significant improvements over the cross-entropy baseline (on multiple datasets, and automatic and human evaluation); next, the CIDEnt-reward model further achieves significant improvements over the CIDEr-based reward. Overall, we achieve the new state-of-the-art on the MSR-VTT dataset.

2 Related Work

Past work has presented several sequence-to-sequence models for video captioning, using attention, hierarchical RNNs, 3D-CNN video features, joint embedding spaces, language fusion, etc., but using word-level cross entropy loss training (Venugopalan et al., 2015a; Yao et al., 2015; Pan et al., 2016a,b; Venugopalan et al., 2016).

Policy gradient for image captioning was recently presented by Ranzato et al. (2016), using a mixed sequence level training paradigm to use non-differentiable evaluation metrics as rewards.[1] Liu et al. (2016b) and Rennie et al. (2016) improve upon this using Monte Carlo roll-outs and a test inference baseline, respectively. Paulus et al. (2017) presented summarization results with ROUGE rewards, in a mixed-loss setup.

Recognizing Textual Entailment (RTE) is a traditional NLP task (Dagan et al., 2006; Lai and Hockenmaier, 2014; Jimenez et al., 2014), boosted by a large dataset (SNLI) recently introduced by Bowman et al. (2015). There have been several leaderboard models on SNLI (Cheng et al., 2016; Rocktäschel et al., 2016); we focus on the decomposable, intra-sentence attention model of Parikh et al. (2016). Recently, Pasunuru and Bansal (2017) used multi-task learning to combine video captioning with entailment and video generation.

3 Models

Attention Baseline (Cross-Entropy) Our attention-based seq-to-seq baseline model is similar to the Bahdanau et al. (2015) architecture, where we encode input frame level video features $\{f_{1:n}\}$ via a bi-directional LSTM-RNN and then generate the caption $w_{1:m}$ using an LSTM-RNN with an attention mechanism. Let θ be the model parameters and $w^*_{1:m}$ be the ground-truth caption, then the cross entropy loss function is:

$$L(\theta) = -\sum_{t=1}^{m} \log p(w^*_t | w^*_{1:t-1}, f_{1:n}) \qquad (1)$$

where $p(w_t|w_{1:t-1}, f_{1:n}) = softmax(W^T h^d_t)$, W^T is the projection matrix, and w_t and h^d_t are the generated word and the RNN decoder hidden state at time step t, computed using the standard RNN recursion and attention-based context vector c_t. Details of the attention model are in the supplementary (due to space constraints).

Reinforcement Learning (Policy Gradient) In order to directly optimize the sentence-level test metrics (as opposed to the cross-entropy loss above), we use a policy gradient p_θ, where θ represent the model parameters. Here, our baseline model acts as an agent and interacts with its environment (video and caption). At each time step, the agent generates a word (action), and the generation of the end-of-sequence token results in a reward r to the agent. Our training objective is to minimize the negative expected reward function:

$$L(\theta) = -\mathbb{E}_{w^s \sim p_\theta}[r(w^s)] \qquad (2)$$

where w^s is the word sequence sampled from the model. Based on the REINFORCE algorithm (Williams, 1992), the gradients of this non-differentiable, reward-based loss function are:

$$\nabla_\theta L(\theta) = -\mathbb{E}_{w^s \sim p_\theta}[r(w^s) \cdot \nabla_\theta \log p_\theta(w^s)] \quad (3)$$

We follow Ranzato et al. (2016) approximating the above gradients via a single sampled word

[1] Several papers have presented the relative comparison of image captioning metrics, and their pros and cons (Vedantam et al., 2015; Anderson et al., 2016; Liu et al., 2016b; Hodosh et al., 2013; Elliott and Keller, 2014).

Ground-truth caption	Generated (sampled) caption	CIDEr	Ent
a man is spreading some butter in a pan	puppies is melting butter on the pan	140.5	0.07
a panda is eating some bamboo	a panda is eating some fried	256.8	0.14
a monkey pulls a dogs tail	a monkey pulls a woman	116.4	0.04
a man is cutting the meat	a man is cutting meat into potato	114.3	0.08
the dog is jumping in the snow	a dog is jumping in cucumbers	126.2	0.03
a man and a woman is swimming in the pool	a man and a whale are swimming in a pool	192.5	0.02

Table 1: Examples of captions sampled during policy gradient and their CIDEr vs Entailment scores.

sequence. We also use a variance-reducing bias (baseline) estimator in the reward function. Their details and the partial derivatives using the chain rule are described in the supplementary.

Mixed Loss During reinforcement learning, optimizing for only the reinforcement loss (with automatic metrics as rewards) doesn't ensure the readability and fluency of the generated caption, and there is also a chance of gaming the metrics without actually improving the quality of the output (Liu et al., 2016a). Hence, for training our reinforcement based policy gradients, we use a mixed loss function, which is a weighted combination of the cross-entropy loss (XE) and the reinforcement learning loss (RL), similar to the previous work (Paulus et al., 2017; Wu et al., 2016). This mixed loss improves results on the metric used as reward through the reinforcement loss (and improves relevance based on our entailment-enhanced rewards) but also ensures better readability and fluency due to the cross-entropy loss (in which the training objective is a conditioned language model, learning to produce fluent captions). Our mixed loss is defined as:

$$L_{\text{MIXED}} = (1-\gamma)L_{\text{XE}} + \gamma L_{\text{RL}} \tag{4}$$

where γ is a tuning parameter used to balance the two losses. For annealing and faster convergence, we start with the optimized cross-entropy loss baseline model, and then move to optimizing the above mixed loss function.[2]

4 Reward Functions

Caption Metric Reward Previous image captioning papers have used traditional captioning metrics such as CIDEr, BLEU, or METEOR as reward functions, based on the match between the generated caption sample and the ground-truth reference(s). First, it has been shown by Vedantam et al. (2015) that CIDEr, based on a consensus measure across several human reference captions, has a higher correlation with human evaluation than other metrics such as METEOR, ROUGE, and BLEU. They further showed that CIDEr gets better with more number of human references (and this is a good fit for our video captioning datasets, which have 20-40 human references per video).

More recently, Rennie et al. (2016) further showed that CIDEr as a reward in image captioning outperforms all other metrics as a reward, not just in terms of improvements on CIDEr metric, but also on all other metrics. In line with these above previous works, we also found that CIDEr as a reward ('CIDEr-RL' model) achieves the best metric improvements in our video captioning task, and also has the best human evaluation improvements (see Sec. 6.3 for result details, incl. those about other rewards based on BLEU, SPICE).

Entailment Corrected Reward Although CIDEr performs better than other metrics as a reward, all these metrics (including CIDEr) are still based on an undirected n-gram matching score between the generated and ground truth captions. For example, the wrong caption "a man is playing football" w.r.t. the correct caption "a man is playing basketball" still gets a high score, even though these two captions belong to two completely different events. Similar issues hold in case of a negation or a wrong action/object in the generated caption (see examples in Table 1).

We address the above issue by using an entailment score to correct the phrase-matching metric (CIDEr or others) when used as a reward, ensuring that the generated caption is logically implied by (i.e., is a paraphrase or directed partial match with) the ground-truth caption. To achieve an accurate entailment score, we adapt the state-of-the-art decomposable-attention model of Parikh et al. (2016) trained on the SNLI corpus (image caption domain). This model gives us a probability for whether the sampled video caption (generated by our model) is entailed by the ground truth caption as premise (as opposed to a contradiction or neu-

[2] We also experimented with the curriculum learning 'MIXER' strategy of Ranzato et al. (2016), where the XE+RL annealing is based on the decoder time-steps; however, the mixed loss function strategy (described above) performed better in terms of maintaining output caption fluency.

tral case).[3] Similar to the traditional metrics, the overall 'Ent' score is the maximum over the entailment scores for a generated caption w.r.t. each reference human caption (around 20/40 per MSR-VTT/YouTube2Text video). CIDEnt is defined as:

$$\text{CIDEnt} = \begin{cases} \text{CIDEr} - \lambda, & \text{if Ent} < \beta \\ \text{CIDEr}, & \text{otherwise} \end{cases} \quad (5)$$

which means that if the entailment score is very low, we penalize the metric reward score by decreasing it by a penalty λ. This agreement-based formulation ensures that we only trust the CIDEr-based reward in cases when the entailment score is also high. Using CIDEr$-\lambda$ also ensures the smoothness of the reward w.r.t. the original CIDEr function (as opposed to clipping the reward to a constant). Here, λ and β are hyperparameters that can be tuned on the dev-set; on light tuning, we found the best values to be intuitive: $\lambda =$ roughly the baseline (cross-entropy) model's score on that metric (e.g., 0.45 for CIDEr on MSR-VTT dataset); and $\beta = 0.33$ (i.e., the 3-class entailment classifier chose contradiction or neutral label for this pair). Table 1 shows some examples of sampled generated captions during our model training, where CIDEr was misleadingly high for incorrect captions, but the low entailment score (probability) helps us successfully identify these cases and penalize the reward.

5 Experimental Setup

Datasets We use 2 datasets: MSR-VTT (Xu et al., 2016) has $10,000$ videos, 20 references/video; and YouTube2Text/MSVD (Chen and Dolan, 2011) has 1970 videos, 40 references/video. Standard splits and other details in supp.

Automatic Evaluation We use several standard automated evaluation metrics: METEOR, BLEU-4, CIDEr-D, and ROUGE-L (from MS-COCO evaluation server (Chen et al., 2015)).

Human Evaluation We also present human evaluation for comparison of baseline-XE, CIDEr-RL, and CIDEnt-RL models, esp. because the automatic metrics cannot be trusted solely. Relevance measures how related is the generated caption w.r.t, to the video content, whereas coherence measures readability of the generated caption.

Training Details All the hyperparameters are tuned on the validation set. All our results (including baseline) are based on a 5-avg-ensemble. See supplementary for extra training details, e.g., about the optimizer, learning rate, RNN size, Mixed-loss, and CIDEnt hyperparameters.

6 Results

6.1 Primary Results

Table 2 shows our primary results on the popular MSR-VTT dataset. First, our baseline attention model trained on cross entropy loss ('Baseline-XE') achieves strong results w.r.t. the previous state-of-the-art methods.[4] Next, our policy gradient based mixed-loss RL model with reward as CIDEr ('CIDEr-RL') improves significantly[5] over the baseline on all metrics, and not just the CIDEr metric. It also achieves statistically significant improvements in terms of human relevance evaluation (see below). Finally, the last row in Table 2 shows results for our novel CIDEnt-reward RL model ('CIDEnt-RL'). This model achieves statistically significant[6] improvements on top of the strong CIDEr-RL model, on all automatic metrics (as well as human evaluation). Note that in Table 2, we also report the CIDEnt reward scores, and the CIDEnt-RL model strongly outperforms CIDEr and baseline models on this entailment-corrected measure. Overall, we are also the new Rank1 on the MSR-VTT leaderboard, based on their ranking criteria.

Human Evaluation We also perform small human evaluation studies (250 samples from the MSR-VTT test set output) to compare our 3 models pairwise.[7] As shown in Table 3 and Table 4, in terms of relevance, first our CIDEr-RL model stat. significantly outperforms the baseline XE model ($p < 0.02$); next, our CIDEnt-RL model significantly outperforms the CIDEr-RL model ($p <$

[3] Our entailment classifier based on Parikh et al. (2016) is 92% accurate on entailment in the caption domain, hence serving as a highly accurate reward score. For other domains in future tasks such as new summarization, we plan to use the new multi-domain dataset by Williams et al. (2017).

[4] We list previous works' results as reported by the MSR-VTT dataset paper itself, as well as their 3 leaderboard winners (http://ms-multimedia-challenge.com/leaderboard), plus the 10-ensemble video+entailment generation multi-task model of Pasunuru and Bansal (2017).

[5] Statistical significance of $p < 0.01$ for CIDEr, METEOR, and ROUGE, and $p < 0.05$ for BLEU, based on the bootstrap test (Noreen, 1989; Efron and Tibshirani, 1994).

[6] Statistical significance of $p < 0.01$ for CIDEr, BLEU, ROUGE, and CIDEnt, and $p < 0.05$ for METEOR.

[7] We randomly shuffle pairs to anonymize model identity and the human evaluator then chooses the better caption based on relevance and coherence (see Sec. 5). 'Not Distinguishable' are cases where the annotator found both captions to be equally good or equally bad).

Models	BLEU-4	METEOR	ROUGE-L	CIDEr-D	CIDEnt	Human*

Table 2: Our primary video captioning results on MSR-VTT. All CIDEr-RL results are statistically significant over the baseline XE results, and all CIDEnt-RL results are stat. signif. over the CIDEr-RL results. Human* refers to the 'pairwise' comparison of human relevance evaluation between CIDEr-RL and CIDEnt-RL models (see full human evaluations of the 3 models in Table 3 and Table 4).

	Relevance	Coherence
Not Distinguishable	64.8%	92.8%
Baseline-XE Wins	13.6%	4.0%
CIDEr-RL Wins	**21.6%**	3.2%

Table 3: Human eval: Baseline-XE vs CIDEr-RL.

	Relevance	Coherence
Not Distinguishable	70.0%	94.6%
CIDEr-RL Wins	11.6%	2.8%
CIDEnt-RL Wins	**18.4%**	2.8%

Table 4: Human eval: CIDEr-RL vs CIDEnt-RL.

0.03). The models are statistically equal on coherence in both comparisons.

6.2 Other Datasets

We also tried our CIDEr and CIDEnt reward models on the YouTube2Text dataset. In Table 5, we first see strong improvements from our CIDEr-RL model on top of the cross-entropy baseline. Next, the CIDEnt-RL model also shows some improvements over the CIDEr-RL model, e.g., on BLEU and the new entailment-corrected CIDEnt score. It also achieves significant improvements on human relevance evaluation (250 samples).[8]

6.3 Other Metrics as Reward

As discussed in Sec. 4, CIDEr is the most promising metric to use as a reward for captioning, based on both previous work's findings as well as ours. We did investigate the use of other metrics as the reward. When using BLEU as a reward (on MSR-VTT), we found that this BLEU-RL model achieves BLEU-metric improvements, but was worse than the cross-entropy baseline on human evaluation. Similarly, a BLEUEnt-RL model achieves BLEU and BLEUEnt metric improvements, but is again worse on human evaluation.

Models	B	M	R	C	CE	H*
Baseline-XE	52.4	35.0	71.6	83.9	68.1	-
CIDEr-RL	53.3	35.1	72.2	89.4	69.4	8.4
CIDEnt-RL	54.4	34.9	72.2	88.6	71.6	13.6

Table 5: Results on YouTube2Text (MSVD) dataset. CE = CIDEnt score. H* refer to the pairwise human comparison of relevance.

We also experimented with the new SPICE metric (Anderson et al., 2016) as a reward, but this produced long repetitive phrases (as also discussed in Liu et al. (2016b)).

6.4 Analysis

Fig. 1 shows an example where our CIDEnt-reward model correctly generates a ground-truth style caption, whereas the CIDEr-reward model produces a non-entailed caption because this caption will still get a high phrase-matching score. Several more such examples are in the supp.

7 Conclusion

We first presented a mixed-loss policy gradient approach for video captioning, allowing for metric-based optimization. We next presented an entailment-corrected CIDEnt reward that further improves results, achieving the new state-of-the-art on MSR-VTT. In future work, we are applying our entailment-corrected rewards to other directed generation tasks such as image captioning and document summarization (using the new multi-domain NLI corpus (Williams et al., 2017)).

Acknowledgments

We thank the anonymous reviewers for their helpful comments. This work was supported by a Google Faculty Research Award, an IBM Faculty Award, a Bloomberg Data Science Research Grant, and NVidia GPU awards.

[8] This dataset has a very small dev-set, causing tuning issues – we plan to use a better train/dev re-split in future work.

Abstract

Verbs can only be used with a few specific arrangements of their arguments (*syntactic frames*). Most theorists note that verbs can be organized into a hierarchy of *verb classes* based on the frames they admit. Here we show that such a hierarchy is objectively well-supported by the patterns of verbs and frames in English, since a systematic hierarchical clustering algorithm converges on the same structure as the handcrafted taxonomy of VerbNet, a broad-coverage verb lexicon. We also show that the hierarchies capture meaningful psychological dimensions of generalization by predicting novel verb coercions by human participants. We discuss limitations of a simple hierarchical representation and suggest similar approaches for identifying the representations underpinning verb argument structure.

1 Introduction

Why can Sally *like to read* but not **appreciate to read*? Key to the grammar of sentences are verbs and the arguments with which they appear. How children learn the constraints that govern the ways verbs and arguments combine is a central question in language acquisition.

Theorists have long noted that verbs can be organized into *classes* based on their syntactic constructions and the events they express (see Levin and Rappaport Hovav, 2005 for review). Verb classes are included in most theories of argument structure acquisition, whether as first class objects (Perfors et al., 2010) or mere epiphenomena of other claims about the structure of form-meaning mappings (Pinker, 1989; Goldberg, 1995).

Most theories also propose further structure between classes. One common assumption is that verb argument structure can be at least partially described by a hierarchy: Each verb belongs to a class, which itself may belong to a number of broader *superclasses*.

While many theories predict more complex structure (e.g. cross-cutting categories; Levin and Rappaport Hovav, 2005), providing (psycho)linguistic evidence for a simple hierarchy of verbs is an important starting point for investigating more complex theories. VerbNet (Kipper et al., 2008), the largest English verb argument structure resource,[1] organizes verbs and classes into a shallow hierarchy, but its structure has been handcrafted incrementally over time (starting with seminal work by Levin, 1993). On the other hand, recently-developed, state-of-the-art machine learning methods offer a unique alternative approach to constructing such a hierarchy.

In this paper, we first conduct a broad-coverage analysis of how verbs might be hierarchically arranged by comparing VerbNet's handcrafted hierarchy to structure systematically inferred by a Bayesian hierarchical clustering algorithm. We find that the two arrive at similar structure, thus substantiating both methods (i.e. intuition vs. clustering) and the common hierarchy they find.

Second, we investigate the psychological validity of this representation: if classes capture meaningful dimensions of generalization, one would intuit that a verb in a class should behave more similarly to verbs in nearby classes than distant classes according to some measure of "distance". Indeed, this kind of assumption plays an important role

[1] VerbNet combines many important expert-crafted verb resources into a single database, and thus is used in diverse NLP applications including semantic parsing (Giuglea and Moschitti, 2006), natural language inference (Palmer et al., 2009), and information extraction (Maynard et al., 2009).

Proceedings of the 2017 Conference on Empirical Methods in Natural Language Processing, pages 986–991
Copenhagen, Denmark, September 7–11, 2017.

in theoretical (Suttle and Goldberg, 2011; Pinker, 1989) and empirical (Ambridge et al., 2011) work. We thus ask human participants to rate the compatibility of a wide range of existing verbs in attested and unattested syntactic frames. We find that such coercions are indeed predicted by a hierarchical taxonomy of verbs.

2 Related work

There is a substantial literature from both the NLP and psycholinguistics communities on unsupervised learning of verb classes from corpora and other resources (e.g. Reichart and Korhonen, 2013; Vlachos et al., 2009; Sun et al., 2008; Joanis and Stevenson, 2003) and computational cognitive models of argument structure acquisition (e.g. Barak et al., 2016; Ambridge and Blything, 2015; Barak et al., 2014; Parisien and Stevenson, 2010; Perfors et al., 2010), respectively.

Our work differs in several ways. First, we do not consider the basic problem of learning verb classes from semantic or syntactic primitives (cf. Sun et al., 2008) or verb usages extracted from corpora; instead, we examine what higher-level structure is implied by the gold-standard catalog of already-clustered verbs and syntactic frames in VerbNet. Second, we do not attempt to model incremental learning (cf. Parisien and Stevenson, 2010) or instantiate a specific theory (cf. Ambridge and Blything, 2015). Rather, we conduct an at-scale investigation of verb argument structure through cluster analysis.

3 Discovering structure via clustering

VerbNet suggests a shallow and disconnected hierarchy of verbs, with lower-level *subclasses* of verbs that take the exact same frames, broader *standard classes*, and at the top, 101 unrelated *superclasses* (Figure 1a). There is a broad assumption of weaker relations between members of higher-level classes than lower-level classes.

We compared this to the hierarchy obtained from Bayesian Hierarchical Clustering (BHC; Heller and Ghahramani, 2005) implemented in R by Savage et al. (2009), a state-of-the-art agglomerative clustering method that can be seen as a bottom-up approximation to a Dirichlet Process Mixture Model. Unlike traditional hierarchical clustering algorithms, BHC uses Bayesian hypothesis testing to merge subtrees: at each proposed merge, BHC evaluates the probability p that the data are generated from a single probabilistic model, rather than two or more different models consistent with the subtrees.[2] Crucially, nodes with probability $p < 0.5$ are merges that BHC prefers *not* to make; the tree can be cut at these nodes to obtain a flat clustering (Figure 1b), which can then be compared to VerbNet.

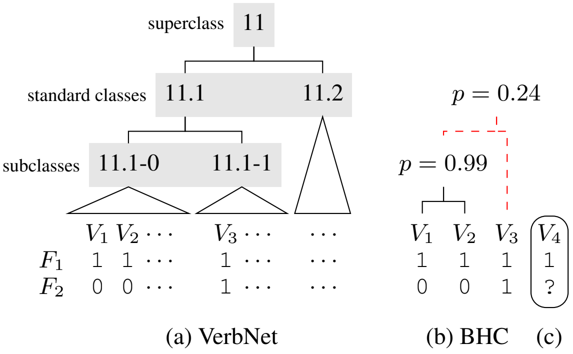

Figure 1: (a) Simplified VerbNet hierarchy, depicting a superclass, standard classes, subclasses, and toy verbs V_i and frames F_i. (b) We train BHC on the frame data $\mathcal{D}$. Dotted lines are merges BHC prefers not to make ($p < 0.5$). To obtain a flat clustering, the tree is cut at nodes where $p < 0.5$ and each subtree is a cluster. (c) Using BHC to evaluate $P(V_4 \text{ admits } F_2 \mid V_4 \text{ admits } F_1, \mathcal{D})$.

3.1 Data

As input to BHC, we used VerbNet's comprehensive set of verb-frame combinations. VerbNet v3.2[3] can be represented as a 6334 verb × n frame binary matrix, with 1s in cells with attested verb-frame pairs (Figure 1a). Thus, each verb is represented as a binary vector of frames.

The number of frames n depends on what semantic and syntactic annotations are considered to be part of the frame. VerbNet includes 3 kinds of annotations: selectional restrictions on arguments, thematic roles, and prepositional literals (Figure 2). For this paper, we included selectional restrictions and thematic roles, resulting in 1613 frames. These annotations made it easiest to produce experimental stimuli in Section 4, although our analysis produced similar results across the other possible frame encodings (see Appendix A).

[2] In our case, the assumed generative model is a set of independent Beta-Bernoulli models predicting the probability of occurrence of each frame, with the priors found by optimizing the marginal likelihood of the overall model. For full details of the algorithm, see Heller and Ghahramani (2005) and Savage et al. (2009).

Figure 2: Information associated with a VerbNet frame entry.

3.2 Evaluation

Here we evaluated the extent to which BHC converged on VerbNet's structure at low (sub and standard classes) and high levels (superclasses).

Comparing flat clusterings with H and C First, we obtained the flat clustering from BHC (Figure 1b) and asked how it compared to VerbNet. Here, we used homogeneity (H) and completeness (C), entropy-based measures of clustering similarity analogous to precision and recall in binary classification (Rosenberg and Hirschberg, 2007). Treating VerbNet classes as ground truth, $H = 1$ indicates that every BHC cluster contains only members of a single VerbNet class. $C = 1$ indicates that members of a VerbNet class are always assigned to the same BHC cluster. The worst case for both is 0.

H and C have different meanings depending on what we consider to be VerbNet's flat ground truth classes. We consider ground truth classes across the levels of VerbNet granularity: low-level subclasses ($H_{\text{sub}}, C_{\text{sub}}$), standard classes ($H_{\text{standard}}, C_{\text{standard}}$), and superclasses ($H_{\text{super}}, C_{\text{super}}$) (Table 1).

Table 1: Homogeneity and completeness. Random baselines are mean statistics across 1000 clusterings made by uniformly sampling a BHC cluster for each verb. C_{sub} is trivially 1, since members of VerbNet subclasses have identical features and were always grouped into the same class by BHC.

Statistic	Granularity	BHC	Random
H	H_{super}	.88	.31
	H_{standard}	.88	.19
	H_{sub}	.83	.34
C	C_{super}	.72	.31
	C_{standard}	.99	.14
	C_{sub}	1	.37

The important comparison is with superclasses, for which both H and C were high. This indicates that BHC clusters rarely included verbs from multiple VerbNet superclasses ($H_{\text{super}} = .88$) and rarely split verbs from the same VerbNet superclass into different BHC clusters ($C_{\text{super}} = .72$).

Tanglegram While H and C focus on the size and membership of two clustering solutions, *tanglegrams* (Huson and Scornavacca, 2012) allow a more general visualization and comparison of two hierarchies. Using the heuristic of Scornavacca et al. (2011),[4] we drew the *optimal tanglegram* of VerbNet and BHC, where the two trees are drawn such that lines connect common leaves and the number of intersections made by these lines is minimized. We computed the *entanglement* of the tanglegram by normalizing the number of intersections to the 0–1 interval by dividing by the worst case; this is a holistic measure of the similarity of the hierarchies (Galili, 2015).

The tanglegram (Figure 3) shows that qualitatively, much of VerbNet's structure aligns well between the trees. We observed an entanglement of 0.20, compared to a random baseline of 0.66.

3.3 Discussion

The high H and C (Table 1) and low entanglement (Figure 3) suggest that both VerbNet's handcrafted hierarchical taxonomy and the one systematically created by BHC converge on similar results. Interestingly, both methods result in a fairly shallow hierarchy with many unrelated subtrees. This suggests that while small clusters of verbs are highly related, the principles governing verb argument structure are relatively narrow and do not generalize across more than a small subset of verbs. Alternatively, it could suggest that a hierarchical taxonomy is too simple to fully capture argument structure patterns.

4 Human coercion judgments

We next evaluated the hierarchies for their ability to account for human generalization. Researchers often test generalization along a specific dimension through extension to novel verbs ("wug tests"; Ambridge et al., 2013; Pinker, 1989). While this works well for studies of specific phenomena, it is difficult to deploy in a large study like ours, where we do not have hypotheses

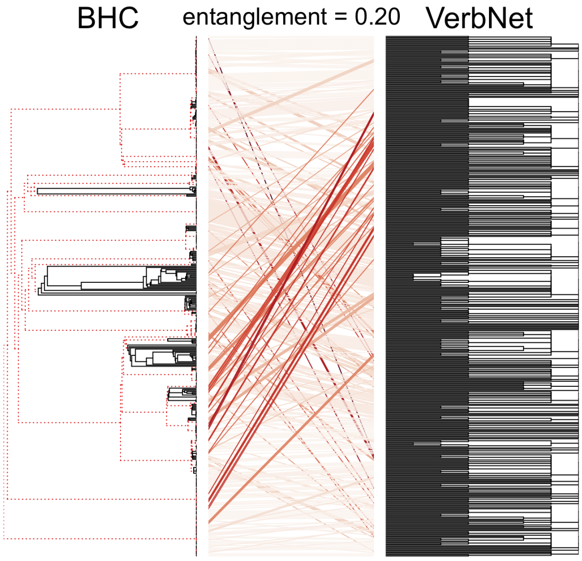

Figure 3: Tanglegram. We prune leaves (verbs) from BHC and VerbNet so that each leaf here represents a VerbNet subclass. Dotted lines are merges BHC prefers not to make. Connectors are colored by shades of red indicating worse alignment, as measured by vertical distance traveled. The vast majority of lines are light-colored, indicating strong alignment.

about what drives generalization language-wide. Thus, we assessed generalization through a coercion task, asking whether speakers are more likely to extend a known verb to a unattested frame if the frame is attested for verbs in a closely-related class. This matches a common theoretical claim that verbs are attracted to the frames of similar verbs, with the notion of similarity varying by theory (Ambridge et al., 2011; Suttle and Goldberg, 2011).

4.1 Predicting verb-frame coercion

VerbNet makes straightforward coarse predictions. For any syntactic frame, we grouped verbs into 3 categories: *Exact*, if the verb can take the frame; *Sibling*, if one of the verb's super or subclasses can take the frame; and *None* otherwise. Conversely, as a Bayesian probabilistic model, BHC defines a predictive distribution on new data. We were interested in whether this precision resulted in better fit, so we also tested BHC: for any verb and frame, we can evaluate the posterior probability that the verb admits the frame of interest while conditioning on the verb's other frames (Figure 1c; see Appendix B for details).

Table 2: 2 sampled frames and their corresponding sentence templates, each with 3 example verbs and predicted compatibilities. To form the stimuli, each verb is placed into the sentence template, e.g. *Beyond the place arose the thing*.

Frame	Sentence	Verb	VN[1]	BHC[2]
BEYOND NP.LOCATION V NP.THEME	Beyond the place V-ed the thing	arise stretch assume	E S N	6.1 −7.6 −9.1
NP.THEME V THROUGH NP.LOCATION	He V-ed through the place	hum motor regard	E S N	6.1 −6.9 −7.3

[1] VerbNet. E = Exact; S = Sibling; N = None
[2] log odds $P(\text{verb takes frame} \mid \text{verb's other frames}, \mathcal{D})$

4.2 Materials and methods

We sampled 10 frames and 10 verbs for each frame, resulting in 100 verb-frame pairs. To control for possible verb frequency effects (Braine and Brooks, 1995), we ensured there was no significant correlation between the predicted compatibility of a verb-frame pair and the Brown corpus (Kučera and Francis, 1967) frequency of the verb ($r = 0.13, p = 0.17$). We then converted verb-frame pairs into sentence stimuli, which required that we choose nouns to represent NPs in frames. We chose the most generic noun compatible with the thematic role restriction, if present. For example, for NP.AGENT, we used a generic name, and for NP.LOCATION, we used *place*. Example stimuli are located in Table 2.

We recruited 50 native English speakers from Mechanical Turk. For each sentence, participants judged the grammaticality of the sentence on a Likert scale, from 1 ("not at all") to 5 ("perfect").

4.3 Results and discussion

First, we noticed that all verbs in some frames received consistently low coercion judgments (< 3). For example, while the verb *fly* and the frame THERE V NP.THEME FOR NP.LOCATION is attested (Exact), *There flew a thing for the place* received a mean judgment of 2.4. We translated judgments so that the mean judgments across verbs for each frame was average (3), to examine the *relative* effects of coercing verbs into frames.

Figure 4a shows that VerbNet's 3 categories predict differences in the mean coercion ratings of verb-frame pairs ($F = 43.46,\ p < 0.001$). Notably, there was a significant difference between the means of the unattested categories (Sibling vs.

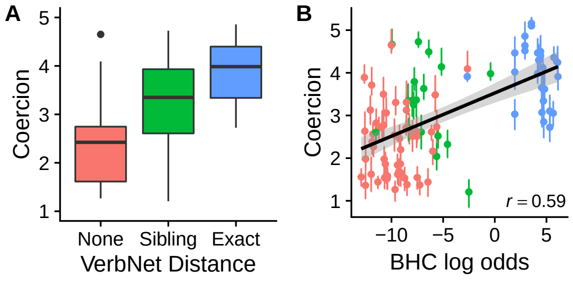

Figure 4: (a) distribution of mean coercion judgments for verb-frame pairs in the 3 VerbNet categories. (b) correlation between the same mean coercion judgments and BHC posterior predictive predictions, colored by VerbNet category. Error bars are bootstrapped 95% confidence intervals.

None; $t = 3.55,\ p < 0.01$). While there was a high correlation between the judgments and BHC predictions (Figure 4b; $r = 0.59$), BHC's hierarchy did not significantly improve fit to the data.

These results provide additional psychological evidence for the effects associated with VerbNet's coarse distinctions: for unattested verb-frame pairs, participants tend to assign a higher compatibility rating when the verb has sibling VerbNet classes that can take the frame. However, the range of compatibility judgments is highly variable across all three categories, and BHC's finer-grained predictions fail to account for much of this variability. Given the similarity of BHC to VerbNet's hierarchy, this result is unsurprising.

5 General discussion

We presented converging evidence that a shallow hierarchy of verbs (1) is well supported by the distribution of verbs and syntactic frames in language, since VerbNet's hand-crafted hierarchy and a systematic unsupervised learner (BHC) reach similar results; and (2) captures important features of verb argument structure by predicting human generalization intuitions in a coercion task.

Of course, it is clear from the variability of our coercion data that a simple hierarchy is not a sufficiently sophisticated representation of argument structure to fully explain language-wide coercion. However, our novel computational framework (unsupervised learning on VerbNet data) opens up many potentially fruitful avenues for providing language-wide evidence for argument structure hypotheses. The lack of broad-coverage predictions is often a limitation of work in this area (see Section 2).

Sophisticated machine learning models that make the assumptions proposed by richer theories of argument structure and can operate at VerbNet scale are only recently coming into fruition. For example, since some theories argue for a cross-categorization of verbs and argument structures (Levin and Rappaport Hovav, 2005), using models that find such a (possibly hierarchical) cross-categorization (e.g. Mansinghka et al., 2016; Li and Shafto, 2011) is a particularly interesting avenue for further exploration.

Abstract

We introduce multi-modal, attention-based Neural Machine Translation (NMT) models which incorporate visual features into different parts of both the encoder and the decoder. Global image features are extracted using a pre-trained convolutional neural network and are incorporated *(i)* as words in the source sentence, *(ii)* to initialise the encoder hidden state, and *(iii)* as additional data to initialise the decoder hidden state. In our experiments, we evaluate translations into English and German, how different strategies to incorporate global image features compare and which ones perform best. We also study the impact that adding synthetic multi-modal, multilingual data brings and find that the additional data have a positive impact on multi-modal models. We report new state-of-the-art results and our best models also significantly improve on a comparable Phrase-Based Statistical MT (PBSMT) model trained on the Multi30k data set according to all metrics evaluated. To the best of our knowledge, it is the first time a purely neural model significantly improves over a PBSMT model on all metrics evaluated on this data set.

1 Introduction

Neural Machine Translation (NMT) has recently been proposed as an instantiation of the *sequence to sequence* (*seq2seq*) learning problem (Kalchbrenner and Blunsom, 2013; Cho et al., 2014b; Sutskever et al., 2014). In this problem, each training example consists of one source and one target variable-length sequence, with no prior information regarding the alignments between the two. A model is trained to *translate* sequences in the source language into corresponding sequences in the target. This framework has been successfully used in many different tasks, such as handwritten text generation (Graves, 2013), image description generation (Hodosh et al., 2013; Kiros et al., 2014; Mao et al., 2014; Elliott et al., 2015; Karpathy and Fei-Fei, 2015; Vinyals et al., 2015), machine translation (Cho et al., 2014b; Sutskever et al., 2014) and video description generation (Donahue et al., 2015; Venugopalan et al., 2015).

Recently, there has been an increase in the number of natural language generation models that explicitly use *attention-based decoders*, i.e. decoders that model an *intra-sequential* mapping between source and target representations. For instance, Xu et al. (2015) proposed an attention-based model for the task of Image Description Generation (IDG) where the model learns to *attend to* specific parts of an image (the source) as it generates its description (the target). In MT, one can intuitively interpret this attention mechanism as inducing an *alignment* between source and target sentences, as first proposed by Bahdanau et al. (2015). The common idea is to explicitly frame a learning task in which the decoder learns to attend to the relevant parts of the source sequence when generating each part of the target sequence.

We are inspired by recent successes in using attention-based models in both IDG and NMT. Our main goal in this work is to propose end-to-end multi-modal NMT models which effectively incorporate visual features in different parts of the attention-based NMT framework. The main contributions of our work are:

- We propose novel attention-based multi-modal NMT models which incorporate visual features into the encoder and the decoder.
- We discuss the impact that adding synthetic

Proceedings of the 2017 Conference on Empirical Methods in Natural Language Processing, pages 992–1003
Copenhagen, Denmark, September 7–11, 2017. ©2017 Association for Computational Linguistics

multi-modal and multilingual data brings to multi-modal NMT.

- We show that images bring useful information to an NMT model and report state-of-the-art results.

One additional contribution of our work is that we corroborate previous findings by Vinyals et al. (2015) that suggested that using image features directly as additional context to update the hidden state of the decoder (at each time step) prevents learning.

The remainder of this paper is structured as follows. In §1.1 we briefly discuss relevant previous related work. We then revise the attention-based NMT framework and further expand it into different multi-modal NMT models (§2). In §3 we introduce the data sets we use in our experiments. In §4 we detail the hyperparameters, parameter initialisation and other relevant details of our models. Finally, in §6 we draw conclusions and provide some avenues for future work.

1.1 Related work

Attention-based encoder-decoder models for MT have been actively investigated in recent years. Some researchers have studied how to improve attention mechanisms (Luong et al., 2015; Tu et al., 2016) and how to train attention-based models to translate between many languages (Dong et al., 2015; Firat et al., 2016).

However, multi-modal MT has only recently been addressed by the MT community in the form of a shared task (Specia et al., 2016). We note that in the official results of this first shared task no submissions based on a purely neural architecture could improve on the Phrase-Based SMT (PBSMT) baseline. Nevertheless, researchers have proposed to include global visual features in reranking n-best lists generated by a PBSMT system or directly in a purely NMT framework with some success (Caglayan et al., 2016; Calixto et al., 2016; Libovický et al., 2016; Shah et al., 2016). The best results achieved by a purely NMT model in this shared task are those of Huang et al. (2016), who proposed to use global and regional image features extracted with the VGG19 (Simonyan and Zisserman, 2014) and the RCNN (Girshick et al., 2014) convolutional neural networks (CNNs).

Similarly to one of the three models we propose,[1] Huang et al. (2016) extract global features for an image, project these features into the vector space of the source words and then add it as a word in the input sequence. Their best model improves over a strong NMT baseline and is comparable to results obtained with a PBSMT model trained on the same data, although not significantly better. For that reason, their models are used as baselines in our experiments. Next, we point out some key differences between the work of Huang et al. (2016) and ours.

Architecture Their implementation is based on the attention-based model of Luong et al. (2015), which has some differences to that of Bahdanau et al. (2015), used in our work (§2.1). Their encoder is a single-layer unidirectional LSTM and they use the last hidden state of the encoder to initialise the decoder's hidden state, therefore indirectly using the image features to do so. We use a bi-directional recurrent neural network (RNN) with GRU (Cho et al., 2014a) as our encoder, better encoding the semantics of the source sentence.

Image features We include image features separately either as a word in the source sentence (§2.2.1) or *directly* for encoder (§2.2.2) or decoder initialisation (§2.2.3), whereas Huang et al. (2016) only use it as a word. We also show it is better to include an image exclusively for the encoder *or* the decoder initialisation (Tables 1 and 2).

Data Huang et al. (2016) use object detections obtained with the RCNN of Girshick et al. (2014) as additional data, whereas we study the impact that additional back-translated data brings.

Performance All our models outperform Huang et al. (2016)'s according to all metrics evaluated, even when they use additional object detections. If we use additional back-translated data, the difference becomes even larger.

2 Attention-based NMT

In this section, we briefly revise the attention-based NMT framework (§2.1) and expand it into a multi-modal NMT framework (§2.2).

2.1 Text-only attention-based NMT

We follow the notation of Bahdanau et al. (2015) and Firat et al. (2016) throughout this section.

[1] This idea has been developed independently by both research groups.

Given a source sequence $X = (x_1, x_2, \cdots, x_N)$ and its translation $Y = (y_1, y_2, \cdots, y_M)$, an NMT model aims at building a single neural network that translates X into Y by directly learning to model $p(Y \mid X)$. Each x_i is a row index in a source lookup matrix $\boldsymbol{W}_x \in \mathbb{R}^{|V_x| \times d_x}$ (the *source word embeddings matrix*) and each y_j is an index in a target lookup matrix $\boldsymbol{W}_y \in \mathbb{R}^{|V_y| \times d_y}$ (the *target word embeddings matrix*). V_x and V_y are source and target vocabularies and d_x and d_y are source and target word embeddings dimensionalities, respectively.

A bidirectional RNN with GRU is used as the encoder. A forward RNN $\overrightarrow{\Phi}_{\text{enc}}$ reads X word by word, from left to right, and generates a sequence of *forward annotation vectors* $(\overrightarrow{\boldsymbol{h}}_1, \overrightarrow{\boldsymbol{h}}_2, \cdots, \overrightarrow{\boldsymbol{h}}_N)$ at each encoder time step $i \in [1, N]$. Similarly, a backward RNN $\overleftarrow{\Phi}_{\text{enc}}$ reads X from right to left, word by word, and generates a sequence of *backward annotation vectors* $(\overleftarrow{\boldsymbol{h}}_1, \overleftarrow{\boldsymbol{h}}_2, \cdots, \overleftarrow{\boldsymbol{h}}_N)$, as in (1):

$$\begin{aligned} \overrightarrow{\boldsymbol{h}}_i &= \overrightarrow{\Phi}_{\text{enc}}\big(\boldsymbol{W}_x[x_i], \overrightarrow{\boldsymbol{h}}_{i-1}\big), \\ \overleftarrow{\boldsymbol{h}}_i &= \overleftarrow{\Phi}_{\text{enc}}\big(\boldsymbol{W}_x[x_i], \overleftarrow{\boldsymbol{h}}_{i+1}\big). \end{aligned} \tag{1}$$

The final annotation vector for a given time step i is the concatenation of forward and backward vectors $\boldsymbol{h}_i = \big[\overrightarrow{\boldsymbol{h}}_i; \overleftarrow{\boldsymbol{h}}_i\big]$.

In other words, each source sequence X is encoded into a sequence of annotation vectors $h = (\boldsymbol{h}_1, \boldsymbol{h}_2, \cdots, \boldsymbol{h}_N)$, which are in turn used by the decoder: essentially a neural language model (LM) (Bengio et al., 2003) conditioned on the previously emitted words and the source sentence via an attention mechanism.

At each time step t of the decoder, we compute a *time-dependent* context vector $\boldsymbol{c}_t$ based on the annotation vectors h, the decoder's previous hidden state $\boldsymbol{s}_{t-1}$ and the target word $\tilde{y}_{t-1}$ emitted by the decoder in the previous time step.[2]

We follow Bahdanau et al. (2015) and use a single-layer feed-forward network to compute an *expected alignment* $e_{t,i}$ between each source annotation vector $\boldsymbol{h}_i$ and the target word to be emitted at the current time step t, as in (2):

$$e_{t,i} = \boldsymbol{v}_a{}^T \tanh(\boldsymbol{U}_a \boldsymbol{s}_{t-1} + \boldsymbol{W}_a \boldsymbol{h}_i). \tag{2}$$

In Equation (3), these expected alignments are normalised and converted into probabilities:

$$\alpha_{t,i} = \frac{\exp\left(e_{t,i}\right)}{\sum_{j=1}^{N} \exp\left(e_{t,j}\right)}, \tag{3}$$

where $\alpha_{t,i}$ are called the model's *attention weights*, which are in turn used in computing the time-dependent context vector $\boldsymbol{c}_t = \sum_{i=1}^{N} \alpha_{t,i} \boldsymbol{h}_i$. Finally, the context vector $\boldsymbol{c}_t$ is used in computing the decoder's hidden state $\boldsymbol{s}_t$ for the current time step t, as shown in Equation (4):

$$\boldsymbol{s}_t = \Phi_{\text{dec}}(\boldsymbol{s}_{t-1}, \boldsymbol{W}_{\boldsymbol{y}}[\tilde{y}_{t-1}], \boldsymbol{c}_t), \tag{4}$$

where $\boldsymbol{s}_{t-1}$ is the decoder's previous hidden state, $\boldsymbol{W}_{\boldsymbol{y}}[\tilde{y}_{t-1}]$ is the embedding of the word emitted in the previous time step, and $\boldsymbol{c}_t$ is the updated time-dependent context vector.

We use a single-layer feed-forward neural network to initialise the decoder's hidden state $\boldsymbol{s}_0$ at time step $t = 0$ and feed it the concatenation of the last hidden states of the encoder's forward RNN ($\overrightarrow{\Phi}_{\text{enc}}$) and backward RNN ($\overleftarrow{\Phi}_{\text{enc}}$), as in (5):

$$\boldsymbol{s}_0 = \tanh\big(\boldsymbol{W}_{di}[\overleftarrow{\boldsymbol{h}}_1; \overrightarrow{\boldsymbol{h}}_N] + \boldsymbol{b}_{di}\big), \tag{5}$$

where $\boldsymbol{W}_{di}$ and $\boldsymbol{b}_{di}$ are model parameters. Since RNNs normally better store information about recent inputs in comparison to more distant ones (Hochreiter and Schmidhuber, 1997; Bahdanau et al., 2015), we expect to initialise the decoder's hidden state with a strong source sentence representation, i.e. a representation with a strong focus on both the first and the last tokens in the source sentence.

2.2 Multi-modal NMT (MNMT)

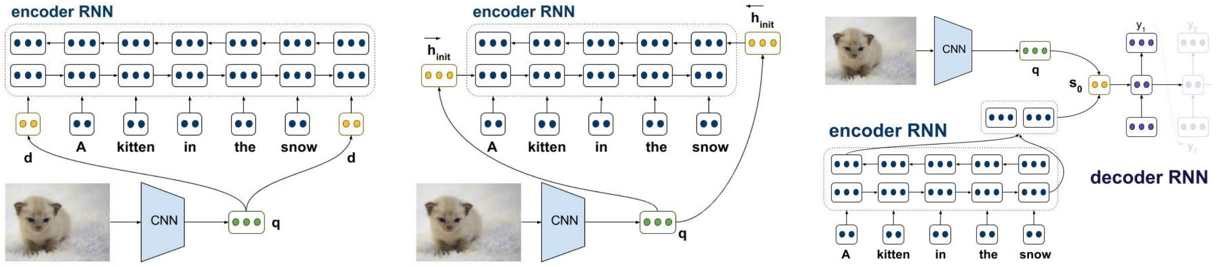
Our models can be seen as expansions of the attention-based NMT framework described in §2 with the addition of a *visual component* to incorporate image features.

Simonyan and Zisserman (2014) trained and evaluated an extensive set of deep Convolutional Neural Networks (CNNs) for classifying images into one out of the 1000 classes in ImageNet (Russakovsky et al., 2015). We use their 19-layer VGG network (VGG19) to extract image feature vectors for all images in our dataset. We feed an image to the pre-trained VGG19 network and use the 4096D activations of the penultimate fully-connected layer FC7[3] as our *image feature vector*, henceforth referred to as $\boldsymbol{q}$.

We propose three different methods to incorporate images into the attentive NMT framework:

[2] At training time, the correct previous target word y_{t-1} is known and therefore used instead of $\tilde{y}_{t-1}$. At test or inference time, y_{t-1} is not known and $\tilde{y}_{t-1}$ is used instead. Bengio et al. (2015) discussed problems that may arise from this difference between training and inference distributions.

[3] We use the activations of the FC7 layer, which encode information about the entire image, of the VGG19 network (configuration E) in Simonyan and Zisserman (2014)'s paper.



(a) An encoder bidirectional RNN that uses image features as words in the source sequence.

(b) Using an image to initialise the encoder hidden states.

(c) Image as additional data to initialise the decoder hidden state s_0.

Figure 1: Multi-modal neural machine translation models IMG_{W}, IMG_{E}, and IMG_{D}.

using an image as words in the source sentence (§2.2.1), using an image to initialise the source language encoder (§2.2.2) and the target language decoder (§2.2.3).

We also evaluated a fourth mechanism to incorporate images into NMT, namely to use an image as one of the different contexts available to the decoder at each time step of the decoding process. We added the image features directly as an additional context, in addition to $\boldsymbol{W}_y[\tilde{y}_{t-1}]$, $\boldsymbol{s}_{t-1}$ and $\boldsymbol{c}_t$, to compute the hidden state $\boldsymbol{s}_t$ of the decoder at a given time step t. We corroborate previous findings by Vinyals et al. (2015) in that adding the image features as such prevents the model from learning.[4]

2.2.1 Images as source words: IMG_{W}

One way we propose to incorporate images into the encoder is to project an image feature vector into the space of the words of the source sentence. We use the projected image as the first and/or last word of the source sentence and let the attention model learn when to attend to the image representation. Specifically, given the global image feature vector $\boldsymbol{q} \in \mathbb{R}^{4096}$, we compute (6):

$$\boldsymbol{d} = \boldsymbol{W}_I^2 \cdot (\boldsymbol{W}_I^1 \cdot \boldsymbol{q} + \boldsymbol{b}_I^1) + \boldsymbol{b}_I^2, \qquad (6)$$

where $\boldsymbol{W}_I^1 \in \mathbb{R}^{4096 \times 4096}$ and $\boldsymbol{W}_I^2 \in \mathbb{R}^{4096 \times d_x}$ are image transformation matrices, $\boldsymbol{b}_I^1 \in \mathbb{R}^{4096}$ and $\boldsymbol{b}_I^2 \in \mathbb{R}^{d_x}$ are bias vectors, and d_x is the source words vector space dimensionality, all trained with the model. We then directly use $\boldsymbol{d}$ as words in the source words vector space: as the first word only (model IMG_{1W}), and as the first and last words of the source sentence (model IMG_{2W}).

An illustration of this idea is given in Figure 1a, where a source sentence that originally contained N tokens, after including the image as source words will contain $N + 1$ tokens (model IMG_{1W}) or $N + 2$ tokens (model IMG_{2W}). In model IMG_{1W}, the image is projected as the first source word only (solid line in Figure 1a); in model IMG_{2W}, it is projected into the source words space as both first and last words (both solid and dashed lines in Figure 1a).

Given a sequence $X = (x_1, x_2, \cdots, x_N)$ in the source language, we concatenate the transformed image vector $\boldsymbol{d}$ to $\boldsymbol{W}_x[X]$ and apply the forward and backward encoder RNN passes, generating hidden vectors as in Figure 1a. When computing the context vector $\boldsymbol{c}_t$ (Equations (2) and (3)), we effectively make use of the transformed image vector, i.e. the $\alpha_{t,i}$ attention weight parameters will use this information to attend or not to the image features.

By including images into the encoder in models IMG_{1W} and IMG_{2W}, our intuition is that *(i)* by including the image as the *first word*, we propagate image features into the source sentence vector representations when applying the forward RNN $\overrightarrow{\Phi}_{\text{enc}}$ (vectors $\overrightarrow{\boldsymbol{h}_i}$), and *(ii)* by including the image as the *last word*, we propagate image features into the source sentence vector representations when applying the backward RNN $\overleftarrow{\Phi}_{\text{enc}}$ (vectors $\overleftarrow{\boldsymbol{h}_i}$).

2.2.2 Images for encoder initialisation: IMG_{E}

In the original attention-based NMT model described in §2, the hidden state of the encoder is initialised with the zero vector $\overrightarrow{0}$. Instead, we propose to use two new single-layer feed-forward neural networks to compute the initial states of the forward RNN $\overrightarrow{\Phi}_{\text{enc}}$ and the backward RNN $\overleftarrow{\Phi}_{\text{enc}}$,

[4] Outputs would typically consist of sets of 2-5 words repeated many times, usually without any syntax. For comparison, translations for the translated Multi30k test set (described in §3) achieve just 3.8 BLEU (Papineni et al., 2002), 15.5 METEOR (Denkowski and Lavie, 2014) and 93.0 TER (Snover et al., 2006).

respectively, as illustrated in Figure 1b.

Similarly to §2.2.1, given a global image feature vector $\boldsymbol{q} \in \mathbb{R}^{4096}$, we compute a vector $\boldsymbol{d}$ using Equation (6), only this time the parameters $\boldsymbol{W}_I^2$ and $\boldsymbol{b}_I^2$ project the image features into the same dimensionality as the textual encoder hidden states.

The feed-forward networks used to initialise the encoder hidden state are computed as in (7):

$$\overleftarrow{\boldsymbol{h}}_{\text{init}} = \tanh\left(\boldsymbol{W}_f \boldsymbol{d} + \boldsymbol{b}_f\right),$$
$$\overrightarrow{\boldsymbol{h}}_{\text{init}} = \tanh\left(\boldsymbol{W}_b \boldsymbol{d} + \boldsymbol{b}_b\right), \qquad (7)$$

where $\boldsymbol{W}_f$ and $\boldsymbol{W}_b$ are multi-modal projection matrices that project the image features $\boldsymbol{d}$ into the encoder forward and backward hidden states dimensionality, respectively, and $\boldsymbol{b}_f$ and $\boldsymbol{b}_b$ are bias vectors.

2.2.3 Images for decoder initialisation: IMG$_\text{D}$

To incorporate an image into the decoder, we introduce a new single-layer feed-forward neural network to be used instead of the one described in Equation 5. Originally, the decoder's initial hidden state was computed using the concatenation of the last hidden states of the encoder forward RNN ($\overrightarrow{\Phi}_{\text{enc}}$) and backward RNN ($\overleftarrow{\Phi}_{\text{enc}}$), respectively $\overrightarrow{\boldsymbol{h}}_N$ and $\overleftarrow{\boldsymbol{h}}_1$.

Our proposal is that we include the image features as additional input to initialise the decoder hidden state at time step $t = 0$, as in (8):

$$\boldsymbol{s}_0 = \tanh\left(\boldsymbol{W}_{di}[\overleftarrow{\boldsymbol{h}}_1; \overrightarrow{\boldsymbol{h}}_N] + \boldsymbol{W}_m \boldsymbol{d} + \boldsymbol{b}_{di}\right), \quad (8)$$

where $\boldsymbol{W}_m$ is a multi-modal projection matrix that projects the image features $\boldsymbol{d}$ into the decoder hidden state dimensionality and $\boldsymbol{W}_{di}$ and $\boldsymbol{b}_{di}$ are the same as in Equation (5).

Once again we compute $\boldsymbol{d}$ by applying Equation (6) onto a global image feature vector $\boldsymbol{q} \in \mathbb{R}^{4096}$, only this time the parameters $\boldsymbol{W}_I^2$ and $\boldsymbol{b}_I^2$ project the image features into the same dimensionality as the decoder hidden states. We illustrate this idea in Figure 1c.

3 Data set

Our multi-modal NMT models need bilingual sentences accompanied by one or more images as training data. The original Flickr30k data set contains 30K images and 5 English sentence descriptions for each image (Young et al., 2014). We use the translated and the comparable Multi30k datasets (Elliott et al., 2016), henceforth referred to as M30k$_\text{T}$ and M30k$_\text{C}$, respectively, which are multilingual expansions of the original Flickr30k.

For each of the 30K images in the Flickr30k, the M30k$_\text{T}$ has one of its English descriptions manually translated into German by a professional translator. Training, validation and test sets contain 29K, 1014 and 1K images, respectively, each accompanied by one sentence pair (the original English sentence and its German translation). For each of the 30K images in the Flickr30k, the M30k$_\text{C}$ has five descriptions in German collected independently of the English descriptions. Training, validation and test sets contain 29K, 1014 and 1K images, respectively, each accompanied by 5 English and 5 German sentences.

We use the scripts in Moses (Koehn et al., 2007) to normalise, truecase and tokenize English and German descriptions and we also convert space-separated tokens into subwords (Sennrich et al., 2016b). All models use a common vocabulary of ∼83K English and ∼91K German subword tokens. If sentences in English or German are longer than 80 tokens, they are discarded.

We use the entire M30k$_\text{T}$ training set for training, its validation set for model selection with BLEU, and its test set to evaluate our models. In order to study the impact that additional training data brings to the models, we use the baseline model described in §2 trained on the textual part of the M30k$_\text{T}$ data set (German→English and English→German) without the images to build back-translation models (Sennrich et al., 2016a). We back-translate the 145K German (English) descriptions in the M30k$_\text{C}$ into English (German) and include the triples (synthetic English description, German description, image) as additional training data when translating into German, and (synthetic German description, English description, image) when translating into English.

We train models to translate from English into German and from German into English, and report evaluation of cased, tokenized sentences with punctuation.

4 Experimental setup

Our encoder is a bidirectional RNN with GRU (one 1024D single-layer forward RNN and one 1024D single-layer backward RNN). Source and target word embeddings are 620D each and both are trained jointly with our model. All non-recurrent matrices are initialised by sampling from a Gaussian ($\mu = 0, \sigma = 0.01$), recurrent matrices are orthogonal and bias vectors are all initialised to zero. Our decoder RNN also uses GRU and is a neural LM (Bengio et al., 2003) conditioned on its previous emissions and the source sentence by means of the source attention mechanism.

Image features are obtained by feeding images to the pre-trained VGG19 network of Simonyan and Zisserman (2014) and using the activations of the penultimate fully-connected layer FC7. We apply dropout with a probability of 0.2 in both source and target word embeddings and with a probability of 0.5 in the image features (in all MNMT models), in the encoder and decoder RNNs inputs and recurrent connections, and before the readout operation in the decoder RNN. We follow Gal and Ghahramani (2016) and apply dropout to the encoder bidirectional RNN and decoder RNN using the same mask in all time steps.

Our models are trained using stochastic gradient descent with Adadelta (Zeiler, 2012) and minibatches of size 40 for improved generalisation (Keskar et al., 2017), where each training instance consists of one English sentence, one German sentence and one image. We apply early stopping for model selection based on BLEU scores, so that if a model does not improve on the validation set for more than 20 epochs, training is halted.

We evaluate our models' translation quality quantitatively in terms of BLEU4 (Papineni et al., 2002), METEOR (Denkowski and Lavie, 2014), TER (Snover et al., 2006), and chrF3 scores[5] (Popović, 2015) and we report statistical significance for the three first metrics using approximate randomisation computed with MultEval (Clark et al., 2011).

Table 1: BLEU4, METEOR, chrF3 (higher is better) and TER scores (lower is better) on the M30k_T test set for the two text-only baselines PBSMT and NMT, the two multi-modal NMT models by Huang et al. (2016) (English→German only) and our MNMT models that: *(i)* use images as words in the source sentence (IMG_{1W}, IMG_{2W}), *(ii)* use images to initialise the encoder (IMG_{E}), and *(iii)* use images as additional data to initialise the decoder (IMG_{D}). Best text-only baselines are underscored and best overall results appear in bold. We highlight in parentheses the improvements brought by our models compared to the best corresponding text-only baseline score. Results differ significantly from PBSMT baseline (†) or NMT baseline (‡) with $p = 0.05$.

As our main baseline we train an attention-based NMT model (§2) in which only the textual part of M30k_T is used for training. We also train a PBSMT model built with Moses on the same English→German (German→English) data, where the LM is a 5–gram LM with modified Kneser-Ney smoothing (Kneser and Ney, 1995) trained on the German (English) of the M30k_T dataset. We use minimum error rate training (Och, 2003) for tuning the model parameters for BLEU scores. Our third baseline (English→German), is the best comparable multi-modal model by Huang et al. (2016) and also their best model with additional object detections: respectively models `m1` (image at head) and `m3` in the authors' paper. Finally, our fourth baseline (German→English) is the best-performing model in the WMT'16 multimodal MT shared task (Shah et al., 2016), henceforth PBSMT^{+}. It uses image features as well as additional data from WordNet (Miller, 1995) to rerank n-best lists.

4.1 Results

The Multi30K dataset contains images and bilingual descriptions. Overall, it is a small dataset with a small vocabulary whose sentences have simple syntactic structures and not much ambiguity (Elliott et al., 2016). This is reflected in the fact that even the simplest baselines perform fairly well on it, i.e. the smallest BLEU scores of 32.9 for translating into German, which are still reasonably good results.

[5] We specifically compute character 6-gram F3 scores.

Table 2: BLEU4, METEOR, TER and chrF3 scores on the M30k$_{T}$ test set for models trained on original and additional back-translated data. Best text-only baselines are underscored and best overall results in bold. We highlight in parentheses the improvements brought by our models compared to the best baseline score. Results differ significantly from PBSMT baseline (†) or NMT baseline (‡) with $p = 0.05$. We also show the improvements each model yields in each metric when only trained on the original M30k$_{T}$ training set vs. also including additional back-translated data. PBSMT^{+} is the best model in the multi-modal MT shared task (Specia et al., 2016).

Multi30k In Table 1, we show results for translating from English→German and German→English. When translating into German, our multi-modal models perform well, with models IMG$_{E}$ and IMG$_{D}$ improving on both baselines according to all metrics analysed. We also note that all models but IMG$_{2W+D}$ perform consistently better than the strong multi-modal NMT baseline of Huang et al. (2016), even when this model has access to more data (+RCNN features).[6] Combining image features in the encoder and the decoder at the same time does not seem to improve results compared to using the image features in only the encoder or the decoder when translating into German. To the best of our knowledge, it is the first time a purely neural model significantly improves over a PBSMT model in all metrics on this data set.

When translating into English, all multi-modal models significantly improve over the NMT baseline, with the only exception being model IMG$_{2W}$'s BLEU scores. In this scenario, model IMG$_{E+D}$ is the best performing one according to all but one metric. However, differences between multi-modal models are not statistically significant, i.e. all multi-modal models but IMG$_{2W}$ and IMG$_{2W+D}$ perform comparably.

Additional back-translated data Arguably, the main downside of applying multi-modal NMT in a real-world scenario is the small amount of publicly available training data (∼30K entries). For that reason, we back-translated the German and English sentences in the M30k$_{C}$ and created two sets of 145K synthetic triples, one for each translation direction, as described in §3.

In Table 2, we present results for some of the models evaluated in Table 1 but when also trained on the additional data. In order to add more data to our PBSMT baseline, we simply added the German sentences in the M30k$_{C}$ to train the LM.[7] We also include results for PBSMT^{+}, which uses image features as well as additional features extracted using WordNet (Shah et al., 2016). When translating into German, both our models IMG$_{E}$ and IMG$_{D}$ that use global image features to initialise the encoder and the decoder, respectively, significantly improve according to BLEU, METEOR and TER with the additional back-translated data, and also achieved better chrF3 scores. When translating into English, IMG$_{E}$ is the only model to significantly improve over both baselines according to all metrics with the additional back-translated data, also improving chrF3 scores. We highlight that our best-performing model IMG$_{E}$ significantly outperforms PBSMT^{+} according to BLEU and TER, and all our other multi-modal models perform comparably to it. This is a noteworthy finding, since

[6] In fact, model IMG$_{2W+D}$ still improves on the multi-modal baseline of Huang et al. (2016) when trained on the same data.

[7] Adding the synthetic sentence pairs to train the baseline PBSMT model, as we did with all neural MT models, deteriorated the results.

Table 3: Results for different combinations of multi-modal models, all trained on the original M30k$_T$ training data only, evaluated on the M30k$_T$ test set.

PBSMT$^+$ uses image features as well as additional data from WordNet and, to the best of our knowledge, is the best published model in this language pair and data set to date.

Ensemble decoding We now report on how can ensemble decoding be used to improve translations obtained with our multi-modal NMT models. In order to do that, we use different combinations of models trained on the original M30k$_T$ training set to translate from English into German. We built ensembles of different models by starting with our best performing multi-modal model on this language pair and data set, IMG$_D$, and by adding new models to the ensemble one by one, until we reach a maximum of four independent models, all of which are trained separately and on the original M30k$_T$ training data only. In Table 3, we show results when translating the M30k$_T$'s test set. These models were also evaluated in our recent participation in the WMT 2017 multi-modal MT shared task (Calixto et al., 2017a).

We first note that to add more models to the ensemble seems to always improve translations, and by a considerable margin ($\sim$ 3 BLEU/METEOR points). Adding model IMG$_{2W}$ to the ensemble already consisting of models IMG$_E$ and IMG$_D$ improves translations according to all metrics evaluated. This is an interesting result, since compared to these other two multi-modal models, model IMG$_{2W}$ performs poorly according to BLEU, METEOR and chrF3. Regardless of that fact, our best results are obtained with an ensemble of four different multi-modal models, including model IMG$_{2W}$.

By using an ensemble of four different multi-modal NMT models trained on the translated Multi30k training data, we were able to obtain translations comparable to or even better than those obtained with the strong multi-modal NMT model of Calixto et al. (2017b), which is pre-trained on large amounts of English–German data and uses local image features. Finally, we have recently participated in the WMT 2017 multi-modal MT shared task, and our system submissions ranked among the best performing systems under the constrained data regime (Calixto et al., 2017a). We note that our models performed particularly well on the ambiguous MSCOCO test set (Elliott et al., 2017), which indicate its ability to use the image information in disambiguating difficult source sentences into their correct translations.

5 Error Analysis

In Table 4 we show translations into German generated by different models for one entry of the M30k test set. In this example, the last three multi-modal models extrapolate the reference+image and describe "ceremony" as a "wedding ceremony" (IMG$_{2W}$) and as an "Olympics ceremony" (IMG$_E$ and IMG$_D$). This could be due to the fact that the training set is small, depicts a small variation of different scenes and contains different forms of biasses (van Miltenburg, 2015).

In Table 5, we draw attention to an example where some models generate what seems to be *novel visual terms*. Neither the source German sentence nor the English reference translation contained the translated units "having fun" or "Mexican restaurant", although both could have been inferred at least partially from the image. In this example, the visual term "having fun" is also generated by the baseline NMT model, making it clear that at times what seems like a translation extracted exclusively from the image may have been learnt from the training text data. However, none of the two baselines translated "Mexikanischen Setting" as "Mexican restaurant", but four out of the five multi-modal models did. The multi-modal models also had problems translating the German "trinkt Shots" (drinking shots). We observe translations such as "having drinks" (IMG$_{2W}$), which

src.	a woman with long hair is at a graduation ceremony .

PBSMT	a group of young people drinking at a Shots Mexikanischen Setting .
IMG$_{2W}$	a group of young people having drinks in a **Mexican restaurant** .
IMG$_{E}$	a group of young people drinking apples in a **Mexican restaurant** .
IMG$_{D}$	a group of young people drinking food in a **Mexican restaurant** .
IMG$_{2W+D}$	a group of young people **having fun** in a Mexican room .
IMG$_{E+D}$	a group of young people drinking dishes in a **Mexican restaurant** .

Table 5: Translations for 300th example in the M30k test set.

although not a novel translation is still correct, but also "drinking apples" (IMG$_{E}$), "drinking food" (IMG$_{D}$), and "drinking dishes" (IMG$_{E+D}$), which are clearly incorrect.

6 Conclusions and future work

In this work, we introduced models that incorporate images into state-of-the-art attention-based NMT, by using images as words in the source sentence, to initialise the encoder's hidden state and as additional data in the initialisation of the decoder's hidden state. The intuition behind our effort is to use images to visually *ground* translations, and consequently increase translation quality. We demonstrate with extensive experiments that adding global image features into NMT significantly improves the translations of image descriptions compared to text-only NMT and PBSMT. It also improves significantly on the previous state-of-the-art model of Huang et al. (2016) (English→German), and performs comparably to the best published results of Shah et al. (2016) (German→English). Overall, we note that using images as words in the source sequence (IMG$_{1W}$, IMG$_{2W}$), an idea similarly entertained by Huang et al. (2016), does not fare as well as to directly incorporate the image either in the encoder or the decoder (IMG$_{E}$ and IMG$_{D}$), independently of the target language. The fact that multi-modal NMT models can benefit from back-translated data is also an interesting finding.

In future work, we will conduct a more systematic study on the impact that synthetic back-translated data brings to multi-modal NMT, and run an error analysis to identify what particular types of errors our models make (and prevent).

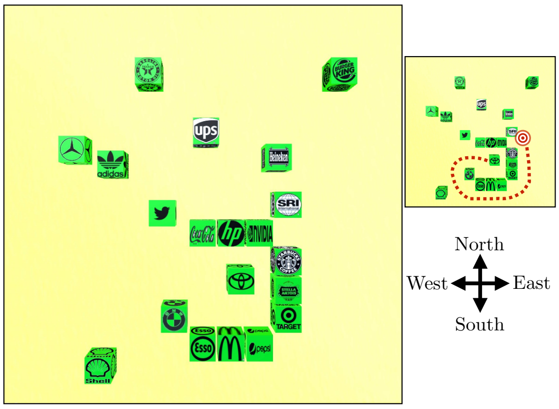
Abstract

We propose to directly map raw visual observations and text input to actions for instruction execution. While existing approaches assume access to structured environment representations or use a pipeline of separately trained models, we learn a single model to jointly reason about linguistic and visual input. We use reinforcement learning in a contextual bandit setting to train a neural network agent. To guide the agent's exploration, we use reward shaping with different forms of supervision. Our approach does not require intermediate representations, planning procedures, or training different models. We evaluate in a simulated environment, and show significant improvements over supervised learning and common reinforcement learning variants.

1 Introduction

An agent executing natural language instructions requires robust understanding of language and its environment. Existing approaches addressing this problem assume structured environment representations (e.g.,. Chen and Mooney, 2011; Mei et al., 2016), or combine separately trained models (e.g., Matuszek et al., 2010; Tellex et al., 2011), including for language understanding and visual reasoning. We propose to directly map text and raw image input to actions with a single learned model. This approach offers multiple benefits, such as not requiring intermediate representations, planning procedures, or training multiple models.



Put the Toyota block in the same row as the SRI block, in the first open space to the right of the SRI block
Move Toyota to the immediate right of SRI, evenly aligned and slightly separated
Move the Toyota block around the pile and place it just to the right of the SRI block
Place Toyota block just to the right of The SRI Block
Toyota, right side of SRI

Figure 1: Instructions in the Blocks environment. The instructions all describe the same task. Given the observed RGB image of the start state (large image), our goal is to execute such instructions. In this task, the direct-line path to the target position is blocked, and the agent must plan and move the Toyota block around. The small image marks the target and an example path, which includes 34 steps.

Figure 1 illustrates the problem in the Blocks environment (Bisk et al., 2016). The agent observes the environment as an RGB image using a camera sensor. Given the RGB input, the agent must recognize the blocks and their layout. To understand the instruction, the agent must identify the block to move (Toyota block) and the destination (just right of the SRI block). This requires solving semantic and grounding problems. For example, consider the topmost instruction in the figure. The agent needs to identify the phrase referring to the block to move, *Toyota block*, and ground it. It must resolve and ground the phrase *SRI block* as a reference position, which is then modified by the spatial meaning recovered from *the same row as* or *first open space to the right of*, to identify the goal position. Finally, the agent needs to generate actions, for example moving the Toyota block around obstructing blocks.

To address these challenges with a single model,

Proceedings of the 2017 Conference on Empirical Methods in Natural Language Processing, pages 1004–1015
Copenhagen, Denmark, September 7–11, 2017. ©2017 Association for Computational Linguistics

we design a neural network agent. The agent executes instructions by generating a sequence of actions. At each step, the agent takes as input the instruction text, observes the world as an RGB image, and selects the next action. Action execution changes the state of the world. Given an observation of the new world state, the agent selects the next action. This process continues until the agent indicates execution completion. When selecting actions, the agent jointly reasons about its observations and the instruction text. This enables decisions based on close interaction between observations and linguistic input.

We train the agent with different levels of supervision, including complete demonstrations of the desired behavior and annotations of the goal state only. While the learning problem can be easily cast as a supervised learning problem, learning only from the states observed in the training data results in poor generalization and failure to recover from test errors. We use reinforcement learning (Sutton and Barto, 1998) to observe a broader set of states through exploration. Following recent work in robotics (e.g., Levine et al., 2016; Rusu et al., 2016), we assume the training environment, in contrast to the test environment, is instrumented and provides access to the state. This enables a simple problem reward function that uses the state and provides positive reward on task completion only. This type of reward offers two important advantages: (a) it is a simple way to express the ideal agent behavior we wish to achieve, and (b) it creates a platform to add training data information.

We use reward shaping (Ng et al., 1999) to exploit the training data and add to the reward additional information. The modularity of shaping allows varying the amount of supervision, for example by using complete demonstrations for only a fraction of the training examples. Shaping also naturally associates actions with immediate reward. This enables learning in a contextual bandit setting (Auer et al., 2002; Langford and Zhang, 2007), where optimizing the immediate reward is sufficient and has better sample complexity than unconstrained reinforcement learning (Agarwal et al., 2014).

We evaluate with the block world environment and data of Bisk et al. (2016), where each instruction moves one block (Figure 1). While the original task focused on source and target prediction only, we build an interactive simulator and formulate the task of predicting the complete sequence of actions. At each step, the agent must select between 81 actions with 15.4 steps required to complete a task on average, significantly more than existing environments (e.g., Chen and Mooney, 2011). Our experiments demonstrate that our reinforcement learning approach effectively reduces execution error by 24% over standard supervised learning and 34-39% over common reinforcement learning techniques. Our simulator, code, models, and execution videos are available at: `https://github.com/clic-lab/blocks`.

2 Technical Overview

Task Let $\mathcal{X}$ be the set of all *instructions*, $\mathcal{S}$ the set of all *world states*, and $\mathcal{A}$ the set of all *actions*. An instruction $\bar{x} \in \mathcal{X}$ is a sequence $\langle x_1, \ldots, x_n \rangle$, where each x_i is a token. The agent executes instructions by generating a sequence of actions, and indicates execution completion with the special action STOP. Action execution modifies the world state following a transition function $T : \mathcal{S} \times \mathcal{A} \rightarrow \mathcal{S}$. The execution $\bar{e}$ of an instruction $\bar{x}$ starting from s_1 is an m-length sequence $\langle (s_1, a_1), \ldots, (s_m, a_m) \rangle$, where $s_j \in \mathcal{S}$, $a_j \in \mathcal{A}$, $T(s_j, a_j) = s_{j+1}$ and $a_m = \texttt{STOP}$. In Blocks (Figure 1), a state specifies the positions of all blocks. For each action, the agent moves a single block on the plane in one of four directions (north, south, east, or west). There are 20 blocks, and 81 possible actions at each step, including STOP. For example, to correctly execute the instructions in the figure, the agent's likely first action is TOYOTA-WEST, which moves the Toyota block one step west. Blocks can not move over or through other blocks.

Model The agent observes the world state via a visual sensor (i.e., a camera). Given a world state s, the agent observes an RGB image I generated by the function $\textsc{Img}(s)$. We distinguish between the world state s and the *agent context*[1] $\tilde{s}$, which includes the instruction, the observed image $\textsc{Img}(s)$, images of previous states, and the previous action. To map instructions to actions, the agent reasons about the agent context $\tilde{s}$ to generate a sequence of actions. At each step, the agent generates a single action. We model the agent with a

[1] We use the term *context* similar to how it is used in the contextual bandit literature to refer to the information available for decision making. While agent contexts capture information about the world state, they do not include physical information, except as captured by observed images.

neural network policy. At each step j, the network takes as input the current agent context $\tilde{s}_j$, and predicts the next action to execute a_j. We formally define the agent context and model in Section 4.

Learning We assume access to training data with N examples $\{(\bar{x}^{(i)}, s_1^{(i)}, \bar{e}^{(i)})\}_{i=1}^N$, where $\bar{x}^{(i)}$ is an instruction, $s_1^{(i)}$ is a start state, and $\bar{e}^{(i)}$ is an execution demonstration of $\bar{x}^{(i)}$ starting at $s_1^{(i)}$. We use policy gradient (Section 5) with reward shaping derived from the training data to increase learning speed and exploration effectiveness (Section 6). Following work in robotics (e.g., Levine et al., 2016), we assume an instrumented environment with access to the world state to compute the reward during training only. We define our approach in general terms with demonstrations, but also experiment with training using goal states.

Evaluation We evaluate task completion error on a test set $\{(\bar{x}^{(i)}, s_1^{(i)}, s_g^{(i)})\}_{i=1}^M$, where $\bar{x}^{(i)}$ is an instruction, $s_1^{(i)}$ is a start state, and $s_g^{(i)}$ is the goal state. We measure execution error as the distance between the final execution state and $s_g^{(i)}$.

3 Related Work

Learning to follow instructions was studied extensively with structured environment representations, including with semantic parsing (Chen and Mooney, 2011; Kim and Mooney, 2012, 2013; Artzi and Zettlemoyer, 2013; Artzi et al., 2014a,b; Misra et al., 2015, 2016), alignment models (Andreas and Klein, 2015), reinforcement learning (Branavan et al., 2009, 2010; Vogel and Jurafsky, 2010), and neural network models (Mei et al., 2016). In contrast, we study the problem of an agent that takes as input instructions and raw visual input. Instruction following with visual input was studied with pipeline approaches that use separately learned models for visual reasoning (Matuszek et al., 2010, 2012; Tellex et al., 2011; Paul et al., 2016). Rather than decomposing the problem, we adopt a single-model approach and learn from instructions paired with demonstrations or goal states. Our work is related to Sung et al. (2015). While they use sensory input to select and adjust a trajectory observed during training, we are not restricted to training sequences. Executing instructions in non-learning settings has also received significant attention (e.g., Winograd, 1972; Webber et al., 1995; MacMahon et al., 2006).

Our work is related to a growing interest in problems that combine language and vision, including visual question answering (e.g., Antol et al., 2015; Andreas et al., 2016b,a), caption generation (e.g., Chen et al., 2015, 2016; Xu et al., 2015), and visual reasoning (Johnson et al., 2016; Suhr et al., 2017). We address the prediction of the next action given a world image and an instruction.

Reinforcement learning with neural networks has been used for various NLP tasks, including text-based games (Narasimhan et al., 2015; He et al., 2016), information extraction (Narasimhan et al., 2016), co-reference resolution (Clark and Manning, 2016), and dialog (Li et al., 2016).

Neural network reinforcement learning techniques have been recently studied for behavior learning tasks, including playing games (Mnih et al., 2013, 2015, 2016; Silver et al., 2016) and solving memory puzzles (Oh et al., 2016). In contrast to this line of work, our data is limited. Observing new states in a computer game simply requires playing it. However, our agent also considers natural language instructions. As the set of instructions is limited to the training data, the set of agent contexts seen during learning is constrained. We address the data efficiency problem by learning in a contextual bandit setting, which is known to be more tractable (Agarwal et al., 2014), and using reward shaping to increase exploration effectiveness. Zhu et al. (2017) address generalization of reinforcement learning to new target goals in visual search by providing the agent an image of the goal state. We address a related problem. However, we provide natural language and the agent must learn to recognize the goal state.

Reinforcement learning is extensively used in robotics (Kober et al., 2013). Similar to recent work on learning neural network policies for robot control (Levine et al., 2016; Schulman et al., 2015; Rusu et al., 2016), we assume an instrumented training environment and use the state to compute rewards during learning. Our approach adds the ability to specify tasks using natural language.

4 Model

We model the agent policy π with a neural network. The agent observes the instruction and an RGB image of the world. Given a world state s, the image I is generated using the function $\textsc{Img}(s)$. The instruction execution is generated one step at a time. At each step j, the agent observes an image I_j of the current world state s_j and the instruction $\bar{x}$, predicts the action a_j, and executes it to transition to the next state s_{j+1}.

Figure 2: Illustration of the policy architecture showing the 10th step in the execution of the instruction *Place the Toyota east of SRI* in the state from Figure 1. The network takes as input the instruction $\bar{x}$, image of the current state I_{10}, images of previous states I_8 and I_9 (with $K = 2$), and the previous action a_9. The text and images are embedded with LSTM and CNN. The actions are selected with the task specific multi-layer perceptron.

This process continues until STOP is predicted and the agent stops, indicating instruction completion. The agent also has access to K images of previous states and the previous action to distinguish between different stages of the execution (Mnih et al., 2015). Figure 2 illustrates our architecture.

Formally,[2] at step j, the agent considers an agent context $\tilde{s}_j$, which is a tuple $(\bar{x}, I_j, I_{j-1}, \ldots, I_{j-K}, a_{j-1})$, where $\bar{x}$ is the natural language instruction, I_j is an image of the current world state, the images $I_{j-1}, \ldots, I_{j-K}$ represent K previous states, and a_{j-1} is the previous action. The agent context includes information about the current state and the execution. Considering the previous action a_{j-1} allows the agent to avoid repeating failed actions, for example when trying to move in the direction of an obstacle. In Figure 2, the agent is given the instruction *Place the Toyota east of SRI*, is at the 10-th execution step, and considers $K = 2$ previous images.

We generate continuous vector representations for all inputs, and jointly reason about both text and image modalities to select the next action. We use a recurrent neural network (RNN; Elman, 1990) with a long short-term memory (LSTM; Hochreiter and Schmidhuber, 1997) recurrence to map the instruction $\bar{x} = \langle x_1, \ldots, x_n \rangle$ to a vector representation $\bar{\mathbf{x}}$. Each token x_i is mapped to a fixed dimensional vector with the learned embedding function $\psi(x_i)$. The instruction representation $\bar{\mathbf{x}}$ is computed by applying the LSTM recurrence to generate a sequence of hidden states $\mathbf{l}_i = \text{LSTM}(\psi(x_i), \mathbf{l}_{i-1})$, and computing the mean $\bar{\mathbf{x}} = \frac{1}{n}\sum_{i=1}^{n} \mathbf{l}_i$ (Narasimhan et al., 2015). The current image I_j and previous images I_{j-1},…,I_{j-K} are concatenated along the channel dimension and embedded with a convolutional neural network (CNN) to generate the visual state $\mathbf{v}$ (Mnih et al., 2013). The last action a_{j-1} is embedded with the function $\psi_a(a_{j-1})$. The vectors $\mathbf{v}_j$, $\bar{\mathbf{x}}$, and $\psi_a(a_{j-1})$ are concatenated to create the agent context vector representation $\tilde{\mathbf{s}}_j = [\mathbf{v}_j, \bar{\mathbf{x}}, \psi_a(a_{j-1})]$.

To compute the action to execute, we use a feedforward perceptron that decomposes according to the domain actions. This computation selects the next action conditioned on the instruction text and observations from both the current world state and recent history. In the block world domain, where actions decompose to selecting the block to move and the direction, the network computes block and direction probabilities. Formally, we decompose an action a to direction a^D and block a^B. We compute the feedforward network:

$$\begin{aligned}
\mathbf{h}^1 &= \max(\mathbf{W}^{(1)}\tilde{\mathbf{s}}_j + \mathbf{b}^{(1)}, 0) \\
\mathbf{h}^D &= \mathbf{W}^{(D)}\mathbf{h}^1 + \mathbf{b}^{(D)} \\
\mathbf{h}^B &= \mathbf{W}^{(B)}\mathbf{h}^1 + \mathbf{b}^{(B)} \quad ,
\end{aligned}$$

and the action probability is a product of the component probabilities:

$$\begin{aligned}
P(a_j^D = d \mid \bar{x}, s_j, a_{j-1}) &\propto \exp(\mathbf{h}_d^D) \\
P(a_j^B = b \mid \bar{x}, s_j, a_{j-1}) &\propto \exp(\mathbf{h}_b^B) \quad .
\end{aligned}$$

At the beginning of execution, the first action a_0 is set to the special value NONE, and previous images are zero matrices. The embedding function ψ is a learned matrix. The function ψ_a concatenates the embeddings of a_{j-1}^D and a_{j-1}^B, which are obtained from learned matrices, to compute the embedding of a_{j-1}. The model parameters θ include $\mathbf{W}^{(1)}$, $\mathbf{b}^{(1)}$, $\mathbf{W}^{(D)}$, $\mathbf{b}^{(D)}$, $\mathbf{W}^{(B)}$, $\mathbf{b}^{(B)}$, the parameters of the LSTM recurrence, the parameters of the convolutional network CNN, and the embedding matrices. In our experiments (Section 7), all parameters are learned without external resources.

5 Learning

We use policy gradient for reinforcement learning (Williams, 1992) to estimate the parameters θ of the agent policy. We assume access to a

[2] We use bold-face capital letters for matrices and bold-face lowercase letters for vectors. Computed input and state representations use bold versions of the symbols. For example, $\bar{\mathbf{x}}$ is the computed representation of an instruction $\bar{x}$.

training set of N examples $\{(\bar{x}^{(i)}, s_1^{(i)}, \bar{e}^{(i)})\}_{i=1}^{N}$, where $\bar{x}^{(i)}$ is an instruction, $s_1^{(i)}$ is a start state, and $\bar{e}^{(i)}$ is an execution demonstration starting from $s_1^{(i)}$ of instruction $\bar{x}^{(i)}$. The main learning challenge is learning how to execute instructions given raw visual input from relatively limited data. We learn in a contextual bandit setting, which provides theoretical advantages over general reinforcement learning. In Section 8, we verify this empirically.

Reward Function The instruction execution problem defines a simple problem reward to measure task completion. The agent receives a positive reward when the task is completed, a negative reward for incorrect completion (i.e., STOP in the wrong state) and actions that fail to execute (e.g., when the direction is blocked), and a small penalty otherwise, which induces a preference for shorter trajectories. To compute the reward, we assume access to the world state. This learning setup is inspired by work in robotics, where it is achieved by instrumenting the training environment (Section 3). The agent, on the other hand, only uses the agent context (Section 4). When deployed, the system relies on visual observations and natural language instructions only. The reward function $R^{(i)} : \mathcal{S} \times \mathcal{A} \rightarrow \mathbb{R}$ is defined for each training example $(\bar{x}^{(i)}, s_1^{(i)}, \bar{e}^{(i)})$, $i = 1 \ldots N$:

$$R^{(i)}(s,a) = \begin{cases} 1.0 & \text{if } s = s_{m^{(i)}} \text{ and } a = \texttt{STOP} \\ -1.0 & s \neq s_{m^{(i)}} \text{ and } a = \texttt{STOP} \\ -1.0 & a \text{ fails to execute} \\ -\delta & \text{else} \end{cases} ,$$

where $m^{(i)}$ is the length of $\bar{e}^{(i)}$.

The reward function does not provide intermediate positive feedback to the agent for actions that bring it closer to its goal. When the agent explores randomly early during learning, it is unlikely to encounter the goal state due to the large number of steps required to execute tasks. As a result, the agent does not observe positive reward and fails to learn. In Section 6, we describe how reward shaping, a method to augment the reward with additional information, is used to take advantage of the training data and address this challenge.

Policy Gradient Objective We adapt the policy gradient objective defined by Sutton et al. (1999) to multiple starting states and reward functions:

$$\mathcal{J} = \frac{1}{N} \sum_{i=1}^{N} V_{\pi}^{(i)}(s_1^{(i)}) \ ,$$

where $V_{\pi}^{(i)}(s_1^{(i)})$ is the value given by $R^{(i)}$ starting from $s_1^{(i)}$ under the policy π. The summation expresses the goal of learning a behavior parameterized by natural language instructions.

Contextual Bandit Setting In contrast to most policy gradient approaches, we apply the objective to a contextual bandit setting where immediate reward is optimized rather than total expected reward. The primary theoretical advantage of contextual bandits is much tighter sample complexity bounds when comparing upper bounds for contextual bandits (Langford and Zhang, 2007) even with an adversarial sequence of contexts (Auer et al., 2002) to lower bounds (Krishnamurthy et al., 2016) or upper bounds (Kearns et al., 1999) for total reward maximization. This property is particularly suitable for the few-sample regime common in natural language problems. While reinforcement learning with neural network policies is known to require large amounts of training data (Mnih et al., 2015), the limited number of training sentences constrains the diversity and volume of agent contexts we can observe during training. Empirically, this translates to poor results when optimizing the total reward (REINFORCE baseline in Section 8). To derive the approximate gradient, we use the likelihood ratio method:

$$\nabla_{\theta}\mathcal{J} = \frac{1}{N} \sum_{i=1}^{N} \mathbb{E}[\nabla_{\theta} \log \pi(\tilde{s}, a) R^{(i)}(s,a)] \ ,$$

where reward is computed from the world state but policy is learned on the agent context. We approximate the gradient using sampling.

This training regime, where immediate reward optimization is sufficient to optimize policy parameters θ, is enabled by the shaped reward we introduce in Section 6. While the objective is designed to work best with the shaped reward, the algorithm remains the same for any choice of reward definition including the original problem reward or several possibilities formed by reward shaping.

Entropy Penalty We observe that early in training, the agent is overwhelmed with negative reward and rarely completes the task. This results in the policy π rapidly converging towards a suboptimal deterministic policy with an entropy of 0. To delay premature convergence we add an entropy term to the objective (Williams and Peng, 1991; Mnih et al., 2016). The entropy term encourages a uniform distribution policy, and in practice stimulates exploration early during training. The regularized gradient is:

$$\nabla_{\theta}\mathcal{J} = \frac{1}{N} \sum_{i=1}^{N} \mathbb{E}[\nabla_{\theta} \log \pi(\tilde{s}, a) R^{(i)}(s,a) + \lambda \nabla_{\theta} H(\pi(\tilde{s}, \cdot))] \ ,$$

Algorithm 1 Policy gradient learning

```
Input: Training set $\{(\bar{x}^{(i)}, s_1^{(i)}, \bar{e}^{(i)})\}_{i=1}^N$, learning rate $\mu$,
    epochs $T$, horizon $J$, and entropy regularization term $\lambda$.
Definitions: $\textsc{Img}(s)$ is a camera sensor that reports an RGB
    image of state $s$. $\pi$ is a probabilistic neural network
    policy parameterized by $\theta$, as described in Section 4.
    $\textsc{Execute}(s, a)$ executes the action $a$ at the state $s$, and
    returns the new state. $R^{(i)}$ is the reward function for
    example $i$. $\textsc{Adam}(\Delta)$ applies a per-feature learning rate
    to the gradient $\Delta$ (Kingma and Ba, 2014).
Output: Policy parameters $\theta$.
 1: » Iterate over the training data.
 2: for $t = 1$ to $T$, $i = 1$ to $N$ do
 3:     $I_{1-K}, \ldots, I_0 = \vec{0}$
 4:     $a_0 = \texttt{NONE}$, $s_1 = s_1^{(i)}$
 5:     $j = 1$
 6:     » Rollout up to episode limit.
 7:     while $j \leq J$ and $a_j \neq \texttt{STOP}$ do
 8:         » Observe world and construct agent context.
 9:         $I_j = \textsc{Img}(s_j)$
10:         $\tilde{s}_j = (\bar{x}^{(i)}, I_j, I_{j-1}, \ldots, I_{j-K}, a_{j-1}^d)$
11:         » Sample an action from the policy.
12:         $a_j \sim \pi(\tilde{s}_j, a)$
13:         $s_{j+1} = \textsc{Execute}(s_j, a_j)$
14:         » Compute the approximate gradient.
15:         $\Delta_j \leftarrow \nabla_\theta \log \pi(\tilde{s}_j, a_j) R^{(i)}(s_j, a_j)$
                $+ \lambda \nabla_\theta H(\pi(\tilde{s}_j, \cdot))$
16:         $j += 1$
17:     $\theta \leftarrow \theta + \mu \textsc{Adam}(\frac{1}{j} \sum_{j'=1}^{j} \Delta_{j'})$
18: return $\theta$
```

where $H(\pi(\tilde{s}, \cdot))$ is the entropy of π given the agent context $\tilde{s}$, λ is a hyperparameter that controls the strength of the regularization. While the entropy term delays premature convergence, it does not eliminate it. Similar issues are observed for vanilla policy gradient (Mnih et al., 2016).

Algorithm Algorithm 1 shows our learning algorithm. We iterate over the data T times. In each epoch, for each training example $(\bar{x}^{(i)}, s_1^{(i)}, \bar{e}^{(i)})$, $i = 1 \ldots N$, we perform a rollout using our policy to generate an execution (lines 7 - 16). The length of the rollout is bound by J, but may be shorter if the agent selected the STOP action. At each step j, the agent updates the agent context $\tilde{s}_j$ (lines 9 - 10), samples an action from the policy π (line 12), and executes it to generate the new world state s_{j+1} (line 13). The gradient is approximated using the sampled action with the computed reward $R^{(i)}(s_j, a_j)$ (line 15). Following each rollout, we update the parameters θ with the mean of the gradients using $\textsc{Adam}$ (Kingma and Ba, 2014).

6 Reward Shaping

Reward shaping is a method for transforming a reward function by adding a *shaping term* to the problem reward. The goal is to generate more informative updates by adding information to the reward. We use this method to leverage the training demonstrations, a common form of supervision for training systems that map language to actions. Reward shaping allows us to fully use this type of supervision in a reinforcement learning framework, and effectively combine learning from demonstrations and exploration.

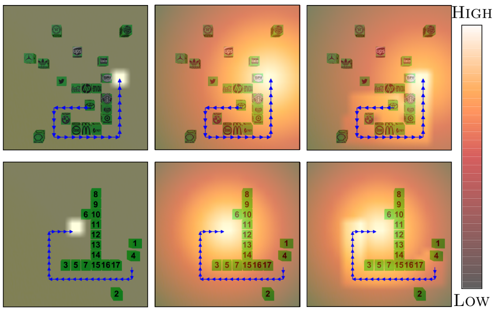

Figure 3: Visualization of the shaping potentials for two tasks. We show demonstrations (blue arrows), but omit instructions. To visualize the potentials intensity, we assume only the target block can be moved, while rewards and potentials are computed for any block movement. We illustrate the sparse problem reward (left column) as a potential function and consider only its positive component, which is focused on the goal. The middle column adds the distance-based potential. The right adds both potentials.

Adding an arbitrary shaping term can change the optimality of policies and modify the original problem, for example by making bad policies according to the problem reward optimal according to the shaped function.[3] Ng et al. (1999) and Wiewiora et al. (2003) outline potential-based terms that realize sufficient conditions for *safe* shaping.[4] Adding a shaping term is safe if the order of policies according to the shaped reward is identical to the order according to the original problem reward. While safe shaping only applies to optimizing the total reward, we show empirically the effectiveness of the safe shaping terms we design in a contextual bandit setting.

We introduce two shaping terms. The final shaped reward is a sum of them and the problem reward. Similar to the problem reward, we define example-specific shaping terms. We modify the reward function signature as required.

Distance-based Shaping (F_1) The first shaping term measures if the agent moved closer to the goal state. We design it to be a safe potential-based

[3] For example, adding a shaping term $F = -R$ will result in a shaped reward that is always 0, and any policy will be trivially optimal with respect to it.

[4] For convenience, we briefly overview the theorems of Ng et al. (1999) and Wiewiora et al. (2003) in Appendix A.

term (Ng et al., 1999):

$$F_1^{(i)}(s_j, a_j, s_{j+1}) = \phi_1^{(i)}(s_{j+1}) - \phi_1^{(i)}(s_j) \ .$$

The potential $\phi_1^{(i)}(s)$ is proportional to the negative distance from the goal state $s_g^{(i)}$. Formally, $\phi_1^{(i)}(s) = -\eta \| s - s_g^{(i)} \|$, where η is a constant scaling factor, and $\|.\|$ is a distance metric. In the block world, the distance between two states is the sum of the Euclidean distances between the positions of each block in the two states, and η is the inverse of block width. The middle column in Figure 3 visualizes the potential $\phi_1^{(i)}$.

Trajectory-based Shaping (F_2) Distance-based shaping may lead the agent to sub-optimal states, for example when an obstacle blocks the direct path to the goal state, and the agent must temporarily increase its distance from the goal to bypass it. We incorporate complete trajectories by using a simplification of the shaping term introduced by Brys et al. (2015). Unlike F_1, it requires access to the previous state and action. It is based on the look-back advice shaping term of Wiewiora et al. (2003), who introduced safe potential-based shaping that considers the previous state and action. The second term is:

$$F_2^{(i)}(s_{j-1}, a_{j-1}, s_j, a_j) = \phi_2^{(i)}(s_j, a_j) - \phi_2^{(i)}(s_{j-1}, a_{j-1}) \ .$$

Given $\bar{e}^{(i)} = \langle (s_1, a_1), \dots, (s_m, a_m) \rangle$, to compute the potential $\phi_2^{(i)}(s, a)$, we identify the closest state s_j in $\bar{e}^{(i)}$ to s. If $\eta \| s_j - s \| < 1$ and $a_j = a$, $\phi_2^{(i)}(s, a) = 1.0$, else $\phi_2^{(i)}(s, a) = -\delta_f$, where δ_f is a penalty parameter. We use the same distance computation and parameter η as in F_1. When the agent is in a state close to a demonstration state, this term encourages taking the action taken in the related demonstration state. The right column in Figure 3 visualizes the effect of the potential $\phi_2^{(i)}$.

7 Experimental Setup

Environment We use the environment of Bisk et al. (2016). The original task required predicting the source and target positions for a single block given an instruction. In contrast, we address the task of moving blocks on the plane to execute instructions given visual input. This requires generating the complete sequence of actions needed to complete the instruction. The environment contains up to 20 blocks marked with logos or digits. Each block can be moved in four directions. Including the STOP action, in each step, the agent selects between 81 actions. The set of actions is constant and is not limited to the blocks present. The transition function is deterministic. The size of each block step is 0.04 of the board size. The agent observes the board from above. We adopt a relatively challenging setup with a large action space. While a simpler setup, for example decomposing the problem to source and target prediction and using a planner, is likely to perform better, we aim to minimize task-specific assumptions and engineering of separate modules. However, to better understand the problem, we also report results for the decomposed task with a planner.

Data Bisk et al. (2016) collected a corpus of instructions paired with start and goal states. Figure 1 shows example instructions. The original data includes instructions for moving one block or multiple blocks. Single-block instructions are relatively similar to navigation instructions and referring expressions. While they present much of the complexity of natural language understanding and grounding, they rarely display the planning complexity of multi-block instructions, which are beyond the scope of this paper. Furthermore, the original data does not include demonstrations. While generating demonstrations for moving a single block is straightforward, disambiguating action ordering when multiple blocks are moved is challenging. Therefore, we focus on instructions where a single block changes its position between the start and goal states, and restrict demonstration generation to move the changed block. The remaining data, and the complexity it introduces, provide an important direction for future work.

To create demonstrations, we compute the shortest paths. While this process may introduce noise for instructions that specify specific trajectories (e.g., *move SRI two steps north and . . .*) rather than only describing the goal state, analysis of the data shows this issue is limited. Out of 100 sampled instructions, 92 describe the goal state rather than the trajectory. A secondary source of noise is due to discretization of the state space. As a result, the agent often can not reach the exact target position. The demonstrations error illustrates this problem (Table 3). To provide task completion reward during learning, we relax the state comparison, and consider states to be equal if the sum of block distances is under the size of one block.

The corpus includes 11,871/1,719/3,177 instructions for training/development/testing. Table 1 shows corpus statistic compared to the commonly used SAIL navigation corpus (MacMahon

	SAIL	Blocks
Number of instructions	3,237	16,767
Mean instruction length	7.96	15.27
Vocabulary	563	1,426
Mean trajectory length	3.12	15.4

Table 1: Corpus statistics for the block environment we use and the SAIL navigation domain.

et al., 2006; Chen and Mooney, 2011). While the SAIL agent only observes its immediate surroundings, overall the blocks domain provides more complex instructions. Furthermore, the SAIL environment includes only 400 states, which is insufficient for generalization with vision input. We compare to other data sets in Appendix D.

Evaluation We evaluate task completion error as the sum of Euclidean distances for each block between its position at the end of the execution and in the gold goal state. We divide distances by block size to normalize for the image size. In contrast, Bisk et al. (2016) evaluate the selection of the source and target positions independently.

Systems We report performance of ablations, the upper bound of following the demonstrations (Demonstrations), and five baselines: (a) STOP: the agent immediately stops, (b) RANDOM: the agent takes random actions, (c) SUPERVISED: supervised learning with maximum-likelihood estimate using demonstration state-action pairs, (d) DQN: deep Q-learning with both shaping terms (Mnih et al., 2015), and (e) REINFORCE: policy gradient with cumulative episodic reward with both shaping terms (Sutton et al., 1999). Full system details are given in Appendix B.

Parameters and Initialization Full details are in Appendix C. We consider $K = 4$ previous images, and horizon length $J = 40$. We initialize our model with the SUPERVISED model.

8 Results

Table 2 shows development results. We run each experiment three times and report the best result. The RANDOM and STOP baselines illustrate the task complexity of the task. Our approach, including both shaping terms in a contextual bandit setting, significantly outperforms the other methods. SUPERVISED learning demonstrates lower performance. A likely explanation is test-time execution errors leading to unfamiliar states with poor later performance (Kakade and Langford, 2002), a form of the covariate shift problem. The low performance of REINFORCE and DQN illustrates the challenge of general reinforcement learning with limited data due to relatively high sample complexity (Kearns et al., 1999; Krishnamurthy et al., 2016). We also report results using ensembles of the three models.

Table 3: Mean and median (Med.) test results.

We ablate different parts of our approach. Ablations of supervised initialization (our approach w/o sup. init) or the previous action (our approach w/o prev. action) result in increase in error. While the contribution of initialization is modest, it provides faster learning. On average, after two epochs, we observe an error of 3.94 with initialization and 6.01 without. We hypothesize that the F_2 shaping term, which uses full demonstrations, helps to narrow the gap at the end of learning. Without supervised initialization and F_2, the error increases to 5.45 (the 0% point in Figure 4). We observe the contribution of each shaping term and their combination. To study the benefit of potential-based shaping, we experiment with a negative distance-to-goal reward. This reward replaces the problem reward and encourages getting closer to the goal (our approach w/distance reward). With this reward, learning fails to converge, leading to a relatively high error.

Figure 4 shows our approach with varying

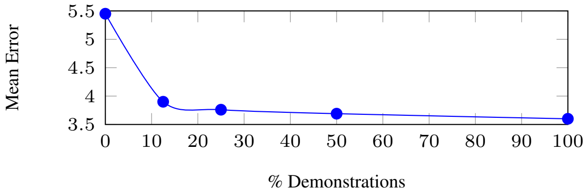

Figure 4: Mean distance error as a function of the ratio of training examples that include complete trajectories. The rest of the data includes the goal state only.

amount of supervision. We remove demonstrations from both supervised initialization and the F_2 shaping term. For example, when only 25% are available, only 25% of the data is available for initialization and the F_2 term is only present for this part of the data. While some demonstrations are necessary for effective learning, we get most of the benefit with only 12.5%.

Table 3 provides test results, using the ensembles to decrease the risk of overfitting the development. We observe similar trends to development result with our approach outperforming all baselines. The remaining gap to the demonstrations upper bound illustrates the need for future work.

To understand performance better, we measure *minimal distance* (min. distance in Tables 2 and 3), the closest the agent got to the goal. We observe a strong trend: the agent often gets close to the goal and fails to stop. This behavior is also reflected in the number of steps the agent takes. While the mean number of steps in development demonstrations is 15.2, the agent generates on average 28.7 steps, and 55.2% of the time it takes the maximum number of allowed steps (40). Testing on the training data shows an average 21.75 steps and exhausts the number of steps 29.3% of the time. The mean number of steps in training demonstrations is 15.5. This illustrates the challenge of learning how to be behave at an absorbing state, which is observed relatively rarely during training. This behavior also shows in our video.[5]

We also evaluate a supervised learning variant that assumes a perfect planner.[6] This setup is similar to Bisk et al. (2016), except using raw image input. It allows us to roughly understand how well the agent generates actions. We observe a mean error of 2.78 on the development set, an improvement of almost two points over supervised learning with our approach. This illustrates the complexity of the complete problem.

We conduct a shallow linguistic analysis to understand the agent behavior with regard to differences in the language input. As expected, the agent is sensitive to unknown words. For instructions without unknown words, the mean development error is 3.49. It increases to 3.97 for instructions with a single unknown word, and to 4.19 for two.[7] We also study the agent behavior when observing new phrases composed of known words by looking at instructions with new n-grams and no unknown words. We observe no significant correlation between performance and new bi-grams and tri-grams. We also see no meaningful correlation between instruction length and performance. Although counterintuitive given the linguistic complexities of longer instructions, it aligns with results in machine translation (Luong et al., 2015).

9 Conclusions

We study the problem of learning to execute instructions in a situated environment given only raw visual observations. Supervised approaches do not explore adequately to handle test time errors, and reinforcement learning approaches require a large number of samples for good convergence. Our solution provides an effective combination of both approaches: reward shaping to create relatively stable optimization in a contextual bandit setting, which takes advantage of a signal similar to supervised learning, with a reinforcement basis that admits substantial exploration and easy avenues for smart initialization. This combination is designed for a few-samples regime, as we address. When the number of samples is unbounded, the drawbacks observed in this scenario for optimizing longer term reward do not hold.

Abstract

We present a machine learning analysis of eye-tracking data for the detection of mild cognitive impairment, a decline in cognitive abilities that is associated with an increased risk of developing dementia. We compare two experimental configurations (reading aloud versus reading silently), as well as two methods of combining information from the two trials (concatenation and merging). Additionally, we annotate the words being read with information about their frequency and syntactic category, and use these annotations to generate new features. Ultimately, we are able to distinguish between participants with and without cognitive impairment with up to 86% accuracy.

1 Introduction

As the global population ages, the prevalence of dementia is increasing (Prince et al., 2013). The term “dementia” refers to an atypical and pathological decline in cognitive abilites, encompassing a range of possible underlying causes. Detecting the onset of dementia as early as possible is important for a number of reasons, including timely access to medication and treatment, increasing support for activities of daily living (such as maintaining proper nutrition and hygiene), reducing the individual’s engagement in potentially risky activities (e.g. driving an automobile), and giving individuals, families, and caregivers time to prepare (Solomon and Murphy, 2005; Ashford et al., 2006; Calzà et al., 2015).

In this study, we investigate the possibility of using eye-tracking data and machine learning to detect early, subtle signs of cognitive impairment. Previous work has suggested that changes in eye movements while reading do occur in Alzheimer’s disease (Lueck et al., 2000; Fernández et al., 2013; Pereira et al., 2014; Biondi et al., 2017). However, our participants do not have a dementia diagnosis; rather, they have been diagnosed with “mild cognitive impairment”, meaning they are starting to show very early signs of cognitive decline, and are at an increased risk of developing dementia. We test the relative merits of collecting eye-tracking data while reading silently and aloud, and explore the idea of augmenting eye-tracking features with linguistic information.

We begin by presenting some background information on cognitive and linguistic changes in dementia, and discuss previous work on eye-tracking and natural language processing approaches to detecting cognitive decline. We then explain our experimental set-up, feature extraction, and machine learning pipeline. We present results for reading silently and reading aloud, and discuss the overall implications and interpretation of our results. Finally we acknowledge the limitations of the current work and suggest areas of future research.

2 Background

There are several different types of dementia, Alzheimer’s disease (AD) being the most common one. AD typically debuts with symptoms related to executive cognitive functioning and memory, but also included are specific linguistic impairments, primarily related to semantic processing. Mild cognitive impairment (MCI) can be seen as a stage of pre-clinical dementia, and may manifest years before an actual dementia diagnosis. Persons with MCI show symptoms across several cognitive domains, where global cognitive ability, episodic memory, perceptual speed, and executive functioning are most clearly affected. However, the performance of persons with MCI over-

Proceedings of the 2017 Conference on Empirical Methods in Natural Language Processing, pages 1016–1026
Copenhagen, Denmark, September 7–11, 2017.

lap greatly with the performance of healthy controls, which highlights the complexity and heterogeneity of the diagnosis (Bäckman et al., 2005).

Taler and Phillips (2008) reviewed the literature on language impairments in MCI and Alzheimer's disease, and found that the linguistic deficits seen in AD are also present in MCI, albeit to a lesser degree. The main deficits are located on the semantic level (for example, difficulty naming pictures or coming up with words from a particular semantic category), whereas there are no clear evidence of problems regarding syntactic processing. Sentence comprehension is typically impaired in persons with MCI, but there is a great degree of individual variation. Previous research suggests that using tasks that include a possibility to analyse temporal measures (such as reaction time) will improve the ability to distinguish between MCI and healthy controls, and may also be useful as a prognostic factor when investigating which subjects with MCI will convert to AD (Taler and Phillips, 2008).

There has been growing interest in applying machine learning techniques to detect mild cognitive impairment from various linguistic data. Roark et al. (2011) measured the complexity and information content of narrative story re-tellings from 37 participants with MCI and 37 healthy controls, and was able to classify the groups with an AUC of 0.73 using these features alone, or 0.86 by combining this information with clinical test scores. Tóth et al. (2015) leveraged acoustic features (including articulation rate, speech rate, utterance length, pause duration, number of pauses, and hesitation rate) to distinguish between 32 participants with MCI and 19 elderly controls with a best accuracy of 80.4%.

Other research has considered the closely related problem of distinguishing dementia patients from controls through automated analysis of speech and language production (Thomas et al., 2005; Pakhomov et al., 2010; Guinn and Habash, 2012; Meilán et al., 2014; Jarrold et al., 2014; Fraser et al., 2016; Rentoumi et al., 2014; Garrard et al., 2014; Prud'hommeaux and Roark, 2015; Yancheva et al., 2015).

In contrast, computational analyses of language processing and comprehension for the goal of detecting cognitive decline are much rarer, possibly because it is more difficult to quantify automatically. Classical studies of language processing in dementia have considered both listening (for example, Rochon et al. 1994; Kempler et al. 1998; Welland et al. 2002) and reading (for example, Patterson et al. 1994; Storandt et al. 1995); here we focus on reading as the input modality. One well-established method for estimating the processing demands during reading comprehension is through eye-tracking. There is a vast literature on eye-tracking in reading which we will not attempt to fully summarize here, but merely introduce some key vocabulary and basic concepts.

When reading, the eye moves through the text in a series of *fixations* and *saccades*. A fixation occurs when the eye temporarily rests on a word. This time is used to process the incoming information, and to plan the next eye movement. Fixations typically last for around 200-300 ms, and are on average slightly longer in oral reading than in silent reading (Rayner, 1998). In between fixations, the eye makes a rapid movement called a *saccade*. Saccades can move the eye forward through the text (a *forward saccade*) or backward (a *saccadic regression* or simply a *regression*). Saccades tend to be around 6-8 characters in size in English (although this is language-dependent; for example, Liversedge et al. (2016) found longer saccades in Finnish and shorter saccades in Chinese), and around 10-15% of saccades in reading are regressions. Both strong and poor readers make regressions, but stronger readers seem to have the ability to accurately direct their eyes back to a difficult or ambiguous passage, whereas weaker readers perform more general back-tracking (Murray and Kennedy, 1988).

Whether a word is fixated on, and for how long, is influenced by a number of word-level and contextual factors. Content words are fixated on approximately 85% of the time, while function words are fixated on only 35% of the time (Rayner, 1998). There is some evidence that word type effects may be even more fine-grained, as work by Barrett et al. (2016) demonstrates the possibility for part-of-speech tagging based on eye-tracking information. The number and duration of fixations is also affected by word frequency (Raney and Rayner, 1995), word predictability in context (Kliegl et al., 2004), the position of the word in the sentence (Rayner et al., 2000), the emotional valence of the word (Scott et al., 2012), and word length (Rayner, 1998).

While sharing several features, silent reading and reading aloud are believed to potentially differ in some ways. The main division between the two types of reading is related to the access of phonological and semantic representations in the brain. In silent reading, there has been a great deal of discussion on whether the decoding of orthographic information is directly mapped to semantic meaning, or whether letters are mapped to phonemes, which are then connected to semantic meaning. By using a computational approach based on previous research about reading, Harm and Seidenberg (2004) investigate the two proposed routes and suggest a combined model, where the phonological path and direct path are simultaneously activated and share the workload depending on factors such as word frequency and spelling-sound consistency. The activation of semantic information during reading aloud is also a matter that has been discussed and researched for some time. It was previously thought that during reading aloud, the semantic level of information did not need to be activated, but rather letters could be matched directly to phonemes and then articulated. However, computational models (Coltheart et al., 2001) and for example fMRI data (Graves et al., 2010) have shown that semantic processing is involved in reading aloud, but to varying degrees.

Previous work has identified differences between the eye-movements of individuals with cognitive impairment relative to healthy controls. Lueck et al. (2000) reported that participants with AD had more irregular eye movements when reading, longer fixation times, and more saccadic regressions. Fernández et al. (2013) found that participants with AD had an increased number of fixations and regressions, and also skipped more words than healthy controls. Pereira et al. (2014) presented a review of the literature on eye-tracking in MCI and AD, and suggested that such techniques may be able to predict the conversion from MCI to AD, partly due to the sensitivity of eye-movements to early changes in memory, visual, and executive processes.

Earlier this year, in a paper posted on arXiv, Biondi et al. (2017) reported a classification accuracy of 88.3% in distinguishing between participants with AD and healthy controls through eye-tracking measures. They recorded eye movements from 40 healthy elderly adults and 20 AD patients while they read 120 sentences. The sentences varied in terms of predictability and familiarity (for example, some of the sentences were well-known proverbs). Each sentence was recorded as a separate trial. After removing 10% of the trials as outliers, 90% of the remaining trials were used to train a deep sparse-autoencoder, and 10% were reserved as test data. It is assumed that some of the training data and test data originated from the same participants.

In this paper, we first aim to reproduce aspects of the Biondi et al. (2017) study, although with some notable differences. Our study was conducted in Swedish, rather than Spanish, and in each trial the participant was presented with an entire paragraph, rather than individual sentences, which affects our feature calculations and choice of classifiers. Additionally, we present a comparison of two different trial configurations (reading silently versus reading aloud), and introduce new word-level features to associate linguistic information with the eye-tracking features. Furthermore, perhaps the most critical difference from a clinical standpoint is that our participants are in a milder stage of cognitive decline, and have not received AD diagnoses. Thus we aim explore whether this promising approach can be used to detect the earliest stages of cognitive impairment.

3 Methods

3.1 Participants

The participants were recruited from the Gothenburg MCI study, which is a large longitudinal study on mild cognitive impairment (Wallin et al., 2016). The overall Gothenburg MCI study is approved by the local ethical committee review board (reference number: L09199, 1999; T479-11, 2011); while the currently described study was approved by the local ethical committee decision 206-16, 2016.

To be included in this study, the participants had to fulfill certain inclusion and exclusion criteria: participants had to be native Swedish speakers and had to be able to read and understand information about the project, and be able to give consent. Participants could not have dyslexia or other reading difficulties not relating to their current cognitive impairment. We also excluded patients with deep depression, ongoing substance abuse, poor vision that cannot be corrected with glasses or contact lenses, and participants that were diagnosed with other serious psychiatric, neurological or brain-related diseases, such as Parkinson's dis-

	MCI ($n = 27$)	HC ($n = 30$)
Age (years)	70.3 (5.8)	68.0 (7.5)
Education (years)	14.2 (3.6)	13.3 (3.7)
Sex (M/F)	13/14	9/21
MMSE	28.2 (1.3)	29.6 (0.6)

Table 1: Demographic information for participants with mild cognitive impairment (MCI) and healthy controls (HC). Age, education, and Mini-Mental State Exam (MMSE) scores are given in the format: mean (standard deviation). The MMSE is a general test of cognitive status and has a maximum score of 30.

ease, amyotrophic lateral sclerosis, brain tumour or stroke. Three groups of participants took part in the study: persons with mild cognitive impairment (MCI), persons with subjective cognitive impairment (SCI), and healthy controls (HC). Participants have all been assessed with a battery of tests, from neuropsychological examinations to structural MRI, blood tests, and lumbar punctures. The groups analysed and compared in this paper are the MCI group and the control group. Six control participants and five MCI participants were excluded from the current analysis as a result of calibration problems with the eye-tracker (e.g. due to cataracts or eye inflammation).

Participant information can be seen in Table 1. There is no significant difference between the groups on age or education. The controls do have significantly higher Mini-Mental State Exam (MMSE) scores, on average ($p < 0.0001$). However, we note that the average MMSE score for our MCI participants is 28.2 (out of 30), which is considered to be “normal” (Grut et al., 1993). We contrast this with the AD participants in the study by Biondi et al. (2017), who had an average MMSE score of 24.2. In fact, the healthy control participants in that study had an average MMSE of 27.8, very similar to our MCI group. This indicates the subtle nature of the impairment seen in the MCI category.

3.2 Eye-tracking experiments

The eye-tracking experiments were carried out in a quiet lab environment. We used an EyeLink 1000 Desktop Mount with monocular eye-tracking, and used a headrest for head stabilization. Head stabilization provides an increased eye-tracking performance. The sampling rate was set to 1000 Hz.

The participants read two short texts, and after each text they answered five questions about the texts. The first text was read silently, while the second text was read aloud. Both texts were taken from the International Reading Speed Texts (IReST), which is a collection of texts that is available in 17 different languages. They are 146 words long in Swedish, and were developed to be used as an evaluation tool for impairments in vision or reading ability (Trauzettel-Klosinski et al., 2012). We chose to present complete paragraphs (rather than individual sentences) to simulate a more natural reading task, requiring the integration and recollection of information from the beginning through to the end of the paragraph.

Areas of interest (AOIs) were defined in the text, and each word was labeled as a separate AOI. Eye movements, such as saccades and fixations, are then calculated with respect to the predefined AOIs. Fixations occurring outside the AOIs are not considered in this analysis.

The eye-tracker was calibrated for each participant using a 9-point calibration procedure, and drift-corrected between Trial 1 and Trial 2. However, visual inspection of the data revealed a tendency for downward drift, particularly in the second trial. This was corrected manually, where necessary, to the degree agreed upon by two of the authors (K.C.F. and K.L.F.).

3.3 Features

As our baseline, we consider the 13 features presented in Biondi et al. (2017), and summarized in Table 2. Duration and amplitude features were log-transformed before computing the mean and standard deviation (Wotschack, 2009). The first fixation of each trial is discarded, and analysis starts from the second fixation (Holmqvist et al., 2011). As in Biondi et al. (2017), we partition the fixations into 4 categories: first-pass first fixations, later-pass first fixations[1], multi-fixations, and refixations. These definitions are given in Table 2, but for the sake of clarity we also present a simple truth table summarizing the four types of fixations in Table 3.

We then augment these baseline features with information about the words in the text, namely their frequency and word type. We first perform basic syntactic and morphological analysis of the

[1] Biondi et al. (2017) refer to these as “unique” fixations, but this terminology could be ambiguous and thus we have avoided it here.

Gaze duration (mean and s.d.) The mean and standard deviation of the length of time spent fixating on a word, averaged over all words in a trial.

Saccade amplitude (mean and s.d.) The mean and standard deviation of the amplitude of the saccades, averaged over all saccades in a trial.

Total fixations The total number of fixations in a trial.

Total first-pass first fixations The total number of first fixations occurring in the first pass of a trial. That is, a first-pass first fixation occurs when it is the first fixation on the given word, and there have been no fixations on any words occurring later in the text.

Total later-pass first fixations The total number of first fixations occurring outside the first-pass of a trial. That is, a later-pass first fixation occurs when it is the first fixation on the given word, but there have already been fixations on words occurring later in the text.

Total multi-fixations The total number of fixations on a word in the first-pass, excluding the first fixation. That is, a multi-fixation occurs when a word is fixated on multiple times in the run which starts with a first-pass first fixation.

Total re-fixations The total number of fixations on a word outside the first pass, excluding the first fixation.

First-pass first fixation duration (mean and s.d.) The mean and standard deviation of the duration of the first-pass first fixations.

Later-pass first fixation duration (mean and s.d.) The mean and standard deviation of the duration of the later-pass first fixations.

Table 2: Eye-movement features.

		Have any later words been visited?	
		No	Yes
Has this word been visited yet?	No	First-pass first fixation	Later-pass first fixation
	Yes	Multi-fixation	Re-fixation

Table 3: Four types of fixations

two texts using the Sparv annotation tool[2] (Borin et al., 2016). Specifically, each word was lemmatized and labeled with its part-of-speech (POS).

We assign a frequency value for each word lemma according to the number of times it occurs (per one million words) in the "Modern" language section of the Korp Swedish language corpus[3], which contained 10.7 billion word tokens at the time of writing (Borin et al., 2012). These frequency values are POS-disambiguated. We then partition the frequency values into *high* and *low* frequencies, with a threshold of 20 occurrences per million words. This threshold was chosen manually by observing the frequency distribution of the words in the two texts. We also partition the POS labels into two categories: *content* words and *function* words. Content words are defined as nouns, verbs, adjectives, and adverbs; everything else is considered to be a function word.

We then define an augmented feature set, hereafter *Biondi+word*, which takes into account these word-level annotations. Specifically, we create new features corresponding to each of the fixation-based baseline features. (The original feature set also includes saccade amplitude, the computation of which is not attached to any one particular word.) When the original feature involves a mean and standard deviation, we compute the ratio of those values computed on the low:high frequency words and the content:function words. To give an example, for "mean gaze duration", we compute the ratio of the mean gaze duration on low frequency words to mean gaze duration on high frequency words, and the ratio of gaze duration on content words to gaze duration on function words. When the original feature is a raw count, we compute a proportion instead. So for "total fixations", we compute the proportion of total fixations which occur on low-frequency words, and the proportion of total fixations which occur on content words. In this way we define 22 new features to augment the

[2] https://spraakbanken.gu.se/eng/research/infrastructure/sparv

[3] https://spraakbanken.gu.se/eng/korp-info

original Biondi set.

Clearly, we expect these new features to be somewhat correlated with each other, since function words tend also be high-frequency words. However, many content words are also labeled as high-frequency in our methodology, such as *bil* (English: *car*) and *potatis* (English: *potato*).

3.4 Classification framework

We consider three classification algorithms: naïve Bayes (NB), support vector machine (SVM), and logistic regression (LR), implemented in WEKA Version 3.9.1 (Hall et al., 2009). Given the small size of our data set, we forego parameter optimization and use the default parameters; i.e., for LR we use a ridge regression parameter of 10^{-8}, and for SVM we use a first degree polynomial kernel and a complexity parameter of 1.0. For feature selection, we use a wrapper method with a NB classifier. We evaluate the classifier using leave-one-out cross validation, in which at every iteration one data point is held out as a test point, and all remaining points are used for feature selection and classifier training. We report the average classification accuracy across folds. For our dataset, the majority class baseline is 52.6%.

4 Results

4.1 Individual trials

We first consider each trial individually, as we expect there may be differences in eye-movements when reading silently (Trial 1) versus reading aloud (Trial 2). The results for each classifier and each feature set for the first trial are given in Table 4a. Using the augmented feature set hurts classification accuracy in all cases, and the best accuracy of 75.4% is achieved using the naïve Bayes classifier and the Biondi feature set.

When using the data from Trial 2 (Table 4b), the augmented feature set again leads to lower accuracies in all cases, and the best result of 66.7% is achieved by the SVM and naïve Bayes classifiers with the Biondi feature set. In every case, we observe that the classification accuracies are the same or worse on Trial 2 compared to Trial 1. That is, we are able to extract less diagnostically-useful information when the participant is reading aloud than when they are reading silently. This makes sense, since reading aloud is a more constrained task: the reader must keep moving forward at a reasonable pace to avoid disruptions in the spoken narrative. This limits the opportunity for the eyes to move freely around the text. Furthermore, in the reading aloud paradigm, the examiner presented the comprehension questions as soon as the participant had reached the end of the text, in contrast to the silent reading paradigm, in which the participants themselves indicated when they were ready for the questions to be displayed.

	SVM	NB	LR
Biondi	66.7	75.4	73.6
Biondi+word	64.9	71.9	68.4

(a) Trial 1: Reading silently

	SVM	NB	LR
Biondi	66.7	66.7	64.9
Biondi+word	63.1	64.9	63.1

(b) Trial 2: Reading aloud

Table 4: Classifier accuracies for individual trials.

4.2 Combining the trials

We now examine whether we can combine information from the two trials to improve classification accuracy. We consider two different methods for combining the data: (1) concatenating the feature vectors from each trial, and (2) computing the features across both trials, as if they are simply two halves of a single trial. The first method has the advantage of preserving any salient differences between the two experimental paradigms (e.g. if a feature is relevant only when reading silently, that signal will remain in the data). The second method, which we will refer to as *merging*, has the benefit of essentially doubling the amount of data used to compute each feature, possibly leading to more accurate estimates.

The results for each combination are given in Table 5. In most cases, the best accuracy is achieved using the Biondi feature set alone. However, the highest accuracy is 86.0%, which occurs in the merged configuration using the naïve Bayes classifier with the Biondi+word feature set. In every case, a higher accuracy is achieved by merging, rather than concatenating, the data.

4.3 Classification summary

Figure 1 shows the results for each trial and feature set, averaged over the three classifiers. In general, the classifiers trained on Trial 2 did worse than those trained on Trial 1. Concatenating the feature vectors from the two trials resulted in better accu-

	SVM	NB	LR

racies than using Trial 2 data alone, but marginally worse accuracies than using Trial 1 data alone. The best results were achieved by merging the data from the two trials. Using the Biondi feature set alone did better than using the augmented feature set in the first three cases, but the Biondi+word feature set led to slightly higher accuracies in the merged configuration.

However, not all of the observed trends are statistically significant. A 2-way ANOVA revealed a significant effect of trial ($p = 5.0 \times 10^{-7}$) but not feature set on classification accuracy. A Tukey post-hoc test determined that the accuracies in the merged trials are significantly better than in Trial 1 ($p = 6.8 \times 10^{-4}$), Trial 2 ($p = 4.0 \times 10^{-7}$), and the concatenated trials ($p = 1.2 \times 10^{-5}$). However, there is no significant difference between Trial 1 and Trial 2, nor between either of those trials and the concatenated trials.

4.4 Feature analysis

To determine which features help distinguish between the groups, we perform a two-tailed heteroscedastic t-test on all of the features, with Bonferroni correction for repeated comparisons. For this analysis, we consider data from the merged trials, since they led to the best accuracies. Only two features were found to be significantly different between the groups after correction; these are given in Table 6. Consistent with the classification results, none of the frequency or word type features are significant. The total number of first-pass first fixations is significantly higher in the control group but, in contrast, the number of later-pass first fixations is higher in the MCI group. This suggests that the controls have a greater tendency to read through the text from start-to-finish, while the MCI participants tend to skip over words and then return to them later. An example of these different reading patterns can be seen in Figure 2. While this figure only shows data for two participants, it is interesting to note that there is a qualitatively greater difference on the silent trial (Figure 2a and Figure 2c) than in the reading aloud trial (Figure 2b and Figure 2d).

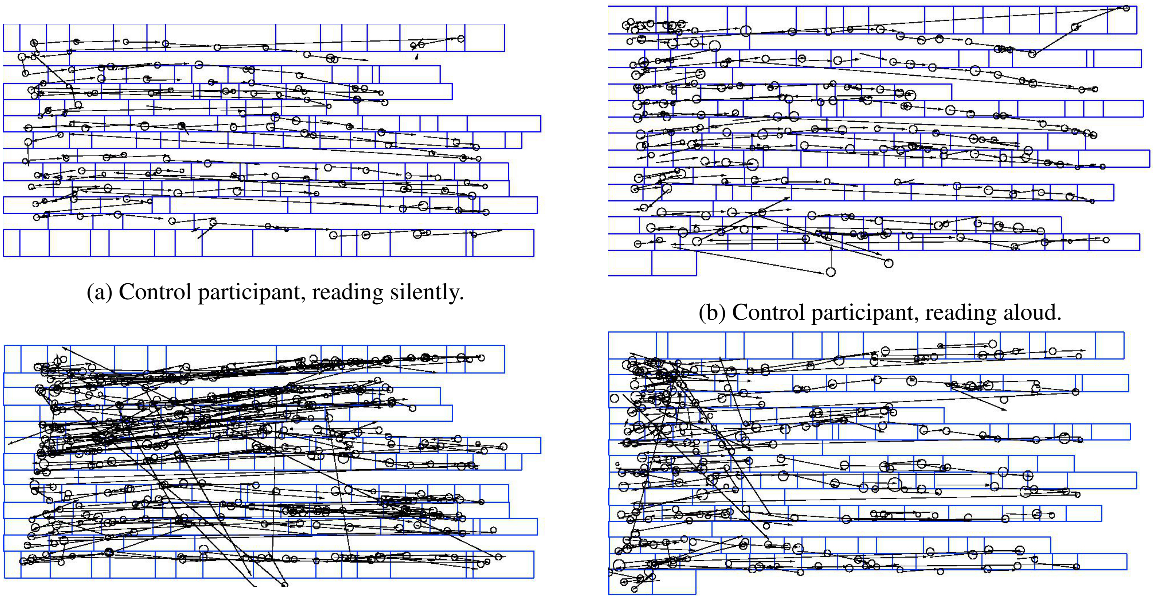
Feature	HC mean	MCI mean	p
First-pass first fixations	98.9	69.1	5.2×10^{-4}
Later-pass first fixations	100.9	133.7	5.8×10^{-6}

Table 6: Features which differ significantly between the groups.

Fernández et al. (2013) found that participants with AD had an increased number of total fixations, first-pass fixations, and second-pass fixations. However, they noted that the second-pass fixations showed an even more striking increase than first-pass fixations. Our results are consistent with this notable increase in second-pass fixations, but not with the reported increase in first pass fixations. One potential reason for this discrepancy could lie in the definition of "first pass fixations", which in Fernández et al. (2013) is given as "the initial reading consisting of all forward fixations on a word", while second-pass fixations are defined as "re-reading"; it is possible that our later-pass first fixations could be classified as first pass fixations under this framework. Nonetheless, both the Fernandez study and our current results suggest a pattern of skipping and back-tracking that is not seen in the control data.

5 Limitations

In this study, as in many studies involving clinical data, our sample is rather small. Furthermore, the two texts were not particularly difficult to read,



(a) Control participant, reading silently.

(b) Control participant, reading aloud.

(c) MCI participant, reading silently.

(d) MCI participant, reading aloud.

Figure 2: Examples of eye movements from a cognitively healthy participant (top) and an MCI participant (bottom), as they read the text from Trial 1 silently (left) and the text from Trial 2 aloud (right). Each blue box in the figures represents an AOI (i.e. a word in the text); the circles indicate fixations and the lines show the movements of the eye. Figure (a) illustrates an example of a relatively straightforward path through the Text 1, while Figure (c) shows one containing more backtracking and re-reading.

nor did they specifically contain words that might be difficult to people with cognitive impairment (for example, low-frequency words with irregular pronunciation, as in Patterson et al. 1994). Additionally, some data had to be either adjusted or in some cases excluded altogether due to calibration quality.

6 Conclusions and future work

In this analysis, we found that we can use eye-tracking information to distinguish between MCI participants and controls with over 80% accuracy, and up to 86% accuracy in the best case. As expected, this is somewhat lower than the accuracy for distinguishing between controls and AD participants reported in Biondi et al. (2017), but demonstrates that eye-tracking may hold promise as a method for detecting the earliest stages of cognitive decline.

We also found that tracking eye movements while the participant reads silently provides more diagnostic information than when reading aloud. Merging data from the two trial conditions led to a significant increase in classification accuracy, compared to using either trial alone. In the merged data set, significant differences between the participant groups were observed for the number of first-pass first fixations (higher in the control group) and later-pass first fixations (higher in the MCI group), suggesting a somewhat disorganized and non-linear path through the text.

Although annotating fixations with the frequency and syntactic category of the word on which the fixation occurs did ultimately lead to the highest classification accuracy, this improvement was not statistically significant, and none of the augmented features showed a significant difference between the HC and MCI groups. It may be that the participants were too early in their decline (and the texts too linguistically simple) for any effect to be seen, or it could be that these variables are not capturing the most relevant linguistic information. In particular, the features were very coarse, making only a binary distinction between high/low frequency words and function/content words. One avenue for future research will be to design more sophisticated ways of incorporating linguistic information into the eye-tracking model, especially features that take into account context, rather than operating at the single word level.

Another untapped source of information is the acoustic signal in the reading aloud trial. Correlating eye movements with acoustic information, such as pauses, fillers, hesitations, and word errors may provide a more complete representation of cognitive processing while reading. Furthermore, other eye-tracking features in addition to those included in the Biondi study may prove to be more sensitive to early cognitive impairment.

In future work we also plan to explore the connection between eye movements and reading comprehension. Each participant in this study also answered comprehension questions related to the passages they read. Analysing the relationship between different eye movement features and the accuracy of the responses may help us better understand the reading strategies used by healthy and cognitively impaired readers.

Finally, future work will include the subjective-cognitive impairment (SCI) group in the analysis. These participants score normally on neuropsychological tests, and so a reliable method for distinguishing them from healthy controls could help provide an early warning system, even before clinical symptoms develop.

A Structured Learning Approach to Temporal Relation Extraction

Abstract

Identifying temporal relations between events is an essential step towards natural language understanding. However, the temporal relation between two events in a story depends on, and is often dictated by, relations among other events. Consequently, effectively identifying temporal relations between events is a challenging problem even for human annotators. This paper suggests that it is important to take these dependencies into account while learning to identify these relations and proposes a structured learning approach to address this challenge. As a byproduct, this provides a new perspective on handling missing relations, a known issue that hurts existing methods. As we show, the proposed approach results in significant improvements on the two commonly used data sets for this problem.

1 Introduction

Understanding temporal information described in natural language text is a key component of natural language understanding (Mani et al., 2006; Verhagen et al., 2007; Chambers et al., 2007; Bethard and Martin, 2007) and, following a series of TempEval (TE) workshops (Verhagen et al., 2007, 2010; UzZaman et al., 2013), it has drawn increased attention. Time-slot filling (Surdeanu, 2013; Ji et al., 2014), storyline construction (Do et al., 2012; Minard et al., 2015), clinical narratives processing (Jindal and Roth, 2013; Bethard et al., 2016), and temporal question answering (Llorens et al., 2015) are all explicit examples of temporal processing.

The fundamental tasks in temporal processing, as identified in the TE workshops, are 1) time expression (the so-called "timex") extraction and normalization and 2) temporal relation (also known as TLINKs (Pustejovsky et al., 2003a)) extraction. While the first task has now been well handled by the state-of-the-art systems (HeidelTime (Strötgen and Gertz, 2010), SUTime (Chang and Manning, 2012), IllinoisTime (Zhao et al., 2012), NavyTime (Chambers, 2013), UWTime (Lee et al., 2014), etc.) with end-to-end F_1 scores being around 80%, the second task has long been a challenging one; even the top systems only achieved F_1 scores of around 35% in the TE workshops.

The goal of the temporal relation task is to generate a *directed temporal graph* whose nodes represent temporal entities (i.e., events or timexes) and edges represent the TLINKs between them. The task is challenging because it often requires global considerations – considering the entire graph, the TLINK annotation is quadratic in the number of nodes and thus very expensive, and an overwhelming fraction of the temporal relations are missing in human annotation. In this paper, we propose a structured learning approach to temporal relation extraction, where local models are updated based on feedback from global inferences. The structured approach also gives rise to a semi-supervised method, making it possible to take advantage of the readily available unlabeled data. As a byproduct, this approach further provides a new, effective perspective on handling those missing relations.

In the common formulations, temporal relations are categorized into three types: the E-E TLINKs (those between a pair of events), the T-T TLINKs (those between a pair of timexes), and the E-T TLINKs (those between an event and a timex). While the proposed approach can be generally applied to all three types, this paper focuses on the majority type, i.e., the E-E TLINKs. For example, consider the following snippet taken from the

Proceedings of the 2017 Conference on Empirical Methods in Natural Language Processing, pages 1027–1037
Copenhagen, Denmark, September 7–11, 2017.

training set provided in the TE3 workshop. We want to construct a temporal graph as in Fig. 1 for the events in boldface in Ex1.

Ex1 *. . . tons of earth* ***cascaded*** *down a hillside,* ***ripping*** *two houses from their foundations. No one was* ***hurt****, but firefighters* ***ordered*** *the evacuation of nearby homes and said they'll* ***monitor*** *the shifting ground. . . .*

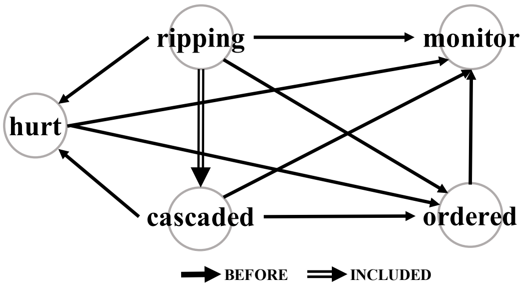

Figure 1: The desired event temporal graph for Ex1. Reverse TLINKs such as ***hurt*** is *after* ***ripping*** are omitted for simplicity.

As discussed in existing work (Verhagen, 2004; Bramsen et al., 2006; Mani et al., 2006; Chambers and Jurafsky, 2008), the structure of a temporal graph is constrained by some rather simple rules:

1. *Symmetry*. For example, if *A* is *before B*, then *B* must be *after A*.
2. *Transitivity*. For example, if *A* is *before B* and *B* is *before C*, then *A* must be *before C*.

This particular structure of a temporal graph (especially the transitivity structure) makes its nodes highly interrelated, as can be seen from Fig. 1. It is thus very challenging to identify the TLINKs between them, even for human annotators: The inter-annotator agreement on TLINKs is usually about 50%-60% (Mani et al., 2006). Fig. 2 shows the actual human annotations provided by TE3. Among all the ten possible pairs of nodes, only three TLINKs were annotated. Even if we only look at main events in consecutive sentences and at events in the same sentence, there are still quite a few missing TLINKs, e.g., the one between ***hurt*** and ***cascaded*** and the one between ***monitor*** and ***ordered***.

Early attempts by Mani et al. (2006); Chambers et al. (2007); Bethard et al. (2007); Verhagen and Pustejovsky (2008) studied *local* methods – learning models that make pairwise decisions between each pair of events. State-of-the-art local methods, including ClearTK (Bethard, 2013), UTTime (Laokulrat et al., 2013), and NavyTime (Chambers, 2013), use better designed rules or more features such as syntactic tree paths and achieve better results. However, the decisions made by these (local) models are often globally inconsistent (i.e., the symmetry and/or transitivity constraints are not satisfied for the entire temporal graph). Integer linear programming (ILP) methods (Roth and Yih, 2004) were used in this domain to enforce global consistency by several authors including Bramsen et al. (2006); Chambers and Jurafsky (2008); Do et al. (2012), which formulated TLINK extraction as an ILP and showed that it improves over local methods for densely connected graphs. Since these methods perform inference ("I") on top of pre-trained local classifiers ("L"), they are often referred to as *L+I* (Punyakanok et al., 2005). In a state-of-the-art method, CAEVO (Chambers et al., 2014), many hand-crafted rules and machine learned classifiers (called sieves therein) form a pipeline. The global consistency is enforced by inferring all possible relations before passing the graph to the next sieve. This best-first architecture is conceptually similar to L+I but the inference is greedy, similar to Mani et al. (2007); Verhagen and Pustejovsky (2008).

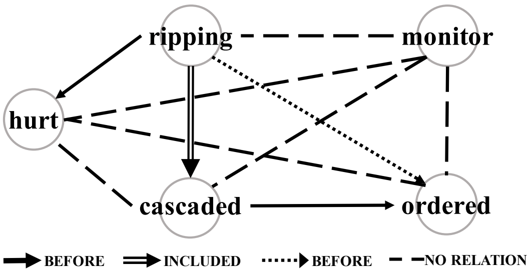

Figure 2: The human-annotation for Ex1 provided in TE3, where many TLINKs are missing due to the annotation difficulty. Solid lines: original human annotations. Dotted lines: TLINKs inferred from solid lines. Dashed lines: missing relations.

Although L+I methods impose global constraints in the inference phase, this paper argues that global considerations are necessary in the learning phase as well (i.e., structured learning). In parallel to the work presented here, Leeuwenberg and Moens (2017) also proposed a structured learning approach to extracting the temporal relations. Their work focuses on a domain-specific dataset from Clinical TempEval (Bethard et al., 2016), so their work does not need to address some of the difficulties of the general problem that our work addresses. More importantly, they compared structured learning to local baselines, while we find that the comparison between structured learning and L+I is more interesting and important for understanding the effect of global considerations in the learning phase. In difference from existing methods, we also discuss how to effectively use unlabeled data and how to handle the overwhelming fraction of missing relations in a principled way. Our solution targets on these issues and, as we show, achieves significant improvements on two commonly used evaluation sets.

The rest of this paper is organized as follows. Section 2 clarifies the temporal relation types and the evaluation metric of a temporal graph used in this paper, Section 3 explains the structured learning approach in detail, and Section 4 discusses the practical issue of missing relations. We provide experiments and discussion in Section 5 and conclusion in Section 6.

2 Background

2.1 Temporal Relation Types

Existing corpora for temporal processing often follows the interval representation of events proposed in Allen (1984), and makes use of 13 relation types in total. In many systems, *vague* or *none* is also included as another relation type when a TLINK is not clear or missing. However, current systems usually use a reduced set of relation types, mainly due to the following reasons.

1. The non-uniform distribution of all the relation types makes it difficult to separate low-frequency ones from the others (see Table 1 in Mani et al. (2006)). For example, relations such as *immediately_before* or *immediately_after* barely exist in a corpus compared to *before* and *after*.

2. Due to the ambiguity in natural language, determining relations like *before* and *immediately_before* can be a difficult task itself (Chambers et al., 2014).

In this work, we follow the reduced set of temporal relation types used in CAEVO (Chambers et al., 2014): *before*, *after*, *includes*, *is_included*, *equal*, and *vague*.

2.2 Quality of A Temporal Graph

The most recent evaluation metric in TE3, i.e., the temporal awareness (UzZaman and Allen, 2011), is adopted in this work. Specifically, let G_{sys} and G_{true} be two temporal graphs from the system prediction and the ground truth, respectively. The precision and recall of temporal awareness are defined as follows.

$$P = \frac{|G_{sys}^- \cap G_{true}^+|}{|G_{sys}^-|},\ R = \frac{|G_{true}^- \cap G_{sys}^+|}{|G_{true}^-|}$$

where G^+ is the closure of graph G, G^- is the reduction of G, "$\cap$" is the intersection between TLINKs in two graphs, and $|G|$ is the number of TLINKs in G. The temporal awareness metric better captures how "useful" a temporal graph is. For example, if system 1 produces ***ripping*** is *before* ***hurt*** and ***hurt*** is *before* ***monitor***, and system 2 adds ***ripping*** is *before* ***monitor*** on top of system 1. Since system 2 is simply a transitive closure of system 1, they would have the same evaluation scores. Note that *vague* relations are usually considered as non-existing TLINKs and are not counted during evaluation.

3 A Structured Training Approach

As shown in Fig. 1, the learning problem in temporal relation extraction is global in nature. Even the top local method in TE3, UTTime (Laokulrat et al., 2013), only achieved F_1=56.5 when presented with a pair of temporal entities (Task C–relation only (UzZaman et al., 2013)). Since the success of an L+I method strongly relies on the quality of the local classifiers, a poor local classifier is obviously a roadblock for L+I methods. Following the insights from Punyakanok et al. (2005), we propose to use a structured learning approach (also called "Inference Based Training" (IBT)).

Unlike the current L+I approach, where local classifiers are trained independently beforehand without knowledge of the predictions on neighboring pairs, we train local classifiers with feedback that accounts for other relations, by performing global inference in each round of the learning process. In order to introduce the structured learning algorithm, we first explain its most important component, the global inference step.

3.1 Inference

In a document with n pairs of events, let $\phi_i \in \mathcal{X} \subseteq \mathbb{R}^d$ be the extracted d-dimensional feature and $y_i \in \mathcal{Y}$ be the temporal relation for the i-th pair of events, $i = 1, 2, \ldots, n$, where $\mathcal{Y} = \{r_j\}_{j=1}^6$ is the label set for the six temporal relations we use. Moreover, let $\mathbf{x} = \{\phi_1, \ldots, \phi_n\} \in \mathcal{X}^n$ and $\mathbf{y} = \{y_1, \ldots, y_n\} \in \mathcal{Y}^n$ be more compact representations of all the features and labels in this document. Given the weight vector $\mathbf{w}_r$ of a linear classifier trained for relation $r \in \mathcal{Y}$ (i.e., using the one-vs-all scheme), the global inference step is to solve the following constrained optimization problem:

$$\hat{\mathbf{y}} = \arg \max_{\mathbf{y}\in\mathcal{C}(\mathcal{Y}^n)} f(\mathbf{x}, \mathbf{y}), \qquad (1)$$

where $\mathcal{C}(\mathcal{Y}^n) \subseteq \mathcal{Y}^n$ constrains the temporal graph to be symmetrically and transitively consistent, and $f(\mathbf{x}, \mathbf{y})$ is the scoring function:

$$f(\mathbf{x}, \mathbf{y}) = \sum_{i=1}^{n} f_{y_i}(\phi_i) = \sum_{i=1}^{n} \frac{e^{\mathbf{w}_{y_i}^T \phi_i}}{\sum_{r\in\mathcal{Y}} e^{\mathbf{w}_r^T \phi_i}}.$$

Specifically, $f_{y_i}(\phi_i)$ is the probability of the i-th event pair having relation y_i. $f(x, y)$ is simply the sum of these probabilities over all the event pairs in a document, which we think of as the confidence of assigning $\mathbf{y} = \{y_1, ..., y_n\}$ to this document and therefore, it needs to be maximized in Eq. (1).

Note that when $\mathcal{C}(\mathcal{Y}^n) = \mathcal{Y}^n$, Eq. (1) can be solved for each $\hat{y}_i$ independently, which is what the so-called local methods do, but the resulting $\hat{\mathbf{y}}$ may not satisfy global consistency in this way. When $\mathcal{C}(\mathcal{Y}^n) \neq \mathcal{Y}^n$, Eq. (1) cannot be decoupled for each $\hat{y}_i$ and is usually formulated as an ILP problem (Roth and Yih, 2004; Chambers and Jurafsky, 2008; Do et al., 2012). Specifically, let $\mathcal{I}_r(ij) \in \{0, 1\}$ be the indicator function of relation r for event i and event j and $f_r(ij) \in [0, 1]$ be the corresponding soft-max score. Then the ILP objective for global inference is formulated as follows.

$$\hat{\mathcal{I}} = \underset{\mathcal{I}}{\text{argmax}} \textstyle\sum_{ij\in\mathcal{E}} \sum_{r\in\mathcal{Y}} f_r(ij)\mathcal{I}_r(ij) \qquad (2)$$

$$\text{s.t.} \quad \underset{\text{(uniqueness)}}{\Sigma_r \mathcal{I}_r(ij) = 1}, \; \underset{\text{(symmetry)}}{\mathcal{I}_r(ij) = \mathcal{I}_{\bar{r}}(ji)},$$

$$\underset{\text{(transitivity)}}{\mathcal{I}_{r_1}(ij) + \mathcal{I}_{r_2}(jk) - \Sigma_{m=1}^{N} \mathcal{I}_{r_3^m}(ik) \leq 1},$$

for all distinct events i, j, and k, where $\mathcal{E} = \{ij \mid \text{sentence dist}(i, j) \leq 1\}$, $\bar{r}$ is the reverse of r, and N is the number of possible relations for r_3 when r_1 and r_2 are true.

Our formulation in Eq. (2) is different from previous work (Chambers and Jurafsky, 2008; Do et al., 2012) in two aspects: 1) We restrict our event pairs ij to a smaller set $\mathcal{E} = \{ij \mid \text{sentence dist}(i, j) \leq 1\}$ where pairs that are more than one sentence away are deleted for computational efficiency and (usually) for better performance. In fact, to make better use of global constraints, we should have allowed more event pairs in Eq. (2). However, $f_r(ij)$ is usually more reliable when i and j are closer in text. Many participating systems in TE3 (UzZaman et al., 2013) have used this *pre-filtering* strategy to balance the trade-off between confidence in $f_r(ij)$ and global constraints. We observe that the strategy fits very well to the existing datasets: As shown in Fig. 3, annotated TLINKs barely exist if two events are two sentences away. 2) Previously, transitivity constraints were formulated as $\mathcal{I}_{r_1}(ij) + \mathcal{I}_{r_2}(jk) - \mathcal{I}_{r_3}(ik) \leq 1$, which is a special case when $N = 1$ and can be understood as "r_1 and r_2 determine a single r_3". However, it was overlooked that, although some r_1 and r_2 cannot uniquely determine r_3, they can still constrain the set of labels r_3 can take. For example, as shown in Fig. 4, when r_1=*before* and r_2=*is_included*, r_3 is not determined but we know that $r_3 \in \{$*before*, *is_included*$\}$[1]. This information can be easily exploited by allowing $N > 1$.

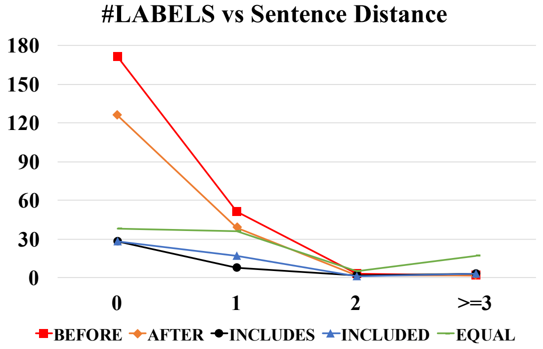

Figure 3: #TLINKs vs sentence distance on the TE3 Platinum dataset. The tail of *equal* is due to event coreference and beyond our focus.

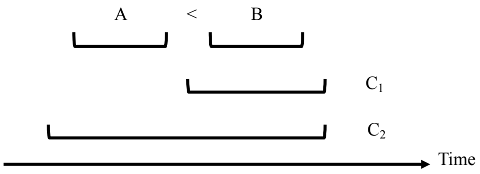

Figure 4: When A *is before* B and B *is_included in* C, A can either be *before* C_1 or *is_included in* C_2. We propose to incorporate this via the transitivity constraints for Eq. (2).

With these two differences, the optimization problem (2) can still be efficiently solved using off-the-shelf ILP packages such as GUROBI

[1] The transitivity table in Allen (1983) shows two more possible relations, *overlap* and *immediately_before*, which are not in our label set.

(Gurobi Optimization, Inc., 2012).

3.2 Learning

With the inference solver defined above, we propose to use the structured perceptron (Collins, 2002) as a representative for the inference based training (IBT) algorithm to learn those weight vectors $\mathbf{w}_r$. Specifically, let $\mathcal{L} = \{\mathbf{x}_k, \mathbf{y}_k\}_{k=1}^K$ be the labeled training set of K instances (usually documents). The structured perceptron training algorithm for this problem is shown in Algorithm 1. The Illinois-SL package (Chang et al., 2010) was used in our experiments for its structured perceptron component. In terms of the features used in this work, we adopt the same set of features designed for E-E TLINKs in Sec. 3.1 of Do et al. (2012).

In Algorithm 1, Line 6 is the inference step as in Eq. (1) or (2), which is augmented with a closure operation on $\hat{\mathbf{y}}$ in the following line. In the case in which there is only one pair of events in each instance (thus no structure to take advantage of), Algorithm 1 reduces to the conventional perceptron algorithm and Line 6 simply chooses the top scoring label. With a structured instance instead, Line 6 becomes slower to solve, but it can provide valuable information so that the perceptron learner is able to look further at other labels rather than an isolated pair. For example in Ex1 and Fig. 1, the fact that (ripping,ordered)=*before* is established through two other relations: 1) ***ripping*** is an adverbial participle and thus *included* in ***cascaded*** and 2) ***cascaded*** is *before* ***ordered***. If (ripping,ordered)=*before* is presented to a local learning algorithm without knowing its predictions on (ripping,cascaded) and (cascaded,ordered), then the model either cannot support it or overfits it. In IBT, however, if the classifier was correct in deciding (ripping,cascaded) and (cascaded,ordered), then (ripping,ordered) would be correct automatically and would not contribute to updating the classifier.

Algorithm 1: Structured perceptron algorithm for temporal relations

```
   Input: Training set $\mathcal{L} = \{\mathbf{x}_k, \mathbf{y}_k\}_{k=1}^K$,
          learning rate $\lambda$
1  Perform graph closure on each $\mathbf{y}_k$
2  Initialize $\mathbf{w}_r = \mathbf{0}$, $\forall r \in \mathcal{Y}$
3  while convergence criteria not satisfied do
4      Shuffle the examples in $\mathcal{L}$
5      foreach $(\mathbf{x}, \mathbf{y}) \in \mathcal{L}$ do
6          $\hat{\mathbf{y}} = \arg\max_{\mathbf{y}\in\mathcal{C}} f(\mathbf{x}, \mathbf{y})$
7          Perform graph closure on $\hat{\mathbf{y}}$
8          if $\hat{\mathbf{y}} \neq \mathbf{y}$ then
9              $\mathbf{w}_r = \mathbf{w}_r + \lambda(\sum_{i:\mathbf{y}_i=r} \phi_i -$
               $\sum_{i:\hat{\mathbf{y}}_i=r} \phi_i), \forall r \in \mathcal{Y}$
10 return $\{\mathbf{w}_r\}_{r\in\mathcal{Y}}$
```

3.3 Semi-supervised Structured Learning

The scarcity of training data and the difficulty in annotation have long been a bottleneck for temporal processing systems. Given the inherent global constraints in temporal graphs, we propose to perform semi-supervised structured learning using the constraint-driven learning (CoDL) algorithm (Chang et al., 2007, 2012), as shown in Algorithm 2, where the function "Learn" in Lines 2 and 9 represents any standard learning algorithm (e.g., perceptron, SVM, or even structured perceptron; here we used the averaged perceptron (Freund and Schapire, 1998)) and subscript "r" means selecting the learned weight vector for relation $r \in \mathcal{Y}$. CoDL improves the model learned from a small amount of labeled data by repeatedly generating feedback through labeling unlabeled examples, which is in fact a semi-supervised version of IBT. Experiments show that this scheme is indeed helpful in this problem.

Algorithm 2: Constraint-driven learning algorithm

```
   Input: Labeled set $\mathcal{L}$, unlabeled set $\mathcal{U}$,
          weighting coefficient $\gamma$
1  Perform closure on each graph in $\mathcal{L}$
2  Initialize $\mathbf{w}_r = \text{Learn}(\mathcal{L})_r, \forall\, r \in \mathcal{Y}$
3  while convergence criteria not satisfied do
4      $\mathcal{T} = \emptyset$
5      foreach $\mathbf{x} \in \mathcal{U}$ do
6          $\hat{\mathbf{y}} = \arg\max_{\mathbf{y}\in\mathcal{C}} f(\mathbf{x}, \mathbf{y})$
7          Perform graph closure on $\hat{\mathbf{y}}$
8          $\mathcal{T} = \mathcal{T} \cup \{(\mathbf{x}, \hat{\mathbf{y}})\}$
9      $\mathbf{w}_r = \gamma\mathbf{w}_r + (1-\gamma)\text{Learn}(\mathcal{T})_r, \forall\, r \in \mathcal{Y}$
10 return $\{\mathbf{w}_r\}_{r\in\mathcal{Y}}$
```

4 Missing Annotations

Since even human annotators find it difficult to annotate temporal graphs, many of the TLINKs are left unspecified by annotators (compare Fig. 2 to Fig. 1). While some of these missing TLINKs can be inferred from existing ones, the vast majority still remain unknown as shown in Table 1. Despite the existence of denser annotation schemes (e.g., Cassidy et al. (2014)), the TLINK annotation task is quadratic in the number of nodes, and it is practically infeasible to annotate complete graphs. Therefore, the problem of identifying these unknown relations in training and test is a major issue that dramatically hurts existing methods.

Table 1: Categories of E-E TLINKs in the TE3 Platinum dataset. Among all pairs of events, 98.2% of them are left unspecified by the annotators. Graph closure can automatically add 8.7%, but most of the event pairs are still unknown.

Type		#TLINK	%
Annotated		582	1.8
Missing	Inferred	2840	8.7
	Unknown	29240	89.5
Total		32662	100

We could simply use these unknown pairs (or some filtered version of them) to design rules or train classifiers to identify whether a TLINK is *vague* or not. However, we propose to exclude both the unknown pairs and the *vague* classifier from the training process – by changing the structured loss function to ignore the inference feedback on *vague* TLINKs (see Line 9 in Algorithm 1 and Line 9 in Algorithm 2). The reasons are discussed below.

First, it is believed that a lot of the unknown pairs are not really *vague* but rather pairs that the annotators failed to look at (Bethard et al., 2007; Cassidy et al., 2014; Chambers et al., 2014). For example, (cascaded, monitor) should be annotated as *before* but is missing in Fig. 2. It is hard to exclude this noise in the data during training. Second, compared to the overwhelmingly large number of unknown TLINKs (89.5% as shown in Table 1), the scarcity of non-vague TLINKs makes it hard to learn a good *vague* classifier. Third, *vague* is fundamentally different from the other relation types. For example, if a *before* TLINK can be established given a sentence, then it always holds as *before* regardless of other events around it, but if a TLINK is *vague* given a sentence, it may still change to other types afterwards if a connection can later be established through other nodes from the context. This distinction emphasizes that *vague* is a consequence of lack of background/contextual information, rather than a concrete relation type to be trained on. Fourth, without the *vague* classifier, the predicted temporal graph tends to become more densely connected, thus the global transitivity constraints can be more effective in correcting local mistakes (Chambers and Jurafsky, 2008).

However, excluding the local classifier for *vague* TLINKs would undesirably assign non-vague TLINKs to every pair of events. To handle this, we take a closer look at the *vague* TLINKs. We note that a *vague* TLINK could arise in two situations if the annotators did not fail to look at it. One is that an annotator looks at this pair of events and decides that multiple relations can exist, and the other one is that two annotators disagree on the relation (similar arguments were also made in Cassidy et al. (2014)). In both situations, the annotators first try to assign all possible relations to a TLINK, and then change the relation to *vague* if more than one can be assigned. This human annotation process for *vague* is different from many existing methods, which either identify the existence of a TLINK first (using rules or machine-learned classifiers) and then classify, or directly include *vague* as a classification label along with other non-vague relations.

In this work, however, we propose to mimic this mental process by a *post-filtering* method[2]. Specifically, we take each TLINK produced by ILP and determine whether it is *vague* using its relative entropy (the Kullback-Leibler divergence) to the uniform distribution. Let $\{r_m\}_{m=1}^M$ be the set of relations that the i-th pair of events can take, we filter the i-th TLINK given by ILP by:

$$\delta_i = \sum_{m=1}^{M} f_{r_m}(\phi_i) \log\left(M f_{r_m}(\phi_i)\right),$$

where $f_{r_m}(\phi_i)$ is the soft-max score of r_m, obtained by the local classifier for r_m. We then compare δ_i to a fixed threshold τ to determine the vagueness of this TLINK; we accept its originally predicted label if $\delta_i > \tau$, or change it to *vague* otherwise. Using relative entropy here is intuitively appealing and empirically useful as shown in the experiments section; better metrics are of course yet to be designed.

5 Experiments

5.1 Datasets

The TempEval3 (TE3) workshop (UzZaman et al., 2013) provided the TimeBank (TB) (Pustejovsky et al., 2003b), AQUAINT (AQ) (Graff, 2002), Silver (TE3-SV), and Platinum (TE3-PT) datasets,

[2] Some systems (e.g., TARSQI (Verhagen and Pustejovsky, 2008)) employed a similar idea from a different standpoint, by thresholding TLINKs based on confidence scores.

where TB and AQ are usually for training, and TE3-PT is usually for testing. The TE3-SV dataset is a much larger, machine-annotated and automatically-merged dataset based on multiple systems, with the intention to see if these “silver” standard data can help when included in training (although almost all participating systems saw performance drop with TE3-SV included in training).

Two popular augmentations on TB are the Verb-Clause temporal relation dataset (VC) and TimebankDense dataset (TD). The VC dataset has specially annotated event pairs that follow the so-called Verb-Clause structure (Bethard et al., 2007), which is usually beneficial to be included in training (UzZaman et al., 2013). The TD dataset contains 36 documents from TB which were re-annotated using the dense event ordering framework proposed in Cassidy et al. (2014). The experiments included in this paper will involve the TE3 datasets as well as these augmentations. Therefore, some statistics on them are shown in Table 2 for the readers’ information.

Table 2: Facts about the datasets used in this paper. The TD dataset is split into train, dev, and test in the same way as in Chambers et al. (2014). Note that the column of TLINKs only counts the non-vague TLINKs, from which we can see that the TD dataset has a much higher ratio of #TLINKs to #Events. The TLINK annotations in TE3-SV is not used in this paper and its number is thus not shown.

Dataset	Doc	Event	TLINK	Note
TB+AQ	256	12K	12K	Training
VC	132	1.6K	0.9K	Training
TD	36	1.6K	5.7K	Training
TD-Train	22	1K	3.8K	Training
TD-Dev	5	0.2K	0.6K	Dev
TD-Test	9	0.4K	1.3K	Eval
TE3-PT	20	0.7K	0.9K	Eval
TE3-SV	2.5K	81K	-	Unlabeled

5.2 Baseline Methods

In addition to the state-of-the-art systems, another two baseline methods were also implemented for a better understanding of the proposed ones. The first is the regularized averaged perceptron (AP) (Freund and Schapire, 1998) implemented in the LBJava package (Rizzolo and Roth, 2010) and is a local method. On top of the first baseline, we performed global inference in Eq.(2), referred to as the L+I baseline (AP+ILP). Both of them used the same feature set (i.e., as designed in Do et al. (2012)) as in the proposed structured perceptron (SP) and CoDL for fair comparisons. To clarify, SP and CoDL are training algorithms and their immediate outputs are the weight vectors $\{\mathbf{w}_r\}_{r\in\mathcal{Y}}$ for local classifiers. An ILP inference was performed on top of them to yield the final output, and we refer to it as “S+I” (i.e., structured learning+inference) methods.

Table 3: Temporal awareness scores on TE3-PT given gold event pairs. Systems that are significantly better (per McNemar’s test with $p < 0.0005$) than the previous rows are underlined. The last column shows the relative improvement in F1 score over AP-1, which identifies the source of improvement: 5.2% from additional training data, 9.3% (14.5%-5.2%) from constraints, and 10.4% from structured learning.

Method	P	R	F1	%
UTTime	55.6	57.4	56.5	+5.0
AP-1	56.3	51.5	53.8	0
AP-2	58.0	55.3	56.6	+5.2
AP+ILP	62.2	61.1	61.6	+14.5
SP+ILP	**69.1**	**65.5**	**67.2**	**+24.9**

5.3 Results and Discussion

5.3.1 TE3 Task C - Relation Only

To show the benefit of using structured learning, we first tested one scenario where the gold pairs of events that have a non-vague TLINK were known priori. This setup was a standard task presented in TE3, so that the difficulty of detecting *vague* TLINKs was ruled out. This setup also helps circumvent the issue that TE3 penalizes systems which assign extra labels that do not exist in the annotated graph, while these extra labels may be actually correct because the annotation itself might be incomplete. UTTime (Laokulrat et al., 2013) was the top system in this task in TE3. Since UTTime is not available to us, and its performance was reported in TE3 in terms of both E-E and E-T TLINKs together, we locally trained an E-T classifier based on Do et al. (2012) and included its prediction only for fair comparison.

UTTime is a local method and was trained on TB+AQ and tested on TE3-PT. We used the same datasets for our local baseline and its performance is shown in Table 3 under the name “AP-1”. Note that the reported numbers below are the temporal awareness scores obtained from the official evaluation script provided in TE3. We can see that UTTime is about 3% better than AP-1 in the absolute value of F_1, which is expected since UTTime included more advanced features derived from syntactic parse trees. By adding the VC and TD datasets into the training set, we retrained our local baseline and achieved comparable performance to

Table 4: Temporal awareness scores given gold events but with no gold pairs, which show that the proposed S+I methods outperformed state-of-the-art systems in various settings. The fourth column indicates the annotation sources used, with additional unlabeled dataset in the parentheses. The "Filters" column shows if the pre-filtering method (Sec. 3.1) or the proposed post-filtering method (Sec. 4) were used. The last column is the relative improvement in F_1 score compared to baseline systems on line 1, 7, and 11, respectively. Systems that are significantly better than the "*"-ed systems are underlined (per McNemar's test with $p < 0.0005$).

No.	System	Method	Anno. (Unlabeled)	Testset	Filters	P	R	F1	%

13	CoDL+ILP	S+I	TD-Train (TE3-SV)	TD-Test	pre+post	45.57	**51.89**	**48.53**	**+6.3**

UTTime ("AP-2" in Table 3). On top of AP-2, a global inference step enforcing symmetry and transitivity constraints ("AP+ILP") can further improve the F_1 score by 9.3%, which is consistent with previous observations (Chambers and Jurafsky, 2008; Do et al., 2012). SP+ILP further improved the performance in precision, recall, and F_1 significantly (per the McNemar's test (Everitt, 1992; Dietterich, 1998) with p <0.0005), reaching an F_1 score of 67.2%. This meets our expectation that structured learning can be better when the local problem is difficult (Punyakanok et al., 2005).

5.3.2 TE3 Task C

In the first scenario, we knew in advance which TLINKs existed or not, so the "pre-filtering" (i.e., ignoring distant pairs as mentioned in Sec. 3.1 and "post-filtering" methods were not used when generating the results in Table 3. We then tested a more practical scenario, where we only knew the events, but did not know which ones are related. This setup was Task C in TE3 and the top system was ClearTK (Bethard, 2013). Again, for fair comparison, we simply added the E-T TLINKs predicted by ClearTK. Moreover, 10% of the training data was held out for development. Corresponding results on the TE3-PT testset are shown in Table 4.

From lines 2-4, all systems see significant drops in performance if compared with the same entries in Table 3. It confirms our assertion that how to handle *vague* TLINKs is a major issue for this temporal relation extraction problem. The improvement of SP+ILP (line 4) over AP (line 2) was small and AP+ILP (line 3) was even worse than AP, which necessitates the use of a better approach towards *vague* TLINKs. By applying the post-filtering method proposed in Sec. 4, we were able to achieve better performances using SP+ILP (line 5), which shows the effectiveness of this strategy. Finally, by setting $\mathcal{U}$ in Algorithm 2 to be the TE3-SV dataset, CoDL+ILP (line 6) achieved the best F_1 score with a relative improvement over ClearTK being 14.8%. Note that when using TE3-SV in this paper, we did not use its annotations on TLINKs because of its well-known large noise (UzZaman et al., 2013).

In UzZaman et al. (2013), we notice that the best performance of ClearTK was achieved when trained on TB+VC (line 7 is higher than its reported values in TE3 because of later changes in ClearTK), so we retrained the proposed systems on the same training set and results are shown on lines 8-9. In this case, the improvement of S+I over Local was small, which may be due to the lack of training data. Note that line 8 was still significantly different to line 7 per the McNemar's test, although there was only 0.2% absolute difference in F_1, which can be explained from their large differences in precision and recall.

5.3.3 Comparison with CAEVO

The proposed structured learning approach was further compared to a recent system, a CAscading EVent Ordering architecture (CAEVO) proposed in Chambers et al. (2014) (lines 10-13). We used the same training set and test set as CAEVO in the S+I systems. Again, we added the E-T TLINKs predicted by CAEVO to both S+I systems. In Chambers et al. (2014), CAEVO was reported on the straightforward evaluation metric including the *vague* TLINKs, but the temporal awareness scores were used here, which explains the difference between line 11 in Table 4 and what was reported in Chambers et al. (2014).

ClearTK was reported to be outperformed by CAEVO on TD-Test (Chambers et al., 2014), but we observe that ClearTK on line 10 was much worse even than itself on line 7 (trained on TB+VC) and on line 1 (trained on TB+AQ+VC+TD) due to the annotation scheme difference between TD and TB/AQ/VC. ClearTK was designed mainly for TE3, aiming for high precision, which is reflected by its high precision on line 10, but it does not have enough flexibility to cope with two very different annotation schemes. Therefore, we have chosen CAEVO as the baseline system to evaluate the significance of the proposed ones. On the TD-Test dataset, all systems other than ClearTK had better F_1 scores compared to their performances on TE3-PT. This notable difference (i.e., 48.53 vs 40.3) indicates the better quality of the dense annotation scheme that was used to create TD (Cassidy et al., 2014). SP+ILP outperformed CAEVO and if additional unlabeled dataset TE3-SV was used, CoDL+ILP achieved the best score with a relative improvement in F_1 score being 6.3%.

We notice that the proposed systems often have higher recall than precision, and that this is less an issue on a densely annotated testset (TD-Test), so their low precision on TE3-PT possibly came from the missing annotations on TE3-PT. It is still under investigation how to control precision and recall in real applications.

6 Conclusion

We develop a structured learning approach to identifying temporal relations in natural language text and show that it captures the global nature of this problem better than state-of-the-art systems do. A new perspective towards *vague* relations is also proved to gain from fully taking advantage of the structured approach. In addition, the global nature of this problem gives rise to a better way of making use of the readily available unlabeled data, which further improves the proposed method. The improved performance on both TE3-PT and TD-Test, two differently annotated datasets, clearly shows the advantage of the proposed method over existing methods. We plan to build on the notable improvements shown here and expand this study to deal with additional temporal reasoning problems in natural language text.

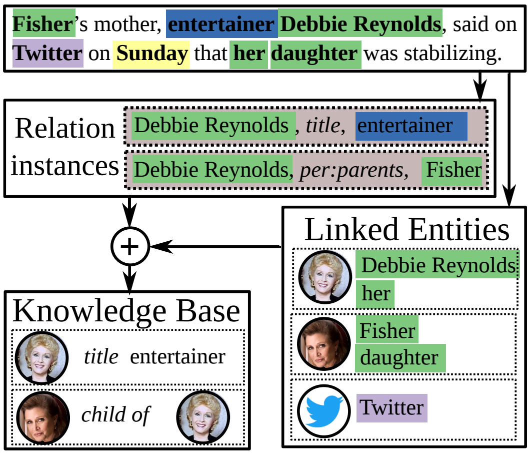
Abstract

Knowledge base population (KBP) systems take in a large document corpus and extract entities and their relations. Thus far, KBP evaluation has relied on judgements on the pooled predictions of existing systems. We show that this evaluation is problematic: when a new system predicts a previously unseen relation, it is penalized even if it is correct. This leads to significant bias against new systems, which counterproductively discourages innovation in the field. Our first contribution is a new importance-sampling based evaluation which corrects for this bias by annotating a new system's predictions on-demand via crowdsourcing. We show this eliminates bias and reduces variance using data from the 2015 TAC KBP task. Our second contribution is an implementation of our method made publicly available as an online KBP evaluation service. We pilot the service by testing diverse state-of-the-art systems on the TAC KBP 2016 corpus and obtain accurate scores in a cost effective manner.

1 Introduction

Harnessing the wealth of information present in unstructured text online has been a long standing goal for the natural language processing community. In particular, knowledge base population seeks to automatically construct a knowledge base consisting of relations between entities from a document corpus. Knowledge bases have found many applications including question answering (Berant et al., 2013; Fader et al., 2014; Reddy et al., 2014), automated reasoning (Kalyanpur et al., 2012) and dialogue (Han et al., 2015).



Fisher's mother, **entertainer** **Debbie Reynolds**, said on **Twitter** on **Sunday** that **her** **daughter** was stabilizing.

Figure 1: An example describing entities and relations in knowledge base population.

Evaluating these systems remains a challenge as it is not economically feasible to exhaustively annotate every possible candidate relation from a sufficiently large corpus. As a result, a pooling-based methodology is used in practice to construct datasets, similar to them methodology used in information retrieval (Jones and Rijsbergen, 1975; Harman, 1993). For instance, at the annual NIST TAC KBP evaluation, all relations predicted by participating systems are pooled together, annotated and released as a dataset for researchers to develop and evaluate their systems on. However, during development, if a new system predicts a previously unseen relation it is considered to be wrong even if it is correct. The discrepancy between a system's true score and the score on the pooled dataset is called *pooling bias* and is typically assumed to be insignificant in practice (Zobel, 1998).

The key finding of this paper contradicts this assumption and shows that the pooling bias is actu-

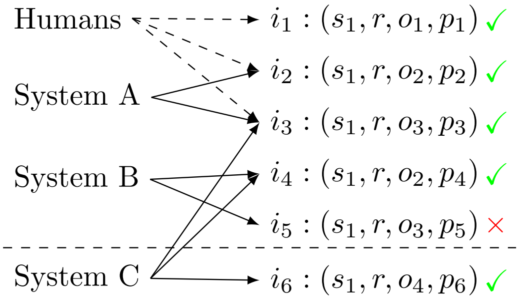
Copenhagen, Denmark, September 7–11, 2017. ©2017 Association for Computational Linguistics

ally significant, and it penalizes newly developed systems by 2% F_1 on average (Section 3). Novel improvements, which typically increase scores by less than 1% F_1 on existing datasets, are therefore likely to be clouded by pooling bias during development. Worse, the bias is larger for a system which predicts qualitatively different relations systematically missing from the pool. Of course, systems participating in the TAC KBP evaluation do not suffer from pooling bias, but this requires researchers to wait a year to get credible feedback on new ideas.

This bias is particularly counterproductive for machine learning methods as they are trained assuming the pool is the complete set of positives. Predicting unseen relations and learning novel patterns is penalized. The net effect is that researchers are discouraged from developing innovative approaches, in particular from applying machine learning, thereby slowing progress on the task.

Our second contribution, described in Section 4, addresses this bias through a new evaluation methodology, *on-demand evaluation*, which avoids pooling bias by querying crowdworkers, while minimizing cost by leveraging previous systems' predictions when possible. We then compute the new system's score based on the predictions of past systems using importance weighting. As more systems are evaluated, the marginal cost of evaluating a new system decreases. We show how the on-demand evaluation methodology can be applied to knowledge base population in Section 5. Through a simulated experiment on evaluation data released through the TAC KBP 2015 Slot Validation track, we show that we are able to obtain unbiased estimates of a new systems score's while significantly reducing variance.

Finally, our third contribution is an implementation of our framework as a publicly available evaluation service at https://kbpo.stanford.edu, where researchers can have their own KBP systems evaluated. The data collected through the evaluation process could even be valuable for relation extraction, entity linking and coreference, and will also be made publicly available through the website. We evaluate three systems on the 2016 TAC KBP corpus for about $150 each (a fraction of the cost of official evaluation). We believe the public availability of this service will speed the pace of progress in developing KBP systems.



Humans
System A
System B
System C
$i_1 : (s_1, r, o_1, p_1)$ ✓
$i_2 : (s_1, r, o_2, p_2)$ ✓
$i_3 : (s_1, r, o_3, p_3)$ ✓
$i_4 : (s_1, r, o_2, p_4)$ ✓
$i_5 : (s_1, r, o_3, p_5)$ ✗
$i_6 : (s_1, r, o_4, p_6)$ ✓

Figure 2: In pooled evaluation, an evaluation dataset is constructed by labeling relation instances collected from the pooled systems (A and B) and from a team of human annotators (Humans). However, when a new system (C) is evaluated on this dataset, some of its predictions (i_6) are missing and can not be fairly evaluated. Here, the precision and recall for C should be $\frac{3}{3}$ and $\frac{3}{4}$ respectively, but its evaluation scores are estimated to be $\frac{2}{3}$ and $\frac{2}{3}$. The discrepancy between these two scores is called *pooling bias*.

2 Background

In knowledge base population, each relation is a triple (SUBJECT, PREDICATE, OBJECT) where SUBJECT and OBJECT are some globally unique entity identifiers (e.g. Wikipedia page titles) and PREDICATE belongm to a specified schema.[1] A KBP system returns an output in the form of *relation instances* (SUBJECT, PREDICATE, OBJECT, PROVENANCE), where PROVENANCE is a description of where exactly in the document corpus the relation was found. In the example shown in Figure 1, CARRIE FISHER and DEBBIE REYNOLDS are identified as the subject and object, respectively, of the predicate CHILD OF, and the whole sentence is provided as provenance. The provenance also identifies that CARRIE FISHER is referenced by **Fisher** within the sentence. Note that the same relation can be expressed in multiple sentences across the document corpus; each of these is a different relation instance.

Pooled evaluation. The primary source of evaluation data for KBP comes from the annual TAC KBP competition organized by NIST (Ji et al.,

[1] The TAC KBP guidelines specify a total of 65 predicates (including inverses) such as per:title or org:founded_on, etc. Subject entities can be people, organizations, geopolitical entities, while object entities also include dates, numbers and arbitrary string-values like job titles.

2011). Let E be a held-out set of *evaluation entities*. There are two steps performed in parallel: First, each participating system is run on the document corpus to produce a set of relation instances; those whose subjects are in E are labeled as either positive or negative by annotators. Second, a team of annotators identify and label correct relation instances for the evaluation entities E by manually searching the document corpus within a time budget (Ellis et al., 2012). These labeled relation instances from the two steps are combined and released as the evaluation dataset. In the example in Figure 2, systems A and B were used in constructing the pooling dataset, and there are 3 distinct relations in the dataset, between s_1 and o_1, o_2, o_3.

A system is evaluated on the precision of its predicted relation instances for the evaluation entities E and on the recall of the corresponding predicted *relations* (not instances) for the same entities (see Figure 2 for a worked example). When using the evaluation data during system development, it is common practice to use the more lenient `anydoc` score that ignores the provenance when checking if a relation instance is true. Under this metric, predicting the relation (CARRIE FISHER, CHILD OF, DEBBIE REYNOLDS) from an ambiguous provenance like "**Carrie Fisher** and **Debbie Reynolds** arrived together at the awards show" would be considered correct even though it would be marked wrong under the official metric.

3 Measuring pooling bias

The example in Figure 2 makes it apparent that pooling-based evaluation can introduce a systematic bias against unpooled systems. However, it has been assumed that the bias is insignificant in practice given the large number of systems pooled in the TAC KBP evaluation. We will now show that the assumption is not valid using data from the TAC KBP 2015 evaluation.[2]

Measuring bias. In total, there are 70 system submissions from 18 teams for 317 evaluation entities (E) and the evaluation set consists of 11,008 labeled relation instances.[3] The original evaluation dataset gives us a good measure of the true scores for the participating systems. Similar to Zobel (1998), which studied pooling bias in information retrieval, we simulate the condition of a team not being part of the pooling process by removing any predictions that are unique to its systems from the evaluation dataset. The pooling bias is then the difference between the true and unpooled scores.

	Median bias		
	Precision	Recall	Macro F_1
Official	17.93%	17.00%	15.51%
`anydoc`	2.34%	1.93%	2.05%

Figure 3: Median pooling bias (difference between pooled and unpooled scores) on the top 40 systems of TAC KBP 2015 evaluation using the official and `anydoc` scores. The bias is much smaller for the lenient `anydoc` metric, but even so, it is larger than the largest difference between adjacent systems (1.5% F_1) and typical system improvements (around 1% F_1).

Results. Figure 3 shows the results of measuring pooling bias on the TAC KBP 2015 evaluation on the F_1 metric using the official and `anydoc` scores.[4][5] We observe that even with lenient `anydoc` heuristic, the median bias (2.05% F_1) is much larger than largest difference between adjacently ranked systems (1.5% F_1). This experiment shows that pooling evaluation is significantly and systematically biased against systems that make novel predictions!

[2] Our results are not qualitatively different on data from previous years of the shared task.

[3] The evaluation set is actually constructed from compositional queries like, "what does Carrie Fisher's parents do?": these queries select relation instances that answer the question "who are Carrie Fisher's parents?", and then use those answers (e.g. "Debbie Reynolds") to select relation instances that answer "what does Debbie Reynolds do?". We only consider instances selected in the first part of this process.

[4] We note that `anydoc` scores are on average 0.88%F_1 larger than the official scores.

[5] The outlier at rank 36 corresponds to a University of Texas, Austin system that only filtered predictions from other systems and hence has no unique predictions itself.

4 On-demand evaluation with importance sampling

Pooling bias is fundamentally a sampling bias problem where relation instances from new systems are underrepresented in the evaluation dataset. We could of course sidestep the problem by exhaustively annotating the entire document corpus, by annotating all mentions of entities and checking relations between all pairs of mentions. However, that would be a laborious and prohibitively expensive task: using the interfaces we've developed (Section 6), it costs about $15 to annotate a single document by non-expert crowdworkers, resulting in an estimated cost of at least $1,350,000 for a reasonably large corpus of 90,000 documents (Dang, 2016). The annotation effort would cost significantly more with expert annotators. In contrast, *labeling* relation instances from system predictions can be an order of magnitude cheaper than finding them in documents: using our interfaces, it costs only about $0.18 to verify each relation instance compared to $1.60 per instance extracted through exhaustive annotations.

We propose a new paradigm called on-demand evaluation which takes a lazy approach to dataset construction by annotating predictions from systems *only when they are underrepresented*, thus correcting for pooling bias as it arises. In this section, we'll formalize the problem solved by on-demand evaluation independent of KBP and describe a cost-effective solution that allows us to accurately estimate evaluation scores without bias using importance sampling. We'll then instantiate the framework for KBP in Section 5.

4.1 Problem statement

Let $\mathcal{X}$ be the universe of (relation) instances, $\mathcal{Y} \subseteq \mathcal{X}$ be the unknown subset of correct instances, $X_1, \ldots X_m \subseteq \mathcal{X}$ be the predictions for m systems, and let $Y_i = X_i \cap \mathcal{Y}$. Let $X = \bigcup_{i=1}^{m} X_i$ and $Y = \bigcup_{i=1}^{m} Y_i$. Let $f(x) \stackrel{\text{def}}{=} \mathbb{I}[x \in \mathcal{Y}]$ and $g_i(x) = \mathbb{I}[x \in X_i]$, then the precision, π_i, and recall, r_i, of the set of predictions X_i is

$$\pi_i \stackrel{\text{def}}{=} \mathbb{E}_{x \sim p_i}[f(x)] \qquad r_i \stackrel{\text{def}}{=} \mathbb{E}_{x \sim p_0}[g_i(x)],$$

where p_i is a distribution over X_i and p_0 is a distribution over $\mathcal{Y}$. We assume that p_i is known, e.g. the uniform distribution over X_i and that we know p_0 up to normalization constant and can sample from it.

In on-demand evaluation, we can query $f(x)$ (e.g. labeling an instance) or draw a sample from p_0; typically, querying $f(x)$ is significantly cheaper than sampling from p_0. We obtain prediction sets $X_1, \ldots, X_m$ sequentially as the systems are submitted for evaluation. Our goal is to estimate π_i and r_i for each system $i = 1, \ldots, m$.

4.2 Simple estimators

We can estimate each π_i and r_i independently with simple Monte Carlo integration. Let $\hat{X}_1, \ldots, \hat{X}_m$ be multi-sets of $n_1, \ldots, n_j$ i.i.d. samples from $X_1, \ldots, X_m$ respectively, and let $\hat{Y}_0$ be a multiset of n_0 samples drawn from $\mathcal{Y}$. Then, the simple estimators for precision and recall are:

$$\hat{\pi}_i^{(\text{simple})} = \frac{1}{n_i} \sum_{x \in \hat{X}_i} f(x) \quad \hat{r}_i^{(\text{simple})} = \frac{1}{n_0} \sum_{x \in \hat{Y}_0} g_i(x).$$

4.3 Joint estimators[6]

The simple estimators are unbiased but have wastefully large variance because evaluating a new system does not leverage labels acquired for previous systems.

On-demand evaluation with the joint estimator works as follows: First $\hat{Y}_0$ is randomly sampled from $\mathcal{Y}$ once when the evaluation framework is launched. For every new set of predictions X_m submitted for evaluation, the minimum number of samples n_m required to accurately evaluate X_m is calculated based on the current evaluation data, $\hat{Y}_0$ and $\hat{X}_1, \ldots, \hat{X}_{m-1}$. Then, the set $\hat{X}_m$ is added to the evaluation data by evaluating $f(x)$ on n_m samples drawn from X_m. Finally, estimates π_i and r_i are updated for each system $i = 1, \ldots, m$ using the joint estimators that will be defined next. In the rest of this section, we will answer the following three questions:

1. How can we use all the samples $\hat{X}_1, \ldots \hat{X}_m$ when estimating the precision π_i of system i?
2. How can we use all the samples $\hat{X}_1, \ldots, \hat{X}_m$ with $\hat{Y}_0$ when estimating recall r_i?
3. Finally, to form $\hat{X}_m$, how many samples should we draw from X_m given existing samples and $\hat{X}_1, \ldots, \hat{X}_{m-1}$ and $\hat{Y}_0$?

Estimating precision jointly. Intuitively, if two systems have very similar predictions X_i and X_j,

[6] Proofs for claims made in this section can be found in Appendix B of the supplementary material.

we should be able to use samples from one to estimate precision on the other. However, it might also be the case that X_i and X_j only overlap on a small region, in which case the samples from X_j do not accurately represent instances in X_i and could lead to a biased estimate. We address this problem by using importance sampling (Owen, 2013), a standard statistical technique for estimating properties of one distribution using samples from another distribution.

In importance sampling, if $\hat{X}_i$ is sampled from q_i, then $\frac{1}{n_i}\sum_{x\in\hat{X}_i}\frac{p_i(x)}{q_i(x)}f(x)$ is an unbiased estimate of π_i. We would like the proposal distribution q_i to both leverage samples from all m systems and be tailored towards system i. To this end, we first define a distribution over systems j, represented by probabilities w_{ij}. Then, define q_i as sampling a j and drawing $x \sim p_j$; formally $q_i(x) = \sum_{j=1}^{m} w_{ij}p_j(x)$.

We note that $q_i(x)$ not only significantly differs between systems, but also changes as new systems are added to the evaluation pool. Unfortunately, the standard importance sampling procedure requires us to draw and use samples from each distribution $q_i(x)$ independently and thus can not effectively reuse samples drawn from different distributions. To this end, we introduce a practical refinement to the importance sampling procedure: we independently draw n_j samples according to $p_j(x)$ from each of the m systems independently and then numerically integrate over these samples using the weights w_{ij} to "mix" them appropriately to produce and unbiased estimate of π_i while reducing variance. Formally, we define the *joint precision estimator*:

$$\hat{\pi}_i^{\text{(joint)}} \overset{\text{def}}{=} \sum_{j=1}^{m} \frac{w_{ij}}{n_j} \sum_{x\in\hat{X}_j} \frac{p_i(x)f(x)}{q_i(x)},$$

where each $\hat{X}_j$ consists of n_j i.i.d. samples drawn from p_j.

It is a hard problem to determine what the optimal mixing weights w_{ij} should be. However, we can formally verify that if X_i and X_j are disjoint, then $w_{ij} = 0$ minimizes the variance of π_i, and if $X_i = X_j$, then $w_{ij} \propto n_j$ is optimal. This motivates the following heuristic choice which interpolates between these two extremes: $w_{ij} \propto n_j \sum_{x\in\mathcal{X}} p_j(x)p_i(x)$.

Estimating recall jointly. The recall of system i can be expressed can be expressed as a product $r_i = \theta\nu_i$, where θ is the *recall of the pool*, which measures the fraction of all positive instances predicted by the pool (any system), and ν_i is the *pooled recall of system* i, which measures the fraction of the pool's positive instances predicted by system i. Letting $g(x) \overset{\text{def}}{=} \mathbb{I}[x \in X]$, we can define these as:

$$\nu_i \overset{\text{def}}{=} \mathbb{E}_{x\sim p_0}[g_i(x) \mid x \in X] \quad \theta \overset{\text{def}}{=} \mathbb{E}_{x\sim p_0}[g(x)].$$

We can estimate θ analogous to the simple recall estimator $\hat{r}_i$, except we use the pool g instead a system g_i. For ν_i, the key is to leverage the work from estimating precision. We already evaluated $f(x)$ on $\hat{X}_i$, so we can compute $\hat{Y}_i \overset{\text{def}}{=} \hat{X}_i \cap \mathcal{Y}$ and form the subset $\hat{Y} = \bigcup_{i=1}^{m} \hat{Y}_i$. $\hat{Y}$ is an approximation of $\mathcal{Y}$ whose bias we can correct through importance reweighting. We then define estimators as follows:

$$\hat{\nu}_i \overset{\text{def}}{=} \frac{\sum_{j=1}^{m}\frac{w_{ij}}{n_j}\sum_{x\in\hat{Y}_j}\frac{p_0(x)g_i(x)}{q_i(x)}}{\sum_{j=1}^{m}\frac{w_{ij}}{n_j}\sum_{x\in\hat{Y}_j}\frac{p_0(x)}{q_i(x)}}$$

$$\hat{r}_i^{\text{(joint)}} \overset{\text{def}}{=} \hat{\theta}\hat{\nu}_i \quad \hat{\theta} \overset{\text{def}}{=} \frac{1}{n_0}\sum_{x\in\hat{Y}_0} g(x).$$

where q_i and w_{ij} are the same as before.

Adaptively choosing the number of samples. Finally, a desired property for on-demand evaluation is to label new instances only when the current evaluation data is insufficient, e.g. when a new set of predictions X_m contains many instances not covered by other systems. We can measure how well the current evaluation set covers the predictions X_m by using a conservative estimate of the variance of $\hat{\pi}_m^{\text{(joint)}}$.[7] In particular, the variance of $\hat{\pi}_m^{\text{(joint)}}$ is a monotonically decreasing function in n_m, the number of samples drawn from X_m. We can easily solve for the minimum number of samples required to estimate $\hat{\pi}_m^{\text{(joint)}}$ within a confidence interval ϵ by using the bisection method (Burden and Faires, 1985).

5 On-demand evaluation for KBP

Applying the on-demand evaluation framework to a task requires us to answer three questions:

1. What is the desired distribution over system predictions p_i?

[7] Further details can be found in Appendix B of the supplementary material.

2. How do we label an instance x, i.e. check if $x \in \mathcal{Y}$?
3. How do we sample from the unknown set of true instances $x \sim p_0$?

In this section, we present practical implementations for knowledge base population.

5.1 Sampling from system predictions

Both the official TAC-KBP evaluation and the on-demand evaluation we propose use micro-averaged precision and recall as metrics. However, in the official evaluation, these metrics are computed over a fixed set of evaluation entities chosen by LDC annotators, resulting in two problems: (a) defining evaluation entities requires human intervention and (b) typically a large source of variability in evaluation scores comes from not having enough evaluation entities (see e.g. (Webber, 2010)). In our methodology, we replace manually chosen evaluation entities by sampling entities from each system's output according p_i. In effect, p_i makes explicit the decision process of the annotator who chooses evaluation entities.

Identifying a reasonable distribution p_i is an important implementation decision that depends on what one wishes to evaluate. Our goal for the on-demand evaluation service we have implemented is to ensure that KBP systems are fairly evaluated on diverse subjects and predicates, while at the same time, ensuring that entities with multiple relations are represented to measure completeness of knowledge base entries. As a result, we propose a distribution that is inversely proportional to the frequency of the subject and predicate and is proportional to the number of unique relations identified for an entity (to measure knowledge base completeness). See Appendix A in the supplementary material for an analysis of this distribution and a study of other potential choices.

5.2 Labeling predicted instances

We label predicted relation instances by presenting the instance's provenance to crowdworkers and asking them to identify if a relation holds between the identified subject and object mentions (Figure 4a). Crowdworkers are also asked to link the subject and object mentions to their canonical mentions within the document and to pages on Wikipedia, if possible, for entity linking. On average, we find that crowdworkers are able to perform this task in about 20 seconds, corresponding to about \$0.05 per instance. We requested 5 crowdworkers to annotate a small set of 200 relation instances from the 2015 TAC-KBP corpus and measured a substantial inter-annotator agreement with a Fleiss' kappa of 0.61 with 3 crowdworkers and 0.62 with 5. Consequently, we take a majority vote over 3 workers in subsequent experiments.

5.3 Sampling true instances

Sampling from the set of true instances $\mathcal{Y}$ is difficult because we can't even enumerate the elements of $\mathcal{Y}$. As a proxy, we assume that relations are identically distributed across documents and have crowdworkers annotate a random subset of documents for relations using an interface we developed (Figure 4b). Crowdworkers begin by identifying every mention span in a document. For each mention, they are asked to identify its type, canonical mention within the document and associated Wikipedia page if possible. They are then presented with a separate interface to label predicates between pairs of mentions within a sentence that were identified earlier.

We compare crowdsourced annotations against those of expert annotators using data from the TAC KBP 2015 EDL task on 10 randomly chosen documents. We find that 3 crowdworkers together identify 92% of the entity spans identified by expert annotators, while 7 crowdworkers together identify 96%. When using a token-level majority vote to identify entities, 3 crowdworkers identify about 78% of the entity spans; this number does not change significantly with additional crowdworkers. We also measure substantial token-level inter-annotator agreement using Fleiss' kappa for identifying typed mention spans ($\kappa = 0.83$), canonical mentions ($\kappa = 0.75$) and entity links ($\kappa = 0.75$) with just three workers. Based on this analysis, we use token-level majority over 3 workers in subsequent experiments.

The entity annotation interface is far more involved and takes on average about 13 minutes per document, corresponding to about \$2.60 per document, while the relation annotation interface takes on average about \$2.25 per document. Because documents vary significantly in length and complexity, we set rewards for each document based on the number of tokens (.75c per token) and mention pairs (5c per pair) respectively. With 3 workers per document, we paid about \$15 per document on average. Each document contained an average

(f)

Figure 4: **(a, b):** Interfaces for annotating relations and entities respectively. **(c, d):** A comparison of bias for the pooling, simple and joint estimators on the TAC KBP 2015 challenge. Each point in the figure is a mean of 500 repeated trials; dotted lines show the 90% quartile. Both the simple and joint estimators are unbiased, and the joint estimator is able to significantly reduce variance. **(e):** A comparison of the number of samples used to estimate scores under the fixed and adaptive sample selection scheme. Each faint line shows the number of samples used during a single trial, while solid lines show the mean over 100 trials. The dashed line shows a square-root relationship between the number of systems evaluated and the number of samples required. Thus joint estimation combined with adaptive sample selection can reduce the number of labeled annotations required by an order of magnitude. **(f):** Precision (P), recall (R) and F_1 scores from a pilot run of our evaluation service for ensembles of a rule-based system (R), a logistic classifier (L) and a neural network classifier (N) run on the TAC KBP 2016 document corpus.

9.2 relations, resulting in a cost of about $1.61 per relation instance. We note that this is about ten times as much as labeling a relation instance.

We defer details regarding how documents themselves should be weighted to capture diverse entities that span documents to Appendix A.

6 Evaluation

Let us now see how well on-demand evaluation works in practice. We begin by empirically studying the bias and variance of the joint estimator proposed in Section 4 and find it is able to correct for pooling bias while significantly reducing variance in comparison with the simple estimator. We then demonstrate that on-demand evaluation can serve as a practical replacement for the TAC KBP evaluations by piloting a new evaluation service we have developed to evaluate three distinct systems on TAC KBP 2016 document corpus.

6.1 Bias and variance of the on-demand evaluation.

Once again, we use the labeled system predictions from the TAC KBP 2015 evaluation and treat them as an exhaustively annotated dataset. To evaluate the pooling methodology we construct an evaluation dataset using instances found by human annotators and labeled instances pooled from 9 randomly chosen teams (i.e. half the total number of participating teams), and use this dataset to evaluate the remaining 9 teams. On average, the pooled evaluation dataset contains between 5,000 and 6,000 labeled instances and evaluates 34 different systems (since each team may have submitted multiple systems). Next, we evaluated sets of 9 randomly chosen teams with our proposed simple and joint estimators using a total of 5,000 samples: about 150 of these samples are drawn from $\mathcal{Y}$, i.e. the full TAC KBP 2015 evaluation data, and 150 samples from each of the systems being evaluated.

We repeat the above simulated experiment 500 times and compare the estimated precision and recall with their true values (Figure 4). The simulations once again highlights that the pooled methodology is biased, while the simple and joint estimators are not. Furthermore, the joint estimators significantly reduce variance relative to the simple estimators: the median 90% confidence intervals reduce from 0.14 to 0.06 precision and from 0.14 to 0.08 for recall.

6.2 Number of samples required by on-demand evaluation

Separately, we evaluate the efficacy of the adaptive sample selection method described in Section 4.3 through another simulated experiment. In each trial of this experiment, we evaluate the top 40 systems in random order. As each subsequent system is evaluated, the number of samples to pick from the system is chosen to meet a target variance and added to the current pool of labeled instances. To make the experiment more interpretable, we choose the target variance to correspond with the estimated variance of having 500 samples. Figure 4 plots the results of the experiment. The number of samples required to estimate systems quickly drops off from the benchmark of 500 samples as the pool of labeled instances covers more systems. This experiment shows that on-demand evaluation using joint estimation can scale up to an order of magnitude more submissions than a simple estimator for the same cost.

6.3 A mock evaluation for TAC KBP 2016

We have implemented the on-demand evaluation framework described here as an evaluation service to which researchers can submit their own system predictions. As a pilot of the service, we evaluated three relation extraction systems that also participated in the official 2016 TAC KBP competition. Each system uses Stanford CoreNLP (Manning et al., 2014) to identify entities, the Illinois Wikifier (Ratinov et al., 2011) to perform entity linking and a combination of a rule-based system (P), a logistic classifier (L), and a neural network classifier (N) for relation extraction. We used 15,000 Newswire documents from the 2016 TAC KBP evaluation as our document corpus. In total, 100 documents were exhaustively annotated for about $2,000 and 500 instances from each system were labeled for about $150 each. Evaluating all three system only took about 2 hours.

Figure 4f reports scores obtained through on-demand evaluation of these systems as well as their corresponding official TAC evaluation scores. While the relative ordering of systems between the two evaluations is the same, we note that precision and recall as measured through on-demand evaluation are respectively higher and lower than the official scores. This is to be expected because on-demand evaluation measures precision using each systems output as opposed to an externally defined set of evaluation entities. Likewise, recall is measured using exhaustive annotations of relations within the corpus instead of annotations from pooled output in the official evaluation.

7 Related work

The subject of pooling bias has been extensively studied in the information retrieval (IR) community starting with Zobel (1998), which examined the effects of pooling bias on the TREC AdHoc task, but concluded that pooling bias was not a significant problem. However, when the topic was later revisited, Buckley et al. (2007) identified that the reason for the small bias was because the submissions to the task were too similar; upon repeating the experiment using a novel system as part of the TREC Robust track, they identified a 23% point drop in average precision scores![8]

Many solutions to the pooling bias problem have been proposed in the context of information retrieval, e.g. adaptively constructing the pool to collect relevant data more cost-effectively (Zobel, 1998; Cormack et al., 1998; Aslam et al., 2006), or modifying the scoring metrics to be less sensitive to unassessed data (Buckley and Voorhees, 2004; Sakai and Kando, 2008; Aslam et al., 2006). Many of these ideas exploit the ranking of documents in IR which does not apply to KBP. While both Aslam et al. (2006) and Yilmaz et al. (2008) estimate evaluation metrics by using importance sampling estimators, the techniques they propose require knowing the set of all submissions beforehand. In contrast, our on-demand methodology can produce unbiased evaluation scores for new development systems as well.

There have been several approaches taken to crowdsource data pertinent to knowledge base population (Vannella et al., 2014; Angeli et al., 2014; He et al., 2015; Liu et al., 2016). The most extensive annotation effort is probably Pavlick et al. (2016), which crowdsources a knowledge base for gun-violence related events. In contrast to previous work, our focus is on *evaluating systems*, not collecting a dataset. Furthermore, our main contribution is not a large dataset, but an evaluation service that allows anyone to use crowdsourcing predictions made by their system.

8 Discussion

Over the last ten years of the TAC KBP task, the gap between human and system performance has barely narrowed despite the community's best efforts: top automated systems score less than 36% F_1 while human annotators score more than 60%. In this paper, we've shown that the current evaluation methodology may be a contributing factor because of its bias against novel system improvements. The new on-demand framework proposed in this work addresses this problem by obtaining human assessments of new system output through crowdsourcing. The framework is made economically feasible by carefully sampling output to be assessed and correcting for sample bias through importance sampling.

Of course, simply providing better evaluation scores is only part of the solution and it is clear that better datasets are also necessary. However, the very same difficulties in scale that make evaluating KBP difficult also make it hard to collect a high quality dataset for the task. As a result, existing datasets (Angeli et al., 2014; Adel et al., 2016) have relied on the output of existing systems, making it likely that they exhibit the same biases against novel systems that we've discussed in this paper. We believe that providing a fair and standardized evaluation platform as a service allows researchers to exploit such datasets and while still being able to accurately measure their performance on the knowledge base population task.

There are many other tasks in NLP that are even harder to evaluate than KBP. Existing evaluation metrics for tasks with a generation component—such as summarization or dialogue—leave much to be desired. We believe that adapting the ideas of this paper to those tasks is a fruitful direction, as progress of a research community is strongly tied to the fidelity of evaluation.

Abstract

In order to adopt deep learning for information retrieval, models are needed that can capture all relevant information required to assess the relevance of a document to a given user query. While previous works have successfully captured unigram term matches, how to fully employ position-dependent information such as proximity and term dependencies has been insufficiently explored. In this work, we propose a novel neural IR model named *PACRR* aiming at better modeling position-dependent interactions between a query and a document. Extensive experiments on six years' TREC Web Track data confirm that the proposed model yields better results under multiple benchmarks.

1 Introduction

Despite the widespread use of deep neural models across a range of linguistic tasks, to what extent such models can improve information retrieval (IR) and which components a deep neural model for IR should include remain open questions. In ad-hoc IR, the goal is to produce a ranking of relevant documents given an open-domain ("ad hoc") query and a document collection. A ranking model thus aims at evaluating the interactions between different documents and a query, assigning higher scores to documents that better match the query. Learning to rank models, like the recent IRGAN model (Wang et al., 2017), rely on handcrafted features to encode query document interactions, e.g., the relevance scores from unsupervised ranking models. Neural IR models differ in that they extract interactions directly based on the queries and documents. Many early neural IR models can be categorized as *semantic matching* models, as they embed both queries and documents into a low-dimensional space, and then assess their similarity based on such dense representations. Examples in this regard include *DSSM* (Huang et al., 2013) and *DESM* (Mitra et al., 2016). The notion of relevance is inherently asymmetric, however, making it different from well-studied semantic matching tasks such as semantic relatedness and paraphrase detection. Instead, *relevance matching* models such as MatchPyramid (Pang et al., 2016), DRMM (Guo et al., 2016) and the recent K-NRM (Xiong et al., 2017) resemble traditional IR retrieval measures in that they directly consider the relevance of documents' contents with respect to the query. The DUET model (Mitra et al., 2017) is a hybrid approach that combines signals from a local model for relevance matching and a distributed model for semantic matching. The two classes of models are fairly distinct. In this work, we focus on relevance matching models.

Given that relevance matching approaches mirror ideas from traditional retrieval models, the decades of research on ad-hoc IR can guide us with regard to the specific kinds of relevance signals a model ought to capture. Unigram matches are the most obvious signals to be modeled, as a counterpart to the term frequencies that appear in almost all traditional retrieval models. Beyond this, positional information, including where query terms occur and how they depend on each other, can also be exploited, as demonstrated in retrieval models that are aware of term proximity (Tao and Zhai, 2007) and term dependencies (Huston and Croft, 2014; Metzler and Croft, 2005). Query coverage is another factor that can be used to ensure that, for queries with multiple terms, top-ranked documents contain multiple query terms rather than emphasizing only one query term. For example, given the query

Proceedings of the 2017 Conference on Empirical Methods in Natural Language Processing, pages 1049–1058
Copenhagen, Denmark, September 7–11, 2017.

"dog adoption requirements", unigram matching signals correspond to the occurrences of the individual terms "dog", "adoption", or "requirements". When considering positional information, text passages with "dog adoption" or "requirements for dog adoption" are highlighted, distinguishing them from text that only includes individual terms. Query coverage, meanwhile, further emphasizes that matching signals for "dog", "adoption", and "requirements" should all be included in a document.

Similarity signals from unigram matches are taken as input by DRMM (Guo et al., 2016) after being summarized as histograms, whereas K-NRM (Xiong et al., 2017) directly digests a query-document similarity matrix and summarizes it with multiple kernel functions. As for positional information, both the MatchPyramid (Pang et al., 2016) and local DUET (Mitra et al., 2017) models account for it by incorporating convolutional layers based on similarity matrices between queries and documents. Although this leads to more complex models, both have difficulty in significantly outperforming the DRMM model (Guo et al., 2016; Mitra et al., 2017). This indicates that it is non-trivial to go beyond unigrams by utilizing positional information in deep neural IR models. Intuitively, unlike in standard sequence-based models, the interactions between a query and a document are sequential along the query axis as well as along the document axis, making the problem multi-dimensional in nature. In addition, this makes it non-trivial to combine matching signals from different parts of the documents and over different query terms. In fact, we argue that both MatchPyramid and local DUET models fail to fully account for one or more of the aforementioned factors. For example, as a pioneering work, MatchPyramid is mainly motivated by models developed in computer vision, resulting in its disregard of certain IR-specific considerations in the design of components, such as pooling sizes that ignore the query and document dimensions. Meanwhile, local DUET's CNN filters match entire documents against individual query terms, neglecting proximity and possible dependencies among different query terms.

We conjecture that a suitable combination of convolutional kernels and recurrent layers can lead to a model that better accounts for these factors. In particular, we present a novel re-ranking model called *PACRR* (*Position-Aware Convolutional-Recurrent Relevance* Matching). Our approach first produces similarity matrices that record the semantic similarity between each query term and each individual term occurring in a document. These matrices are then fed through a series of convolutional, max-k-pooling, and recurrent layers so as to capture interactions corresponding to, for instance, bigram and trigram matches, and finally to aggregate the signals in order to produce global relevance assessments. In our model, the convolutional layers are designed to capture both unigram matching and positional information over text windows with different lengths; k-max pooling layers are along the query dimension, preserving matching signals over different query terms; the recurrent layer combines signals from different query terms to produce a query-document relevance score.

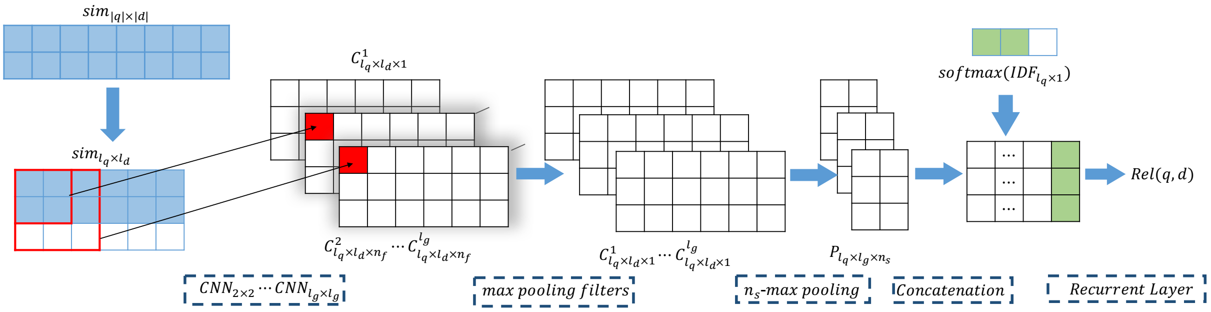
Organization. The rest of this paper unfolds as follows. Section 2 describes our approach for computing similarity matrices and the architecture of our deep learning model. The setup and results of our extensive experimental evaluation can be found in Section 3, before concluding in Section 4.

2 The PACRR Model

We now describe our proposed *PACRR* approach, which consists of two main parts: a relevance matching component that converts each query-document pair into a similarity matrix $sim_{|q|\times|d|}$ and a deep architecture that takes a given query-document similarity matrix as input and produces a query-document relevance score $rel(q,d)$. Note that in principle the proposed model can be trained end-to-end by backpropagating through the word embeddings, as in (Xiong et al., 2017). In this work, however, we focus on highlighting the building blocks aiming at capturing positional information, and freeze the word embedding layer to achieve better efficiency. The pipeline is summarized in Figure 1.

2.1 Relevance Matching

We first encode the query-document relevance matching via query-document similarity matrices $sim_{|q|\times|d|}$ that encodes the similarity between terms from a query q and a document d, where sim_{ij} corresponds to the similarity between the i-th term from q and the j-th term from d. When using cosine similarity, we have



$sim_{|q|\times|d|}$
$sim_{l_q\times l_d}$
$C^1_{l_q\times l_d\times 1}$
$C^2_{l_q\times l_d\times n_f}\cdots C^{l_g}_{l_q\times l_d\times n_f}$
$C^1_{l_q\times l_d\times 1}\cdots C^{l_g}_{l_q\times l_d\times 1}$
$P_{l_q\times l_g\times n_s}$
$softmax(IDF_{l_q\times 1})$
...
$Rel(q,d)$
$CNN_{2\times 2}\cdots CNN_{l_g\times l_g}$
max pooling filters
n_s-max pooling
Concatenation
Recurrent Layer

Figure 1: The pipeline of *PACRR*. Each query q and document d is first converted into a query-document similarity matrix $sim_{|q|\times|d|}$. Thereafter, a distillation method (*firstk* is displayed) transforms the raw similarity matrix into unified dimensions, namely, $sim_{l_q\times l_d}$. Here, $l_g - 1$ convolutional layers (CNN) are applied to the distilled similarity matrices. As $l_g = 3$ is shown, layers with kernel size 2 and 3 are applied. Next, max pooling is applied, leading to l_g matrices $C^1 \cdots C^{l_g}$. Following this, n_s-max pooling captures the strongest n_s signals over each query term and n-gram size, and the case for $n_s = 2$ is shown here. Finally, the similarity signals from different n-gram sizes are concatenated, the query terms' normalized IDFs are added, and a recurrent layer combines these signals for each query term into a query-document relevance score $rel(q, d)$.

$sim \in [-1, 1]^{|q|\times|d|}$. As suggested in (Hui et al., 2017), query-document similarity matrices preserve a rich signal that can be used to perform relevance matching beyond unigram matches. In particular, n-gram matching corresponds to consecutive document terms that are highly similar to at least one of the query terms. Query coverage is reflected in the number of rows in *sim* that include at least one cell with high similarity. The similarity between a query term q and document term d is calculated by taking the cosine similarity using the pre-trained[1] *word2vec* (Mikolov et al., 2013).

The subsequent processing in PACRR's convolutional layers requires that each query-document similarity matrix have the same dimensionality. Given that the lengths of queries and documents vary, we first transform the raw similarity matrices $sim_{|q|\times|d|}$ into $sim_{l_q\times l_d}$ matrices with uniform l_q and l_d as the number of rows and columns. We unify the query dimension l_q by zero padding it to the maximum query length. With regard to the document dimension l_d, we describe two strategies: *firstk* and *kwindow*.

PACRR-firstk. Akin to (Mitra et al., 2017), the *firstk* distillation method simply keeps the first k columns in the matrix, which correspond to the first k terms in the document. If $k > |d|$, the remaining columns are zero padded.

PACRR-kwindow. As suggested in (Guo et al., 2016), relevance matching is local. Document terms that have a low query similarity relative to a document's other terms cannot contribute substantially to the document's relevance score. Relevance matching can be extracted in terms of pieces of text that include relevant information. That is, one can segment documents according to relevance relative to the given query and retain only the text that is highly relevant to the given query. Given this observation, we prune query-document similarity cells with a low similarity score. In the case of unigrams, we simply choose the top l_d terms with the highest similarity to query terms. In the case for *text snippets* beyond length n, we produce a similarity matrix $sim^n_{l_q\times l_d}$ for each query-document pair and each n, because n consecutive terms must be co-considered later on. For each text snippet with length n in the document, *kwindow* calculates the maximum similarity between each term and the query terms, and then calculates the average similarity over each n-term window. It then selects the top $k = \lfloor l_d/n \rfloor$ windows by averaging similarity and discards all other terms in the document. The document dimension is zero padded if $\lfloor l_d/n \rfloor$ is not a multiple of k. When the convolutional layer later operates on a similarity matrix produced by *kwindow*, the model's stride is set to n (i.e., the sliding window moves ahead n terms at a time rather than one term at a time) since it can consider at most n consecutive terms that are

[1] https://code.google.com/archive/p/word2vec/

present in the original document. This variant's output is a similarity matrix $sim^n_{l_q \times l_d}$ for each n.

2.2 Deep Retrieval Model

Given a query-document similarity matrix $sim_{l_q \times l_d}$ as input, our deep architecture relies on convolutional layers to match every text snippet with length n in a query and in a document to produce similarity signals for different n. Subsequently, two consecutive max pooling layers extract the document's strongest similarity cues for each n. Finally, a recurrent layer aggregates these salient signals to predict a global query-document relevance score $rel(q, d)$.

Convolutional relevance matching over local text snippets. The purpose of this step is to match text snippets with different length from a query and a document given their query-document similarity matrix as input. This is accomplished by applying multiple two-dimensional convolutional layers with different kernel sizes to the input similarity matrix. Each convolutional layer is responsible for a specific n; by applying its kernel on $n \times n$ windows, it produces a similarity signal for each window. When the *firstk* method is used, each convolutional layer receives the same similarity matrix $sim_{l_q \times l_d}$ as input because *firstk* produces the same similarity matrix regardless of the n. When the *kwindow* method is used, each convolutional layer receives a similarity matrix $sim^n_{l_q \times l_d}$ corresponding to the convolutional layer with a $n \times n$ kernel. We use $l_g - 1$ different convolutional layers with kernel sizes $2 \times 2, 3 \times 3, \ldots, l_g \times l_g$, corresponding to bi-gram, tri-gram, ..., l_g-gram matching, respectively, where the length of the longest text snippet to consider is governed by a hyperparameter l_g. The original similarity matrix corresponds to unigram matching, while a convolutional layer with kernel size $n \times n$ is responsible for capturing matching signals on n-term text snippets. Each convolutional layer applies n_f different filters to its input, where n_f is another hyperparameter. We use a stride of size (1, 1) for the *firstk* distillation method, meaning that the convolutional kernel advances one step at a time in both the query and document dimensions. For the *kwindow* distillation method, we use a stride of (1, n) to move the convolutional kernel one step at a time in the query dimension, but n steps at a time in the document dimension. This ensures that the convolutional kernel only operates over consecutive terms that existed in the original document. Thus, we end up with $l_g - 1$ matrices $\mathcal{C}^n_{l_q \times l_d \times n_f}$, and the original similarity matrix is directly employed to handle the signals over unigrams.

Two max pooling layers. The purpose of this step is to capture the n_s strongest similarity signals for each query term. Measuring the similarity signals separately for each query term allows the model to consider query term coverage, while capturing the n_s strongest similarity signals for each query term allows the model to consider signals from different kinds of relevance matching patterns, e.g., n-gram matching and non-contiguous matching. In practice, we use a small n_s to prevent the model from being biased by document length; while each similarity matrix contains the same number of document term scores, longer documents have more opportunity to contain terms that are similar to query terms. To capture the strongest n_s similarity signals for each query term, we first perform max pooling over the filter dimension n_f to keep only the strongest signal from the n_f different filters, assuming that there only exists one particular true matching pattern in a given $n \times n$ window, which serves different purposes compared with other tasks, such as the sub-sampling in computer vision. We then perform k-max pooling (Kalchbrenner et al., 2014) over the query dimension l_q to keep the strongest n_s similarity signals for each query term. Both pooling steps are performed on each of the $l_g - 1$ matrices $\mathcal{C}^i$ from the convolutional layer and on the original similarity matrix, which captures unigram matching, to produce the 3-dimensional tensor $\mathcal{P}_{l_q \times l_g \times n_s}$. This tensor contains the n_s strongest signals for each query term and for each n-gram size across all n_f filters.

Recurrent layer for global relevance. Finally, our model transforms the query term similarity signals in $\mathcal{P}_{l_q \times l_g \times n_s}$ into a single document relevance score $rel(q, d)$. It achieves this by applying a recurrent layer to $\mathcal{P}$, taking a sequence of vectors as input and learning weights to transform them into the final relevance score. More precisely, akin to (Guo et al., 2016), the IDF of each query term q_i is passed through a softmax layer for normalization. Thereafter, we split up the query term dimension to produce a matrix $\mathcal{P}_{l_g \times n_s}$ for each query term q_i, subsequently forming the recurrent layer's input by flattening each matrix $\mathcal{P}_{l_g \times n_s}$ into a vector by concatenating the matrix's rows together and appending query term q_i's normalized

IDF onto the end of the vector. This sequence of vectors for each query term q_i is passed into a Long Short-Term Memory (LSTM) recurrent layer (Hochreiter and Schmidhuber, 1997) with an output dimensionality of one. That is, the LSTM's input is a sequence of query term vectors where each vector is composed of the query term's normalized IDF and the aforementioned salient signals for the query term along different kernel sizes. The LSTM's output is then used as our document relevance score $rel(q, d)$.

Training objective. Our model is trained on triples consisting of a query q, relevant document d^+, and non-relevant document d^-, minimizing a standard pairwise max margin loss as in Eq. 1.

$$\mathcal{L}(q,d^+,d^-;\Theta)=max(0,1-rel(q,d^+)+rel(q,d^-)) \qquad (1)$$

3 Evaluation

In this section, we empirically evaluate *PACRR* models using manual relevance judgments from the standard TREC Web Track. We compare them against several state-of-the-art neural IR models[2], including *DRMM* (Guo et al., 2016), DUET (Mitra et al., 2017), *MatchPyramid* (Pang et al., 2016), and *K-NRM* (Xiong et al., 2017). The comparisons are over three task settings: re-ranking search results from a simple initial ranker (RERANKSIMPLE); re-ranking all runs from the TREC Web Track (RERANKALL); and examining neural IR models' classification accuracy between document pairs (PAIRACCURACY).

3.1 Experimental Setup

We rely on the widely-used 2009–2014 TREC Web Track ad-hoc task benchmarks[3]. The benchmarks are based on the CLUEWEB09 and CLUEWEB12 datasets as document collections. In total, there are 300 queries and more than 100k judgments (qrels). Three years (2012–14) of query-likelihood baselines[4] provided by TREC[5] serve as baseline runs in the RERANKSIMPLE benchmark. In the RERANKALL setting, the search results from runs submitted by participants from each year are also considered: there are 71 (2009), 55 (2010), 62 (2011), 48 (2012), 50 (2013), and 27 (2014) runs. ERR@20 (Chapelle et al., 2009) and nDCG@20 (Järvelin and Kekäläinen, 2002) are employed as evaluation measures, and both are computed with the script from TREC[6].

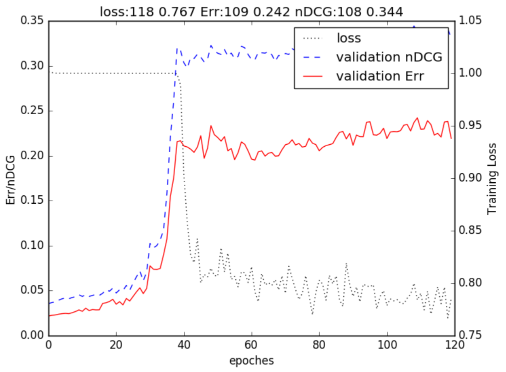


Figure 2: The training loss, ERR@20 and nDCG@20 per iteration on validation data when training on Web Track 2010–14. The x-axis denotes the iterations. The y-axis indicates the ERR@20/nDCG@20 (left) and the loss (right). The best performance appears on 109th iteration with ERR@20=0.242. The lowest training loss (0.767) occurs after 118 iterations.

Training. At each step, we perform Stochastic Gradient Descent (SGD) with a mini-batch of 32 triples. For the purpose of choosing the triples, we consider all documents that are judged with a label more relevant than *Rel*[7] as *highly relevant*, and put the remaining relevant documents into a *relevant* group. To pick each triple, we sample a relevance group with probability proportional to the number of documents in the group within the training set, and then we randomly sample a document with the chosen label to serve as the positive document d^+. If the chosen group is the highly relevant group, we randomly sample a document from the relevant group to serve as the negative document d^-. If the chosen group is the relevant group, we randomly sample a non-relevant document as d^-. This sampling procedure ensures that we differentiate between highly relevant documents (i.e., those with a relevance label of *HRel*, *Key* or *Nav*) and relevant documents (i.e., those are labeled as *Rel*). The training continues until a

[2] We also attempted to include IRGAN (Wang et al., 2017) model as a baseline, but failed to obtain reasonable results when training on TREC data.

[7] Judgments from TREC include junk pages (*Junk*), non-relevance (*NRel*), relevance (*Rel*), high relevance (*HRel*), key pages (*Key*) and navigational pages (*Nav*).

given number of iterations is reached. The model is saved at every iteration. We use the model with the best ERR@20 on the validation set to make predictions. Proceeding in a round-robin manner, we report test results on one year by exploiting the respective remaining five years (250 queries) for training. From these 250 queries, we reserve 50 random queries as a held-out set for validation and hyper-parameter tuning, while the remaining 200 queries serve as the actual training set.

As mentioned, model parameters and training iterations are chosen by maximizing the ERR@20 on the validation set. The selected model is then used to make predictions on the test data. An example of this training procedure is shown in Figure 2. There are four hyper-parameters that govern the behavior of the proposed *PACRR-kwindow* and *PACRR-firstk*: the unified length of the document dimension l_d, the k-max pooling size n_s, the maximum n-gram size l_g, and the number of filters used in convolutional layers n_f. Due to limited computational resources, we determine the range of hyper-parameters to consider based on pilot experiments and domain insights. In particular, we evaluate $l_d \in [256, 384, 512, 640, 768]$, $n_s \in [1, 2, 3, 4]$, and $l_g \in [2, 3, 4]$. Due to the limited possible matching patterns given a small kernel size (e.g., $l_g = 3$), n_f is fixed to 32. For *PACRR-firstk*, we intuitively desire to retain as much information as possible from the input, and thus l_d is always set to 768.

DRMM (*DRMM*$_{LCH \times IDF}$), *DUET*, *MatchPyramid* and *K-NRM* are trained under the same settings using the hyperparameters described in their respective papers. In particular, as our focus is on the deep relevance matching model as mentioned in Section 1, we only compare against DUET's local model, denoted as *DUETL*. In addition, *K-NRM* is trained slightly different from the one described in (Xiong et al., 2017), namely, with a frozen word embedding layer. This is to guarantee its fair comparison with other models, given that most of the compared models can be enhanced by co-training the embedding layers, whereas the focus here is the strength coming from the model architecture. A fully connected middle layer with 30 neurons is added to compensate for the reduction of trainable parameters in *K-NRM*, mirroring the size of DRMM's first fully connected layer.

All models are implemented with Keras (Chollet et al., 2015) using Tensorflow as backend, and are trained on servers with multiple CPU cores. In particular, the training of *PACRR* takes 35 seconds per iteration on average, and in total at most 150 iterations are trained for each model variant.

3.2 Results

RERANKSIMPLE. We first examine the proposed model by re-ranking the search results from the *QL* baseline on Web Track 2012–14. The results are summarized in Table 1. It can be seen that *DRMM* can significantly improve *QL* on WT12 and WT14, whereas *MatchPyramid* fails on WT12 under ERR@20. While *DUETL* and *K-NRM* can consistently outperform *QL*, the two variants of *PACRR* are the only models that can achieve significant improvements at a 95% significance level on all years under both ERR@20 and nDCG@20. More remarkably, by solely re-ranking the search results from *QL*, *PACRR-firstk* can already rank within the top-3 participating systems on all three years as measured by both ERR and nDCG. The re-ranked search results from *PACRR-kwindow* also ranks within the top-5 based on nDCG@20. On average, both *PACRR-kwindow* and *PACRR-firstk* achieve 60% improvements over *QL*.

RERANKALL. In this part, we would like to further examine the performance of the proposed models in re-ranking different sets of search results. Thus, we extend our analysis to re-rank search results from all submitted runs from six years of the TREC Web Track ad-hoc task. In particular, we only consider the judged documents from TREC, which loosely correspond to top-20 documents in each run. The tested models make predictions for individual documents, which are used to re-rank the documents within each submitted run. Given that there are about 50 runs for each year, it is no longer feasible to list the scores for each re-ranked run. Instead, we summarize the results by comparing the performance of each run before and after re-ranking, and provide statistics over each year to compare the methods under consideration in Table 2. In the top portion of Table 2, we report the relative changes in metrics before and after re-ranking in terms of percentages ("average Δ measure score"). In the bottom portion, we report the percentage of systems whose results have increased after re-ranking. Note that these results assess two different aspects: the average Δ measure score in Table 2 captures the degree to which a model can improve an initial run, while

Measure	Years	PACRR-firstk	Rank	PACRR-kwindow	Rank	DUETL	Rank	DRMM	Rank	MatchPyramid	Rank	K-NRM	Rank	QL	Rank

Table 2: The average statistics when re-ranking all runs from the TREC Web Track 2009–14 based on ERR@20 and nDCG@20. The average differences of the scores for individual runs are reported in the top portion. The comparisons are conducted between two variants of PACRR and DRMM (D/d), DUETL (L/l), MatchPyramid (M/m) and K-NRM (K/k). The upper/lower-case characters in parentheses indicate a significant difference under two-tailed paired Student's t-tests at 95% or 90% confidence levels, respectively, relative to the corresponding approach. The percentage of runs that show improvements in terms of a measure is summarized in the bottom portion.

the percentages of runs indicate to what extent an improvement can be achieved over runs from different systems. In other words, the former measures the strength of the models, while the latter measures the adaptability of the models. Both *PACRR* variants improve upon existing rankings by at least 10% across different years. Remarkably, in terms of nDCG@20, at least 80% of the submitted runs are improved after re-ranking by the proposed models on individual years, and on 2010–12, all submitted runs are consistently improved by *PACRR-firstk*. Moreover, both variants of *PACRR* can significantly outperform all baseline models on at least three years out of the six years in terms of average improvement. However, it is clear that none of the tested models can make consistent improvements over all submitted runs across all six years. In other words, there still exist document pairs that are predicted contradicting to the judgments from TREC. Thus, in the next part, we further investigate the performance in terms of prediction over document pairs.

Label Pairs	Volume (%)	# Queries	Tested Methods					
			PACRR-firstk	*PACRR-kwindow*	*DUETL*	*DRMM*	*MatchPyramid*	*K-NRM*
Nav-HRel	0.3%	49	45.8%	45.5%	45.2%	48.2%	47.3%	51.6%
Nav-Rel	1.1%	65	56.0% (m)	56.3% (M)	54%	57% (M)	53.2% (D)	57.4%
Nav-NRel	3.6%	67	76.1% ($DLMK$)	76.6% ($DLMK$)	67.1% (M)	71.5% (M)	64.7% (DLK)	70.8% (M)
HRel-Rel	8.4%	257	57.3%	57.0%	55.5%	55.8%	52.8%	56.1%
HRel-NRel	23.1%	262	76.7% ($DLMK$)	76.4% ($DLMK$)	68.4% (K)	70.1% (MK)	65.6% (DK)	72.5% (DLM)
Rel-NRel	63.5%	290	73.0% ($DLMK$)	72.5% ($DLMK$)	63.9% (DMK)	65.9% (LMK)	61.4% (DLK)	68.7% (DLM)
weighted average			72.4%	72.0%	64.2%	66.1%	61.6%	68.4%

Table 3: Comparison among tested methods in terms of accuracy when comparing document pairs with different labels. The "volume" column indicates the percentage of occurrences of each label combination out of the total pairs. The "# Queries" column records the number of queries that include a particular label combination. The comparisons are conducted between two variants of PACRR and DRMM (D/d), DUETL (L/l), MatchPyramid (M/m) and K-NRM (K/k). The upper/lower-case characters in parentheses indicate a significant difference under two-tailed paired Student's t-tests at 95% or 90% confidence levels, respectively, relative to the corresponding approach. In the last row, the average accuracy among different kinds of label combinations is computed, weighted by their corresponding volume.

PAIRACCURACY. The ranking of documents can be decomposed into rankings of document pairs as suggested in (Radinsky and Ailon, 2011). Specifically, a model's retrieval quality can be examined by checking across a range of individual document pairs, namely, how likely a model can assign a higher score for a more relevant document. Thus, it is possible for us to compare different models over the same set of complete judgments, removing the issue of different initial runs. Moreover, although ranking is our ultimate target, a direct inspection of pairwise prediction results can indicate which kinds of document pairs a model succeeds at or fails on. We first convert the graded judgments from TREC into ranked document pairs by comparing their labels. Document pairs are created among documents that have different labels. A prediction is counted as correct if it assigns a higher score to the document from the pair that is labeled with a higher degree of relevance. The judgments from TREC contain at most six relevance levels, and we merge and unify the original levels from the six years into four grades, namely, *Nav*, *HRel*, *Rel* and *NRel*. We compute the accuracy for each pair of labels. The statistics are summarized in Table 3. The volume column lists the percentage of a given label combination out of all document pairs, and the # query column provides the number of queries for which the label combination exists. In Table 3, we observe that both *PACRR* models always perform better than all baselines on label combinations *HRel* vs. *NRel*, *Rel* vs. *NRel* and *Nav* vs. *NRel*, which in total cover 90% of all document pairs. Meanwhile, apart from *Nav-Rel*, there is no significant difference when distinguishing *Nav* from other types. *K-NRM* and *DRMM* perform better than the other two baseline models.

3.3 Discussion

Hyper-parameters. As mentioned, models are selected based on the ERR@20 over validation data. Hence, it is sufficient to use a reasonable and representative validation dataset, rather than handpicking a specific set of parameter settings. However, to gain a better understanding of the influence of different hyper-parameters, we explore *PACRR-kwindow*'s effectiveness when several hyper-parameters are varied. The results when re-ranking *QL* search results are given in Figure 3. The results are reported based on the models with the highest validation scores after fixing certain hyper-parameters. For example, the ERR@20 in the leftmost figure is obtained when fixing l_d to the values shown. The crosses in Figure 3 correspond to the models that were selected for use on the test data, based on their validation set scores. It can be seen that the selected models are not necessarily the best model on the test data, as evidenced by the differences between validation and test data results, but we consistently obtain scores within a reasonable margin. Owing to space constraints, we omit the plots for *PACRR-firstk*.

Choice between *kwindow* and *firstk* approaches. As mentioned, both *PACRR-kwindow* and *PACRR-firstk* serve to address the variable-length chal-

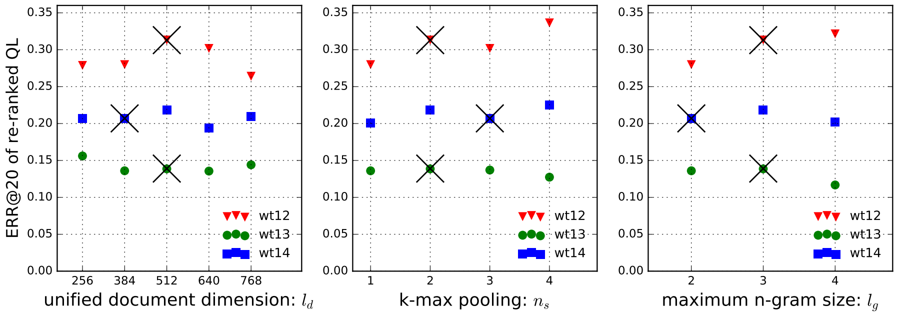

Figure 3: The ERR@20 of re-ranked *QL* with *PACRR-kwindow* when applying different hyper-parameters: l_d, n_s and l_g. The x-axis reflects the settings for hyper-parameters, and the y-axis is the ERR@20. Crosses correspond to the selected models.

lenge for documents and queries, and to make the training feasible and more efficient. In general, if both training and test documents are known to be short enough to fit in memory, then *PACRR-firstk* can be used directly. Otherwise, *PACRR-kwindow* is a reasonable choice to provide comparable results. Alternatively, one can regard this choice as another hyper-parameter, and make a selection based on held-out validation data.

Accuracy in PAIRACCURACY. Beyond the observations in Section 3.2, we further examine the methods' accuracy over binary judgments by merging the *Nav*, *HRel* and *Rel* labels. The accuracies become 73.5%, 74.1% and 67.4% for *PACRR-kwindow*, *PACRR-firstk*, and *DRMM*, respectively. Note that the manual judgments that indicate a document as relevant or non-relevant relative to a given query contain disagreements (Carterette et al., 2008; Voorhees, 2000) and errors (Alonso and Mizzaro, 2012). In particular, a 64% agreement (cf. Table 2 (b) therein) is observed over the inferred relative order among document pairs based on graded judgments from six trained judges (Carterette et al., 2008). When reproducing TREC judgments, Al-Maskari et al. (Al-Maskari et al., 2008) reported a 74% agreement (cf. Table 1 therein) with the original judgments from TREC when a group of users re-judged 56 queries on the TREC-8 document collections. Meanwhile, Alonso and Mizzaro (Alonso and Mizzaro, 2012) observed a 77% agreement relative to judgments from TREC when collecting judgments via crowdsourcing. Therefore, the more than 73% agreement achieved by both *PACRR* methods is close to the aforementioned agreement levels among different human assessors. However, when distinguishing *Nav*, *HRel*, and *Rel*, the tested models still fall significantly short of the human judges' agreement levels. These distinctions are important for a successful ranker, especially when measuring with graded metrics such as ERR@20 and nDCG@20. Hence, further research is needed for better discrimination among relevant documents with different degrees of relevance. In addition, as for the distinction between *Nav* documents and *Rel* or *HRel* documents, we argue that since *Nav* actually indicates that a document mainly satisfies a navigational intent, this makes such documents qualitatively different from *Rel* and *HRel* documents. Specifically, a *Nav* is more relevant for a user with navigational intent, whereas for other users it may in some cases be less useful than a document that directly includes highly pertinent information content. Therefore, we hypothesize that further improvements can be obtained by introducing a classifier for user intents, e.g., navigational pages, before employing neural IR models.

4 Conclusion

In this work, we have demonstrated the importance of preserving positional information for neural IR models by incorporating domain insights into the proposed *PACRR* model. In particular, *PACRR* captures term dependencies and proximity through multiple convolutional layers with different sizes. Thereafter, following two max-pooling layers, it combines salient signals over different query terms with a recurrent layer. Extensive experiments show that *PACRR* substantially outperforms four state-of-the-art neural IR models on TREC Web Track ad-hoc datasets and can dramatically improve search results when used as a re-ranking model.

Abstract

Rapid progress has been made towards question answering (QA) systems that can extract answers from text. Existing neural approaches make use of expensive bidirectional attention mechanisms or score all possible answer spans, limiting scalability. We propose instead to cast extractive QA as an iterative search problem: select the answer's sentence, start word, and end word. This representation reduces the space of each search step and allows computation to be conditionally allocated to promising search paths. We show that globally normalizing the decision process and back-propagating through beam search makes this representation viable and learning efficient. We empirically demonstrate the benefits of this approach using our model, Globally Normalized Reader (GNR), which achieves the second highest single model performance on the Stanford Question Answering Dataset (68.4 EM, 76.21 F1 dev) and is 24.7x faster than bi-attention-flow. We also introduce a data-augmentation method to produce semantically valid examples by aligning named entities to a knowledge base and swapping them with new entities of the same type. This method improves the performance of all models considered in this work and is of independent interest for a variety of NLP tasks.

1 Introduction

Question answering (QA) and information extraction systems have proven to be invaluable in wide variety of applications such as medical information collection on drugs and genes (Quirk and Poon, 2016), large scale health impact studies (Althoff et al., 2016), or educational material development (Koedinger et al., 2015). Recent progress in neural-network based extractive question answering models are quickly closing the gap with human performance on several benchmark QA tasks such as SQuAD (Rajpurkar et al., 2016), MS MARCO (Nguyen et al., 2016), or NewsQA (Trischler et al., 2016a). However, current approaches to extractive question answering face several limitations:

Question

Figure 1: GNR answering a question. It first picks a sentence, then start word, then end word. Probabilities are global and normalized over the beam. Model initially picks the wrong sentence, but global normalization lets it recover. Final prediction's probability (0.64) exceeds sentence pick (0.49), whereas with local normalization each probability is upper bounded by the previous step.

Proceedings of the 2017 Conference on Empirical Methods in Natural Language Processing, pages 1059–1069
Copenhagen, Denmark, September 7–11, 2017. ©2017 Association for Computational Linguistics

1. Computation is allocated equally to the entire document, regardless of answer location, with no ability to ignore or focus computation on specific parts. This limits applicability to longer documents.

2. They rely extensively on expensive bi-directional attention mechanisms (Seo et al., 2016) or must rank all possible answer spans (Lee et al., 2016).

3. While data-augmentation for question answering have been proposed (Zhou et al., 2017), current approaches still do not provide training data that can *improve* the performance of existing systems.

In this paper we demonstrate a methodology for addressing these three limitations, and make the following claims:

1. Extractive Question Answering can be cast as a nested search process, where sentences provide a powerful document decomposition and an easy to learn search step. This factorization enables conditional computation to be allocated to sentences and spans likely to contain the right answer.

2. When cast as a search process, models without bi-directional attention mechanisms and without ranking all possible answer spans can achieve near state of the art results on extractive question answering.

3. Preserving narrative structure and explicitly incorporating type and question information into synthetic data generation is key to generating examples that actually improve the performance of question answering systems.

Our claims are supported by experiments on the SQuAD dataset where we show that the Globally Normalized Reader (GNR), a model that performs an iterative search process through a document (shown visually in Figure 1), and has computation conditionally allocated based on the search process, achieves near state of the art Exact Match (EM) and F1 scores without resorting to more expensive attention or ranking of all possible spans. Furthermore, we demonstrate that Type Swaps, a type-aware data augmentation strategy that aligns named entities with a knowledge base and swaps them out for new entities that share the same type, improves the performance of all models on extractive question answering.

We structure the paper as follows: in Section 2 we introduce the task and our model. Section 3 describes our data-augmentation strategy. Section 4 introduces our experiments and results. In Section 5 we discuss our findings. In Section 6 we relate our work to existing approaches. Conclusions and directions for future work are given in Section 7.

2 Model

Given a document d and a question q, we pose extractive question answering as a search problem. First, we select the sentence, the first word of the span, and finally the last word of the span. A example of the output of the model is shown in Figure 1, and the network architecture is depicted in Figure 2.

More formally, let $d_1, \ldots, d_n$ denote each sentence in the document, and for each sentence d_i, let $d_{i,1}, \ldots, d_{i,m_i}$ denote the word vectors corresponding to the words in the sentence. Similarly, let $q_1, \ldots, q_\ell$ denote the word vectors corresponding to words in the question. An answer is a tuple $a = (i^*, j^*, k^*)$ indicating the correct sentence i^*, start word in the sentence j^* and end word in the sentence k^*. Let $\mathcal{A}(d)$ denote the set of valid answer tuples for document d. We now describe each stage of the model in turn.

2.1 Question Encoding

Each question is encoded by running a stack of bidirectional LSTM (Bi-LSTM) over each word in the question, producing hidden states $(h_1^{\text{fwd}}, h_1^{\text{bwd}}), \ldots, (h_\ell^{\text{fwd}}, h_\ell^{\text{bwd}})$ (Graves and Schmidhuber, 2005). Following Lee et al. (2016), these hidden states are used to compute a *passage-independent question embedding*, q^{indep}. Formally,

$$s_j = w_q^\top \text{MLP}([h_j^{\text{bwd}}; h_j^{\text{fwd}}]) \tag{1}$$

$$\alpha_j = \frac{\exp(s_j)}{\sum_{j'=1}^{\ell} \exp(s_{j'})} \tag{2}$$

$$q^{\text{indep}} = \sum_{j=1}^{\ell} \alpha_j [h_j^{\text{bwd}}; h_j^{\text{fwd}}], \tag{3}$$

where w_q is a trainable embedding vector, and MLP is a two-layer neural network with a Relu non-linearity. The question is represented by concatenating the final hidden states of the forward and backward LSTMs and the passage-independent embedding, $q = [h_1^{\text{bwd}}; h_\ell^{\text{fwd}}; q^{\text{indep}}]$.

2.2 Question-Aware Document Encoding

Conditioned on the question vector, we compute a representation of each document word that is sensitive to both the surrounding context and the question. Specifically, each word in the document is represented as the concatenation of its word vector $d_{i,j}$, the question vector q, boolean features indicating if a word appears in the question or is repeated, and a *question-aligned embedding* from Lee et al. (2016). The question-aligned embedding $q_{i,j}^{\text{align}}$ is given by

$$s_{i,j,k} = \text{MLP}(d_{i,j})^\top \text{MLP}(q_k) \tag{4}$$

$$\alpha_{i,j,k} = \frac{\exp(s_{i,j,k})}{\sum_{k'=1}^{\ell} \exp(s_{i,j,k'})} \tag{5}$$

$$q_{i,j}^{\text{align}} = \sum_{k=1}^{\ell} \alpha_{i,j,k} q_k. \tag{6}$$

The document is encoded by a separate stack of Bi-LSTMs, producing a sequence of hidden states $(h_{1,1}^{\text{fwd}}, h_{1,1}^{\text{bwd}}), \ldots, (h_{n,m_n}^{\text{fwd}}, h_{n,m_n}^{\text{bwd}})$. The search procedure then operates on these hidden states.

2.3 Answer Selection

Sentence selection. The first phase of our search process picks the sentence that contains the answer span. Each sentence d_i is represented by the hidden state of the first and last word in the sentence for the backward and forward LSTM respectively, $[h_{i,1}^{\text{bwd}}; h_{i,m_i}^{\text{fwd}}]$, and is scored by passing this representation through a fully connected layer that outputs the unnormalized sentence score for sentence d_i, denoted $\phi_{\text{sent}}(d_i)$.

Span start selection. After selecting a sentence d_i, we pick the start of the answer span within the sentence. Each potential start word $d_{i,j}$ is represented as its corresponding document encoding $[h_{i,j}^{\text{fwd}}; h_{i,j}^{\text{bwd}}]$, and is scored by passing this encoding through a fully connected layer that outputs the unnormalized start word score for word j in sentence i, denoted $\phi_{\text{sw}}(d_{i,j})$.

Span end selection. Conditioned on sentence d_i and starting word $d_{i,j}$, we select the end word from the remaining words in the sentence $d_{i,j}, \ldots, d_{i,m_i}$. To do this, we run a Bi-LSTM over the remaining document hidden states $(h_{i,j}^{\text{fwd}}, h_{i,j}^{\text{bwd}}), \ldots, (h_{i,m_i}^{\text{fwd}}, h_{i,m_i}^{\text{bwd}})$ to produce representations $(\tilde{h}_{i,j}^{\text{fwd}}, \tilde{h}_{i,j}^{\text{bwd}}), \ldots, (\tilde{h}_{i,m_i}^{\text{fwd}}, \tilde{h}_{i,m_i}^{\text{bwd}})$. Each end word $d_{i,k}$ is then scored by passing $[\tilde{h}_{i,k}^{\text{fwd}}; \tilde{h}_{i,k}^{\text{bwd}}]$ through a fully connected layer that outputs the unnormalized end word score for word k in sentence i, with start word j, denoted $\phi_{\text{ew}}(d_{i,j:k})$.

2.4 Global Normalization

The scores for each stage of our model can be normalized at the local or global level. Previous work demonstrated that locally-normalized models have a weak ability to correct mistakes made in previous decisions, while globally normalized models are strictly more expressive than locally normalized models (Andor et al., 2016; Zhou et al., 2015; Collins and Roark, 2004).

In a locally normalized model each decision is made conditional on the previous decision. The probability of some answer $a = (i, j, k)$ is decomposed as

$$\begin{aligned}\mathbb{P}(a|d,q) =& \mathbb{P}_{\text{sent}}(i|d,q) \cdot \mathbb{P}_{\text{sw}}(j|i,d,q) \cdot \\ & \mathbb{P}_{\text{ew}}(k|j,i,d,q).\end{aligned} \tag{7}$$

Each sub-decision is locally normalized by applying a softmax to the relevant selection scores:

$$\mathbb{P}_{\text{sent}}(i|d,q) = \frac{\exp(\phi_{\text{sent}}(d_i))}{\sum_{x=1}^{n} \exp(\phi_{\text{sent}}(d_x))}, \tag{8}$$

$$\mathbb{P}_{\text{sw}}(j|i,d,q) = \frac{\exp(\phi_{\text{sw}}(d_{i,j}))}{\sum_{x=1}^{m_i} \exp(\phi_{\text{sw}}(d_{i,x}))}, \tag{9}$$

$$\mathbb{P}_{\text{ew}}(k|j,i,d,q) = \frac{\exp(\phi_{\text{ew}}(d_{i,j:k}))}{\sum_{x=j}^{m_i} \exp(\phi_{\text{ew}}(d_{i,j:x}))}. \tag{10}$$

To allow our model to recover from incorrect sentence or start word selections, we instead globally normalize the scores from each stage of our procedure. In a globally normalized model, we define

$$\text{score}(a,d,q) = \phi_{\text{sent}}(d_i) + \phi_{\text{sw}}(d_{i,j}) + \phi_{\text{ew}}(d_{i,j:k}). \tag{11}$$

Then, we model

$$\mathbb{P}(a \mid d,q) = \frac{\exp(\text{score}(a,d,q))}{Z}, \tag{12}$$

where Z is the partition function

$$Z = \sum_{a' \in \mathcal{A}(d)} \exp(\text{score}(a',d,q)). \tag{13}$$

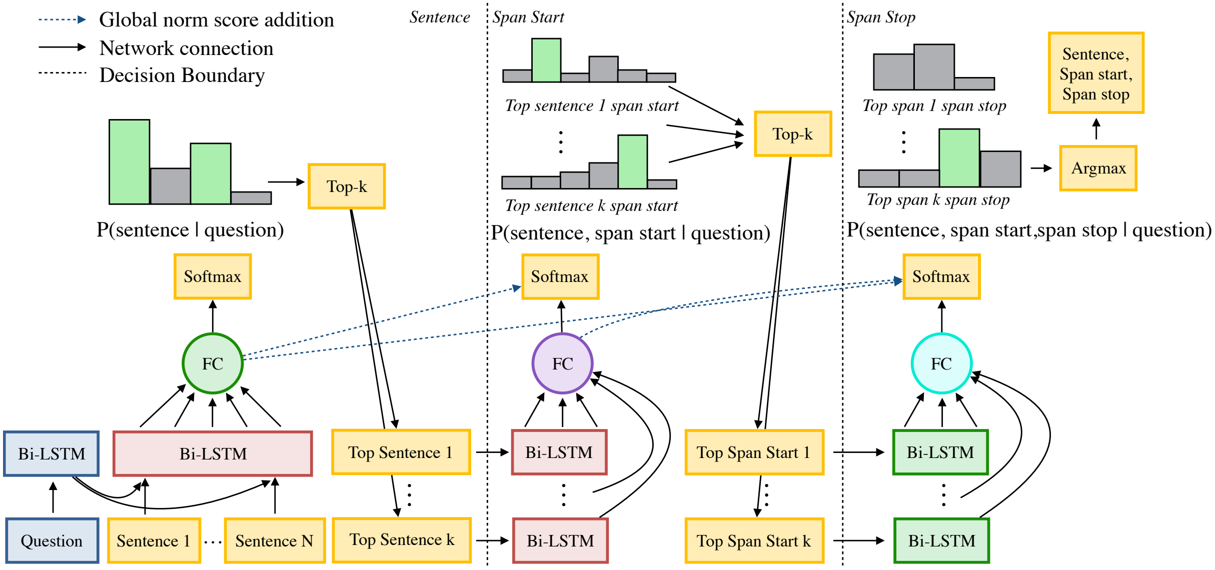

Figure 2: Globally Normalized Reader's search process. Same color Bi-LSTMs share weights.

In contrast to locally-normalized models, the model is normalized over all possible search paths instead of normalizing each step of search procedure. At inference time, the problem is to find

$$\arg\max_{a \in \mathcal{A}(d)} \mathbb{P}(a \mid d, q), \tag{14}$$

which can be approximately computed using beam search.

2.5 Objective and Training

We minimize the negative log-likelihood on the training set using stochastic gradient descent. For a single example (a, d, q), the negative log-likelihood

$$-\text{score}(a, d, q) + \log Z \tag{15}$$

requires an expensive summation to compute $\log Z$. Instead, to ensure learning is efficient, we use beam search during training and early updates (Andor et al., 2016; Zhou et al., 2015; Collins and Roark, 2004). Concretely, we approximate Z by summing only over candidates on the final beam $\mathcal{B}$:

$$Z \approx \sum_{a' \in \mathcal{B}} \exp(\text{score}(a', d, q)). \tag{16}$$

At training time, if the gold sequence falls off the beam at step t during decoding, a stochastic gradient step is performed on the partial objective computed through step t and normalized over the beam at step t.

2.6 Implementation

Our best performing model uses a stack of 3 Bi-LSTMs for the question and document encodings, and a single Bi-LSTM for the end of span prediction. The hidden dimension of all recurrent layers is 200.

We use the 300 dimensional 8.4B token Common Crawl GloVe vectors (Pennington et al., 2014). Words missing from the Common Crawl vocabulary are set to zero. In our experiments, all architectures considered have sufficient capacity to overfit the training set. We regularize the models by fixing the word embeddings throughout training, dropping out the inputs of the Bi-LSTMs with probability 0.3 and the inputs to the fully-connected layers with probability 0.4 (Srivastava et al., 2014), and adding gaussian noise to the recurrent weights with $\sigma = 10^{-6}$. Our models are trained using Adam with a learning rate of 0.0005, $\beta_1 = 0.9$, $\beta_2 = 0.999$, $\epsilon = 10^{-8}$ and a batch size of 32 (Kingma and Ba, 2014).

All our experiments are implemented in Tensorflow (Abadi et al., 2016), and we tokenize using Ciseau (Raiman, 2017). Despite performing beam-search during training, our model trains to convergence in under 4 hours through the use of efficient LSTM primitives in CuDNN (Chetlur et al., 2014) and batching our computation over examples and search beams. We release our code and augmented dataset.[1]

[1] https://github.com/baidu-research/GloballyNormalizedReader

Our implementation of the GNR is 24.7 times faster at inference time than the official Bi-Directional Attention Flow implementation[2]. Specifically, on a machine running Ubuntu 14 with 40 Intel Xeon 2.6Ghz processors, 386GB of RAM, and a 12GB TitanX-Maxwell GPU, the GNR with beam size 32 and batch size 32 requires 51.58 ± 0.266 seconds (mean ± std)[3] to process the SQUAD validation set. By contrast, the Bi-Directional Attention Flow model with batch size 32 requires 1260.23 ± 17.26 seconds. We attribute this speedup to avoiding expensive bi-directional attention mechanisms and making computation conditional on the search beams.

3 Type Swaps

Question: Who said in $\underset{\text{December 2012}}{\underline{\text{April 25, 2011}}}$ that the fight would change from military to law enforcement?
Answer: $\underset{\text{Jeh Johnson}}{\underline{\text{Sheryl Sandberg}}}$
Document (snippet): …Basic objectives of the $\underset{\text{Bush administration}}{\underline{\text{Cabinet of Japan}}}$ "war on terror", such as targeting al Qaeda and building international counterterrorism alliances, remain in place. In $\underset{\text{December 2012}}{\underline{\text{April 25, 2011}}}$, $\underset{\text{Jeh Johnson}}{\underline{\text{Sheryl Sandberg}}}$, the General Counsel of the $\underset{\text{Department of Defense}}{\underline{\text{ministry of education}}}$, stated that the military fight will be replaced by a law enforcement operation when speaking at $\underset{\text{Oxford University}}{\underline{\text{Ain Shams University}}}$···

Figure 3: Type Swaps example. Replacements underlined with originals underneath.

In extractive question answering, the set of possible answer spans can be pruned by only keeping answers whose nature (person, object, place, date, etc.) agrees with the question type (Who, What, Where, When, etc.). While this heuristic helps human readers filter out irrelevant parts of a document when searching for information, no explicit supervision of this kind is present in the dataset. Despite this absence, the distribution question representations learned by our models appear to utilize this heuristic. The final hidden state of the question-encoding LSTMs naturally cluster based on question type (Table 1).

In other words, the task induces a question encoding that superficially respects type information. This property is a double-edged sword: it allows the model to easily weed out answers that are inapplicable, but also leads it astray by selecting a text span that shares the answer's type but has the wrong underlying entity. A similar observation was made in the error analysis of (Weissenborn et al., 2017). We propose Type Swaps, an augmentation strategy that leverages this emergent behavior in order to improve the model's ability to prune wrong answers, and make it more robust to surface form variation. This strategy has three steps:

1. Locate named entities in document and question.
2. Collect surface variation for each entity type:

   human → {Ada Lovelace, Daniel Kahnemann,...},

   country → {USA, France, ...}, ...
3. Generate new document-question-answer examples by swapping each named entity in an original triplet with a surface variant that shares the same type from the collection.

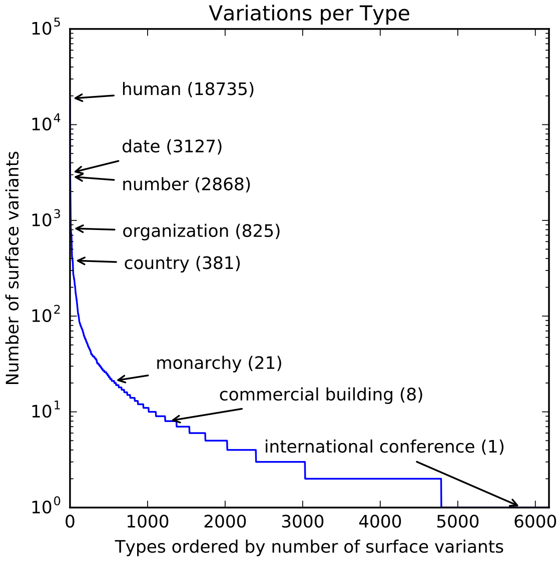

Figure 4: The majority of the surface variations occur for people, numbers, dates, and organizations.

Assigning types to named entities in natural language is an open problem, nonetheless when faced

in what	52	3	9	727	110	1827	518
where did	0	0	0	13	1	0	955
where is	0	1	0	11	0	0	665

with documents where we can safely assume that the majority of the entities will be contained in a large knowledge base (KB) such as Wikidata Vrandečić and Krötzsch (2014) we find that simple string matching techniques are sufficiently accurate. Specifically, we use a part of speech tagger (Honnibal, 2017) to extract nominal groups in the training data and string-match them with entities in Wikidata. Using this technique, we are able to extract 47,598 entities in SQuAD that fall under 6,380 Wikidata `instance of`[4] types. Additionally we assign "number types" (e.g. *year*, *day of the week*, *distance*, etc.) to nominal groups that contain dates, numbers, or quantities[5]. These extraction steps produce 84,632 unique surface variants (on average 16.93 per type) with the majority of the variation found in humans, numbers or organizations as visible in Figure 4.

With this method, we can generate $2.92 \cdot 10^{369}$ unique documents (average of $3.36 \cdot 10^{364}$ new documents for each original document). To ensure there is sufficient variation in the generated documents, we sample from this set and only keep variations where the question or answer is mutated. At each training epoch, we train on T Type Swap examples and the full original training data. An example output of the method is shown in Figure 3.

4 Results

We evaluate our model on the 100,000 example SQuAD dataset (Rajpurkar et al., 2016) and perform several ablations to evaluate the relative importance of the proposed methods.

4.1 Learning to Search

In our first experiment, we aim to quantify the importance of global normalization on the learning and search process. We use $T = 10^4$ Type Swap samples and vary beam width B between 1 and 32 for a locally and globally normalized models and summarize the Exact-Match and F1 score of the model's predicted answer and ground truth computed using the evaluation scripts from (Rajpurkar et al., 2016) (Table 3). We additionally report another metric, the *Sentence* score, which is a measure for how often the predicted answer came from the correct sentence. This metric provides a measure for where mistakes are made during prediction.

4.2 Type Swaps

In our second experiment, we evaluate the impact of the amount of augmented data on the performance of our model. In this experiment, we use

[4] `https://www.wikidata.org/wiki/Property:P31`

[5] In our experiments we found that not including numerical variation in the generated examples led to an imbalanced dataset and lower final performance.

Table 2: Model comparison

Model	EM	F1
Human (Rajpurkar et al., 2016)	80.3	90.5
Single model		
Sliding Window (Rajpurkar et al., 2016)	13.3	20.2
Match-LSTM (Wang and Jiang, 2016)	64.1	73.9

Global	$5 \cdot 10^4$	66.8	75.3	88.3
Global	10^5	66.1	74.3	86.9

Table 5: Impact of Type Swaps on the DCN+

T	Train F1	Dev F1
0	81.3	78.1
$5 \cdot 10^4$	72.5	**78.2**

the best beam sizes for each model ($B = 10$ for local and $B = 32$ for global) and vary the augmentation from $T = 0$ (no augmentation) to $T = 5 \cdot 10^4$. The results of this experiment are summarized in (Table 4).

We observe that both models improve in performance with $T > 0$ and performance degrades past $T = 10^4$. Moreover, data augmentation and global normalization are complementary. Combined, we obtain 1.6 EM and 2.0 F1 improvement over the locally normalized baseline.

We also verify that the effects of Type Swaps are not limited to our specific model by observing the impact of augmented data on the DCN+ (Xiong et al., 2016)[6]. We find that it strongly reduces generalization error, and helps improve F1, with potential further improvements coming by reducing other forms of regularization (Table 5).

5 Discussion

In this section we will discuss the results presented in Section 4, and explain how they relate to our main claims.

5.1 Extractive Question Answering as a Search Problem

Sentences provide a natural and powerful document decomposition for search that can be easily learnt as a search step: for all the models and configurations considered, the *Sentence* score was

[6] The DCN+ is the DCN with additional hyperparameter tuning by the same authors as submitted on the SQuAD leaderboard `https://rajpurkar.github.io/SQuAD-explorer/`.

above 88% correct (Table 3)[7]. Thus, sentence selection is the easy part of the problem, and the model can allocate more computation (such as the end-word selection Bi-LSTM) to spans likely to contain the answer. This approach avoids wasteful work on unpromising spans and is important for further scaling these methods to long documents.

5.2 Global Normalization

The Globally Normalized Reader outperforms previous approaches and achieves the second highest EM behind (Wang et al., 2017), without using bi-directional attention and only scoring spans in its final beam. Increasing the beam width improves the results for both locally and globally normalized models (Table 3), suggesting search errors account for a significant portion of the performance difference between models. Models such as Lee et al. (2016) and Wang and Jiang (2016) overcome this difficulty by ranking all possible spans and thus never skipping a possible answer. Even with large beam sizes, the locally normalized model underperforms these approaches. However, by increasing model flexibility and performing search during training, the globally normalized model is able to recover from search errors and achieve much of the benefits of scoring all possible spans.

5.3 Type-Aware Data Augmentation

Type Swaps, our data augmentation strategy, offers a way to incorporate the nature of the question and the types of named entities in the answers into the learning process of our model and reduce sensitivity to surface variation. Existing neural-network approaches to extractive QA have so far ignored this information. Augmenting the dataset with additional type-sensitive synthetic examples improves performance by providing better coverage of different answer types. Growing the number of augmented samples used improves the performance of all models under study (Table 4-5). With $T \in [10^4, 5 \cdot 10^4]$, (EM, F1) improve from $(65.8 \rightarrow 66.7, 74.0 \rightarrow 75.0)$ for locally normalized models, and $(66.6 \rightarrow 68.4, 75.0 \rightarrow 76.21)$ for globally normalized models.

Past a certain amount of augmentation, we observe performance degradation. This suggests that despite efforts to closely mimic the original training set, there is a train-test mismatch or excess duplication in the generated examples.

Our experiments are conducted on two vastly different architectures and thus these benefits are expected to carry over to different models (Weissenborn et al., 2017; Seo et al., 2016; Wang et al., 2017), and perhaps more broadly in other natural language tasks that contain named entities and have limited supervised data.

6 Related Work

Our work is closely related to existing approaches in learning to search, extractive question answering, and data augmentation for NLP tasks.

Learning to Search. Several approaches to learning to search have been proposed for various NLP tasks and conditional computation. Most recently, Andor et al. (2016) and Zhou et al. (2015) demonstrated the effectiveness of globally normalized networks and training with beam search for part of speech tagging and transition-based dependency parsing, while Wiseman and Rush (2016) showed that these techniques could also be applied to sequence-to-sequence models in several application areas including machine translation. These works focus on parsing and sequence prediction tasks and have a fixed computation regardless of the search path, while we show that the same techniques can also be straightforwardly applied to question answering and extended to allow for conditional computation based on the search path.

Learning to search has also been used in context of modular neural networks with conditional computation in the work of Andreas et al. (2016) for image captioning. In their work reinforcement learning was used to learn how to turn on and off computation, while we find that conditional computation can be easily learnt with maximum likelihood and the help of early updates (Andor et al., 2016; Zhou et al., 2015; Collins and Roark, 2004) to guide the training process.

Our framework for conditional computation whereby the search space is pruned by a sequence of increasingly complex models is broadly reminiscent of the structured prediction cascades of (Weiss and Taskar, 2010). Trischler et al. (2016b)

[7] The objective function difference explains the lower performance of globally versus locally normalized models on the *Sentence* score: local models must always assign the highest probability to the correct sentence, while global models only ensure the correct span has the highest probability. Thus global models do not need to enforce a high margin between the correct answer's sentence score and others and are more likely to keep alternate sentences around.

also explored this approach in the context of question answering.

Extractive Question Answering. Since the introduction of the SQuAD dataset, numerous systems have achieved strong results. Seo et al. (2016); Wang et al. (2017) and Xiong et al. (2016) make use of a bi-directional attention mechanisms, whereas the GNR is more lightweight and achieves similar results without this type of attention mechanism. The document representation used by the GNR is very similar to Lee et al. (2016). However, both Lee et al. (2016) and Wang and Jiang (2016) must score all $O(N^2)$ possible answer spans, making training and inference expensive. The GNR avoids this complexity by learning to search during training and outperforms both systems while scoring only $O(B)$ spans. Weissenborn et al. (2017) is a locally normalized model that first predicts start and then end words of each span. Our experiments lead us to believe that further factorizing the problem and using global normalization along with our data augmentation would yield corresponding improvements.

Data augmentation. Several works use data augmentation to control the generalization error of deep learning models. Zhang and LeCun (2015) use a thesaurus to generate new training examples based on synonyms. Vijayaraghavan et al. (2016) employs a similar method, but uses Word2vec and cosine similarity to find similar words. Jia and Liang (2016) use a high-precision synchronous context-free grammar to generate new semantic parsing examples. Our data augmentation technique, Type Swaps, is unique in that it leverages an external knowledge-base to provide new examples that have more variation and finer-grained changes than methods that use only a thesaurus or Word2Vec, while also keeping the narrative and grammatical structure intact.

More recently Zhou et al. (2017) proposed a sequence-to-sequence model to generate diverse and realistic training question-answer pairs on SQuAD. Similar to their approach, our technique makes use of existing examples to produce new examples that are fluent, however we also are able to explicitly incorporate entity type information into the generation process and use the generated data to improve the performance of question answering models.

7 Conclusions and Future Work

In this work, we provide a methodology that overcomes several limitations of existing approaches to extractive question answering. In particular, our proposed model, the Globally Normalized Reader, reduces the computational complexity of previous models by casting the question answering as search and allocating more computation to promising answer spans. Empirically, we find that this approach, combined with global normalization and beam search during training, leads to near state of the art results. Furthermore, we find that a type-aware data augmentation strategy improves the performance of all models under study on the SQuAD dataset. The method is general, only requiring that the training data contains named entities from a large KB. We expect it to be applicable to other NLP tasks that would benefit from more training data.

As future work we plan to apply the GNR to other question answering datasets such as MS MARCO (Nguyen et al., 2016) or NewsQA (Trischler et al., 2016a), as well as investigate the applicability and benefits of Type Swaps to other tasks like named entity recognition, entity linking, machine translation, and summarization. Finally, we believe there a broad range of structured prediction problems (code generation, generative models for images, audio, or videos) where the size of original search space makes current techniques intractable, but if cast as learning-to-search problems with conditional computation, might be within reach.

Acknowledgments

We would like to thank the anonymous reviewers for their valuable feedback. In addition, we thank Adam Coates, Carl Case, Andrew Gibiansky, and Szymon Sidor for thoughtful comments and fruitful discussion. We also thank James Bradbury and Bryan McCann for running Type Swap experiments on the DCN+.

Speech segmentation with a neural encoder model of working memory

Micha Elsner and **Cory Shain**
melsner0@gmail.com and shain.3@osu.edu
Department of Linguistics
The Ohio State University, Columbus, OH 43210

Abstract

We present the first unsupervised LSTM speech segmenter as a cognitive model of the acquisition of words from unsegmented input. Cognitive biases toward phonological and syntactic predictability in speech are rooted in the limitations of human memory (Baddeley et al., 1998); compressed representations are easier to acquire and retain in memory. To model the biases introduced by these memory limitations, our system uses an LSTM-based encoder-decoder with a small number of hidden units, then searches for a segmentation that minimizes autoencoding loss. Linguistically meaningful segments (e.g. words) should share regular patterns of features that facilitate decoder performance in comparison to random segmentations, and we show that our learner discovers these patterns when trained on either phoneme sequences or raw acoustics. To our knowledge, ours is the first fully unsupervised system to be able to segment both symbolic and acoustic representations of speech.

1 Introduction

This paper describes a new cognitive model of the acquisition of word-like units from unsegmented input. The model is intended to describe the process by which pre-linguistic infants learn their earliest words, a stage they pass through during the first year of life (Jusczyk and Aslin, 1995; Bergelson and Swingley, 2012). Our model is based on the standard memory model of Baddeley and Hitch (1974) in which the listener encodes lexical items into phonological working memory, but represents the entire sentence as a higher-level syntactic structure without phonological detail. Our model implements this architecture using encoder-decoder LSTMs with limited memory capacity, then searches for word segmentations which make it easy to remember the sentence.[1]

Word learning has been extensively studied in previous research, both with transcribed symbolic input and acoustics. Why attempt yet another approach? Our model has three main advantages. First, as a cognitive model, it relates the kinds of learning biases used in previous work to the wider literature on working memory. Second, its sequence-to-sequence neural architecture allows it to handle either one-hot symbolic input or dense vectors of acoustic features. In contrast, existing models are typically designed for "clean" symbolic input, then retrofitted with additional mechanisms to cope with acoustics. Finally, neural networks have been impressively successful in supervised language processing domains, yet are still underused in unsupervised learning. Even systems which do use neural nets to model lexical acquisition generally require an auxiliary model for clustering the embeddings, which can make their learning objectives difficult to understand. Our system uses the well-understood autoencoder objective to perform the segmentation task without requiring auxiliary clustering, and thus suggests a new direction for neural unsupervised learning.

In an experiment conducted on the widely used Brent corpus (Brent, 1999), our system achieves performance close to that of Fleck (2008), although subsequent systems outperform ours by a wider margin. We show that memory limitations do indeed drive the performance of the system, with smaller LSTM hidden states outperforming larger ones in the development set.

In a follow-up experiment designed to ex-

[1] The system is available from https://github.com/melsner/neural-segmentation.

Proceedings of the 2017 Conference on Empirical Methods in Natural Language Processing, pages 1070–1080
Copenhagen, Denmark, September 7–11, 2017.

plore the flexibility of our model, we deploy the segmenter on acoustic input: the English portion of the Zerospeech 2015 challenge (Versteegh et al., 2015). Our model outperforms the winning model from that challenge (Räsänen et al., 2015), although we underperform more recent unsupervised acoustic segmentation systems (Kamper et al., 2016; Räsänen et al., under review).

To our knowledge, our system is the first unsupervised LSTM speech segmenter, as well as the first unsupervised speech segmenter to succeed on both symbolic and acoustic representations of speech. Our results are of note for several reasons. First, they provide modeling support for the claim that memory limitations encourage lexical acquisition. Second, they show that a general strategy of searching for maximally compressible representations can realistically guide lexical acquisition without explicit reference to perceptual biases (c.f. e.g. Räsänen et al., 2015), regardless of input representation. And third, they demonstrate the benefits of our adaptation of neural sequence modeling to unsupervised learning.

2 Motivations

We begin with a short overview of previous approaches to the word learning problem, then explain each of our main contributions in detail. Many cognitive models of the word learning problem draw on Brent (1999), which used a simple unigram model of the lexicon to discover repeated patterns in phonemically transcribed input. Brent's model laid the groundwork for later generative models with more sophisticated prior distributions over word frequencies, co-occurrence statistics and phonological shapes (Johnson and Goldwater, 2009, among others). Other modeling architectures for segmentation have focused on detecting phonological boundaries between words using transitional probabilities (Christiansen et al., 1998, among others) or inducing words procedurally by "subtracting" known word forms from utterances (Lignos, 2011).

All these modeling architectures are designed to work with phonemically transcribed input, and require some degree of retrofitting to work with more realistic inputs. In the Bayesian framework, this typically takes the form of a transducer which probabilistically transforms "underlying" lexical items to "surface" acoustics (Lee et al., 2015) or discrete symbols (Elsner et al., 2013); the same framework is used for morphological segmentation in Cotterell et al. (2015). For transition-based models, the input must be transformed into discrete symbols from which segment-to-segment probabilities can be extracted; this transformation requires an externally trained preprocessor (a phone recognizer). Transition-based models are fairly robust to variation in the symbols (Rytting, 2007; Rytting et al., 2010; Daland and Pierrehumbert, 2011; Fleck, 2008) and can be relatively successful in this framework. Extensions using neural nets (Christiansen et al., 1998; Rytting et al., 2010) are discussed in more detail below (subsec. 2.3). Lignos (2011) requires the most complex preprocessing of the input (segmentation into syllables, with marked lexical stresses); adapting it to noisy input is an open problem.

2.1 Working memory and learning biases

Cognitive models of word segmentation rely on two kinds of learning biases to structure their inferred lexicons: predictability within words (often expressed as a prior over phonological forms), and Zipfian unigram and bigram frequencies of words (a prior over word distributions). These biases control the entropy of utterances, making it easy for adult listeners to remember what they hear and reconstruct any missing parts from context (Piantadosi et al., 2012). The biases correspond to different components in a standard model of working memory (Baddeley, 2007; Baddeley and Hitch, 1974). In this model, listeners can store the last few items they heard in a *phonological loop*, from which words are transferred into *episodic memory* which represents them at a syntactic/semantic level.

Baddeley et al. (1998) claim that the phonological loop functions in word *learning* as well as processing by proficient listeners, aiding in the acquisition of unfamiliar words. They summarize a number of studies showing that the vocabulary size of typically developing infants correlates with their ability to remember a sequence of phonologically plausible non-words, a test of phonological loop capacity. Children with Specific Language Impairment, meanwhile, remember nonwords poorly, a deficit which may contribute to their atypically small vocabularies. Baddeley et al. (1998) argue that the ability to remember an unfamiliar phonological form in the short term is essential if it is to be transferred to long-term memory as a datapoint for lexical learning. This account of word learning is one of a growing number which attempt to unify acquisition and speech processing in terms of the same real-time, resource-constrained mechanisms (Apfelbaum and McMurray, 2016).

In our model, memorization itself can be viewed as the objective for early word learning. The model attempts to reconstruct its input from memory; chunks that are easy to reconstruct (and that make the context reconstructible) are good candidate words. The working memory model accounts for the two types of bias normally found in Bayesian segmenters. Phonological predictability due to consistent word shapes (Börschinger and Johnson, 2014; Johnson and Goldwater, 2009) reduces the load on the phonological loop. Predictability between words reduces the load on syntactic memory. The two memory systems draw on different cognitive resources, which correspond to different parameters of the model.

2.2 Input representations

As stated above, traditional segmentation models operate on phonemic transcriptions and must be adapted to cope with phonetic or acoustic input. For models which infer an explicit lexicon (i.e., those which do not simply count segment transitions), this takes the form of a mapping between the data and the space of "underlying" latent word forms.

Learning such a mapping can be problematic. Traditional generative learning models use parametric distributions over the data— for acoustics, Gaussians (Vallabha et al., 2007; Feldman et al., 2009) or Gaussian-HMMs (Lee and Glass, 2012; Lee et al., 2015). But these are a notoriously poor fit to real speech sounds (Glass, 2003).

An example of an alternative approach to representation learning from acoustics is Räsänen et al. (2015). They exploit known acoustic indicators of syllable boundaries to infer syllable segments, cluster those segments using expectation-maximization (EM), and then identify multisyllabic words by searching for recurring cluster n-grams. As a result, their system is constrained to propose word boundaries only at proposed syllable boundaries regardless of the representations acquired downstream. Furthermore, EM is known to find non-optimal solutions for many problems in natural language (Johnson, 2007). To the extent that this inhibits their system's ability to exploit information in the acoustic feature space, it might lead to misidentification of recurrent syllable n-grams and consequently to segmentation error.

Latent underlying representations can also cause search problems, since the model must explore all the possible underlying forms which might map to some utterance on the surface. In a probabilistic system capable of mapping every word to every possible realization, this quickly becomes intractable. Many systems use dynamic programming (Mochihashi et al., 2009; Neubig et al., 2010), sometimes with pruning (Van Gael et al., 2008). But these algorithms require Markov models with small context windows, and in any case can still be slow and prone to search errors.

Neural nets, on the other hand, learn a nonlinear mapping between input and output. This allows them to model speech more flexibly, outcompeting Gaussian/HMMs for supervised speech recognition (Graves et al., 2013; Hinton et al., 2012). Recurrent neural nets also produce hidden representations differently than HMMs. Rather than use dynamic programming to search a latent space, they produce a single vector deterministically at each timestep. Models such as LSTMs (Hochreiter and Schmidhuber, 1997) can learn long-distance sequential dependencies in their input without making inference more expensive.

2.3 Neural unsupervised learning

A few previous papers have used neural networks for word segmentation. Christiansen et al. (1998), drawing on older work with Simple Recurrent Networks (Elman, 1990), trains a recurrent network as a language model. Word boundaries are extracted at points where the network predicts an upcoming utterance boundary; that is, utterance boundaries are used as distant supervision for the locations of word boundaries. While effective, this system uses symbolic rather than acoustic input. Moreover, it may have trouble with word endings which do not end utterances, such as the endings of function words; experiments show that infants learn detailed representations of function words by 13 months (Shi et al., 2006) and use known words as "anchors" for segmentation within utterances (Bortfeld et al., 2005).

Rytting (2007) adapts the Christiansen model to variable input by using the posterior probability distribution from a phone recognizer as its feature representation. This system was run on natural data; results for word boundary detection were significantly above chance, though still much less accurate than results for symbolic input. The use of utterance boundaries as distant supervision may create problems for this system similar to those pointed out for Christiansen above. Moreover, the use of an SRN rather than an LSTM means that the system is essentially phonotatic; it makes its decisions based on the previous one or two phones, without the capacity to remember whole lexical items.

Recent work (Kamper et al., 2016) has attempted to harness the flexibility of neural feature extractors within the generative model framework. This model has a hybrid architecture consisting of a neural feature extractor, the Correspondence Autoencoder, pretrained using distant supervision (Kamper et al., 2015), and a Bayesian clustering/segmentation model. The system represents each word by neurally encoding its frames, then downsampling to obtain a fixed-dimensional word vector; the clustering model assumes that these vectors can be modeled with Gaussian clusters. The advantage of this approach is its ability to exploit the known strengths of both Bayesian and neural learning systems. The disadvantage is its indirectness: there is no end-to-end objective to be optimized, and the system's lexical learning does not inform its phonetic representations.

Even outside the domain of segmentation, neural networks have been most successful for supervised problems, and are not widely used for unsupervised learning of discrete structures (trees, clusters, segment boundaries). While some researchers have proposed information-theoretic objectives for learning clusters (Klapper-Rybicka et al., 2001), the most widely used unsupervised objective is the one used here: autoencoding. Yet autoencoders are rarely used to learn discrete hidden structures. One exception, Socher et al. (2011), uses autencoders to find a latent tree structure for sentiment analysis by greedily merging adjacent nodes so as to minimize the reconstruction error.

Chung et al. (2017) describe a model similar to our own which performs a segmentation task using autoencoders. Both models use multiscale autoencoding to learn a sequence model with unknown segment boundaries. The main difference is the different technique used to deal with the discontinuities caused by switching discrete segment boundary variables. However, they evaluate their model on downstream tasks (notably, character language modeling) without evaluating the segmentations directly.

3 The Model

The model uses a basic encoder-decoder architecture now typical in machine translation (Cho et al., 2014) and image captioning (Vinyals et al., 2015). In a typical encoder-decoder, the input is fed into an LSTM sequence model (Hochreiter and Schmidhuber, 1997) which represents it as a latent numeric embedding. This embedding is then fed into another sequence model, which uses it to generate an output sequence. Our two-level model performs this process in stages, first encoding every word, character-by-character, and then encoding the word sequence, vector-by-vector. In an autoencoder, the objective is to make input and output match; thus, the decoder performs the encoding stages in reverse. We provide the final encoder hidden state as input to each decoder unit. To force the system's learned embeddings to be robust to noise caused by mishearing or misremembering, we use dropout (Srivastava et al., 2014) at the input (deleting individual timesteps) and at the word encoding layer (deleting entire words). This architecture is illustrated in Figure 1.

The encoder-decoder does not predict segment boundaries directly, but gives an objective function (reconstruction loss) which can be used to guide segmentation. Because the segment boundary decisions are hard (there are no "partial" boundaries), the loss function is not differentiable as a function of the boundary indicators. We use sampling to estimate the gradient, as in previous work (Mnih et al., 2014; Xu et al., 2015). Our sampling system works as follows: we begin with a proposal distribution P_{seg} over sequences of segment boundaries for the current utterance x. We sample m sequences of boundaries, $B_{1:m}$ from P_{seg}. Each boundary sequence splits the utterance into words. We use the autoencoder network to encode and decode the words, and obtain the loss (the cross-entropy of the reconstructed input) for each sequence, $L_{1:m}$.

We can use the cross-entropy to estimate the posterior probability of the data given a breakpoint sequence (Eq. 1), assuming a uniform prior over

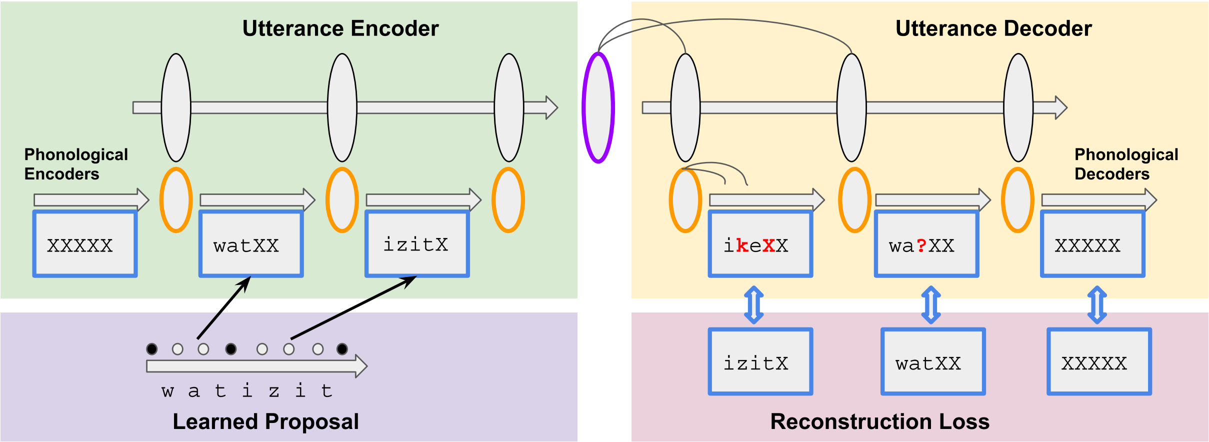

Figure 1: Architecture of the model: top two panels show the encoder/decoder, bottom panels show computation of breakpoints and resulting loss. Horizontal arrows represent LSTMs.

break positions. We then treat each breakpoint t in the utterance independently: for each one, we use the losses and the proposal probabilities to compute an importance weight w_i^t for sample i and position t (Eq. 2), then compute the expected probability of a boundary at that position by summing over the weighted samples (Eq. 3). Essentially, a breakpoint will be more likely if it appeared in samples with low reconstruction loss, especially if it is not encouraged by the current proposal.

$$P(x|B_i) = \frac{P(B_i|x)P(B_i)}{P(x)} \approx \frac{\exp(L_i)}{\sum_j \exp(L_j)} \quad (1)$$

$$w_i^t = \frac{P(x|B_i)}{P_{seg}^t(B_i^t)} \quad (2)$$

$$\mathbb{E}[B(t)] \approx \frac{1}{\sum_i w_i^t} \sum_i w_i^t B_i^t \quad (3)$$

We initialize by making random breakpoint proposals (with probability .1 at each position). The random proposal does not search the space of segmentation boundaries particularly efficiently, so we train a better proposal using another LSTM. This LSTM simply reads the input from left to right and predicts a binary output (segment or not) at each timestep. We update the proposal LSTM by using the sampling-derived P_{seg} as a training target after each batch. Thus, the proposal learns to predict segment boundaries that are likely to result in low reconstruction loss for the main network. To force the system to explore the space, we smooth the learned proposal by interpolating it with a uniform distribution: $P_{seg} = .9 \times P_{LSTM} + .1 \times \frac{1}{2}$.

We control the memory capacity of the system using four tunable parameters: the number of hidden states at the phonological level (H_p) and at the utterance level (H_u) and the dropout probability of mishearing a phonological segment (D_p) or a word (D_u). We discuss parameter tuning results below.

The system also has several other parameters which were not tuned against the evaluation metric. For convenience in GPU training, we treat all sequences as fixed length, either clipping them or padding with a dummy symbol. This requires us to set a maximum length for each word (in characters), and each utterance (in words and characters); we set these parameters to ensure 99% coverage of the input (for the Brent corpus, 7, 10, and 30 respectively).

Clipping creates the possibility of pathological outcomes where the system deliberately creates extremely long words, exploiting the fact that the excess characters will be discarded and will not have to be predicted in the output. We penalize this by subtracting 50 for each deleted character. Finally, we find that, despite pre-training, the system may settle into an initial state where the phonological network simply embeds the characters and the utterance network learns a character LM. To avoid this, we subtract 10 from the objective for each one-symbol word. These parameters were tuned only lightly; we increased the values until the problematic behavior (segmentation of the entire utterance as one word, or each character as a word) ceased.

We implemented the network in Keras (Chollet, 2015), using Adam (Kingma and Ba, 2014) with default settings for optimization. We use minibatches of 128 and take 100 samples of potential segment boundaries per sequence. We perform 10 iterations of pretraining with random boundaries, 10 iterations of boundary induction with random proposals, and 70 iterations of full training with the learned LSTM proposal.

4 Results

4.1 Brent Corpus

The Brent corpus (Brent, 1999) is a standard benchmark dataset for segmentation, consisting of 9790 utterances from Bernstein-Ratner (1987), translated into phonemic transcription using the CMU dictionary. The standard metrics for segmentation are F-score for word boundary detection (treating each boundary in isolation) and F-score for word token segmentation (a word is correct only if both its boundaries are correct and no spurious boundaries intervene). Although early work on Brent used all 9790 utterances for both development and test, we use the first 8000 utterances for parameter tuning. Thus, we present results for the whole corpus (for comparison with previous work) and clean test results for the last 1790.

We tune the four parameters of our system, H_p, H_u, D_p and D_u, using a grid search (see Figure 2). Each subplot shows a particular dropout setting, D_p/D_u; the cells within represent settings of H_p (rows) and H_u (columns), where darker cells have higher boundary F-score. Excessive noise decreases scores, especially high word dropout (right side of the plot). For low levels of dropout, the best systems tend to have small numbers of hidden units (dark regions in the lower left); for larger dropout, more hidden units can be useful. For instance, compare the top left subplot, with 0 dropout and good performance with $H_p = 20, H_u = 100$, to subplot 3,3, with optimal performance at $H_p = 80, H_u = 200$. In other words, limiting the system's memory resources is indeed the key to its performance. The best score occurs at $H_p = 80, H_u = 400, D_p = 0.5, D_u = 0.25$ with a dev boundary F-score of 83%. We used these parameters for our final evaluation, along with 100 hidden units in the proposal network.

To further demonstrate that limited memory can bias the network to learn a low-entropy lexicon, we perform a separate experiment using the phonological encoder/decoder alone. We create networks with varying H_p (setting D_p to 0); for each network size, we train one net on real words from the gold segmentation of Brent, and another on length-matched pseudowords sampled by randomly segmenting the Brent corpus. Figure 3 shows the reconstruction error rates as a function of H_p. The gap between the green and orange lines shows the difference in reconstruction error obtained by using real words rather than pseudowords. For the smallest H_p, neither network does a good job; for the largest, both networks learn the sequences perfectly. For values in between, however, the lines are relatively far apart, showing that the real words are easier for the network to remember.

Our results for Brent, along with selected comparisons, are shown in Table 1.[2] Our system per-

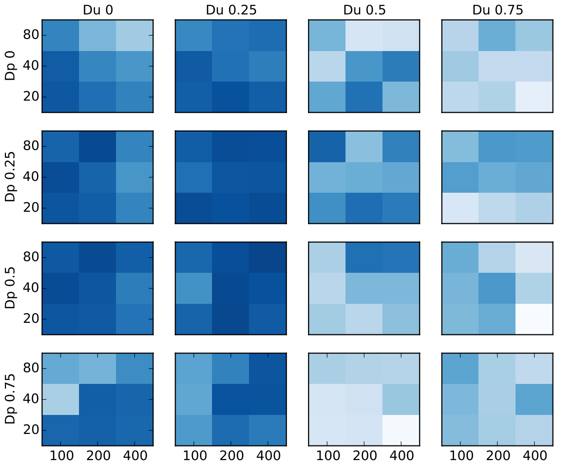

Figure 2: Tuning results on Brent development. Cell axes represent H_u and H_p, darker cells have higher scores (best 83%, worst 60%).

forms at the lower end of the reported range for Brent segmenters, scoring 83% for boundary detection and 72% for word detection (comparable to (Fleck, 2008)). (Lignos (2011) scores 93% boundary F on a different corpus with marked syllable boundaries.) From a cognitive modeling point of view, it is not clear what performance we should expect on Brent to model the performance of a young human infant. Models of early word segmentation are motivated by studies showing that, by their first birthday, infants can distinguish many common words from nonwords (Vihman et al., 2004; Swingley, 2005). But this does not imply that they learn every word they hear, or that they can use their word knowledge to segment every utterance correctly. Thus, while our result is not state-of-the-art, it is good enough to conform with the reported infant results and suggest that our neural architecture is a promising direction.

Learning curves for segmentation on the Brent corpus are shown in Figure 4. The first 10 iterations show a gradual increase in segmentation performance using the random proposal. Performance increases sharply with the activation of the learned proposal, then climbs slowly over time. Precision initially exceeds recall (that is, the system proposes too few boundaries) but recall climbs over time as the system exploits known words as "anchors" to discover new ones, a pattern consistent with the infant data (Bortfeld et al., 2005).

4.2 Zerospeech 2015 acoustic segmentation

We began by claiming that an advantage of our model was its flexible architecture that permits dense acoustic features as input (rather than symbolic phone labels) with little modification. In this section, we present preliminary results from a follow-up experiment in which we tested this claim by deploying our system as an acoustic segmenter on the English portion of the Zerospeech 2015 challenge dataset (Versteegh et al., 2015). We preprocess the raw acoustic data by extracting 25ms 13-dimensional mel frequency cepstral coefficients with first and second order deltas at a step size of 10ms. We then train the network on the resulting sequences of 39-dimensional frames.

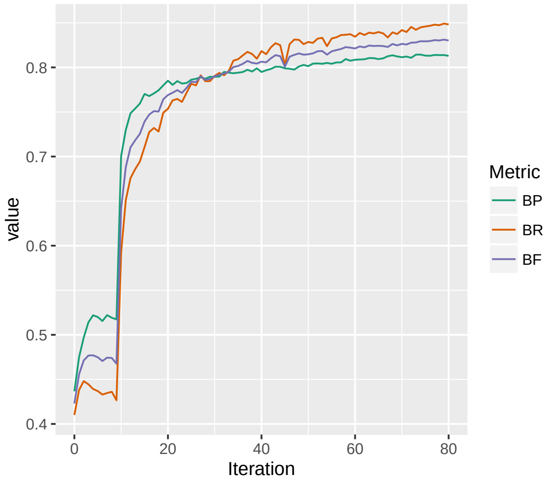

Figure 4: Boundary precision, recall, and F1 score by iteration on the entire Brent dataset.

Given that the goal of the experiment was to test the existing architecture on a novel task, we intentionally conducted this experiment with minimal parameter tuning or architectural modification. However, we made several key changes in response to the unique challenges presented by acoustic input.

First, since we are now reconstructing dense vectors of acoustic features, we use mean squared error (MSE) instead of categorical cross-entropy as the autoencoder loss function. We consequently rescale our clipping penalty from 50 to 1, a coefficient which seemed more in balance with the variation in decoder loss produced by MSE. We also increase our one-letter penalty from 10 to 50, modeling our strong prior assumption that a 1-frame segment will never correspond to a word.

Second, in contrast to the phoneme sequences in the Brent corpus discussed above, utterance boundaries are not observed in acoustic input. The input to the two-level autoencoder must be divided into sequences of utterances, so we imposed utterance boundaries by iteratively consuming the next discovered word in the time series up to the maxi-

respective publications, except for Goldwater et al. (2009), which are corrected numbers published with their software release. Not all systems report all metrics.

Kamper 16	66.5	58.8	62.4	20.6
Ours	62.4	43.2	51.1	9.3

Table 2: Selected word segmentation results on the the Zerospeech 2015 English corpus.

mum utterance length (in frames). The aforementioned clipping penalties punish the system for utterances that contain too many words, preventing it from optimizing its autoencoder loss by segmenting everywhere.

Third, for our initial proposal distribution we use the speech region segmentation provided by the Zerospeech challenge, consisting of speech intervals identified through automatic voice activity detection (VAD), rather than using the uniform initialization described above for symbolic mode. We interpolate the initial distribution with a uniform prior as described above.

Fourth, we discovered in practice that the assumption of independence between samples made by the importance scoring scheme as implemented for symbolic mode was distortionary in acoustic mode, such that the "best" segmentation discovered through sampling often contained many times more segments than any of its component samples.[3] To prevent this from happening, we simply used 1-best rather than importance sampling for acoustic segmentation.

We trained the system for 80 iterations using parameters $H_p = 20, H_u = 400, D_p = 0, D_u = 0.25$ and 1500 hidden units in the proposal LSTM. In the auto-encoder network, we limited frames per utterance, words per utterance, and frames per word to 400, 16, and 100, respectively. Results are presented in Table 2, along with a comparison to results from other systems. Lyzinski et al. (2015) and Räsänen et al. (2015) were entrants in the Zerospeech 2015 challenge, in which Räsänen et al. (2015) performed best in the word boundary detection measure. As shown in the table, our system beats both of these competitors' boundary detection scores, with a word detection score comparable to that of Räsänen et al. (2015). However, since the challenge concluded, Räsänen et al. (under review) have modified their system and improved their segmentation score,[4] and Kamper et al. (2016) have established a new state of the art for this task. While our system currently remains far from these newer benchmarks, we expect that with systematic parameter tuning and investigation into appropriate sampling procedures for acoustic input, we might be able to improve substantially on the results presented here. We believe that the results of this preliminary investigation into the acoustic domain are promising, and that they bear out our claims about the flexibility of our general architecture.

5 Conclusions and future directions

This work presented a new unsupervised LSTM architecture for discovering meaningful segments in representations of continuous speech. Memory limitations in the autoencoder part of the network apply pressure to discover compressed representations much as human memory limitations have been argued to guide lexical acquisition. By varying the size of the LSTM's hidden state, we showed that word segmentation performance on the Brent corpus is driven by memory limitations, with performance improving (up to a point) as we constrain the system's memory capacity. And by successfully deploying our system on both symbolic (character) and acoustic representations of speech, we demonstrated that our approach is flexible enough to adapt to either representation of the speech stimulus.

In the future we hope to pursue a number of lines of inquiry. We plan to conduct more detailed parameter tuning in the acoustic domain and to segment the Xitsonga dataset supplied with the Zerospeech 2015 challenge. We also intend to introduce additional layers into the autoencoder network so as to allow for joint acquisition of phone-like, morph-like, and/or word-like units in the acoustic signal; this may benefit from the alternate model structure of Chung et al. (2017). And we plan to explore clustering techniques that

[3] We believe this is driven by training batches in which multiple samples receive similar scores but have fairly non-overlapping segmentations. In this case, the output segmentation can contain something close to the union of the best samples' segmentation points, leading to oversegmentation. This effect is likely exaggerated in acoustic mode as compared to symbolic mode because acoustic word segments are generally much longer (in frames) than their corresponding symbolic word segments (in characters).

[4] The new results are not yet published. Those reported above are copied from the results summary in Kamper et al. (2016).

would allow our system to discover categories in addition to probable segmentation points.

Acknowledgments

We thank members of the Clippers discussion group (especially Joo-Kyung Kim, Eric Fosler-Lussier and Wei Xu) and three anonymous reviewers. Computations for this project were run on a Titan-X GPU donated by the NVIDIA Hardware Grant program and on the Ohio Supercomputer (1987). Funding was provided by NSF #1422987.

Abstract

Research in computational semantics is increasingly guided by our understanding of human semantic processing. However, semantic models are typically studied in the context of natural language processing system performance. In this paper, we present a systematic evaluation and comparison of a range of widely-used, state-of-the-art semantic models in their ability to predict patterns of conceptual representation in the human brain. Our results provide new insights both for the design of computational semantic models and for further research in cognitive neuroscience.

1 Introduction

Recent years have witnessed many breakthroughs in data-driven semantic modelling: from the log-linear skip-gram model of Mikolov et al. (2013a) to multi-modal meaning representations (Bruni et al., 2012; Kiela and Bottou, 2014; Kiela and Clark, 2015; Kiela et al., 2015a). These models boast of a higher performance accuracy in numerous semantic tasks, including modeling semantic similarity and relatedness (Silberer and Lapata, 2012), lexical entailment (Kiela et al., 2015b), analogy (Mikolov et al., 2013b) and metaphor (Shutova et al., 2016). However, less is known about the extent to which such models correlate with and reflect human conceptual representation.

Much research in the cognitive neuroscience community has been concerned with uncovering how the brain represents conceptual knowledge, by leveraging brain activation data associated with the meanings of concepts obtained during functional magnetic resonance imaging (fMRI) experiments. In the computational linguistics community, the availability of such fMRI data provides researchers with a benchmark for evaluating semantic model performance in terms of their ability to represent human semantic memory. Mitchell et al. (2008) were the first to demonstrate that distributional semantic models encode some of the patterns found in the fMRI data. Other researchers followed in their steps, evaluating traditional count-based distributional models (Devereux et al., 2010; Murphy et al., 2012), topic model-based semantic features (Pereira et al., 2013), psycholinguistic and behavioural features (Palatucci et al., 2009; Chang et al., 2010; Fernandino et al., 2015) and visual representations (Anderson et al., 2013, 2017). While all of these studies report correlation between the investigated semantic models and patterns found in the brain imaging data, their focus on individual models and the use of different datasets and prediction methods make their results difficult to compare and to integrate into a coherent evaluation landscape. The work of Murphy et al. (2012) is an exception, in that the authors systematically compare several distributional models with a range of parameters on the same brain imaging dataset. However, they focus on the traditional count-based distributional models only.

We take inspiration from the works of Mitchell et al. (2008) and Murphy et al. (2012); however, we conduct a more extensive study of the ability of different types of semantic models to predict the patterns of brain activity associated with conceptual representation. We evaluate and compare several kinds of semantic models, using different modalities and data sources: (1) traditional count-based distributional models (with word window-based and dependency-based contexts) learnt from text; (2) log-linear skip-gram models (with word window-based and dependency-based contexts); (3) behavioural models based on the free association task; (4) word representations learnt from

Proceedings of the 2017 Conference on Empirical Methods in Natural Language Processing, pages 1081–1091
Copenhagen, Denmark, September 7–11, 2017. ©2017 Association for Computational Linguistics

visual data; and (5) multi-modal word representations combining linguistic and visual information. Unlike previous studies, where evaluations were typically conducted using a single technique, we evaluate our models using several methods: ridge regression (Hoerl and Kennard, 1970), similarity-based encoding and similarity-based decoding (Anderson et al., 2016). Such an experimental setup allows for a comprehensive evaluation and comparison of the models.

To the best of our knowledge the dependency-based skip-gram model and the free association-based model, as well as their multimodal counterparts, have not been previously evaluated on the brain activity prediction task. Other models have been evaluated individually and have not yet been systematically compared within a single evaluation framework. Providing such a comparison, our experiments and results demonstrate that (1) visual information is a stronger predictor of brain activity than the linguistic information for concrete nouns; (2) sparse text-based models, whether dependency-based or built using linear bag-of-words context, tend to predict neural activity more accurately than dense models; (3) cognitively-motivated association-based models perform on par with or better than other linguistic models, which suggests that they provide an interesting avenue in computational semantics research.

2 Related work

The seminal work of Mitchell et al. (2008) introduced a new semantic model able to predict brain activation data associated with the meanings of concrete nouns from their corpus-harvested semantic representations. They chose a set of 25 verbs to act as semantic features in their distributional model, inspired by the importance of sensory-motor features in neural representations of concepts (Cree and McRae, 2003).

Since then, various studies have shown that distributional semantic models encode and are able to predict neural activation patterns associated with concepts (Devereux et al., 2010; Murphy et al., 2012; Pereira et al., 2013). Devereux et al. (2010) build on the work of Mitchell et al. (2008) and show that automatically acquired feature-norm like semantic representations can make equally powerful predictions about brain activity associated with the presentation of words. Pereira et al. (2013) use semantic features learnt from topic models on Wikipedia to predict neural activation patterns for unseen concepts.

Several other studies have demonstrated the fit of semantic models built from human behavioural data with regard to predicting neural activation patterns (Palatucci et al., 2009; Chang et al., 2010; Fernandino et al., 2015). Chang et al. (2010) use brain region encodings as well as detailed taxonomic encodings of McRae et al. (2005) feature norms to predict brain activation patterns using a linear regression model. They demonstrate that learned brain activity patterns can be used to decode mental states. Fernandino et al. (2015) use human elicited attribute salience scores based on five sensory-motor attributes (sound, color, visual motion, shape and manipulation) to derive fMRI brain activation patterns for concrete words, but are unsuccessful at modeling neural activation patterns for abstract words.

Recent advances in multi-modal semantics have shown that grounding semantic models in sensory modalities improves performance on a variety of tasks (Silberer and Lapata, 2012; Bruni et al., 2012; Kiela and Bottou, 2014; Bulat et al., 2016). Anderson et al. (2013) show that semantic models built from visual data correlate highly with fMRI-based brain activation patterns. Anderson et al. (2015) find that similarity in activity in the brain areas related to linguistic processing can be better predicted from text-based semantic representations, whilst image-based representations perform better at predicting similarity in the visual processing areas of the brain. In line with the dual coding theory, Anderson et al. (2017) demonstrate an advantage in decoding brain activity patterns of abstract words for text-based semantic models over the image-based ones. Contrary to previous findings, Anderson et al. (2017) find no advantage in decoding neural activity patterns associated with concrete words for image-based models.

Murphy et al. (2012) present the first study systematically comparing several text-based semantic models on the brain activity prediction task. They focus on the traditional count-based distributional models and achieve the best performance using dependency-based features. Our study is more extensive than that of Murphy et al. (2012), as we evaluate both the count-based models and the more recent skip-gram word embeddings, as well as comparing them to free association-based, visual and multi-modal semantic representations. While Murphy and colleagues evaluate the models using one method only — linear regression, we compare predicted neural activation patterns obtained using both regression and the similarity-based encoding and decoding methods proposed by Anderson et al. (2016).

3 Brain imaging data

We use the dataset of fMRI neural activation patterns associated with the meanings of nouns, created by Mitchell et al. (2008) as described below.

3.1 fMRI experiment

Nine right-handed adults between the age of 18 and 32 (five female) participated in the study. They were presented with line drawings and noun labels for 60 concrete nouns from 12 semantic classes – animals, body parts, buildings, building parts, clothing, furniture, insects, kitchen items, tools, vegetables, vehicles and man-made objects – with five exemplars per class. The task for the participants during the scanning was to think about the properties of the noun stimuli they were presented with. The entire set of 60 stimulus words was presented six times to every participant, in a different order for each presentation.

The fMRI images were acquired on a Siemens Allegra 3.0T scanner. The initial data was corrected for slice timing, motion and linear trend; spatially normalised and resampled to 3x3x6mm^3 voxels. Only those voxels overlapping with the cortex were selected (approximately 20000 for every participant).

3.2 Voxel selection

We employ the same voxel selection procedure as Mitchell et al. (2008) for evaluating the similarity between actual fMRI images and model-predicted fMRI images. Similarity is computed by only taking into account 500 voxels with the most stable activation profile across words – with profiles compared across the six presentations. The evaluation is performed using leave-two-out cross validation. Voxel selection was performed independently for each of the cross validation folds, at training time. A voxel's stability score across the six presentations was approximated as the mean pairwise Pearson correlation between its activation profiles over the 58 training words in the cross-validation fold. The 500 voxels with the highest stability score were chosen.

3.3 Brain activity vectors

We evaluate our models on the data of each participant independently. Following Mitchell et al. (2008), we obtain a single fMRI image per concept (a representative image) by first computing the mean fMRI response over its six presentations, and then subtracting the mean of all 60 of these representative images from each. In the rest of this paper we will refer to these representations as *brain activity vectors*.

4 Semantic models

MITCHELL As a benchmark for all other semantic models, we use the publicly available[1] co-occurrence based semantic vectors developed in the Mitchell et al. (2008) study. The features of this semantic space are 25 sensory-motor verbs. Co-occurrence statistics were collected using a window size of 5 words either side of the target word, on a trillion-word corpus provided by Google.

4.1 Text-based semantic models

We train a variety[2] of context-counting and context-predicting text-based semantic models on the January 2016 dump of Wikipedia, which was tokenised using the Stanford NLP tools[3], lemmatised with the Morpha lemmatiser (Minnen et al., 2001), and parsed with the C&C parser (Clark and Curran, 2007).

DISTRIB We obtain count-based distributional semantic models, using the top 10K most frequent lemmatised words in the corpus (excluding stopwords) as contexts. The context window is defined as sentence boundaries. Counts are reweighted using positive pointwise mutual information (PPMI) and vectors are L2-normalised.

SVD300 We also construct 300-dimensional dense semantic representations by applying singular value decomposition (SVD) (Deerwester et al., 1990) to DISTRIB.

[1] https://www.cs.cmu.edu/afs/cs/project/theo-73/www/science2008/data.html

[2] We have experimented with different parameter settings for each type of language-based semantic space (e.g. size of the vectors, number of iterations when learning the embeddings etc.) and found that the reported vectors with "standard' settings perform the best (or do not get significantly outperformed).

[3] https://nlp.stanford.edu/software/index.shtml

DEPS Following Murphy et al. (2012), who find that dependency-based semantic vectors perform best on a neurosemantic decoding task, we also include such a semantic space in our comparison. Vector representations are created by leveraging the dependency relations output by the C&C parser (Clark and Curran, 2007) as features. We use both the incoming and outgoing dependency relations as features; for example, given the dependency relation (RUN, DOBJ, MARATHON) we extract the tuple (DOBJ, MARATHON) as a feature for RUN and (!DOBJ, RUN) as a feature for MARATHON. The top 10K most frequent dependency features are used as contexts and counts are re-weighted using PPMI.

DEPS-SVD300 We also obtain 300-dimensional dense dependency-based semantic representations by applying SVD to DEPS.

EMBED-BOW We train 300-dimensional embeddings using the standard log-linear skipgram model with negative sampling of Mikolov et al. (2013a). The embeddings were trained using linear bag-of-words contexts, with the window defined as $k = 2$ (**EMBED-BOW2**) or $k = 5$ (**EMBED-BOW5**) words either side of the target word. We use 10 negative samples per word-context pair and 15 iterations over the corpus.

EMBED-DEPS In addition to the embeddings trained with linear bag-of-words contexts, we also obtain 300-dimensional dependency-based word embeddings using the Levy and Goldberg (2014) implementation of the generalised skip-gram with arbitrary contexts model. Using both incoming and outgoing dependency relations output by the C&C parser, we create word-context pairs using all words and contexts occurring more than 400 times in the corpus. This resulted in a vocabulary of about 92,000 words, with over 250,000 distinct syntactic contexts. We use 10 negative samples per word-context pair and 15 iterations over the corpus.

4.2 Association-based semantic model

Free word association datasets (Nelson et al., 2004; De Deyne et al., 2016) represent a rich source of semantic information and have been successfully used in NLP, including research on semantic memory (Steyvers et al., 2004) and multi-modal semantics (Hill and Korhonen, 2014). Recent studies have shown the superiority of semantic models built using data collected from *multiple-response* free association tasks — where subjects are asked to list multiple associative cues for every target word rather than a single association — over the models built from single-response ones (De Deyne et al., 2013). Moreover, such association-based semantic models have been shown to outperform current state-of-the-art text-based language models on concept relatedness and similarity judgments (De Deyne et al., 2016).

We make use of the word association dataset collected as part of the Small World of Words[4] project, where more than 100K fluent English speakers were asked to list three associations for each target word. The dataset contains multiple-response association data for over 10K words. We use a subset of this dataset, where all target words have at least 50 primary, 50 secondary and 50 tertiary responses and all responses also appear as normed target words[5].

ASSOC We construct a count-based semantic model of word associations (henceforth ASSOC) similarly to a count-based distributional model: the responses are treated as semantic features, and counts are replaced by the sum of primary, secondary and tertiary association frequencies between the target word and the responses. Counts are re-weighted using PPMI and vectors are L2-normalised. The association-based representations obtained for the 60 target words in the Mitchell et al. (2008) dataset under this model are 9854-dimensional.

4.3 Image-based semantic model

We also build state-of-the-art deep visual semantic representations (henceforth VISUAL) for the 60 concepts in the Mitchell et al. (2008) dataset. Following previous work in multi-modal semantics (Bergsma and Goebel, 2011; Kiela and Bottou, 2014) and the findings of a recent study of system architectures and data sources for constructing visual representations (Kiela et al., 2016), we retrieve 10 images per concept from Google Images. We use the MMFeat toolkit[6] (Kiela, 2016) to build our image representations. We extract the 4096-dimensional pre-softmax layer from a for-

[4] `https://smallworldofwords.org/`

[5] Total of 9854 words (appearing as both target and responses) and 1092251 association pairs

[6] `https://github.com/douwekiela/mmfeat`

ward pass through a convolutional neural network (Krizhevsky et al., 2012), which has been pre-trained on the ImageNet classification task using Caffe (Jia et al., 2014). We obtain the visual representation for a given concept by taking the mean of the 10 resulting image representations.

4.4 Multi-modal semantic models

We also included multi-modal semantic spaces in our analysis, as these are currently widely used in NLP and have been previously shown to achieve the best performance at predicting conceptual encodings in the brain (Anderson et al., 2015). Multi-modal semantic spaces are constructed by combining the visual (VISUAL) and respective linguistic (e.g. MITCHELL, DISTRIB, DEPS) or association-based (ASSOC) representations into a multi-modal representation by concatenating their respective L2-normalized vectors.

5 Methods

In this study, we use two different ways of analysing the correlation between the semantic models described in Section 4 and the fMRI brain activation patterns used as a proxy for human conceptual representation. First, we compare these semantic models in their predictive power, by looking at how well they can synthesise, i.e. predict, brain activation patterns for unseen concepts (Section 5.1). Secondly, we look at how well they are able to decode neural activation patterns by measuring their success at predicting the stimulus that produced an unlabeled (unseen) fMRI pattern (Section 5.2).

5.1 Predicting brain activity patterns

The brain activity prediction task has been used in previous NLP research as a method of evaluating different semantic models in their ability to model conceptual representation. Most of these studies learn a mapping function between the semantic model of choice and the fMRI neural activity patterns using regression techniques (Mitchell et al., 2008; Devereux et al., 2010; Murphy et al., 2012). Recent work by Anderson et al. (2016) introduce a new method for synthesising fMRI activity patterns through similarity-based encoding that does not require model fitting. We compare the prediction performance of the semantic models detailed in Section 4 by implementing both a regression-based model and the similarity-based encoding algorithm of Anderson et al. (2016).

Regression-based learning Following previous work (Mitchell et al., 2008; Devereux et al., 2010; Murphy et al., 2012), for every participant, we learn a mapping function between semantic model features and brain activation vectors using linear regression. The learned weights are used to make predictions about brain activation vectors associated with concepts that were not seen during training. We implement Ridge regression (Hoerl and Kennard, 1970), a multiple linear regression model that uses a least squares loss function and L2 regularisation.

Similarity-based encoding We implement the similarity-based encoding method introduced by Anderson et al. (2016). This method predicts the brain activity vector for an unseen concept by exploiting its similarity (with respect to a particular semantic model) to words for which we have observed brain activity vectors.

The first step in predicting a brain activity vector for an unseen concept is to compute its *semantic model similarity code*. This is a N-dimensional[7] vector of similarity scores — computed using Pearson's correlation — between the unseen concept and the N words for which we have brain activation vectors[8]. The predicted brain activity vector for the unseen concept is then "synthesised" by using its semantic model similarity code to weight a superposition of brain activity vectors:

$$\vec{b\prime} = \frac{1}{C}\sum_{i=1}^{N} \vec{b}_i \cdot corr(\vec{v}_i, \vec{v}_{N+1}) \qquad (1)$$

Assuming the unseen word is indexed $N+1$ and $\vec{v}_j$ is the semantic model representation of word j, C is a normalisation constant defined as the sum of absolute values of elements in the semantic model similarity code:

$$C = |\sum_{i=1}^{N} corr(\vec{v}_i, \vec{v}_{N+1})| \qquad (2)$$

5.2 Decoding neural activity patterns

We then evaluate our semantic models in terms of their ability to decode unseen fMRI activation patterns. The analysis in this case does not involve

[7] Assuming that we have N words for which we have both semantic model representations (e.g. DISTRIB vectors) and observed brain activation vectors.

[8] The similarities are measured w.r.t. the semantic model we use as "predictor", e.g. DISTRIB, SVD300 or VISUAL

synthesising brain activation vectors for new concepts, but predicting the correct label (stimulus) associated with a given fMRI pattern.

We implement the similarity-based decoding procedure as detailed in Anderson et al. (2016). The first step is to obtain the *semantic model similarity matrix* — by computing the semantic model similarity codes for each of the 60 concepts in the Mitchell et al. (2008) dataset (as described above) — and the *brain activity similarity matrix* — by computing brain activity similarity codes.

At test time, two of the N words are chosen for decoding, together with their respective semantic model similarity codes $(\vec{s}_i, \vec{s}_j)$ and brain activity similarity codes $(\vec{a}_i, \vec{a}_j)$. Next, $\vec{s'_i}$, $\vec{s'_j}$, $\vec{a'_i}$ and $\vec{a'_j}$ are obtained by removing the i-th and j-th elements in $\vec{s}_i$, $\vec{s}_j$, $\vec{a}_i$ and $\vec{a}_j$ respectively, because entries in the similarity vectors corresponding to the test words would reveal the correct answer in the matching task. We will refer to $\vec{s'_i}$ and $\vec{s'_j}$ as *reduced semantic model similarity codes*, and by analogy to $\vec{a'_i}$ and $\vec{a'_j}$ as *reduced neural similarity codes*.

Decoding is considered a success if the sum of Pearson's correlations for the correct pairings ($corr(\vec{s'_i}, \vec{a'_i}) + corr(\vec{s'_j}, \vec{a'_j})$) is higher than the sum of Pearson's correlations for the incorrect pairings ($corr(\vec{s'_i}, \vec{a'_j}) + corr(\vec{s'_j}, \vec{a'_i})$).

6 Experiments

All semantic spaces presented in Section 4 have full coverage on the Mitchell et al. (2008) dataset. All experiments detailed in this section were performed separately for every participant and evaluated using leave-two-out cross validation.

6.1 Regression experiments

We repeatedly train a regression model to fit brain activation vectors for each of the semantic spaces described in Section 4, using only 58 of the 60 available concept representations (leave-two-out cross validation). This resulted in 1770 cross-validation folds.[9] The only hyperparameter in the regression is λ, which controls the degree of regularisation. The λ hyperparameter was optimised when training each cross-validation fold, by choosing from the range 0.0001 to 100 through generalised cross validation (i.e. λ was optimised by only looking at the training items during each cross-validation fold).

During each testing round, we used the learned mapping function to construct predicted brain activation vectors for the two held out words.We evaluated each of the semantic models by computing its accuracy of matching the two predicted brain activation vectors with the two observed ones. A matching score was computed by analysing the cosine similarity between the predicted and the observed brain activation vectors. If the sum of similarities for the correct pairing was higher than the one for the incorrect pairing the matching accuracy was set to 1 for this cross-validation fold, and otherwise it was set to 0. If the model was choosing the match at random, the expected accuracy is 0.50. The similarity between two brain activation vectors was computed by only taking into account the 500 most stable voxels (during each cross-validation fold) as detailed in Section 3.2. The cross-validated accuracies for each of our semantic models are presented in Table 1, with selected results also shown in Figure 1. We only report results on two multi-modal models (VISUAL+MITCHELL and VISUAL+ASSOC), as there was no significant difference in performance between any pair of multi-modal models.

All semantic models learn to predict neural activation patterns for unseen words significantly above chance level. Association-based semantic models (ASSOC) significantly[10] outperform all dense semantic representations (whether embedding-based or SVD-reduced), with $p < 0.05$. Sparse text-based representations with linear context (DISTRIB and DEPS) significantly outperform some dense semantic representations. However, no dense semantic models significantly outperform DISTRIB and DEPS. There is no significant difference between the performance of ASSOC, DISTRIB and DEPS. Contrary to the findings of Murphy et al. (2012), we do not find any advantage in predicting brain activation patterns from dependency-based text models.

Both VISUAL and multi-modal models significantly outperform text-based models overall ($p < 0.05$), excepting MITCHELL with $p < 0.11$ when comparing to VISUAL and $p < 0.09$ when comparing against multi-modal semantic models. These results support previous findings regarding the importance of grounding semantic models in perceptual input. These grounded semantic models per-

[9] There are (60 choose 2) ways to choose two test items from the 60 Mitchell et al. (2008) concepts.

[10] We used (pairwise) paired t-tests to judge the statistical significance of the difference in performance between any two models within the same experiment.

MODEL	P1	P2	P3	P4	P5	P6	P7	P8	P9	*mean*

form as well as models that encode mental representations through associations (ASSOC). There is no significant advantage for multi-modal models over VISUAL.

6.2 Similarity-based encoding experiments

We also compare performance of the semantic models when the predicted brain activation vector is computed using the Anderson et al. (2016) similarity based encoding method. We use a leave-two-out cross validation strategy, to match previous work and our experiments detailed in Section 6.1. The similarity-based encoding approach does not require any mapping function to be learned, hence is a robust and fast way to obtain synthesised brain activation vectors for unseen words.

During each cross-validation fold, semantic model similarity codes of the two test words were computed using the procedure outlined in Section 5.1. Predicted brain activation vectors were then synthesised for the two test words by weighting a superposition of brain activity vectors using their semantic model similarity codes. The matching score for each of the cross-validation folds was computed in the same way as in the case of the regression model (Section 6.1). The only difference was that we measured the similarity between the two brain activation vectors using Pearson's correlation coefficient, following Anderson et al. (2016). As in the previous experiment, the expected chance performance of this method is 0.5. The cross-validated accuracies for each of our semantic models are shown in Table 2, with selected results also shown in Figure 1.

All semantic models perform significantly above chance level. As in the case of the regression experiments, there is a clear advantage in synthesising brain activation vectors for visually grounded models (VISUAL and multi-modal models) over the language-based ones (this time including MITCHELL), as well as ASSOC. When looking at the performance of the text-based models in general, there is no difference in performance when comparing context-predicting models to count-based ones, or sparse semantic models to dense ones.

6.3 Brain activation pattern decoding

In the similarity-based decoding experiments, we assess the ability of semantic models to identify the correct stimulus for a given brain activation pattern, using the same leave-two-out cross-validation strategy. At test time, we obtain the reduced semantic model similarity codes and the reduced neural similarity codes for the two test items as described in Section 5.2. It is important to note that these similarity code vectors do not contain any information about the true labeling, since entries corresponding to the test items were removed. Decoding is considered successful if the matching score (computed as the sum of Pearson's correlations) is higher for the congruent pair than for the incorrect one. Again, the expected performance for a model decoding at random is 0.50. Table 3 shows the performance of our semantic models, with selected results also shown in Figure 1.

The performance of all semantic models in the decoding task is significantly above chance level. Grounded semantic models (visual and multi-modal) prove once again to have a significant advantage in decoding brain activation patterns over the text-based models and association-based model ($p < 0.05$). There is no signifi-

6.4 Discriminating between words in the same semantic class

Following Mitchell et al. (2008), we also compare the models in their ability to make accurate predictions when the two test words are exemplars of the same semantic category[11]. This formulation of the task is more difficult, since items in the same semantic class (e.g. *dog* and *cat*) are more similar than items from different semantic classes (e.g. *eye* and *desk*).

In order to measure the performance of our models in this task, we recompute the cross-validated accuracies for all three experiments (regression-based learning, encoding and decoding) by only taking into account the performance on the 120 cross-validation folds where the test items share the same semantic class. The results across models and experiments show very similar trends as the ones computed using all 1770 cross-validation folds. The majority of the models still perform above chance level, but as expected they perform worse than when evaluated using the entire dataset. Visually-grounded models still perform the best in all three experiments (mean performance across participants for multimodal models in all three tasks is in the [0.61-0.63] range).

7 Conclusion and future work

We presented the first systematic comparison of a range of widely-used, state-of-the-art semantic models in their ability to predict patterns of conceptual representation in the human brain. Firstly, we demonstrated that visual information is a stronger predictor of brain activity than linguistic information for concrete nouns. These findings provide further support to the existing hypotheses about the interplay of linguistic, conceptual and perceptual systems in the human brain (Barsalou, 2008). These results also resonate with the success of the rapidly growing field of multimodal semantics (Kiela et al., 2016).

[11] The 60 concepts are exemplars of 12 semantic classes.

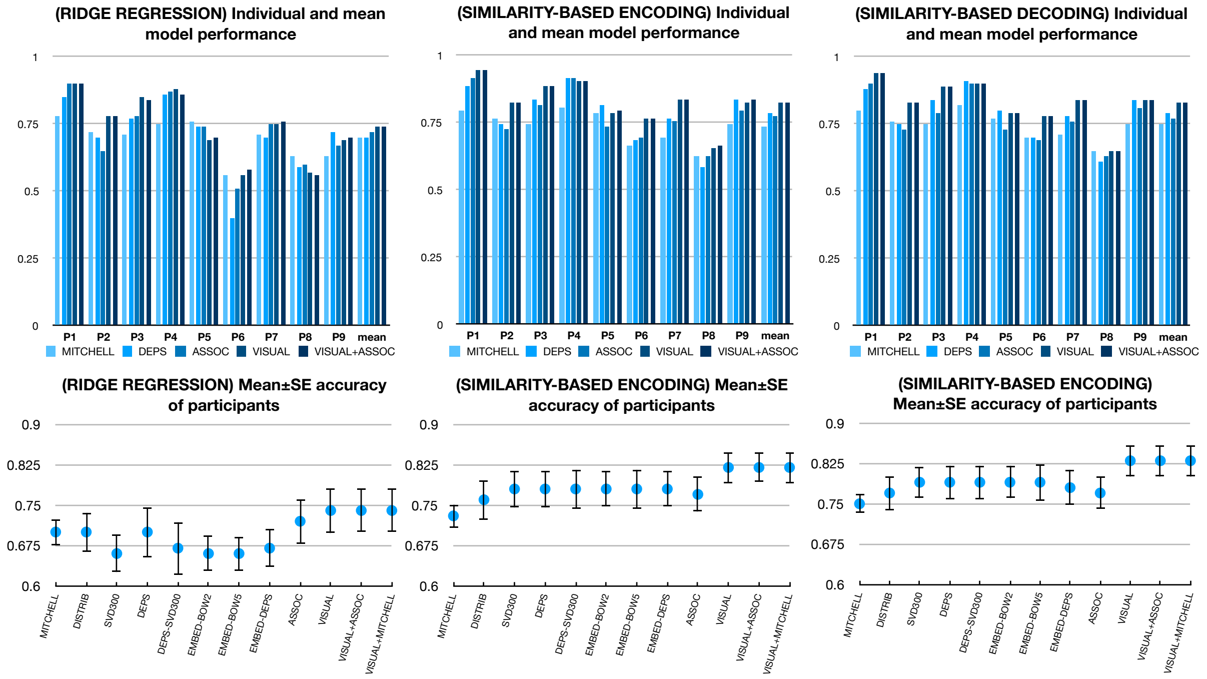

Figure 1: (*TOP*) Comparison of individual and mean model performance for five selected models (MITCHELL, DEPS, ASSOC, VISUAL, VISUAL+ASSOC), using results in Table 1 (*Ridge regression*), Table 2 (*Similarity-based encoding*) and Table 3 (*Similarity-based decoding*). (*BOTTOM*) Mean±SE accuracy of participants for all models.

Secondly, our results suggest that sparse text-based models, whether dependency-based or built using linear bag-of-words context, predict neural activity more accurately than dense models. We also show that the structure of the text-based semantic model (sparse vs. dense) has more influence on the performance than the type of information used to construct the context (linear bag-of-words vs. dependency-based).

Finally, we found that cognitively-motivated association-based models perform on par with or better than other linguistic models. These results are in line with the previous findings of behavioural research suggesting that humans represent the meanings of concepts through association with other concepts (Barsalou et al., 2008) which in turn endorses the association-based semantic models as a promising direction in computational semantics research.

An interesting avenue for future work would be to investigate the variance of results amongst individual participants (Figure 1). Previous studies that use fMRI data always report variation across participants (Devereux et al., 2010; Anderson et al., 2017) and most often attribute it to head motion. However, understanding how individual variations in participants can impact modeling decisions would be of great value to the computational semantics community.

Abstract

The rapid increase in multimedia data transmission over the Internet necessitates the multi-modal summarization (MMS) from collections of text, image, audio and video. In this work, we propose an extractive multi-modal summarization method that can automatically generate a textual summary given a set of documents, images, audios and videos related to a specific topic. The key idea is to bridge the semantic gaps between multi-modal content. For audio information, we design an approach to selectively use its transcription. For visual information, we learn the joint representations of text and images using a neural network. Finally, all of the multi-modal aspects are considered to generate the textual summary by maximizing the salience, non-redundancy, readability and coverage through the budgeted optimization of submodular functions. We further introduce an MMS corpus in English and Chinese, which is released to the public[1]. The experimental results obtained on this dataset demonstrate that our method outperforms other competitive baseline methods.

1 Introduction

Multimedia data (including text, image, audio and video) have increased dramatically recently, which makes it difficult for users to obtain important information efficiently. Multi-modal summarization (MMS) can provide users with textual summaries that can help acquire the gist of multimedia data in a short time, without reading documents or watching videos from beginning to end.

The existing applications related to MMS include meeting record summarization (Erol et al., 2003; Gross et al., 2000), sport video summarization (Tjondronegoro et al., 2011; Hasan et al., 2013), movie summarization (Evangelopoulos et al., 2013; Mademlis et al., 2016), pictorial storyline summarization (Wang et al., 2012), timeline summarization (Wang et al., 2016b) and social multimedia summarization (Del Fabro et al., 2012; Bian et al., 2013; Schinas et al., 2015; Bian et al., 2015; Shah et al., 2015, 2016). When summarizing meeting recordings, sport videos and movies, such videos consist of synchronized voice, visual and captions. For the summarization of pictorial storylines, the input is a set of images with text descriptions. None of these applications focus on summarizing multimedia data that contain asynchronous information about general topics.

In this paper, as shown in Figure 1, we propose an approach to a generate textual summary from a set of asynchronous documents, images, audios and videos on the same topic.

Since multimedia data are heterogeneous and contain more complex information than pure text does, MMS faces a great challenge in addressing the semantic gap between different modalities. The framework of our method is shown in Figure 1. For the audio information contained in videos, we obtain speech transcriptions through Automatic Speech Recognition (ASR) and design a method to use these transcriptions selectively. For visual information, including the key-frames extracted from videos and the images that appear in documents, we learn the joint representations of texts and images by using a neural network; we then can identify the text that is relevant to the image. In this way, audio and visual information can be integrated into a textual summary.

Traditional document summarization involves two essential aspects: (1) Salience: the summa-

ry should retain significant content of the input documents. (2) Non-redundancy: the summary should contain as little redundant content as possible. For MMS, we consider two additional aspects: (3) Readability: because speech transcriptions are occasionally ill-formed, we should try to get rid of the errors introduced by ASR. For example, when a transcription provides similar information to a sentence in documents, we should prefer the sentence to the transcription presented in the summary. (4) Coverage for the visual information: images that appear in documents and videos often capture event highlights that are usually very important. Thus, the summary should cover as much of the important visual information as possible. All of the aspects can be jointly optimized by the budgeted maximization of submodular functions (Khuller et al., 1999).

Our main contributions are as follows:

- We design an MMS method that can automatically generate a textual summary from a set of asynchronous documents, images, audios and videos related to a specific topic.

- To select the representative sentences, we consider four criteria that are jointly optimized by the budgeted maximization of submodular functions.

- We introduce an MMS corpus in English and Chinese. The experimental results on this dataset demonstrate that our system can take advantage of multi-modal information and outperforms other baseline methods.

2 Related Work

2.1 Multi-document Summarization

Multi-document summarization (MDS) attempts to extract important information for a set of documents related to a topic to generate a short summary. Graph based methods (Mihalcea and Tarau, 2004; Wan and Yang, 2006; Zhang et al., 2016) are commonly used. LexRank (Erkan and Radev, 2011) first builds a graph of the documents, in which each node represents a sentence and the edges represent the relationship between sentences. Then, the importance of each sentence is computed through an iterative random walk.

2.2 Multi-modal Summarization

In recent years, much work has been done to summarize meeting recordings, sport videos, movies, pictorial storylines and social multimedia.

Erol et al. (2003) aim to create important segments of a meeting recording based on audio, text and visual activity analysis. Tjondronegoro et al. (2011) propose a way to summarize a sporting event by analyzing the textual information extracted from multiple resources and identifying the important content in a sport video. Evangelopoulos et al. (2013) use an attention mechanism to detect salient events in a movie. Wang et al. (2012) and Wang et al. (2016b) use image-text pairs to generate a pictorial storyline and timeline summarization. Li et al. (2016) develop an approach for multimedia news summarization for searching results on the Internet, in which the hLDA model is introduced to discover the topic structure of the news documents. Then, a news article and an image are chosen to represent each topic. For social media summarization, Fabro et al. (2012) and Schinas et al. (2015) propose to summarize the real-life events based on multimedia content such as photos from Flickr and videos from YouTube. Bian et al. (2013; 2015) propose a multimodal LDA to detect topics by capturing the correlations between textual and visual features of microblogs with embedded images. The output of their method is a set of representative images that describe the events. Shah et al. (2015; 2016) introduce EventBuilder which produces text summaries for a social event leveraging Wikipedia and visualizes the event with social media activities.

Most of the above studies focus on synchronous multi-modal content, i.e., in which images are paired with text descriptions and videos are paired with subtitles. In contrast, we perform summarization from asynchronous (i.e., there is no given description for images and no subtitle for videos) multi-modal information about news topics, including multiple documents, images and videos, to generate a fixed length textual summary. This task is both more general and more challenging.

3 Our Model

3.1 Problem Formulation

The input is a collection of multi-modal data $\mathcal{M} = \{D_1, ..., D_{|D|}, V_1, ..., V_{|V|}\}$ related to a news topic $\mathcal{T}$, where each document $D_i = \{T_i, I_i\}$ consists of text T_i and image I_i (there may be no image for some documents). V_i denotes video. $|\cdot|$ denotes the cardinality of a set. The objective of our work is to automatically generate textual summary to represent the principle content of $\mathcal{M}$.

3.2 Model Overview

There are many essential aspects in generating a good textual summary for multi-modal data. The salient content in documents should be retained, and the key facts in videos and images should be covered. Further, the summary should be readable and non-redundant and should follow the fixed length constraint. We propose an extraction-based method in which all these aspects can be jointly optimized by the budgeted maximization of submodular functions defined as follows:

$$\max_{S \subseteq T} \{\mathcal{F}(S) : \sum_{s \in S} l_s \leq \mathcal{L}\} \tag{1}$$

where T is the set of sentences, S is the summary, l_s is length (number of words) of sentence s, $\mathcal{L}$ is budget, i.e., length constraint for the summary, and submodular function $\mathcal{F}(S)$ is the summary score related to the above-mentioned aspects.

Text is the main modality of documents, and in some cases, images are embedded in documents. Videos consist of at least two types of modalities: audio and visual. Next, we give overall processing methods for different modalities.

Audio, i.e., speech, can be automatically transcribed into text by using an ASR system[2]. Then, we can leverage a graph-based method to calculate the salience score for all of the speech transcriptions and for the original sentences in documents. Note that speech transcriptions are often ill-formed; thus, to improve the readability, we should try to avoid the errors introduced by ASR. In addition, audio features including acoustic confidence (Valenza et al., 1999), audio power (Christel et al., 1998) and audio magnitude (Dagtas and Abdel-Mottaleb, 2001) have proved to be helpful for speech and video summarization which will benefit our method.

For visual, which is actually a sequence of images (frames), because most of the neighboring frames contain redundant information, we first extract the most meaningful frames, i.e., the keyframes, which can provide the key facts for the whole video. Then, it is necessary to perform semantic analysis between text and visual. To this end, we learn the joint representations for textual and visual modalities and can then identify the sentence that is relevant to the image. In this way, we can guarantee the coverage of generated summary for the visual information.

3.3 Salience for Text

We apply a graph-based LexRank algorithm (Erkan and Radev, 2011) to calculate salience score of the text unit, including the sentences in documents and the speech transcriptions from videos. LexRank first constructs a graph based on the text units and their relationship and then conducts an iteratively random walk to calculate the salience score of the text unit, $sa(t_i)$, until convergence using the following equation:

$$Sa(t_i) = \mu \sum_j Sa(t_j) \cdot M_{ji} + \frac{1-\mu}{N} \tag{2}$$

where μ is the damping factor that is set to 0.85. N is the total number of the text units. M_{ji} is the relationship between text unit t_i and t_j, which is computed as follows:

$$M_{ji} = sim(t_j, t_i) \tag{3}$$

The text unit t_i is represented by averaging the embeddings of the words (except stop-words) in t_i. $sim(\cdot)$ denotes cosine similarity between two texts (negative similarities are replaced with 0).

[2] We use IBM Watson Speech to Text service: www.ibm.com/watson/developercloud/speech-to-text.html

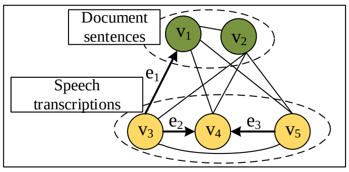

Figure 2: LexRank with guidance strategies. e_1 is guided because speech transcription v_3 is related to document sentence v_1; e_2 and e_3 are guided because of audio features. Other edges without arrow are bidirectional.

For MMS task, we propose two guidance strategies to amend the affinity matrix M and calculate salience score of the text as shown in Figure 2.

3.3.1 Readability Guidance Strategies

The random walk process can be understood as a recommendation: M_{ji} in Equation 2 denotes that t_j will recommend t_i to the degree of M_{ji}. The affinity matrix M in the LexRank model is symmetric, which means $M_{ij} = M_{ji}$. In contrast, for MMS, considering the unsatisfactory quality of speech recognition, symmetric affinity matrices are inappropriate. Specifically, to improve the readability, for a speech transcription, if there is a sentence in document that is related to this transcription, we would prefer to assign the text sentence a higher salience score than that assigned to the transcribed one. To this end, the process of a random walk should be guided to control the recommendation direction: when a document sentence is related to a speech transcription, the symmetric weighted edge between them should be transformed into a unidirectional edge, in which we invalidate the direction from document sentence to the transcribed one. In this way, speech transcriptions will not be recommended by the corresponding document sentences. Important speech transcriptions that cannot be covered by documents still have the chance to obtain high salience scores. For the pair of a sentence t_i and a speech transcription t_j, M_{ij} is computed as follows:

$$M_{ij} = \begin{cases} 0, & \text{if } sim(t_i, t_j) > T_{text} \\ sim(t_i, t_j), & \text{otherwise} \end{cases} \tag{4}$$

where threshold T_{text} is used to determine whether a sentence is related to others. We obtain the proper semantic similarity threshold by testing on Microsoft Research Paraphrase (MSRParaphrase) dataset (Quirk et al., 2004). It is a publicly available paraphrase corpus that consists of 5801 pairs of sentences, of which 3900 pairs are semantically equivalent.

3.3.2 Audio Guidance Strategies

Some audio features can guide the summarization system to select more important and readable speech transcriptions. Valenza et al. (1999) use acoustic confidence to obtain accurate and readable summaries of broadcast news programs. Christel et al. (1998) and Dagtas and Abdel-Mottaleb (2001) apply audio power and audio magnitude to find significant audio events. In our work, we first balance these three feature scores for each speech transcription by dividing their respective maximum values among the whole amount of audio, and we then average these scores to obtain the final audio score for speech transcription. For each adjacent speech transcription pair $(t_k, t_{k'})$, if the audio score $a(t_k)$ for t_k is smaller than a certain threshold while $a(t_{k'})$ is greater, which means that $t_{k'}$ is more important and readable than t_k, then t_k should recommend $t_{k'}$, but $t_{k'}$ should not recommend t_k. We formulate it as follows:

$$\begin{cases} M_{kk'} = sim(t_k, t_{k'}) \\ M_{k'k} = 0 \end{cases} \\ \text{if } a(t_k) < T_{audio} \text{ and } a(t_{k'}) > T_{audio} \tag{5}$$

where the threshold T_{audio} is the average audio score for all the transcriptions in the audio.

Finally, affinity matrices are normalized so that each row adds up to 1.

3.4 Text-Image Matching

The key-frames contained in videos and the images embedded in documents often captures news highlights in which the important ones should be covered by the textual summary. Before measuring the coverage for images, we should train the model to bridge the gap between text and image, i.e., to match the text and image.

We start by extracting key-frames of videos based on shot boundary detection. A shot is defined as an unbroken sequence of frames. The abrupt transition of RGB histogram features often indicates shot boundaries (Zhuang et al., 1998). Specifically, when the transition of the RGB histogram feature for adjacent frames is greater than a certain ratio[3] of the average transition for the whole video, we segment the shot. Then, the frames

[3] The ratio is determined by testing on the

in the middle of each shot are extracted as key-frames. These key-frames and images in documents make up the image set that the summary should cover.

Next, it is necessary to perform a semantic analysis between the text and the image. To this end, we learn the joint representations for textual and visual modalities by using a model trained on the Flickr30K dataset (Young et al., 2014), which contains 31,783 photographs of everyday activities, events and scenes harvested from Flickr. Each photograph is manually labeled with 5 textual descriptions. We apply the framework of Wang et al. (2016a), which achieves state-of-the-art performance for text-image matching task on the Flickr30K dataset. The image is encoded by the VGG model (Simonyan and Zisserman, 2014) that has been trained on the ImageNet classification task following the standard procedure (Wang et al., 2016a). The 4096-dimensional feature from the pre-softmax layer is used to represent the image. The text is first encoded by the Hybrid Gaussian-Laplacian mixture model (HGLMM) using the method of Klein et al. (2014). Then, the HGLMM vectors are reduced to 6000 dimensions through PCA. Next, the sentence vector v_s and image vector v_i are mapped to a joint space by a two-branch neural network as follows:

$$\begin{cases} x = W_2 \cdot f(W_1 \cdot v_s + b_s) \\ y = V_2 \cdot f(V_1 \cdot v_i + b_i) \end{cases} \tag{6}$$

where $W_1 \in \mathbb{R}^{2048\times 6000}$, $b_s \in \mathbb{R}^{2048}$, $W_2 \in \mathbb{R}^{512\times 2048}$, $V_1 \in \mathbb{R}^{2048\times 4096}$, $b_i \in \mathbb{R}^{2048}$, $V_2 \in \mathbb{R}^{512\times 2048}$, f is Rectified Linear Unit (ReLU).

The max-margin learning framework is applied to optimize the neural network as follows:

$$\begin{aligned} L = &\sum_{i,k} \max[0, m + s(x_i, y_i) - s(x_i, y_k)] \\ &+ \lambda_1 \sum_{i,k} \max[0, m + s(x_i, y_i) - s(x_k, y_i)] \end{aligned} \tag{7}$$

where for positive text-image pair (x_i, y_i), the top K most violated negative pairs (x_i, y_k) and (x_k, y_i) in each mini-batch are sampled. The objective function L favors higher matching score $s(x_i, y_i)$ (cosine similarity) for positive text-image pairs than for negative pairs[4].

Note that the images in Flickr30K are similar to our task. However, the image descriptions are much simpler than the text in news, so the model trained on Flickr30K cannot be directly used for our task. For example, some of the information contained in the news, such as the time and location of events, cannot be directly reflected by images. To solve this problem, we simplify each sentence and speech transcription based on semantic role labelling (Gildea and Jurafsky, 2002), in which each predicate indicates an event and the arguments express the relevant information of this event. ARG0 denotes the agent of the event, and ARG1 denotes the action. The assumption is that the concepts including agent, predicate and action compose the body of the event, so we extract "ARG0+predicate+ARG1" as the simplified sentence that is used to match the images. It is worth noting that there may be multiple predicate-argument structures for one sentence and we extract all of them.

After the text-image matching model is trained and the sentences are simplified, for each text-image pair (T_i, I_j) in our task, we can identify the matched pairs if the score $s(T_i, I_j)$ is greater than a threshold T_{match}. We set the threshold as the average matching score for the positive text-image pair in Flickr30K, although the matching performance for our task could in principle be improved by adjusting this parameter.

3.5 Multi-modal Summarization

We model the salience of a summary S as the sum of salience scores $Sa(t_i)$[5] of the sentence t_i in the summary, combining a λ-weighted redundancy penalty term:

$$\mathcal{F}_s(S) = \sum_{t_i \in S} Sa(t_i) - \frac{\lambda_s}{|S|} \sum_{t_i, t_j \in S} sim(t_i, t_j) \tag{8}$$

We model the summary S coverage for the image set I as the weighted sum of image covered by the summary:

$$\mathcal{F}_c(S) = \sum_{p_i \in I} Im(p_i) b_i \tag{9}$$

where the weight $Im(p_i)$ for the image p_i is the length ratio between the shot p_i and the whole videos. b_i is a binary variable to indicate

shot detection dataset of TRECVID. http://www-nlpir.nist.gov/projects/trecvid/

[4] In the experiments, $K = 50$, $m = 0.1$ and $\lambda_1 = 2$. Wang et al. (2016a) also proved that structure-preserving constraints can make 1% Recall@1 improvement.

[5] Normalized by the maximum value among all the sentences.

whether an image p_i is covered by the summary, i.e., whether there is at least one sentence in the summary matching the image.

Finally, considering all the modalities, the objective function is defined as follows:

$$\mathcal{F}_m(S) = \frac{1}{M_s}\sum_{t_i \in S} Sa(t_i) + \frac{1}{M_c}\sum_{p_i \in I} Im(p_i)b_i - \frac{\lambda_m}{|S|}\sum_{i,j \in S} sim(t_i, t_j) \tag{10}$$

where M_s is the summary score obtained by Equation 8 and M_c is the summary score obtained by Equation 9. The aim of M_s and M_c is to balance the aspects of salience and coverage for images. λ_s, and λ_m are determined by testing on development set. Note that to guaranteed monotone of $\mathcal{F}$, λ_s, and λ_m should be lower than the minimum salience score of sentences. To further improve non-redundancy, we make sure that similarity between any pair of sentences in the summary is lower than T_{text}.

Equations 8,9 and 10 are all monotone submodular functions under the budget constraint. Thus, we apply the greedy algorithm (Lin and Bilmes, 2010) guaranteeing near-optimization to solve the problem.

4 Experiment

4.1 Dataset

There is no benchmark dataset for MMS. We construct a dataset as follows. We select 50 news topics in the most recent five years, 25 in English and 25 in Chinese. We set 5 topics for each language as a development set. For each topic, we collect 20 documents within the same period using Google News search[6] and 5-10 videos in CCTV.com[7] and Youtube[8]. More details of the corpus are illustrated in Table 1. Some examples of news topics are provided Table 2.

We employ 10 graduate students to write reference summaries after reading documents and watching videos on the same topic. We keep 3 reference summaries for each topic. The criteria for summarizing documents lie in: (1) retaining important content of the input documents and videos; (2) avoiding redundant information; (3) having a good readability; (4) following the length limit. We set the length constraint for each English and Chinese summary to 300 words and 500 characters, respectively.

	#Sentence	#Word	#Shot	Video Length
English	492.1	12,104.7	47.2	197s
Chinese	402.1	9,689.3	49.3	207s

Table 1: Corpus statistics.

English	(1) Nepal earthquake (2) Terror attack in Paris (3) Train derailment in India (4) Germanwings crash (5) Refugee crisis in Europe
Chinese	(6) “东方之星”客船翻沉 (“Oriental Star”passenger ship sinking) (7) 银川公交大火 (The bus fire in Yinchuan) (8) 香港占中 (Occupy Central in HONG KONG) (9) 李娜澳网夺冠 (Li Na wins Australian Open) (10) 抗议“萨德”反导系统 (Protest against “THAAD”anti-missile system)

Table 2: Examples of news topics.

4.2 Comparative Methods

Several models are compared in our experiments, including generating summaries with different modalities and different approaches to leverage images.

Text only. This model generates summaries only using the text in documents.

Text + audio. This model generates summaries using the text in documents and the speech transcriptions but without guidance strategies.

Text + audio + guide. This model generates summaries using the text in documents and the speech transcriptions with guidance strategies.

The following models generate summaries using both documents and videos but take advantage of images in different ways. The salience scores for text are obtained with guidance strategies.

Image caption. The image is first captioned using the model of Vinyals et al. (2016) which achieved first place in the 2015 MSCOCO Image Captioning Challenge. This model generates summaries using text in documents, speech transcription and image captions.

Note that the above-mentioned methods generate summaries by using Equation 8 and the follow-

[6] http://news.google.com/

[7] http://www.cctv.com/

[8] https://www.youtube.com/

ing methods using Equation 8 ,9 and 10.

Image caption match. This model uses generated image captions to match the text; i.e., if the similarity between a generated image caption and a sentence exceeds the threshold T_{text}, the image and the sentence match.

Image alignment. The images are aligned to the text in the following ways: The images in a document are aligned to all the sentences in this document and the key-frames in a shot are aligned to all the speech transcriptions in this shot.

Image match. The texts are matched with images using the approach introduced in Section 3.4.

4.3 Implementation Details

We perform sentence[9] and word tokenization, and all the Chinese sentences are segmented by Stanford Chinese Word Segmenter (Tseng et al., 2005). We apply Stanford CoreNLP toolkit (Levy and D. Manning, 2003; Klein and D. Manning, 2003) to perform lexical parsing and use semantic role labelling approach proposed by Yang and Zong (2014). We use 300-dimension skip-gram English word embeddings which are publicly available[10]. Given that text-image matching model and image caption generation model are trained in English, to create summaries in Chinese, we first translate the Chinese text into English via Google Translation[11] and then conduct text and image matching.

4.4 Multi-modal Summarization Evaluation

We use the ROUGE-1.5.5 toolkit (Lin and Hovy, 2003) to evaluate the output summaries. This evaluation metric measures the summary quality by matching n-grams between generated summary and reference summary. Table 3 and Table 4 show the averaged ROUGE-1 (R-1), ROUGE-2 (R-2) and ROUGE-SU4 (R-SU4) F-scores regarding to the three reference summaries for each topic in English and Chinese.

For the results of the English MMS, from the first three lines in Table 3 we can see that when summarizing without visual information, the method with guidance strategies performs slightly better than do the first two methods. Because Rouge mainly measures word overlaps, manual evaluation is needed to confirm the impact of guidance strategies on improving readability. It is introduced in Section 4.5. The rating ranges from 1 (the poorest) to 5 (the best). When summarizing with textual and visual modalities, performances are not always improved, which indicates that the models of **image caption**, **image caption match** and **image alignment** are not suitable to MMS. The **image match** model has a significant advantage over other comparative methods, which illustrates that it can make use of multi-modal information.

Method	R-1	R-2	R-SU4
Text only	0.422	0.114	0.166
Text + audio	0.422	0.109	0.164
Text + audio + guide	0.440	0.117	0.171
Image caption	0.435	0.111	0.167
Image caption match	0.429	0.115	0.166
Image alignment	0.409	0.082	0.082
Image match	**0.442**	**0.133**	**0.187**

Table 3: Experimental results (F-score) for English MMS.

Method	R-1	R-2	R-SU4
Text only	0.409	0.113	0.167
Text + audio	0.407	0.111	0.166
Text + audio + guide	0.411	0.115	**0.173**
Image caption match	0.381	0.092	0.149
Image alignment	0.368	0.096	0.143
Image match	**0.414**	**0.125**	**0.173**

Table 4: Experimental results (F-score) for Chinese MMS.

Table 4 shows the Chinese MMS results, which are similar to the English results that the **image match** model achieves the best performance. We find that the performance enhancement for the **image match** model is smaller in Chinese than it is in English, which may be due to the errors introduced by machine translation.

We provides a generated summary in English using the **image match** model, which is shown in Figure 3.

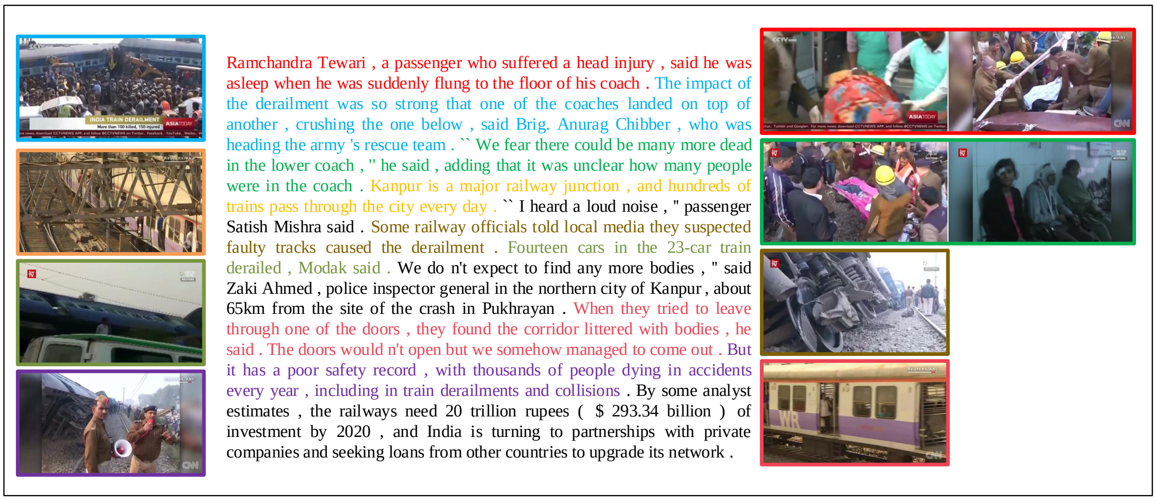
4.5 Manual Summary Quality Evaluation

The readability and informativeness for summaries are difficult to evaluate formally. We ask five graduate students to measure the quality of summaries generated by different methods. We calculate the average score for all of the topics, and the results are displayed in Table 5. Overall, our method with guidance strategies achieves higher scores than do the other methods, but it is still obviously poorer than the reference sum-

[9] We exclude sentences containing less than 5 words.

[10] https://code.google.com/archive/p/word2vec/

[11] https://translate.google.com



Ramchandra Tewari , a passenger who suffered a head injury , said he was asleep when he was suddenly flung to the floor of his coach . The impact of the derailment was so strong that one of the coaches landed on top of another , crushing the one below , said Brig. Anurag Chibber , who was heading the army 's rescue team . `` We fear there could be many more dead in the lower coach , '' he said , adding that it was unclear how many people were in the coach . Kanpur is a major railway junction , and hundreds of trains pass through the city every day . `` I heard a loud noise , '' passenger Satish Mishra said . Some railway officials told local media they suspected faulty tracks caused the derailment . Fourteen cars in the 23-car train derailed , Modak said . We do n't expect to find any more bodies , '' said Zaki Ahmed , police inspector general in the northern city of Kanpur , about 65km from the site of the crash in Pukhrayan . When they tried to leave through one of the doors , they found the corridor littered with bodies , he said . The doors would n't open but we somehow managed to come out . But it has a poor safety record , with thousands of people dying in accidents every year , including in train derailments and collisions . By some analyst estimates , the railways need 20 trillion rupees ($ 293.34 billion) of investment by 2020 , and India is turning to partnerships with private companies and seeking loans from other countries to upgrade its network .

Figure 3: An example of generated summary for the news topic "India train derailment". The sentences covering the images are labeled by the corresponding colors. The text can be partly related to the image because we use simplified sentence based on SRL to match the images. We can find some mismatched sentences, such as the sentence "Fourteen cars in the 23-car train derailed , Modak said ." where our text-image matching model may misunderstand the "car " as a "motor vehicle" but not a "coach".

maries. Specifically, when speech transcriptions are not considered, the informativeness of the summary is the worst. However, adding speech transcriptions without guidance strategies decreases readability to a large extent, which indicates that guidance strategies are necessary for MMS. The **image match** model achieves higher informativeness scores than do the other methods without using images.

We give two instances of readability guidance that arise between document text (DT) and speech transcriptions (ST) in Table 6. The errors introduced by ASR include segmentation (instance A) and recognition (instance B) mistakes.

	Method	Read	Inform
English	Text only	3.72	3.28
	Text + audio	3.08	3.44
	Text + audio + guide	3.68	3.64
	Image match	3.67	3.83
	Reference	4.52	4.36
Chinese	Text only	3.64	3.40
	Text + audio	3.16	3.48
	Text + audio + guide	3.60	3.72
	Image match	3.62	3.92
	Reference	4.88	4.84

Table 5: Manual summary quality evaluation. "Read" denotes "Readability" and "Inform" denotes "informativeness".

A	DT	There were 12 bodies at least pulled from the rubble in the square.
	ST	Still being pulled from the rubble.
	CST	Many people are still being pulled from the rubble.
B	DT	Conflict between police and protesters lit up on Tuesday.
	ST	Late night tensions between police and protesters briefly lit up this Baltimore neighborhood Tuesday.
	CST	Late-night tensions between police and protesters briefly lit up in a Baltimore neighborhood Tuesday.

Table 6: Guidance examples. "CST" denotes manually modified correct ST. ASR errors are marked red and revisions are marked blue.

4.6 How Much is the Image Worth

Text-image matching is the toughest module for our framework. Although we use a state-of-the-art approach to match the text and images, the performance is far from satisfactory. To find a somewhat strong upper-bound of the task, we choose five topics for each language to manually label the text-image matching pairs. The MMS results on these topics are shown in Table 7 and Table 8. The experiments show that with the ground truth text-image matching result, the summary quality can be promoted to a considerable extent, which indicates visual information is crucial for MMS.

An image and the corresponding texts obtained using different methods are given in Figure 4 an d Figure 5. We can conclude that the **image caption**

Image caption:
A group of people standing on top of a lush green field.
Image caption match:
We could barely stay standing.
Image hard alignment:
The need for doctors would grow as more survivors were pulled from the rubble.
Image match:
The search, involving US, Indian and Nepali military choppers and a battalion of 400 Nepali soldiers, has been joined by two MV-22B Osprey.
Image manually match:
The military helicopter was on an aid mission in Dolakha district near Tibet.

Figure 4: An example image with corresponding English texts that different methods obtain.

and the **image caption match** contain little of the image's intrinsically intended information. The **image alignment** introduces more noise because it is possible that the whole text in documents or the speech transcriptions in shot are aligned to the document images or the key-frames, respectively. The **image match** can obtain similar results to the **image manually match**, which illustrates that the **image match** can make use of visual information to generate summaries.

Method	R-1	R-2	R-SU4

(On that day, thousands of people gathered in Seongju to protest the local deployment of "THAAD".)

Figure 5: An example image with corresponding Chinese texts that different methods obtain.

5 Conclusion

This paper addresses an asynchronous MMS task, namely, how to use related text, audio and video information to generate a textual summary. We formulate the MMS task as an optimization problem with a budgeted maximization of submodular functions. To selectively use the transcription of audio, guidance strategies are designed using the graph model to effectively calculate the salience score for each text unit, leading to more readable and informative summaries. We investigate various approaches to identify the relevance between the image and texts, and find that the **image match** model performs best. The final experimental results obtained using our MMS corpus in both English and Chinese demonstrate that our system can benefit from multi-modal information.

Adding audio and video does not seem to improve dramatically over text only model, which indicates that better models are needed to capture the interactions between text and other modalities, especially for visual. We also plan to enlarge our MMS dataset, specifically to collect more videos.

Abstract

Multimodal sentiment analysis is an increasingly popular research area, which extends the conventional language-based definition of sentiment analysis to a multimodal setup where other relevant modalities accompany language. In this paper, we pose the problem of multimodal sentiment analysis as modeling *intra-modality* and *inter-modality* dynamics. We introduce a novel model, termed Tensor Fusion Network, which learns both such dynamics end-to-end. The proposed approach is tailored for the volatile nature of spoken language in online videos as well as accompanying gestures and voice. In the experiments, our model outperforms state-of-the-art approaches for both multimodal and unimodal sentiment analysis.

1 Introduction

Multimodal sentiment analysis (Morency et al., 2011; Zadeh et al., 2016b; Poria et al., 2015) is an increasingly popular area of affective computing research (Poria et al., 2017) that focuses on generalizing text-based sentiment analysis to opinionated videos, where three communicative modalities are present: language (spoken words), visual (gestures), and acoustic (voice).

This generalization is particularly vital to part of the NLP community dealing with opinion mining and sentiment analysis (Cambria et al., 2017) since there is a growing trend of sharing opinions in videos instead of text, specially in social media (Facebook, YouTube, etc.). The central challenge in multimodal sentiment analysis is to model the *inter-modality* dynamics: the interactions between language, visual and acoustic behaviors that change the perception of the expressed sentiment.

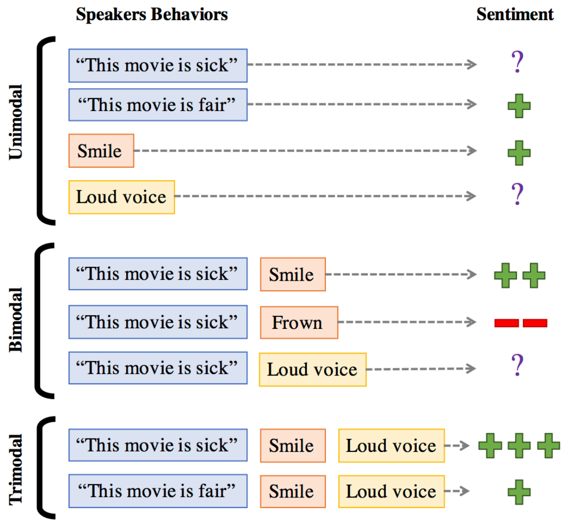

Figure 1: Unimodal, bimodal and trimodal interaction in multimodal sentiment analysis.

Figure 1 illustrates these complex inter-modality dynamics. The utterance "This movie is sick" can be ambiguous (either positive or negative) by itself, but if the speaker is also smiling at the same time, then it will be perceived as positive. On the other hand, the same utterance with a frown would be perceived negatively. A person speaking loudly "This movie is sick" would still be ambiguous. These examples are illustrating **bimodal** interactions. Examples of **trimodal** interactions are shown in Figure 1 when loud voice increases the sentiment to strongly positive. The complexity of inter-modality dynamics is shown in the second trimodal example where the utterance "This movie is fair" is still weakly positive, given the strong influence of the word "fair".

A second challenge in multimodal sentiment analysis is efficiently exploring *intra-modality* dynamics of a specific modality (**unimodal** interaction). Intra-modality dynamics are particularly

[†] means equal contribution

Proceedings of the 2017 Conference on Empirical Methods in Natural Language Processing, pages 1103–1114
Copenhagen, Denmark, September 7–11, 2017. ©2017 Association for Computational Linguistics

challenging for the language analysis since multimodal sentiment analysis is performed on spoken language. A spoken opinion such as "I think it was alright . . . Hmmm . . . let me think . . . yeah . . . no . . . ok yeah" almost never happens in written text. This volatile nature of spoken opinions, where proper language structure is often ignored, complicates sentiment analysis. Visual and acoustic modalities also contain their own intra-modality dynamics which are expressed through both space and time.

Previous works in multimodal sentiment analysis does not account for both intra-modality and inter-modality dynamics directly, instead they either perform early fusion (a.k.a., feature-level fusion) or late fusion (a.k.a., decision-level fusion). Early fusion consists in simply concatenating multimodal features mostly at input level (Morency et al., 2011; Pérez-Rosas et al., 2013; Poria et al., 2016). This fusion approach does not allow the intra-modality dynamics to be efficiently modeled. This is due to the fact that inter-modality dynamics can be more complex at input level and can dominate the learning process or result in overfitting. Late fusion, instead, consists in training unimodal classifiers independently and performing decision voting (Wang et al., 2016; Zadeh et al., 2016a). This prevents the model from learning inter-modality dynamics in an efficient way by assuming that simple weighted averaging is a proper fusion approach.

In this paper, we introduce a new model, termed Tensor Fusion Network (TFN), which learns both the intra-modality and inter-modality dynamics end-to-end. Inter-modality dynamics are modeled with a new multimodal fusion approach, named Tensor Fusion, which explicitly aggregates unimodal, bimodal and trimodal interactions. Intra-modality dynamics are modeled through three Modality Embedding Subnetworks, for language, visual and acoustic modalities, respectively.

In our extensive set of experiments, we show (a) that TFN outperforms previous state-of-the-art approaches for multimodal sentiment analysis, (b) the characteristics and capabilities of our Tensor Fusion approach for multimodal sentiment analysis, and (c) that each of our three Modality Embedding Subnetworks (language, visual and acoustic) are also outperforming unimodal state-of-the-art unimodal sentiment analysis approaches.

2 Related Work

Sentiment Analysis is a well-studied research area in NLP (Pang et al., 2008). Various approaches have been proposed to model sentiment from language, including methods that focus on opinionated words (Hu and Liu, 2004; Taboada et al., 2011; Poria et al., 2014b; Cambria et al., 2016), n-grams and language models (Yang and Cardie, 2012), sentiment compositionality and dependency-based analysis (Socher et al., 2013; Poria et al., 2014a; Agarwal et al., 2015; Tai et al., 2015), and distributional representations for sentiment (Iyyer et al., 2015).

Multimodal Sentiment Analysis is an emerging research area that integrates verbal and nonverbal behaviors into the detection of user sentiment. There exist several multimodal datasets that include sentiment annotations, including the newly-introduced CMU-MOSI dataset (Zadeh et al., 2016b), as well as other datasets including ICT-MMMO (Wöllmer et al., 2013), YouTube (Morency et al., 2011), and MOUD (Pérez-Rosas et al., 2013), however CMU-MOSI is the only English dataset with utterance-level sentiment labels. The newest multimodal sentiment analysis approaches have used deep neural networks, including convolutional neural networks (CNNs) with multiple-kernel learning (Poria et al., 2015), SAL-CNN (Wang et al., 2016) which learns generalizable features across speakers, and support vector machines (SVMs) with a multimodal dictionary (Zadeh, 2015).

Audio-Visual Emotion Recognition is closely tied to multimodal sentiment analysis (Poria et al., 2017). Both audio and visual features have been shown to be useful in the recognition of emotions (Ghosh et al., 2016a). Using facial expressions and audio cues jointly has been the focus of many recent studies (Glodek et al., 2011; Valstar et al., 2016; Nojavanasghari et al., 2016).

Multimodal Machine Learning has been a growing trend in machine learning research that is closely tied to the studies in this paper. Creative and novel applications of using multiple modalities have been among successful recent research directions in machine learning (You et al., 2016; Donahue et al., 2015; Antol et al., 2015; Specia et al., 2016; Tong et al., 2017).

3 CMU-MOSI Dataset

Multimodal Opinion Sentiment Intensity (CMU-MOSI) dataset is an annotated dataset of video

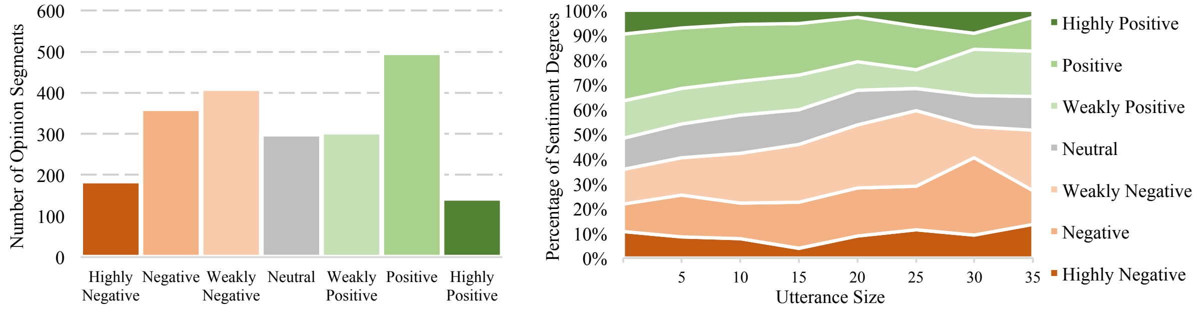

Figure 2: Distribution of sentiment across different opinions (left) and opinion sizes (right) in CMU-MOSI.

opinions from YouTube movie reviews (Zadeh et al., 2016a). Annotation of sentiment has closely followed the annotation scheme of the Stanford Sentiment Treebank (Socher et al., 2013), where sentiment is annotated on a seven-step Likert scale from very negative to very positive. However, whereas the Stanford Sentiment Treebank is segmented by sentence, the CMU-MOSI dataset is segmented by opinion utterances to accommodate spoken language where sentence boundaries are not as clear as text. There are 2199 opinion utterances for 93 distinct speakers in CMU-MOSI. There are an average 23.2 opinion segments in each video. Each video has an average length of 4.2 seconds. There are a total of 26,295 words in the opinion utterances. These utterance are annotated by five Mechanical Turk annotators for sentiment. The final agreement between the annotators is high in terms of Krippendorf's alpha $\alpha = 0.77$. Figure 2 shows the distribution of sentiment across different opinions and different opinion sizes. CMU-MOSI dataset facilitates three prediction tasks, each of which we address in our experiments: 1) *Binary Sentiment Classification* 2) *Five-Class Sentiment Classification* (similar to Stanford Sentiment Treebank fine-grained classification with seven scale being mapped to five) and 3) *Sentiment Regression* in range $[-3, 3]$. For sentiment regression, we report Mean-Absolute Error (lower is better) and correlation (higher is better) between the model predictions and regression ground truth.

4 Tensor Fusion Network

Our proposed TFN consists of three major components: 1) *Modality Embedding Subnetworks* take as input unimodal features, and output a rich modality embedding. 2) *Tensor Fusion Layer* explicitly models the unimodal, bimodal and trimodal interactions using a 3-fold Cartesian product from modality embeddings. 3) *Sentiment Inference Subnetwork* is a network conditioned on the output of the Tensor Fusion Layer and performs sentiment inference. Depending on the task from Section 3 the network output changes to accommodate binary classification, 5-class classification or regression. Input to the TFN is an opinion utterance which includes three modalities of language, visual and acoustic. The following three subsections describe the TFN subnetworks and their inputs in detail.

4.1 Modality Embedding Subnetworks

Spoken Language Embedding Subnetwork: Spoken text is different than written text (reviews, tweets) in compositionality and grammar. We revisit the spoken opinion: "I think it was alright . . . Hmmm . . . let me think . . . yeah . . . no . . . ok yeah". This form of opinion rarely happens in written language but variants of it are very common in spoken language. The first part conveys the actual message and the rest is speaker thinking out loud eventually agreeing with the first part. The key factor in dealing with this volatile nature of spoken language is to build models that are capable of operating in presence of unreliable and idiosyncratic speech traits by focusing on important parts of speech.

Our proposed approach to deal with challenges of spoken language is to learn a rich representation of spoken words at each word interval and use it as input to a fully connected deep network (Figure 3). This rich representation for ith word contains information from beginning of utterance through time, as well as ith word. This way as the model is discovering the meaning of the utterance through time, if it encounters unusable information in word $i + 1$ and arbitrary number of words after, the representation up until i is not diluted or lost. Also, if the model encounters usable information again, it can recover by embedding those in the long short-term memory (LSTM). The time-dependent

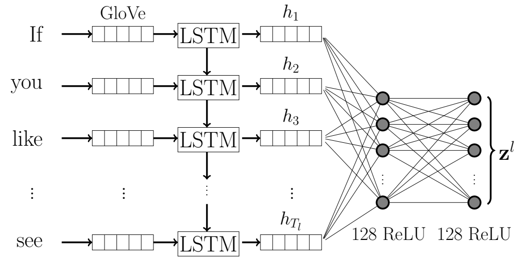

Figure 3: Spoken Language Embedding Subnetwork ($\mathcal{U}_l$)

encodings are usable by the rest of the pipeline by simply focusing on relevant parts using the non-linear affine transformation of time-dependent embeddings which can act as a dimension reducing attention mechanism. To formally define our proposed Spoken Language Embedding Subnetwork ($\mathcal{U}_l$), let $\mathbf{l} = \{l_1, l_2, l_3, \dots, l_{T_l}; l_t \in \mathbb{R}^{300}\}$, where T_l is the number of words in an utterance, be the set of spoken words represented as a sequence of 300-dimensional GloVe word vectors (Pennington et al., 2014).

A LSTM network (Hochreiter and Schmidhuber, 1997) with a forget gate (Gers et al., 2000) is used to learn time-dependent language representations $\mathbf{h_l} = \{h_1, h_2, h_3, \dots, h_{T_l}; h_t \in \mathbb{R}^{128}\}$ for words according to the following LSTM formulation.

$$\begin{pmatrix} i \\ f \\ o \\ m \end{pmatrix} = \begin{pmatrix} sigmoid \\ sigmoid \\ sigmoid \\ tanh \end{pmatrix} W_{l_d} \begin{pmatrix} X_t W_{l_e} \\ h_{t-1} \end{pmatrix}$$

$$c_t = f \odot c_{t-1} + i \odot m$$

$$h_t = o \otimes tanh(c_t)$$

$$\mathbf{h_l} = [h_1; h_2; h_3; \dots; h_{T_l}]$$

$\mathbf{h_l}$ is a matrix of language representations formed from concatenation of $h_1, h_2, h_3, \dots h_{T_l}$. $\mathbf{h_l}$ is then used as input to a fully-connected network that generates language embedding $\mathbf{z}^l$:

$$\mathbf{z}^l = \mathcal{U}_l(\mathbf{l};\ W_l) \in \mathbb{R}^{128}$$

where W_l is the set of all weights in the $\mathcal{U}_l$ network (including W_{l_d}, W_{l_e},$W_{l_{fc}}$, and $b_{l_{fc}}$), σ is the sigmoid function.

Visual Embedding Subnetwork: Since opinion videos consist mostly of speakers talking to the audience through close-up camera, face is the most important source of visual information. The speaker's face is detected for each frame (sampled at 30Hz) and indicators of the seven basic emotions (anger, contempt, disgust, fear, joy, sadness, and surprise) and two advanced emotions (frustration and confusion) (Ekman, 1992) are extracted using FACET facial expression analysis framework[1]. A set of 20 Facial Action Units (Ekman et al., 1980), indicating detailed muscle movements on the face, are also extracted using FACET. Estimates of head position, head rotation, and 68 facial landmark locations also extracted per frame using OpenFace (Baltrušaitis et al., 2016; Zadeh et al., 2017).

Let the visual features $\hat{\mathbf{v}}_j = [v_j^1, v_j^2, v_j^3, \dots, v_j^p]$ for frame j of utterance video contain the set of p visual features, with T_v the number of total video frames in utterance. We perform mean pooling over the frames to obtain the expected visual features $\mathbf{v} = [\mathbb{E}[v^1], \mathbb{E}[v^2], \mathbb{E}[v^3], \dots, \mathbb{E}[v^l]]$. $\mathbf{v}$ is then used as input to the Visual Embedding Subnetwork $\mathcal{U}_v$. Since information extracted using FACET from videos is rich, using a deep neural network would be sufficient to produce meaningful embeddings of visual modality. We use a deep neural network with three hidden layers of 32 ReLU units and weights W_v. Empirically we observed that making the model deeper or increasing the number of neurons in each layer does not lead to better visual performance. The subnetwork output provides the visual embedding $\mathbf{z}^v$:

$$\mathbf{z}^v = \mathcal{U}_v(\mathbf{v};\ W_v) \in \mathbb{R}^{32}$$

Acoustic Embedding Subnetwork: For each opinion utterance audio, a set of acoustic features are extracted using COVAREP acoustic analysis framework (Degottex et al., 2014), including 12 MFCCs, pitch tracking and Voiced/UnVoiced segmenting features (using the additive noise robust *Summation of Residual Harmonics* (SRH) method (Drugman and Alwan, 2011)), glottal source parameters (estimated by glottal inverse filtering based on GCI synchronous IAIF (Drugman et al., 2012; Alku, 1992; Alku et al., 2002, 1997; Titze and Sundberg, 1992; Childers and Lee, 1991)), peak slope parameters (Degottex et al., 2014), maxima dispersion quotients (MDQ) (Kane and Gobl, 2013), and estimations of the R_d shape parameter of the Liljencrants-Fant (LF) glottal model (Fujisaki and Ljungqvist, 1986). These extracted features capture different characteristics of human voice and have been shown to be related to emotions (Ghosh et al., 2016b).

[1] http://goo.gl/1rh1JN

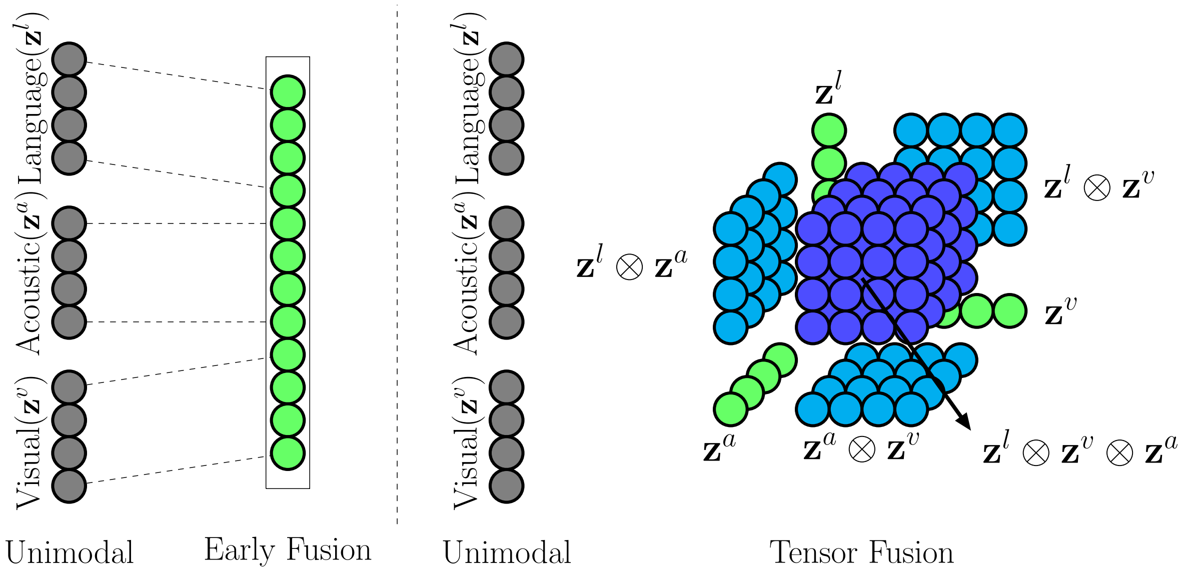

Figure 4: Left: Commonly used early fusion (multimodal concatenation). Right: Our proposed tensor fusion with three types of subtensors: unimodal, bimodal and trimodal.

For each opinion segment with T_a audio frames (sampled at 100Hz; i.e., 10ms), we extract the set of q acoustic features $\hat{\mathbf{a}}_j = [a_j^1, a_j^2, a_j^3, \dots, a_j^q]$ for audio frame j in utterance. We perform mean pooling per utterance on these extracted acoustic features to obtain the expected acoustic features $\mathbf{a} = [\mathbb{E}[a_1], \mathbb{E}[a_2], \mathbb{E}[a_3], \dots, \mathbb{E}[q]]$. Here, $\mathbf{a}$ is the input to the Audio Embedding Subnetwork $\mathcal{U}_a$. Since COVAREP also extracts rich features from audio, using a deep neural network is sufficient to model the acoustic modality. Similar to $\mathcal{U}_v, \mathcal{U}_a$ is a network with 3 layers of 32 ReLU units with weights W_a.

Here, we also empirically observed that making the model deeper or increasing the number of neurons in each layer does not lead to better performance. The subnetwork produces the audio embedding $\mathbf{z}^a$:

$$\mathbf{z}^a = \mathcal{U}_a(\mathbf{a}; W_a) \in \mathbb{R}^{32}$$

4.2 Tensor Fusion Layer

While previous works in multimodal research has used feature concatenation as an approach for multimodal fusion, we aim to build a fusion layer in TFN that disentangles unimodal, bimodal and trimodal dynamics by modeling each of them explicitly. We call this layer Tensor Fusion, which is defined as the following vector field using three-fold Cartesian product:

$$\left\{ (z^l, z^v, z^a) \mid z^l \in \begin{bmatrix} \mathbf{z}^l \\ 1 \end{bmatrix}, z^v \in \begin{bmatrix} \mathbf{z}^v \\ 1 \end{bmatrix}, z^a \in \begin{bmatrix} \mathbf{z}^a \\ 1 \end{bmatrix} \right\}$$

The extra constant dimension with value 1 generates the unimodal and bimodal dynamics. Each neural coordinate (z_l, z_v, z_a) can be seen as a 3-D point in the 3-fold Cartesian space defined by the language, visual, and acoustic embeddings dimensions $[\mathbf{z}^l 1]^T$, $[\mathbf{z}^v 1]^T$, and $[\mathbf{z}^a 1]^T$.

This definition is mathematically equivalent to a differentiable outer product between $\mathbf{z}^l$, the visual representation $\mathbf{z}^v$, and the acoustic representation $\mathbf{z}^a$.

$$\mathbf{z}^m = \begin{bmatrix} \mathbf{z}^l \\ 1 \end{bmatrix} \otimes \begin{bmatrix} \mathbf{z}^v \\ 1 \end{bmatrix} \otimes \begin{bmatrix} \mathbf{z}^a \\ 1 \end{bmatrix}$$

Here $\otimes$ indicates the outer product between vectors and $\mathbf{z}^m \in \mathbb{R}^{129 \times 33 \times 33}$ is the 3D cube of all possible combination of unimodal embeddings with seven semantically distinct subregions in Figure 4. The first three subregions $\mathbf{z}^l$, $\mathbf{z}^v$, and $\mathbf{z}^a$ are unimodal embeddings from Modality Embedding Subnetworks forming unimodal interactions in Tensor Fusion. Three subregions $\mathbf{z}^l \otimes \mathbf{z}^v$, $\mathbf{z}^l \otimes \mathbf{z}^a$, and $\mathbf{z}^v \otimes \mathbf{z}^a$ capture bimodal interactions in Tensor Fusion. Finally, $\mathbf{z}^l \otimes \mathbf{z}^v \otimes \mathbf{z}^a$ captures trimodal interactions.

Early fusion commonly used in multimodal research dealing with language, vision and audio, can be seen as a special case of Tensor Fusion with only unimodal interactions. Since Tensor Fusion is mathematically formed by an outer product, it has no learnable parameters and we empirically observed that although the output tensor is high dimensional, chances of overfitting are low.

We argue that this is due to the fact that the output neurons of Tensor Fusion are easy to interpret and semantically very meaningful (i.e., the manifold that they lie on is not complex but just high dimensional). Thus, it is easy for the subsequent layers of the network to decode the meaningful information.

4.3 Sentiment Inference Subnetwork

After Tensor Fusion layer, each opinion utterance can be represented as a multimodal tensor $\mathbf{z}^m$. We use a fully connected deep neural network called Sentiment Inference Subnetwork $\mathcal{U}_s$ with weights W_s conditioned on $\mathbf{z}^m$. The architecture of the network consists of two layers of 128 ReLU activation units connected to decision layer. The likelihood function of the Sentiment Inference Subnetwork is defined as follows, where ϕ is the sentiment prediction:

$$\underset{\phi}{\arg\max}\ \mathrm{p}(\phi \mid \mathbf{z}^m; W_s) = \underset{\phi}{\arg\max}\ \mathcal{U}_s(\mathbf{z}^m; W_s)$$

In our experiments, we use three variations of the $\mathcal{U}_s$ network. The first network is trained for binary sentiment classification, with a single sigmoid output neuron using binary cross-entropy loss. The second network is designed for five-class sentiment classification, and uses a softmax probability function using categorical cross-entropy loss. The third network uses a single sigmoid output, using mean-squarred error loss to perform sentiment regression.

5 Experiments

In this paper, we devise three sets of experiments each addressing a different research question:

Experiment 1: We compare our TFN with previous state-of-the-art approaches in multimodal sentiment analysis.

Experiment 2: We study the importance of the TFN subtensors and the impact of each individual modality (see Figure 4). We also compare with the commonly-used early fusion approach.

Experiment 3: We compare the performance of our three modality-specific networks (language, visual and acoustic) with state-of-the-art unimodal approaches.

Section 5.4 describes our experimental methodology which is kept constant across all experiments. Section 6 will discuss our results in more details with a qualitative analysis.

Multimodal Baseline	Binary		5-class	Regression	
	Acc(%)	F1	Acc(%)	MAE	r

Δ^{SOTA}	↑ 4.0	↑ 2.7	↑ 6.7	↓ 0.23	↑ 0.17

Table 1: Comparison with state-of-the-art approaches for multimodal sentiment analysis. TFN outperforms both neural and non-neural approaches as shown by Δ^{SOTA}.

5.1 E1: Multimodal Sentiment Analysis

In this section, we compare the performance of TFN model with previously proposed multimodal sentiment analysis models. We compare to the following baselines:

C-MKL (Poria et al., 2015) Convolutional MKL-based model is a multimodal sentiment classification model which uses a CNN to extract textual features and uses multiple kernel learning for sentiment analysis. It is current SOTA (state of the art) on CMU-MOSI.

SAL-CNN (Wang et al., 2016) Select-Additive Learning is a multimodal sentiment analysis model that attempts to prevent identity-dependent information from being learned in a deep neural network. We retrain the model for 5-fold cross-validation using the code provided by the authors on github.

SVM-MD (Zadeh et al., 2016b) is a SVM model trained on multimodal features using early fusion. The model used in (Morency et al., 2011) and (Pérez-Rosas et al., 2013) also similarly use SVM on multimodal concatenated features. We also present the results of Random Forest **RF-MD** to compare to another non-neural approach.

The results first experiment are reported in Table 1. TFN outperforms previously proposed neural and non-neural approaches. This difference is specifically visible in the case of 5-class classification.

5.2 E2: Tensor Fusion Evaluation

Table 4 shows the results of our ablation study. The first three rows are showing the performance of each modality, when no intermodality dynamics are modeled. From this first experiment, we observe that the language modality is the most predictive.

Baseline	Binary		5-class	Regression	
	Acc(%)	F1	Acc(%)	MAE	r
TFN$_{language}$	74.8	75.6	38.5	0.99	0.61
TFN$_{visual}$	66.8	70.4	30.4	1.13	0.48
TFN$_{acoustic}$	65.1	67.3	27.5	1.23	0.36
TFN$_{bimodal}$	75.2	76.0	39.6	0.92	0.65
TFN$_{trimodal}$	74.5	75.0	38.9	0.93	0.65
TFN$_{notrimodal}$	75.3	76.2	39.7	0.919	0.66
TFN	**77.1**	**77.9**	**42.0**	**0.87**	**0.70**
TFN$_{early}$	75.2	76.2	39.0	0.96	0.63

Table 2: Comparison of TFN with its subtensor variants. All the unimodal, bimodal and trimodal subtensors are important. TFN also outperforms early fusion.

As a second set of ablation experiments, we test our TFN approach when only the bimodal subtensors are used (TFN$_{bimodal}$) or when only the trimodal subtensor is used (TFN$_{bimodal}$). We observe that bimodal subtensors are more informative when used without other subtensors. The most interesting comparison is between our full TFN model and a variant (TFN$_{notrimodal}$) where the trimodal subtensor is removed (but all the unimodal and bimodal subtensors are present). We observe a big improvement for the full TFN model, confirming the importance of the trimodal dynamics and the need for all components of the full tensor.

We also perform a comparison with the early fusion approach (TFN$_{early}$) by simply concatenating all three modality embeddings $< z^l, z^a, z^v >$ and passing it directly as input to $\mathcal{U}_s$. This approach was depicted on the left side of Figure 4. When looking at Table 4 results, we see that our TFN approach outperforms the early fusion approach[2].

5.3 E3: Modality Embedding Subnetworks Evaluation

In this experiment, we compare the performance of our Modality Embedding Networks with state-of-the-art approaches for language-based, visual-based and acoustic-based sentiment analysis.

5.3.1 Language Sentiment Analysis

We selected the following state-of-the-art approaches to include variety in their techniques, based on dependency parsing (RNTN), distributional representation of text (DAN), and convolutional approaches (DynamicCNN). When possible, we retrain them on the CMU-MOSI dataset (performances of the original pre-trained models are shown in parenthesis in Table 3) and compare them to our language only TFN$_{language}$.

Language Baseline	Binary		5-class	Regression	
	Acc(%)	F1	Acc(%)	MAE	r
RNTN	- (73.7)	- (73.4)	- (35.2)	- (0.99)	- (0.59)
DAN	73.4 (68.8)	73.8 (68.4)	**39.2** (36.7)	- -	- -
D-CNN	65.5 (62.1)	66.9 (56.4)	32.0 (32.4)	- -	- -
CMKL-L	71.2	72.4	34.5	-	-
SAL-CNN-L	73.5	-	-	-	-
SVM-MD-L	70.6	71.2	33.1	1.18	0.46
TFN$_{language}$	**74.8**	**75.6**	38.5	**0.98**	**0.62**
$\Delta^{SOTA}_{language}$	↑ 1.1	↑ 1.8	↓ 0.7	↓ 0.01	↑ 0.03

Table 3: Language Sentiment Analysis. Comparison of with state-of-the-art approaches for language sentiment analysis. $\Delta^{SOTA}_{language}$ shows improvement.

RNTN (Socher et al., 2013)The Recursive Neural Tensor Network is among the most well-known sentiment analysis methods proposed for both binary and multi-class sentiment analysis that uses dependency structure.

DAN (Iyyer et al., 2015) The Deep Average Network approach is a simple but efficient sentiment analysis model that uses information only from distributional representation of the words and not from the compositionality of the sentences.

DynamicCNN (Kalchbrenner et al., 2014) DynamicCNN is among the state-of-the-art models in text-based sentiment analysis which uses a convolutional architecture adopted for the semantic modeling of sentences.

CMK-L, **SAL-CNN-L** and **SVM-MD-L** are multimodal models from section using only language modality 5.1.

Results in Table 3 show that our model using only language modality outperforms state-of-the-art approaches for the CMU-MOSI dataset. While previous models are well-studied and suitable models for sentiment analysis in written language, they underperform in modeling the sentiment in spoken language. We suspect that this underperformance is due to: RNTN and similar approaches rely heavily on dependency structure, which may not be present

[2] We also performed other comparisons with variants of the early fusion model TFN$_{early}$ where we increased the number of parameters and neurons to replicate the numbers from our TFN model. In all cases, the performances were similar to TFN$_{early}$ (and lower than our TFN model). Because of space constraints, we could not include them in this paper.

Visual Baseline	Binary		5-class	Regression	
	Acc(%)	F1	Acc(%)	MAE	r
3D-CNN	56.1	58.4	24.9	1.31	0.26

SVM-MD-V	59.2	60.1	25.6	1.24	0.36
TFN$_{visual}$	**69.4**	**71.4**	**31.0**	**1.12**	**0.50**
Δ^{SOTA}_{visual}	↑ 5.6	↑ 7.7	↑ 1.7	↓ 0.11	↑ 0.14

Table 4: Visual Sentiment Analysis. Comparison with state-of-the-art approaches for visual sentiment analysis and emotion recognition. Δ^{SOTA}_{visual} shows the improvement.

Acoustic Baseline	Binary		5-class	Regression	
	Acc(%)	F1	Acc(%)	MAE	r
HL-RNN	63.4	64.2	25.9	**1.21**	0.34
Adieu-Net	59.2	60.6	25.1	1.29	0.31
SER-LSTM	55.4	56.1	24.2	1.36	0.23
CMKL-A	52.6	58.5	**29.1**	-	-
SAL-CNN-A	62.1	-	-	-	-
SVM-MD-A	56.3	58.0	24.6	1.29	0.28
TFN$_{acoustic}$	**65.1**	**67.3**	27.5	1.23	**0.36**
$\Delta^{SOTA}_{acoustic}$	↑ 1.7	↑ 3.1	↓ 1.6	↑ 0.02	↑ 0.02

Table 5: Acoustic Sentiment Analysis. Comparison with state-of-the-art approaches for audio sentiment analysis and emotion recognition. $\Delta^{SOTA}_{acoustic}$ shows improvement.

in spoken language; DAN and similar sentence embeddings approaches can easily be diluted by words that may not relate directly to sentiment or meaning; D-CNN and similar convolutional approaches rely on spatial proximity of related words, which may not always be present in spoken language.

5.3.2 Visual Sentiment Analysis

We compare the performance of our models using visual information (TFN$_{visual}$) with the following well-known approaches in visual sentiment analysis and emotion recognition (retrained for sentiment analysis):

3DCNN (Byeon and Kwak, 2014) a network using 3D CNN is trained using the face of the speaker. Face of the speaker is extracted in every 6 frames and resized to 64×64 and used as the input to the proposed network.

CNN-LSTM (Ebrahimi Kahou et al., 2015) is a recurrent model that at each timestamp performs convolutions over facial region and uses output to an LSTM. Face processing is similar to 3DCNN.

LSTM-FA similar to both baselines above, information extracted by FACET is used every 6 frames as input to an LSTM with a memory dimension of 100 neurons.

SAL-CNN-V, **SVM-MD-V**, **CMKL-V**, **RF-V** use only visual modality in multimodal baselines from Section 5.1.

The results in Table 5 show that $\mathcal{U}_v$ is able to outperform state-of-the-art approaches on visual sentiment analysis.

5.3.3 Acoustic Sentiment Analysis

We compare the performance of our models using visual information (TFN$_{acoustic}$) with the following well-known approaches in audio sentiment analysis and emotion recognition (retrained for sentiment analysis):

HL-RNN (Lee and Tashev, 2015) uses an LSTM on high-level audio features. We use the same features extracted for $\mathcal{U}_a$ averaged over time slices of every 200 intervals.

Adieu-Net (Trigeorgis et al., 2016) is an end-to-end approach for emotion recognition in audio using directly PCM features.

SER-LSTM (Lim et al., 2016) is a model that uses recurrent neural networks on top of convolution operations on spectrogram of audio.

SAL-CNN-A, **SVM-MD-A**, **CMKL-A**, **RF-A** use only acoustic modality in multimodal baselines from Section 5.1.

5.4 Methodology

All the models in this paper are tested using five-fold cross-validation proposed by CMU-MOSI (Zadeh et al., 2016a). All of our experiments are performed independent of speaker identity, as no speaker is shared between train and test sets for generalizability of the model to unseen speakers in real-world. The best hyperparameters are chosen using grid search based on model performance on a validation set (using last 4 videos in train fold). The TFN model is trained using the Adam optimizer (Kingma and Ba, 2014) with the learning rate 5e4. $\mathcal{U}_v$ and $\mathcal{U}_a, \mathcal{U}_s$ subnetworks are regularized using dropout on all hidden layers with $p = 0.15$ and L2 norm coefficient 0.01. The train, test and validation folds are exactly the same for all baselines.

6 Qualitative Analysis

We analyze the impact of our proposed TFN multimodal fusion approach by comparing it with the

#	Spoken words + acoustic and visual behaviors	TFN- Acoustic	TFN- Visual	TFN- Language	TFN- Early	TFN	Ground Truth
1	“You can’t even tell funny jokes” + frowning expression	-0.375	-1.760	-0.558	-0.839	-1.661	-1.800
2	“I gave it a B” + smile expression + excited voice	1.967	1.245	0.438	0.467	1.215	1.400
3	“But I must say those are some pretty big shoes to fill so I thought maybe it has a chance” + headshake	-0.378	-1.034	1.734	1.385	0.608	0.400
4	“The only actor who can really sell their lines is Erin Eckart” + frown + low-energy voice	-0.970	-0.716	0.175	-0.031	-0.825	-1.000

Table 6: Examples from the CMU-MOSI dataset. The ground truth sentiment labels are between strongly negative (-3) and strongly positive (+3). For each example, we show the prediction output of the three unimodal models (TFN$_{acoustic}$, TFN$_{visual}$ and TFN$_{language}$), the early fusion model TFN$_{early}$ and our proposed TFN approach. TFN$_{early}$ seems to be mostly replicating language modality while our TFN approach successfully integrate intermodality dynamics to predict the sentiment level.

early fusion approach TFN$_{early}$ and the three unimodal models. Table 6 shows examples taken from the CMU-MOSI dataset. Each example is described with the spoken words as well as the acoustic and visual behaviors. The sentiment predictions and the ground truth labels range between strongly negative (-3) and strongly positive (+3).

As a first general observation, we observe that the early fusion model TFN$_{early}$ shows a strong preference for the language modality and seems to be neglecting the intermodality dynamics. We can see this trend by comparing it with the language unimodal model TFN$_{language}$. In comparison, our TFN approach seems to capture more complex interaction through bimodal and trimodal dynamics and thus performs better. Specifically, in the first example, the utterance is weakly negative where the speaker is referring to lack of funny jokes in the movie. This example contains a bimodal interaction where the visual modality shows a negative expression (frowning) which is correctly captured by our TFN approach.

In the second example, the spoken words are ambiguous since the model has no clue what a B is except a token, but the acoustic and visual modalities are bringing complementary evidences. Our TFN approach correctly identify this trimodal interaction and predicts a positive sentiment. The third example is interesting since it shows an interaction where language predicts a positive sentiment but the strong negative visual behaviors bring the final prediction of our TFN approach almost to a neutral sentiment. The fourth example shows how the acoustic modality is also influencing our TFN predictions.

7 Conclusion

We introduced a new end-to-end fusion method for sentiment analysis which explicitly represents unimodal, bimodal, and trimodal interactions between behaviors. Our experiments on the publicly-available CMU-MOSI dataset produced state-of-the-art performance when compared against both multimodal approaches. Furthermore, our approach brings state-of-the-art results for language-only, visual-only and acoustic-only multimodal sentiment analysis on CMU-MOSI.

Abstract

Manual annotations are a prerequisite for many applications of machine learning. However, weaknesses in the annotation process itself are easy to overlook. In particular, scholars often choose what information to give to annotators without examining these decisions empirically. For subjective tasks such as sentiment analysis, sarcasm, and stance detection, such choices can impact results. Here, for the task of political stance detection on Twitter, we show that providing too little context can result in noisy and uncertain annotations, whereas providing too strong a context may cause it to outweigh other signals. To characterize and reduce these biases, we develop ConStance, a general model for reasoning about annotations across information conditions. Given conflicting labels produced by multiple annotators seeing the same instances with different contexts, ConStance simultaneously estimates gold standard labels and also learns a classifier for new instances. We show that the classifier learned by ConStance outperforms a variety of baselines at predicting political stance, while the model's interpretable parameters shed light on the effects of each context.

1 Introduction

When annotators are asked for objective judgments about a text (e.g., POS tags), the broader context in which the text is situated is often irrelevant. However, many NLP tasks focus on inference of factors beyond words and syntax. For example, the present work addresses the task of detecting political stance on Twitter. We ask annotators to determine whether a given Twitter user supports Donald Trump or Hillary Clinton. However, inferring something about a *user* from a single tweet that she writes may prove difficult. Prior work on stance has relied on annotations collected this way (Mohammad et al., 2016b), but individual tweets do not always contain clear indicators.

One solution to this issue is to supply the annotator with more information about the user. For example, for the similar task of classifying a Twitter user's political affiliation, Cohen and Ruths (2013) display the user's last 10 tweets. Nguyen et al. (2013), studying gender and age, ask annotators to label users by leveraging all information available in their profile. Thus, researchers have provided a range of contexts (or more broadly, information conditions) to annotators in an attempt to balance annotators' exposure to the data needed for accuracy with reasonable costs in terms of time, money and cognitive load.

However, while scholars routinely make such decisions about what information to show annotators, they rarely examine how such decisions actually impact annotations. The first contribution of this paper (Section 3) is to show that, at least for political stance detection on Twitter, displaying different kinds of context to annotators yields significantly different annotations *for the same user*. As a result of these discrepancies, the accuracy of models trained on these annotations varies widely.

While it is possible one could select a "best" context for a given task, our results suggest that doing so *a priori* is difficult and that, moreover, different contexts provide complementary information. What we would prefer, instead, is a model that *learns* how contexts affect annotators and *combines* annotations from multiple contexts to create gold standard labels.

Fortunately, prior work suggests mechanisms for such a model. Typically in annotation tasks,

Proceedings of the 2017 Conference on Empirical Methods in Natural Language Processing, pages 1115–1124
Copenhagen, Denmark, September 7–11, 2017.

each item is judged by several annotators, and the resulting labels are aggregated, usually by majority vote, to create a gold standard. As an alternative to majority vote, Raykar et al. (2010) develop an elegant probabilistic approach for learning to aggregate labels produced by annotators of varying quality. Their model jointly estimates gold standard labels (in the form of probability scores), infers annotator error rates, and learns a classifier for use on out-of-sample data.

Our second contribution (Section 4) is an extension of Raykar et al.'s model to handle labels not only created by annotators of varying quality, but also produced under *information conditions* of varying quality. We call this model ConStance[1]. Like Raykar et al. (2010), who find that even low-quality annotators are useful, we find that low-quality contexts can be useful. Specifically, we find that the classifier produced from our model performs better than any classifier trained by majority vote from the same labels. Furthermore, the model provides an unsupervised method for comparing the information conditions by examining their respective error patterns.

Intuitively, ConStance performs a role analogous to boosting for annotations: for an arbitrary task, it permits collection of labels that capture different aspects of the instances at hand, then combines them automatically to determine which are more reliable and to produce a classifier that takes all this into account.

2 Annotating Political Stance

2.1 Political Stance Detection

Stance detection is defined as the task of determining whether an individual is in favor of, against, or neutral towards a target concept based on the content they have generated (Mohammad et al., 2016b). It is related to but distinct from sentiment analysis: a given document can have negative sentiment but a positive stance towards a particular target, or vice versa. Further, for stance detection, the target need not be explicitly mentioned. These points are best illustrated via example: the tweet "I hope that the Democrats get destroyed in this election!" has a negative sentiment (towards Democrats), and (therefore, most likely) implies a positive stance towards Donald Trump.

As a case study for how context impacts annotations, we focus on political stance detection on Twitter—specifically, determining stance towards Hillary Clinton and Donald Trump during the 2016 U.S. election season. This task illustrates the challenges of annotation, since individual tweets are often ambiguous with respect to stance, contexts on Twitter are inherently fractured, and differing contexts can make annotators lean in different directions.

Note that a user's stance, as we use the term in this paper, is a latent (and stable) property of the user. However, short of interviewing the user, we can never be completely certain of her stance. As such, the examples here and evaluations later rely on the authors' best estimates of stance, using all available information.

A user's tweets, in turn, may or may not reveal her stance. This means that, by our definitions, an annotator might accurately perceive no stance in a tweet, yet have their annotation be considered incorrect with respect to the user's true stance. We would consider this case an annotator error caused by lack of context.

As examples of the task, consider annotating the following three tweets: (i) "*crooked Hillary - #lockHerUp*," (ii) "*Lester thinks he can control the crowd when he can't even keep Trump on topic lmao*," and (iii) "*Settling in for #debatenight Hoping to hear an adult conversation*." In the case of (i), a passing familiarity with American politics gives us high confidence that the author is pro-Trump. The tweets in (ii) and (iii) are more ambiguous, but the authors' stances become clearer with access to varying forms of context. For (ii), a Pepe the frog image (a symbol used by the American alt-right movement) in the user profile reveals that the user is probably a Trump supporter. Similarly, for (iii), a profile description that reads "*Stereotypical Iowan who enjoys Hillary Clinton, progressive politics. Chair of CYDIWomen. Previously @HillaryForIA and @NARAL.*" suggests support for Clinton and distaste for Trump.

In order to explore the effects on annotation quality of providing these kinds of context to annotators, we crowd-source annotations for a set of tweets and vary the additional information provided to annotators. For ease of comparison with related work and within our own study, we associate each user with a single anchor tweet. Thus, both annotators and classifiers are asked to deter-

[1] Replication materials for this work, including code for ConStance, are available at https://github.com/kennyjoseph/constance. The paper's Supplementary Material can also be accessed there.

mine the stance of a user using data from one particular time window.

2.2 Data

We collected tweets during the general election season (7/29/2016–11/7/2016) from over 40,000 Twitter users we had previously matched to voter registration records. Matching Twitter users to voter registrations (using methods similar to Barberá, 2016; Hobbs et al., 2017) helps ensure that the accounts we study are controlled by humans, and it supplies additional demographic variables: gender, race and party registered with.

We identified as a political tweet any tweet that mentioned the official handle for Donald Trump (@realDonaldTrump) or Hillary Clinton (@HillaryClinton), or that contained one or more of the following terms or hashtags: Hillary, Clinton, Trump, Donald, #maga, #imwithher, #debatenight, #election2016, #electionnight. We removed all reply tweets, quote tweets and tweets that directly retweeted the candidates. Finally, we kept only those users who posted at least three political tweets.

From these users, we sampled 562 political tweets for crowd-sourced stance annotation, selecting at most one tweet per user. These tweets were all sampled from users who were registered Democrats or Republicans. Half the tweets were paired with Hillary Clinton as the target, the other half with Donald Trump. We also sampled and set aside an additional 250 + 318 tweet/target pairs to use as development and validation data, respectively (see Section 2.5).

2.3 Annotation Task

We used Amazon Mechanical Turk (AMT) for annotation. Annotators were presented a triplet of {tweet, target, context} and were asked to make their decisions on a 5-point Likert scale, ranging from “Definitely Opposes [target]” to “Definitely Supports [target]”. Both prior work (Mohammad et al., 2016b) and our pilot studies suggested confusion between options for a tweet’s irrelevance towards a target and the tweet’s neutrality towards the target, so we used the center of the scale for both options. For this paper, we use a narrower three-point scale formed by merging the “Definitely” and “Probably” options.

Further, while tweets were annotated with respect to different targets, we combine all annotations into a single task by assuming that “anti-Trump” means “pro-Clinton”, and vice-versa. This assumption seems reasonable given that the voting population was strongly polarized during the general (post-primary) election season, and it doubles the amount of data we can use to train the models. Thus, throughout this work the labels we use are taken from the set {“Support Trump / Oppose Clinton” $= -1$, “Neutral / I don’t know” $= 0$, “Oppose Trump / Support Clinton” $= 1$}.

Context	Displays the anchor tweet plus ...
No Context	No additional information
Partial Profile	Profile image, name, and handle
Full Profile	Author’s profile image, name, handle, and description
Previous Tweets	Author’s two most recent tweets *in general* prior to the anchor
(Previous) Political Tweets	Author’s two most recent *political* tweets prior to the anchor
Political Party	Political affiliation (if any) from the author’s voter registration

Table 1: Descriptions of the six contexts (information conditions) presented to the annotators.

2.4 Contexts Studied

Each of the 562 “anchor” tweets was annotated under six different *contexts* (also referred to as information conditions) described in Table 1. (The Supplementary Material provides visual examples of each.) We collected at least three annotations for each tweet/condition pair. Every AMT worker was shown 40 different tweets, one by one, randomly distributed across contexts. Two additional artificial tweets were used to control for task competency.

We selected the conditions in Table 1 based on two factors. First, we included conditions that varied in how much we expected them to impact annotations. For example, we expected the partial profile information to have a relatively small effect, and political party a larger one. Second, we restricted our options to sets of information that we believed would minimally impact task completion times. We confirmed this empirically by regressing the (logged) time to completion for each annotator on the number of tweets she saw for each context, finding no significant effects from any context.

2.5 Gold Standard Labels

Ideally, we would evaluate annotation quality and downstream performance by comparing to ground truth. Unfortunately, ground truth is difficult to characterize for tasks as subjective as stance detection or sentiment analysis (Passonneau and Carpenter, 2014; DiMaggio, 2015). In light of this, we constructed our own labels, using all available information about users, and we use them as an approximation of ground truth.

We constructed these labels in order to evaluate downstream classification performance, and they cover a set of users not shown to the AMT workers. Given our resource constraints and the numerous (at least 18), often conflicting labels already available for tweets shown to AMT workers, we did not create definitive labels for that set.

To create these "gold standard" (GS) labels, we considered all information found on the user's Twitter timeline, including everything AMT annotators could see, plus friend/following relationships, all of their previous tweets, demographics from the voter file, etc. Anecdotally, we found certain cases time-consuming to investigate, which argues for continuing to limit how much information we ask annotators to consider. All gold standard labels were agreed upon by at least two authors, who first labeled the data independently and then came together to discuss disagreements.

Our GS set consists of 318 users (with their associated anchor tweets). Each user is assigned a label from the tertiary Trump/Neutral/Clinton scale. Another 250 manually labeled accounts were used for model development but are not part of reported results. The GS is approximately equally divided among registered Democrats, registered Republicans, and people not registered with either party; the last category includes self-declared Independents and voters not affiliated with any party. We include this third set in order to ensure the models generalize beyond registered Democrats and Republicans.

3 Annotation Quality For Individual Contexts

In this section, we examine how annotator agreement varies depending on the context in which the labels were obtained, and how classifiers trained on majority-vote labels from each individual context, as well as on labels from all contexts combined, perform on the GS. First, we introduce the classifier and features used for the latter task, then discuss results for agreement and classifier performance.

3.1 Classifier, Labels, Features, & Evaluation

For each of the six contexts separately, we construct labels with which to train a classifier. Training labels are constructed using majority vote; we also tried weighting the training instances to match the distribution of labels, but it did not perform as well. We also construct a seventh set of labels using all annotations from all conditions. We then train a classifier on each set of labels. We use Random Forest models, as they outperformed regularized logistic regression and SVMs with linear kernels on the development set. Note that the only difference among the models in this section is the *labels* they are *trained* on.

The feature set used, shown in Table 2, is meant as a straightforward representation of the information seen by annotators; parts of it follow Ebrahimi et al. (2016). We construct three types of features for each tweet: text, sentiment and user features. For text features, we collapse the anchor tweet plus all additional textual context seen by any annotator into a single string, then compute various n-grams from it. For sentiment, we compute various scores from the anchor tweet alone. For user features, we include the user's race and gender, which annotators might have learned from the user's profile picture. Note that because we want models to generalize beyond registered Democrats or Republicans, we *do not* include a feature for political party.

Classifier performance on the GS is measured, following prior work (Mohammad et al., 2016a; Ebrahimi et al., 2016), on the average of the F1 scores on the two classes of interest ("Clinton" and "Trump"). Additionally, we report the average log-loss (the negative log-likelihood, according to the classifier, of the true label). Log-loss and F1 can be seen as complementary measures: whereas F1 evaluates the quality of the ranking of test instances, log-loss evaluates the quality of their individual probability estimates. To compute the probability estimate from a Random Forest, we compute mean class probabilities across all trees.

To assess the statistical significance of differences between two models, we first obtain probability estimates for all GS items. For log-loss, we use a Mann-Whitney test on the scores from the two models being compared. For F1, we create 1000 bootstrap iterations of the sample, compute the average F1 of each, and run a non-parametric difference-in-means test, using 95% confidence

Category	Data Source	Feature Representation
Text	Anchor tweet, previous (political) tweets, profile description	Character n-grams ($n \in [3, 5]$), word n-grams ($n \in [1, 3]$). Preprocessing: only use tokens appearing $\geq$ 10 times, apply tf-idf weighting.
Sentiment	Anchor tweet	VADER score (Hutto and Gilbert, 2014)
		Dictionary approach (Joseph et al., 2017): valence, dominance & arousal scores
User	Voter registration record	Race, gender

Table 2: Features used in classification.

Model	Agreement	Log-Loss	Avg F1
No Context	0.84	0.72	0.61
Partial Profile	0.83	0.71	0.68
Full Profile	0.82	0.69	0.62
Previous Tweets	0.84	0.65	**0.71**
Political Tweets	**0.88**	**0.61**	0.70
Political Party	**0.88**	0.63	0.68
All Combined	0.77	0.62	**0.71**

Table 3: Inter-annotator agreement, then performance of classifier trained on majority vote labels. (Best possible is 1 for agreement and F1, 0 for log-loss.)

intervals.

3.2 Effects of the Contexts

Before evaluating classification results, we consider annotator agreement within each context, calculated like Mohammad et al. (2016b) as the average, across tweets, of the percentage of annotations that match the majority vote. As shown in Table 3, annotators shown No Context achieve an agreement score of 0.84, similar to the 0.8185 reported by Mohammad et al. (2016b). Relative to this baseline, some contexts increase agreement more than others. As one might expect, Previous Political Tweets and Political Party show the strongest signals. Their effects are statistically ($p < .01$, Mann-Whitney test) and practically significant, increasing the number of labels having *full* agreement by 15% and 10%, respectively.

However, annotators shown different contexts did not necessarily converge to the same labels. Notice the low agreement for the All Combined condition: the majority labels held stronger majorities within any individual context than across all of them. In fact, if we look at the six majority vote labels for each tweet, only in 43% of the tweets are these labels in full agreement. At the end of Section 5, we return to the question of why agreement was so low across conditions, with the help of parameters estimated by ConStance.

In the classification task, the results in Table 3 further suggest that Previous Political Tweets serves as the strongest single context. There is a good case to be made for choosing this individual context, which is statistically significantly better than many others. For example, providing annotators with Previous Political Tweets provides a statistically significant increase in both average F1 scores and log-loss (with $p < .01$) over both the No Context and Full Profile conditions. Perhaps most noteworthy is that the All Combined classifier, created from the naive combination of all annotations, is no better than the classifiers from the individual conditions.

To summarize, results suggest that providing annotators with appropriate additional context can improve annotation quality, as measured via annotator agreement and downstream classification performance. However, it was not obvious in advance which context would be most helpful, and performing such an analysis as this requires the time-intensive construction of better "gold standard" labels against which to check the labels already being outsourced to annotators. In addition, the heterogeneity of the labels produced in different contexts suggests that the contexts provide diverse signals we might be able to leverage; however, simply combining all the annotations does not result in improvements.

4 ConStance: General Unified Model

The prior section thus suggests that it may be better to limit a priori decisions and instead to leverage multiple kinds of context during annotation. Like Raykar et al. (2010) assumes for annotators, we might expect (and indeed find) that even those contexts that turn out to be worse on some metrics still might be useful for other purposes. Here, we present a model for such an approach.

ConStance learns a classifier for *items*. For our purposes here, an item is a user together with their anchor tweet and the additional information from which features were derived (see Table 2); more broadly, it is whatever we choose to put into the feature vector. One could choose a differ-

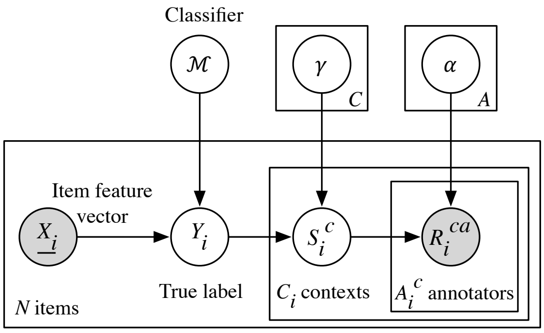

Figure 1: Graphical model for ConStance.

Var.	Meaning
$\underline{X_i}$	Feature vector of item i
Y_i	Latent true label of item i
S_i^c	Latent context-specific label of item i after noise from context c
R_i^{ca}	Label given by annotator a to item i in context c
V	Set of values for labels and annotations: $\{-1, 0, 1\}$
N	# of items, indexed by i
C	Set of contexts, indexed by c
A	Set of annotators, indexed by a
$\mathcal{M}$	Learned classifier
γ^c	$V \times V$ parameter matrix for context c
α^a	$V \times V$ parameter matrix for annotator a
$\mathcal{D}$	All observed data: all values of $\underline{X_i}$ and R_i^{ca}
Z	All latent variables: all values of Y_i and $\underline{S_i}$
θ	All model parameters: $\mathcal{M}, \gamma, \alpha$
T_i	All latent variables for item i: $(Y_i, \underline{S_i})$
$\tau_{i(y\underline{s})}$	Current estimate of all latent values for item i: $p(Y_i = y, \underline{S_i} = \underline{s} \mid \mathcal{D}, \theta)$

Table 4: Model variables.

ent setup; for example, an item could be a user and ten anchor tweets. However, the current arrangement allows for straightforward comparison to prior stance work on Twitter (Mohammad et al., 2016a).

Note that in general, the features need not be restricted to those annotators could have seen. Rather, they could include anything useful to a classifier. Note also that the feature set provided to ConStance is the same used by the baseline models; only the models themselves differ.

4.1 Overview

The model we develop is shown in Figure 1. There are N items to be labeled. Each item can be viewed in up to C different contexts. Finally, there are A total annotators labeling the items; each annotator sees multiple items. Each item can have a different number of annotations, produced by any assignment of annotators and information conditions to items. In our dataset, every item is labeled in 6 conditions (every $|C_i| = 6$), and within every context, every item is labeled by at least 3 annotators (every $|A_i^c| \geq 3$).

The model's generative story works as follows. Item i has feature vector $\underline{X_i}$ and a "true" label $Y_i \in V$. The relationship between $\underline{X_i}$ and Y_i can be described by some model $\mathcal{M}$, which we will ultimately learn. When the item is viewed with context c, the item's true label Y_i is transformed by noise into a "context-specific" label $S_i^c \in V$. In other words, the true label may appear differently when seen through the lens of each context. The variable S_i^c represents what an ideal annotator would say about item i given only as much information as is preserved by context c.

The "noise" introduced by context c is described by parameter γ^c. The parameter γ^c is a $V \times V$ matrix of transition probabilities from true labels to context-specific labels. These probabilities depend only on Y_i and γ^c, not on the item's features $\underline{X_i}$.

Importantly, annotators themselves are also imperfect. When annotator a sees item i, she may also distort the label she sees, S_i^c, into the observed annotation $R_i^{ca} \in V$. The annotator-specific noise process is described by parameter α^a, another $V \times V$ transition matrix.

For a better understanding of the role of γ^c (and by anology, α^a), consider the depictions in Figure 2. The matrix on the top left refers to the No Context condition. Its top row describes what an annotator with perfect judgment would think about a user whose true label is Trump [supporter], with no context. The top left cell, with a value around 0.65, is the probability the annotator would think Trump; the lighter middle cell, with a value around 0.35, is the probability she would think Neutral/Don't know; and the probability she would think Clinton is almost 0.

4.2 Learning

Like Raykar et al. (2010), we perform inference using Expectation Maximization (EM). A full derivation is provided in the Supplementary Material; here, we sketch the main steps.

The model's incomplete data likelihood function, Eq. (1), describes the joint probability, across all items, of Y_i, all values of S_i^c, and all values of R_i^{ca} assuming $\underline{X_i}$ is known and fixed. Uppercase denotes random variables; lowercase, specific values. In line (2), we substitute in the equivalent model parameters.

$$p(\mathcal{D}|\theta, X) = \prod_{i=1}^{N} \sum_{y}^{V} p(Y_i = y|\underline{x_i}, \mathcal{M}) \prod_{c}^{C_i} \sum_{s}^{V} p(S_i^c = s|y, \gamma) \prod_{a}^{A_i^c} p(r_i^{ca}|s, \alpha) \quad (1)$$

$$= \prod_{i=1}^{N} \sum_{y}^{V} \mathcal{M}_y(\underline{x_i}) \prod_{c}^{C_i} \sum_{s}^{V} \gamma_{ys}^c \prod_{a}^{A_i^c} \alpha_{sr}^a \quad (2)$$

The EM derivation is difficult because both Y_i and $\underline{S_i}$ are unobserved. Our solution is to treat the latent variables as a block, describing their joint configuration with a single term $T_i = (Y_i, \underline{S_i})$. In our data, since $|C_i| = 6$, T_i can take on $7^{|V|}$ possible values, a number small enough to enumerate over when we need to marginalize out T_i.

We define membership indicator variables $T_{i(y\underline{s})} \in \{0, 1\}$ such that $T_{i(y\underline{s})} = 1$ if T_i has the specific values $(y, \underline{s})$. During learning, we use analogous variables $\tau_{i(y\underline{s})} \in [0, 1]$ to represent the posterior probabilities of each configuration: $\tau_{i(y\underline{s})} = p(T_{i(y\underline{s})} = 1 \mid \mathcal{D}, \theta)$. The expected value of the complete data log-likelihood is:

$$\mathbb{E}_Z[\ell(\mathcal{D}, Z|\theta, X)] = \sum_{i=1}^{N} \sum_{y}^{V} \left(\sum_{s_i^1}^{V} \cdots \sum_{s_i^{C_i}}^{V} \right) \tau_{i(y\underline{s})}(\log p(T_{i(y\underline{s})} \mid \underline{x_i}, \mathcal{M}, \gamma) + \sum_{c}^{C_i} \sum_{a}^{A_i^c} \log \alpha_{sr}^a) \quad (3)$$

For the E step, we update the membership estimates $\tau_{i(y\underline{s})}$ using the current parameters θ. With Bayes' rule, each item's new value of $\tau_{i(y\underline{s})}$ is shown to be the full joint likelihood of item i (see Eq. (2)) when setting $Y_i = y$ and $\underline{S_i} = \underline{s}$, divided by the sum, over all possible settings of Y_i and $\underline{S_i}$, of that same joint likelihood.

For the M step, we update the model parameters using the current membership estimates. To update the classifier $\mathcal{M}$, following the guidance of Raykar et al. (2010), we retrain the classifier using the current estimates of Y_i as weights for items. The estimates of Y_i can be obtained from $\tau_{iy\underline{s}}$ by marginalizing out $\underline{S_i}$, thus $\mathbb{E}_Z[Y_i = y] = \sum_{s_i^1}^{V} \cdots \sum_{s_i^{C_i}}^{V} \tau_{iy\underline{s}}$. We then use sampling to construct a discrete set of labels for model training based on these weights.

Model	Log-Loss	Avg F1
Best baselines	*0.61*	*0.71*
ConStance	**0.57**	**0.77**
Ablations		
1. Only Political Tweets	0.59	*0.73*
2. Context Labels Masked	**0.57**	0.75
3. Annotator Labels Masked	*0.65*	0.75

Table 5: Classification performance of ConStance and model ablations. Boldface highlights best scores. Significance tests use the the $p < .05$ level for log-loss. Compared to the best baselines, all scores that appear better are statistically significant. Italics indicate the scores that are significantly worse than ConStance.

To update γ and α, we maximize them with respect to Eq. (3). For γ, the entry γ_{ys}^c (i.e., row y, column s of matrix γ^c) denotes $p(S_i^c = s \mid Y_i = y)$. Each matrix entry can be updated individually by taking the partial derivative of Eq. (3) and using, as a Lagrange multiplier term, the constraint that the row must sum to 1. The updated value for γ_{ys}^c turns out to be a fraction in which the numerator is the weighted (by τ) number of items having $Y_i = y$ and $S_i^c = s$, and the denominator is the weighted number of items having $Y_i = y$ (and any value for S_i^c). For α, a similar derivation yields the following update to α_{sr}^a: the weighted number of labels by annotator a, in any context, having $S_i^c = s$ and $R_i^{ca} = r$, divided by the weighted number of labels by annotator a, in any context, having $S_i^c = s$.

5 Model Results and Discussion

The top portion of Table 5 displays ConStance's performance compared to the best results from Section 3. Using the same experimental setup as Section 3—the model type and features, $\mathcal{M}$ and X respectively, are the same as in the baselines—ConStance improves over the best baseline models for each metric. This improvement is statistically significant for both metrics (at the $p < .05$ level for log-loss). Further, the model converges rapidly, within 5-7 iterations of the EM algorithm and 3-5 minutes on a single machine.[2]

In addition to comparing to the baselines provided in Section 3, we investigate which information the model is leveraging to be successful. We do so by exploring three ablations of the model. Variation #1 ("Only Political Tweets" in Table 5)

[2] As above, a development set is used for coarse hyperparameter tuning; see the Supplementary Material for details.

uses the full model, but only gives it the annotations from the Political Tweets condition. This tests whether simply modeling differences in annotators' error rates, as Raykar et al. (2010) do, with a single ("best") context is helpful. We find that it is: the performance of this variation is significantly better on both metrics than the Political Tweets baseline from Table 3.

In the second and third variations, we check whether the effectiveness of ConStance stems from modeling differences between annotators rather than differences in contexts, or vice versa. Variation #2 ("Context Labels Masked"), like #1, models only annotator effects; however, it instead uses the entire set of annotations, treating them as if from a single context (i.e., "masking" context information from the model). Variation #3 ("Annotator Labels Masked") is the complement of Variation #2: it models differences in contexts, and it uses the entire set of annotations, treating them as if from a single annotator.

The results of the model ablation experiments are three-fold. First, we see that each piece of the model on its own is effective in moving beyond baseline approaches that use only one context or naively combine labels across contexts and annotators (the "All Combined" baseline). All model variations achieve significantly higher Avg. F1 than the baselines, and Variations #1 and #2 improve on log-loss. Second, we see that modeling annotators alone is clearly better than not: not only does Variation #1 outperform the Political Tweets baseline (significantly), but also Variation #2 outperforms the All Combined baseline (significantly) and ConStance outperforms Variation #3 (with significance in one measure). Finally, the best results come from using the full model. Even if the differences between ConStance and the variations are not all statistically significant, modeling both annotators and contexts appears to be the most complete and effective approach.

In addition to model performance, we can also examine what ConStance has learned about the quality of labels from each context. Recall that the model produces a parameter matrix for each context, γ^c, which describes how a context distorts the "true" labels the model assumes. Each γ^c is a transition matrix, so a context that perfectly preserves true labels would show up as the identity matrix; off-diagonal entries show error patterns.

Figure 2 visualizes parameter estimates for γ.

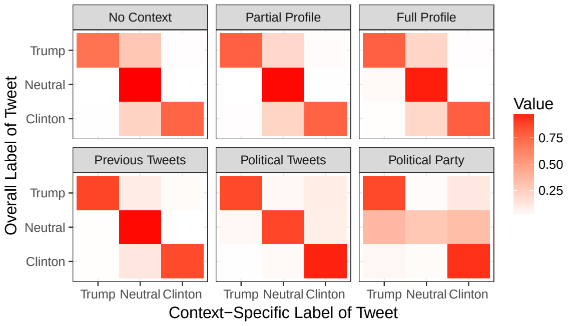

Figure 2: Parameter matrices γ^c learned by ConStance for each context. Darker shading indicates higher values.

We see that in the No Context, Partial Profile and Full Profile conditions, annotators often selected the "Neutral" option (x-axis) when the model inferred the true label was "Clinton" or "Trump" (y-axis). This finding is in line with intuitions; annotators who saw these conditions simply lacked enough information to determine any label.

On the other extreme, in the Political Party context, annotators selected "Trump" or "Clinton" too often when the model settled on the "Neutral" option. That is, even when a user's stance was not clear to annotators in other conditions, annotators who saw political party still inferred stance from the text. Here, one could argue annotators were shown "too much" or "too strong" a context—they saw stance even where the content produced by the user did not suggest one. Indeed, further manual inspection of 90 tweets on which annotations disagreed across contexts implies that annotators who saw political affiliation were often wrong because they focused too little on text content relative to the provided political affiliations.

In presenting these findings, a key point to highlight is that unlike the results of Section 3, Figure 2 was produced without access to any full information labels, which depend on a significant level of manual effort beyond annotations gathered on AMT.

6 Related Work

Recent work has shown that cognitive biases such as stereotypes (Carpenter et al., 2016) and anchoring (Berzak et al., 2016) can negatively impact text annotation and resulting models, even for objective tasks like POS tagging (Blodgett et al., 2016). Still, researchers often decide what context to show annotators without rigorously evaluating how their decisions will affect annotations, on tasks from gender identification to political leanings (Chen et al., 2015; Nguyen et al., 2014; Burger et al., 2011; Cohen and Ruths, 2013). Our work suggests an interesting avenue of development towards reducing annotation bias by explicitly modeling it and reducing the need for a priori decisions on which context is best for which particular task.

In doing so, we draw on a large body of work around improving annotation quality for NLP data. Our work aligns with efforts to improve task design (e.g. Schneider et al., 2013; Morstatter and Liu, 2016; Schneider, 2015), and to develop better models of annotation. With respect to the former and specific to Twitter, Frankenstein et al. (2016) show that for the task of labeling the sentiment of reply tweets, annotations vary depending on whether or not the original tweet (being replied to) is also shown. With respect to the latter, several recent models beyond Raykar et al. (2010) have been proposed (Guan et al., 2017; Tian and Zhu, 2012; Wauthier and Jordan, 2011; Passonneau and Carpenter, 2014). However, our work is most similar to efforts outside the domain of NLP, where Dai et al. (2013) have developed a method of switching between task workflows based on annotation quality for particular items, and Nguyen et al. (2016) have developed a Bayesian model similar to ours to study annotation quality for other kinds of slightly subjective tasks.

In a closely related vein, recent work has also considered how text annotations may vary in important ways based on the characteristics of annotators (rather than how the task is posed, as we study here) (Sen et al., 2015). An interesting avenue of future work is to understand the intersection between the design of NLP annotation tasks and the characteristics of the annotating population.

7 Conclusion and Future Work

Annotated data serves as a foundational layer for many NLP tasks. While some annotation tasks only require information from short texts, in many others, we can elicit higher-quality labels by providing annotators with additional contextual information. However, asking annotators to consider too much information would make their task slow and burdensome.

In this paper we demonstrate how exposing annotators to short contextual information leads to better labels and better classification results. However, different contexts lead to results of different quality, and it is not obvious a priori which context is best, nor—even given ground truth—how to combine labels produced across contexts to exploit the information present in each. We then propose ConStance, a generalizable model that learns the effects of both individual contexts and individual annotators on the labeling process. The model infers (probability estimates for) ground truth labels, plus learns a classifier that can be applied to new instances. We show that this classifier significantly improves classification of political stance compared to the standard practice of training models on majority vote labels.

The focus of this work is on improving both the annotation process for nuanced, context-dependent tasks and the use of the resulting labels. While ConStance's label estimation can be used in conjunction with any classification method, this paper does not address the optimization of the classifier itself. Thus, while we consider an assortment of contexts and use a rich feature representation, using additional contexts or different features may lead to better performance on stance detection. Finally, the model is versatile enough we could consider treating different tweets as different "contexts" for the same user, augmenting the extensively annotated tweets with other types of data, and, naturally, applying the same framework to other annotation tasks.

Abstract

Experimenting with a new dataset of 1.6M user comments from a news portal and an existing dataset of 115K Wikipedia talk page comments, we show that an RNN operating on word embeddings outpeforms the previous state of the art in moderation, which used logistic regression or an MLP classifier with character or word n-grams. We also compare against a CNN operating on word embeddings, and a word-list baseline. A novel, deep, classification-specific attention mechanism improves the performance of the RNN further, and can also highlight suspicious words for free, without including highlighted words in the training data. We consider both fully automatic and semi-automatic moderation.

1 Introduction

User comments play a central role in social media and online discussion fora. News portals and blogs often also allow their readers to comment to get feedback, engage their readers, and build customer loyalty.[1] User comments, however, and more generally user content can also be abusive (e.g., bullying, profanity, hate speech) (Cheng et al., 2015). Social media are under pressure to combat abusive content, but so far rely mostly on user reports and tools that detect frequent words and phrases of reported posts.[2] Wulczyn et al. (2017) estimated that only 17.9% of personal attacks in Wikipedia discussions were followed by moderator actions. News portals also suffer from abusive user comments, which damage their reputations and make them liable to fines, e.g., when hosting comments encouraging illegal actions. They often employ moderators, who are frequently overwhelmed, however, by the volume and abusiveness of comments.[3] Readers are disappointed when non-abusive comments do not appear quickly online because of moderation delays. Smaller news portals may be unable to employ moderators, and some are forced to shut down their comments sections entirely.

We examine how deep learning (Goodfellow et al., 2016; Goldberg, 2016, 2017) can be employed to moderate user comments. We experiment with a new dataset of approx. 1.6M manually moderated (accepted or rejected) user comments from a Greek sports news portal (called Gazzetta), which we make publicly available.[4] This is one of the largest publicly available datasets of moderated user comments. We also provide word embeddings pre-trained on 5.2M comments from the same portal. Furthermore, we experiment on the 'attacks' dataset of Wulczyn et al. (2017), approx. 115K English Wikipedia talk page comments labeled as containing personal attacks or not.

In a fully automatic scenario, there is no moderator and a system accepts or rejects comments. Although this scenario may be the only available one, e.g., when news portals cannot afford moderators, it is unrealistic to expect that fully automatic moderation will be perfect, because abusive comments may involve irony, sarcasm, harassment without profane phrases etc., which are particularly difficult for a machine to detect. When moderators are available, it is more realistic to develop semi-

Table 1: Statistics of the datasets used.

automatic systems aiming to assist, rather than replace the moderators, a scenario that has not been considered in previous work. In this case, comments for which the system is uncertain (Fig. 1) are shown to a moderator to decide; all other comments are accepted or rejected by the system. We discuss how moderation systems can be tuned, depending on the availability and workload of the moderators. We also introduce additional evaluation measures for the semi-automatic scenario.

On both datasets (Gazzetta and Wikipedia comments) and for both scenarios (automatic, semi-automatic), we show that a recurrent neural network (RNN) outperforms the system of Wulczyn et al. (2017), the previous state of the art for comment moderation, which employed logistic regression or a multi-layer Perceptron (MLP), and represented each comment as a bag of (character or word) n-grams. We also propose an attention mechanism that improves the overall performance of the RNN. Our attention mechanism differs from most previous ones (Bahdanau et al., 2015; Luong et al., 2015) in that it is used in a classification setting, where there is no previously generated output subsequence to drive the attention, unlike sequence-to-sequence models (Sutskever et al., 2014). In that sense, our attention is similar to that of of Yang et al. (2016), but our attention mechanism is a deeper MLP and it is only applied to words, whereas Yang et al. also have a second attention mechanism that assigns attention scores to entire sentences. In effect, our attention detects the words of a comment that affect most the classification decision (accept, reject), by examining them in the context of the particular comment.

Although our attention mechanism does not always improve the performance of the RNN, it has the additional advantage of allowing the RNN to highlight suspicious words that a moderator could consider to decide more quickly if a comment should be accepted or rejected. The highlighting comes for free, i.e., the training data do not contain highlighted words. We also show that words highlighted by the attention mechanism correlate well with words that moderators would highlight.

Our main contributions are: (i) We release a dataset of 1.6M moderated user comments. (ii) We introduce a novel, deep, classification-specific attention mechanism and we show that an RNN with our attention mechanism outperforms the previous state of the art in user comment moderation. (iii) Unlike previous work, we also consider a semi-automatic scenario, along with threshold tuning and evaluation measures for it. (iv) We show that the attention mechanism can automatically highlight suspicious words for free, without manually highlighting words in the training data.

2 Datasets

We first discuss the datasets we used, to help acquaint the reader with the problem.

2.1 Gazzetta comments

There are approx. 1.45M training comments (covering Jan. 1, 2015 to Oct. 6, 2016) in the Gazzetta dataset; we call them G-TRAIN-L (Table 1). Some experiments use only the first 100K comments of G-TRAIN-L, called G-TRAIN-S. An additional set of 60,900 comments (Oct. 7 to Nov. 11, 2016) was split to development (G-DEV, 29,700 comments), large test (G-TEST-L, 29,700), and small test set (G-TEST-S, 1,500). Gazzetta's moderators (2 full-time, plus journalists occasionally helping) are occasionally instructed to be stricter (e.g., during violent events). To get a more accurate view of performance in normal situtations, we manually re-moderated (labeled as 'accept' or 'reject') the comments of G-TEST-S, producing G-TEST-S-R. The reject ratio is approx. 30% in all subsets, except for G-TEST-S-R where it drops to 22%, because there are no occasions where the moderators were instructed to be stricter in G-TEST-S-R.

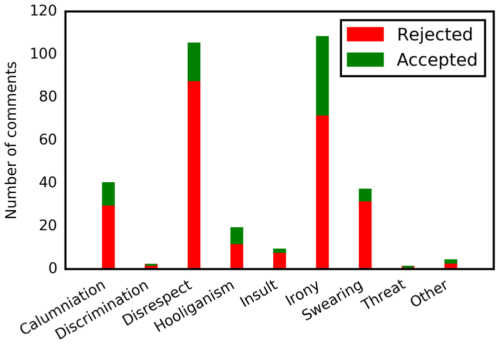

Figure 2: Re-moderated comments with at least one snippet of the corresponding category.

Each G-TEST-S-R comment was re-moderated by five annotators. Krippendorff's (2004) alpha was 0.4762, close to the value (0.45) reported by Wulczyn et al. (2017) for the Wikipedia 'attacks' dataset. Using Cohen's Kappa (Cohen, 1960), the mean pairwise agreement was 0.4749. The mean pairwise percentage of agreement (% of comments each pair of annotators agreed on) was 81.33%. Cohen's Kappa and Krippendorff's alpha lead to lower scores, because they account for agreement by chance, which is high when there is class imbalance (22% reject, 78% accept in G-TEST-S-R).

During the re-moderation of G-TEST-S-R, the annotators were also asked to highlight snippets they considered suspicious, i.e., words or phrases that could lead a moderator to consider rejecting each comment.[5] We also asked the annotators to classify each snippet into one of the following categories: calumniation (e.g., false accusations), discrimination (e.g., racism), disrespect (e.g., looking down at a profession), hooliganism (e.g., calling for violence), insult (e.g., making fun of appearance), irony, swearing, threat, other. Figure 2 shows how many comments of G-TEST-S-R contained at least one snippet of each category, according to the majority of annotators; e.g., a comment counts as containing irony if at least 3 annotators annotated it with an irony snippet (not necessarily the same). The gold class of each comment (accept or reject) is determined by the majority of the annotators. Irony and disrespect are particularly frequent in both classes, followed by calumniation, swearing, hooliganism, insults. Notice that comments that contain irony, disrespect etc. are not necessarily rejected. They are, however, more likely in the rejected class, considering that the accepted comments are 2.5 times more than the rejected ones (78% vs. 22%).

We also provide 300-dimensional word embeddings, pre-trained on approx. 5.2M comments (268M tokens) from Gazzetta using WORD2VEC (Mikolov et al., 2013a,b).[6] This larger dataset cannot be used to directly train classifiers, because most of its comments are from a period (before 2015) when Gazzetta did not employ moderators.

2.2 Wikipedia comments

The Wikipedia 'attacks' dataset (Wulczyn et al., 2017) contains approx. 115K English Wikipedia talk page comments, which were labeled as containing personal attacks or not. Each comment was labeled by at least 10 annotators. Inter-annotator agreement, measured on a random sample of 1K comments using Krippendorff's (2004) alpha, was 0.45. The gold label of each comment is determined by the majority of annotators, leading to *binary labels* (accept, reject). Alternatively, the gold label is the percentage of annotators that labeled the comment as 'accept' (or 'reject'), leading to *probabilistic labels*.[7] The dataset is split in three parts (Table 1): training (W-ATT-TRAIN, 69,526 comments), development (W-ATT-DEV, 23,160), and test (W-ATT-TEST, 23,178). In all three parts, the rejected comments are 12%, but this is an artificial ratio (Wulczyn et al. oversampled comments posted by banned users). By contrast, the ratio of rejected comments in all the Gazzetta subsets is the truly observed one. The Wikipedia comments are also longer (median length 38 tokens) compared to Gazzetta's (median length 25 tokens).

Wulczyn et al. (2017) also provide two additional datasets of English Wikipedia talk page comments, which are not used in this paper. The first one, called 'aggression' dataset, contains the same comments as the 'attacks' dataset, now labeled as 'aggressive' or not. The (probabilistic) labels of the 'attacks' and 'aggression' datasets are very highly correlated (0.8992 Spearman, 0.9718 Pearson) and we did not consider the aggression dataset any further. The second additional dataset, called 'toxicity' dataset, contains approx. 160K comments labeled as being toxic or not. Experiments we reported elsewhere (Pavlopoulos et al., 2017) show that results on the 'attacks' and 'toxicity' datasets are very similar; we do not include

[5] Treating snippet overlaps as agreements, the mean pairwise Dice coefficient for snippet highlighting was 50.03%.

[6] We used CBOW, window size 5, min. term freq. 5, negative sampling, obtaining a vocabulary size of approx. 478K.

[7] We also construct probabilistic labels for G-TEST-S-R, where there are five annotators.

results on the latter in this paper to save space.

3 Methods

We experimented with an RNN operating on word embeddings, the same RNN enhanced with our attention mechanism (a-RNN), a vanilla convolutional neural network (CNN) also operating on word embeddings, the DETOX system of Wulczyn et al. (2017), and a baseline that uses word lists.

3.1 DETOX

DETOX (Wulczyn et al., 2017) was the previous state of the art in comment moderation, in the sense that it had the best reported results on the Wikipedia datasets (Section 2.2), which were in turn the largest previous publicly available dataset of moderated user comments.[8] DETOX represents each comment as a bag of word n-grams ($n \leq 2$, each comment becomes a bag containing its 1-grams and 2-grams) or a bag of character n-grams ($n \leq 5$, each comment becomes a bag containing character 1-grams, …, 5-grams). DETOX can rely on a logistic regression (LR) or MLP classifier, and it can use binary or probabilistic gold labels (Section 2.2) during training.

We used the DETOX implementation provided by Wulczyn et al. and the same grid search (and code) to tune the hyper-parameters of DETOX that select word or character n-grams, classifier (LR or MLP), and gold labels (binary or probabilistic). For Gazzetta, only binary gold labels were possible, since G-TRAIN-L and G-TRAIN-S have a single gold label per comment. Unlike Wulczyn et al., we tuned the hyper-parameters by evaluating (computing AUC and Spearman, Section 4) on a random 2% of held-out comments of W-ATT-TRAIN or G-TRAIN-S, instead of the development subsets, to be able to obtain more realistic results from the development sets while developing the methods. For both Wikipedia and Gazzetta, the tuning selected character n-grams, as in the work of Wulczyn et al. Also, for both Wikipedia and Gazzetta, it preferred LR to MLP, whereas Wulczyn et al. reported slightly higher performance for the MLP on W-ATT-DEV.[9] The tuning also selected probabilistic labels for Wikipedia, as in the work of Wulczyn et al.

3.2 RNN-based methods

RNN: The RNN method is a chain of GRU cells (Cho et al., 2014) that transforms the tokens $w_1 \ldots, w_k$ of each comment to the hidden states $h_1 \ldots, h_k$, followed by an LR layer that uses h_k to classify the comment (accept, reject). Formally, given the vocabulary V, a matrix $E \in \mathbb{R}^{d \times |V|}$ containing d-dimensional word embeddings, an initial h_0, and a comment $c = \langle w_1, \ldots, w_k \rangle$, the RNN computes $h_1, \ldots, h_k$ as follows ($h_t \in \mathbb{R}^m$):

$$\begin{aligned}
\tilde{h}_t &= \tanh(W_h x_t + U_h(r_t \odot h_{t-1}) + b_h) \\
h_t &= (1 - z_t) \odot h_{t-1} + z_t \odot \tilde{h}_t \\
z_t &= \sigma(W_z x_t + U_z h_{t-1} + b_z) \\
r_t &= \sigma(W_r x_t + U_r h_{t-1} + b_r)
\end{aligned}$$

where $\tilde{h}_t \in \mathbb{R}^m$ is the proposed hidden state at position t, obtained by considering the word embedding x_t of token w_t and the previous hidden state h_{t-1}; $\odot$ denotes element-wise multiplication; $r_t \in \mathbb{R}^m$ is the reset gate (for r_t all zeros, it allows the RNN to forget the previous state h_{t-1}); $z_t \in \mathbb{R}^m$ is the update gate (for z_t all zeros, it allows the RNN to ignore the new proposed $\tilde{h}_t$, hence also x_t, and copy h_{t-1} as h_t); σ is the sigmoid function; $W_h, W_z, W_r \in \mathbb{R}^{m \times d}$; $U_h, U_z, U_r \in \mathbb{R}^{m \times m}$; $b_h, b_z, b_r \in \mathbb{R}^m$. Once h_k has been computed, the LR layer estimates the probability that comment c should be rejected, with $W_p \in \mathbb{R}^{1 \times m}$, $b_p \in \mathbb{R}$:

$$P_{\text{RNN}}(\textit{reject}|c) \quad = \quad \sigma(W_p h_k + b_p)$$

***a*-RNN:** When the attention mechanism is added, the LR layer considers the weighted sum h_{sum} of all the hidden states, instead of just h_k (Fig. 3):[10]

$$\begin{aligned}
h_{sum} &= \sum_{t=1}^{k} a_t h_t \qquad (1) \\
P_{a-\text{RNN}}(\textit{reject}|c) &= \sigma(W_p h_{sum} + b_p)
\end{aligned}$$

The weights a_t are produced by an attention mech-

[8] Two of the co-authors of Wulczyn et al. (2017) are with Jigsaw, who recently announced Perspective, a system to detect ‘toxic’ comments. Perspective is not the same as DETOX (personal communication), but we were unable to obtain scientific articles describing it. An API for Perspective is available at `https://www.perspectiveapi.com/`, but we did not have access to the API at the time the experiments of this paper were carried out.

[9] We repeated the tuning by evaluating on W-ATT-DEV, and again character n-grams with LR were selected.

[10] We tried replacing the LR layer by a deeper classification MLP, and the RNN chain by a bidirectional RNN (Schuster and Paliwal, 1997), but there were no improvements.

anism, which is an MLP with l layers:

$$\begin{aligned} a_t^{(1)} &= \text{RELU}(W^{(1)} h_t + b^{(1)}) \qquad (2) \\ &\ldots \\ a_t^{(l-1)} &= \text{RELU}(W^{(l-1)} a_t^{(l-2)} + b^{(l-1)}) \\ a_t^{(l)} &= W^{(l)} a_t^{(l-1)} + b^{(l)} \\ a_t &= \mathtt{softmax}(a_t^{(l)}; a_1^{(l)}, \ldots, a_k^{(l)}) \ (3) \end{aligned}$$

where $a_t^{(1)}, \ldots, a_t^{(l-1)} \in \mathbb{R}^r$, $a_t^{(l)}, a_t \in \mathbb{R}$, $W^{(1)} \in \mathbb{R}^{r \times m}$, $W^{(2)}, \ldots, W^{(l-1)} \in \mathbb{R}^{r \times r}$, $W^{(l)} \in \mathbb{R}^{1 \times r}$, $b^{(1)}, \ldots, b^{(l-1)} \in \mathbb{R}^r$, $b^{(l)} \in \mathbb{R}$. The softmax operates across the $a_t^{(l)}$ ($t = 1, \ldots, k$), making the weights a_t sum to 1. Our attention mechanism differs from most previous ones (Mnih et al., 2014; Bahdanau et al., 2015; Xu et al., 2015; Luong et al., 2015) in that it is used in a classification setting, where there is no previously generated output subsequence (e.g., partly generated translation) to drive the attention (e.g., assign more weight to source words to translate next), unlike seq2seq models (Sutskever et al., 2014). It assigns larger weights a_t to hidden states h_t corresponding to positions where there is more evidence that the comment should be accepted or rejected.

Yang et al. (2016) use a similar attention mechanism, but ours is deeper. In effect they always set $l = 2$, whereas we allow l to be larger (tuning selects $l = 4$).[11] On the other hand, the attention mechanism of Yang et al. is part of a classification method for longer texts (e.g., product reviews). Their method uses two GRU RNNs, both bidirectional (Schuster and Paliwal, 1997), one turning the word embeddings of each sentence to a sentence embedding, and one turning the sentence embeddings to a document embedding, which is then fed to an LR layer. Yang et al. use their attention mechanism in both RNNs, to assign attention scores to words and sentences. We consider shorter texts (comments), we have a single RNN, and we assign attention scores to words only.[12]

***da*-CENT:** We also experiment with a variant of *a*-RNN, called *da*-CENT, which does not use the hidden states of the RNN. The input to the first layer of the attention mechanism is now directly the embedding x_t instead of h_t (cf. Eq. 2), and

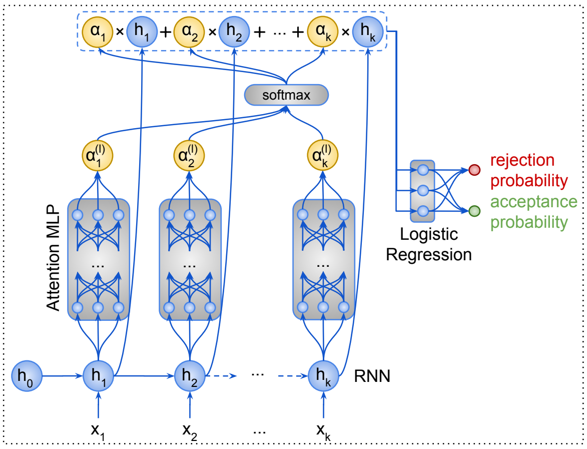

Figure 3: Illustration of *a*-RNN.

h_{sum} is now the weighted sum (centroid) of word embeddings $h_{sum} = \sum_{t=1}^{k} a_t x_t$ (cf. Eq. 1).[13]

We set $l = 4, d = 300, r = m = 128$, having tuned all hyper-parameters on the same 2% held-out comments of W-ATT-TRAIN or G-TRAIN-S that were used to tune DETOX. We use Glorot initialization (Glorot and Bengio, 2010), categorical cross-entropy loss, and Adam (Kingma and Ba, 2015).[14] Early stopping evaluates on the same held-out subsets. For Gazzetta, word embeddings are initialized to the WORD2VEC embeddings we provide (Section 2.1). For Wikipedia, they are initialized to GLOVE embeddings (Pennington et al., 2014).[15] In both cases, the embeddings are updated during backpropagation. Out of vocabulary (OOV) words, meaning words for which we have no initial embeddings, are mapped to a single randomly initialized embedding, also updated.

3.3 CNN

We also compare against a vanilla CNN operating on word embeddings. We describe the CNN only briefly, because it is very similar to that of of Kim (2014); see also Goldberg (2016) for an introduction to CNNs, and Zhang and Wallace (2015).

For Wikipedia comments, we use a 'narrow' convolution layer, with kernels sliding (stride 1) over (entire) embeddings of word n-grams of sizes $n = 1, \ldots, 4$. We use 300 kernels for each n value, a total of 1,200 kernels. The outputs of each kernel, obtained by applying the kernel to the different n-grams of a comment c, are then

[11] Yang et al. use tanh instead of RELU in Eq. 2, which works worse in our case, and no bias $b^{(l)}$ in the l-th layer.

[12] We tried a bidirectional instead of unidirectional GRU chain in our methods, also replacing the LR layer by a deeper classification MLP, but there were no improvements.

[13] For experiments with additional variants of *a*-RNN, consult Pavlopoulos et al. (2017).

[14] We implemented the methods of this sub-section using Keras (`keras.io`) and TensorFlow (`tensorflow.org`).

[15] See `https://nlp.stanford.edu/projects/glove/`. We use 'Common Crawl' (840B tokens).

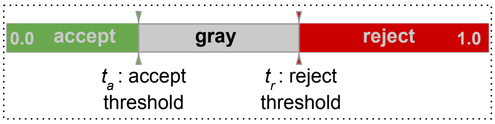

Figure 4: Illustration of threshold tuning.

max-pooled, leading to a single output per kernel. The resulting feature vector (1,200 max-pooled outputs) goes through a dropout layer (Hinton et al., 2012) ($p = 0.5$), and then to an LR layer, which provides $P_{\text{CNN}}(\textit{reject}|c)$. For Gazzetta, the CNN is the same, except that $n = 1, \dots, 5$, leading to 1,500 features per comment. All hyper-parameters were tuned on the 2% held-out comments of W-ATT-TRAIN or G-TRAIN-S that were used to tune the other methods. Again, we use 300-dimensional embeddings, which are now randomly initialized, since tuning indicated this was better than initializing to pre-trained embeddings. OOV words are treated as in the RNN-based methods. All embeddings are updated during back-propagation. Early stopping evaluates on the held-out subsets. Again, we use Glorot initialization, categorical cross-entropy loss, and Adam.[16]

3.4 LIST baseline

A baseline, called LIST, collects every word w that occurs in more than 10 (for W-ATT-TRAIN, G-TRAIN-S) or 100 comments (for G-TRAIN-L) in the training set, along with the precision of w, i.e., the ratio of rejected training comments containing w divided by the total number of training comments containing w. The resulting lists contain 10,423, 16,864, and 21,940 word types, when using W-ATT-TRAIN, G-TRAIN-S, G-TRAIN-L, respectively. For a comment c, LIST returns as $P_{\text{LIST}}(\textit{reject}|c)$ the maximum precision of all the words in c.

3.5 Tuning thresholds

All methods produce a $p = P(\textit{reject}|c)$ per comment c. In semi-automatic moderation (Fig. 1), a comment is directly rejected if its p is above a rejection theshold t_r, it is directly accepted if p is below an acceptance threshold t_a, and it is shown to a moderator if $t_a \leq p \leq t_r$ (gray zone of Fig. 4).

In our experience, moderators (or their employers) can easily specify the approximate percentage of comments they can afford to check manually (e.g., 20% daily) or, equivalently, the approximate percentage of comments the system should handle automatically. We call *coverage* the latter percentage; hence, $1 - \textit{coverage}$ is the approximate percentage of comments to be checked manually. By contrast, moderators are baffled when asked to tune t_r and t_a directly. Consequently, we ask them to specify the approximate desired coverage. We then sort the comments of the development set (G-DEV or W-ATT-DEV) by p, and slide t_a from 0.0 to 1.0 (Fig. 4). For each t_a value, we set t_r to the value that leaves a $1 - \textit{coverage}$ percentage of development comments in the gray zone ($t_a \leq p \leq t_r$). We then select the t_a (and t_r) that maximizes the weighted harmonic mean $F_\beta(P_{\textit{reject}}, P_{\textit{accept}})$ on the development set:

$$F_\beta(P_{\textit{reject}}, P_{\textit{accept}}) = \frac{(1+\beta^2) \cdot P_{\textit{reject}} \cdot P_{\textit{accept}}}{\beta^2 \cdot P_{\textit{reject}} + P_{\textit{accept}}}$$

where $P_{\textit{reject}}$ is the *rejection precision* (correctly rejected comments divided by rejected comments) and $P_{\textit{accept}}$ is the *acceptance precision* (correctly accepted divided by accepted). Intuitively, coverage sets the width of the gray zone, whereas $P_{\textit{reject}}$ and $P_{\textit{accept}}$ show how certain we can be that the red (reject) and green (accept) zones are free of misclassified comments. We set $\beta = 2$, emphasizing $P_{\textit{accept}}$, because moderators are more worried about wrongly accepting abusive comments than wrongly rejecting non-abusive ones.[17] The selected t_a, t_r (tuned on development data) are then used in experiments on test data. In fully automatic moderation, $\textit{coverage} = 100$ and $t_a = t_r$; otherwise, threshold tuning is identical.

4 Experimental results

4.1 Comment classification evaluation

Following Wulczyn et al. (2017), we report in Table 2 AUC scores (area under ROC curve), along with Spearman correlations between system-generated probabilities $P(\textit{accept}|c)$ and human probabilistic gold labels (Section 2.2) when probabilistic gold labels are available.[18] Wulczyn et al. reported DETOX results only on W-ATT-DEV, shown in brackets. Table 2 shows that RNN is

[16] We implemented the CNN directly in TensorFlow.

[17] More precisely, when computing F_β, we reorder the development comments by time posted, and split them into batches of 100. For each t_a (and t_r) value, we compute F_β per batch and macro-average across batches. The resulting thresholds lead to F_β scores that are more stable over time.

[18] When computing AUC, the gold label is the majority label of the annotators. When computing Spearman, the gold label is probabilistic (% of annotators that accepted the comment). The decisions of the systems are always probabilistic.

Training	Evaluation	Score	RNN	*a*-RNN	*da*-CENT	CNN	DETOX	LIST

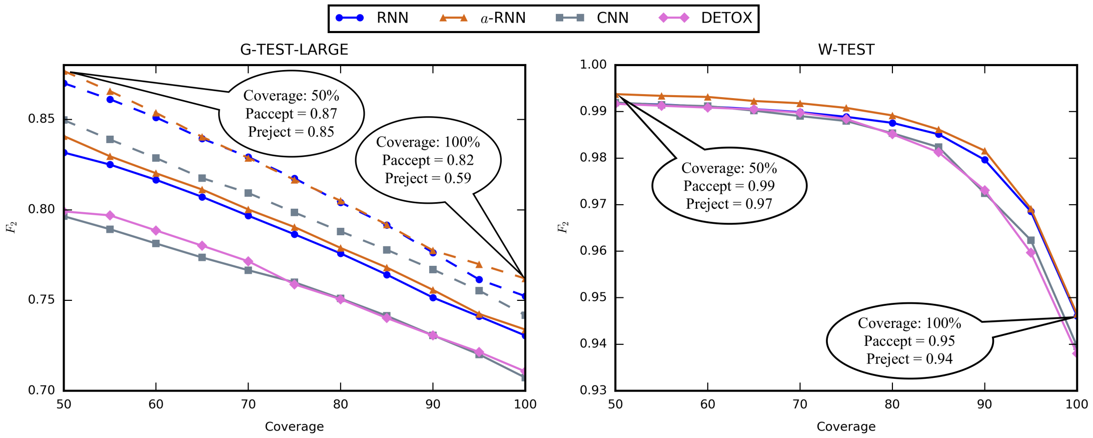

Figure 5: F_2 scores for varying coverage. Dotted lines were obtained using a larger training set.

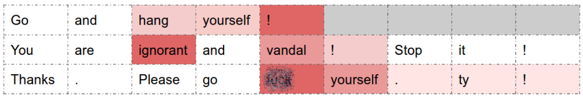
always better than CNN and DETOX; there is no clear winner between CNN and DETOX. Furthermore, *a*-RNN is always better than RNN on Gazzetta comments, but not on Wikipedia comments, where RNN is overall slightly better according to Table 2. Also, *da*-CENT is always worse than *a*-RNN and RNN, confirming that the hidden states (intuitively, context-aware word embeddings) of the RNN chain are important, even with the attention mechanism. Increasing the size of the Gazzetta training set (G-TRAIN-S to G-TRAIN-L) significantly improves the performance of all methods. The implementation of DETOX could not handle the size of G-TRAIN-L, which is why we do not report DETOX results for G-TRAIN-L. Notice, also, that the Wikipedia dataset is easier than the Gazzetta one (all methods perform better on Wikipedia comments, compared to Gazzetta).

Figure 5 shows $F_2(P_{reject}, P_{accept})$ on G-TEST-L and W-ATT-TEST, when t_a, t_r are tuned on G-DEV, W-ATT-DEV for varying coverage. For G-TEST-L, we show results training on G-TRAIN-S (solid lines) and G-TRAIN-L (dotted). The differences between RNN and *a*-RNN are again small, but it is now easier to see that *a*-RNN is overall better. Again, *a*-RNN and RNN are better than CNN and DETOX. All three deep learning methods benefit from the larger training set (dotted). In Wikipedia, *a*-RNN obtains $P_{accept}, P_{reject} \geq 0.94$ for all coverages (Fig. 5, call-outs). On the more difficult Gazzetta dataset, *a*-RNN still obtains $P_{accept}, P_{reject} \geq 0.85$ when tuned for 50% coverage. When tuned for 100% coverage, comments for which the system is uncertain (gray zone) cannot be avoided and there are inevitably more misclassifications; the use of F_2 during threshold tuning places more emphasis on avoiding wrongly accepted comments, leading to high P_{accept} (0.82), at the expense of wrongly rejected comments, i.e., sacrificing P_{reject} (0.59). On the re-moderated G-TEST-S-R (similar diagrams, not shown), P_{accept}, P_{reject} become 0.96, 0.88 for coverage 50%, and 0.92, 0.48 for coverage 100%.

We also repeated the *annotator ensemble* experiment of Wulczyn et al. (2017) on 8K randomly chosen comments of W-ATT-TEST (4K comments



Go	and	hang	yourself	!				
You	are	ignorant	and	vandal	!	Stop	it	!

Figure 6: Word highlighting by *a*-RNN.

from random users, 4K comments from banned users).[19] The decisions of 10 randomly chosen annotators (possibly different per comment) were used to construct the gold label of each comment. The gold labels were then compared to the decisions of the systems and the decisions of an ensemble of k other annotators, k ranging from 1 to 10. Table 3 shows the mean AUC and Spearman scores, averaged over 25 runs of the experiment, along with standard errrors (in brackets). We conclude that RNN and *a*-RNN are as good as an ensemble of 7 human annotators; CNN is as good as 4 annotators; DETOX is as good as 4 in AUC and 3 annotators in Spearman correlation, which is consistent with the results of Wulczyn et al. (2017).

k	AUC	Spearman

Table 3: Comparing to an ensemble of k humans.

4.2 Snippet highlighting evaluation

To investigate if the attention scores of *a*-RNN can highlight suspicious words, we focused on G-TEST-S-R, the only dataset with suspicious snippets annotated by humans. We removed comments with no human-annotated snippets, leaving 841 comments (515 accepted, 326 rejected), a total of 40,572 tokens, of which 13,146 were inside a suspicious snippet of at least one annotator. In each remaining comment, each token was assigned a *gold suspiciousness* score, defined as the percentage of annotators that included it in their snippets.

We evaluated three methods that score each token w_t of a comment c for suspiciousness. The first one assigns to each w_t the attention score a_t (Eq. 3) of *a*-RNN (trained on G-TRAIN-L). The second method assigns to each w_t its precision, as computed by LIST (Section 3.4). The third method (RAND) assigns to each w_t a random (uniform distribution) score between 0 and 1. In the latter two methods, a `softmax` is applied to the scores of all the tokens per comment, as in *a*-RNN. Figure 6 shows three comments (from W-ATT-TEST) highlighted by *a*-RNN; heat corresponds to attention.[20]

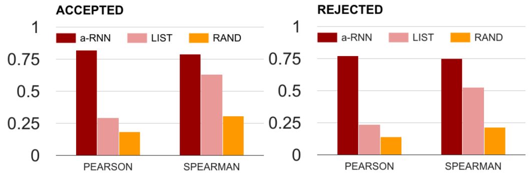

Figure 7: Suspicious snippet highlighting results.

We computed Pearson and Spearman correlations between the gold suspiciousness scores and the scores of the three methods on the 40,572 tokens. Figure 7 shows the correlations on comments that were accepted (left) and rejected (right) by the majority of moderators. In both cases, *a*-RNN performs better than LIST and RAND by both Pearson and Spearman correlations. The high Pearson correlations of *a*-RNN also show that its attention scores are to a large extent linearly related to the gold ones. By contrast, LIST performs reasonably well in terms of Spearman correlation, but much worse in terms of Pearson, indicating that its precision scores rank reasonably well the tokens from most to least suspicious ones, but are not linearly related to the gold scores.

5 Related work

Djuric et al. (2015) experimented with 952K manually moderated comments from Yahoo Finance, but their dataset is not publicly available. They convert each comment to a comment embedding using DOC2VEC (Le and Mikolov, 2014), which is then fed to an LR classifier. Nobata et al. (2016) experimented with approx. 3.3M manually moderated comments from Yahoo Finance and News; their data are also not available.[21] They used Vowpal Wabbit[22] with character n-grams ($n = 3, \ldots, 5$) and word n-grams ($n = 1, 2$), hand-crafted features (e.g., number of capitalized or black-listed words), features based on dependency

[19] We used the protocol, code, and data of Wulczyn et al.

[20] In innocent comments, *a*-RNN spreads its attention to all tokens, leading to quasi-uniform low color intensity.

[21] According to Nobata et al., their clean test dataset (2K comments) would be made available, but it is currently not.

[22] See http://hunch.net/~vw/.

trees, averages of WORD2VEC embeddings, and DOC2VEC-like embeddings. Character n-grams were the best, on their own outperforming Djuric et al. (2015). The best results, however, were obtained using all features. We use no hand-crafted features and parsers, making our methods more easily portable to other domains and languages.

Mehdad et al. (2016) train a (token or character-based) RNN language model per class (accept, reject), and use the probability ratio of the two models to accept or reject user comments. Experiments on the dataset of Djuric et al. (2015), however, showed that their method (RNNLMs) performed worse than a combination of SVM and Naive Bayes classifiers (NBSVM) that used character and token n-grams. An LR classifier operating on DOC2VEC-like comment embeddings (Le and Mikolov, 2014) also performed worse than NBSVM. To surpass NBSVM, Mehdad et al. used an SVM to combine features from their three other methods (RNNLMs, LR with DOC2VEC, NBSVM).

Wulczyn et al. (2017) experimented with character and word n-grams. We included their dataset and moderation system (DETOX) in our experiments. Waseem et al. (2016) used approx. 17K tweets annotated for hate speech. Their best results were obtained using an LR classifier with character n-grams ($n = 1, \dots, 4$), plus gender. Warner and Hirschberg (2012) aimed to detect anti-semitic speech, experimenting with 9K paragraphs and a linear SVM. Their features consider windows of at most 5 tokens, examining the tokens of each window, their order, POS tags, Brown clusters etc., following Yarowsky (1994).

Cheng et al. (2015) aimed to predict which users would be banned from on-line communities. Their best system used a random forest or LR classifier, with features examining readability, activity (e.g., number of posts daily), community and moderator reactions (e.g., up-votes, number of deleted posts).

Sood et al. (2012a; 2012b) experimented with 6.5K comments from Yahoo Buzz, moderated via crowdsourcing. They showed that a linear SVM, representing each comment as a bag of word bigrams and stems, performs better than word lists. Their best results were obtained by combining the SVM with a word list and edit distance.

Yin et al. (2009) used posts from chat rooms and discussion fora (<15K posts in total) to train an SVM to detect online harassment. They used TF-IDF, sentiment, and context features (e.g., similarity to other posts in a thread). Our methods might also benefit by considering threads, rather than individual comments. Yin at al. point out that unlike other abusive content, spam in comments or dicsussion fora (Mishne et al., 2005; Niu et al., 2007) is off-topic and serves a commercial purpose. Spam is unlikely in Wikipedia discussions and not an issue in the Gazzetta dataset (Fig. 2).

For a more extensive discussion of related work, consult Pavlopoulos et al. (2017).

6 Conclusions

We experimented with a new publicly available dataset of 1.6M moderated user comments from a Greek sports news portal and an existing dataset of 115K English Wikipedia talk page comments. We showed that a GRU RNN operating on word embeddings outpeforms the previous state of the art, which used an LR or MLP classifier with character or word n-gram features, also outperforming a vanilla CNN operating on word embeddings, and a baseline that uses an automatically constructed word list with precision scores. A novel, deep, classification-specific attention mechanism improves further the overall results of the RNN, and can also highlight suspicious words for free, without including highlighted words in the training data. We considered both fully automatic and semi-automatic moderation, along with threshold tuning and evaluation measures for both.

We plan to consider user-specific information (e.g., ratio of comments rejected in the past) (Cheng et al., 2015; Waseem and Hovy, 2016) and explore character-level RNNs or CNNs (Zhang et al., 2015), e.g., as a first layer to produce embeddings of unknown words from characters (dos Santos and Zadrozny, 2014; Ling et al., 2015), which would then be passed on to our current methods that operate on word embeddings.

Acknowledgments

This work was funded by Google's Digital News Initiative (project ML2P, contract 362826).[23] We are grateful to Gazzetta for the data they provided. We also thank Gazzetta's moderators for their feedback, insights, and advice.

Abstract

This article evaluates three proposed laws of semantic change. Our claim is that in order to validate a putative law of semantic change, the effect should be observed in the genuine condition but absent or reduced in a suitably matched control condition, in which no change can possibly have taken place. Our analysis shows that the effects reported in recent literature must be substantially revised: (i) the proposed negative correlation between meaning change and word frequency is shown to be largely an artefact of the models of word representation used; (ii) the proposed negative correlation between meaning change and prototypicality is shown to be much weaker than what has been claimed in prior art; and (iii) the proposed positive correlation between meaning change and polysemy is largely an artefact of word frequency. These empirical observations are corroborated by analytical proofs that show that count representations introduce an inherent dependence on word frequency, and thus word frequency cannot be evaluated as an independent factor with these representations.

1 Introduction

The increasing availability of digitized historical corpora, together with newly developed tools of computational analysis, make the quantitative study of language change possible on a larger scale than ever before. Thus, many important questions may now be addressed using a variety of NLP tools that were originally developed to study synchronic similarities between words. This has catalyzed the evolution of an exciting new field of *historical distributional semantics*, which has yielded findings that inform our understanding of the dynamic structure of language (Sagi et al., 2009; Wijaya and Yeniterzi, 2011; Mitra et al., 2014; Hilpert and Perek, 2015; Fremann and Lapata, 2016; Dubossarsky et al., 2016). Recent research has even proposed *laws of change* that predict the conditions under which the meaning of words is likely to change (Dubossarsky et al., 2015; Xu and Kemp, 2015; Hamilton et al., 2016). This is an important development, as traditional historical linguistics has generally been unable to provide predictive models of semantic change.

However, these preliminary results should be addressed with caution. To date, analyses of changes in words' meanings have relied on the comparison of word representations at different points in time. Thus any proposed change in meaning is contingent on a particular model of word representation and the method used to measure change. Distributional semantic models typically count words and their co-occurrence statistics (*explicit* models) or predict the embedding contexts of words (*implicit* models). In this paper, we show that the choice of model may introduce biases into the analysis. We therefore suggest that empirical findings may be used to support laws of semantic change only after a proper control can be shown to eliminate artefactual factors as the underlying cause of the empirical observations.

Regardless of the specific representation used, a frequent method of measuring the semantic change a word has undergone (Gulordava and Baroni, 2011; Jatowt and Duh, 2014; Kim et al., 2014; Dubossarsky et al., 2015; Kulkarni et al., 2015; Hamilton et al., 2016) is to compare the word's vector representations between two points in time using the cosine distance:

$$cosDist(x, y) = 1 - \frac{x \cdot y}{\|x\|_2 \|y\|_2} \quad (1)$$

Proceedings of the 2017 Conference on Empirical Methods in Natural Language Processing, pages 1136–1145
Copenhagen, Denmark, September 7–11, 2017. ©2017 Association for Computational Linguistics

This choice naturally assumes that greater distances correspond to greater semantic changes. However, this measure introduces biases that may affect our interpretation of meaning change.

We examine various representations of word meaning, in order to identify inherent confounds when meaning change is evaluated using the cosine distance. In addition to the empirical evaluation, in Section 5 we provide an analytical account of the influence of word frequency on cosine distance scores when using these representations.

In our empirical investigation, we highlight the critical role of control conditions in the validation of experimental findings. Specifically, we argue that every observation about a change of meaning over time should be subjected to a control test. The control condition described in Section 2.1 is based on the construction of an artificially generated corpus, which resembles the historical corpus in most respects but where no change of meaning over time exists. In order to establish the validity of an observation about meaning change - and even more importantly, the validity of a law-like generalization about meaning change - the result obtained in a genuine experimental condition should be demonstrated to be lacking (or at least significantly diminished) in the control condition.

As we show in Section 4, some recently reported laws of historical meaning change do not survive this proposed test. In other words, similar results are obtained in the genuine and control conditions. These include the correlation of meaning change with word frequency, polysemy (the number of different meanings a word has), and prototypicality (how representative a word is of its category). These factors lie at the basis of the following proposed laws of semantic change:

- The Law of Conformity, according to which frequency is negatively correlated with semantic change (Hamilton et al., 2016).
- The Law of Innovation, according to which polysemy is positively correlated with semantic change (Hamilton et al., 2016).
- The Law of Prototypicality, according to which prototypicality is negatively correlated with semantic change (Dubossarsky et al., 2015).

Our analysis shows that these laws have only residual effects, suggesting that frequency and prototypicality may play a smaller role in semantic change than previously claimed. The main artefact underlying the emergence of the first two laws in both the genuine and control conditions may be due to the SVD step used for the embedding of the PPMI word representation (see Section 2.5).

2 Methods

The historical corpus used here is Google Books 5-grams of English fiction. Equally sized samples of 10 million 5-grams per year were randomly sampled for the period of 1900-1999 (Kim et al., 2014) to prevent the more prolific publication years from biasing the results, and were grouped into ten-year bins. Uncommon words were removed, keeping the 100,000 most frequent words as the vocabulary for subsequent model learning. All words were lowercased and stripped of punctuation.

This corpus served as the genuine condition, and was used to replicate and evaluate findings from previous studies. In this corpus, words are expected to change their meaning between decadal bins, as they do in a truly random sample of texts. According to the distributional hypothesis (Firth, 1957), one can extract a word's meaning from the contexts in which it appears. Therefore, if words' meanings change over time, as has been argued at least since Reisig (1839), it follows that the words' contexts should change accordingly, and this change should be detected by our model.

2.1 Control condition setup

Complementary to the genuine condition, a control condition was created where no change of meaning is expected. Therefore, any observed change in a word's meaning in the control condition can only stem from random “noise“, while changes in meaning in the genuine condition are attributed to “real“ semantic change in addition to “noise“. Two methods were used to construct the corpus in the control condition:

Chronologically shuffled corpus (shuffle): 5-grams were randomly shuffled between decadal bins, so that each bin contained 5-grams from all the decades evenly. This was chosen as a control condition for two reasons. First, this condition resembles the genuine condition in size of the vocabulary, size of the corpus, overall variance in words' usage, and size of the decadal bins. Second and crucially, words are not expected to show any apparent change in their meaning between decades in the control condition, because their various usage contexts are shuffled across decades.

One synchronous corpus (subsample): All 5-grams of the year 1999, which amount to 250 million 5-grams, were selected from Google Books English fiction. 10 million 5-grams were randomly subsampled from this selection, and this process was repeated 30 times. This is suggested as an additional control condition since the underlying assumption is always that words in the same year do not change their meaning. Again, unlike in the genuine condition, any changes that are observed based on these 30 subsamples can be attributed *only* to "noise" that stems from random sampling, rather than real change in meaning.

2.2 Measures of interest

Meaning change: Meaning change was evaluated as the cosine distance between vector representations of the same word in consecutive decades. This was done separately for each processing stage (see Section 2.5). For the subsample condition, this was defined as the average cosine distance between the vectors in all 30 samples.

Frequency: Words' frequencies were computed separately for each decadal bin as the number of times a word appeared divided by the total number of words in that decade. For the subsample control condition, it was computed as the number of times a word appeared among the 250 million 5-grams, divided by the total number of words.

2.3 Construct validity

To establish the adequacy of our control condition, we compared the meaning change scores (before log-transformation and standardization) between the genuine and the shuffled control conditions. Change scores were obtained by taking the average meaning change over all words in each decade using the representation of the final processing stage (SVD). An adequate control condition will exhibit a lower degree of change compared to the genuine condition, and is expected to show a fixed rate of change across decades (see 3a).

2.4 Statistical analysis

Following common practice (Hamilton et al., 2016), the 10k most frequent words, as measured by their average decadal bin frequencies, were used for the analysis of semantic change. Change scores and frequencies were log-transformed, and all variables were subsequently standardized.

A linear mixed effects model was used to evaluate meaning change in both the genuine and shuffled control conditions. Frequency was set as a fixed effect while random intercepts were set per word. The model attempts to account for semantic change scores using frequency, while controlling for the variability between words by assuming that each word's behavior is strongly correlated across decades and independent across words as follows:

$$\Delta w_i^{(t)} = \beta_0 + \beta_f freq_{w_i}^{(t)} + z_{w_i} + \varepsilon_{w_i}^{(t)} \quad (2)$$

Here $\Delta w_i^{(t)}$ is the semantic change score of the i'th word measured between two specific consecutive decades, β_0 is the model's intercept, β_f is the fixed-effect predictor coefficient for frequency, $z_{w_i} \sim N(0, \sigma)$ is a random intercept for the i'th word, and $\varepsilon_{w_i}^{(t)}$ is an error term associated with the i'th word. We report the predictor coefficient as well as the proportion of variance explained[1] by each model. Only statistically significant results ($p < .01$) are reported. All statistical tests are performed in R (lme4 and MuMln packages).

2.5 Word meaning representation

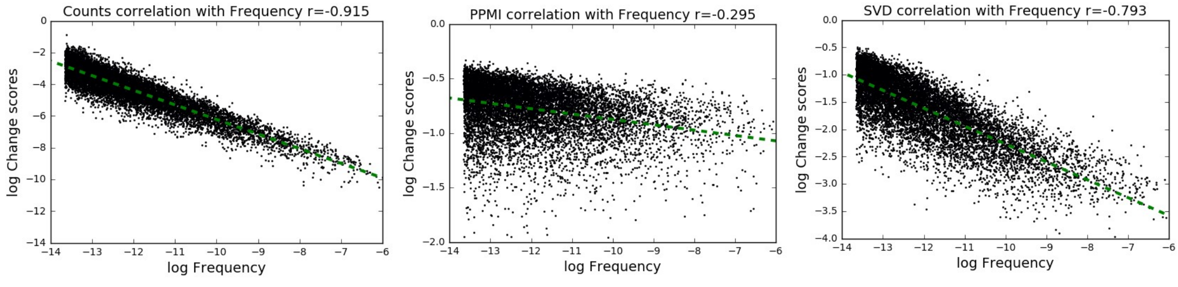
We used a cascade of processing stages based on the *explicit meaning* representation of words (i.e., word counts, PPMI, SVD, as explained below) as commonly practiced (Baroni et al., 2014; Levy et al., 2015). For each of these stages, we sought to evaluate the relationship between word frequency and meaning change, by computing the corresponding correlations between these two factors in the subsample control condition.

Counts: Co-occurrence counts were collected for all the words in the vocabulary per decade.

PPMI: Sparse square matrices of vocabulary size containing positive pointwise mutual information (PPMI) scores were constructed for each decade based on the co-occurrence counts. We used the context distribution smoothing parameter $\alpha = 0.75$, as recommended by (Levy et al., 2015), using the following procedure:

$$PPMI_\alpha(w, c) = \max\left(log\left(\frac{\hat{P}(w, c)}{\hat{P}(w)\hat{P}_\alpha(c)}\right), 0\right)$$

[1] R^2 for mixed linear models (Nakagawa and Schielzeth, 2013)



(a) (b) (c)

Figure 1: Correlations in the control condition between change scores in the year 1999 and word frequency for three word representation types, based on: (a) Counts, (b) PPMI, (c) SVD. Correlation coefficients are reported above each subplot. LS regression lines are shown in dashed green.

where $\hat{P}(w,c)$ denotes the probability that word c appears as a context word of w, while $\hat{P}(w)$ and $\hat{P}_\alpha(c) = \frac{\#(c)^\alpha}{\sum_C \#(c)^\alpha}$ denote the marginal probabilities of the word and its context, respectively.

SVD: Each PPMI matrix was approximated by a truncated singular value decomposition as described in (Levy et al., 2015). This embedding was shown to improve results on downstream tasks (Baroni et al., 2014; Bullinaria and Levy, 2012; Turney and Pantel, 2010). Specifically, the top 300 elements of the diagonal matrix of singular values Σ, denoted Σ_d, were retained to represent a new, dense embedding of the word vectors, using the truncated left hand orthonormal matrix U_d:

$$W_i^{SVD} = (U_d \cdot \Sigma_d)_i \tag{3}$$

These representations were subsequently aligned with the orthogonal Procrustes method following (Hamilton et al., 2016).

Relation to other models: (Levy and Goldberg) have shown that the Skip-Gram with Negative Sampling (SGNS) embedding model, e.g. word2vec (Mikolov et al., 2013) - perhaps the most popular model of word meaning representation, implicitly factorizes the values of the word-context PMI matrix. Hence, the optimization goal and the sources of information available to SGNS and our model are in fact very similar. We therefore hypothesize that conclusions similar to those reported below can be drawn for SGNS models.

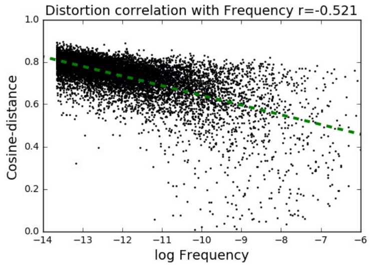


Figure 2: Cosine distances between PPMI and approximated PPMI representations (y-axis), plotted against frequency (x-axis). Correlation coefficient is reported above the plot.

3 Results

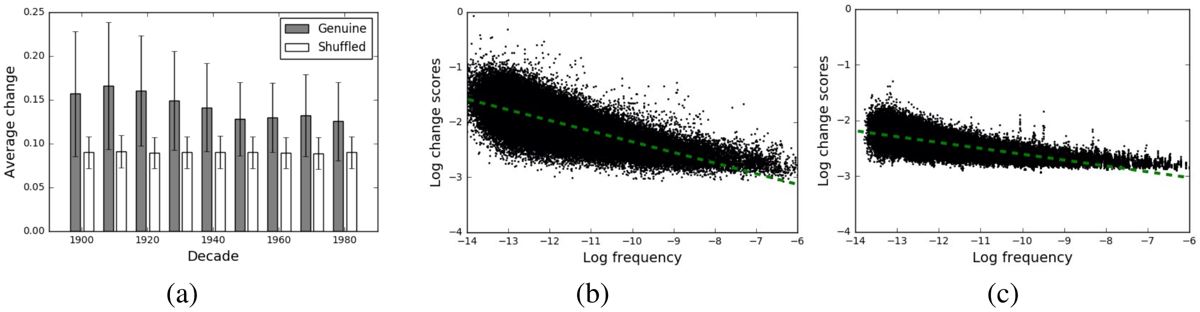
3.1 Confound of frequency

There are many factors that may confound the measurement of meaning change. Here we focus on frequency, and investigate the existence of an artefactual relation between frequency and meaning change. This is done by evaluating this relation in the subsample control condition. Any changes observed in this condition must be the consequence of inherent noise, since this control condition contains random samples from the same year (and the baseline assumption is that no change can be observed within the same year).

We first plotted the change scores that use the representation based on word count vs. word frequency. This resulted in a robust correlation ($r = -0.915$) between the two variables, as shown in Fig. 1a (see the analytical account in Section 5). We repeated the same procedure using the PPMI representation, which showed a much weaker correlation with frequency ($r = -0.295$), see Fig. 1b.

Finally, we repeated the same procedure using the final *explicit representation* after SVD embedding[2], see Fig. 1c. Surprisingly, the negative correlation with frequency was reinstated ($r = -0.793$). To investigate how this came about,

[2] Similar results were obtained for the implicit embedding (word2vec-SGNS) described in Section 2.5.



(a) (b) (c)

Figure 3: (a) Average change score per decade for the genuine and control conditions. Bars represent standard deviations. (b-c) Change scores (y-axis), relative to their frequency (x-axis): (b) genuine historical corpus, (c) chronologically shuffled historical corpus. LS regression lines are shown in dashed green.

we computed the change in the PPMI vectors before and after the low-rank SVD embedding using the cosine-distance. As apparent from Fig. 2, it turns out that the SVD procedure distorts data in an uneven manner - frequent words are distorted less than infrequent words. Thus we demonstrate that this reinstatement of correlation between frequency and change scores is merely an artefactual consequence of the truncated SVD factorization.

3.2 Construct validity

Potential confounding factors can be addressed by comparing any experimental finding to a validated control condition. Here we validate the use of the shuffled condition as a proper control. To this end, the average change scores of words per decade in both the genuine and shuffled conditions are compared within each processing stage. In the genuine condition, words appear in different usage contexts between decades, while in the shuffled condition they do not, because the random shuffling creates a homogeneous corpus. Therefore, the validity of the control condition is established if: (a) the change scores are diminished as compared to the genuine condition; (b) change scores are uniform across decades (since decades are shuffled); (c) the variance of change scores is smaller that in the genuine condition. As seen in Fig. 3a, all these requirements are met by the control condition. Note that the change scores in the shuffled condition are all significantly positive, namely, meaning change allegedly exists in this control condition. This supports the claim that any measurement is significantly affected by unrelated noise.

Thus, we have established that the shuffled condition is a suitable control for meaning change. While validity was established for each of the processing stages, the most robust effect was seen for the PPMI representation, following by SVD and word counts.

3.3 Accounting for the frequency confound

In Section 3.1 we used the subsample control condition to establish the confounding effect of frequency on meaning change. We now examine the extent to which this frequency confound exists in a historical corpus. We do so by comparing the frequency confound between the genuine historical corpus and the shuffled historical corpus.

To visualize the frequency confound in a manner comparable to the analysis presented in Section 3.1, we again plot change scores vs. frequency, ignoring the time dimension of the data. Fig. 3b presents this plot for the genuine condition. The same analysis is repeated in the shuffled condition, see Fig. 3c.

Both plots reveal a highly significant correlation between change scores and frequency. Furthermore, the fact that the correlation coefficients are virtually identical in the genuine and shuffled conditions, with $r = -0.748$ and $r = -0.747$ respectively, suggests that they are due to artefactual factors in both conditions and not to true change of meaning over time. In fact, this pattern of results is reminiscent of the spurious pattern we see in Fig. 1c.

The relation between frequency and meaning change can also be represented by a linear mixed effect model, with the benefit that this model enables the addition of more explanatory variables to the data. The regression model found frequency to have a negative influence on change scores,

		PPMI + SVD		PPMI	
		Genuine	Shuffled	Genuine	Shuffled
Frequency (one-predictor)	β	-0.91	-0.75	-0.29	0.06
	explained variance (σ^2)	67%	56%	8%	0%
Frequency + Polysemy (two-predictor)	β frequency	-1.22	-1.12	-0.69	0.53
	β polysemy	0.43	0.40	0.49	-0.52
	explained variance (σ^2)	68%	60%	9%	4%
Frequency + Prototypicality (two-predictor)	β frequency	-0.71	-0.70	-0.02	0.07
	β polysemy	0.22	0.21	0.12	0.02
	explained variance (σ^2)	65%	60%	2%	0%

Table 1: Results of one-predictor and two-predictor regression analysis in all conditions.

with β_f=-0.91 and β_f=-0.75, for the genuine and shuffled conditions respectively. Importantly, frequency accounted for 67% of the variance in the change scores in the genuine condition, and was only slightly diminished in the shuffled condition, accounting for 56% of the variance. Similar results were obtained for the PPMI representation (see Table 1).

4 Revisiting previous studies

We replicated three recent results that were affected by this frequency effect, since they all define change as the word's cosine distance relative to itself at two time points. These studies report laws of semantic change that measure the role of frequency in semantic change either directly (Law of Conformity), or indirectly through another linguistic variable that is dependent on frequency (Laws of Innovation and Prototypicality).

4.1 Laws of conformity and innovation

Continuing the work described in Section 3.1, we replicated the model and analysis procedure described in (Hamilton et al., 2016), where **two predictors** were used together to explain the change scores: frequency and polysemy. Polysemy, which describes the number of different senses a word has, naturally differs among words, where some words are more polysemous than others (compare *bank* and *date* to *wine*). Following (Hamilton et al., 2016), we defined polysemy as the words' secondary connections patterns - the connections between each word's co-occurring words (using the entries in the PPMI representation for that word). The more interconnected these secondary connections are, the less polysemic a word is, and vice versa. Polysemy scores were computed using the authors' provided code[3]. We then log-transformed and standardized the polysemy scores. Next, frequency and polysemy were set as two fixed effect predictors in a linear mixed effect model, like the one described in Section 2.4.

Thus we were able to replicate the results in the genuine condition as reported in (Hamilton et al., 2016). Interestingly, the same pattern of results emerged, again, in the shuffled condition (see Table 1). Importantly, the difference in effect size between conditions, as evaluated by the explained variance of frequency and polysemy together, showed a modest effect of 8% over the shuffled condition, pointing to the conclusion that the putative effects may indeed be real, but to a far lesser extent than had been claimed. We conclude that adding polysemy to the analysis contributed very little to the model's predictive power.

Since the PPMI representation (the *explicit representation* without dimensionality reduction with SVD) seems much less affected by spurious effects correlated with frequency (see Fig. 1b), we repeated the analysis of frequency described here and in Section 3.1 while using this representation. The results are listed in Table 1, showing a similar pattern of rather small frequency effect.

4.2 Prototypicality

Prototypicality is the degree to which a word is representative of the category of which it is a member (a *robin* is a more prototypical bird than a *parrot*). According to the proposed Law of Prototypicality, words with more prototypical meanings will show less semantic change, and vice versa. Following (Dubossarsky et al., 2015), we computed words' prototypicality scores for each decade as the cos-distance between a word's vec-

[3] https://github.com/williamleif/histwords

tor and its k-means cluster's centroid, and extended the analysis to encompass the entire 20th century. The previous regression model assumed independence between words, and therefore assigned words to a random effect variable. However, when modeling prototypicality, this assumption is invalid as relations between words are what inherently define prototypicality. We therefore designed a model in which decades, rather than words, are the random effect variable.

With this analysis the prototypicality effect seems to be substantiated in two ways. First, the addition of prototypicality explains an additional 5% of the variance. Second, the effect of prototypicality meets the more stringent requirement of being diminished in the shuffle condition (see Table 1). Nevertheless, here too the effect originally reported was found to be drastically reduced after being compared with the proper control.

5 Theoretical analysis

We show in Section 5.1 that the average cosine distance between two vectors representing the same word is equivalent to the variance of the population of vectors representing the same word in independent samples, and is therefore always positive. This is true for any word vector representation.

In Sections 5.2-5.3 we prove that the average cosines distance between two *count* vectors representing the same word is negatively correlated with the frequency of the word, and positively correlated with the polysemy score of the word.

5.1 Sampling variability and the cos distance

Lemma 1. *Assume two random variables x, y of length $\|x\|_2 = \|y\|_2 = 1$, distributed iid with expected value μ and covariance matrix Σ. The expected value of the cosine distance between them is equal to the sum of the diagonal elements of Σ.*

Proof.

$$\begin{aligned}E(x-y)^2 =& E(x-\mu)^2 + E(y-\mu)^2 + \\ & 2E(x-\mu)(y-\mu) \\ =& 2\sum E(x_i-\mu_i)^2 = 2\sum Var(x_i) \\ E(x-y)^2 =& E(x^2) + E(y^2) - 2E(x\cdot y) \\ =& 2 - 2E\left(\frac{x\cdot y}{\|x\|_2\|y\|_2}\right) \\ =& 2E(cosDist(x,y))\end{aligned}$$

It follows that

$$E(cosDist(x,y)) = \sum Var(x_i) \quad (4)$$

□

Implication: The average cosine distance between two samples of the same random variables is directly related to the variance of the variable, or the sampling noise. This variance should be measured empirically whenever cosine distance is used, since only distances that are larger than the empirical variance can be relied upon to support significant observations.

5.2 Cos distance of count vectors: frequency

Next, we analyze the cosine distance between 2 iid samples from a normalized multinomial random variable. This distribution models the distribution of the count vector representation. Let $k_i,\ 1 \le i \le m$ denote the number of times word i appeared in the context of word w, and let m denote the size of the dictionary not including w. Let $n = \sum k_i$ denote the number of words in the count vector of w; n determines the word's frequency score. Assume that the counts are sampled from the distribution Multinomial$(n, \vec{p})$, namely

$$Prob(k_1, \cdots, k_m) = \binom{n}{k_1 \cdots, k_m} p_1^{k_1} \cdots p_m^{k_m}$$

Lemma 2. *The expected value of the cosine distance between two count vectors x, y sampled iid from this distribution is monotonically decreasing with n.*

Proof. By definition, $1 - E[cosDist(x,y)]$ equals

$$E\left[\frac{x\cdot y}{\|x\|_2\|y\|_2}\right] = \sum_i \left[E\frac{x_i}{\|x\|_2}\right]^2 = \sum_i E_i^2 \quad (5)$$

We compute the expected value of E_i directly:

$$E_i = \sum_{(k_1,\cdots,k_m)} \frac{k_i}{\sqrt{\sum_j k_j^2}} \binom{n}{k_1 \cdots, k_m} p_1^{k_1} \cdots p_m^{k_m}$$

Using Taylor expansion:

$$\begin{aligned}\frac{k_i}{\sqrt{\sum_j k_j^2}} =& \frac{\frac{k_i}{n}}{\sqrt{(\sum_j \frac{k_j}{n})^2 - \sum_{l\neq j}\frac{k_j k_l}{n^2}}} \\ =& \frac{k_i}{n}\frac{1}{\sqrt{1 - \sum_{l\neq j}\frac{k_j k_l}{n^2}}} \\ =& \frac{k_i}{n}\left(1 + \frac{\varepsilon}{2} + O(\varepsilon^2)\right) \quad (6)\end{aligned}$$

where $\varepsilon = \sum_{l \neq j} \frac{k_j k_l}{n^2}$.

The expected value of the 0-order term with respect to ε in (6) equals p_i, which is independent of n. We conclude the proof by focusing on the first order term with respect to ε in (6), to be denoted f_1, showing that its expected value is monotonically decreasing with n. Specifically:

$$f_1 = \sum_{\vec{k}} \sum_{l \neq j} \frac{k_i}{n} \frac{k_j}{n} \frac{k_l}{n} \binom{n}{k_1 \cdots, k_m} p_1^{k_1} \cdots p_m^{k_m}$$

We switch the summation order and compute each expression in the external sum, considering two cases separately: when $l \neq j \neq i$

$$\sum_{(k_1, \cdots, k_m)} \frac{k_i}{n} \frac{k_j}{n} \frac{k_l}{n} \binom{n}{k_1 \cdots, k_m} p_1^{k_1} \cdots p_m^{k_m}$$
$$= \frac{n(n-1)(n-2)}{n^3} p_i p_j p_l$$

When $l \neq j = i$ w.l.g, we rewrite $k_i k_j = k_i(k_i - 1) + k_i$, and the sum above becomes $\frac{n(n-1)(n-2)}{n^3} p_i^2 p_l + \frac{n(n-1)}{n^2} p_i p_l$. Thus

$$f_1 = \frac{n-1}{n} p_i \left[\frac{n-2}{n} \sum_{l,j:l \neq j} p_j p_l + (1 - p_i) \right]$$

and it readily follows that f_1 is monotonically increasing with n.

Since n measures the frequency score of word w, it follows from (5) that the expected value of the cosine distance between two iid samples from the distribution of the count vector of w is monotonically decreasing with the word's frequency. □

5.3 Cos distance of count vectors: polysemy

We start our investigation of polysemy by modeling the distribution of the parameters of the multinomial distribution from which count vectors are sampled. A common prior distribution on the vector $\vec{p}^w$ in m-simplex, which defines the multinomial distribution generating the context of word w, is the Dirichlet distribution $f(\vec{p}^w; \vec{\alpha}^w) = f(p_1, \cdots, p_m; \alpha_1, \cdots, \alpha_m)$.

$\vec{\alpha}^w$ is a sparse vector of prior counts on all the words in the dictionary, by which the cooccurrence context of word w is modeled. We divide the set of none-zero indices of $\vec{\alpha}^w$ into two subsets: $i_1, \cdots, i_{m_0}$ correspond to the words which always appear in the context of w, while $j_1, \cdots, i_{m_1}$ correspond to the words which appear in the context of w in one given meaning. If w is polysemous and has two meanings, then there is a third set of indices $k_1, \cdots, k_{m_2}$ which correspond to the words appearing in the context of w in its second meaning. If w has more then two meanings, they can be modeled with additional sets of disjoint indices.

Lemma 3. *Under certain conditions specified in the proof, given two count vectors x, y sampled iid from the above distribution of w, the expected value of the cosine distance between them increases with the number of sets of disjoint indices which represent different meanings of w.*

Proof. We will prove that when w has two meanings, the expected value of the cosine distance is larger than in the case of a single meaning. The proof for the general case immediately follows.

Starting from (6) while keeping only the 0-order term in ε, it follows from the derivations in the proof of Lemma 2 that the expected cosine distance between two count vector samples of w, to be denoted M, is $1 - \sum p_i^2$. In our current model $\vec{p}$ is a random variable, and we shall compute the expected value of this random variable under the two conditions, when w has either one or two meanings.

We start by observing that, given the definition of the Dirichlet distribution, it follows that

$$E(p_i^2) = Var(p_i) + E(p_i)^2 = \frac{\alpha_i(1+\alpha_i)}{\alpha_0(1+\alpha_0)}$$
$$\alpha_o = \sum \alpha_i$$
$$\Longrightarrow M = \sum E(p_i^2) = \frac{\alpha_0 + \sum \alpha_i^2}{\alpha_0(1+\alpha_0)} \qquad (7)$$

Considering the different sets of indices in isolation, let $\varphi_o = \sum_{i=i_1}^{i_{m_0}} \alpha_i$, $\varphi_1 = \sum_{i=j_1}^{j_{m_1}} \alpha_i$, and $\varphi_2 = \sum_{i=k_1}^{k_{m_2}} \alpha_i$. Let $\psi_o = \sum_{i=i_1}^{i_{m_0}} \alpha_i^2$, $\psi_1 = \sum_{i=j_1}^{j_{m_1}} \alpha_i^2$, and $\psi_2 = \sum_{i=k_1}^{k_{m_2}} \alpha_i^2$.

We rewrite (7) for the two conditions:

1. w has one meaning:

$$M^{(1)} = \frac{\varphi_0 + \varphi_1 + \psi_0 + \psi_1}{(\varphi_0 + \varphi_1)(1 + \varphi_0 + \varphi_1)}$$

2. w has two meanings:

$$M^{(2)} = \frac{\varphi_0 + \varphi_1 + \varphi_2 + \psi_0 + \psi_1 + \psi_2}{(\varphi_0 + \varphi_1 + \varphi_2)(1 + \varphi_0 + \varphi_1 + \varphi_2)}$$

With some algebraic manipulations, it can be shown that $M^{(1)} > M^{(2)}$ if the following holds:

$$\begin{aligned}&(\varphi_0+\varphi_1)^2\varphi_2+(\psi_0+\psi_1)\varphi_2^2 \\ &+2(\psi_0+\psi_1)(\varphi_0+\varphi_1)\varphi_2+(\psi_0+\psi_1)\varphi_2 \\ &+(\varphi_0+\varphi_1)(\varphi_2^2-\psi_2) > \psi_2(\varphi_0+\varphi_1)^2\end{aligned} \tag{8}$$

Thus when (8) holds, the average cosine distance between two samples of a certain word w gets larger as w acquires more meanings. □

(8) readily holds under reasonable conditions, e.g., when the prior counts for each meaning are similar (as a set) and much bigger than the prior counts of the joint context words (i.e., $\varphi_0 = \psi_0 = \varepsilon$, $\varphi_1 = \varphi_2$, $\psi_1 = \psi_2$).

6 Conclusions and discussion

In this article we have shown that some reported laws of semantic change are largely spurious results of the word representation models on which they are based. While identifying such laws is probably within the reach of NLP analyses of massive digital corpora, we argued that a more stringent standard of proof is necessary in order to put them on a firm footing. Specifically, it is necessary to demonstrate that any proposed law of change has to be observable in the genuine condition, but to be diminished or absent in a control condition. We replicated previous studies claiming to establish such laws, which propose that semantic change is negatively correlated with frequency and prototypicality, and positively correlated with polysemy. None of these laws - at least in their strong versions - survived the more stringent standard of proof, since the observed correlations were found in the control conditions.

In our analysis, the Law of Conformity, which claims a negative correlation between word frequency and meaning change, was shown to have a much smaller effect size than previously claimed. This indicates that word frequency probably does play a role - but a small one - in semantic change. According to the Law of Innovation, polysemy was claimed to correlate positively with meaning change. However, our analysis showed that polysemy is highly collinear with frequency, and as such, did not demonstrate independent contribution to semantic change. For similar reasons, the alleged role of prototypicality was diminished.

These results may be more consonant than previous ones with the findings of historical linguistics, as it is commonly assumed that the factors leading to semantic change are more diverse than purely distributional factors. For example, sociocultural, political, and technological changes are known to impact semantic change (Bochkarev et al., 2014; Newman, 2015). Furthermore, some regularities of semantic change have been imputed to ‘channel bias‘, inherent biases of utterance production and interpretation on the part of speakers and listeners, e.g., (Moreton, 2008). As such, it would be surprising if word frequency, polysemy, and prototypicality were to capture *too high* a degree of variance. In other words, since semantic change may result from the interaction of many factors, small effects may be a priori more credible than large ones.

The results of our empirical analysis showed that the spurious effects of frequency were much weaker for the explicit PPMI representation unaugmented by SVD dimensionality reduction. We therefore conclude that the artefactual frequency effects reported are inherent to the type of word representations upon which these analyses are based. As the analytical proof in Section 5 demonstrates, it is count vectors that introduce an artefactual dependence on word frequency.

Intuitively, one might expect that the average value for the cosine distance between a given word's vector in any two samples would be 0. However, Lemma 1 above shows that this is not the case, and the average distance is the variance of the population of vectors representing the same word. This result is independent of the specific method used to represent words as vectors. Lemma 2 proves that the average cosine distance between two samples of the same word, when using count vector representations, is negatively correlated with the word's frequency. Thus, the role of frequency cannot be evaluated as an independent predictor in any model based on count vector representations. It remains for future research to establish whether other approaches to word representation, e.g. (Blei et al., 2003; Mikolov et al., 2013), have inherent biases.

While our findings may seem to be mainly negative, since they invalidate proposed laws of semantic change, we would like to point to the positive contribution made by articulating more stringent standards of proof and devising replicable control conditions for future research on language change based on distributional semantics representations.

Abstract

We pose the general task of *user-factor adaptation* — adapting supervised learning models to real-valued user factors inferred from a background of their language, reflecting the idea that a piece of text should be understood within the context of the user that wrote it. We introduce a *continuous* adaptation technique, suited for real-valued user factors that are common in social science and bringing us closer to personalized NLP, adapting to each user uniquely. We apply this technique with known user factors including age, gender, and personality traits, as well as latent factors, evaluating over five tasks: POS tagging, PP-attachment, sentiment analysis, sarcasm detection, and stance detection. Adaptation provides statistically significant benefits for 3 of the 5 tasks: up to +1.2 points for PP-attachment, +3.4 points for sarcasm, and +3.0 points for stance.

1 Introduction

Language use is personal. Knowing who wrote a piece of text can help to better understand it. For instance, knowing the age and gender groups of authors has been shown to improve document classification (Hovy, 2015) and sentiment analysis (Volkova et al., 2013).

However, putting people into discrete groups (e.g. age groups, binary gender) often relies on arbitrary boundaries which may not correspond to meaningful changes in language use. A wealth of psychological research suggests people should not be characterized as discrete *types* (or domains) but rather as mixtures of continuous *factors* (McCrae and Costa Jr., 1989; Ruscio and Ruscio, 2000; Widiger and Samuel, 2005).

Here, we ask how one can adapt NLP models to real-valued human *factors* – continuous valued attributes that capture fine-grained differences between users (e.g. real-valued age, continuous gender scores). We refer to this problem as *user-factor adaptation*, and investigate a solution to it in the context of social media, a genre where language is generated by a particularly diverse set of users (Duggan and Smith, 2013). Importantly, *user-factor adaptation* brings us closer to personalized NLP in that with real-valued factors we can now adapt uniquely for each user.

Our approach composes user factor information with the linguistic features, similar to feature augmentation (Daumé III, 2007), a widely used domain adaptation technique which allows for easy integration with most feature-based learning models. Since relevant user information often is not explicitly available, we use a background of tweets from the user to infer user factors. We evaluate our approach over five tasks — POS tagging, PP-attachment, sentiment analysis, sarcasm detection, and stance detection — and with a variety of inferred user factors including (a) *known factors*: age, gender, and personality traits, as well as (b) *latent factors* derived from past user tweets.

Contributions. The main contributions of this work include (a) adaptation based simply on background language (e.g. past tweets; no required *a priori* user knowledge or "domain"), (b) a method for adapting models based on continuous variables, (c) adaptation to other user attributes beyond age and gender (personality and latent factors), and (d) empirical evidence that standard NLP models can often be improved by user-factor adaptation with a range of inferred factors.

2 User-Factor Adaptation

User-factor adaptation is especially critical for social media, where content is generated by a diverse user base (Duggan and Smith, 2013). Adaptation requires two components: 1) a user factor representation that captures salient traits indicative of language differences between users, and 2) an adaptation technique that uses this representation to modify learning appropriately.

User factors, even simple ones such as age and gender, may not always be readily available. The messages posted by users, however, are often public and can be used to infer many known linguistically relevant user traits including personality, as well as latent language factors (described next). Given this *background* information about users, the *user-factor adaptation problem* is to learn a single model that is sensitive to both the variations and commonalities in language across different users.

3 User Factors

The first step in our adaptation approach is to create a representation of users that relates to their language use. To this end, we explore two sets of factors: 1) inferred demographics and personality traits, and 2) latent language factors that directly capture language use variations among users.

Different from prior work, we model these human attributes as *real-valued factors*, as is common in psychology literature. Although they may refer to discrete classes such as cluster membership, a factor representation is able to capture more nuanced differences and characteristics that are best understood as a continuum (McCrae and Costa Jr., 1989; Ruscio and Ruscio, 2000; Widiger and Samuel, 2005). This is critical for our goal of moving beyond group-level adaptation toward personalization.

3.1 Demographic and Personality Factors

Many studies have linked language variations with demographic (Argamon et al., 2007; Cheshire, 2005), occupational (Preoţiuc-Pietro et al., 2016) and other psychosocial variables such as personality (Schwartz et al., 2013). We investigate the relevance of a subset of these social variables as user factors for adaptation.

However, we may not have direct access to such information. Unlike the tweets posted by a user, their demographic and personality traits are not always publicly available. We use automatic classification models for obtaining real-valued age and gender estimates (Sap et al., 2014) and personality traits (Park et al., 2015). In addition to being reasonably accurate (e.g. age prediction has a Pearson r of .83 with true age), language based estimation of factor scores may capture linguistic preferences more clearly. For instance, Bamman et al. (2014b) found that *perceived* gender was strongly linked to the gender makeup of a user's social network, and may be a better descriptor of linguistic preferences than self-reported gender.

3.2 Latent Language Factors

We also explore methods to derive latent factors that capture language use similarities and variations across users. The main idea is to derive a latent d-dimensional representation of each user using their background tweets. While there are many choices here, we explore a factorization technique (generative factor analysis), a clustering technique (k-means with TF-IDF), and a hybrid (word2vec with k-means).

Generative Factor Analysis. Factorization methods allow us to build latent representations of users by finding low-rank approximations of the original high-dimensional representations of their text. We use a general method called factor analysis (FA) (Lawley and Maxwell, 1971). Intuitively, FA seeks to capture the variability across correlated variables as a weighted linear combination of a given number of latent dimensions, thus allowing a low-dimensional representation of words[1].

Formally, let $\mathbf{M}_{|\mathcal{U}|\times|\mathcal{V}|}$ denote the user-term matrix, whose entries $\mathbf{M}_{ij}$ indicate the number of times word j is used by user i. FA factorizes this high-dimensional representation into two matrices $\mathbf{F}$ and $\mathbf{L}$ as follows: $\mathbf{M} = \mathbf{FL} + \mathbf{E}$ where $\mathbf{E}$ is an error matrix consisting of residual errors not captured by $\mathbf{FL}$ and where the residual noise is assumed to be Gaussian distributed with zero mean.

Clustering. We also explore commonly used text clustering-based methods to derive *latent factors* from the users' tweets. The idea is to cluster the users based on their tweets. In one case we use TF-IDF based representations, and in the other we use word2vec embeddings (Mikolov et al., 2013).

[1] In this sense FA is a more flexible method than singular value decomposition in that it allows factors to be correlated.

We produce a k-means clustering on this reduced dimensional space to create clusters of users who have similar language use. We derive real-valued factors from these clusters using the distance of the user to the centers of each cluster. Cluster membership yields the discrete representation. Refer to section 5.1 for implementation details.

4 Adaptation Models

Given a factor representation of each user, the adaptation task is to learn a model that is sensitive to both the differences and commonalities across all users. This is similar to the objective for domain adaptation tasks, where the task data is drawn from one or more underlying domains and learning needs to account for both the similarities and differences in the domains. We formulate user-factor adaptation as a domain adaptation technique based on feature augmentation (Daumé III, 2007) but rather than force users into discrete domains, we develop a continuous formulation that allows us to make good use of the real-valued user factors.

Here we first describe a direct discrete formulation of feature augmentation and then describe our proposed continuous formulation.

4.1 Discrete Adaptation

Feature augmentation uses domain information to transform instances into a new augmented space such that instances from the same domain have higher similarity in the augmented space compared to instances from different domains. A learner operating over this augmented space can now learn to model both domain-specific and domain-general influences of the features.

The discrete adaptation method is a direct application of this idea, where the training and test instances are mapped into domains based on some grouping that we induce from the user factors. For example, the user factor *age* induces three discrete *domains*: `low` (*age* < 24), `middle` ($24 <$ *age* $<$ 28), and `high` (*age* > 28).

User	Factor Classes	Augmented Instance $\Phi(\mathbf{x}, u)$
User 1	F_1	$\langle \mathbf{x}, \mathbf{x}, \mathbf{0}, \mathbf{0}, \cdots, 0 \rangle$
User 2	F_2	$\langle \mathbf{x}, \mathbf{0}, \mathbf{x}, \mathbf{0}, \cdots, 0 \rangle$
User 3	F_1, F_3	$\langle \mathbf{x}, \mathbf{x}, \mathbf{0}, \mathbf{x}, \cdots, 0 \rangle$
User 4	F_k	$\langle \mathbf{x}, \mathbf{0}, \mathbf{0}, \cdots, 0, \mathrm{x} \rangle$

Table 1: Discrete Factor Adaptation: Augmentations of an original instance vector $\mathbf{x}$ under different factor class mappings. With k domains the augmented feature vector is of length $n(k+1)$.

Given the instance domain mapping, feature augmentation transforms the instances based on their domain. Suppose the original instances have n features and suppose there are d discrete factor classes ($F_1, \cdots, F_d$) i.e., d domains. Given an instance which is mapped to a factor class F_i, augmentation creates a new feature vector that has $d+1$ feature sets of length n each. The original features are copied over to the first feature set for all instances regardless of their domain. For instances from domain i, the original features are copied over to feature set $i+1$. The other feature sets are zeroes. Table 1 shows some examples of this augmentation strategy for a single instance, $\mathbf{x}$, under different factor class mappings.

These augmented instances are used for training and testing without any further modifications to the original learning formulation.

4.2 Continuous Adaptation

Discrete adaptation ignores the continuous nature of user factors. Unlike the commonly considered domains, people don't fit neatly into discrete bins. Many psychological studies have shown the ineffectiveness of treating user factors as discrete types (McCrae and Costa Jr., 1989); we expect an adaptation method which does so to be similarly ineffective. For most factors the boundaries for determining classes is unclear, and such arbitrarily-drawn boundaries may not correspond to big changes in language use.

Figure 1 illustrates the advantage of continuous adaptation for a single feature — whether the current instance contains an intensifier — using sarcasm detection as an example. The colored shapes show the feature values for instances from four users, with green squares representing "sarcastic" tweets and yellow circles representing "not sarcastic" ones. The model is unable to distinguish between sarcastic and non-sarcastic tweets in the no adaptation and discrete adaptation case. While discrete adaptation could induce some separability, in this case it fails to account for the variations between differently-aged *over 30* users. On the other hand, if we use features values that are proportional to the actual age, it can result in a better

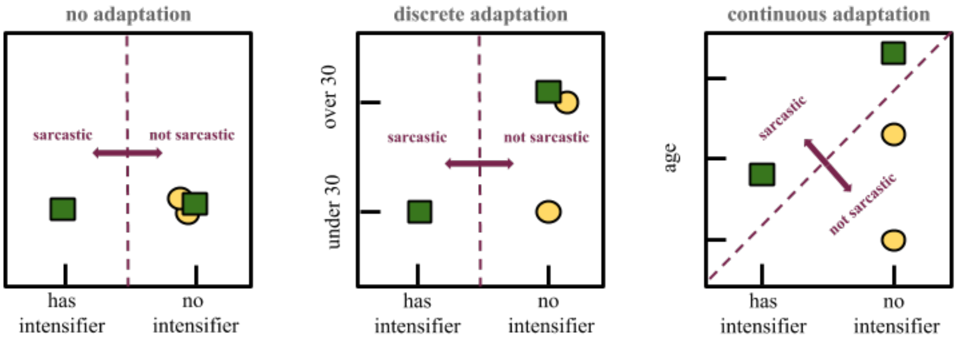

Figure 1: Comparison of feature augmentation under discrete and continuous adaptations. Each shape represents a particular observation (e.g. a tweet) to be classified, each from a different user. The x-axis represents a particular boolean feature: whether the tweet has an intensifier. The y-axis represents how the feature is augmented by the users' age using both discrete adaptation (middle) and continuous adaptation (right). Continuous adaptation allows us to distinguish observations where discrete may not.

separation as shown in the figure.

A compositional function c combines d user factor scores $f_{u,d}$ with original feature values $\mathbf{x}$:

$$\Phi(\mathbf{x}, u) = \langle \mathbf{x}, c(f_{u,1}, \mathbf{x}), c(f_{u,2}, \mathbf{x}), \cdots, c(f_{u,d}, \mathbf{x}) \rangle$$

Thus, a version of each feature exists with and without the factor information integrated. We will explore a simple multiplicative compositional function (i.e., $c(f_{u,d}, \mathbf{x}) = f_{u,d} \cdot \mathbf{x}$) but others can be imagined (e.g. additive, multiplicative with kernel functions).

Multiplicative composition has the property of reducing Φ to discrete adaptation when the factors are binary i.e., $c(f_{u,d}, \mathbf{x}) = \mathbf{x}$ when $u \in F_d$ and $c(f_{u,d}, \mathbf{x}) = 0$ otherwise. As with discrete adaptation, learning then proceeds unmodified with these augmented instances.

The *augmented training data* (train$_{aug}$) is thus associated with the features x of the tweet, the task labels y, and the user information u. Following the feature augmentation formulation, any supervised learning task of finding a parametrized function h_θ over the original labeled training data can now be specified in terms of the augmented training data along with the transformed instances:

$$\arg\min_{\theta} \sum_{(x,y,u) \in train_{aug}} loss \left(h_\theta \left(\Phi(x, u), y \right) \right)$$

For test instances we apply the same transformation function Φ before prediction.

5 Evaluation

We apply user-factor adaptation to five popular NLP tasks: part-of-speech tagging, prepositional-phrase attachment, sentiment analysis, sarcasm detection, and stance detection. These represent both syntactic and semantic tasks; include some of the key steps in an NLP application pipeline; and use different types of learning formulations including logistic regression, conditional random fields, and support vector machines.

We demonstrate the value of user-factor adaptation on strong baselines for each task. Table 2 provides the specific details for each task including the systems used and their configurations.

5.1 Implementation Details

We learn factors from a user's *background language*, or past tweets[2]. To do so, we collect up to 200 tweets per user; users with fewer than 20 tweets were excluded. Retweets were not included and all tweets were tokenized using the Happier Fun Tokenizer[3].

Demographics and Personality. We derive real-valued demographics and personality scores using the models introduced in section 3.1. For demographics, our model predicts continuous age and a gender score where higher values imply more "femaleness". For personality, these scores represent the Big Five personality traits: openness to experience, conscientiousness, extraversion, agreeableness, and neuroticism (Goldberg, 1990; McCrae and Costa Jr., 1997). Age, gender, and the five personality dimensions are each a single factor.

Table 2: Overview of the experimental setup for all tasks. Choices were dictated primarily by the literature on top performing systems for each task.

Latent Language Factors. We use three methods to derive latent factors: (1) **tf-idf**: The TF-IDF approach uses unigrams, bigrams, and trigrams occurring in more than 20% but fewer than 80% of documents. (2) **word2vec**: The skip-grams algorithm (Mikolov et al., 2013) was used to produce 50-dimensional word embeddings. (3) **user-embed**: d-dimensional user embeddings from generative factor analysis (Child, 1990) over relative frequencies of n-grams per user-background. The TF-IDF and word2vec representations are then clustered to produce a low-dimensional representation of the users. Each dimension is a single factor. We primarily report results for d=5 for all latent factors, although we explore alternate values in Section 5.3.

Discrete Adaptation. Each user is mapped to a single "domain" per factor. For inferred age, we select three equally-sized domains: $age < 24$, $24 < age < 28$, and $age > 28$. TF-IDF and word2vec define their domains based on cluster membership. Gender, personality, and user embeddings have two domains, above and below the mean, which is done on a per-dimension basis.

Continuous Adaptation. We apply transformations to the raw factor scores before using them for adaptation. For demographic and personality factors, we apply a min-max transformation. Because language often does not vary linearly with age (Pennebaker and Stone, 2003), we additionally use the square root of the predicted age. For the cluster based latent factors, we use the inverse of the Euclidean distance of the user-background from the cluster centroid, amplifying the power of those users who are closest to each cluster. User embeddings from factor analysis are used without any transforms since they naturally produce a Gaussian distribution.

5.2 Results

Table 3 presents the main adaptation results. We compare the performance of adaptation techniques against two baselines: no inclusion of additional factors or adaptation, and models with factors randomly drawn from a Gaussian distribution – a situation requiring learning the same number of parameters as our most augmented models. For the random factor baseline, we take the average performance across five iterations for both discrete and continuous adaptation. To establish significance of difference in error between adaptation results and the no-adaptation baseline, we use permutation testing for stance detection and McNemar's test for the others. Our findings follow. While these conclusions were drawn from our own experiments, we encourage future researchers to see what works best on their own tasks and datasets.

(i) Adaptation improves over unadapted baselines: The results show significant gains with adaptation for PP-attachment (+1.0), sentiment (+1.0), sarcasm (+3.4), and stance (+3.0). Adaptation yields better results for sarcasm and stance, semantic tasks where we'd expect user preferences to be an important factor. While prior studies have shown POS variations across demographic factors (Pennebaker and Stone, 2003; Schwartz

Table 3: Results of user-factor adaptation across all tasks. Adaptation results are shown in comparison with baseline performance (1) without adaptation and (2) with adaptation using randomly-assigned factors. *disc* denotes discrete adaptation results, and *cont* denotes continuous adaptation results. † indicates statistically significant results at 0.05 level, in comparison to the no-adaptation baseline.

et al., 2013), we hypothesize that the ambiguity in POS reduces greatly when conditioning on local context compared to demographic preferences. This coupled with the ceiling effect in a strong baseline may explain the lack of improvements.

(ii) Continuous is better than discrete: For PP-attachment, sarcasm, and sentiment, continuous adaptation is better than discrete in all but three of the eighteen configurations. Binning people into discrete groups is hard and lossy; using continuous weights helps avoid this issue. Stance, however, is the one task where discrete works better for most factors. As we show in Section 5.4, demographics and personality scores are themselves highly predictive of stances on issues; we believe this makes the simpler binning approach more reliable than the continuous model.

(iii) Both known and latent factors are helpful: Sarcasm benefits from age, gender and personality based adaptations, while stance benefits from personality. The demographic and personality factors do not help PP-attachment. Language factors help all tasks except POS tagging.

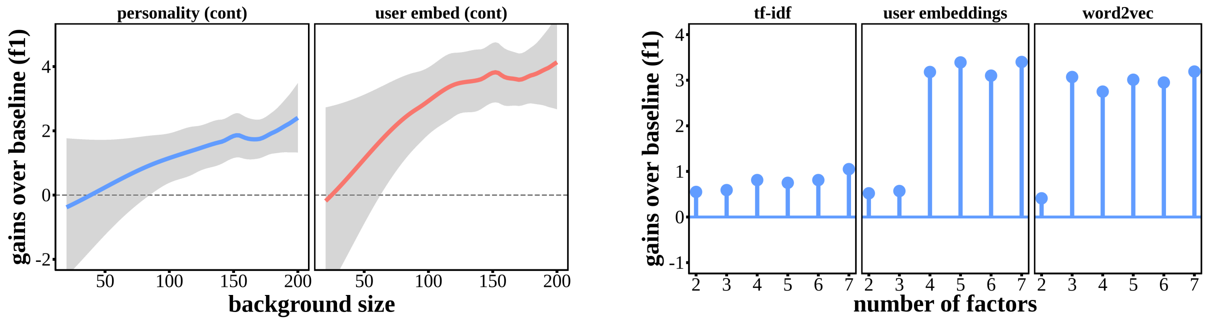
(iv) Latent factors provide best gains: The latent language factors provide the best observed gains for all of the tasks where we saw a significant improvement: PP-attachment, sentiment, sarcasm, and stance. The language factors model users directly in terms of the similarities (and differences) in their entire language use, whereas the inferred demographic and personality factors focus more on a subset of their language as it relates to the particular attribute.

(v) Expanding feature space alone is not enough: One possible explanation for the gains with factors are that the expanded feature space could somehow provide more capacity for learners to generalize. However, adapting to random factors typically lowered results, suggesting that models using more features but not more information naturally take a hit.

5.3 Background Size and Number of Factors

The amount of background available directly affects the factor measurement, which in turn may impact adaptation effectiveness. Figure 2a shows how varying the background size affects adaptation effectiveness for sarcasm. In general, larger backgrounds lead to bigger gains as expected. Even with small amounts of background (50 tweets) adaptation can provide gains, suggesting that even with imperfect predictions of the user attributes, there is still some benefit to adaptation.

Figure 2b compares how performance varies with the number of latent factors for sarcasm. We see gains for all *d* sizes we explored. Performance improves with *d* first and then tapers off; its best is +3.4 at *d*=5 and 7. As the number of factors increases, there is greater potential for a fine-grained characterization of language use differences. However, this is offset by the increased risk of overwhelming the learner with too many parameters to learn during adaptation. We also find that the impact of number of factors also varies with the type of task (e.g., for PP-attachment we find *d*=3 gives the best performance of 72.2, a +1.2 gain over the baseline).



(a) Background size effects for cases with large adaptation gains: sarcasm when using personality and user-embedding factors.

(b) Gains over unadapted baseline for sarcasm using TF-IDF, user embeddings, and word2vec with varying number of factors.

Figure 2: Adaptation performance compared against background size and number of factors.

5.4 Factors as Direct Features

One way to use the factors is to add them as direct features to the instances, without adaptation. Table 4 compares how the most beneficial known factor, personality, performs when added directly as a feature to the two tasks where it had the highest impact.

task	base	direct	adapt	best
sarcasm	73.9	**75.6**†	**75.6**†	**77.3**†
stance	64.9	**65.5**	**67.7**†	**67.9**†

Table 4: Effects of including personality scores as direct features, rather than doing adaptation. Other tasks had no benefit from direct features. Best column shows best result achieved with adaptation using any factor.

For sarcasm, adding personality as a direct feature itself leads to a strong improvement on par with using it for adaptation. For stance, however, we see that while there is an improvement over the baseline, it is not as large as that from adaptation. We observed little-to-no improvement for POS tagging, sentiment or PP-attachment when using personality as direct features. This reflects the relative complexity of the relationships between user factors and class labels for each task. Note that while direct features provide benefits, the overall possible gain with adaptation using any factor (shown in best column) is larger.

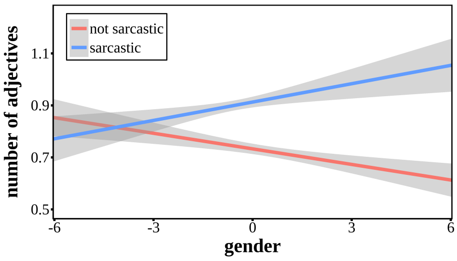


Figure 3: There is a positive correlation between gender and adjective use for sarcastic tweets, and a negative correlation for non-sarcastic tweets. Higher gender scores indicate a greater degree of "femaleness", whereas lower scores represent more "maleness" according to the gender prediction model.

Including user factors as direct features is beneficial when there is a linear relationship with the class label, such as with gender and sarcasm use. In contrast, user-factor adaptation can capture more complex relationships between user groups and their language expression. Figure 3, for instance, shows a three-way interaction between gender scores, adjective use and sarcasm. Increase in the number of adjectives is a positive indicator of sarcasm for women (high gender scores) but is a negative indicator for men (low gender scores). We observe similar trends for age: phrases such as "thanks" and "love it" tend to be meant sarcastically by younger users and sincerely by older ones. User-factor adaptation can model these interaction relationships when direct features alone may not.

5.5 Comparison of Latent Representations

To understand the advantage of continuous latent adaptation, we look at how well discrete and continuous factor representations capture meaningful information about users. To do so, we select two dimensions from the TF-IDF latent factors for stance detection and examine the extent to which they differentiate users based on their attributes (i.e. age) and posting behavior (i.e. URL use). This is shown in Figure 4. The top row gives the

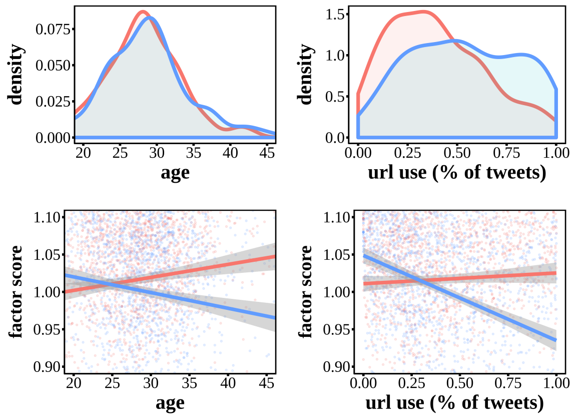

Figure 4: Kernel densities (top) and scatter plots (bottom) of users' age and use of URLs broken down by TF-IDF latent dimension. Colors represent each dimension and are consistent across plots. Lines in scatter plots represent best-fit linear regression. Shaded regions indicate standard error. On the left, discrete latent factors do not seem to distinguish by age (top) but come apart when treated continuously (bottom). On the other hand, discrete and continuous seem to partially capture a dimension of how often someone mentions URLs.

discrete representation: kernel density plots show age and URL use distributions for users binned into the two factor dimensions, shown here in red and blue. The bottom gives the continuous representation: scatter plots show the relationship between age and URL use and the factor score for each dimension.

In the discrete view, age distributions are similar for both factors; there is no apparent relationship between factor membership and age. However, in the continuous view there is a clear negative correlation for age with the factor score for blue and a positive one for red. This indicates that the factors are capturing meaningful information about user age: those with a high factor score for blue tend to be younger, whereas those with a low factor score are older. The reverse is true for red. The URL use shows some difference between the two dimensions in the discrete view, and again we see strong and differing linear relationships with the continuous view.

Overall, the latent factors appear to capture both user attributes and posting behavior, with the continuous version providing additional benefits in characterizing these relationships. The lack of a clear differentiation in the discrete case hints at the difficulty in capturing linguistic variance by splitting users into discrete groups.

6 Related Work

Modeling users has a long history of successful applications in providing personalized information access (Dou et al., 2007; Teevan et al., 2005) and recommendations (Guy et al., 2009; Li et al., 2010; Morales et al., 2012). In contrast, this work models users to better understand their content via language processing tasks following ideas from demographics-aware and domain adaptation.

User-level language variance affects lexical choices (Preoţiuc-Pietro et al., 2016) and even syntactic aspects of language (Johannsen et al., 2015). Such variations can result in demographics-based bias in low-level tasks such as POS tagging (Hovy and Søgaard, 2015) and can also impact high-level applications such as sentiment analysis (Volkova et al., 2013) and machine translation (Mirkin et al., 2015), motivating demographics and personality-based adaptations.

Consequently, recent works have explored demographics-aware NLP (Volkova et al., 2013; Bamman et al., 2014a; Kulkarni et al., 2016; Hovy, 2015; Yang and Eisenstein, 2015). Volkova et al. (2013) propose a gender-aware model and demonstrate superior performance over a gender-agnostic model on the task of sentiment analysis. Bamman et al. (2014a) and Kulkarni et al. (2016) analyze regional linguistic variation using region-specific word embeddings on online social media. Hovy (2015) advances this line of research further and learns group-specific word embeddings, showing improvements over general embeddings on three types of text classification tasks. When author demographics are not available, Yang and Eisenstein (2015) show that learning community-specific embeddings using social networks can help improve sentiment analysis. A similar approach with a social theory-based optimization also showed improvements for sentiment analysis (Hu et al., 2013). For sarcasm detection, historical information about the author and their past context (e.g. entities they discuss) have been shown to be helpful (Bamman and Smith, 2015; Khattri et al., 2015; Rajadesingan et al., 2015).

Our work builds on these ideas and explores the general task of user-factor adaptation. Compared to past work, our method (a) is more general – working with both continuous and discrete factors, (b) uses factors beyond demographics – characteristics like personality are known to influence language beyond demographics (Schwartz et al., 2013), and (c) only requires a background of language – by using inferred factors from a background of language, we require no *a priori* knowledge of user traits.

7 Conclusion

Language on social media reflects the diversity in its user base and motivates the need for robust models that can handle the resulting variations by user attributes. We have introduced user-factor adaptation, a method to adapt typical supervised language classifiers based on factors of the user authoring the language. Our approach requires nothing more than a background of language by the user and only needs access to the features used by the supervised learner. Since it requires no other modifications to the learner, our approach can be easily applied to many NLP tasks.

To the best of our knowledge, this represents the first work to use the idea of continuous-valued variables for language processing adaptation. Continuous adaptation to a variety of user factors brings us closer to personalized NLP and outperforms discrete adaptation over four different tasks: part-of-speech tagging, preposition-phrase attachment, sentiment analysis, and sarcasm detection. Adaptations with data-driven latent factors produced the largest gains. We see this work as part of a growing trend to put language not just within its document-wide context, but also within the context of the human being that wrote it.

Neural Sequence Learning Models for Word Sense Disambiguation

Alessandro Raganato, Claudio Delli Bovi and **Roberto Navigli**

Sapienza University of Rome
{raganato,dellibovi,navigli}@di.uniroma1.it

Abstract

Word Sense Disambiguation models exist in many flavors. Even though supervised ones tend to perform best in terms of accuracy, they often lose ground to more flexible knowledge-based solutions, which do not require training by a word expert for every disambiguation target. To bridge this gap we adopt a different perspective and rely on sequence learning to frame the disambiguation problem: we propose and study in depth a series of end-to-end neural architectures directly tailored to the task, from bidirectional Long Short-Term Memory to encoder-decoder models. Our extensive evaluation over standard benchmarks and in multiple languages shows that sequence learning enables more versatile all-words models that consistently lead to state-of-the-art results, even against word experts with engineered features.

1 Introduction

As one of the long-standing challenges in Natural Language Processing (NLP), Word Sense Disambiguation (Navigli, 2009, WSD) has received considerable attention over recent years. Indeed, by dealing with lexical ambiguity an effective WSD model brings numerous benefits to a variety of downstream tasks and applications, from Information Retrieval and Extraction (Zhong and Ng, 2012; Delli Bovi et al., 2015) to Machine Translation (Carpuat and Wu, 2007; Xiong and Zhang, 2014; Neale et al., 2016). Recently, WSD has also been leveraged to build continuous vector representations for word senses (Chen et al., 2014; Iacobacci et al., 2015; Flekova and Gurevych, 2016).

Inasmuch as WSD is described as the task of associating words in context with the most suitable entries in a pre-defined sense inventory, the majority of WSD approaches to date can be grouped into two main categories: supervised (or semi-supervised) and knowledge-based. Supervised models have been shown to consistently outperform knowledge-based ones in all standard benchmarks (Raganato et al., 2017), at the expense, however, of harder training and limited flexibility. First of all, obtaining reliable sense-annotated corpora is highly expensive and especially difficult when non-expert annotators are involved (de Lacalle and Agirre, 2015), and as a consequence approaches based on unlabeled data and semi-supervised learning are emerging (Taghipour and Ng, 2015b; Başkaya and Jurgens, 2016; Yuan et al., 2016; Pasini and Navigli, 2017).

Apart from the shortage of training data, a crucial limitation of current supervised approaches is that a dedicated classifier (*word expert*) needs to be trained for every target lemma, making them less flexible and hampering their use within end-to-end applications. In contrast, knowledge-based systems do not require sense-annotated data and often draw upon the structural properties of lexico-semantic resources (Agirre et al., 2014; Moro et al., 2014; Weissenborn et al., 2015). Such systems construct a model based only on the underlying resource, which is then able to handle multiple target words at the same time and disambiguate them jointly, whereas word experts are forced to treat each disambiguation target in isolation.

In this paper our focus is on supervised WSD, but we depart from previous approaches and adopt a different perspective on the task: instead of framing a separate classification problem for each given word, we aim at modeling the joint disambiguation of the target text as a whole in terms of a sequence labeling problem. From this standpoint, WSD amounts to translating a sequence of words into a sequence of potentially sense-tagged tokens.

Proceedings of the 2017 Conference on Empirical Methods in Natural Language Processing, pages 1156–1167
Copenhagen, Denmark, September 7–11, 2017. ©2017 Association for Computational Linguistics

With this in mind, we design, analyze and compare experimentally various neural architectures of different complexities, ranging from a single bidirectional Long Short-Term Memory (Graves and Schmidhuber, 2005, LSTM) to a sequence-to-sequence approach (Sutskever et al., 2014). Each architecture reflects a particular way of modeling the disambiguation problem, but they all share some key features that set them apart from previous supervised approaches to WSD: they are trained end-to-end from sense-annotated text to sense labels, and learn a single all-words model from the training data, without fine tuning or explicit engineering of local features.

The contributions of this paper are twofold. First, we show that neural sequence learning represents a novel and effective alternative to the traditional way of modeling supervised WSD, enabling a single all-words model to compete with a pool of word experts and achieve state-of-the-art results, while also being easier to train, arguably more versatile to use within downstream applications, and directly adaptable to different languages without requiring additional sense-annotated data (as we show in Section 6.2); second, we carry out an extensive experimental evaluation where we compare various neural architectures designed for the task (and somehow left underinvestigated in previous literature), exploring different configurations and training procedures, and analyzing their strengths and weaknesses on all the standard benchmarks for all-words WSD.

2 Related Work

The literature on WSD is broad and comprehensive (Agirre and Edmonds, 2007; Navigli, 2009): new models are continuously being developed (Yuan et al., 2016; Tripodi and Pelillo, 2017; Butnaru et al., 2017) and tested over a wide variety of standard benchmarks (Edmonds and Cotton, 2001; Snyder and Palmer, 2004; Pradhan et al., 2007; Navigli et al., 2007, 2013; Moro and Navigli, 2015). Moreover, the field has been explored in depth from different angles by means of extensive empirical studies and evaluation frameworks (Pilehvar and Navigli, 2014; Iacobacci et al., 2016; McCarthy et al., 2016; Raganato et al., 2017).

As regards supervised WSD, traditional approaches are generally based on extracting local features from the words surrounding the target, and then training a classifier (Zhong and Ng, 2010; Shen et al., 2013) for each target lemma. In their latest developments, these models include more complex features based on word embeddings (Taghipour and Ng, 2015b; Rothe and Schütze, 2015; Iacobacci et al., 2016).

The recent upsurge of neural networks has also contributed to fueling WSD research: Yuan et al. (2016) rely on a powerful neural language model to obtain a latent representation for the whole sentence containing a target word w; their instance-based system then compares that representation with those of example sentences annotated with the candidate meanings of w. Similarly, Context2Vec (Melamud et al., 2016) makes use of a bidirectional LSTM architecture trained on an unlabeled corpus and learns a context vector for each sense annotation in the training data. Finally, Kågebäck and Salomonsson (2016) present a supervised classifier based on bidirectional LSTM for the lexical sample task (Kilgarriff, 2001; Mihalcea et al., 2004). All these contributions have shown that supervised neural models can achieve state-of-the-art performances without taking advantage of external resources or language-specific features. However, they all consider each target word as a separate classification problem and, to the best of our knowledge, very few attempts have been made to disambiguate a text jointly using sequence learning (Ciaramita and Altun, 2006).

Sequence learning, especially using LSTM (Hochreiter and Schmidhuber, 1997; Graves and Schmidhuber, 2005; Graves, 2013), has become a well-established standard in numerous NLP tasks (Zhou and Xu, 2015; Ma and Hovy, 2016; Wang and Chang, 2016). In particular, sequence-to-sequence models (Sutskever et al., 2014) have grown increasingly popular and are used extensively in, e.g., Machine Translation (Cho et al., 2014; Bahdanau et al., 2015), Sentence Representation (Kiros et al., 2015), Syntactic Parsing (Vinyals et al., 2015), Conversation Modeling (Vinyals and Le, 2015), Morphological Inflection (Faruqui et al., 2016) and Text Summarization (Gu et al., 2016). In line with this trend, we focus on the (so far unexplored) context of supervised WSD, and investigate state-of-the-art all-words approaches that are based on neural sequence learning and capable of disambiguating all target content words within an input text, a key feature in several knowledge-based approaches.

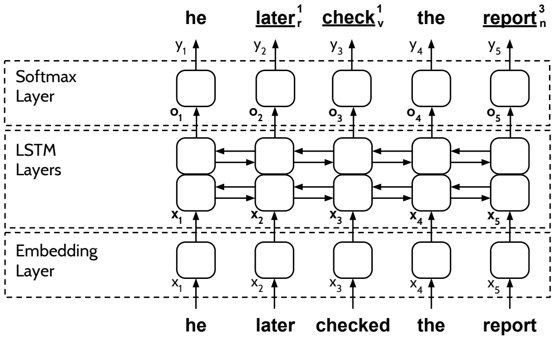

Figure 1: Bidirectional LSTM sequence labeling architecture for WSD (2 hidden layers). We use the notation of Navigli (2009) for word senses: w_p^i is the i-th sense of w with part of speech p.

3 Sequence Learning for Word Sense Disambiguation

In this section we define WSD in terms of a sequence learning problem. While in its classical formulation (Navigli, 2009) WSD is viewed as a classification problem for a given word w in context, with word senses of w being the class labels, here we consider a variable-length sequence of input symbols $\vec{x} = \langle x_1, ..., x_T \rangle$ and we aim at predicting a sequence of output symbols $\vec{y} = \langle y_1, ..., y_{T'} \rangle$.[1] Input symbols are word tokens drawn from a given vocabulary V.[2] Output symbols are either drawn from a pre-defined sense inventory S (if the corresponding input symbols are open-class content words, i.e., nouns, verbs, adjectives or adverbs), or from the same input vocabulary V (e.g., if the corresponding input symbols are function words, like prepositions or determiners). Hence, we can define a WSD model in terms of a function that maps sequences of symbols $x_i \in V$ into sequences of symbols $y_j \in O = S \cup V$.

Here all-words WSD is no longer broken down into a series of distinct and separate classification tasks (one per target word) but rather treated directly at the sequence level, with a single model handling all disambiguation decisions. In what follows, we describe three different models for accomplishing this: a traditional LSTM-based model (Section 3.1), a variant that incorporates an attention mechanism (Section 3.2), and an encoder-decoder architecture (Section 3.3).

3.1 Bidirectional LSTM Tagger

The most straightforward way of modeling WSD as formulated in Section 3 is that of considering a sequence labeling architecture that tags each symbol $x_i \in V$ in the input sequence with a label $y_j \in O$. Even though the formulation is rather general, previous contributions (Melamud et al., 2016; Kågebäck and Salomonsson, 2016) have already shown the effectiveness of recurrent neural networks for WSD. We follow the same line and employ a bidirectional LSTM architecture: in fact, important clues for disambiguating a target word could be located anywhere in the context (not necessarily before the target) and for a model to be effective it is crucial that it exploits information from the whole input sequence at every time step.

Architecture. A sketch of our bidirectional LSTM tagger is shown in Figure 1. It consists of:

- An embedding layer that converts each word $x_i \in \vec{x}$ into a real-valued d-dimensional vector $\mathbf{x}_i$ via the embedding matrix $\mathbf{W} \in \mathbb{R}^{d \times |V|}$;
- One or more stacked layers of bidirectional LSTM (Graves and Schmidhuber, 2005). The hidden state vectors $\mathbf{h}_i$ and output vectors $\mathbf{o}_i$ at the i^{th} time step are then obtained as the concatenations of the forward and backward pass vectors $\overrightarrow{\mathbf{h}}_i, \overrightarrow{\mathbf{o}}_i$ and $\overleftarrow{\mathbf{h}}_i, \overleftarrow{\mathbf{o}}_i$;
- A fully-connected layer with softmax activation that turns the output vector $\mathbf{o}_i$ at the i^{th} time step into a probability distribution over the output vocabulary O.

Training. The tagger is trained on a dataset of N labeled sequences $\{(\vec{x}_k, \vec{y}_k)\}_{k=1}^{N}$ directly obtained from the sentences of a sense-annotated corpus, where each $\vec{x}_k$ is a sequence of word tokens, and each $\vec{y}_k$ is a sequence containing both word tokens and sense labels. Ideally $\vec{y}_k$ is a copy of $\vec{x}_k$ where each content word is sense-tagged. This is, however, not the case in many real-world datasets, where only a subset of the content words is annotated; hence the architecture is designed to deal with both fully and partially annotated sentences. Apart from sentence splitting and tokenization, no preprocessing is required on the training data.

[1] In general $\vec{x}$ and $\vec{y}$ might have different lengths, e.g., if $\vec{x}$ contains a multi-word expression (*European Union*) which is mapped to a unique sense identifier ($\texttt{European Union}^1_n$).

[2] V generalizes traditional vocabularies used in WSD and includes both word lemmas and inflected forms.

3.2 Attentive Bidirectional LSTM Tagger

The bidirectional LSTM tagger of Section 3.1 exploits information from the whole input sequence $\vec{x}$, which is encoded in the hidden state $\mathbf{h}_i$. However, certain elements of $\vec{x}$ might be more discriminative than others in predicting the output label at a given time step (e.g., the syntactic subject and object when predicting the sense label of a verb).

We model this hunch by introducing an attention mechanism, already proven to be effective in other NLP tasks (Bahdanau et al., 2015; Vinyals et al., 2015), into the sequence labeling architecture of Section 3.1. The resulting *attentive* bidirectional LSTM tagger augments the original architecture with an attention layer, where a context vector $\mathbf{c}$ is computed from all the hidden states $\mathbf{h}_1, ..., \mathbf{h}_T$ of the bidirectional LSTM. The attentive tagger first reads the entire input sequence $\vec{x}$ to construct $\mathbf{c}$, and then exploits $\mathbf{c}$ to predict the output label y_j at each time step, by concatenating it with the output vector $\mathbf{o}_j$ of the bidirectional LSTM (Figure 2).

We follow previous work (Vinyals et al., 2015; Zhou et al., 2016) and compute $\mathbf{c}$ as the weighted sum of the hidden state vectors $\mathbf{h}_1, ..., \mathbf{h}_T$. Formally, let $H \in \mathbb{R}^{n \times T}$ be the matrix of hidden state vectors $[\mathbf{h}_1, ..., \mathbf{h}_T]$, where n is the hidden state dimension and T is the input sequence length (cf. Section 3). $\mathbf{c}$ is obtained as follows:

$$\begin{aligned}\mathbf{u} &= \omega^T \tanh(H)\\ \mathbf{a} &= softmax(\mathbf{u})\\ \mathbf{c} &= H\mathbf{a}^T \qquad (1)\end{aligned}$$

where $\omega \in \mathbb{R}^n$ is a parameter vector, and $\mathbf{a} \in \mathbb{R}^T$ is the vector of normalized attention weights.

3.3 Sequence-to-Sequence Model

The attentive tagger of Section 3.2 performs a two-pass procedure by first reading the input sequence $\vec{x}$ to construct the context vector $\mathbf{c}$, and then predicting an output label y_j for each element in $\vec{x}$. In this respect, the attentive architecture can effectively be viewed as an encoder for $\vec{x}$. A further generalization of this model would then be a complete encoder-decoder architecture (Sutskever et al., 2014) where WSD is treated as a sequence-to-sequence mapping (*sequence-to-sequence WSD*), i.e., as the "translation" of word sequences into sequences of potentially sense-tagged tokens.

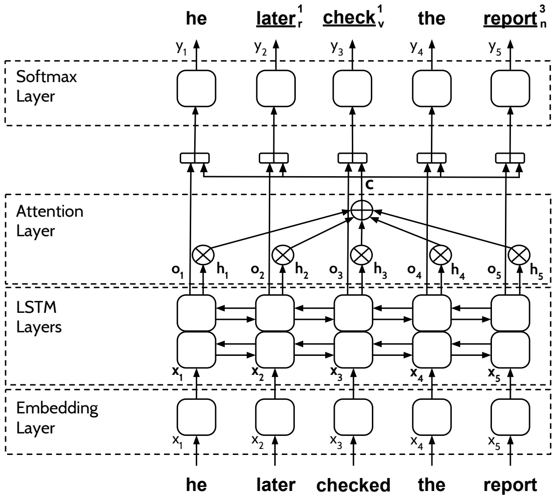

Figure 2: Attentive bidirectional LSTM sequence labeling architecture for WSD (2 hidden layers).

In the sequence-to-sequence framework, a variable-length sequence of input symbols $\vec{x}$ is represented as a sequence of vectors $\vec{\mathbf{x}} = \langle \mathbf{x}_1, ..., \mathbf{x}_T \rangle$ by converting each symbol $x_i \in \vec{x}$ into a real-valued vector $\mathbf{x}_i$ via an embedding layer, and then fed to an encoder, which generates a fixed-dimensional vector representation of the sequence. Traditionally, the encoder function is a Recurrent Neural Network (RNN) such that:

$$\begin{aligned}\mathbf{h}_t &= f(\mathbf{h}_{t-1}, \mathbf{x}_t)\\ \mathbf{c} &= q(\{\mathbf{h}_1, ..., \mathbf{h}_T\}) \qquad (2)\end{aligned}$$

where $\mathbf{h}_t \in \mathbb{R}^n$ is the n-dimensional hidden state vector at time t, $\mathbf{c} \in \mathbb{R}^n$ is a vector generated from the whole sequence of input states, and f and q are non-linear functions.[3] A decoder is then trained to predict the next output symbol y_t given the encoded input vector $\mathbf{c}$ and all the previously predicted output symbols $\langle y_1, ..., y_{t-1} \rangle$. More formally, the decoder defines a probability over the output sequence $\vec{y} = \langle y_1, ..., y_{T'} \rangle$ by decomposing the joint probability into ordered conditionals:

$$p(\vec{y} \mid \vec{x}) = \prod_{t=1}^{T'} p(y_t \mid \mathbf{c}, \langle y_1, ..., y_{t-1} \rangle) \qquad (3)$$

Typically a decoder RNN defines the hidden state at time t as $\mathbf{s}_t = g(\mathbf{s}_{t-1}, \{\mathbf{c}, y_{t-1}\})$ and then feeds $\mathbf{s}_t$ to a softmax layer in order to obtain a conditional probability over output symbols.

[3] For instance, Sutskever et al. (2014) used an LSTM as f, and $q(\{\mathbf{h}_1, ..., \mathbf{h}_T\}) = \mathbf{h}_T$.

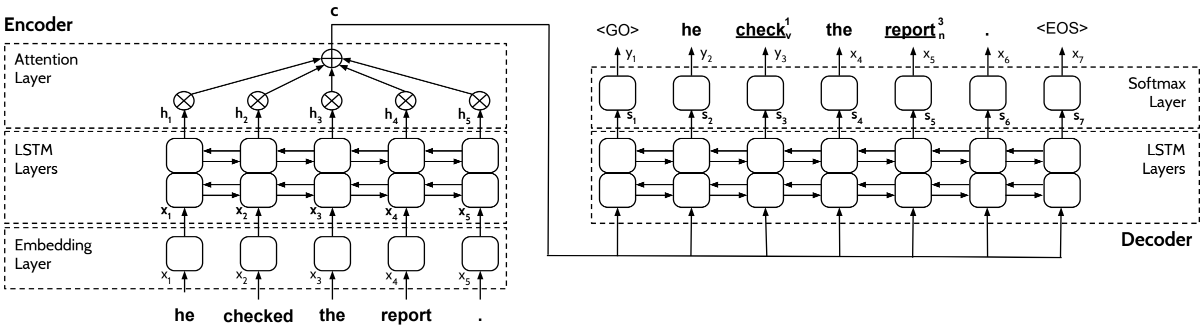

Figure 3: Encoder-decoder architecture for sequence-to-sequence WSD, with 2 bidirectional LSTM layers and an attention layer.

In the context of WSD framed as a sequence learning problem, a sequence-to-sequence model takes as input a training set of labeled sequences (cf. Section 3.1) and learns to replicate an input sequence $\vec{x}$ while replacing each content word with its most suitable word sense from S. In other words, sequence-to-sequence WSD can be viewed as the combination of two sub-tasks:

- A *memorization* task, where the model learns to replicate the input sequence token by token at decoding time;
- The actual *disambiguation* task where the model learns to replace content words across the input sequence with their most suitable senses from the sense inventory S.

In the latter stage, multi-word expressions (such as nominal entity mentions or phrasal verbs) are replaced by their sense identifiers, hence yielding an output sequence that might have a different length than $\vec{x}$.

Architecture. The encoder-decoder architecture generalizes over both the models in Sections 3.1 and 3.2. In particular, we include one or more bidirectional LSTM layers at the core of both the encoder and the decoder modules. The encoder utilizes an embedding layer (cf. Section 3.1) to convert input symbols into embedded representations, feeds it to the bidirectional LSTM layer, and then constructs the context vector $\mathbf{c}$, either by simply letting $\mathbf{c} = \mathbf{h}_T$ (i.e., the hidden state of the bidirectional LSTM layer after reading the whole input sequence), or by computing the weighted sum described in Section 3.2 (if an attention mechanism is employed). In either case, the context vector $\mathbf{c}$ is passed over to the decoder, which generates the output symbols sequentially based on $\mathbf{c}$ and the current hidden state $\mathbf{s}_t$, using one or more bidirectional LSTM layers as in the encoder module. Instead of feeding $\mathbf{c}$ to the decoder only at the first time step (Sutskever et al., 2014; Vinyals and Le, 2015), we condition each output symbol y_t on $\mathbf{c}$, allowing the decoder to peek into the input at every step, as in Cho et al. (2014). Finally, a fully-connected layer with softmax activation converts the current output vector of the last LSTM layer into a probability distribution over the output vocabulary O. The complete encoder-decoder architecture (including the attention mechanism) is shown in Figure 3.

4 Multitask Learning with Multiple Auxiliary Losses

Several recent contributions (Søgaard and Goldberg, 2016; Bjerva et al., 2016; Plank et al., 2016; Luong et al., 2016) have shown the effectiveness of *multitask learning* (Caruana, 1997, MTL) in a sequence learning scenario. In MTL the idea is that of improving generalization performance by leveraging training signals contained in related tasks, in order to exploit their commonalities and differences. MTL is typically carried out by training a single architecture using multiple loss functions and a shared representation, with the underlying intention of improving a main task by incorporating joint learning of one or more related auxiliary tasks. From a practical point of view, MTL works by including one task-specific output layer per additional task, usually at the outermost level of the architecture, while keeping the remaining hidden layers common across all tasks.

In line with previous approaches, and guided by the intuition that WSD is strongly linked to other NLP tasks at various levels, we also design and study experimentally a multitask augmentation of the models described in Section 3. In particular, we consider two auxiliary tasks:

- **Part-of-speech (POS) tagging**, a standard auxiliary task extensively studied in previous work (Søgaard and Goldberg, 2016; Plank et al., 2016). Predicting the part-of-speech tag for a given token can also be informative for word senses, and help in dealing with cross-POS lexical ambiguities (e.g., *book a flight* vs. *reading a good book*);

- **Coarse-grained semantic labels (LEX)** based on the WordNet (Miller et al., 1990) lexicographer files,[4] i.e., 45 coarse-grained semantic categories manually associated with all the synsets in WordNet on the basis of both syntactic and logical groupings (e.g., *noun.location*, or *verb.motion*). These very coarse semantic labels, recently employed in a multitask setting by Alonso and Plank (2017), group together related senses and help the model to generalize, especially over senses less covered at training time.

We follow previous work (Plank et al., 2016; Alonso and Plank, 2017) and define an auxiliary loss function for each additional task. The overall loss is then computed by summing the main loss (i.e., the one associated with word sense labels) and all the auxiliary losses taken into account.

As regards the architecture, we consider both the models described in Sections 3.2 and 3.3 and modify them by adding two softmax layers in addition to the one in the original architecture. Figure 4 illustrates this for the attentive tagger of Section 3.2, considering both POS and LEX as auxiliary tasks. At the j^{th} time step the model predicts a sense label y_j together with a part-of-speech tag POS_j and a coarse semantic label LEX_j.[5]

5 Experimental Setup

In this section we detail the setup of our experimental evaluation. We first describe the training corpus and all the standard benchmarks for all-words WSD; we then report technical details on the architecture and on the training process for all the models described throughout Section 3 and their multitask augmentations (Section 4).

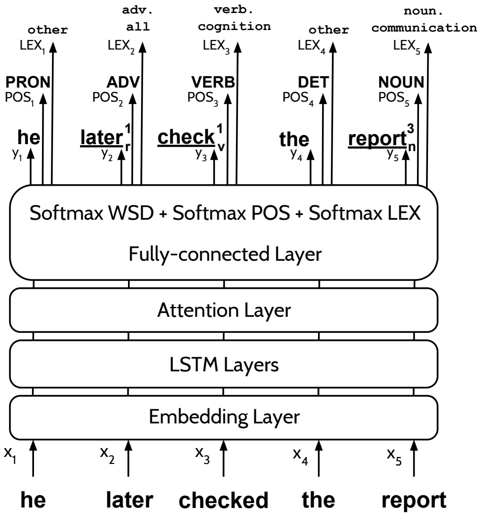

Figure 4: Multitask augmentation (with both POS and LEX as auxiliary tasks) for the attentive bidirectional LSTM tagger of Section 3.2.

Evaluation Benchmarks. We evaluated our models on the English all-words WSD task, considering both the fine-grained and coarse-grained benchmarks (Section 6.1). As regards fine-grained WSD, we relied on the evaluation framework of Raganato et al. (2017), which includes five standardized test sets from the Senseval/SemEval series: Senseval-2 (Edmonds and Cotton, 2001, **SE2**), Senseval-3 (Snyder and Palmer, 2004, **SE3**), SemEval-2007 (Pradhan et al., 2007, **SE07**), SemEval-2013 (Navigli et al., 2013, **SE13**) and SemEval-2015 (Moro and Navigli, 2015, **SE15**). Due to the lack of a reasonably large development set for our setup, we considered the smallest among these test sets, i.e., **SE07**, as development set and excluded it from the evaluation of Section 6.1. As for coarse-grained WSD, we used the SemEval-2007 task 7 test set (Navigli et al., 2007), which is not included in the standardized framework, and mapped the original sense inventory from WordNet 2.1 to WordNet 3.0.[6] Finally, we carried out an experiment on multilingual WSD using the Italian, German, French and Spanish data of **SE13**. For these benchmarks we relied on BabelNet (Navigli and Ponzetto, 2012)[7] as unified sense inventory.

[4] https://wordnet.princeton.edu/man/lexnames.5WN.html

[5] We use a dummy LEX label (other) for punctuation and function words.

[6] We utilized the original sense-key mappings available at http://wordnetcode.princeton.edu/3.0 for nouns and verbs, and the automatic mappings by Daudé et al. (2003) for the remaining parts of speech (not available in the original mappings).

Table 1: F-scores (%) for English all-words fine-grained WSD on the test sets in the framework of Raganato et al. (2017) (including the development set **SE07**). The first system with a statistically significant difference from our best models is marked with $\star$ (unpaired t-test, $p < 0.05$).

At testing time, given a target word w, our models used the probability distribution over O, computed by the softmax layer at the corresponding time step, to rank the candidate senses of w; we then simply selected the top ranking candidate as output of the model.

Architecture Details. To set a level playing field with comparison systems on English all-words WSD, we followed Raganato et al. (2017) and, for all our models, we used a layer of word embeddings pre-trained[8] on the English ukWaC corpus (Baroni et al., 2009) as initialization, and kept them fixed during the training process. For all architectures we then employed 2 layers of bidirectional LSTM with 2048 hidden units (1024 units per direction).

As regards multilingual all-words WSD (Section 6.2), we experimented, instead, with two different configurations of the embedding layer: the pre-trained bilingual embeddings by Mrkšić et al. (2017) for all the language pairs of interest (EN-IT, EN-FR, EN-DE, and EN-ES), and the pre-trained multilingual 512-dimensional embeddings for 12 languages by Ammar et al. (2016).

Training. We used SemCor 3.0 (Miller et al., 1993) as training corpus for all our experiments. Widely known and utilized in the WSD literature, SemCor is one of the largest corpora annotated manually with word senses from the sense inventory of WordNet (Miller et al., 1990) for all open-class parts of speech. We used the standardized version of SemCor as provided in the evaluation framework[9] which also includes coarse-grained POS tags from the universal tagset. All models were trained for a fixed number of epochs $E = 40$ using Adadelta (Zeiler, 2012) with learning rate 1.0 and batch size 32. After each epoch we evaluated our models on the development set, and then compared the best iterations (E^*) on the development set with the reported state of the art in each benchmark.

6 Experimental Results

Throughout this section we identify the models based on the LSTM tagger (Sections 3.1-3.2) by the label **BLSTM**, and the sequence-to-sequence models (Section 3.3) by the label **Seq2Seq**.

dividual test set, as well as the F1-score obtained on the concatenation of all four test sets, divided by part-of-speech tag.

We compared against the best supervised and knowledge-based systems evaluated on the same framework. As supervised systems, we considered **Context2Vec** (Melamud et al., 2016) and It Makes Sense (Zhong and Ng, 2010, **IMS**), both the original implementation and the best configuration reported by Iacobacci et al. (2016, **IMS+emb**), which also integrates word embeddings using exponential decay.[10] All these supervised systems were trained on the standardized version of SemCor. As knowledge-based systems we considered the embeddings-enhanced version of Lesk by Basile et al. (2014, **Lesk**$_{ext}$**+emb**), UKB (Agirre et al., 2014) (**UKB**$_{gloss}$ **w2w**) , and **Babelfy** (Moro et al., 2014). All these systems relied on the Most Frequent Sense (**MFS**) baseline as back-off strategy.[11] Overall, both **BLSTM** and **Seq2Seq** achieved results that are either state-of-the-art or statistically equivalent (unpaired t-test, $p < 0.05$) to the best supervised system in each benchmark, performing on par with word experts tuned over explicitly engineered features (Iacobacci et al., 2016). Interestingly enough, **BLSTM** models tended consistently to outperform their **Seq2Seq** counterparts, suggesting that an encoder-decoder architecture, despite being more powerful, might be suboptimal for WSD. Furthermore, introducing LEX (cf. Section 4) as auxiliary task was generally helpful; on the other hand, POS did not seem to help, corroborating previous findings (Alonso and Plank, 2017; Bingel and Søgaard, 2017).

The overall performance by part of speech was consistent with the above analysis, showing that our models outperformed all knowledge-based systems, while obtaining results that are superior or equivalent to the best supervised models. It is worth noting that RNN-based architectures outperformed classical supervised approaches (Zhong and Ng, 2010; Iacobacci et al., 2016) when dealing with verbs, which are shown to be highly ambiguous (Raganato et al., 2017).

The performance on coarse-grained WSD followed the same trend (Table 2). Both **BLSTM** and **Seq2Seq** outperformed UKB (Agirre et al., 2014) and IMS trained on SemCor (Taghipour and Ng, 2015a), as well as recent supervised approaches based on distributional semantics and neural architectures (Chen et al., 2014; Yuan et al., 2016).

6.2 Multilingual All-words WSD

All the neural architectures described in this paper can be readily adapted to work with different languages without adding sense-annotated data in the target language. In fact, as long as the first layer (cf. Figures 1-3) is equipped with *bilingual* or *multilingual* embeddings where word vectors in the training and target language are defined in the same space, the training process can be left unchanged, even if based only on English data. The underlying assumption is that words that are translations of each other (e.g., *house* in English and *casa* in Italian) are mapped to word embeddings that are as close as possible in the vector space.

In order to assess this, we considered one of our best models (**BLSTM+att.+LEX**) and replaced the monolingual embeddings with bilingual and multilingual embeddings (as specified in Section 5), leaving the rest of the architecture unchanged. We then trained these architectures on the same English training data, and ran the resulting models on the multilingual benchmarks of SemEval-2013 for Italian, French, German and Spanish. While doing this, we exploited BabelNet's inter-resource mappings to convert WordNet sense labels (used at training time) into BabelNet synsets compliant with the sense inventory of the task.

F-score figures (Table 3) show that bilingual and multilingual models, despite being trained only on English data, consistently outperformed the MFS

[10] We are not including Yuan et al. (2016), as their models are not available and not replicable on the standardized test sets, being based on proprietary data.

[11] Since each system always outputs an answer, F-score equals both precision and recall, and statistical significance can be expressed with respect to any of these measures.

baseline and achieved results that are competitive with the best participating systems in the task. We also note that the overall F-score performance did not change substantially (and slightly improved) when moving from bilingual to multilingual models, despite the increase in the number of target languages treated simultaneously.

6.3 Discussion and Error Analysis

All the neural models evaluated in Section 6.1 utilized the MFS back-off strategy for instances unseen at training time, which amounted to 9.4% overall for fine-grained WSD and 10.5% for coarse-grained WSD. Back-off strategy aside, 85% of the times the top candidate sense for a target instance lay within the 10 most probable entries in the probability distribution over O computed by the softmax layer.[12] In fact, our sequence models learned, on the one hand, to associate a target word with its candidate senses (something word experts are not required to learn, as they only deal with a single word type at a time); on the other, they tended to generate softmax distributions reflecting the semantics of the surronding context. For example, in the sentence:

(a) The two *justices* have been attending federalist society events for years,

our model correctly disambiguated *justices* with the WordNet sense $\texttt{justice}_n^3$ (public official) rather than $\texttt{justice}_n^1$ (the quality of being just), and the corresponding softmax distribution was heavily biased towards words and senses related to persons or groups (*commissioners*, *defendants*, *jury*, *cabinet*, *directors*). On the other hand, in the sentence:

(b) Xavi Hernandez, the player of Barcelona, has 106 *matches*,

the same model disambiguated *matches* with the wrong WordNet sense $\texttt{match}_n^1$ (tool for starting a fire). This suggests that the signal carried by discriminative words like *player* vanishes rather quickly. In order to enforce global coherence further, recent contributions have proposed more sophisticated models where recurrent architectures are combined with Conditional Random Fields (Huang et al., 2015; Ma and Hovy, 2016). Finally, a number of errors were connected to shorter sentences with limited context for disambiguation: in fact, we noted that the average precision of our model, without MFS back-off, increased by 6.2% (from 74.6% to 80.8%) on sentences with more than 20 word tokens.

7 Conclusion

In this paper we adopted a new perspective on supervised WSD, so far typically viewed as a classification problem at the word level, and framed it using neural sequence learning. To this aim we defined, analyzed and compared experimentally different end-to-end models of varying complexities, including augmentations based on an attention mechanism and multitask learning.

Unlike previous supervised approaches, where a dedicated model needs to be trained for every content word and each disambiguation target is treated in isolation, sequence learning approaches learn a single model in one pass from the training data, and then disambiguate jointly all target words within an input text. The resulting models consistently achieved state-of-the-art (or statistically equivalent) figures in all benchmarks for all-words WSD, both fine-grained and coarse-grained, effectively demonstrating that we can overcome the so far undisputed and long-standing word-expert assumption of supervised WSD, while retaining the accuracy of supervised word experts.

Furthermore, these models are sufficiently flexible to allow them, for the first time in WSD, to be readily adapted to languages different from the one used at training time, and still achieve competitive results (as shown in Section 6.2). This crucial feature could potentially pave the way for cross-lingual supervised WSD, and overcome the shortage of sense-annotated data in multiple languages that, to date, has prevented the development of supervised models for languages other than English.

As future work, we plan to extend our evaluation to larger sense-annotated corpora (Raganato et al., 2016) as well as to different sense inventories and different languages. We also plan to exploit the flexibility of our models by integrating them into downstream applications, such as Machine Translation and Information Extraction.

Abstract

Search systems are often focused on providing relevant results for the "now", assuming both corpora and user needs that focus on the present. However, many corpora today reflect significant longitudinal collections ranging from 20 years of the Web to hundreds of years of digitized newspapers and books. Understanding the *temporal intent* of the user and retrieving the most relevant historical content has become a significant challenge. Common search features, such as query expansion, leverage the relationship between terms but cannot function well across all times when relationships vary temporally. In this work, we introduce a temporal relationship model that is extracted from longitudinal data collections. The model supports the task of identifying, given two words, *when* they relate to each other. We present an algorithmic framework for this task and show its application for the task of query expansion, achieving high gain.

1 Introduction

The focus of large-scale Web search engines is largely on providing the best access to present snapshots of text – what we call the "Now Web". The system constraints and motivating use cases of traditional information retrieval (IR) systems, coupled with the relatively short history of the Web, has meant that little attention has been paid to how search engines will function when search must scale not only to the number of documents but also temporally. Most IR systems assume fixed language models and lexicons. They focus only on the leading edge of query behavior (i.e., what does the user likely mean today when they type "Jaguar"). In this context, features as basic as disambiguation and spelling corrections are fixed to what is most likely today or within the past few years (Radinsky et al., 2013), query expansions and synonyms are weighted towards current information (Shokouhi and Radinsky, 2012), and results tend to include the most recent and popular content. While this problem would seem to be speculative in that it will be years until we need to address it, the reality is the rate of change (Adar et al., 2009) of the Web, language, and culture have simply compressed the time in which critical changes happen.

The "Now Web" assumptions are entirely reasonable for temporally coherent text collections and allow users (and search engines) to ignore the complexity of changing language and concentrate on a narrower (though by no means simpler) set of issues. The reality is that this serves a significant user population effectively. There are nonetheless a growing number of both corpora and users who require access not just to what is relevant at a particular instant (e.g., Hathitrust (Willis and Efron, 2013), historical news corpora, the Internet Archives, and even fast changing Twitter feeds). Within such contexts, a search engine will need to vary the way it functions (e.g., disambiguation) and interacts (e.g., suggested query expansions) depending on the period and temporal scale of documents being queried. This, of course, is further complicated by the fact that Web pages are constantly evolving and replaced.

Take for example the query "Prime Minister Ariel Sharon". When fed into a news archive search engine, the likely intent was finding results about *Sharon's* role as Israel's *Prime Minister*, a role held from *2001 to 2006*. Singh et al. (2016) refer to this as a *Historical Query Intent*. However, most popular search engines return results about Sharon's death in 2011, when he was no longer

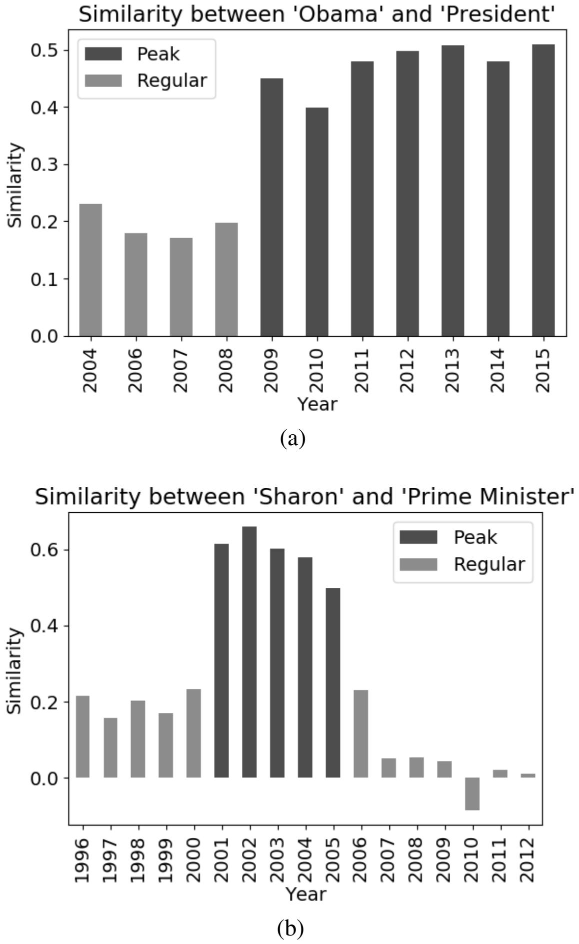
Proceedings of the 2017 Conference on Empirical Methods in Natural Language Processing, pages 1168–1178
Copenhagen, Denmark, September 7–11, 2017.

prime minister. The searcher may take the additional step of filtering results to a time period, but this requires knowing what that period should be. Other query features are also unresponsive to temporal context. For example, the top query suggestions for this query focus on more recent events of his death: "Former prime minister Sharon dies at 85", "Former prime minister Sharon's condition worsens", etc. While these *might* satisfy the searcher if they are looking for the latest results, or the results most covered by the press, there are clearly other possible needs (Bingham, 2010).

In this paper, we focus on the task of measuring word relatedness over time. Specifically, we infer whether two words (tokens) relate to each other during a certain time range. This task is an essential building block of many temporal applications and we specifically target *time-sensitive query expansion (QE)*. Our focus is on *semantic relatedness* rather than *semantic similarity*. Relatedness assumes many different kinds of specific relations (e.g. meronymy, antonymy, functional association) and is often more useful for computational linguistics applications than the more narrow notion of similarity (Budanitsky and Hirst, 2006).

We present several temporal word-relatedness algorithms. Our method utilizes a large scale temporal corpus spanning over 150 years (The New York Times archive) to generate *temporal deep word embeddings*. We describe several algorithms to measure word relatedness over time using these temporal embeddings. Figure 1a presents the performance of one of those algorithms on the words "Obama" and "President". Note that the highest relatedness score for the words appears during the presidential term of Barack Obama. Similarly, Figure 1b shows a high score for "Ariel Sharon" and "prime minister" only during his term.

Using the approach above, we present a specific application – producing temporally appropriate query-expansions. For example, consider the query: "Trump Businessman". Figure 2 shows the non-temporal query expansion suggestions which focus heavily on the first entity (i.e., "Trump") and his current "state" (i.e., a focus on Donald Trump as President, rather than presenting suggestions about Trump's business activity as implied by the query). We present an empirical analysis presenting the strengths and weaknesses of the different temporal query-expansion algorithms and comparing them to current word-embeddings-based QE algorithms (Kuzi et al., 2016; Diaz et al., 2016).



(a)

(b)

Figure 1: Similarity identified by our algorithms between words over time. Dark gray indicates high similarity whereas light gray indicates non-significant similarity.

In this paper we describe a novel problem of evaluating word relatedness over time and contribute our datasets to evaluate this task to the community[1]. Second, we present novel representations and algorithms for evaluating this task and show high performance. We share our code with the community as well. Finally, we present the application of this task to query-expansion and present several methods built on top of the temporal relatedness algorithms that show high performance for QE.

2 Related Work

Understanding the semantic change of words has become an active research topic (Section 2.1). Most work has focused on identifying semantic

drifts and word meaning changes. A lot of effort has been made into analyzing texts temporally: several methods for temporal information extraction were recently proposed (Ling and Weld, 2010; Kuzey and Weikum, 2012; Talukdar et al., 2012), as well as publicly released knowledge bases, such as YAGO2 (Hoffart et al., 2013). These methods automatically extract temporal relational facts from free text or semi-structured data. In addition, Pustejovsky et al. (2003); UzZaman et al. (2012) and others annotated texts temporally, and extracted events as well as temporal expressions.

Work in Information Retrieval (IR, Section 2.2) has discussed the concept of 'time' as a contextual parameter for understanding user intent. Largely, this research utilizes query-log analysis with the time *of the query* as a context signal. In this work, we leverage the temporal variation in word relatedness to understand, and better accommodate, intent.

2.1 Word Dynamics

Continuous word embeddings (Mikolov et al., 2013) have been shown to effectively encapsulate relatedness between words. Radinsky et al. (2011) used temporal patterns of words from a large corpus for the task of word similarity. They showed that words that co-occur in history have a stronger relation. In our work, we focus on identifying *when* a relation holds. Numerous projects have studied the change of word meanings over time, and specifically focused on identification of the change itself. Sagi et al. (2009) used Latent Semantic Analysis for detecting changes in word meaning. Wijaya and Yeniterzi (2011) characterized 20 clusters to describe the nature of meaning change over time, whereas Mitra et al. (2014) used other clustering techniques to find changes in word senses. Mihalcea and Nastase (2012) identified changes in word usage over time by the change in their related part-of-speech. Others have investigated the use of word frequency to identify epochs (Popescu and Strapparava, 2013).

Jatowt and Duh (2014) represented a word embedding over the Google Books corpus (granularity of decades) and presented qualitative evaluation for several words. Hamilton et al. (2016) built Word2Vec embedding models on the Google Books corpus to detect known word shifts over 30 words and presented a dozen new shifts from the data. The authors presented two laws that govern the change of words – frequent words change more slowly and polysemous words change more quickly. Finally, Kenter et al. (2015) studied changes in meaning (represented by a few seed words), and monitored the changing set of words that are used to denote it.

In our work, we focus on learning relatedness of words over time. We evaluate the technique using a large scale analysis showing its prediction accuracy. Moreover, we define the task of identifying the temporality of relatedness between two words. We show that understanding the temporal behavior of entities improves performance on IR tasks.

2.2 Temporal Search

The temporal aspects of queries and ranking gained significant attention in IR literature. Some have focused on characterizing query behavior over time. For example, different queries change in popularity over time (Wang et al., 2003) and even by time of day (Beitzel et al., 2004). Jones and Diaz (2007) described queries to have three temporarilty patterns: atemporal, temporally unambiguous and temporally ambiguous. Others have leveraged temporal variance to look for indicators of query intent (Kulkarni et al., 2011). Several efforts (Shimshoni et al., 2009; Chien and Immorlica, 2005; M. Vlachos and Gunopulos, 2004; Zhao et al., 2006; Shokouhi, 2011; Radinsky et al., 2012) were done to not only characterize the temporal query behavior but also model it via time-series analysis. Radinsky and colleagues modeled changes in the frequency of clicked URLs, queries, and clicked query-URL pairs by using time-series analysis and show its application for improving ranking and query auto-suggestions (Radinsky et al., 2013; Shokouhi and Radinsky, 2012). Singh et al. (2016) focused on serving the specific needs of historians, and introduced the notion of a *Historical Query Intent* for this purpose.

Whereas prior work mainly focuses on query-log analysis and understanding the user's intent based on the time the query was issued or the document was changed, our work focuses on understanding the subtle changes of language over time that indicate a temporal intent. We show that understanding the temporal relatedness between words is a building block needed for understanding better query intent. Given two words or entities we identify when their relatedness was the strongest to help produce better query expansions.

3 Temporal Relatedness Dynamics and Semantics

To address the task of understanding temporal relatedness, our approach consists of three main steps: (1) Represent relatedness using word embeddings over time (Section 3.1). (2) Model relatedness *change* over time as a time series (Section 3.2). (3) Combine these to identify when relatedness relations hold temporally (Section 3.3).

3.1 Representing Relatedness using Word Embeddings

In our work we leverage the distributed representation framework of Word2Vec (Mikolov et al., 2013) (specifically skip-grams). Intuitively, given a word w_t, skip-grams attempt to predict surrounding words, e.g. $w_{t-2}, w_{t-1}, w_{t+1}, w_{t+2}$ for a window size of $c = 2$.

Definition 3.1. Let C_i be the word context for a word w_i. In this work, we consider the context to be the surrounding words of a window size of n $C_i = \{w_{i-n}, w_{i-1}, w_{i+1}, w_{i+n}\}$. We define C_i^t to be the context for a word w_i in time period t, i.e. only in the documents written during time t.

Definition 3.2. We define the word context of a **specific embedding** of a year y for a word w_i, to be $\{w_c \in C_i^y\}$. Intuitively, a specific embedding represents the embedding of a word in a certain year. We denote the vector representation of a word w_i in a year y by v_i^y.

Definition 3.3. We define the word context of a **global embedding** for a word w_i to be C_i. Intuitively, a global embedding represents the embedding of a word over all time periods. We denote the vector representation of a word w_i by v_i.

Using Word2Vec, we approximate the semantic relatedness between two entities by the cosine similarity between their embeddings (Turney et al., 2010).

Definition 3.4. A **temporal relation** (e_1, e_2, t), where e_i are entities and t is a referenced time period, is said to be true if e_1, e_2 relate during t, i.e. their semantic relatedness during that time is relatively high. For example: *(Christopher Nolan, The Dark Knight, 2008)* is true, due to the fact that the movie, which was released in 2008, was directed by Nolan.

Definition 3.5. The **dynamics** of two entities e_1, e_2 is defined to be the time series of the semantic relatedness of e_1 and e_2:

$$Dynamics(e_1, e_2) = \left\langle cos(v_1^{t_1}, v_2^{t_1}), \dots, cos(v_1^{t_n}, v_2^{t_n}) \right\rangle \quad (1)$$

where $t_1, \dots, t_n$ are all the time periods.

We model entities' relatedness change over time by constructing their *dynamics*. Recall Figure 1a, which shows the semantic distance between the vector representations of *Barack Obama* and *President* over the years. Semantic distance is an accurate indicator of the time period when Obama was president. Therefore, our goal is to detect the time periods of high relatedness using peak detection.

3.2 Understanding Relatedness Dynamics

When considering a relationship between entities, detecting time periods of high relatedness enables us to reveal and identify what we call "periods of interest" – time periods in which the entities were the closest. In this section, we present an algorithm to identify these "periods of interest". Intuitively, when considering the *dynamics* of two entities, its peaks represent the lowest distances over time. More formally, given two entities e_1, e_2 we want to construct their *dynamics* and find peaks in it, i.e. the following sequence of time periods: $\left\{t_i \mid cos(v_1^{t_i}, v_2^{t_i}) \text{ is relatively high, and } t_i < t_j \text{ if } i < j\right\}$.

Traditional peak detection algorithms focus on detecting peaks that are sharp and isolated (i.e. not too many surrounding points have similar values) (Palshikar et al., 2009). In our case, relations often imply continuous periods of peaks, e.g. Obama was president for eight years. Therefore, we need to detect peaks, as well as periods of continuous peaks (i.e., steps).

Let $L = (t_1, v_1), (t_2, v_2), \dots, (t_n.v_n)$ be a list of tuples, where t_i are time periods and v_i are values. Given L, the algorithm returns a list of peak periods, i.e. $\{t \in L \mid t \text{ contains a peak}\}$.

The first step is to find relative maxima: we scan L and look for pairs (t_i, v_i) such that $v_{i-1} < v_i > v_{i+1}$, i.e. v_i is a local maximum. We apply two minimum thresholds in order to filter insignificant points: An absolute threshold, which below it we consider the peak not to be significant enough, and a relative threshold which facilitates removing points that are much lower than the highest maximum. The final step of the algorithm is to find plateaus which will also be considered part of the peak. For each peak point, the algorithm considers the point's surrounding neighbors. Using a threshold relative to the current peak, those identified as close in their value to the current peak are added to the peak list.

3.3 Learning Temporal Relatedness

We define the task of learning temporal relatedness: given two entities e_1, e_2, identify whether they relate to each other during a certain year y, i.e., whether the temporal relation (e_1, e_2, y) is true. For example, in Figure 1a, Obama was related to President in 2010 but not in 2005.

3.3.1 Specific Classifier

The first method we present to classify word relatedness, employs a classifier that receives as inputs v_i corresponding to the entities e_i and an additional feature of the year. In our evaluation (Section 4) we will use about 40 years of data, i.e. the year feature will have 40 possible values. The classifier will predict, given two entities, whether they relate to each other during a referenced year.

Let $Cl \colon \mathbb{R}^n \to \{0, 1\}$ be a classifier mapping a vector of n features $F = (f_1, \ldots, f_n)$ to a label $L \in \{0, 1\}$. Let our feature vector be of the form:

$$F = (v_1^y \| v_2^y \| y) \tag{2}$$

where v_1^y is the first entity's specific embedding (i.e. at time y), v_2^y is the second entity's specific embedding and y is the year. As a preliminary step, we need to train Cl on a diverse dataset of positive and negative examples, i.e. true and false temporal relations. For this purpose, we utilize our temporal relations dataset (Section 3.4.2). From each relation, we extract a temporal relation (e_1, e_2, y), calculate its feature vector and use it for training.

Given a new temporal relation, we apply Cl to predict whether it is true, i.e. whether its entities relate during the referenced time.

3.3.2 Temporal Classifier

Here we use a classifier similar to the one described in Section 3.3.1 (training is performed the same way), combined with input from the entities *dynamics*. First, we build the *dynamics*, i.e. build specific word embeddings of e_1 and e_2 for every year y, and calculate their cosine similarity $cos(v_1^y, v_2^y)$. We then apply our peak detection algorithm (Section 3.2) on the *dynamics* and use its output as one of the classifier's features (denoted by *isPeak*). As a result, our feature vector is:

$$F = (v_1^y \| v_2^y \| y \| isPeak) \tag{3}$$

3.4 Leveraging World Knowledge

We apply our techniques to two corpora: the first is a temporal corpora (Section 3.4.1), which we used for creating word embeddings, and the second is a relational corpora (Section 3.4.2), which we used for training our models and for evaluation.

3.4.1 Temporal Corpora

For constructing the corpora, we used The New York Times archive[2], with articles from 1981 to 2016 (9GB of text in total). Specific word embeddings were generated for every time period (i.e., year) using Word2Vec. Each year's data was used to create word embeddings using Word2Vec's skip-gram with negative sampling approach (Mikolov et al., 2013), with the Gensim library (Řehůřek and Sojka, 2010). We trained the models with the following parameters: window size of 5, learning rate of 0.05 and dimensionality of 140. We filtered out words with less than 30 occurrences during that year.

We observe both *ambiguity* (Apple, the company and the fruit) and *variability* (different phrases referring to the same entity, e.g., *President Obama*, *Barack H. Obama*, *Obama*). While such 'noise' may be problematic, both the scale of the data and stylistic standards of The New York Times help. Additionally, we ensure a connection to an entity database (Wikipedia) and perform additional cleaning methods (lemmatization, removing stopwords).

3.4.2 Relational Corpora

In this work, we use YAGO2 (Hoffart et al., 2013) as our relational corpora due to its temporal focus. The YAGO2 knowledge base contains millions of facts about entities, automatically extracted from

[2] http://spiderbites.nytimes.com/

Relation Type	Count	%
Directed	37713	47.42
HoldsPoliticalPosition	2765	3.48
IsMarriedTo	2210	2.78
PlaysFor	4376	5.50
Produced	23567	29.63
HappenedIn	8899	11.19
Total	79530	100

Table 1: Relations Dataset Composition

Wikipedia and other sources. We use relations from YAGO2 to build our own dataset of temporal relations, which we use in all of our algorithms and evaluation – as a source for temporal relations.

The dataset consists of temporal relations in the following format: *(entity*$_1$*, entity*$_2$*, year, type, class)*, where $entity_1$ and $entity_2$ are entities, $type$ is a relation type, and $class$ is true if the relation holds on $year$. For example, *(Tim Burton, Batman Returns, 1992, Directed, true)* and *(Battle Mogadishu, Somalia, 2010, HappenedIn, true)*. Table 1 shows the exact dataset composition. We built our dataset on all the relation types that have a temporal dimension in YAGO2: *Directed, HoldsPoliticalPosition, IsMarriedTo, Produced, PlaysFor, HappenedIn*. The dataset contains 80K of such relations.

4 Evaluation

4.1 Experimental Methodology

We compare the methods described in Section 3.3, where for Cl we chose to use a Support Vector Machine (SVM)[3], with an RBF kernel and C=1.0 (chosen empirically). Two baselines were used for comparison. The first is the common non-temporal model, i.e. a classifier that uses the global (all-time) word embeddings and the following features: the two entities' global embeddings, and a year. More formally,

$$F = (v_1||v_2||y) \tag{4}$$

Given a new temporal relation, the classifier predicts whether it is true during the referenced year, and we output the classifier's prediction. The second baseline we compare against is a standard text classifier that uses the global word embeddings as its only features, i.e. $F = (v_1||v_2)$.

The dataset on which we perform the evaluation is described in Section 4.2. The dataset is not balanced: it contains more negative examples than positive ones. Therefore, for evaluating the methods that involve a classifier we use stratified 10-fold cross validation. We remove relations from consideration if there is insufficient data in the corpora for that year (i.e., one of the entities was filtered out due to low incidence).

4.2 Dataset Construction

Recall that our relational corpora consists of 80K temporal relations in the following format: *(entity*$_1$*, entity*$_2$*, year, type, class)*, where $type$ is a relation type, and $class$ is true if the relation holds on $year$.

For training and evaluating our classifiers we need negative examples as well as positive examples. We generate negative examples in the following way: for every relation in the corpora, we randomly sample 10 negative examples. We exclude the years of the true examples from the dataset's year range, and then randomly choose years for the negative examples. To illustrate, let us observe the case of *Obama, President*: Obama was president from 2009-2016, so we sample negative examples from 1981 to 2008, such as *(Obama, President, 1990, HoldsPoliticalPosition, false)*. The resulting dataset contains 420K relations. We refer to it as the *Temporal Relations Dataset*[4].

4.3 Main Results

Table 2 presents the results of our experiments.

Baselines: The Global and Global+Year baselines produced an AUC of 0.55 and 0.57, respectively. They both performed much worse compared to our methods, with F1 of 0.13.

Specific Classifier produced an AUC of 0.72. It has the highest recall score of all methods (0.88), but its other scores are relatively low.

Temporal Classifier produced an AUC of 0.83. As reported in Table 2, it performed significantly better compared to all other methods, with $p < 0.05$. We applied the Wilcoxon signed-rank test to calculate statistical significance.

[3] We used the implementation by the scikit-learn library (Pedregosa et al., 2011).

[4] `https://github.com/guyrosin/learning-word-relatedness`

Algorithm	Acc.	Rec.	Pr.	F1	AUC
Global	0.67	0.26	0.08	0.13	0.57
Global+Year	0.52	0.39	0.08	0.13	0.55
Specific	0.52	**0.91**	0.32	0.47	0.73
Temporal	**0.81**	0.67	**0.58**	**0.62**	**0.84**

Table 2: Relatedness Learning Evaluation Results (Accuracy, Recall, Precision, F1, AUC)

4.4 Performance Analysis

We tuned Word2Vec parameters by empirically testing on a random subset of our dataset: we set the vector size to be 140 and used a minimum threshold of 30 occurrences (per year). We found that this balanced the removal of noisy data while ensuring that key entities were retained. For constructing the Word2Vec models, the amount of data is crucial or it may lead to unreliable (Hellrich and Hahn, 2016) or inaccurate results. We saw a clear correlation between accuracy and number of occurrences of a participating word. That drove our decision to evaluate our algorithms only on New York Times articles from 1981 onwards – where the number of articles per year is sufficiently large.

5 Task Example: Query Expansion

Temporal relatedness learning can be used for various NLP and IR-related tasks. For example, it is a common practice in IR to expand user queries to improve retrieval performance (Carpineto and Romano, 2012). Our technique allows us to produce temporally appropriate expansions. Specifically, given a query of n entities $Q = \{e_1, e_2, \ldots, e_n\}$, our task is to expand Q with additional search terms to add to it to improve retrieval of relevant documents.

For example, consider the query "Trump Businessman" (Figure 2). Current QE methods, which do not have a temporal aspect, focus on Donald Trump as President of the United States, a potentially erroneous result depending on the temporal focus of the searcher. A reasonable temporal expansion, might contain terms that relate to Donald Trump's business activity, such as "billionaire" or "real estate". Using our technique, the temporal focus of a query can be identified and appropriate expansions offered to the end-user. Specifically, we can analyze the relationship between the query entities to identify the "most relevant" time period – when those entities were strongly connected. Intuitively, the QE algorithms will identify the most relevant time period t for the query entities, and find semantically related terms from that time, to expand the query with.

To tackle this task, we use the algorithms described in Section 3.3. Several different algorithms can utilize the temporal relation models for the task of query expansion. Let us introduce the following definitions for our QE algorithms:

Definition 5.1. Let $NN_K^t(e)$ be the set of K terms that are the closest to an entity e in time t.

Definition 5.2. Let $NN_K(e)$ be the set of "globally" (all-time) closest terms to an entity e .

Definition 5.3. Mutual closeness between an entity x and a query Q is defined by the sum of cosine similarities between x and every $e \in Q$, i.e.

$$M_{cos}(x, Q) := \sum_{e \in Q} cos(x, e) \tag{5}$$

5.1 Query Expansion Algorithms

We describe alternative strategies to provide temporal query expansion ranging from a generic baseline to algorithms that leverage our embedding and classifiers. As a running example, we use the query: "Steven Spielberg, Saving Private Ryan" (Spielberg directed the movie in 1998). 'Reasonable' (temporally relevant) expansions for this query might include: actors who played in this movie, other Spielberg films or similar films from the same time and genre, etc.

5.1.1 Baseline

Following the results of Roy et al. (2016), we consider a baseline method that expands each entity separately, based on global Word2Vec similarity. We define the set of candidate expansion terms as

$$C = \bigcup_{e \in Q} NN_K(e) \tag{6}$$

i.e., for each entity, we choose the closest K global terms. For each $c \in C$, we compute the mutual closeness $M_{cos}(c, Q)$ and sort the terms in C on the basis of this value. The top K candidates are selected as the actual expansion terms. The baseline (poorly) expands the query "Steven Spielberg, Saving Private Ryan" with "Inglourious [Basterds], George Lucas". In some sense, one can see the relation – both are war movies, and

Lucas and Spielberg have worked together. However, Inglourious Basterds was created at 2009 and was directed by Quentin Tarantino.

5.1.2 Globally-Based Classifier

We use a heuristic and assume that the most relevant time period t for the entities of the query is the time when the entities were the closest. We use the classifier from our baseline method in Section 4.1, whose goal is to estimate how relevant a year is to a given set of n entities. Its features are the global word embeddings, as well as a year: $F = (v_1 \| v_2 \| \ldots \| v_n \| y)$.

We apply the classifier to every year y, and choose the one with the highest returned probability of the true label as the most relevant time t.

$$t = \arg\max_{y} \{Cl(v_1, v_2, \ldots, v_n, y)\} \tag{7}$$

We take as candidate-expansion terms the K closest terms to each entity from that year, separately:

$$C = \bigcup_{e \in Q} NN_K^t(e) \tag{8}$$

C is then filtered as described in the baseline.

To train the classifier, for each temporal relation in our temporal relations dataset, we calculate its feature vector and use it for training. Considering our example, this method wrongly chooses $t = 2004$. In that year the entity *Saving Private Ryan* does not exist, so we end up with a wrong expansion of “Francis Ford Coppola film”.

5.1.3 Temporal Classifier

As we have seen in the previous subsection, the globally-based classifier is limited in cases where time-specific knowledge might yield better results. Thus, in this method we use the specific classifier from Section 3.3.1. Its features are the entities’ specific embeddings, and a year: $F = (v_1^y \| v_2^y \| \ldots \| v_n^y \| y)$. We then continue as described in the previous method (find t, choose candidate terms and filter).

For our example, this method chooses correctly $t = 1998$, which is exactly the year of *Saving Private Ryan* release. Its expansion is “Tom Hanks, Movie”. Since Tom Hanks had a lead role in the movie, the expansion is reasonable. The next algorithm produces the same expansion as well.

5.1.4 Temporal Model Classifier

This method uses the temporal classifier from Section 3.3.2. Its feature vector is: $F = (v_1^y \| v_2^y \| \ldots \| v_n^y \| y \| isPeak)$. The rest is the same as described in Section 5.1.3.

5.2 Query Expansion Evaluation

Dataset. To evaluate temporal query expansion we use our temporal relations dataset, which will be made publicly available (described in Section 3.4.2). First, we evaluate on queries consisting of two entities ($n = 2$): for each relation, we create a distinct query that consists of its two entities concatenated. We search The New York Times corpus with this query[5]. We compare search performance when applying the various QE methods described in Section 5.1. To evaluate the methods that involve a classifier, we use stratified 10-fold cross validation, as the previous task was evaluated (Section 4.1). We use $K = 2$ for all methods, i.e. we generate two expansion terms per query.

In addition, we evaluate on queries consisting of three entities ($n = 3$): we created a new dataset, which contains triplets of entities instead of pairs, by merging every two related (true) relations from our relations dataset. Two relations are considered related if they share an entity, and their time periods overlap. We then generate negative relations as described in Section 4.2. In this new dataset, each temporal relation consists of three entities, a year and a binary classification.

Evaluation Metrics. Though a complete evaluation of QE is beyond the scope of this paper we describe here an evaluation suited for the temporal case. It should be noted that the technique we propose here would likely be used alongside established QE techniques (e.g., log mining).

First, when providing query expansions and suggestions we would like for them to not only retrieve relevant content, but *temporally*-relevant content. To test the latter we say that given a temporal relation, a retrieved article is considered “true” if it were published within the referenced time, and “false” otherwise. Additional manual validation was done to evaluate its relevance to the query. This metric, while not the most accurate one, allows us to distinguish between results from the most relevant time period and others. Precision of the top 10 retrieved documents (P@10) is used to evaluate the retrieval effectiveness.

Results. The results of the QE evaluation are reported in Table 3. We observe a consistent be-

[5] the archive was indexed using Solr (`https://lucene.apache.org/solr/`)

Method	P@10	
	$n = 2$	$n = 3$
Baseline (Roy et al., 2016)	14.0%	17.7%
Globally-Based Classifier	18.0%	22.7%
Temporal Classifier	27.1%	38.5%
Temporal Model Classifier	**29.4%**	**39%**

Table 3: Results of QE Algorithms Evaluation

havior for different query sizes ($n = 2, 3$). For our temporal classifiers, for $n = 3$ there is a 30% increase in precision, compared to $n = 2$.

All of our methods performed significantly better compared to the baseline (statistical significance testing has been performed using paired t-test with $p < 0.05$). This establishes our claim that utilizing temporal knowledge yields more temporal–promising results. The *Temporal Model Classifier* showed the best performance of all. This, too, suits our claim and fits to the results from the previous task (Section 4.3).

5.3 Textual Relevance

To validate results, we compared our query expansion algorithms' performance on different relation types and found big differences. On the relations *HoldsPoliticalPosition, HappenedIn* and *IsMarriedTo*, the temporal algorithms achieved around 50% accuracy, while on *Directed* and *Produced* they got only 20%. This difference is reasonable, as our models were built upon a news corpus.

Let us observe an example of using the QE algorithms with the query “Vicente Fox President” (Fox was president of Mexico from 2000 to 2006). The baseline expands with Mexico's two previous presidents (Zedillo and Salinas). This makes sense as the baseline doesn't take time into account. The globally-based classifier expands with Roh Moo-hyun, who was president of Korea during the same time period. *Temporal Classifier* expands with “Ricardo Lagos, National Action Party” (Lagos was president of Chile during that time. The latter is Fox's political party). The *Temporal Model Classifier* expands with ‘presidential’ and Francisco Labastida (the candidate who lost the elections to Fox).

Figure 3 shows the similarity between Apple and its top products since 1990. We can infer which products were the most significant at each time. Take as example the query “Apple Steve Jobs”. Using our technique, we can find the most relevant time period for this query, which is from Apple's foundation in 1976 until Jobs' death in 2011. Leveraging Figure 3, we can expand this query focusing on the most popular products of that time.

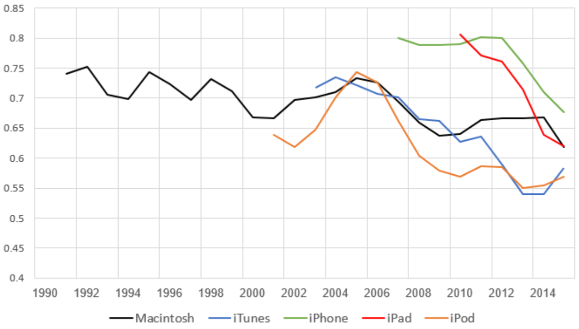

Figure 3: Similarity between Apple and its top products over time. The y-axis is cosine similarity.

6 Conclusions

We believe that as corpora evolve to include temporally-varying datasets, new techniques must be devised to support traditional and new IR methods. In this paper, we introduced a novel technique for extracting relations in temporal datasets. The technique is efficient at large scales and works in an unsupervised manner. Our experiments demonstrate the viability of the extraction technique as well as describing ways that it can be used in downstream applications. We specifically demonstrate a number of query expansion algorithms that can benefit from this technique.

Abstract

Sentence pair modeling is a crucial problem in the field of natural language processing. In this paper, we propose a model to measure the similarity of a sentence pair focusing on the interaction information. We utilize the word level similarity matrix to discover fine-grained alignment of two sentences. It should be emphasized that each word in a sentence has a different importance from the perspective of semantic composition, so we exploit two novel and efficient strategies to explicitly calculate a weight for each word. Although the proposed model only use a sequential LSTM for sentence modeling without any external resource such as syntactic parser tree and additional lexicon features, experimental results show that our model achieves state-of-the-art performance on three datasets of two tasks.

1 Introduction

Given two pieces of sentences S and T, sentence pair modeling (SPM) is a fundamental task whose applications include question answering (Lin, 2007), natural language inference (Bowman et al., 2015), paraphrase identification (Socher et al., 2011a) and sentence completion (Wan et al., 2016) and so on. In general, each of the two sentences are firstly mapped to a representation, and then a model is designed to determine the relation between them. Traditional methods use lexicon features such as Bag-of-Words(BOW) to map sentences. As we know, features design and selection are time-consuming and high dimensional features may suffer from sparsity because of the variation of linguistic. Recently, deep learning techniques have been applied to develop end-to-end models for NLP tasks, such as sentence modeling (Socher et al., 2011b; Kim, 2014), relation classification (Socher et al., 2012) and machine translation (Sutskever et al., 2014). These works show that deep learning models can be comparable with hand-crafted features based models and often outperform them.

Existing DNN models are based on pre-trained word embeddings which map each word to one low dimensional vector and compose word embeddings to represent sentence. Some models are developed directly from the sentence models. They obtain single vector representation for each sentence separately and then determine the relation based on two vectors (Huang et al., 2013; Qiu and Huang, 2015; Palangi et al., 2016). Because of the absence of interaction, these models can not achieve state-of-the-art performance.

Inspired by attention mechanism in computer vision and machine translation, some elaborate models have been proposed (Rocktäschel et al., 2016; Zhou et al., 2016; Wang and Jiang, 2016) which take interaction information into consideration. Meanwhile, to grasp the fine-grained information for semantic similarity, some prior works (Pang et al., 2016; He and Lin, 2016) firstly compute a word level similarity matrix according to word representation, and utilize multiple convolution layers and extract features from the similarity matrix in a perspective of image recognition.

In this paper, we focus on solving SPM problem by measuring semantic similarity between two sentences. We propose a new deep learning model based on two facts that previous works always neglected. As we know, in the aspect of semantic, each word in the sentence is of different importance. When calculating a sentence representation we should endow each word with a weight indicating its importance. Taking following sentences

Copenhagen, Denmark, September 7–11, 2017.

as an example:

A: a man with a red helmet is riding a motorbike along a roadway.

B: a man is riding a motorbike along a roadway.

C: a man with a red helmet is riding a bicycle along a roadway.

We can see that sentence A is more similar with sentence B than with sentence C while a conventional model probably makes an opposite conclusion because the phrase ”with a red helmet” will bias the meaning of A to C meanwhile the difference between ”motorbike” and ”bicycle” is not large enough. If the model can realize that the phrase ”with a red helmet” has little effect on semantic composition, the mistake will be avoided. Since we have to analyse a pair of sentences, the weights should be related to not only the sentence itself, but also its partner. From this point, we propose a novel inter-weighted layer to measure the importance of each word.

On the other hand, the more similar two sentences are, the more probably we can align each word of sentence S with several words of sentence T, and vice versa. On account of the variety of expression, the position and length of two aligned parts are very likely different, so we apply soft-alignment mechanism and build an effective alignment layer.

In summary, our contributions are as follows:

1. We propose an Inter-Weighted Alignment Network (IWAN) for SPM, which builds an alignment layer to compute similarity score according to the degree of alignment.

2. Considering the importance of each word in a sentence is different, we argue that an inter-weighted layer for evaluating the weight of each word is crucial to semantic composition. We propose two strategies for calculating weights. Experimental results demonstrate their effectiveness.

3. Experimental results on semantic relatedness benchmark dataset SICK and two answer selection datasets show that proposed model achieves state-of-the-art performances without any external information.

2 Related Work

2.1 Sentence Models

For sentence modeling, RNN (Elman, 1990; Mikolov et al., 2010) and CNN (Kim, 2014) are both powerful and widely used. RNN models a sentence sequentially by updating the hidden state which represents context recurrently. As sentence length grows, RNN will suffer from gradient vanishing problem. However, gated mechanism, such as Long Short Term Memory(LSTM) (Hochreiter and Schmidhuber, 1997) is introduced to address it. RecNN exploits syntatic information and models sentences under a tree structure. Gated mechanism can also improve the performance of RecNN (Tai et al., 2015). CNN can extract and combine important local context meanwhile model sentences in a hierarchical way (Kim, 2014; Kalchbrenner et al., 2014). All of the above models can be adapted to SPM by modeling two sentences separately.

2.2 Attentive Models

Hermann et al. (2015) firstly introduces attention mechanism into question answering under an RNN architecture. Rocktäschel et al. (2016) applies a similar model to natural language inference which attends over the premise conditioned on the hypothesis. Zhou et al. (2016) combines attention mechanism with tree-structured RecNN encoder. Some prior works (Wang et al., 2016b; Parikh et al., 2016; Wang et al., 2017) compute soft-alignment representation for each word in sentences attentively with word level similarity and then compose the alignment representations to determine the relation. Our model is also under this framework however we focus on explicitly calculating weights for each word to get more reasonable semantic composition.

2.3 Similarity Matrix Based Models

Pang et al. (2016) adopts CNN on word level similarity matrix to extract fine-grained matching patterns from different text granularity. He and Lin (2016) uses a similar architecture with a 19-layer CNN in order to make full use of its power. Yin and Schütze (2015) proposes a hierarchical architecture to model different granularity representation and computes several similarity matrices for interaction.

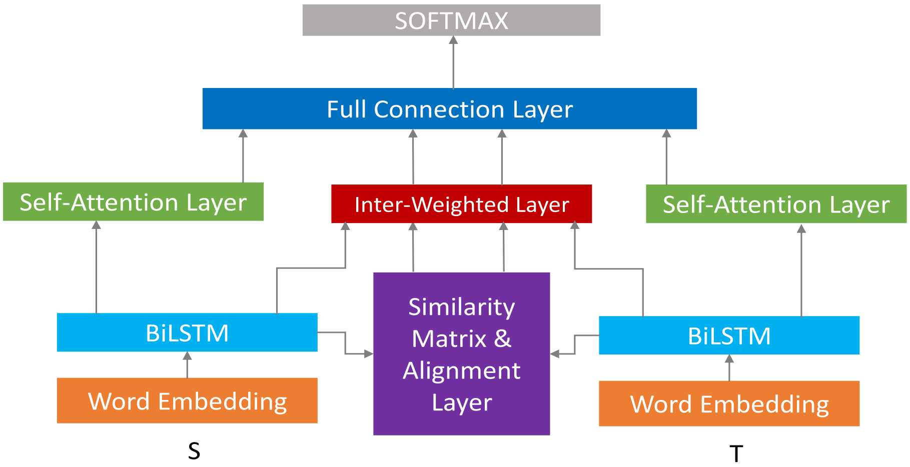

Figure 1: The architecture of IWAN. The blocks with same color have shared parameters.

3 Proposed Model

Given two sentences S and T, we aim to calculate a score to measure their similarity. Figure 1 shows the architecture of IWAN model. To learn representations with context information, we firstly use a bi-direction LSTM sentence model which takes word embeddings as inputs to obtain a context-aware representation for each position (Sec. 3.1). The context-aware representations are used to compute the word level similarity matrix (Sec. 3.2). Inspired by attention mechanism, we exploit soft-alignment to find semantic counterpart in one sentence for each position in the other and compute a weighted sum vector of one sentence as the alignment representation of each position of the other with an alignment layer (Sec. 3.3). Meanwhile, taking the context-aware representation of S and T as inputs, we apply an inter-weighted layer to compute a weight for each position in S and T. We argue that this weight can indicate the importance in semantic interaction and a weighted summation of the representations at each position is more interpretable than other composition method including max or average pooling and LSTM layer. We propose two strategies for computing those weights (Sec. 3.4). The weighted vectors are fed to full connection layers and a softmax layer is used to give the final prediction(Sec. 3.5).

As Figure 1 illustrates, our model is symmetric about S and T. So for simplicity, we only describe the left part of IWAN model which is mainly about modeling S from here. Right part is exactly same except the roles of S and T exchange.

3.1 BiLSTM Layer

With pre-trained d dimension word embedding, we can obtain sentence matrices $S_e = [s_e^1, \dots, s_e^m]$ and $T_e = [t_e^1, \dots, t_e^n]$ where $s_e^i \in \mathbb{R}^d$ is embedding of the i-th word in sentence S. m and n are the length of S and T respectively. In order to capture contextual information, we run a bi-direction LSTM (Hochreiter and Schmidhuber, 1997) on two matrices. Let hidden layer dimension of LSTM be u. Given the word embedding x_t at time step t, previous hidden vector h_{t-1} and cell state c_{t-1}, LSTM recurrently computes h_t and c_t as follows:

$$\begin{aligned}
g_t &= \phi(W_g x_t + V_g h_{t-1} + b_g), \\
i_t &= \sigma(W_i x_t + W_i h_{t-1} + b_i), \\
f_t &= \sigma(W_f x_t + W_f h_{t-1} + b_f), \\
o_t &= \sigma(W_o x_t + W_o h_{t-1} + b_o), \\
c_t &= g_t \odot i_t + c_{t-1} \odot f_t, \\
h_t &= c_t \odot o_t.
\end{aligned}$$

where all $W \in \mathbb{R}^{u \times d}$, $V \in \mathbb{R}^{u \times u}$ and $b \in \mathbb{R}^u$. σ is *sigmoid* function and ϕ is *tanh* function. $\odot$ indicates the element-wise multiplication of two vectors. The input gates i, forget gates f and output gates o control information flow self-adaptively, moreover cell state c_t can memorize long-distance information. h_t is regarded as the representation of time step t.

We feed S_e and T_e separately into a parameter shared LSTM sentence model. If we run an LSTM model on the sequence of S_e from left to right, we can get the forward hidden vector $S_{fh} = [s_{fh}^1, \dots, s_{fh}^m]$. For applying bi-direction LSTM, we also run another LSTM backward and get

$S_{bh} = [s_{bh}^1, \dots, s_{bh}^m]$. Then we concatenate them to one vector representation. So after bi-direction LSTM layer, we obtain $S_h = [s_h^1, \dots, s_h^m]$ and $T_h = [t_h^1, \dots, t_h^n]$ where $s_h^i = \begin{bmatrix} s_{fh}^i \\ s_{bh}^i \end{bmatrix}$.

3.2 Word Level Similarity Matrix

As mentioned above, the word level similarity matrix is crucial to making use of the interaction information. Pang et al. (2016) and Wang et al. (2016b) compute the similarity matrix between two word embeddings. We have argued that word embedding can not express the word meaning in context. From the view of RNN, s_{fh}^i contains the most semantic information about i-th word in S and less about the leftmost words, while s_{bh}^i also contains the most semantic information about i-th word in S and less about the rightmost words. Therefore, the hidden vector of BiLSTM keeps the most information of corresponding word as well as integrated with the context information. Computing similarity matrix between BiLSTM hidden vectors is expected to improve the interaction results. We regard the inner dot of two vectors as their similarity. For the similarity matrix M, its element M_{ij} indicates the similarity between s_h^i and t_h^j:

$$M_{ij} = s_h^{iT} \cdot t_h^j.$$

3.3 Alignment Layer

We design the alignment layer for an intuitive idea: more similar S and T are, more probably we can find semantic counterpart in T for each part in S, and vice versa. To some degree, people are likely to find semantic correspondences between two sentences and evaluate their similarity. He and Lin (2016) are also inspired by similar intuition, but they use deep CNN to recognize the alignment patterns implicitly. However, for each sentence, we explicitly calculate the alignment representation and alignment residual which we believe are good indicators of sentence pair similarity.

For calculating the alignment representation, we apply attention mechanism (Bahdanau et al., 2014) to conduct a soft-alignment. The original attention mechanism outputs the alignment weights from an extra full connection layer while we think the inner dot can represent the semantic relatedness adequately. Therefore, we consider the i-th row of M as the similarity between the i-th position of S and each position in T and normalize it as follows:

$$\alpha_{ij} = \frac{exp(M_{ij})}{\sum_{k=1}^{n} exp(M_{ik})}, \quad i = 1, \dots, m$$

while we also normalize each column of M for T counterpart. α_{ij} always belongs to $[0, 1]$ and can be regarded as weight. Then the alignment representation $S_a = [s_a^1, \dots, s_a^m]$ is computed as a weighted sum of $\{t_h^j\}$:

$$s_a^i = \sum_{k=1}^{n} \alpha_{ik} t_h^k, \quad i = 1, \dots, m$$

For T counterpart, the alignment representation is $T_a = [t_a^1, \dots, t_a^n]$.

In order to measure the gap between the alignment representation and original representation, a *direct* strategy is to compute the absolute value of their difference: $s_r^i = |s_h^i - s_a^i|$. We call $S_r = [s_r^1, \dots, s_r^m]$ alignment residual which is considered as alignment feature for subsequent processing.

We also utilize an *orthogonal decomposition* strategy which is first proposed by Wang et al. (2016b): the component s_p^i of s_h^i parallel to s_a^i represents the alignment component and component s_o^i orthogonal to s_a^i represents alignment residual. We compute these two component as follows:

$$s_p^i = \frac{s_h^i \cdot s_a^i}{s_a^i \cdot s_a^i} s_a^i, \quad parallel\ component$$

$$s_o^i = s_h^i - s_p^i, \quad orthogonal\ component$$

Then we can replace S_r with S_p and S_o to measure the degree of alignment where $S_p = [s_p^1, \dots, s_p^m]$ and $S_o = [s_o^1, \dots, s_o^m]$.

3.4 Inter-Weighted Layer

3.4.1 Inter-Attention Layer

(Lin et al., 2017) firstly proposes a self-attention sentence model which explicitly computes a weight for each word and uses the weighted summation of word representations as sentence embedding. Inspired by this work, we apply a full connection neural network to measure the importance to semantic interaction of every word. We extend the self-attention model to inter-attention layer in order to compute the weights combined with interaction information which composing the alignment representation benefits from. As the

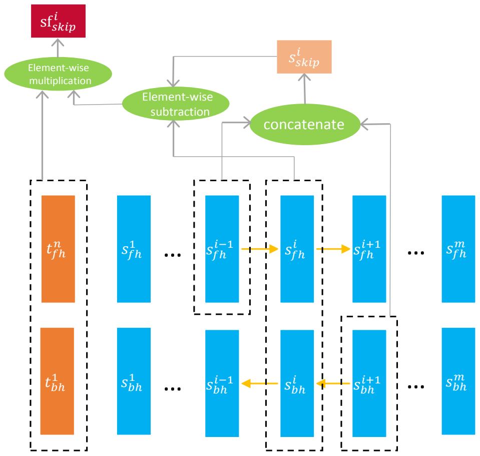

Figure 2: The illustration of computing sf^i_{skip}.

name suggests, these weights of S are not only dependent on S but also T and the parameters of the inter-attention layer are shared for S and T.

Formally, we take S_h and T_h as inputs and the inter-attention layer outputs a vector w_s with size m for S:

$$w_s = softmax(w_2 tanh(W_1 \begin{bmatrix} S_h \\ (t_{avg} \otimes e_m) \end{bmatrix})),$$

where $t_{avg} = \frac{1}{n}\sum_{k=1}^{n} t_h^k$ and $S_h \in \mathbb{R}^{2u \times m}$. We calculate the average of $\{t_h^k\}$ as the representation of T. We also try to replace average operator with a self-attention layer (Lin et al., 2017) but get a worse performance. e_m is a vector of 1s with size m and $\otimes$ represents outer product operator. We feed the concatenated matrix containing pairwise information into a 2-layer neural network. The parameter $W_1 \in \mathbb{R}^{s \times 4u}$ projects inputs into a hidden layer with s units. The output layer is parameterized by a vector w_2 with size s and a $softmax$ operator ensures all the element of output sum up to 1. Then we can use w_s to sum up S_r, S_p and S_o weightedly across the position dimension:

$$\begin{aligned} s_{wr} &= S_r * (w_s)^T, \\ s_{wp} &= S_p * (w_s)^T, \\ s_{wo} &= S_o * (w_s)^T. \end{aligned}$$

We can get t_{wr}, t_{wp} and t_{wo} in the same way. We call these inter-features for final prediction.

3.4.2 Inter-Skip Layer

We also explore another novel strategy to compute w_s from the intuition that if the i-th word in S has a low contribution to semantic composition, we will obtain a similar representation s^i_{skip} if we feed all word embeddings sequentially except s^i_e into BiLSTM. Unfortunately, the $O(m^2)$ complexity of running BiLSTM model m times is too high so we exploit an approximate method to compute $\{s^i_{skip}\}$:

$$s^i_{skip} = \begin{bmatrix} s^{i-1}_{fh} \\ s^{i+1}_{bh} \end{bmatrix}$$

Then we compute a skip feature as following:

$$sf^i_{skip} = (s^i_{skip} - S^i_h) \odot t_h,$$

where $t_h = \begin{bmatrix} t^n_{fh} \\ t^1_{bh} \end{bmatrix}$ is the BiLSTM hidden representation of T. Figure 2 illustrates how to compute sf^i_{skip}. We think the difference between s^i_{skip} and s^i_h approximately reflects the contribution the i-th word makes to semantic composition. On the one hand, if the difference is small or even close to zero, the importance of correspond word should be small. On the other hand, if the difference (a vector) is not similar to the representation of T, correspond word is probably of less importance in measuring semantic similarity. From these two points, we think $sf_{skip} = [sf^1_{skip}, \ldots, sf^m_{skip}]$ is a good feature to measure word importance. The process of computing w_s is similar:

$$w_s = softmax(w_2 tanh(W_1 sf_{skip})),$$

We can use w_s outputted by inter-skip layer to obtain inter-features in the same way.

3.5 Output Layer

For more rich information, we combine alignment information with sentence embeddings of S and T for final prediction. We run the simple but effective self-attention (Lin et al., 2017) model on S_h to obtain its embedding s_{wh}:

$$s_{wh} = S_h * (softmax(w_2' tanh(W_1' * S_h)))^T,$$

where W_1' and w_2' are trainable. We compute s_{wh} and t_{wh} with parameter shared self-attention layer which is similar with the inter-attention layer except inputs.

Following Tai et al. (2015), we compute their element-wise product $h_\times = s_{wh} \odot t_{wh}$ and their absolute difference $h_+ = |s_{wh} - t_{wh}|$ as self-features. If we use *direct strategy*, we combine the features as follows:

$$h_{di} = [h_\times^T; h_+^T; s_{wr}^T; t_{wr}^T]^T.$$

Strategy	SICK			TrecQA		WikiQA	
	r	ρ	MSE	MAP	MRR	MAP	MRR
DI	0.8774	0.8229	0.2374	0.815	0.882	0.724	0.739
OD	**0.8810**	**0.8261**	**0.2289**	**0.822**	**0.889**	**0.730**	**0.744**

Table 1: Performances of our model with different strategies in alignment layer on three datasets.

If we use *orthogonal decomposition strategy*, we combine the features as follows:

$$h_{od} = [h_{\times}^T; h_{+}^T; s_{wp}^T; t_{wp}^T; s_{wo}^T; t_{wo}^T]^T.$$

Following previous works, the sentence pair modeling problem can always be considered as a classification task, so we finally calculate a probability distribution with a 2-layer neural network:

$$\hat{p_\theta} = softmax(V_2 ReLU(V_1 h + b_1) + b_2),$$

where h can be h_{di} or h_{od} and the hidden size is l. We use rectified linear units (ReLU) as activation function.

4 Experimental Setup

4.1 Dataset and Evaluation Metric

To evaluate the proposed model, we conduct experiments on two tasks: semantic relatedness and answer selection.

For semantic relatedness task, we use the Sentences Involving Compositional Knowledge (SICK) dataset (Marelli et al., 2014), which consists of 9927 sentence pairs in a 4500/500/4927 train/dev/test split. The sentences are derived from existing image and video description and each sentence pair has a relatedness score $y \in [1, 5]$, where the larger score indicates more similarity between two sentences. As the goal of this task is to calculate sentence pair similarity, we can directly evaluate our model on SICK. Following previous works, we use Pearson's Correlation r, Spearman's Correlation ρ and mean square error (MSE) as evaluation metrics.

For answer selection task, we experiment on two datasets: TrecQA and WikiQA. The TrecQA dataset (Wang et al., 2007) from the Text Retrieval Conferences has been widely used for the answer selection task during the past decade. The original TrecQA train dataset consists of 1,229 questions with 53,417 question-answer pairs, 82 questions with 1,148 pairs in development set, and 100 questions with 1,517 pairs in test set. Recent works (dos Santos et al., 2016; Rao et al., 2016; Wang et al., 2016b) removed questions in development and test set with no answers or with only positive/negative answers, thus there are 65 questions with 1,117 pairs in *Clean version* development set and 68 questions with 1,442 pairs in *Clean version* test set. Rao et al. (2016) has showed the performances on Original TrecQA and *Clean version* TrecQA are not comparable. Therefore, for a fair comparison, we only display the results on *Clean version* TrecQA which are posted on the website of Wiki of the Association for Computational Linguistics[1]. The open domain question-answering WikiQA (Yang et al., 2015) is constructed from real queries of Bing and Wikipedia. We follow Yang et al. (2015) to remove all questions with no correct candidate answers. The excluded WikiQA has 873/126/243 questions and 8627/1130/2351 question-answer pairs for train/dev/test split. To adapt our model to this task, we use semantic similarity to measure the probability of matching between a question and a candidate answer. We evaluate models by mean average precision (MAP) and mean reciprocal rank (MRR).

4.2 Training Details

For experiments on SICK, we follows Tai et al. (2015) to transform the relatedness score y to a sparse target distribution p:

$$p_i = \begin{cases} y - \lfloor y \rfloor, & i = \lfloor y \rfloor + 1 \\ \lfloor y \rfloor + 1 - y, & i = \lfloor y \rfloor \\ 0, & otherwise \end{cases}$$

for $1 \leq i \leq 5$. The training objective is to minimize the KL-divergence loss between p and $\hat{p_\theta}$:

$$loss = \frac{1}{|D|} \sum_{k=1}^{|D|} KL(p^{(k)} \parallel \hat{p_\theta}^{(k)})$$

where $|D|$ is the number of training examples.

We regard the answer selection problem as "yes" or "no" binary classification and the training objective is to minimize the negative log-likelihood in training stage:

$$loss = -\frac{1}{|D|} \sum_{k=1}^{|D|} log\hat{p_\theta}^{(k)}(y^{(k)}|x^{(k)})$$

where $x^{(k)}$ represents a question-answer pair and $y^{(k)}$ indicates whether the candidate answer is cor-

[1] https://www.aclweb.org/aclwiki/index.php?title=Question_Answering_(State_of_the_art)

rect to the question. In test stage, we sort condidate answers for same question in descending order by probability of "yes" category and calculate MAP and MRR.

In all experiments, we use 300-dimension GloVe word embeddings[2] (Pennington et al., 2014) and fix the embeddings during training. The LSTM hidden size u is set to 150. The hidden size of inter-attention and self-attention layer s and full connection network l are both set to 50. The L2 regularization strength is set to 3×10^{-5}. We train the model with Adagrad (Duchi et al., 2011) optimization algorithm with a learning rate of 0.05. The minibatch size is always 25. We exploit early stopping strategy according to MSE on development set for SICK and MAP on development set for TrecQA and WikiQA.

4.3 Results

Firstly, we evaluate the effectiveness of two strategies in alignment layer. We use inter-attention model in inter-weighted layer and we find *orthogonal decomposition* (OD) strategy has a superior performance to *direct* (DI) strategy on all datasets. The comparison results are posted in Table 1. In following experiments, we always choose OD strategy in alignment layer.

Semantic Relatedness Table 3 shows the performances of our model and compared models on SICK dataset. IWAN-att and IWAN-skip represents our models using inter-attention layer and inter-skip layer respectively. IWAN-skip outperforms IWAN-att in all metrics by a small margin. The traditional feature engineering based models in first group have much poorer performances than deep learning models. MaLSTM (Mueller and Thyagarajan, 2016) benefits from the data argumentation strategy with Wordnet information and pre-training process. Ablation experiments (Mueller and Thyagarajan, 2016) illustrates a 0.04 degradation of Pearson's r without data argumentation strategy. Therefore it is unfair to compare with this model directly, but our models achieve a comparable performance with it. Our models both outperform all other deep learning models. IWAN-skip outperforms Attentive Tree-LSTM (Zhou et al., 2016) by 0.01 in Pearson's r, over 0.01 in Spearman's ρ and almost 0.02 in MSE, although it exploits syntactic parser information. Our model significantly outperforms sentence modeling based models with CNN or RNN which results from the absence of interaction information. He and Lin (2016) proposes Pairwise Word Interaction Model (PWIM) which constructs 19-layer CNN on similarity matrix to capture fine-grained interaction information and shows most competitive. However our model outperforms it in all metrics with much fewer parameters (about 0.65 million versus 1.7 million (He and

[2] http://nlp.stanford.edu/projects/glove/

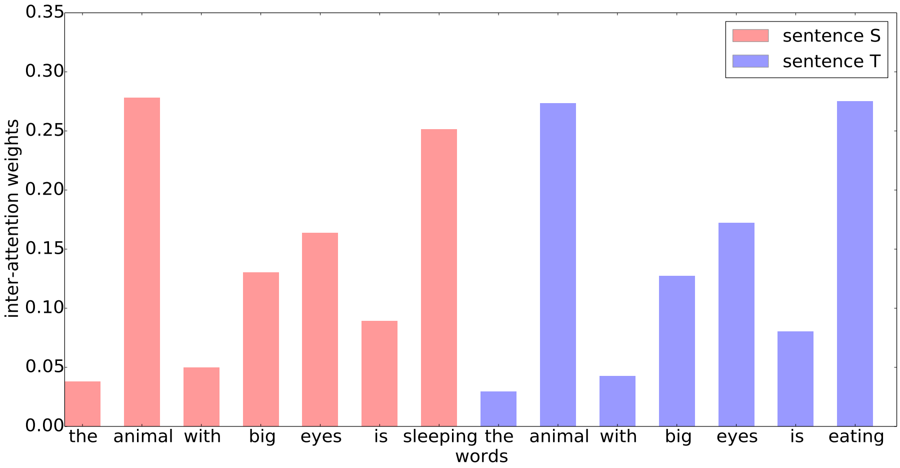

Figure 3: Visualization of weights outputted by inter-weighted layer of words in a sentence pair in SICK test set.

Lin, 2016)).

Answer Selection We compare our model with several state-of-the-art models on *Clean version* TrecQA and WikiQA in Table 3 and Table 4 respectively. Our two models both have a state-of-the-art performance on two datasets. IWAN-att outperform all previous works on TrecQA and make a significant improvement of state-of-the-art. IWAN-skip and IARNN (Wang et al., 2016a) which solves bias problem of attention mechanism beat all other models on WikiQA, while the latter is trained on an argumented dataset with negative sampling. Wang et al. (2016b) first proposes the orthogonal decomposition but their LDC model compute the similarity matrix between word embeddings which are lack of context information and IWAN-att outperforms it dramatically by 0.02-0.05 in MAP and MRR on both datasets. The PWIM (He and Lin, 2016) is still competitive on WikiQA but gets an inferior performance on TrecQA. However, our models both have state-of-the-art performances on three datasets which demonstrates our models have excellent generalization ability in different datasets.

4.4 Ablation Tests

Table 5 show the results of ablations tests on SICK dataset in r metric. From IWAN-att, we remove or replace one component at a time and evaluate performance of partial models. If removing inter-features, the r degrades with a 0.013 decline which proves the interaction information is crucial for sentence pair modeling. Whereas, the degradation from removing self-features is much smaller. We found a large decline when removing BiLSTM layer, which confirms our conjecture that context information is useful. It is worth mentioning that He and Lin (2016) posts the degradation of their model from removing BiLSTM is 0.1225 in r which is much larger than 0.0387 of us. Removing inter-attention layer means we perform a mean-pooling on inter-features instead of a weighted summation. A 0.0075 r degradation proves importance weighting can result in a significant improvement. If the weights are only about single sentence information, the performance still gets worse. The last two settings show both components from orthogonal decomposition are informative. More or less unexpected, parallel component is almost as useful as orthogonal component.

Ablation setting	**Pearson's r**
Full Model (IWAN-att)	0.8810
• w/o inter-features	-0.0130
• w/o self-features	-0.0070
• w/o BiLSTM layer	-0.0387
• w/o inter-attention layer	-0.0075
• Replace inter-attention weights with self-attention weights	-0.0063
• w/o parallel component	-0.0037
• w/o orthogonal component	-0.0046

Table 5: Ablation test on SICK dataset, removing each component separately.

4.5 Visualization of Inter-Weighted Layer

In order to illustrate the effect of inter-weighted layer in proposed model, we take a sentence pair in SICK test set as an example and display the weights outputted by inter-attention layer of each word in Figure 3. The ground truth of this pair is

3.2 and the prediction given by IWAN-att model is 3.507 which is much more accurate than 4.356 given by the model without inter-attention layer. We can find the inter-attention layer gives very high weights over 0.25 (while the average weight is about 0.14) to “sleeping” and “eating” which are the only difference between two sentences. Therefore, the difference will be attended in following processing. Meanwhile, the weights of the article “the” and the preposition “with” which are not as important as other real words in semantic composition are much lower. These prove the inter-weighted mechanism is reasonable and effective.

5 Conclusion

This work proposes a weighted alignment model for sentence pair modeling. We utilize an alignment layer to measure the similarity of sentence pairs according to their degree of alignment. Moreover, we propose an inter-weighted layer to measure the importance of different parts in sentences. Two strategies for this layer have been explored which are both effective. The composition of alignment features can benefit from the inter-weighted weights. Experiment results shows that proposed models achieve the state-of-the-art performance on three datasets. In the future work, we will improve the inter-weighted layer with more sophisticated module and evaluate our model on other large scale datasets.

chywang2013@gmail.com, {xfhe,ayzhou}@sei.ecnu.edu.cn

Abstract

A taxonomy is a semantic hierarchy, consisting of concepts linked by is-a relations. While a large number of taxonomies have been constructed from human-compiled resources (e.g., Wikipedia), learning taxonomies from text corpora has received a growing interest and is essential for long-tailed and domain-specific knowledge acquisition. In this paper, we overview recent advances on taxonomy construction from free texts, reorganizing relevant subtasks into a complete framework. We also overview resources for evaluation and discuss challenges for future research.

1 Introduction

A taxonomy is a semantic hierarchy that organizes concepts by is-a relations, which exhibits the capability of improving many NLP and IR tasks, such as query understanding (Hua et al., 2017), personalized recommendation (Zhang et al., 2014), question answering (Yang et al., 2017), etc. It also supports a variety of real-world applications, including information management (Nickerson et al., 2013), e-commerce (Aanen et al., 2015) and biomedical systems (Köhler et al., 2014).

With massive Web data available, a number of taxonomies are constructed from human-compiled resources such as Wikipedia, Wikidata, etc (Suchanek et al., 2007; Ponzetto and Navigli, 2009; Flati et al., 2014; Mahdisoltani et al., 2015). But even large taxonomies may lack domain-specific and long-tailed knowledge. Recently, several methods have been developed to induce taxonomies from text corpora (Wu et al., 2012; Yang, 2012; Luu et al., 2014). However, this task is far from being solved for three reasons: i) Text corpora may vary in size, topic and quality. It is unlikely to develop a "one-size-fits-all" solution for all scenarios. For example, given an extremely large corpus, Hearst-pattern based method is employed to build Probase (Wu et al., 2012). For domain-specific corpora, learning hypernymy embedding is more suitable (Luu et al., 2016b). ii) The accuracy of free-text taxonomies is usually lower than many Wikipedia-based taxonomies because it is difficult to extract knowledge completely from texts; iii) The task of taxonomy learning is still insufficiently studied a) in emerging and specific domains and b) for non-English or under-resourced languages (Wei et al., 2014; Alfarone and Davis, 2015; Wang et al., 2015).

In this paper, we overview recent advances on taxonomy construction from text corpora, reorganizing relevant subtasks into a complete framework. The subtasks include hyponym acquisition, hypernym prediction, taxonomy induction, etc. We also summarize resources, evaluation metrics and state-of-the-art results. We also discuss issues and directions for future research.

2 Taxonomy Construction Techniques

Although workflows of different methods vary, a free text-based taxonomy construction system typically operates in two steps: i) extracting is-a relations using *pattern-based* (Sect. 2.1) or *distributional* methods (Sect. 2.2); ii) constructing a complete taxonomy from is-a relations (Sect. 2.3).

2.1 Pattern-based Methods

Traditional pattern based methods predict that there is an is-a relation between a term pair (x, y), if x and y appear in the same sentence and satisfy a particular pattern. The earliest and most influential work in this field is Hearst (1992), which handcrafts several lexical patterns to harvest is-a relations. A typical pattern is "[C] such as [E]", where

Copenhagen, Denmark, September 7–11, 2017. ©2017 Association for Computational Linguistics

[C] and [E] are placeholders of noun phrases that are regarded as the hypernym (class) y and the hyponym (entity) x respectively for an is-a relation (x, y). Based on Hearst patterns, Probase is constructed from billions of Web pages. It consists of 2.65 million concepts and 20.76 million is-a relations (Wu et al., 2012). Similar approaches are presented in Etzioni et al. (2004); Kozareva and Hovy (2010), which employ Hearst patterns to induce taxonomies from Web pages.

Despite the successful applications, these patterns are too specific to cover all linguistic circumstances, thus recall is sacrificed (Wu et al., 2012). Simple pattern matching is prone to error due to idiomatic expressions, parsing errors, incomplete/uninformative extractions and ambiguous issues (Kozareva et al., 2008; Etzioni et al., 2004). In the next part, we summarize key techniques to improve precision and recall for pattern-based methods. Note that a robust is-a relation extraction system may combine multiple techniques to achieve high precision and recall.

2.1.1 Methods Improving Recall

Pattern Generalization Several approaches either extend original Hearst patterns by linguistic rules or learn more generalized lexico-syntactic patterns. Ritter et al. (2009) increase recall by replacing the noun phrase "[E]" (i.e., candidate hyponym) in Hearst patterns with a list of k noun phrases. Luu et al. (2014) design more flexible patterns where a few words in such patterns are interchangeable. Automatic methods mine is-a patterns given a collection of seed instances as input. Snow et al. (2004) use the dependency path of two terms to represent the pattern, where both syntactic and lexical connections of two terms can be modeled. This practice is more resistent to noise than surface matching and is employed by a number of relation extraction systems (Snow et al., 2006; Banko et al., 2007; Shwartz et al., 2016).

The number of patterns generated from a text corpus is sufficiently large, causing the feature sparsity problem. Learning more abstract patterns from these "raw" patterns can improve the generality of these patterns, hence increases recall. Navigli and Velardi (2010) introduce the concept "star pattern" (which use wildcards to replace non-frequent words in sentences). More general patterns are created by clustering star patterns. In the PATTY system (Nakashole et al., 2012), a subset of words along the dependency path are replaced by their POS tags, ontological types or wildcards.

Iterative Extraction Incorrect relations are frequently extracted from overly generalized patterns due to language ambiguity and *semantic drift* (Carlson et al., 2010). In contrast to above-mentioned approaches, an opposite idea is to use extremely specific patterns. Kozareva et al. (2008) employ "doubly-anchored" patterns (e.g., "cars such as Ford and *") to harvest hyponyms for a particular hypernym and expand both hyponyms and hypernyms by a bootstrapping loop. It uses each pattern as a query and takes search engine results as a Web corpus. Another advantage is that the ambiguity of terms can be eliminated by "doubly-anchored" patterns. Similar to Kozareva and Hovy (2010); Carlson et al. (2010), new is-a relations and hypernym patterns are iteratively extracted in an automatic manner.

Hypernym Inference This type of methods overcome the limitation where x and y must appear in the same sentence. The idea of Ritter et al. (2009) is that if y is a hypernym of x and another term $x^{'}$ is sufficiently similar to x, there is a high probability that y is a hypernym of $x^{'}$. They train an HMM to learn a better similarity measure than vector-based approaches. In the Syntactic Contextual Subsumption (SCS) method (Luu et al., 2014), given a non-taxonomic relation r, denote $S_r(x)$ as the collection of objects such that for each $s \in S_r(x)$, x and s has the relation r. If $S_r(y)$ mostly contains $S_r(x)$ but not vice versa, we can infer y is a hypernym of x.

Syntactic inference on hyponym modifiers can generate additional is-a relations. For example, the machine can infer a grizzly bear is a bear based on the evidence that the head word of "grizzly bear" is "bear". In Taxify (Alfarone and Davis, 2015), the system adds the linguistic head of a multi-word term as its direct hypernym if the term is added to the taxonomy. Suchanek et al. (2007) link conceptual Wikipedia categories to WordNet synsets based on category head words. Gupta et al. (2016) introduce linguistic heuristics to derive is-a relations from Wikipedia category network. Besides English, a similar observation also holds for Chinese, as shown in Fu et al. (2013); Li et al. (2015).

2.1.2 Methods Improving Precision

Confidence Assessment After candidate is-a pairs (x, y) are extracted, statistical measures can be used to estimate confidence scores. Relations with low scores are discarded. In KnowItAll (Etzioni et al., 2004), the system estimates the pointwise mutual information (PMI) of x and y by search engine hit counts. Probase (Wu et al., 2012) employs the ratio of likelihood to determine the most possible hypernym y for a concept x, and reversely the most possible hyponym x for a concept y. Wu et al. (2012) further calculate the plausibility of extracted is-a pairs based on a Naive Bayes classifier. Besides statistics from extraction results, Luu et al. (2014, 2015) consider external factors, such as the inclusion of concepts in WordNet and dictionaries, as well as the trustworthiness of data sources (e.g. Web pages). The experience of building Google's Knowledge Vault (Dong et al., 2014) shows that assessing confidence scores is essential for acquiring and fusing knowledge from different extractors.

It is worth nothing that the negative evidence can be also employed to estimate confidence scores. A recent approach (Wang and He, 2016) uses statistics of both hypernym and co-hyponym patterns to give each pair a positive score and a negative score. Experiments show that using negative scores improves precision by discarding co-hyponym relations that are incorrectly predicted as is-a relations by their model.

Classification-based Validation These methods train a classifier f to predict the correctness of an extracted pair (x, y). Models of choice typically include SVM, logistic regression and neural nets. The features for f can be roughly divided into following categories: surface name, syntax, statistics, external resources, etc. In the literature, Snow et al. (2004, 2006) use the dependency paths between x and y as features in the corresponding lexico-syntactic patterns. Ritter et al. (2009) introduce a list of features based the frequency of matches between a pair and Hearst patterns, such as the number of matches for "x is a y" in a corpus. Surface name features (Bansal et al., 2014) consider the word formation of x and y, including whether x and y are capitalized, whether x ends with y. Bansal et al. (2014) further employ statistics derived from matches of Hearst patterns in the corpus and Wikipedia abstracts. This is because abstracts in Wikipedia contain definitions and summaries about concepts that can be used for inferring is-a relations.

Using both pattern-based and distributional representations of x and y can also enhance the performance of the classifier, as shown in Shwartz et al. (2016). This technique can be viewed as a combination of pattern-based and distributional methods, which will be discussed in details in Sect. 2.2.4.

2.2 Distributional Methods

Distributional methods predict is-a relations between terms based on their distributional representations, by either *unsupervised measures* (Sect. 2.2.2) or *supervised models* (Sect. 2.2.3). Because they directly *predict* is-a relations instead of *extracting* all is-a relations in a corpus, we briefly introduce how to obtain key terms to form term pairs as candidate is-a relations (Sect. 2.2.1).

2.2.1 Key Term Extraction

The first step for predicting is-a relations is to generate candidate hyponyms/hypernyms. For free texts, they are usually *key terms*, which are nouns, noun phases and/or named entities that frequently appear in the corpus. The key terms can be identified by applying POS tagging or NER tools to the corpora and then using rule-based extractors (Yang, 2012; Zhu et al., 2013; Luu et al., 2014). Existing keyword or key phrase extractors can be also used to recognize these terms automatically (Navigli et al., 2011; Qureshi et al., 2012; da Silva Conrado et al., 2013; Liu et al., 2015).

For learning domain-specific taxonomies, an important post-processing step after extracting key terms is *domain filtering*. This filters out terms not in the domain of interest, improving the taxonomy precision. A term can be filtered by statistics-based cuts, which include TF, TF-IDF, domain relevance, domain consensus (Navigli and Velardi, 2004; de Knijff et al., 2013) and domain specificity scores (Alfarone and Davis, 2015). To ensure the extracted terms are important concepts in a particular domain, several methods only harvest terms from domain definitive sentences (Navigli et al., 2011; Velardi et al., 2013; Anke et al., 2016b). Specially, Navigli et al. (2011) propose to use domain weights to select sentences that define unambiguous terms pertained to the domain of interest.

2.2.2 Unsupervised Measures

We first survey various unsupervised measures for is-a relation identification. After that, feature representations are introduced for these measures.

Distributional Similarity Measures Early work of *distributional similarity measures* mostly focuses on *symmetric* measures such as cosine, Jaccard, Jensen-Shannon divergence and the widely cited LIN measure (Lin, 1998):

$$\text{LIN}(x,y) = \frac{\sum_{f \in F_x \cap F_y} w_x(f) + w_y(f)}{\sum_{f \in F_x} w_x(f) + \sum_{f \in F_y} w_y(f)}$$

where x and y are candidate hyponyms and hypernyms respectively. F_x and F_y are features of x and y. $w_x(f)$ is the weight of feature f for word x. But they only learn semantic similarity of words.

Asymmetric measures model the *asymmetric* property of is-a relations, following the *Distributional Inclusion Hypothesis* (DIH) (Geffet and Dagan, 2005; Zhitomirsky-Geffet and Dagan, 2009). It assumes that a hyponym only appears in some of its hypernym's contexts, but a hypernym appears in all contexts of its hyponyms. For example, the concept "fruit" has a broader spectrum of contexts than its hyponyms, such as "apple", "banana" and "pear". As an example, Weeds et al. (2004) propose a simple measure *WeedsPrec* to compute the weighted inclusion of features of y within features of x:

$$\text{WeedsPrec}(x,y) = \frac{\sum_{f \in F_x \cap F_y} w_y(f)}{\sum_{f \in F_y} w_y(f)}$$

Other asymmetric measures are introduced in a variety of research, e.g., WeedsRec (Weeds et al., 2004), BalAPInc (Kotlerman et al., 2010), ClarkeDE (Clarke, 2009), cosWeeds, invCL (Lenci and Benotto, 2012), WeightedCosine (Rei and Briscoe, 2014). Detailed summarization of distributional similarity measures can be found in an early survey on vector space semantic models (Turney and Pantel, 2010).

More recently, several studies suggest that DIH is not correct for all the cases (Santus et al., 2014; Rimell, 2014). For example, "American" is a hypernym of "Barack Obama" but the (politics-related) contexts of "Barack Obama" cannot be covered by those of "American". Most contexts of a hypernym are less informative and more general than those of its hyponyms. To solve this problem, Santus et al. (2014) propose an entropy-based measure SLQS for hypernym detection. Roller et al. (2014) introduce the *Selective Distributional Inclusion Hypothesis*, which means the original DIH is correct, but only for relevant dimensions.

Features For each term x, a collection of features F_x are generated from the text corpus, where each feature $f \in F_x$ represents a contextual word with which x co-occurs (Lin, 1998; Weeds et al., 2004). In some work, f also specifies the syntactic relation between x and f (Lin, 1998). As stated in Padó and Lapata (2003), the usage of syntactic-based vector space model can better distinguish different lexical relations than the simple "Bag-of-Words" co-occurrence model. In addition, Schütze (1993) use the context word and the position relative to the target term as features. Baroni and Lenci (2010) propose a Distributional Memory framework to generate word-link-word features. Yamada et al. (2009) use raw verb-noun dependencies and cluster such dependencies to generate feature vectors

The value of each feature is determined by a weight function $w_x(f)$, which quantifies the statistical association between the feature f and the corresponding word x. Choices of $w_x(f)$ include the (point-wise) Mutual Information (PPMI) (Weeds et al., 2004), Local Mutual Information (LMI) (Evert, 2005). Dimension reduction methods such as SVD can be employed to create dense vectors (Roller and Erk, 2016).

2.2.3 Supervised Models

With training sets available, *classification/ranking methods* train a model to predict hypernymy based on the representations of a term pair (x, y). *Hypernym generation* approaches directly model how to "generate" hypernyms based on the representations of hyponyms in the embedding space.

Classification In classification methods, the most popular representations for x and y are word embeddings generated by pre-trained neural language models such as Word2Vec (Mikolov et al., 2013), GloVe (Pennington et al., 2014) and ivLBL (Mnih and Kavukcuoglu, 2013). SensEmbed (Iacobacci et al., 2015) generates different embeddings for different senses of the same word.

The *concat* model combines term-pair vectors by $\vec{x} \oplus \vec{y}$ where $\vec{x}$ is the embedding vector of word x, then trains an off-the-shelf classifier such as SVM (Baroni et al., 2012). This model is regarded as a strong baseline in some papers (Kruszewski et al., 2015; Shwartz et al., 2016; Mirza and Tonelli, 2016). Recent work points out that it has a serious problem of *lexical memorization* (Roller et al., 2014; Levy et al., 2015; Weeds et al., 2014). It means that the classifier learns the semantics of terms rather than the relations between the terms.

Consequently, when the training sets and testing sets are significantly different, the model suffers from a poor performance.

To over this problem, the *diff* model uses vector offsets as features, represented as $\vec{y} - \vec{x}$ (Rimell, 2014; Weeds et al., 2014; Fu et al., 2014). The *asym* model is presented in Roller et al. (2014), using both vector difference and squared vector difference features. The *simDiff* model (Turney and Mohammad, 2015) employs the difference of two word-context matrices (i.e., domain matrix and function matrix) as features for relation classification. Additionally, other combinations of vectors are mentioned in the literature, such as vector sum $\vec{x} + \vec{y}$, and dot-product $\vec{x} \cdot \vec{y}$ (Shwartz et al., 2016). Roller and Erk (2016) exploit Hearst patterns in distributional vectors and introduce a PCA-like iterative procedure to learn *concat* classifiers. Kruszewski et al. (2015) learn mappings from distributional vectors to boolean-valued vectors, where the output vectors correspond to entailment between words.

In neural language models (Mikolov et al., 2013; Pennington et al., 2014), words that occur in similar contexts have similar embeddings. Yu et al. (2015) argue that this modeling technique is not strong enough to learn term embeddings for is-a relation prediction. For each word x, they learn two types of embeddings $\vec{x}_o$ and $\vec{x}_e$, representing the embeddings of x when x functions as a hyponym and a hypernym, respectively. The embeddings are generated by training a distance-margin based neural net. Luu et al. (2016b) further extend this approach by modeling the contexts between hypernyms and hyponyms in a dynamic weighting neural net. Li et al. (2016) design a joint model based on negative sampling to embed entities and categories jointly into the same semantic space. The high performance shows that using task-specific embeddings is more effective than general-purpose embeddings.

Hypernym Generation *Hypernym generation* approaches make prediction for a pair (x, y) by whether the model can map $\vec{x}$ to a vector close to $\vec{y}$. Fu et al. (2014) is a pioneer work in this field, which employs uniform linear projection and piecewise linear projection to map the embeddings of a hyponym to its hypernym. After that, three approaches (Wang and He, 2016; Yamane et al., 2016; Tan et al., 2015) have been proposed to extend Fu et al. (2014). Wang and He (2016) update transition matrices and extract new is-a relations iteratively. They improve the performance of the piecewise projection model when training sets and test sets have little overlap in the semantic space. Yamane et al. (2016) learn the number of clusters and transition matrices jointly by dynamically clustering is-a pairs. Tan et al. (2015) replace the transition matrix with the embedding of “is-a”. As shown in Yamane et al. (2016), these methods are comparable to state-of-the-art classification approaches in terms of F-measure. Additionally, by domain clustering, the approach (Fu et al., 2014) is modified to a transfer learning version that is sensitive to target data sources for domain adaptation (Anke et al., 2016a).

The negative sampling technique proves effective to enhance projection learning. This is because the representations of hypernymy relations are sometimes confused with synonymy, co-hyponymy and meronymy. In Ustalov et al. (2017), an additional regularization term is added to the model of Fu et al. (2014) to take the advantage of the semantics of not-is-a relations. Wang et al. (2017) explicitly learn the representations of not-is-a relations so that the true hypernymy relations are better distinguished. This method considers the representations of both is-a and not-is-a relations, hypernym-level similarity and linguistic rules in a transductive learning setting.

Ranking As an alternative approach, Fu et al. (2013) present a ranking model to select the most probable hypernym for an entity. Replacing a classification model with a ranking model is not a common practice for extracting is-a relations, due to its low recall. However, this method is specifically engineered for the Chinese language. As shown in (Fu et al., 2014; Wang et al., 2015; Li et al., 2015; Wang and He, 2016), learning Chinese is-a relations is fundamentally challenging due to flexible language expressions. Thus it is necessary to train a ranking model to extract Chinese is-a relations with high precision.

2.2.4 Discussion

In the literature, there are some disagreements on which methods are more effective for is-a relation prediction. For example, Shwartz et al. (2016) claim that distributional methods outperform pattern-based approaches, while Levy et al. (2015) hold the opinion that distributional methods do not even work. We overview major viewpoints in the research community and analyze pros and cons for both types of methods.

Pattern-based methods extract is-a relations (x, y) based on the lexico-syntactic paths connecting x and y in a corpus, which explicitly express the relation. The original Hearst patterns (Hearst, 1992) and more generalized patterns have been used in a large number of taxonomies (Wu et al., 2012; Navigli et al., 2011). A disadvantage is that using patterns as features may result in the sparsity of the feature space (Nakashole et al., 2012). Most methods require x and y to co-occur in the same sentence. Hence, the recall is limited. Besides, they are overly language-dependent and difficult to use if there are few Hearst-like patterns in other languages. For example, as shown in Fu et al. (2014); Wang and He (2016), they suffer from extremely low recall for the Chinese language.

In contrast, distributional approaches use word representations derived from contexts, independent of its hyponym or hypernym. The usage of word embeddings (Mikolov et al., 2013) allows machines to make predictions based on the entire corpus. However, distributional methods are less precise in detecting specific, strict is-a relations and tend to discover broad semantic similarity between terms (Shwartz et al., 2016; Yu et al., 2015). As Weeds et al. (2014) discover, some terms detected by distributional methods are co-hyponyms and meronyms, rather than hypernyms. Another drawback is that the representations are domain dependent and the models are heavily related to the training set (Roller et al., 2014). Yet a further criticism is pointed out by Levy et al. (2015). They find that supervised distributional methods actually learn whether y is a "prototypical hypernym", instead of the relation between x and y. This is because the features $\vec{x}$ and $\vec{y}$ are generated independently. They integrate the intra-pair similarity with the *diff* model by kernel functions but only achieves an incremental improvement.

Despite their own disadvantages, pattern-based and distributional methods have been considered complementary. The idea of integrating them has been proposed early (Mirkin et al., 2006; Kaji and Kitsuregawa, 2008) but have not drawn much attention over the years. Recently, the HyperNET system (Shwartz et al., 2016) represents a pair (x, y) by both distributional and pattern-based features. Each pattern is represented by a dependency path, and embedded by an LSTM model (Hochreiter and Schmidhuber, 1997). Experiments show that the joint representation improves the performance notably, having F1-scores of 0.901 and 0.700 over two large datasets. In contrast, the best pattern-based method (i.e., an extension of Snow et al. (2004)) has the performance of 0.761 and 0.660. The best distributional approach based on the *concat* model has the performance of 0.746 and 0.637. An extension of the previous model named LexNET (Shwartz and Dagan, 2016) is proposed to recognize multiple relations.

2.3 Taxonomy Induction

In this part, we summarize techniques for creating taxonomies from is-a relations.

Incremental Learning Several methods construct an entire taxonomy from a "seed" taxonomy via incremental learning. Snow et al. (2006) enrich WordNet by maximizing the probability of an extended taxonomy based on the evidence of is-a and cousin relations harvested from texts. They focus on extracting new entities and attaching them to the semantic hierarchy of WordNet. Shen et al. (2012) observe that the extracted terms can either refer to existing entities in the taxonomy or new ones, and propose a graph-based method to link these terms to the taxonomy or insert new entities into the taxonomy. While these methods rely heavily on existing taxonomies, Kozareva and Hovy (2010) take a root concept as input only and iteratively extract is-a relations to expand the taxonomy. Alfarone and Davis (2015) further consider the problem that a "seed" taxonomy cannot be obtained in a specific domain. They construct the "seed" taxonomy by Hearst pattern matching and heuristic rules.

Clustering Taxonomy learning can be modeled as a clustering problem where similar terms clustered together may share the same hypernym. Hierarchical clustering is employed to cluster similar terms into a taxonomy (Hjelm and Buitelaar, 2008; de Knijff et al., 2013; Meijer et al., 2014). Song et al. (2015) improve the hierarchical clustering technique by scalable Bayesian Rose Trees. A similar idea is also introduced in Alfarone and Davis (2015) where the lowest common ancestor of a collection of terms clustered by K-Medoids is inferred as their common hypernym. The SCS method (Luu et al., 2014) (see Sect. 2.1.1) is also related to clustering because it groups similar terms by non-taxonomic relations, and infer its hypernyms to improve the taxonomy coverage.

Graph-based Induction Graph-based approaches are naturally suitable for this task because taxonomies are generally graphs. Kozareva and Hovy (2010) derive the path from the root to a target term by finding the longest path in a raw graph where edges represent noisy is-a relations. Anke et al. (2016b) calculate the path weights by multiplying the domain pertinence scores of its edges. Another frequently used algorithm is the *optimal branching algorithm* (Velardi et al., 2013; Luu et al., 2014). It first assigns edge weights based on graph connectivity (e.g., in-degree, betweenness, etc.), and finds an optimal branching based on *Chu-Liu/Edmonds's algorithm* (Karp, 1971). After noisy edge removal, a rooted tree is constructed with maximum weights. Bansal et al. (2014) employ a factor graph model to represent terms and is-a relations. The learning of a taxonomy is regarded as a structured learning problem for the model, solved by loopy belief propagation.

Taxonomy Cleansing The final step of taxonomy learning is *taxonomy cleansing*, which removes wrong is-a relations to improve the quality. A recent study on Probase (Wu et al., 2012) shows that incorrect is-a relations may exist in taxonomies in the form of cycles (Liang et al., 2017a). By eliminating cycles, 74K wrong is-a relations are detected. This cycle removal process is also applied in Deshpande et al. (2013); Fu et al. (2014); Li et al. (2015).

Another issue is entity ambiguity. As discussed in Liang et al. (2017b), the transitivity property does not necessarily hold in automatically constructed taxonomies. For example, the facts "(Albert Einstein, is-a, professor)" and "(professor, is-a, position)" do not mean that "(Albert Einstein, is-a, position)". The ambiguity issue has been addressed in a few systems (Anke et al., 2016b; Wu et al., 2012; Ponzetto and Navigli, 2009) by word sense disambiguation. However, it is not fully solved. While learning multiple senses of the word "bank" (a financial institution or riverside) is easy nowadays, it is more challenging to distinguish whether the word "professor" refers to a particular person or a job title in the taxonomy learning process. Based on Liang et al. (2017b), we can safely conclude that there is a long way towards learning a fully-disambiguated taxonomy.

3 Resources and Analysis

In this section, we summarize resources and metrics for taxonomy learning. Results and recommendations for future research are also discussed.

3.1 Resources

There have been a variety of resources for the research of is-a relation prediction. The first type is high-quality taxonomies. knowledge bases and semantic networks. The knowledge in these systems can be used for generating training sets for distant supervised model learning. Typical English resources include WordNet (Miller, 1995), YAGO (Suchanek et al., 2007), WiBi (Flati et al., 2014) and DefIE (Bovi et al., 2015). For languages other than English, refer to multilingual systems (e.g., YAGO3 (Mahdisoltani et al., 2015), BabelNet (Navigli and Ponzetto, 2012), Multi-WiBi (Flati et al., 2016)). We need to point out that these systems are not necessarily all taxonomies but contain rich type hierarchical knowledge. We also summarize some recent (2010$\sim$) test sets and statistics in Table 1[1].

Two shared tasks are designed specifically for taxonomy learning, i.e., TExEval (SemEval-2015 Task 17) (Bordea et al., 2015) and TExEval-2 (SemEval-2016 Task 13) (Bordea et al., 2016)[2]. In TExEval, the goal is to construct taxonomies in four target domains (i.e. chemicals, equipment, food and science), each with gold-standard provided. The setting is expanded to cover four European languages (i.e., English, Dutch, French and

[1] Statistics combine training, validation and test sets. Papers that use subsets of these datasets are not listed. Dataset (Jurgens et al., 2012) is not directly capable of evaluating the task and is processed by Turney and Mohammad (2015).

[2] Due to the relatively large number of submissions, we do not provide citations to every system submitted to TExEval tracks. Readers can refer to the two reports for details.

Italian) in TExEval-2. In this task, the participants are encouraged to use the Wikipedia corpus as input but there are no restrictions on the data sources. In previous studies, several domain-specific corpora have also been employed as inputs for taxonomies, including AI papers (Velardi et al., 2013), biomedical corpora (Alfarone and Davis, 2015), Web pages related to animals, plants and vehicles (Kozareva et al., 2008) and MH370 (Luu et al., 2016a), terrorism reports (Luu et al., 2014), disease reports and emails (Luu et al., 2016a) and Wikipedia corpora related to specific topics.

3.2 Evaluation Metrics

Evaluating hypernymy prediction algorithms is by no means easy. Given a collection of is-a and not-is-a term pairs as ground truth, standard relation classification metrics such as Precision (P), Recall (R) and F-score (F) can be employed to make the comparison (Shwartz et al., 2016; Yu et al., 2015).

However, evaluating the quality of an entire taxonomy is a non-trivial task due to i) the large size of a taxonomy, ii) the difficulty of obtaining gold standard and iii) the existence of multiple aspects that should be considered such as topology, correctness and coverage. If gold standard taxonomies are available, denote $S = (V_S, E_S)$ and $G = (V_G, E_G)$ as the extracted and gold standard taxonomies where V_S and V_G are node sets, E_S and E_G are edge sets. Evaluation metrics introduced in the two shared tasks (Bordea et al., 2015, 2016) are briefly summarized as follows:

- Node coverage: $|V_S \cap V_G|$, $|V_S \cap V_G|/|V_G|$;
- Edge coverage: $|E_S \cap E_G|$, $|E_S \cap E_G|/|E_G|$, $(|E_S| - |E_S \cap E_G|)/|E_G|$;
- Edge correctness: $P = |E_S \cap E_G|/|E_S|$, $R = |E_S \cap E_G|/|E_G|$, $F = 2(P \cdot R)/(P + R)$;
- Cumulative Fowlkes&Mallows (Cumulative F&M) measure (Velardi et al., 2013).

The second type of metrics compares taxonomies generated by different methods. Size ($|V_S|$ and $|E_S|$) and quality are two factors to be considered. Human assessment is required to estimate the accuracy by sampling and labeling edges. Additionally, topological statistics, including the numbers of simple directed cycles, connected components and intermediate nodes, can check whether the taxonomy is a Direct Acyclic Graph (DAG) and well-structured.

3.3 Result Analysis and Discussion

While we have discussed is-a relation prediction in Sect. 2.2.4, we mostly focus on the overall performance for taxonomy learning in this part.

We first analyze results of the two shared tasks (Bordea et al., 2015, 2016) as they report performance of a variety of methods. In both task, two pattern-based methods (i.e., INRIASAC (Grefenstette, 2015) in TExEval and TAXI (Panchenko et al., 2016) in TExEval-2) consistently outperform others. INRIASAC uses frequency-based co-occurrence statistics, and substring inclusion heuristics to extract a set of hypernyms for hyponyms. TAXI crawls a domain-specific corpora and employs lexico-syntactic patterns and substrings for domain is-a relation extraction. However, the potential of distributional methods is not fully exploited as only one system uses such techniques. Besides, different systems may use their own corpora in these tasks and hence the results do not directly reflect the "goodness" of these algorithms. In multilingual tasks, there is a large decrease in performance w.r.t. other languages in TAXI. The research (Fu et al., 2014; Wang and He, 2016) shares a similar experience when several effective algorithms for English do not really work for Chinese. This phenomenon calls for language-specific algorithms for non-English language sources.

For other works, although knowledge sources and domains may differ, we notice that they suffer from the *low recall* problem. For example, recall values of Bansal et al. (2014); Luu et al. (2014); Navigli et al. (2011); Kozareva and Hovy (2010) are lower than 50% in most cases and domains. While improving precision is relatively easy by imposing constraints, increasing recall is more challenging because we aim to identify all is-a relations, no matter whether the relations are expressed explicitly or implicitly, in one or multiple sentences (Shwartz et al., 2016). This problem becomes severe when less focused and dynamic domains are considered (Velardi et al., 2013).

3.4 Our Recommendations

Based on our analysis, we discuss our recommendations to improve the performance of taxonomy learning that have not been sufficiently addressed.

Ensemble Representations and Deep Architectures Shwartz et al. (2016) show that combining pattern-based and distributional methods can improve the performance of is-a relation extraction. We suggest that the performance can be further improved by studying how the two types of approaches reinforce each other. Neural network models (Yu et al., 2015; Luu et al., 2016b) are effective to learn deeper representations of both features. In our opinion, It is also possible to solve the problem put forward by Levy et al. (2015) by adding the information of semantic relatedness between term pairs mined from patterns to distributed representations.

Another related topic is that despite several embedding learning methods mentioned above, there is only limited success of deep learning paradigms for the taxonomy induction. We believe this is mostly because it is difficult to design a single objective for neural networks to optimize for this task. Hence how to take advantage of the deep learning boom for taxonomy induction is worth researching in the future.

Benchmarks and Evaluation Benchmarks for taxonomy learning are crucial to quantify the performance of state-of-the-arts. Benchmarks should contain text corpora, gold standards and evaluation metrics. Bordea et al. (2015, 2016) have provided some gold standard taxonomies in several domains and languages but do not require all the systems to run over the same corpus. Other works use standard test sets and data sources, as we have summarized in Sect. 3.1.

Several issues in current benchmarks and methods have already been pointed out by previous works. Levy et al. (2015) show that supervised systems actually over-perform due to the lexical memorization problem. Shwartz et al. (2017) suggest that unsupervised approaches are more robust than supervised methods but supervised methods outperform unsupervised ones. Camacho-Collados (2017) discuss whether the hypernymy detection task is indeed an appropriate task for evaluating is-a relations in the context of taxonomy learning systems or their integration in downstream applications. We can see that more in-depth research should be done towards a complete, widely-accepted benchmark for evaluation.

Unambiguous and Canonicalized Terms For lexical taxonomies, a term may have multiple surface forms and senses. The ambiguity issue makes taxonomy-based applications prone to error (Liang et al., 2017b). It is desirable to construct taxonomies where each node represents an unambiguous term associated with its possible surface forms and their contexts. In this way, the taxonomy automatically supports entity linking and is beneficial for IR applications (e.g., Web search) (Shen et al., 2015; Hua et al., 2017).

Incorporating Domain Knowledge Domain knowledge is essential for term and relation extraction in domain-specific corpora but it is difficult to obtain from such limited corpora. By exploiting facts derived from domain knowledge bases, a domain taxonomy would be learned via distant supervision and have higher coverage than existing methods (Alfarone and Davis, 2015). Thus, it is an important task to construct a taxonomy based on a text corpus and a knowledge base of a specific domain.

Non-English and Under-resourced Languages The task addressed in this paper has not been extensively studied for under-resourced languages. Specifically, pattern-based methods, although effective for English, are language-dependent to a large extent. How to apply existing approaches to languages that are significantly different from English (e.g., Chinese, Arabic and Japanese) is worthy of research.

4 Conclusion

In this paper, we present a survey on taxonomy learning from text corpora. We overview pattern-based and distributional methods to learn hypernymy from texts, and discuss how to induce taxonomies from is-a relations. While there is significant success, this task is still far from being solved. By addressing the issues discussed in this paper, we suggest that high-quality taxonomies can be constructed in more domains and languages, having a greater influence in NLP and IR research.

Abstract

Idioms are peculiar linguistic constructions that impose great challenges for representing the semantics of language, especially in current prevailing end-to-end neural models, which assume that the semantics of a phrase or sentence can be literally composed from its constitutive words. In this paper, we propose an idiom-aware distributed semantic model to build representation of sentences on the basis of understanding their contained idioms. Our models are grounded in the literal-first psycholinguistic hypothesis, which can adaptively learn semantic compositionality of a phrase literally or idiomatically. To better evaluate our models, we also construct an idiom-enriched sentiment classification dataset with considerable scale and abundant peculiarities of idioms. The qualitative and quantitative experimental analyses demonstrate the efficacy of our models. The newly-introduced datasets are publicly available at `http://nlp.fudan.edu.cn/data/`

1 Introduction

Currently, neural network models have achieved great success for many natural language processing (NLP) tasks , such as text classification (Zhao et al., 2015; Liu et al., 2017), semantic matching (Liu et al., 2016a,b), and machine translation (Cho et al., 2014). The key factor of these neural models is how to compose a phrase or sentence representation from its constitutive words. Typically, a shared compositional function is used to compose word vectors recursively until obtaining the representation of the phrase or sentence. The form of compositional function involves many kinds of neural networks, such as recurrent neural networks (Hochreiter and Schmidhuber, 1997; Chung et al., 2014), convolutional neural networks (Collobert et al., 2011; Kalchbrenner et al., 2014), and recursive neural networks (Socher et al., 2013; Tai et al., 2015; Zhu et al., 2015).

However, these methods show an obvious defect in representing idiomatic phrases, whose semantics are not literal compositions of the individual words. For example, “`pulling my leg`” is idiomatic, and its meaning cannot be directly derived from a literal combination of its contained words. Due to its importance, some previous work focuses on automatic identification of idioms (Katz and Giesbrecht, 2006; Li and Sporleder, 2009; Fazly et al., 2009; Peng et al., 2014; Salton et al., 2016). However, challenge remains to take idioms into account to improve neural based semantic representations of phrases or sentences.

Motivated by the **literal-first** psycholinguistic hypothesis proposed by Bobrow and Bell (1973), in this paper, we propose an end-to-end neural model for idiom-aware distributed semantic representation, in which we adopt a neural architecture of recursive network (Socher et al., 2013; Tai et al., 2015; Zhu et al., 2015) to learn the compositional semantics over a constituent tree. More concretely, we introduce a neural idiom detector for each phrase in a sentence to adaptively determine their compositionality: literal or idiomatic manner. For the literal phrase, we compute its semantics from its constituents while for the idiomatic phrase, we design two different ways to learn representations of idioms grounded in two different linguistic views of idioms (Katz, 1963; Fraser, 1970; Nunberg et al., 1994).

To evaluate our models towards the ability to understand sentences with idioms, we conduct our

[*] Corresponding author.

Copenhagen, Denmark, September 7–11, 2017. ©2017 Association for Computational Linguistics

experiments on sentiment classification task due to the following reasons: 1) Idioms typically imply an affective stance toward something and they are common in reviews and comments (Williams et al., 2015). 2) The error analysis of sentiment classification results reveals that a large number of errors are caused by idioms (Balahur et al., 2013).

The contributions of this work are summarized as follows:

- We grow the capacity of recursive neural network, enabling it to model idiomatic phrases and handle ubiquitous phenomenon of idiomatic variations when learning a sentential representation.
- We integrate idioms understanding into a real-world NLP task instead of evaluating idiom detection as a standalone task.
- We construct a new real-world dataset covering abundant idioms with original and variational forms. The elaborate qualitative and quantitative experimental analyses show the effectiveness of our models.

2 Linguistic Interpretation of Idioms

Recently, idioms have raised eyebrows among linguists, psycholinguists, and lexicographers due to their pervasiveness in daily discourse and their fascinating properties in linguistics literature (Villavicencio et al., 2005; Salton et al., 2014). As peculiar linguistic constructions (Villavicencio et al., 2005; Salton et al., 2014), idioms have three following properties:

Invisibility Idioms always disguise themselves as normal multi-words in sentences. It makes end-to-end training hard since we should detect idioms first, and then understand them.

Idiomaticity Idioms are semantically opaque, whose meanings cannot be derived from their constituent words. Existing compositional distributed approaches fail due to the hypothesis that the meaning of any phrase can be composed of the meanings of its constituents.

Flexibility While structurally fixed, idioms allow variations. The words of some idioms can be removed or substituted by other words.

Table 1 shows the three properties of idioms and the resulting challenges for distributed compositional semantics. To address these challenges, two different perspectives have been held for idiom comprehension.

Property	**Challenges**	**V1**	**V2**
Invisibility	End-to-end training is difficult	✓	✓
Idiomaticity	Difficult to predict meanings of idioms	×	✓
Flexibility	Hard to handle variation and generalize	✓	×

Table 1: The main properties of idioms and corresponding challenges. **V1** and **V2** represent two different linguistic perspectives towards idiom comprehension: arbitrary and compositional perspectives. ✓ indicates the perspective suffers from the corresponding challenge.

The first perspective treats idioms as long words whose meanings are stipulated arbitrarily and can not be predict from its constituent (Katz, 1963; Fraser, 1970). However, a lot of idioms have shown certain degree of flexibility in term of morphology and lexeme, so this kind of method handles variation badly and fails to generalize.

The second perspective considers idioms as linguistic expressions (Nunberg et al., 1994), whose meanings are determined by the meanings of their constituent parts and some compositional rules can be used to combine them. This fully compositional view may handle lexical variations, but it suffers from the idiomaticity problem, for the meanings of idioms are opaque.

3 Proposed Models

We propose an end-to-end neural model for idiom-aware distributed semantic representation. Specifically, in terms of invisibility, we introduce a neural idiom detector to adaptively distinguish literal and idiomatic meaning of each phrase when learning sentence representations. For the literal phrase, we compute its semantics from its constituents with Tree-structured LSTM (TreeLSTM) (Tai et al., 2015; Zhu et al., 2015). For the idiomatic phrase, we design two different ways to learn representations of idioms grounded in two different linguistic views of idioms, which considers the idiomaticity and flexibility properties of idioms. Figure 1 illustrates the framework of our proposed models, which consist of three modules: literal interpreter, idiom detector and idiomatic interpreter.

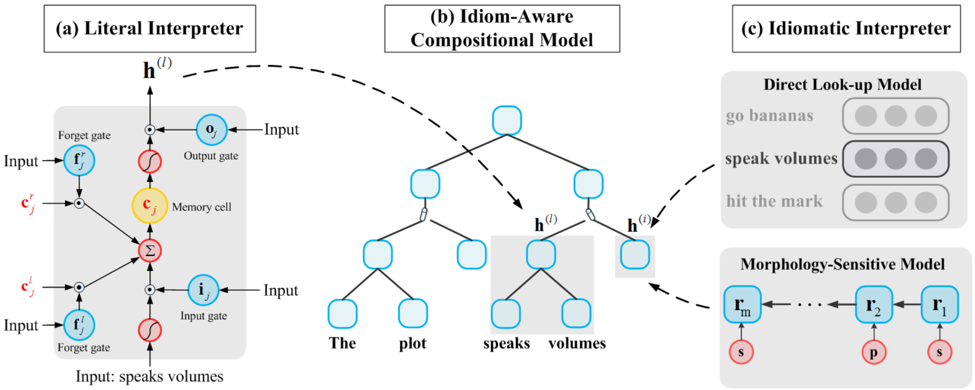

Figure 1: Illustration of different modules for our proposed idiom-aware composition network corresponding to the sentence “`The plot speaks volumes`”

3.1 Literal Interpreter

The literal interpreter is basically a compositional semantic model, in which the semantics of a phrase is composed by literal meanings of its constituent words. Several existing models could serve as literal interpreter. In this paper, we adopt TreeLSTM (Tai et al., 2015) due to its superior performance.

Formally, given a binary constituency tree T induced by a sentence, each non-leaf node corresponds to a phrase. We refer to $\mathbf{h}_j$ and $\mathbf{c}_j$ as the hidden state and memory cell of each node j. The transition equations of node j are as follows:

$$\begin{bmatrix} \tilde{\mathbf{c}}_j \\ \mathbf{o}_j \\ \mathbf{i}_j \\ \mathbf{f}_j^l \\ \mathbf{f}_j^r \end{bmatrix} = \begin{bmatrix} \tanh \\ \sigma \\ \sigma \\ \sigma \\ \sigma \end{bmatrix} T_{\mathbf{A},\mathbf{b}} \begin{bmatrix} \mathbf{x}_j \\ \mathbf{h}_j^l \\ \mathbf{h}_j^r \end{bmatrix}, \qquad (1)$$

$$\mathbf{c}_j = \tilde{\mathbf{c}}_j \odot \mathbf{i}_j + \mathbf{c}_j^l \odot \mathbf{f}_j^l + \mathbf{c}_j^r \odot \mathbf{f}_j^r, \qquad (2)$$

$$\mathbf{h}_j = \mathbf{o}_j \odot \tanh\left(\mathbf{c}_j\right), \qquad (3)$$

where $\mathbf{x_j}$ denotes the input vector and is non-zero if and only if it is a leaf node. The superscript l and r represent the left child and right child respectively. σ represents the logistic sigmoid function and $\odot$ denotes element-wise multiplication. $T_{\mathbf{A},\mathbf{b}}$ is an affine transformation which depends on parameters of the network $\mathbf{A}$ and $\mathbf{b}$. Figure 1-(a) gives an illustration of TreeLSTM unit.

3.2 Idiom Detector

Despite the success of TreeLSTM, there is still existing potential weakness of the hypothesis that the meaning of a phrase or a sentence can be composed from the meanings of its constituents. Previous neural sentence models are poor at learning the meanings of idiomatic phrases, not to mention modeling the idiomatic variations.

Therefore, we introduce a parameterized idiom detector, which is used for detecting the boundary between literal and idiomatic meanings. Specifically, if a compositional interpretation is nonsensical in the context of a sentence, then the detector is supposed to check whether an idiomatic sense should be taken and whether it makes sense. This **literal-first** model of idiom comprehension is motivated by the psycholinguistic hypothesis proposed by Bobrow and Bell (1973).

Due to ignoring the context information, TreeLSTM suffers from the problem of disambiguation. For example, the phrase “`in the bag`” is compositional in the sentence “`The dictionary is in the bag`” while it has idiomatic meaning in the sentence “`The election is in the bag unless the voters find out about my past`”. To address this problem, we explicitly model the context representation and integrate it into the process of sentence composition.

Context Representation More concretely, for each non-leaf node i and its corresponding phrase p_i, we define C as a word set which contains words surrounding the phrase p_i. Then the context representation s_i can be obtained as follow:

$$\mathbf{s}_i = f(c_1, c_2, ..., c_k; \theta) \qquad (4)$$

where f is a function with learnable parameter θ. Here, the function is implemented in two approaches, NBOW and LSTM.

Detector The detector outputs a scalar α to determine whether the meaning of a phrase is literal or idiomatic. Formally, for the phrase i (non-leaf node i) with its context information $\mathbf{s}_i$ and literal meaning $\mathbf{h}_i^{(l)}$, we compute the semantic compositional score α_i using a single layer multilayer perceptron.

$$\alpha_i = \sigma(\mathbf{v}_s^T \tanh(\mathbf{W}_s[\mathbf{h}_i^{(l)}, \mathbf{s}_i])), \tag{5}$$

where $\mathbf{W}_s \in \mathbb{R}^{d\times 2d}$ and $\mathbf{v}_s \in \mathbb{R}^d$ are learnable parameters.

3.3 Idiomatic Interpreter

Idiomatic phrases pose a clear challenge to current compositional models of language comprehension. However, until recently, there is little investigation of learning idiomatic phrases in a real-world task. Here, based on different views of idioms (Katz, 1963; Fraser, 1970; Nunberg et al., 1994), we propose two idiomatic interpreters to model them.

Direct Look-Up Model Inspired by the direct access theory for idiom comprehension (Glucksberg, 1993), in this model, once a phrase p is detected as an idiom, it will be regarded as a long word like a key, and then their meanings can be directly retrieved from an external memory M, which is a table and stores idiomatic information for each idiom as depicted in the top subfigure in Figure 1-(c). Formally, the idiomatic meaning for a phrase can be obtained as:

$$\mathbf{h}^{(i)} = \mathbf{M}[k] \tag{6}$$

where k denotes the index of the corresponding phrase p.

Morphology-Sensitive Model Since most idioms enjoy certain flexibility in morphology, lexicon, syntax, the above model suffers from the problem of idiom variations. To remedy this, inspired by the compositional view of idioms (Nunberg et al., 1994) and recent success of character-based models (Kim et al., 2016; Lample et al., 2016; Chung et al., 2016), we propose to use CharLSTM to directly encode the meaning of a phrase in an idiomatic space and generate an idiomatic representation, which is not contaminated by its literal meaning and sensitive to different variations.

Formally, for each non-leaf node i and its corresponding phrase p_i in a constituency tree, we apply charLSTM to phrase p_i as depicted in the bottom subfigure in Figure 1-(c) and utilize the emitted hidden states $\mathbf{r}_j$ to represent the idiomatic meaning of the phrase.

$$\mathbf{r}_j = \textbf{Char-LSTM}(\mathbf{r}_{j-1}, \mathbf{c}_{j-1}, \mathbf{x}_j) \tag{7}$$

where $j = 1, 2, \cdots, m$ and m represents the length of the input phrase.

Then, we can obtain the idiomatic representation:

$$\mathbf{h}^{(i)} = \mathbf{r}_m \tag{8}$$

After obtaining the literal or idiomatic meanings, we can compute the final representation for phrase p_i:

$$\mathbf{h}_i = \alpha_i \mathbf{h}_i^{(i)} + (1 - \alpha_i)\mathbf{h}_i^{(l)} \tag{9}$$

3.4 Analysis of Two Proposed Idiomatic Interpreters

Given a phrase, both interpreters can generate a corresponding semantic representation, which is not contaminated by its literal meaning. The difference is that Look-Up Model takes a totally non-compositional view that the meanings of idioms can be directly accessed from an external dictionary. This straightforward retrieval mechanism is more efficient and can introduce external prior knowledge by utilizing pre-trained external dictionary.

By contrast, Morphology-Sensitive Model holds the idea that idiomatic meanings can still be composed in an idiomatic space, which allows this model to understand idioms better in terms of flexibility. Besides, this kind of model does not require an extra dictionary.

4 iSent: A Benchmark for Idiom-Enriched Sentiment Classification Dataset

To evaluate our models, we need a task that heavily depends on the understanding of idioms. In this paper, we choose sentiment classification task due to following reasons: 1) Idioms typically imply an affective stance toward something and they are common in reviews and comments (Williams et al., 2015). 2) The error analysis of sentiment classification results reveals that a large number of errors are caused by idioms (Balahur et al., 2013).

In this section, we will first give a brief description of the most commonly used datasets for sentiment classification so as to motivate the need for a new benchmark dataset.

Dataset	Train	Dev.	Test	Class	L_{avg}	$\lvert\mathcal{V}\rvert$
MR	9596	-	1066	2	22	21K
SST-1	8544	1101	2210	5	19	18K
SST-2	6920	872	1821	2	18	15K
SUBJ	9000	-	1000	2	21	21K

Table 2: Statistics of the four mainstream datasets for sentiment classification. L_{avg} denotes the average length of documents; $|\mathcal{V}|$ denotes the size of vocabulary.

4.1 Mainstream Datasets for Sentiment Classification

We list four kinds of datasets which are most commonly used for sentiment classification in NLP community. Additionally, we also evaluate our models on these datasets to make a comparison with many recent proposed models. Each dataset is briefly described as follows.

- **SST-1** The movie reviews with five classes (negative, somewhat negative, neutral, somewhat positive, positive) in the Stanford Sentiment Treebank[1] (Socher et al., 2013).
- **SST-2** The movie reviews with binary classes. It is also derived from the Stanford Sentiment Treebank.
- **MR** The movie reviews with two classes [2](Pang and Lee, 2005).
- **SUBJ** Subjectivity data set where the goal is to classify each instance (snippet) as being subjective or objective. (Pang and Lee, 2004)

The detailed statistics about these four datasets are listed in Table 2.

4.2 Reasons for a New Dataset

Differing from previous work, which evaluating idiom detection as a standalone task, we want to integrate idiom understanding into sentiment classification task. However, most of existing sentiment datasets do not cover enough idioms or related linguistic phenomenon. To better evaluate our models on idiom understanding task, we proposed an idiom-enriched sentiment classification dataset, in which each sentence contains at least one idiom.

Additionally, considering most idioms have certain flexibility in morphology, lexicon and syntax, we enrich our dataset by introducing different types of idiom variations so that we can further evaluate the ability that the model handle different idiomatic variations. As shown in Table 3, we sum up two types of phenomena towards idiom variations and, for each variation, we obtain several corresponding sentences from a large corpora.

4.3 Data collection

We crawl the website `rottentomatoes.com` to excerpt movie reviews with corresponding scores and collect the idioms from dictionary (Flavell and Flavell, 2006). The idiom dictionary contains lexical variations while has no morphology variations. To address this problem, we manually annotate the morphological variation of each idiom in term of verb(tense), noun(plural or singular).

Then we filter these movie reviews with idioms ensuring that each sentence covers at least one idiom. After that, we obtain nearly 15K movie reviews covering 1K idioms. To further improve the quality of these idiom-enriched sentences, we take some strategies to filter the dataset and finally construct 13K idiom-enriched sentences.

- If the occurrence of an idiom in all the reviews is less than 3, we threw this idiom and corresponding reviews. [3]
- We find some "idioms" in sentences are movie names rather than expressing idiomatic meanings and we filtered this kind of noise.

4.4 Statistics

The iSent dataset finally contains 9752 training samples , 1020 development samples and 2003 test samples. Besides, the development and test sets cover different types of idiom variations allowing us to test the model's generalization. Table 4 shows the detailed statistics and Figure 2 shows the distribution of the number of reviews over different lengths.

5 Experiment

We first evaluate our proposed models on four popular sentiment datasets, so that we can make a comparison with varieties of competitors. And then, we use the newly-introduced dataset to make more detailed experiment analyses.

[1] `http://nlp.stanford.edu/sentiment.`

[2] `https://www.cs.cornell.edu/people/pabo/movie-review-data/.`

[3] The reason is that, for some idioms, we should split their corresponding reviews into train/dev/test sets.

Variations		Examples
Morp.	Verb Noun	go bananas → went bananas in a nutshell → in nutshells
Lexical	Add. Sub.	in the lurch → in the big lurch on the same page → on different pages

Table 3: Idiom variations at morphological and lexical level. Add. and Sub. refer to lexical addition and substitution respectively.

	Train	Dev			Test		
		O	M	L	O	M	L
Idiom	1247	124	21	40	124	21	40
Sent.	9752	720	200	100	1403	400	200

Table 4: Key statistics for the idioms and sentences in iSent dataset. O(Original) denotes the idioms in dev/test sets are in original forms and have appeared in training set. M(Morphology) and L(Lexical) represent the morphology and lexical idiom variations respectively and they are unseen in training set.

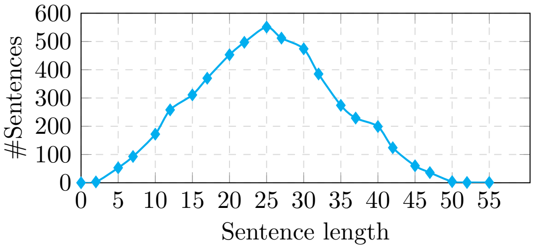

Figure 2: The distribution of the number of reviews over different lengths.

5.1 Experimental Settings

Loss Function Given a sentence and its label, the output of neural network is the probabilities of the different classes. The parameters of the network are trained to minimise the cross-entropy of the predicted and true label distributions. To minimize the objective, we use stochastic gradient descent with the diagonal variant of AdaGrad (Duchi et al., 2011).

Initialization and Hyperparameters In all of our experiments, the word embeddings for all of the models are initialized with the GloVe vectors (Pennington et al., 2014). The other parameters are initialized by randomly sampling from uniform distribution in $[-0.1, 0.1]$.

For each task, we take the hyperparameters which achieve the best performance on the development set via a small grid search over combinations of the initial learning rate $[0.1, 0.01, 0.001]$, l_2 regularization $[0.0, 5E{-}5, 1E{-}5]$ The final hyper-parameters are as follows. The initial learning rate is 0.1. The regularization weight of the parameters is $1E{-}5$.

For all the sentences from the five datasets, we parse them with constituency parser (Klein and Manning, 2003) to obtain the trees for our and some competitor models.

5.2 Competitor Models

We give some descriptions about the setting of our models and several baseline models.

- CharLSTM: Character level LSTM.
- TLSTM: Vanilla tree-based LSTM, proposed by Tai et al. (2015).
- Cont-TLSTM: Context-dependent tree-based LSTM, introduced by Bowman et al. (2016).
- iTLSTM-Lo: Proposed model with Look-Up idiomatic interpreter.
- iTLSTM-Mo: Proposed model with Morphology-Sensitive interpreter.

5.3 Evaluation over Mainstream Datasets

The experimental results are shown in Table 5. We can see Cont-TLSTM outperforms TLSTM on all four tasks, showing the importance of context-sensitive composition. Besides, both iTLSTM-Lo and iTLSTM-Mo achieve better results than TLSTM and Cont-LSTM, which indicates the effectiveness of our introduced modules (detector and idiomatic interpreter). Additionally, compared with iTLSTM-Lo, iTLSTM-Mo behaves better, suggesting its char-based idiomatic interpreter is more powerful.

Although four mainstream datasets are not rich in idioms, we could also observe substantial improvement gained from our models. We attribute this success to the power of introduced detector in identifying other non-compositional collocations besides idioms. We will discuss about this later.

5.4 Evaluation over iSent Dataset

Since iSent is a newly-introduced dataset, there is no existing baselines. Nevertheless, we provide several strong baselines implemented by ourselves as shown in Table 6, and we can observe that:

- Differing from the improvement achieved on mainstream datasets, proposed models have shown their advantages on idiom-enriched sentences. They obtain more significant improvements.

Model	MR	SST-1	SST-2	SUBJ
NBOW	77.2	42.4	80.5	91.3
RAE (Socher et al., 2011)	77.7	43.2	82.4	-
MV-RNN (Socher et al., 2012)	79.0	44.4	82.9	-
RNTN (Socher et al., 2013)	-	45.7	85.4	-
DCNN (Kalchbrenner et al., 2014)	-	48.5	86.8	-
CNN-multichannel (Kim, 2014)	81.5	47.4	88.1	93.2
CharLSTM	75.2	44.0	85.2	90.2
TLSTM	78.7	48.5	86.1	91.0
Cont-TLSTM	79.5	48.9	86.4	91.7
iTLSTM-Lo	81.6	49.9	87.7	93.2
iTLSTM-Mo	**82.5**	**51.2**	**88.2**	**94.5**

Table 5: Accuracies of our models on four datasets against state-of-the-art neural models.

Model	Train	Dev.	Test
NBOW	80.9	77.1	74.5
LSTM	87.5	76.9	75.0
BiLSTM	93.4	76.8	76.3
CharLSTM	92.4	75.1	74.4
TLSTM	88.2	75.3	74.9
Cont-TLSTM	90.8	76.2	75.5
iTLSTM-Lo	88.9	79.6	78.1
iTLSTM-Mo	91.3	81.1	80.0

Table 6: Accuracies of our models on iSent dataset against typical baselines. BiLSTM represents bidirectional LSTM.

- Additionally, iTLSTM-Lo performs worse than iTLSTM-Mo while still surpasses baseline models, which also indicates the variation-sensitive model (iTLSTM-Mo) of idioms could further improve the performance.

5.5 Analysis

In this section, we will provide more detailed quantitative and qualitative analysis in terms of three properties of idioms described in Table 1: flexibility, invisibility and idiomaticity.

Flexibility Besides the overall accuracies on the test set, we also list the performance achieved by different models over the different parts of test set: original, morphological and lexical, which represents different types of variations and have been described in Table 4.

We can see from Figure 3, both idiom-aware models achieve better performance than Cont-TLSTM by a large margin on the original part of test set, which indicates the importance of understanding idiomatic phrases during sentence modelling. Additionally, iTLSTM+Mo outperforms the other two models on the test set, suggesting the effectiveness of morphology-based model for modeling idiom variations.

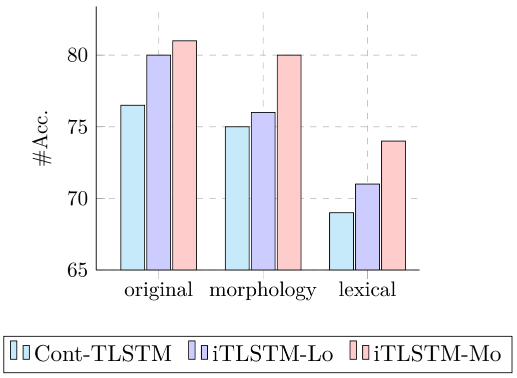

Figure 3: Performances achieved by different models are subdivided into three parts. Original, Morphology, Lexical represents accuracies achieved by corresponding part of test data.

Invisibility and Idiomaticity Previous experimental results have shown the effectiveness of our models. Here, we want to know how the introduced idiom detector contributes to the improvement of performance. Toward this end, we analyze all the 157 samples which our model predicts correctly while baseline model (Cont-TLSTM) fails on iSent, and find more than 120 sentences are given wrong sentiment by Cont-TLSTM due to ignoring the figurative meanings of idioms. For example, as shown in Figure 4, we randomly sample a sentence and analyze the changes of the predicted sentiment score at different nodes of the tree.

The sentence "`The movie enable my friends to blow a gasket`" has negative sentiment. Cont-TLSTM gives a wrong prediction due to ignoring the information expressed by the idiomatic phrase "`blow a gasket`". By contrast, our model correctly detects this idiom, whose meaning plays a major role in final sentiment prediction.

Non-compositional Phrases Detection Besides idioms, we find the introduced detector can also pick up other types of non-compositional phrases[4]. We roughly sum up these non-

[4] An idiom itself is a non-compositional phrase.

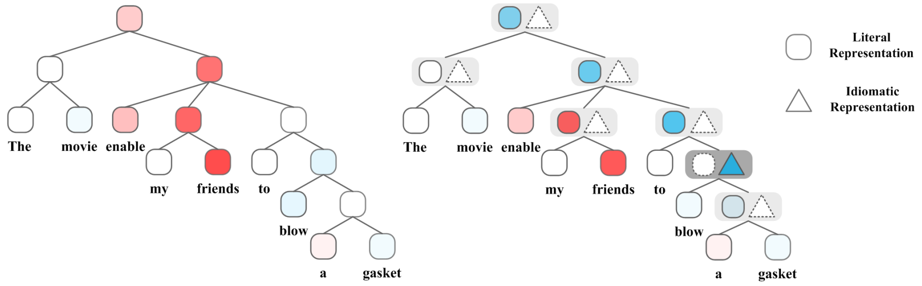

Figure 4: The change of the predicted sentiment score at different nodes of the tree. The red and blue color represent positive and negative sentiment respectively, where darker indicates higher confidence. Dashed triangle or square box denote not being selected by detector.

PN	VP	NP	AP
Notting Hill	*let alone*	*short cuts*	*on earth*
Holly Bolly	*take cover*	*deja vu*	*at once*
star wars saga	*rips off*	*black comedy*	*all in all*
Barry Skolnick	*thumb down*	*femme fatale*	*not only*
Apollo 13	*fall apart*	*no problem*	*at times*

Table 7: PN, VP, NP and AP represent proper noun, noun phrase, verb phrase and adverbial phrase respectively.

compositional phrases picked up by introduced detector from all the five development sets and list them in Table 7.

From the table, we can see that most of these phrases either imply an affective stance toward something: "`thumbs down`", or are critical to the understanding of sentences such as the "Verb Phrases" and "Adverb Phrases". For example, the sentence "`More often than not, this mixed bag hit its mark`" has a positive sentiment. Cont-TLSTM pays much more attention to the word "`not`" without realizing that it belongs to the collocation "`more often than not`", which expresses neutral emotion. In comparison, our model regards this collocation as a whole with neutral sentiment, which is crucial for the final prediction.

6 Related Work

Previous work related to idioms focused on their identification, which falls in two kinds of paradigms: idiom type classification (Gedigian et al., 2006; Shutova et al., 2010) and idiom token classification (Katz and Giesbrecht, 2006; Li and Sporleder, 2009; Fazly et al., 2009; Peng et al., 2014; Salton et al., 2016). Different with these work, we integrate idioms understanding into a real-world task and consider different peculiarities of idioms in an end-to-end trainable framework.

Recently, there are some work exploring the compositionality of various types of phrases (Kartsaklis et al., 2012; Muraoka et al., 2014; Hermann, 2014; Hashimoto and Tsuruoka, 2016). Compared with these work, we focus on how to properly model idioms under the context of sentence representations.

More recently, Zhu et al. (2016) propose a DAG-structured LSTM to incorporate external semantics including non-compositional or holistically learned semantics. Its key characteristic is that a DAG needs be built in advance, which merges some detected n-grams as the non-compositional phrases based on external knowledge. Different from this work, we focus on how to integrate detection and understanding of idioms into a unified end-to-end model, in which an idiomatic detector is introduced to adaptively control the semantic compositionality. Particularly, in the whole process no extra information is given to tell which phrases should be regarded as non-compositional.

7 Conclusion and Future Work

In this paper, we lay idioms understanding in the context of sentence-level semantic representation based on two linguistic perspectives. To apply our model into the real-world task, we introduce a sizeable idiom-enriched sentiment classification dataset, which covers abundant peculiarities of idioms. We make an elaborate experiment design and case analysis to evaluate the effectiveness of our proposed models.

In future work, we would like to investigate more complicated idiom-enriched NLP tasks, such as machine translation.

Macro Grammars and Holistic Triggering for Efficient Semantic Parsing

Yuchen Zhang and **Panupong Pasupat** and **Percy Liang**
{zhangyuc,ppasupat,pliang}@cs.stanford.edu
Computer Science Department, Stanford University

Abstract

To learn a semantic parser from denotations, a learning algorithm must search over a combinatorially large space of logical forms for ones consistent with the annotated denotations. We propose a new online learning algorithm that searches faster as training progresses. The two key ideas are using *macro grammars* to cache the abstract patterns of useful logical forms found thus far, and *holistic triggering* to efficiently retrieve the most relevant patterns based on sentence similarity. On the WikiTableQuestions dataset, we first expand the search space of an existing model to improve the state-of-the-art accuracy from 38.7% to 42.7%, and then use macro grammars and holistic triggering to achieve an 11x speedup and an accuracy of 43.7%.

1 Introduction

We consider the task of learning a semantic parser for question answering from question-answer pairs (Clarke et al., 2010; Liang et al., 2011; Berant et al., 2013; Artzi and Zettlemoyer, 2013; Pasupat and Liang, 2015). To train such a parser, the learning algorithm must somehow search for *consistent* logical forms (i.e., logical forms that execute to the correct answer denotation). Typically, the search space is defined by a compositional grammar over logical forms (e.g., a context-free grammar), which we will refer to as the *base grammar*.

To cover logical forms that answer complex questions, the base grammar must be quite general and compositional, leading to a huge search space that contains many useless logical forms. For example, the parser of Pasupat and Liang (2015) on Wikipedia table questions (with beam size 100) generates and featurizes an average of 8,400 partial logical forms per example. Searching for consistent logical forms is thus a major computational bottleneck.

	Rank	**Nation**	**Gold**	**Silver**	**Bronze**
r_1 :	1	France	3	1	1
r_2 :	2	Ukraine	2	1	2
r_3 :	3	Turkey	2	0	1
r_4 :	4	Sweden	2	0	0
r_5 :	5	Iran	1	2	1

Table 1: A knowledge base for the question x = "*Who ranked right after Turkey?*". The target denotation is $y = \{\texttt{Sweden}\}$.

In this paper, we propose *macro grammars* to bias the search towards structurally sensible logical forms. To illustrate the key idea, suppose we managed to parse the utterance "*Who ranked right after Turkey?*" in the context of Table 1 into the following consistent logical form (in lambda DCS) (Section 2.1):

$$\mathbf{R}[\texttt{Nation}].\mathbf{R}[\texttt{Next}].\texttt{Nation}.\texttt{Turkey},$$

which identifies the cell under the Nation column in the row after Turkey. From this logical form, we can abstract out all relations and entities to produce the following *macro*:

$$\mathbf{R}[\{\mathit{Rel}\#1\}].\mathbf{R}[\texttt{Next}].\{\mathit{Rel}\#1\}.\{\mathit{Ent}\#2\},$$

which represents the abstract computation: "identify the cell under the $\{\mathit{Rel}\#1\}$ column in the row after $\{\mathit{Ent}\#2\}$." More generally, macros capture the overall shape of computations in a way that generalizes across different utterances and knowledge bases. Given the consistent logical forms of utterances parsed so far, we extract a set of macro rules. The resulting macro grammar consisting of these rules generates only logical forms conforming to these macros, which is a much smaller and

higher precision set compared to the base grammar.

Though the space of logical forms defined by the macro grammar is smaller, it is still expensive to parse with them as the number of macro rules grows with the number of training examples. To address this, we introduce *holistic triggering*: for a new utterance, we find the K most similar utterances and only use the macro rules induced from any of their consistent logical forms. Parsing now becomes efficient as only a small subset of macro rules are triggered for any utterance. Holistic triggering can be contrasted with the norm in semantic parsing, in which logical forms are either triggered by specific phrases (anchored) or can be triggered in any context (floating).

Based on the two ideas above, we propose an online algorithm for jointly inducing a macro grammar and learning the parameters of a semantic parser. For each training example, the algorithm first attempts to find consistent logical forms using holistic triggering on the current macro grammar. If it succeeds, the algorithm uses the consistent logical forms found to update model parameters. Otherwise, it applies the base grammar for a more exhaustive search to enrich the macro grammar. At test time, we only use the learned macro grammar.

We evaluate our approach on the WIKITABLEQUESTIONS dataset (Pasupat and Liang, 2015), which features a semantic parsing task with open-domain knowledge bases and complex questions. We first extend the model in Pasupat and Liang (2015) to achieve a new state-of-the-art test accuracy of 42.7%, representing a 10% relative improvement over the best reported result (Haug et al., 2017). We then show that training with macro grammars yields an 11x speedup compared to training with only the base grammar. At test time, using the learned macro grammar achieves a slightly better accuracy of 43.7% with a 16x run time speedup over using the base grammar.

2 Background

We base our exposition on the task of question answering on a knowledge base. Given a natural language utterance x, a semantic parser maps the utterance to a logical form z. The logical form is executed on a knowledge base w to produce denotation $[\![z]\!]_w$. The goal is to train a semantic parser from a training set of utterance-denotation pairs.

2.1 Knowledge base and logical forms

A knowledge base refers to a collection of entities and relations. For the running example "*Who ranked right after Turkey?*", we use Table 1 from Wikipedia as the knowledge base. Table cells (e.g., `Turkey`) and rows (e.g., r_3 = the 3rd row) are treated as entities. Relations connect entities: for example, the relation `Nation` maps r_3 to `Turkey`, and a special relation `Next` maps r_3 to r_4.

A logical form z is a small program that can be executed on the knowledge base. We use lambda DCS (Liang, 2013) as the language of logical forms. The smallest units of lambda DCS are entities (e.g., `Turkey`) and relations (e.g., `Nation`). Larger logical forms are composed from smaller ones, and the denotation of the new logical form can be computed from denotations of its constituents. For example, applying the join operation on `Nation` and `Turkey` gives `Nation.Turkey`, whose denotation is $[\![\texttt{Nation.Turkey}]\!]_w = \{r_3\}$, which corresponds to the 3rd row of the table. The partial logical form `Nation.Turkey` can then be used to construct a larger logical form:

$$z = \mathbf{R}[\texttt{Nation}].\mathbf{R}[\texttt{Next}].\texttt{Nation}.\texttt{Turkey}, \quad (1)$$

where $\mathbf{R}[\cdot]$ represents the reverse of a relation. The denotation of the logical form z with respect to the knowledge base w is equal to $[\![z]\!]_w = \{\texttt{Sweden}\}$. See Liang (2013) for more details about the semantics of lambda DCS.

2.2 Grammar rules

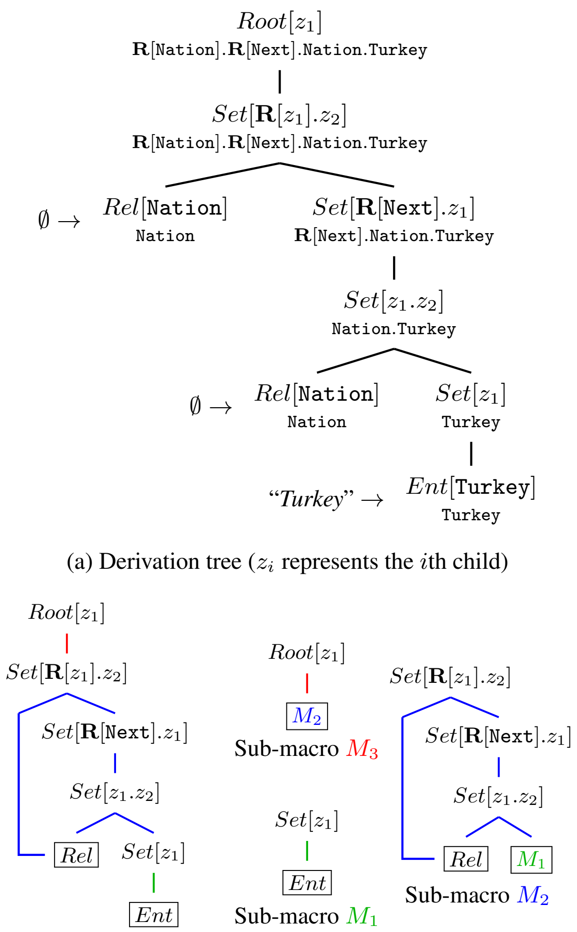
The space of logical forms is defined recursively by grammar rules. In this setting, each constructed logical form belongs to a category (e.g., $Entity$, Rel, Set), with a special category $Root$ for complete logical forms. A rule specifies the categories of the arguments, category of the resulting logical form, and how the logical form is constructed from the arguments. For instance, the rule

$$Rel[z_1] + Set[z_2] \rightarrow Set[z_1.z_2] \quad (2)$$

specifies that a partial logical form z_1 of category Rel and z_2 of category Set can be combined into $z_1.z_2$ of category Set. With this rule, we can construct `Nation.Turkey` if we have constructed `Nation` of type Rel and `Turkey` of type Set.

We consider the rules used by Pasupat and Liang (2015) for their floating parser.[1] The rules

[1] Their grammar and our implementation use more fine-grained categories ($Atomic$, $Values$, $Records$) instead of Set. We use the coarser category here for simplicity.



(a) Derivation tree (z_i represents the ith child)

(b) Macro

(c) Atomic sub-macros

Figure 1: From the derivation tree (a), we extract a macro (b), which can be further decomposed into atomic sub-macros (c). Each sub-macro is converted into a macro rule.

are divided into *compositional rules* and *terminal rules*. Rule (2) above is an example of a compositional rule, which combines one or more partial logical forms together. A terminal rule has one of the following forms:

$$TokenSpan[span] \to c[f(span)] \qquad (3)$$

$$\emptyset \to c[f(\emptyset)] \qquad (4)$$

where c is a category. A rule with the form (3) converts an utterance token span (e.g., "*Turkey*") into a partial logical form (e.g., `Turkey`). A rule with the form (4) generates a partial logical form without any trigger. This allows us to generate logical predicates that do not correspond to any part of the utterance (e.g., `Nation`).

A complete logical form is generated by recursively applying rules. We can represent the derivation process by a *derivation tree* such as in Figure 1a. Every node of the derivation tree corresponds to one rule. The leaf nodes correspond to terminal rules, and the intermediate nodes correspond to compositional rules.

2.3 Learning a semantic parser

Parameters of the semantic parser are learned from training data $\{(x_i, w_i, y_i)\}_{i=1}^n$. Given a training example with an utterance x, a knowledge base w, and a target denotation y, the learning algorithm constructs a set of candidate logical forms indicated by $\mathcal{Z}$. It then extracts a feature vector $\phi(x, w, z)$ for each $z \in \mathcal{Z}$, and defines a log-linear distribution over the candidates z:

$$p_\theta(z \mid x, w) \propto \exp(\theta^\top \phi(x, w, z)), \qquad (5)$$

where θ is a parameter vector. The straightforward way to construct $\mathcal{Z}$ is to enumerate all possible logical forms induced by the grammar. When the search space is prohibitively large, it is a common practice to use beam search. More precisely, the algorithm constructs partial logical forms recursively by the rules, but for each category and each search depth, it keeps only the B highest-scoring logical forms according to the model probability (5).

During training, the parameter θ is learned by maximizing the regularized log-likelihood of the correct denotations:

$$J(\theta) = \frac{1}{n} \sum_{i=1}^{n} \log p_\theta(y_i \mid x_i, w_i) - \lambda \|\theta\|_1, \qquad (6)$$

where the probability $p_\theta(y_i \mid x_i, w_i)$ marginalizes over the space of candidate logical forms:

$$p_\theta(y_i \mid x_i, w_i) = \sum_{z \in \mathcal{Z}_i : [\![z]\!]_{w_i} = y_i} p_\theta(z \mid x_i, w_i).$$

The objective is optimized using AdaGrad (Duchi et al., 2010). At test time, the algorithm selects a logical form $z \in \mathcal{Z}$ with the highest model probability (5), and then executes it on the knowledge base w to predict the denotation $[\![z]\!]_w$.

3 Learning a macro grammar

The base grammar usually defines a large search space containing many irrelevant logical forms. For example, the grammar in Pasupat and Liang (2015) can generate long chains of join operations (e.g., $\mathbf{R}$[`Silver`].`Rank`.$\mathbf{R}$[`Gold`].`Bronze`.`2`) that rarely express meaningful computations.

Algorithm 1: Processing a training example

```
Data: example $(x, w, y)$, macro grammar,
      base grammar with terminal rules $\mathcal{T}$
Select a set $\mathcal{R}$ of macro rules (Section 3.4);
Generate a set $\mathcal{Z}$ of candidate logical forms
  from rules $\mathcal{R} \cup \mathcal{T}$ (Section 2.3);
if $\mathcal{Z}$ contains consistent logical forms then
    Update model parameters (Section 3.5);
else
    Apply the base grammar to search for a
      consistent logical form (Section 2.3);
    Augment the macro grammar
      (Section 3.6);
end
Associate utterance $x$ with the highest-
  scoring consistent logical form found;
```

The main contribution of this paper is a new algorithm to speed up the search based on previous searches. At a high-level, we incrementally build a *macro grammar* which encodes useful logical form macros discovered during training. Algorithm 1 describes how our learning algorithm processes each training example. It first tries to use an appropriate subset of rules in the macro grammar to search for logical forms. If the search succeeds, then the semantic parser parameters are updated as usual. Otherwise, it falls back to the base grammar, and then add new rules to the macro grammar based on the consistent logical form found. Only the macro grammar is used at test time.

We first describe macro rules and how they are generated from a consistent logical form. Then we explain the steps of the training algorithm in detail.

3.1 Logical form macros

A *macro* characterizes an abstract logical form structure. We define the macro for any given logical form z by transforming its derivation tree as illustrated in Figure 1b. First, for each terminal rule (leaf node), we substitute the rule by a placeholder, and name it with the category on the right-hand side of the rule. Then we merge leaf nodes that represent the same partial logical form. For example, the logical form (1) uses the relation `Nation` twice, so in Figure 1b, we merge the two leaf nodes to impose such a constraint.

While the resulting macro may not be tree-like, we call each node *root* or *leaf* if it is a root node or a leaf node of the associated derivation tree.

3.2 Constructing macro rules from macros

For any given macro M, we can construct a set of *macro rules* that, when combined with terminal rules from the base grammar, generates exactly the logical forms that satisfy the macro M. The straightforward approach is to associate a unique rule with each macro: assuming that its k leaf nodes contain categories $c_1, \ldots, c_k$, we can define a rule:

$$c_1[z_1] + \cdots + c_k[z_k] \rightarrow \mathit{Root}[f(z_1, \ldots, z_k)], \tag{7}$$

where f substitutes $z_1, \ldots, z_k$ into the corresponding leaf nodes of macro M. For example, the rule for the macro in Figure 1b is

$$\mathit{Rel}[z_1]+\mathit{Ent}[z_2] \rightarrow \mathit{Root}[\mathbf{R}[z_1].\mathbf{R}[\texttt{Next}].z_1.z_2].$$

3.3 Decomposed macro rules

Defining a unique rule for each macro is computationally suboptimal since the common structures shared among macros are not being exploited. For example, while $\texttt{max}(\mathbf{R}[\texttt{Rank}].\texttt{Gold.Num.2})$ and $\mathbf{R}[\texttt{Nation}].\texttt{argmin}(\texttt{Gold.Num.2}, \texttt{Index})$ belong to different macros, the partial logical form `Gold.Num.2` is shared, and we wish to avoid generating and featurizing it more than once.

In order to reuse such shared parts, we decompose macros into *sub-macros* and define rules based on them. A subgraph M' of M is a sub-macro if (1) M' contains at least one non-leaf node; and (2) M' connects to the rest of the macro $M \backslash M'$ only through one node (the root of M'). A macro M is called *atomic* if the only sub-macro of M is itself.

Given a non-atomic macro M, we can find an atomic sub-macro M' of M. For example, from Figure 1b, we first find sub-macro $M' = M_1$. We detach M' from M and define a macro rule:

$$c'_1[z_1] + \cdots + c'_k[z_k] \rightarrow c'_{\text{out}}[f(z_1, \ldots, z_k)], \tag{8}$$

where $c'_1, \ldots, c'_k$ are categories of the leaf nodes of M', and f substitutes $z_1, \ldots, z_k$ into the sub-macro M'. The category c'_{out} is computed by serializing M' as a string; this way, if the sub-macro M' appears in a different macro, the category name will be shared. Next, we substitute the subgraph M' in M by a placeholder node with name c'_{out}. The procedure is repeated on the new graph until the remaining macro is atomic. Finally, we define a single rule for the atomic macro. The macro grammar uses the decomposed macro rules in replacement of Rule (7).

For example, the macro in Figure 1b is decomposed into three macro rules:

$$\begin{aligned} \mathit{Ent}[z_1] &\rightarrow M_1[z_1], \\ \mathit{Rel}[z_1] + M_1[z_2] &\rightarrow M_2[\mathbf{R}[z_1].\mathbf{R}[\texttt{Next}].z_1.z_2], \\ M_2[z_1] &\rightarrow \mathit{Root}[z_1]. \end{aligned}$$

These correspond to the three atomic sub-macros M_1, M_2 and M_3 in Figure 1c. The first and the second macro rules can be reused by other macros.

Having defined macro rules, we now describe how Algorithm 1 uses and updates the macro grammar when processing each training example.

3.4 Triggering macro rules

Throughout training, we keep track of a set $\mathcal{S}$ of training utterances that have been associated with a consistent logical form. (The set $\mathcal{S}$ is updated by Step 9 of Algorithm 1.) Then, given a training utterance x, we compute its K-nearest neighbor utterances in $\mathcal{S}$, and select all macro rules that were extracted from their associated logical forms. These macro rules are used to parse utterance x.

We use token-level Levenshtein distance as the distance metric for computing nearest neighbors. More precisely, every utterance is written as a sequence of lemmatized tokens $x = (x^{(1)}, \ldots, x^{(m)})$. After removing all determiners and infrequent nouns that appear in less than 2% of the training utterances, the distance between two utterances x and x' is defined as the Levenshtein distance between the two sequences. When computing the distance, we treat each word token as an atomic element. For example, the distance between "highest score" and "best score" is 1. Despite its simplicity, the Levenshtein distance does a good job in capturing the structural similarity between utterances. Table 2 shows that nearest neighbor utterances often map to consistent logical forms with the same macro.

In order to compute the nearest neighbors efficiently, we pre-compute a sorted list of $K_{\text{max}} = 100$ nearest neighbors for every utterance before training starts. During training, calculating the intersection of this sorted list with the set $\mathcal{S}$ gives the nearest neighbors required. For our experiments, the preprocessing time is negligible compared to the overall training time (less than 3%), but if computing nearest neighbors is expensive, then parallelization or approximate algorithms (e.g., Indyk, 2004) could be used.

Table 2: Examples of nearest neighbor utterances in the WIKITABLEQUESTIONS dataset.

3.5 Updating model parameters

Having computed the triggered macro rules $\mathcal{R}$, we combine them with the terminal rules $\mathcal{T}$ from the base grammar (e.g., for building Ent and Rel) to create a per-example grammar $\mathcal{R} \cup \mathcal{T}$ for the utterance x. We use this grammar to generate logical forms using standard beam search. We follow Section 2.3 to generate a set of candidate logical forms $\mathcal{Z}$ and update model parameters.

However, we deviate from Section 2.3 in one way. Given a set $\mathcal{Z}$ of candidate logical forms for some training example (x_i, w_i, y_i), we pick the logical form z_i^+ with the highest model probability among consistent logical forms, and pick z_i^- with the highest model probability among inconsistent logical forms, then perform a gradient update on the objective function:

$$J(\theta) = \frac{1}{n} \sum_{i=1}^{n} \left[\log \frac{p_i^+}{p_i^+ + p_i^-} \right] - \lambda \|\theta\|_1, \quad (9)$$

$$\text{where} \quad \begin{aligned} p_i^+ &= p_\theta(z_i^+ \mid x_i, w_i) \\ p_i^- &= p_\theta(z_i^- \mid x_i, w_i). \end{aligned}$$

Compared to (6), this objective function only considers the top consistent and inconsistent logical forms for each example instead of all candidate logical forms. Empirically, we found that optimizing (9) gives a 2% gain in prediction accuracy compared to optimizing (6).

3.6 Updating the macro grammar

If the triggered macro rules fail to find a consistent logical form, we fall back to performing a beam search on the base grammar. For efficiency, we stop the search either when a consistent logical form is found, or when the total number of generated logical forms exceeds a threshold T. The two stopping criteria prevent the search algorithm from spending too much time on a complex example. We might miss consistent logical forms on such examples, but because the base grammar is only used for generating macro rules, not for updating model parameters, we might be able to induce the same macro rules from other examples. For instance, if an example has an utterance phrase that matches too many knowledge base entries, it would be more efficient to skip the example; the macro that would have been extracted from this example can be extracted from less ambiguous examples with the same question type. Such omissions are not completely disastrous, and can speed up training significantly.

When the algorithm succeeds in finding a consistent logical form z using the base grammar, we derive its macro M following Section 3.1, then construct macro rules following Section 3.3. These macro rules are added to the macro grammar. We also associate the utterance x with the consistent logical form z, so that the macro rules that generate z can be triggered by other examples. Parameters of the semantic parser are not updated in this case.

3.7 Prediction

At test time, we follow Steps 1–2 of Algorithm 1 to generate a set $\mathcal{Z}$ of candidate logical forms from the triggered macro rules, and then output the highest-scoring logical form in $\mathcal{Z}$. Since the base grammar is never used at test time, prediction is generally faster than training.

4 Experiments

We report experiments on the WIKITABLEQUESTIONS dataset (Pasupat and Liang, 2015). Our algorithm is compared with the parser trained only with the base grammar, the floating parser of Pasupat and Liang (2015) (PL15), the Neural Programmer parser (Neelakantan et al., 2016) and the Neural Multi-Step Reasoning parser (Haug et al., 2017). Our algorithm not only outperforms the others, but also achieves an order-of-magnitude speedup over the parser trained with the base grammar and the parser in PL15.

4.1 Setup

The dataset contains 22,033 complex questions on 2,108 Wikipedia tables. Each question comes with a table, and the tables during evaluation are disjoint from the ones during training. The training and test sets contain 14,152 and 4,344 examples respectively.[2] Following PL15, the development accuracy is averaged over the first three 80-20 training data splits given in the dataset package. The test accuracy is reported on the train-test data split.

"Which driver appears the most?" $\texttt{argmax}(\mathbf{R}[\texttt{Driver}].\texttt{Type.Row}, \mathbf{R}[\lambda\texttt{x.count}(\texttt{Driver.x})])$
"What language was spoken more during the Olympic oath, English or French?" $\texttt{argmax}(\texttt{English} \sqcup \texttt{French}, \mathbf{R}[\lambda\texttt{x.count}(\texttt{Language.x})])$
"Who is taller, Rose or Tim?" $\texttt{argmax}(\texttt{Rose} \sqcup \texttt{Tim}, \mathbf{R}[\lambda\texttt{x}.\mathbf{R}[\texttt{Num}].\mathbf{R}[\texttt{Height}].\texttt{Name.x})])$

Table 3: Several example logical forms our grammar can generate that are not covered by PL15.

We use the same features and logical form pruning strategies as PL15, but generalize their base grammar. To control the search space, the actual system in PL15 restricts the superlative operators `argmax` and `argmin` to be applied only on the set of table rows. We allow these operators to be applied on the set of tables cells as well, so that the grammar captures certain logical forms that are not covered by PL15 (see Table 3). Additionally, for terminal rule (3), we allow $f(span)$ to produce entities that approximately match the token span in addition to exact matches. For example, the phrase "Greenville" can trigger both entities `Greenville_Ohio` and `Greensville`.

We chose hyperparameters using the first train-dev split. The beam size B of beam search is chosen to be $B = 100$. The K-nearest neighbor parameter is chosen as $K = 40$. Like PL15, our algorithm takes 3 passes over the dataset for training. The maximum number of logical forms generated in step 6 of Algorithm 1 is set to $T = 5{,}000$ for the first pass. For subsequent passes, we set $T = 0$ (i.e., never fall back to the base grammar) so that we stop augmenting the macro grammar. During the first pass, Algorithm 1 falls back to the base grammar on roughly 30% of the training examples.

For training the baseline parser that only relies on the base grammar, we use the same beam size $B = 100$, and take 3 passes over the dataset for training. There is no maximum constraint on the

[2] The remaining 3,537 examples were not included in the original data split.

This paper: macro grammar	40.4%	**43.7%**

Table 4: Results on WIKITABLEQUESTIONS.

number of logical forms that can be generated for each example.

4.2 Coverage of the macro grammar

With the base grammar, our parser generates 13,700 partial logical forms on average for each training example, and hits consistent logical forms on 81.0% of the training examples. With the macro rules from holistic triggering, these numbers become 1,300 and 75.6%. The macro rules generate much fewer partial logical forms, but at the cost of slightly lower coverage.

However, these coverage numbers are computed based on finding any logical form that executes to the correct denotation. This includes spurious logical forms, which do not reflect the semantics of the question but are coincidentally consistent with the correct denotation. (For example, the question "*Who got the same number of silvers as France?*" on Table 1 might be spuriously parsed as $\mathbf{R}[\texttt{Nation}].\mathbf{R}[\texttt{Next}].\texttt{Nation}.\texttt{France}$, which represents the nation listed after France.) To evaluate the "true" coverage, we sample 300 training examples and manually label their logical forms. We find that on 48.7% of these examples, the top consistent logical form produced by the base grammar is semantically correct. For the macro grammar, this ratio is also 48.7%, meaning that the macro grammar's effective coverage is as good as the base grammar.

The macro grammar extracts 123 macros in total. Among the 75.6% examples that were covered by the macro grammar, the top 34 macros cover 90% of consistent logical forms. By examining the top 34 macros, we discover explicit semantic meanings for 29 of them, which are described in detail in the supplementary material.

4.3 Accuracy and speedup

We report prediction accuracies in Table 4. With a more general base grammar (additional superlatives and approximate matching), and by optimizing the objective function (9), our base parser outperforms PL15 (42.7% vs 37.1%). Learning a macro grammar slightly improves the accuracy to 43.7% on the test set. On the three train-dev splits, the averaged accuracy achieved by the base grammar and the macro grammar are close (40.6% vs 40.4%).

		Time (ms/ex)	
	Acc.	Train	Pred
PL15	37.0%	619	645
Ours: base grammar	40.6%	1,117	1,150
Ours: macro grammar	40.4%	99	70
no holistic triggering	40.1%	361	369
no macro decomposition	40.3%	177	159

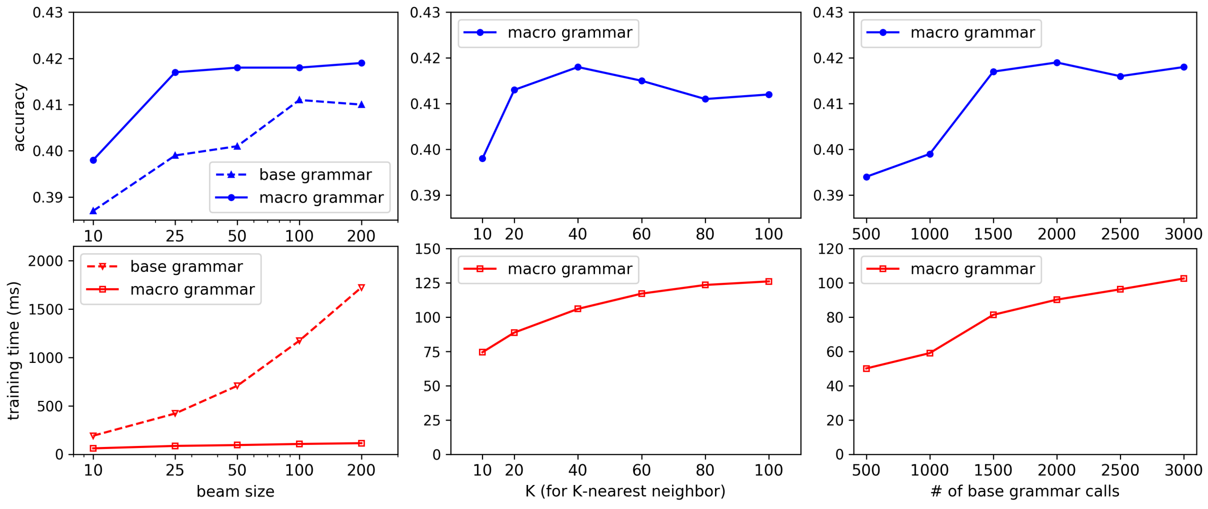
Table 5: Comparison and ablation study: the columns report averaged prediction accuracy, training time, and prediction time (milliseconds per example) on the three train-dev splits.

In Table 5, we compare the training and prediction time of PL15 as well as our parsers. For a fair comparison, we trained all parsers using the SEMPRE toolkit (Berant et al., 2013) on a machine with Xeon 2.6GHz CPU and 128GB memory without parallelization. The time for constructing the macro grammar is included as part of the training time. Table 5 shows that our parser with the base grammar is more expensive to train than PL15. However, training with the macro grammar is substantially more efficient than training with only the base grammar— it achieves 11x speedup for training and 16x speedup for test time prediction.

We run two ablations of our algorithm to evaluate the utility of holistic triggering and macro decomposition. The first ablation triggers all macro rules for parsing every utterance without holistic triggering, while the second ablation constructs Rule (7) for every macro without decomposing it into smaller rules. Table 5 shows that both variants result in decreased efficiency. This is because holistic triggering effectively prunes irrelevant macro rules, while macro decomposition is important for efficient beam search and featurization.

4.4 Influence of hyperparameters

Figure 2a shows that for all beam sizes, training with the macro grammar is more efficient than training with the base grammar, and the speedup rate grows with the beam size. The test time ac-



(a) Varying beam size

(b) Varying neighbor size

(c) Varying base grammar usage count

Figure 2: Prediction accuracy and training time (per example) with various hyperparameter choices, reported on the first train-dev split.

curacy of the macro grammar is robust to varying beam sizes as long as $B \geq 25$.

Figure 2b shows the influence of the neighbor size K. A smaller neighborhood triggers fewer macro rules, leading to faster computation. The accuracy peaks at $K = 40$ then decreases slightly for large K. We conjecture that the smaller number of neighbors acts as a regularizer.

Figure 2c reports an experiment where we limit the number of fallback calls to the base grammar to m. After the limit is reached, subsequent training examples that require fallback calls are simply skipped. This limit means that the macro grammar will get augmented at most m times during training. We find that for small m, the prediction accuracy grows with m, implying that building a richer macro grammar improves the accuracy. For larger m, however, the accuracies hardly change. According to the plot, a competitive macro grammar can be built by calling the base grammar on less than 15% of the training data.

Based on Figure 2, we can trade accuracy for speed by choosing smaller values of (B, K, m). With $B = 50$, $K = 40$ and $m = 2000$, the macro grammar achieves a slightly lower averaged development accuracy (40.2% rather than 40.4%), but with an increased speedup of 15x (versus 11x) for training and 20x (versus 16x) for prediction.

5 Related work and discussion

A traditional semantic parser maps natural language phrases into partial logical forms and composes these partial logical forms into complete logical forms. Parsers define composition based on a grammar formalism such as Combinatory Categorial Grammar (CCG) (Zettlemoyer and Collins, 2007; Kwiatkowski et al., 2011, 2013; Kushman and Barzilay, 2013; Krishnamurthy and Kollar, 2013), Synchronous CFG (Wong and Mooney, 2007), and CFG (Kate and Mooney, 2006; Chen and Mooney, 2011; Berant et al., 2013; Desai et al., 2016), while others use the syntactic structure of the utterance to guide composition (Poon and Domingos, 2009; Reddy et al., 2016). Recent neural semantic parsers allow any sequence of logical tokens to be generated (Dong and Lapata, 2016; Jia and Liang, 2016; Kociský et al., 2016; Neelakantan et al., 2016; Liang et al., 2017; Guu et al., 2017). The flexibility of these composition methods allows arbitrary logical forms to be generated, but at the cost of a vastly increased search space.

Whether we have annotated logical forms or not has dramatic implications on what type of approach will work. When logical forms are available, one can perform grammar induction to mine grammar rules *without search* (Kwiatkowski et al., 2010). When only annotated denotations are available, as in our setting, one must use a base grammar to define the output space of logical forms. Usually these base grammars come with many restrictions to guard against combinatorial explosion (Pasupat and Liang, 2015).

Previous work on higher-order unification for lexicon induction (Kwiatkowski et al., 2010) using factored lexicons (Kwiatkowski et al., 2011) also learns logical form macros with an online algorithm. The result is a lexicon where each entry contains a logical form template and a set of possible phrases for triggering the template. In contrast, we have avoided binding grammar rules to particular phrases in order to handle lexical variations. Instead, we use a more flexible mechanism—holistic triggering—to determine which rules to fire. This allows us to generate logical forms for utterances containing unseen lexical paraphrases or where the triggering is spread throughout the sentence. For example, the question "*Who is X, John or Y*" can still trigger the correct macro extracted from the last example in Table 3 even when *X* and *Y* are unknown words.

Our macro grammars bears some resemblance to adaptor grammars (Johnson et al., 2006) and fragment grammars (O'Donnell, 2011), which are also based on the idea of caching useful chunks of outputs. These generative approaches aim to solve the modeling problem of assigning higher probability mass to outputs that use reoccurring parts. In contrast, our learning algorithm uses caching as a way to constrain the search space for computational efficiency; the probabilities of the candidate outputs are assigned by a separate discriminative model. That said, the use of macro grammars does have a small positive modeling contribution, as it increases test accuracy from 42.7% to 43.7%.

An orthogonal approach for improving search efficiency is to adaptively choose which part of the search space to explore. For example, Berant and Liang (2015) uses imitation learning to strategically search for logical forms. Our holistic triggering method, which selects macro rules based on the similarity of input utterances, is related to the use of paraphrases (Berant and Liang, 2014; Fader et al., 2013) or string kernels (Kate and Mooney, 2006) to train semantic parsers. While the input similarity measure is critical for scoring logical forms in these previous works, we use the measure only to retrieve candidate rules, while scoring is done by a separate model. The retrieval bar means that our similarity metric can be quite crude.

6 Summary

We have presented a method for speeding up semantic parsing via macro grammars. The main source of efficiency is the decreased size of the logical form space. By performing beam search on a few macro rules associated with the K-nearest neighbor utterances via holistic triggering, we have restricted the search space to semantically relevant logical forms. At the same time, we still maintain coverage over the base logical form space by occasionally falling back to the base grammar and using the consistent logical forms found to enrich the macro grammar. The higher efficiency allows us expand the base grammar without having to worry much about speed: our model achieves a state-of-the-art accuracy while also enjoying an order magnitude speedup.

Abstract

A major challenge in paraphrase research is the lack of parallel corpora. In this paper, we present a new method to collect large-scale sentential paraphrases from Twitter by linking tweets through shared URLs. The main advantage of our method is its simplicity, as it gets rid of the classifier or human in the loop needed to select data before annotation and subsequent application of paraphrase identification algorithms in the previous work. We present the largest human-labeled paraphrase corpus to date of 51,524 sentence pairs and the first cross-domain benchmarking for automatic paraphrase identification. In addition, we show that more than 30,000 new sentential paraphrases can be easily and continuously captured every month at ∼70% precision, and demonstrate their utility for downstream NLP tasks through phrasal paraphrase extraction. We make our code and data freely available.[1]

1 Introduction

A paraphrase is a restatement of meaning using different expressions (Bhagat and Hovy, 2013). It is a fundamental semantic relation in human language, as formalized in the Meaning-Text linguistic theory which defines meaning as 'invariant of paraphrases' (Milićević, 2006). Researchers have shown benefits of using paraphrases in a wide range of applications (Madnani and Dorr, 2010), including question answering (Fader et al., 2013), semantic parsing (Berant and Liang, 2014), information extraction (Sekine, 2006; Zhang et al., 2015), machine translation (Mehdizadeh Seraj et al., 2015), textual entailment (Dagan et al., 2006; Bjerva et al., 2014; Marelli et al., 2014; Izadinia et al., 2015), vector semantics (Faruqui et al., 2015; Wieting et al., 2015), and semantic textual similarity (Agirre et al., 2015; Li and Srikumar, 2016). Studying paraphrases in Twitter can also help track unfolding events (Vosoughi and Roy, 2016) or the spread of information (Bakshy et al., 2011) on social networks.

In this paper, we address a major challenge in paraphrase research — the lack of parallel corpora. There are **only two** publicly available datasets of naturally occurring sentential paraphrases and non-paraphrases:[2] the MSRP corpus derived from clustered news articles (Dolan and Brockett, 2005) and the PIT-2015 corpus from Twitter trending topics (Xu et al., 2014, 2015). Our goal is not only to create a new annotated paraphrase corpus, but to identify a new data source and method that can narrow down the search space of paraphrases without using the classifier-biased or human-in-the-loop data selection as in MSRP and PIT-2015. This is so that sentential paraphrases can be conveniently and continuously harvested in large quantities to benefit downstream applications.

We present an effective method to collect sentential paraphrases from tweets that refer to the same URL and contribute a new gold-standard annotated corpus of 51,524 sentence pairs, which is the largest to date (Table 1). We show the different characteristics of this new dataset contrasting the two existing corpora through the first system-

[1] The code and data can be obtained from the first and last author's websites.

[2] Meaningful non-paraphrases (pairs of sentences that have similar wordings or topics but different meanings, and that are not randomly or artificially generated) have been very difficult to obtain but are very important, because they serve as necessary distractors in training and evaluation.

Proceedings of the 2017 Conference on Empirical Methods in Natural Language Processing, pages 1224–1234
Copenhagen, Denmark, September 7–11, 2017.

Name	Genre	Size	Sentence Length	Multi-Ref.	Non-Para.
MSR Paraphrase Corpus (MSRP)	news	5801 pairs	18.9 words	no	yes
Twitter Paraphrase Corpus (PIT-2015)	Twitter	18,762 pairs	11.9 words	some	yes
Twitter News URL Corpus (this work)	Twitter	44,365 pairs	14.8 words	yes	yes
MSR Video Description Corpus	YouTube	123,626 sentences	7.03 words	yes	no

Table 1: Summary of publicly available large sentential paraphrase corpora with manual quality assurance. Our Twitter News URL Corpus has the advantages of including both meaningful non-paraphrases (Non-Para.) and multiple references (Multi-Ref.), which are important for training paraphrase identification and evaluating paraphrase generation, respectively.

atic study of paraphrase identification across multiple datasets. Our new corpus is complementary to previous work, as the corpus contains multiple references of both formal well-edited and informal user-generated texts. This is also the first work that provides a continuously growing collection, with more than 30,000 new sentential paraphrases per month automatically labeled at ∼70% precision. We demonstrate that up-to-date phrasal paraphrases can then be extracted via word alignment (see examples in Table 2). We plan to continue collecting paraphrases using our method and release a constantly updating paraphrase resource.

Table 2: Up-to-date phrasal paraphrases automatically extracted from Twitter with our new method.

2 Existing Paraphrase Corpora and Their Limitations

To date, there exist only two publicly available corpora of both sentential paraphrases and non-paraphrases:

MSR Paraphrase Corpus [MSRP] (Dolan et al., 2004; Dolan and Brockett, 2005) This corpus contains 5,801 pairs of sentences from news articles, with 4,076 for training and the remaining 1,725 for testing. It was created from clustered news articles by using an SVM classifier (using features including string similarity and WordNet synonyms) to gather likely paraphrases, then annotated by human on semantic equivalence. The MSRP corpus has a known deficiency skewed toward over-identification (Das and Smith, 2009), because the "purpose was not to evaluate the potential effectiveness of the classifier itself, but to identify a reasonably large set of both positive and plausible 'near-miss' negative examples" (Dolan and Brockett, 2005). It contains a large portion of sentence pairs with many ngrams shared in common.

Twitter Paraphrase Corpus [PIT-2015] (Xu et al., 2014, 2015) This corpus was derived from Twitter's trending topic data. The training set contains 13,063 sentence pairs on 400 distinct topics, and the test set contains 972 sentence pairs on 20 topics. As numerous Twitter users spontaneously talk about varied topics, this dataset contains many lexically divergent paraphrases. However, this method requires a manual step of selecting topics to ensure the quality of collected paraphrases, because many topics detected automatically are either incorrect or too broad. For example, the topic "New York" relates to tweets with a wide range of information and cannot narrow the search space down enough for human annotation and the subsequent application of classification algorithms.

3 Constructing the Twitter URL Paraphrase Corpus

For paraphrase acquisition, it has been crucial to find a simple and effective way to locate paraphrase candidates (see related work in Section 6). We show the efficacy of tracking URLs in Twitter. This method does not rely on automatic news clustering as in MSRP or topic detection as in PIT-2015, but it keeps collecting good candidate paraphrase pairs in large quantities.

[3] Another 12 name variations are omitted in the paper due to their offensive nature.

Twitter News URL Corpus	
Original Tweet	Samsung halts production of its Galaxy Note 7 as battery problems linger
Paraphrase	#Samsung temporarily suspended production of its Galaxy #Note7 devices following reports
	News hit that @Samsung is temporarily halting production of the #GalaxyNote7.
	Samsung still having problems with their Note 7 battery overheating. Completely halt production.
	SAMSUNG HALTS PRODUCTS OF GALAXY NOTE 7 . THE BATTERIES ARE * STILL * EXPLODING .
Non-Paraphrase	in which a phone bonfire in 1995–a real one–is a metaphor for samsung's current note 7 problems
	samsung decides, "if we don't build it, it won't explode."
	Samsung's Galaxy Note 7 Phones AND replacement phones have been going up in flames due to the defective batteries

Table 3: A representative set of tweets linked by a URL originated from news agencies (this work).

Twitter Streaming URL Data	1 dasviness louistomlinson overhears harrystyles on the phone
	when she likes tall guys ??? ??? vine by justjamiie
	shineeasvines jonghyun when he wears shoe lifts
	idaliaorellana kimmvanny ladyfea 21 hahaha if he does it he needs heels

Table 4: A representative set of tweets linked by a URL in streaming data (generally poor readability).

3.1 Data Source: News Tweets vs. Streaming

We extracted the embedded URL in each tweet and used Twitter's Search API to retrieve all tweets that contain the same URL. Some tweets use shortened URLs, which we resolve as full URLs. We tracked 22 English news accounts in Twitter to create the paraphrase corpus in this paper (see examples in Table 3). We will extend the corpus to include other languages and domains in future work.

As shown in Table 5, nearly all the tweets posted by news agencies have embedded URLs. About 51.17% of posts contain two URLs, usually one pointing to a news article and the other to media such as a photo or video. Although close to half of the tweets in Twitter streaming data[4] contain at least one URL, most of them are very hard to read (see examples in Table 4).

Data Source	**tweets w/o url**	**avg #url per tweet**	**avg # url (news) per tweet**
Streaming Data	55.8%	0.52	
@nytimes	1.2%	1.31	0.988
@cnnbrk	0.0%	1.17	1
@BBCBreaking	1.0%	1.32	0.99
@CNN	0.0%	1.85	1
@ABC	1.7%	1.26	0.983
@NBCNews	1.1%	1.63	0.989

Table 5: Statistics of tweets in Twitter's streaming data and news account data. Many tweets contain more than one URL because media such as photo or video is also represented by URLs.

3.2 Filtering of Retweets

Retweeting is an important feature in Twitter. There are two types: automatic and manual retweets. An automatic retweet is done by clicking the retweet button on Twitter and is easy to remove using the Twitter API. A manual retweet occurs when the user creates a new tweet by copying and pasting the original tweet and possibly adding some extras, such as hashtags, usernames or comments. It is crucial to remove these redundant tweets with minor variations, which otherwise represent a significant portion of the data (Table 6). We preprocessed the tweets using a tokenizer[5] (Gimpel et al., 2011) and an in-house sentence splitter. We then filtered out manual retweets using a set of rules, checking if one tweet was a sub- string of the other, or if it only differed in punctuation, or the contents of the "twitter:title" or "twitter:description" tag in the linked HTML file of the news article.

Table 6 shows the effectiveness of the filtering. We used PINC, a standard paraphrase metric, to measure ngram-based dissimilarity (Chen and Dolan, 2011), and Jaccard metric to measure token-based string similarity (Jaccard, 1912). After filtering, the dataset contains tweets with more significant rephrasing as indicated by higher PINC and lower Jaccard scores.

	avg #tweets (STD)	**avg PINC**	**avg Jaccard**
before filtering	205.51 (219.66)	0.6153	0.3635
after filtering	74.75 (94.39)	0.7603	0.2515

Table 6: Impact of filtering of manual retweets.

[4] We used Twitters Streaming API which provided a real-time stream of public tweets posted on Twitter.

[5] `http://www.cs.cmu.edu/~ark/TweetNLP/`

3.3 Gold Standard Corpus

To get the gold-standard paraphrase corpus, we obtained human labels on Amazon Mechanical Turk. We showed annotators an original sentence, and asked them to select sentences with the same meaning from 10 candidate sentences. For each question, we recruited 6 annotators and paid $0.03 to each worker.[6] On average, each question took about 53 seconds to finish. For each sentence pair, we aggregated the paraphrase and non-paraphrase labels using the majority vote.

We constructed the largest gold standard paraphrase corpus to date, with 42,200 tweets of 4,272 distinct URLs annotated in the training set and 9,324 tweets of 915 distinct URLs in the test set. The training data was collected between 10/10/2016 and 11/22/2016, and testing data between 01/09/2017 and 01/19/2017. In Section 4, we contrast the characteristics of our data against existing paraphrase corpora.

Quality Control We evaluated the annotation quality of each worker using Cohen's kappa agreement (Artstein and Poesio, 2008) against the majority vote of other workers. We asked the best workers (the top 528 out of 876) to label more data by republishing the questions done by workers with low reliability (Cohen's kappa <0.4).

Inter-Annotator Agreement In addition, we had 300 sampled sentence pairs independently annotated by an expert. The annotated agreement is 0.739 by Cohen's kappa between the expert and the majority vote of 6 crowdsourcing workers. If we assume the expert annotation is gold, the precision of worker vote is 0.871, the recall is 0.787, and F1 is 0.827, similar to those of PIT-2015.

3.4 Continuous Harvesting of Sentential Paraphrases

Since our method directly applies to raw tweets, it can continuously extract sentential paraphrases from Twitter. In Section 4, we show that this approach can produce a silver-standard paraphrase corpus at about 70% precision that grows by more than 30,000 new sentential paraphrases *per month*. Section 5 presents experiments demonstrating the utility of these automatically identified sentential paraphrases.

4 Comparison of Paraphrase Corpora

Though paraphrasing has been widely studied, supporting analyses and experiments have thus far often only been conducted on a single dataset. In this section, we present a comparative analysis of our newly constructed gold-standard corpus with two existing corpora by 1) individually examining the instances of paraphrase phenomena and 2) benchmarking a range of automatic paraphrase identification approaches.

4.1 Paraphrase Phenomena

In order to show the differences across these three datasets, we sampled 100 sentential paraphrases from each training set and counted occurrences of each phenomenon in the following categories: Elaboration (textual pairs can differ in total information content, such as *Trump's ex-wife Ivana* and *Ivana Trump*), Phrasal (alternates of phrases, such as *taking over* and *replaces*), Spelling (spelling variants, such as *Trump* and *Trumpf*), Synonym (such as *said* and *told*), Anaphora (a full noun phrase in one sentence that corresponds to the counterpart, such as *@MarkKirk* and *Kirk*) and Reordering (when a word, phrase or the whole sentence reorders, or even logically reordered, such as *Matthew Fishbein questioned him* and *under questioning by Matthew Fishbein*). We report the average number of occurrences of each paraphrase type per sentence pair for each corpus in Table 7. As sentences tend to be longer in MSRP and shorter in PIT-2015, we also normalized the numbers by the length of sentences to be more comparable to the URL dataset.

These three datasets exhibit distinct and complementary compositions of paraphrase phenom-

per sentence	**MSRP**	**PIT-2015**	**URL**
Elaboration	0.60	0.23	**0.79**
Spelling	0.17	0.13	**0.35**
Synonym	**0.26**	0.10	0.13
Phrasal	0.42	**0.56**	0.35
Anaphora	0.27	0.08	**0.33**
Reordering	**0.53**	0.33	0.49
adjusted by sent length*	**MSRP***	**PIT-2015***	**URL**
Elaboration	0.42	0.36	**0.79**
Spelling	0.12	0.21	**0.35**
Synonym	**0.18**	0.16	0.13
Phrasal	0.29	**0.89**	0.35
Anaphora	0.19	0.13	**0.33**
Reordering	0.37	**0.52**	0.49

Table 7: Mean number of instances of paraphrase phenomena per sentence pair across three corpora.

[6] The low pricing helps to not attract spammers to this easy-to-finish task. We gave bonus to workers based on quality and the average hourly pay for each worker is about $7.

ena. MSRP has more synonyms, because authors of different news articles may use different and rather sophisticated words. PIT-2015 contains many phrasal paraphrases, probably due to the fact that most tweets under the same trending topic are written spontaneously and independently. Our URL dataset shows more elaboration, spelling and anaphora paraphrase phenomena, showing that many URL-embedded tweets are created by users with a conscious intention to rephrase the original news headline.

4.2 Automatic Paraphrase Identification

We provide a benchmark on paraphrase identification to better understand various models, as well as the characteristics of our new corpus compared to the existing ones. We focus on binary classification of paraphrase/non-paraphrase, and report the maximum F1 measure of any point on the precision-recall curve.

4.2.1 Models

We chose several representative technical approaches for automatic paraphrase identification:

GloVe (Pennington et al., 2014) This is a word representation model trained on aggregated global word-word co-occurrence statistics from a corpus. We used 300-dimensional word vectors trained on Common Crawl and Twitter, summed the vectors for each sentence, and computed the cosine similarity.

LR The logistic regression (LR) model incorporates 18 features based on 1-3 gram overlaps between two sentences (s_1 and s_2) (Das and Smith, 2009). The features are of the form precision$_n$ (number of n-gram matches divided by the number of n-grams in s_1), recall$_n$ (number of n-gram matches divided by the number of n-grams in s_2), and F$_n$ (harmonic mean of recall and precision). The model also includes lemmatized versions of these features.

WMF/OrMF Weighted Matrix Factorization (WMF) (Guo and Diab, 2012) is an unsupervised latent space model. The unobserved words are carefully handled, which results in more robust embeddings for short texts. Orthogonal Matrix Factorization (OrMF) (Guo et al., 2014) is the extension of WMF, with an additional objective to obtain nearly orthogonal dimensions in matrix factorization to discount redundant information.

Method	F1	Precision	Recall

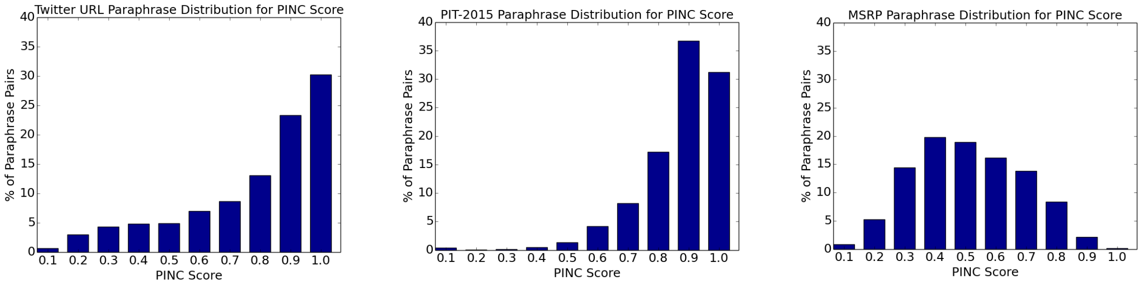
Table 10: Paraphrase models in Twitter URL Corpus (this work).



(a) Twitter URL

(b) PIT-2015

(c) MSRP

Figure 1: Comparison of ngram dissimilarity (PINC score) in sentential paraphrases across three corpora. The MSRP contains sentential paraphrases with more ngram overlaps (low PINC). Our URL corpus and PIT-2015 contain more lexically divergent paraphrases (high PINC).

Specifically, for the **(vec)** version, vectors of a pair of sentences $\vec{v_1}$ and $\vec{v_2}$ are converted into one feature vector, $[\vec{v_1} + \vec{v_2}, |\vec{v_1} - \vec{v_2}|]$, by concatenating the element-wise sum $\vec{v_1} + \vec{v_2}$ and absolute difference $|\vec{v_1} - \vec{v_2}|$. We also provide the **(sim)** variation, which directly uses the single cosine similarity score between two sentence vectors.

LEX-WMF/LEX-OrMF This is an open-sourced adaptation (Xu et al., 2014) of LEXDISCRIM (Ji and Eisenstein, 2013) that have shown comparable performance. It combines WMF/OrMF with n-gram overlapping features to train a LR classifier.

MultiP MultiP (Xu et al., 2014) is a multi-instance learning model suited for short messages on Twitter. The at-least-one-anchor assumption in this model looks for two sentences that have a topical phrase in common, plus at least one pair of anchor words that carry a similar key meaning. This model achieved the best performance in the PIT-2015 (Xu et al., 2014) dataset.

DeepPairwiseWord He et al. (2016) developed a deep neural network model that focuses on important pairwise word interactions across input sentences. This model innovates in proposing a similarity focus layer and a 19-layer very deep convolutional neural network to guide model attention to important word pairs. It has shown state-of-the-art performance on several textual similarity measurement datasets.

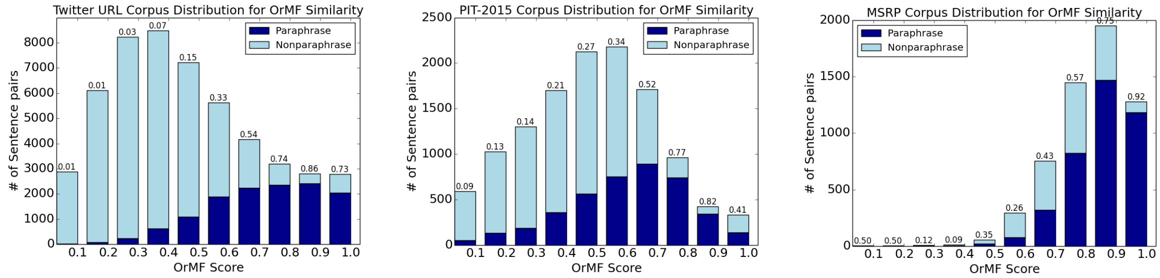
4.2.2 Model Performance and Dataset Difference

The results on three benchmark paraphrase corpora are shown in Table 8, 9 and 10. The random baseline reflects that close to 80% sentence pairs are paraphrases in the MSPR corpus. This is atypical in the real-world text data and may cause falsely positive predictions.

Both the edit distance and the LR models exploit surface word features. In particular, the LR model that uses lemmatization and ngram overlap features achieves very competitive performance on all datasets. Figure 1 shows a closer look at ngram differences across datasets measured by the PINC metric (Chen and Dolan, 2011), which is the opposite of BLEU (Papineni et al., 2002). MSRP consists of paraphrases with more ngram overlap (lower PINC), while PIT-2015 contains shorter and more lexically dissimilar sentences. Our new URL corpus is in between the two, and is more similar to PIT-2015. It includes user's intentional rephrasing of an original tweet from a news agency with some words untouched, as well as some dramatic paraphrases that are challenging for any automatic identification methods, such as *CO2 levels mark 'new era' in the world's changing climate* and *CO2 levels haven't been this high for 3 to 5 million years*.

MultiP exploits a restrictive constraint that the candidate sentence pairs share a same topical phrase. It achieves the best performance on PIT-2015, which naturally contains such phrases. For MSRP and URL datasets, we uses the named entity tagged with the longest span as an approximation of a shared topic phrase and thus suffered a performance drop.

Both Glove and WMT/OrMF utilize the underlying co-occurrence statistics of the text corpus. WMT/OrMF use global matrix factorization to project sentences into lower dimension and show great advantages on measuring sentence-level semantic similarities over Glove, which focuses on



(a) Twitter URL

(b) PIT-2015

(c) MSRP

Figure 2: Comparison of OrMF-based distributional semantic similarity across three paraphrase corpora.

word representations. Figure 2 shows that the fine-grained distribution of the OrMF-based cosine similarities and that the URL-linked Twitter data works well with OrMF to yield sentential paraphrases. Once combined with ngram overlap features, LEX-WMF and LEX-OrMF show consistently high performance across different datasets, close to the more complicated DeepPairwiseWord. The similarity focus mechanism on important pairwise word interactions in DeepPairwiseWord is more helpful for the two Twitter datasets, due to the fact that they contain lexically divergent paraphrases while MSRP has an artificial bias toward sentences with high n-gram overlap.

5 Extracting Phrasal Paraphrases

We can apply paraphrase identification models trained on our gold standard corpus to unlabeled Twitter data and continuously harvest sentential paraphrases in large quantities. We used the open-sourced LEX-OrMF model and obtained 114,025 sentential paraphrases (system predicted probability $\geq$ 0.5 and average precision = 69.08%) from raw 1% free Twitter data between 10/10/2016 and 01/10/2017. To demonstrate the utility, we show that we can extract up-to-date lexical and phrasal paraphrases from this data.

5.1 Phrase Extraction and Ranking

One of the most successful ideas to obtain lexical and phrasal paraphrases in large quantities is through word alignment, then ranking for better quality. This approach was proposed by Bannard (Bannard and Callison-Burch, 2005) and previously applied to bilingual parallel data to create PPDB (Ganitkevitch et al., 2013; Pavlick et al., 2015). There has been little previous work utilizing monolingual parallel data to learn paraphrases since it is not as naturally available as bitexts.

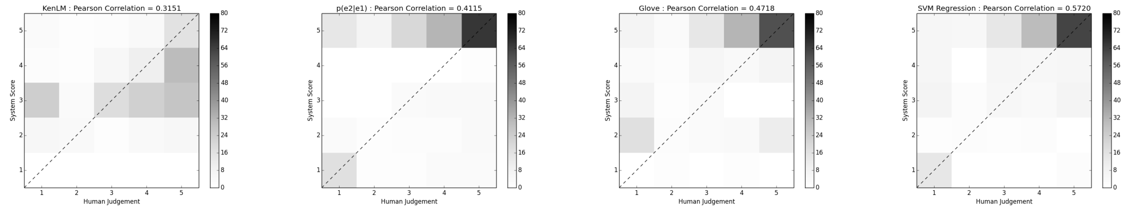
We used the GIZA++ word aligner in the Moses machine translation toolkit (Koehn et al., 2007) and extracted 245,686 phrasal paraphrases. Some examples are shown in Table 2. We additionally explored two supervised monolingual aligners: Jacana aligner (Yao et al., 2013) and Md Sultan's aligner (Sultan et al., 2014). We ranked the phrase pairs using four different scores:

- **Language Model Score** Let $w_{-2}w_{-1}pw_1w_2$ be the context of the phrase p. We considered a phrase p' to be a good substitute for p if $w_{-2}w_{-1}p'w_1w_2$ is a likely sequence according to a language model (Heafield, 2011) trained on Twitter data.
- **Translation Score** Moses provides translation probabilities $\varphi(p|p')$.
- **Glove Score** We used Glove (Pennington et al., 2014) pretrained 100-dimensional Twitter word vectors and cosine similarity.
- **Our Score** We trained a supervised SVM regression model using 500 phrase pairs with human ratings. We used the language model, translation, and glove scores as features, and additionally used the inverse phrase translation probability $\varphi(p'|p)$, lexical weighting $lex(p|p')$, and $lex(p'|p)$ from Moses.

Figure 3 compares the different ranking methods against the human judgments on 200 phrase pairs randomly sampled from GIZA++.

5.2 Paraphrase Quality Evaluation

We compared the quality of paraphrases extracted by our method with the closest previous work (BUCC-2013) (Xu et al., 2013), in which a similar phrase table was created using Moses from monolingual parallel tweets that contain the same named entity and calendar date. We randomly



(a) Language Model Score ($\rho = 0.3151$)

(b) Translation Score ($\rho = 0.4115$)

(c) Glove Score ($\rho = 0.4718$)

(d) Our Score ($\rho = 0.5720$)

Figure 3: Correlation between automatic scores (vertical axis) and 5-point human scores (horizontal axis) for ranking phrasal paraphrases. The darker squares along the diagonal line indicate a higher ranking.

sampled 500 phrase pairs from each phrase table and collected human judgements on a 5-point Likert scale, as described in Callison-Burch (Callison-Burch, 2008). Table 11 shows the evaluation results. We focused on the highest-quality paraphrases that rated as 5 (“all of the meaning of the original phrase is retained, and nothing is added”) and their presence among all extracted paraphrases sorted by ranking scores.

We were also interested in how these phrasal paraphrases compared with those in PPDB. We sampled an equal amount of 420 paraphrase pairs from our phrase tables and PPDB, and then checked what percentage out of the total 840 could be found in our phrase tables and PPDB, respectively. As shown in Table 12, there is little overlap between URL data and PPDB, only 1.3% (51.3-50%) plus 0.8% (50.8-50%). Our Twitter URL data complements well with the existing paraphrase resources, such as PPDB, which are primarily derived from well-edited texts.

Top Rankings	BUCC 2013	GIZA++	Jacana	Sultan
10%	76.0	85.5	90.0	90.0
20%	65.6	86.5	91.0	91.0
30%	62.7	79.2	86.0	88.0
40%	56.6	73.2	85.5	84.5
50%	52.1	68.1	83.4	84.8
100% (all)	36.3	49.8	75.8	77.2

6 Related Work

Sentential Paraphrase Data Researchers have found several data sources from which to collect sentential paraphrases: multiple news agencies reporting the same event (MSRP) (Dolan et al., 2004; Dolan and Brockett, 2005), multiple translated versions of a foreign novel (Barzilay and Elhadad, 2003; Barzilay and Lee, 2003) or other texts (Cohn et al., 2008), multiple definitions of the same concept (Hashimoto et al., 2011), descriptions of the same video clip from multiple workers (Chen and Dolan, 2011) or rephrased sentences (Burrows et al., 2013; Toutanova et al., 2016). However, all these data collection methods are incapable of obtaining sentential paraphrases on a large scale (i.e. limited number of news agencies or books with multiple translated versions), and/or lack meaningful negative examples. Both of these properties are crucial for developing machine learning models that identify paraphrases and measure semantic similarities.

	PPDB	URL	GIZA++	Jacana	Sultan
Sample Size	50%	50%	16.7%	16.7%	16.7%
Coverage	51.3%	50.8%	18.7%	32.1%	34.4%

Table 12: Coverage comparison of phrasal paraphrases extracted from Twitter URL data (sampled 1:1:1 from GIZA++, Jacana and Sultan’s aligner outputs) and the PPDB (Ganitkevitch et al., 2013).

Non-sentential Paraphrase Data There are other phrasal and syntactic paraphrase data, such as DIRT (Lin and Pantel, 2001), POLY (Grycner et al., 2016), PATTY (Nakashole et al., 2012), DEFIE (Bovi et al., 2015), and PPDB (Ganitkevitch et al., 2013; Pavlick et al., 2015). Most of these works focus on news or web data. Other earlier works on Twitter paraphrase extraction used unsupervised approaches (Xu et al., 2013; Wang et al., 2013) or small datasets (Zanzotto et al., 2011; Antoniak et al., 2015).

7 Conclusion and Future Work

In this paper, we show how a simple method can effectively and continuously collect large-scale sentential paraphrases from Twitter. We rigorously evaluated our data with automatic identification classification models and various measurements. We will share our new dataset with the research community; this dataset includes 51,524 sentence pairs manually labeled and a monthly growth of 30,000 sentential paraphrases automatically labeled. Future work could include expanding into many different languages present in social media and developing language-independent automatic paraphrase identification models.

Cross-domain Semantic Parsing via Paraphrasing

Abstract

Existing studies on semantic parsing mainly focus on the in-domain setting. We formulate cross-domain semantic parsing as a domain adaptation problem: train a semantic parser on some source domains and then adapt it to the target domain. Due to the diversity of logical forms in different domains, this problem presents unique and intriguing challenges. By converting logical forms into canonical utterances in natural language, we reduce semantic parsing to paraphrasing, and develop an attentive sequence-to-sequence paraphrase model that is general and flexible to adapt to different domains. We discover two problems, *small micro variance* and *large macro variance*, of pretrained word embeddings that hinder their direct use in neural networks, and propose standardization techniques as a remedy. On the popular OVERNIGHT dataset, which contains eight domains, we show that both cross-domain training and standardized pre-trained word embedding can bring significant improvement.

1 Introduction

Semantic parsing, which maps natural language utterances into computer-understandable logical forms, has drawn substantial attention recently as a promising direction for developing natural language interfaces to computers. Semantic parsing has been applied in many domains, including querying data/knowledge bases (Woods, 1973; Zelle and Mooney, 1996; Berant et al., 2013), controlling IoT devices (Campagna et al., 2017), and communicating with robots (Chen and Mooney, 2011; Tellex et al., 2011; Artzi and Zettlemoyer, 2013; Bisk et al., 2016).

Despite the wide applications, studies on semantic parsing have mainly focused on the *in-domain* setting, where both training and testing data are drawn from the same domain. How to build semantic parsers that can learn across domains remains an under-addressed problem. In this work, we study *cross-domain semantic parsing*. We model it as a domain adaptation problem (Daumé III and Marcu, 2006), where we are given some *source* domains and a *target* domain, and the core task is to adapt a semantic parser trained on the source domains to the target domain (Figure 1). The benefits are two-fold: (1) by training on the source domains, the cost of collecting training data for the target domain can be reduced, and (2) the data of source domains may provide information complementary to the data collected for the target domain, leading to better performance on the target domain.

This is a very challenging task. Traditional domain adaptation (Daumé III and Marcu, 2006; Blitzer et al., 2006) only concerns natural languages, while semantic parsing concerns both natural and formal languages. Different domains often involve different predicates. In Figure 1, from the source BASKETBALL domain a semantic parser can learn the semantic mapping from natural language to predicates like `team` and `season`, but in the target SOCIAL domain it needs to handle predicates like `employer` instead. Worse still, even for the same predicate, it is legitimate to use arbitrarily different predicate symbols, e.g., other symbols like `hired_by` or even `predicate1` can also be used for the `employer` predicate, reminiscent of the symbol grounding problem (Harnad, 1990). Therefore, directly transferring the mapping from natural language to predicate symbols learned from source domains to the target domain may not be much beneficial.

Figure 1: Cross-domain semantic parsing via paraphrasing framework. In a deterministic way, logical forms are first converted into canonical utterances in natural language. A paraphrase model then learns from the source domains and adapts to the target domain. External language resources can be incorporated in a consistent way across domains.

Inspired by the recent success of paraphrasing based semantic parsing (Berant and Liang, 2014; Wang et al., 2015), we propose to use natural language as an intermediate representation for cross-domain semantic parsing. As shown in Figure 1, logical forms are converted into canonical utterances in natural language, and semantic parsing is reduced to paraphrasing. It is the knowledge of paraphrasing, at lexical, syntactic, and semantic levels, that will be transferred across domains.

Still, adapting a paraphrase model to a new domain is a challenging and under-addressed problem. To give some idea of the difficulty, for each of the eight domains in the popular OVERNIGHT (Wang et al., 2015) dataset, 30% to 55% of the words never occur in any of the other domains, a similar problem observed in domain adaptation for machine translation (Daumé III and Jagarlamudi, 2011). The paraphrase model therefore can get little knowledge for a substantial portion of the target domain from the source domains. We introduce pre-trained word embeddings such as WORD2VEC (Mikolov et al., 2013) to combat the vocabulary variety across domains. Based on recent studies on neural network initialization, we conduct a statistical analysis of pre-trained word embeddings and discover two problems that may hinder their direct use in neural networks: *small micro variance*, which hurts optimization, and *large macro variance*, which hurts generalization. We propose to *standardize* pre-trained word embeddings, and show its advantages both analytically and experimentally.

On the OVERNIGHT dataset, we show that cross-domain training under the proposed framework can significantly improve model performance. We also show that, compared with directly using pre-trained word embeddings or normalization as in previous work, the proposed standardization technique can lead to about 10% absolute improvement in accuracy.

2 Cross-domain Semantic Parsing

2.1 Problem Definition

Unless otherwise stated, we will use u to denote input utterance, c for canonical utterance, and z for logical form. We denote $\mathcal{U}$ as the set of all possible utterances. For a domain, suppose $\mathcal{Z}$ is the set of logical forms, a semantic parser is a mapping $f: \mathcal{U} \rightarrow \mathcal{Z}$ that maps every input utterance to a logical form (a `null` logical form can be included in $\mathcal{Z}$ to reject out-of-domain utterances).

In cross-domain semantic parsing, we assume there are a set of K source domains $\{\mathcal{Z}_i\}_{i=1}^{K}$, each with a set of training examples $\{(u_j^i, z_j^i)\}_{j=1}^{N_i}$. It is in principle advantageous to model the source domains separately (Daumé III and Marcu, 2006), which retains the possibility of separating domain-general information from domain-specific information, and only transferring the former to the target domain. For simplicity, here we merge the source domains into a single domain $\mathcal{Z}_s$ with training data $\{(u_i, z_i)\}_{i=1}^{N_s}$. The task is to learn a semantic parser $f: \mathcal{U} \rightarrow \mathcal{Z}_t$ for a target domain $\mathcal{Z}_t$, for which we have a set of training examples $\{(u_i, z_i)\}_{i=1}^{N_t}$. Some characteristics can be summarized as follows:

- $\mathcal{Z}_t$ and $\mathcal{Z}_s$ can be totally disjoint.
- The input utterance distribution of the source and the target domains can be independent and differ remarkably.

- Typically $N_t \ll N_s$.

In the most general and challenging case, $\mathcal{Z}_t$ and $\mathcal{Z}_s$ can be defined using different formal languages. Because of the lack of relevant datasets, here we restrain ourselves to the case where $\mathcal{Z}_t$ and $\mathcal{Z}_s$ are defined using the same formal language, e.g., λ-DCS (Liang, 2013) as in the OVERNIGHT dataset.

2.2 Framework

Our framework follows the research line of semantic parsing via paraphrasing (Berant and Liang, 2014; Wang et al., 2015). While previous work focuses on the in-domain setting, we discuss its applicability and advantages in the cross-domain setting, and develop techniques to address the emerging challenges in the new setting.

Canonical utterance. We assume a *one-to-one* mapping $g\colon \mathcal{Z} \rightarrow \mathcal{C}$, where $\mathcal{C} \subset \mathcal{U}$ is the set of canonical utterances. In other words, every logical form will be converted into a unique canonical utterance deterministically (Figure 1). Previous work (Wang et al., 2015) has demonstrated how to design such a mapping, where a domain-general grammar and a domain-specific lexicon are constructed to automatically convert every logical form to a canonical utterance. In this work, we assume the mapping is given[1], and focus on the subsequent paraphrasing and domain adaptation problems.

This design choice is worth some discussion. The grammar, or at least the lexicon for mapping predicates to natural language, needs to be provided by domain administrators. This indeed brings an additional cost, but we believe it is reasonable and even necessary for three reasons: (1) Only domain administrators know the predicate semantics the best, so it has to be them to reveal that by grounding the predicates to natural language (the symbol grounding problem (Harnad, 1990)). (2) Otherwise, predicate semantics can only be learned from supervised training data of each domain, bringing a significant cost on data collection. (3) Canonical utterances are understandable by average users, and thus can also be used for training data collection via crowdsourcing (Wang et al., 2015; Su et al., 2016), which can amortize the cost.

Take comparatives as an example. In logical forms, comparatives can be legitimately defined using arbitrarily different predicates in different domains, e.g., `<`, `smallerInSize`, or even predicates with an ambiguous surface form, like `lt`. When converting logical form to canonical utterance, however, domain administrators have to choose common natural language expressions like "*less than*" and "*smaller*", providing a shared ground for cross-domain semantic parsing.

Paraphrase model. In the previous work based on paraphrasing (Berant and Liang, 2014; Wang et al., 2015), semantic parsers are implemented as log-linear models with hand-engineered domain-specific features (including paraphrase features). Considering the recent success of representation learning for domain adaptation (Glorot et al., 2011; Chen et al., 2012), we propose a paraphrase model based on the sequence-to-sequence (Seq2Seq) model (Sutskever et al., 2014), which can be trained end to end without feature engineering. We show that it outperforms the previous log-linear models by a large margin in the in-domain setting, and can easily adapt to new domains.

Pre-trained word embeddings. An advantage of reducing semantic parsing to paraphrasing is that external language resources become easier to incorporate. Observing the vocabulary variety across domains, we introduce pre-trained word embeddings to facilitate domain adaptation. For the example in Figure 1, the paraphrase model may have learned the mapping from "play for" to "whose team is" in a source domain. By acquiring word similarities ("play"-"work" and "team"-"employer") from pre-trained word embeddings, it can establish the mapping from "work for" to "whose employer is" in the target domain, even without in-domain training data. We analyze statistical characteristics of the pre-trained word embeddings, and propose standardization techniques to remedy some undesired characteristics that may bring a negative effect to neural models.

Domain adaptation protocol. We will use the following protocol: (1) train a paraphrase model using the data of the source domain, (2) use the learned parameters to initialize a model in the target domain, and (3) fine-tune the model using the training data of the target domain.

[1] In the experiments we use the provided canonical utterances of the OVERNIGHT dataset.

2.3 Prior Work

While most studies on semantic parsing so far have focused on the in-domain setting, there are a number of studies of particular relevance to this work. In the recent efforts of scaling semantic parsing to large knowledge bases like Freebase (Bollacker et al., 2008), researchers have explored several ways to infer the semantics of knowledge base relations unseen in training, which are often based on at least one (often both) of the following assumptions: (1) *Distant supervision*. Freebase entities can be linked to external text corpora, and serve as anchors for seeking semantics of Freebase relations from text. For example, Cai and Alexander (2013), among others (Berant et al., 2013; Xu et al., 2016), use sentences from Wikipedia that contain any entity pair of a Freebase relation as the support set of the relation. (2) *Self-explaining predicate symbols*. Most Freebase relations are described using a carefully chosen symbol (surface form), e.g., `place_of_birth`, which provides strong cues for their semantics. For example, Yih et al. (2015) directly compute the similarity of input utterance and the surface form of Freebase relations via a convolutional neural network. Kwiatkowski et al. (2013) also extract lexical features from input utterance and the surface form of entities and relations. They have actually evaluated their model on Freebase subdomains not covered in training, and have shown impressive results. However, in the more general setting of cross-domain semantic parsing, we may have neither of these luxuries. Distant supervision may not be available (e.g., IoT devices involving no entities but actions), and predicate symbols may not provide enough cues (e.g., `predicate1`). In this case, seeking additional inputs from domain administrators is probably necessary.

In parallel of this work, Herzig and Berant (2017) have explored another direction of semantic parsing with multiple domains, where they use all the domains to train a single semantic parser, and attach a domain-specific encoding to the training data of each domain to help the semantic parser differentiate between domains. We pursue a different direction: we train a semantic parser on some source domains and adapt it to the target domain. Another difference is that their work directly maps utterances to logical forms, while ours is based on paraphrasing.

Cross-domain semantic parsing can be seen as a way to reduce the cost of training data collection, which resonates with the recent trend in semantic parsing. Berant et al. (2013) propose to learn from utterance-denotation pairs instead of utterance-logical form pairs, while Wang et al. (2015) and Su et al. (2016) manage to employ crowd workers with no linguistic expertise for data collection. Jia and Liang (2016) propose an interesting form of data augmentation. They learn a grammar from existing training data, and generate new examples from the grammar by recombining segments from different examples.

We use natural language as an intermediate representation to transfer knowledge across domains, and assume the mapping from the intermediate representation (canonical utterance) to logical form can be done deterministically. Several other intermediate representations have also been used, such as combinatory categorial grammar (Kwiatkowski et al., 2013; Reddy et al., 2014), dependency tree (Reddy et al., 2016, 2017), and semantic role structure (Goldwasser and Roth, 2013). But their main aim is to better represent input utterances with a richer structure. A separate ontology matching step is needed to map the intermediate representation to logical form, which requires domain-dependent training.

A number of other related studies have also used paraphrasing. For example, Fader et al. (2013) leverage question paraphrases to for question answering, while Narayan et al. (2016) generate paraphrases as a way of data augmentation.

Cross-domain semantic parsing can greatly benefit from the rich literature of domain adaptation and transfer learning (Daumé III and Marcu, 2006; Blitzer et al., 2006; Pan and Yang, 2010; Glorot et al., 2011). For example, Chelba and Acero (2004) use parameters trained in the source domain as prior to regularize parameters in the target domain. The feature augmentation technique from Daumé III (2009) can be very helpful when there are multiple source domains. We expect to see many of these ideas to be applied in the future.

3 Paraphrase Model

In this section we propose a paraphrase model based on the Seq2Seq model (Sutskever et al., 2014) with soft attention. Similar models have been used in semantic parsing (Jia and Liang, 2016; Dong and Lapata, 2016) but for directly mapping utterances to logical forms. We demonstrate that it can also be used as a paraphrase model for semantic parsing. Several other neural models have been proposed for paraphrasing (Socher et al., 2011; Hu et al., 2014; Yin and Schütze, 2015), but it is not the focus of this work to compare all the alternatives.

For an input utterance $u = (u_1, u_2, \ldots, u_m)$ and an output canonical utterance $c = (c_1, c_2, \ldots, c_n)$, the model estimates the conditional probability $p(c|u) = \prod_{j=1}^{n} p(c_j|u, c_{1:j-1})$. The tokens are first converted into vectors via a word embedding layer ϕ. The initialization of the word embedding layer is critical for domain adaptation, which we will further discuss in Section 4.

The *encoder*, which is implemented as a bi-directional recurrent neural network (RNN), first encodes u into a sequence of state vectors $(h_1, h_2, \ldots, h_m)$. The state vectors of the forward RNN and the backward RNN are respectively computed as:

$$\overrightarrow{h}_i = GRU_{fw}(\phi(u_i), \overrightarrow{h}_{i-1})$$
$$\overleftarrow{h}_i = GRU_{bw}(\phi(u_i), \overleftarrow{h}_{i+1})$$

where gated recurrent unit (GRU) as defined in (Cho et al., 2014) is used as the recurrence. We then concatenate the forward and backward state vectors, $h_i = [\overrightarrow{h}_i, \overleftarrow{h}_i], i = 1, \ldots, m$.

We use an attentive RNN as the *decoder*, which will generate the output tokens one at a time. We denote the state vectors of the decoder RNN as $(d_1, d_2, \ldots, d_n)$. The attention takes a form similar to (Vinyals et al., 2015). For the decoding step j, the decoder is defined as follows:

$$\begin{aligned} d_0 &= \tanh(W_0[\overrightarrow{h}_m, \overleftarrow{h}_1]) \\ u_{ji} &= v^T \tanh(W_1 h_i + W_2 d_j) \\ \alpha_{ji} &= \frac{u_{ji}}{\sum_{i'=1}^{m} u_{ji'}} \\ h'_j &= \sum_{i=1}^{m} \alpha_{ji} h_i \\ d_{j+1} &= GRU([\phi(c_j), h'_j], d_j) \\ p(c_j|u, c_{1:j-1}) &\propto \exp(U[d_j, h'_j]) \end{aligned}$$

where W_0, W_1, W_2, v and U are model parameters. The decoder first calculates normalized attention weights α_{ji} over encoder states, and get a summary state h'_j. The summary state is then used to calculate the next decoder state d_{j+1} and the output probability distribution $p(c_j|u, c_{1:j-1})$.

Training. Given a set of training examples $\{(u_i, c_i)\}_{i=1}^{N}$, we minimize the cross-entropy loss $-\frac{1}{N}\sum_{i=1}^{N} \log p(c_i|u_i)$, which maximizes the log probability of the correct canonical utterances. We apply dropout (Hinton et al., 2012) on both input and output of the GRU cells to prevent overfitting.

Testing. Given a domain $\{\mathcal{Z}, \mathcal{C}\}$, there are two ways to use a trained model. One is to use it to *generate* the most likely output utterance u' given an input utterance u (Sutskever et al., 2014),

$$u' = \arg\max_{u' \in \mathcal{U}} p(u'|u).$$

In this case u' can be any utterance permissable by the output vocabulary, and may not necessarily be a legitimate canonical utterance in $\mathcal{C}$. This is more suitable for large domains with a lot of logical forms, like Freebase. An alternative way is to use the model to *rank* the legitimate canonical utterances (Kannan et al., 2016):

$$c = \arg\max_{c \in \mathcal{C}} p(c|u),$$

which is more suitable for small domains having a limited number of logical forms, like the ones in the OVERNIGHT dataset. We will adopt the second strategy. It is also very challenging; random guessing leads to almost no success. It is also possible to first find a smaller set of candidates to rank via beam search (Berant et al., 2013; Wang et al., 2015).

4 Pre-trained Word Embedding for Domain Adaptation

Pre-trained word embeddings like WORD2VEC have a great potential to combat the vocabulary variety across domains. For example, we can use pre-trained WORD2VEC vectors to initialize the word embedding layer of the source domain, with the hope that the other parameters in the model will co-adapt with the word vectors during training in the source domain, and generalize better to the out-of-vocabulary words (but covered by WORD2VEC) in the target domain. However, deep neural networks are very sensitive to initialization (Erhan et al., 2010), and a statistical analysis of the pre-trained WORD2VEC vectors reveals some characteristics that may not be desired for initializing deep neural networks. In this section we present the analysis and propose a standardization technique to remedy the undesired characteristics.

Initialization	L2 norm	Micro Variance	Cosine Sim.
Random	17.3 ± 0.45	1.00 ± 0.05	0.00 ± 0.06
word2vec	2.04 ± 1.08	0.02 ± 0.02	0.13 ± 0.11
word2vec + ES	17.3 ± 0.05	1.00 ± 0.00	0.13 ± 0.11
word2vec + FS	16.0 ± 8.47	1.09 ± 1.31	0.12 ± 0.10
word2vec + EN	1.00 ± 0.00	0.01 ± 0.00	0.13 ± 0.11

Table 1: Statistics of the word embedding matrix with different initialization strategies. Random: random sampling from $U(-\sqrt{3}, \sqrt{3})$, thus unit variance. word2vec: raw word2vec vectors. ES: per-example standardization. FS: per-feature standardization. EN: per-example normalization. Cosine similarity is computed on a randomly selected (but fixed) set of 1M word pairs.

Analysis. Our analysis will be based on the 300-dimensional word2vec vectors trained on the 100B-word Google News corpus[2]. It contains 3 million words, leading to a 3M-by-300 word embedding matrix. The "rule of thumb" to randomly initialize word embedding in neural networks is to sample from a uniform or Gaussian distribution with *unit variance*, which works well for a wide range of neural network models in general. We therefore use it as a reference to compare different word embedding initialization strategies. Given a word embedding matrix, we compute the L2 norm of each row and report the mean and the standard deviation. Similarly, we also report the variance of each row (denoted as *micro variance*), which indicates how far the numbers in the row spread out, and pair-wise cosine similarity, which indicates the word similarity captured by word2vec.

The statistics of the word embedding matrix with different initialization strategies are shown in Table 1. Compared with random initialization, two characteristics of the word2vec vectors stand out: (1) *Small micro variance*. Both the L2 norm and the micro variance of the word2vec vectors are much smaller. (2) *Large macro variance*. The variance of different word2vec vectors, reflected by the standard deviation of L2 norm, is much larger (e.g., the maximum and the minimum L2 norm are 21.1 and 0.015, respectively). Small micro variance can make the variance of neuron activations starts off too small[3], implying a poor starting point in the parameter space. On the other hand, because of the magnitude difference, large macro variance may make a model hard to generalize to words unseen in training.

Standardization. Based on the above analysis, we propose to do *unit variance standardization* (standardization for short) on pre-trained word embeddings. There are two possible ways, *per-example standardization*, which standardizes each row of the embedding matrix to unit variance by simply dividing by the standard deviation of the row, and *per-feature standardization*, which standardizes each column instead. We do not make the rows or columns zero mean. Per-example standardization enjoys the goodness of both random initialization and pre-trained word embeddings: it fixes the small micro variance problem as well as the large macro variance problem of pre-trained word embeddings, while still preserving cosine similarity, i.e., word similarity. Per-feature standardization does not preserve cosine similarity, nor does it fix the large macro variance problem. However, it enjoys the benefit of *global* statistics, in contrast to the *local* statistics of individual word vectors used in per-example standardization. Therefore, in problems where the testing and training vocabularies are similar, per-feature standardization may be more advantageous. Both standardizations lose vector magnitude information. Levy et al. (2015) have suggested *per-example normalization*[4] of pre-trained word embeddings for lexical tasks like word similarity and analogy, which do no involve deep neural networks. Making the word vectors unit length alleviates the large macro variance problem, but the small micro variance problem remains (Table 1).

Discussion. This is indeed a pretty simple trick, and per-feature standardization (with zero mean) is also a standard data preprocessing method. However, it is not self-evident that this kind of standardization shall be applied on pre-trained word embeddings before using them in deep neural networks, especially with the obvious downside of rendering the word embedding algorithm's loss function sub-optimal.

We expect this to be less of a issue for large-scale problems with a large vocabulary and abundant training examples. For example, Vinyals et al. (2015) have found that directly using the word2vec vectors for initialization can bring a

[2] https://code.google.com/archive/p/word2vec/

[3] Under some conditions, including using Xavier initialization (also introduced in that paper and now widely used) for weights, Glorot and Bengio (2010) have shown that the activation variances in a feedforward neural network will be roughly the same as the input variances (word embedding here) at the beginning of training.

[4] It can also be found in the implementation of Glove (Pennington et al., 2014): https://github.com/stanfordnlp/GloVe

consistent, though small, improvement in neural constituency parsing. However, for smaller-scale problems (e.g., an application domain of semantic parsing can have a vocabulary size of only a few hundreds), this issue becomes more critical. Initialized with the raw pre-trained vectors, a model may quickly fall into a poor local optimum and may not have enough signal to escape. Because of the large macro variance problem, standardization can be critical for domain adaptation, which needs to generalize to many words unseen in training.

The proposed standardization technique appears in a similar spirit to batch normalization (Ioffe and Szegedy, 2015). We notice two computational differences, that ours is applied on the inputs while batch normalization is applied on internal neuron activations, and that ours standardizes the whole word embedding matrix beforehand while batch normalization standardizes each mini-batch on the fly. In terms of motivation, the proposed technique aims to remedy some undesired characteristics of pre-trained word embeddings, and batch normalization aims to reduce the internal covariate shift. It is of interest to study the combination of the two in future work.

5 Evaluation

5.1 Data Analysis

The OVERNIGHT dataset (Wang et al., 2015) contains 8 different domains. Each domain is based on a separate knowledge base, with logical forms written in λ-DCS (Liang, 2013). Logical forms are converted into canonical utterances via a simple grammar, and the input utterances are collected by asking crowd workers to paraphrase the canonical utterances. Different domains are designed to stress different types of linguistic phenomena. For example, the CALENDAR domain requires a semantic parser to handle temporal language like "*meetings that start after 10 am*", while the BLOCKS domain features spatial language like "*which block is above block 1*".

Vocabularies vary remarkably across domains (Table 2). For each domain, only 45% to 70% of the words are covered by any of the other 7 domains. A model has to learn the out-of-vocabulary words from scratch using in-domain training data. The pre-trained WORD2VEC embedding covers most of the words of each domain, and thus can connect the domains to facilitate domain adaptation. Words that are still missing are mainly stop words and typos, e.g., "*ealiest*".

5.2 Experiment Setup

We compare our model with all the previous methods evaluated on the OVERNIGHT dataset. Wang et al. (2015) use a log-linear model with a rich set of features, including paraphrase features derived from PPDB (Ganitkevitch et al., 2013), to rank logical forms. Xiao et al. (2016) use a multi-layer perceptron to encode the unigrams and bigrams of the input utterance, and then use a RNN to predict the derivation sequence of a logical form under a grammar. Similar to ours, Jia and Liang (2016) also use a Seq2Seq model with bi-directional RNN encoder and attentive decoder, but it is used to predict linearized logical forms. They also propose a data augmentation technique, which further improves the average accuracy to 77.5%. But it is orthogonal to this work and can be incorporated in any model including ours, therefore not included.

The above methods are all based on the in-domain setting, where a separate parser is trained for each domain. In parallel of this work, Herzig and Berant (2017) have explored another direction of cross-domain training: they use all of the domains to train a single parser, with a special domain encoding to help differentiate between domains. We instead model it as a domain adaptation problem, where training on the source and the target domains are separate. Their model is the same as Jia and Liang (2016). It is the current best-performing method on the OVERNIGHT dataset.

We use the standard 80%/20% split of training and testing, and randomly hold out 20% of training for validation. In cross-domain experiments, for each target domain, all the other domains are combined as the source domain. Hyper-parameters are selected based on the validation set. State size of both the encoder and the decoder are set to 100, and word embedding size is set to 300. Input and output dropout rate of the GRU cells are 0.7 and 0.5, respectively, and mini-batch size is 512. We use Adam with the default parameters suggested in the paper for optimization. We use gradient clipping with a cap for global norm at 5.0 to alleviate the exploding gradients problem of recurrent neural networks. Early stopping based on the validation set is used to decide when to stop training. The selected model is retrained using the whole training set (training + validation). The

evaluation metric is accuracy, i.e., the proportion of testing examples for which the top prediction yields the correct denotation. Our model is implemented in Tensorflow (Abadi et al., 2016), and the code can be found at `https://github.com/ysu1989/CrossSemparse`.

5.3 Experiment Results

5.3.1 Comparison with Previous Methods

The main experiment results are shown in Table 3. Our base model (Random + I) achieves an accuracy comparable to the previous best in-domain model (Jia and Liang, 2016). With our main novelties, cross-domain training and word embedding standardization, our full model is able to outperform the previous best model, and achieve the best accuracy on 6 out of the 8 domains. Next we examine the novelties separately.

5.3.2 Word Embedding Initialization

The in-domain results clearly show the sensitivity of model performance to word embedding initialization. Directly using the raw WORD2VEC vectors or with per-example normalization, the performance is significantly worse than random initialization (6.2% and 7.3%, respectively). Based on the previous analysis, however, one should not be too surprised. The small micro variance problem hurts optimization. In sharp contrast, both of the proposed standardization techniques lead to better in-domain performance than random initialization (1.4% and 2.5%, respectively), setting a new best in-domain accuracy (78.2%) on OVERNIGHT. The results show that the pre-trained WORD2VEC vectors can indeed provide useful information, but only when they are properly standardized.

5.3.3 Cross-domain Training

A consistent improvement from cross-domain training is observed across all word embedding initialization strategies. Even for raw WORD2VEC embedding or per-example normalization, cross-domain training helps the model escape the poor initialization, though still inferior to the alternative initializations. The best results are again obtained with standardization, with per-example standardization bringing a slightly larger improvement than per-feature standardization. We observe that the improvement from cross-domain training is correlated with the abundance of the in-domain training data of the target domain. To further examine this observation, we use the ratio between the number of examples (N) and the vocabulary size ($\lvert\mathcal{V}\rvert$) to indicate the data abundance of a domain (the higher, the more abundant), and compute the Pearson correlation coefficient between data abundance and accuracy improvement from cross-domain training (X$-$I). The results in Ta-

Word Embedding Initialization	Correlation
Random	−0.698

WORD2VEC + FS	−0.770
WORD2VEC + ES	−0.514

Table 4: Correlation between in-domain data abundance and improvement from cross-domain training. The gain of cross-domain training is more significant when in-domain training data is less abundant.

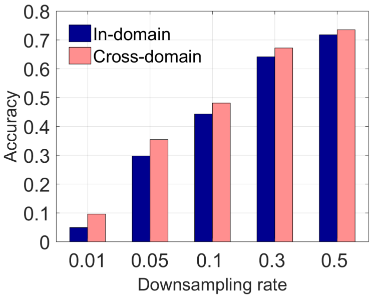

Figure 2: Results with downsampled in-domain training data. The experiment with each downsampling rate is repeated for 3 times and average results are reported. For simplicity, we only report the average accuracy over all domains. Pre-trained word embedding with per-example standardization is used in both settings.

ble 4 show a consistent, moderate to strong negative correlation between the two variables. In other words, cross-domain training is more beneficial when in-domain training data is less abundant, which is reasonable because in that case the model can learn more from the source domain data that is missing in the training data of the target domain.

5.3.4 Using Downsampled Training Data

Compared with the vocabulary size and the number of logical forms, the in-domain training data in the OVERNIGHT dataset is indeed abundant. In cross-domain semantic parsing, we are more interested in the scenario where there is insufficient training data for the target domain. To emulate this scenario, we downsample the in-domain training data of each target domain, but still use all training data from the source domain (thus $N_t \ll N_s$). The results are shown in Figure 2. The gain of cross-domain training is most significant when in-domain training data is scarce. As we collect more in-domain training data, the gain becomes smaller, which is expected. These results reinforce those from Table 4. It is worth noting that the effect of downsampling varies across domains. For domains with quite abundant training data like SOCIAL, using only 30% of the in-domain training data, the model can achieve an accuracy almost as good as when using all the data.

6 Discussion

Scalability, including *vertical scalability*, i.e., how to scale up to handle more complex inputs and logical constructs, and *horizontal scalability*, i.e., how to scale out to handle more domains, is one of the most critical challenges semantic parsing is facing today. In this work, we took an early step towards horizontal scalability, and proposed a paraphrasing based framework for cross-domain semantic parsing. With a sequence-to-sequence paraphrase model, we showed that cross-domain training of semantic parsing can be quite effective under a domain adaptation setting. We also studied how to properly standardize pre-trained word embeddings in neural networks, especially for domain adaptation.

This work opens up a number of future directions. As discussed in Section 2.3, many conventional domain adaptation and representation learning ideas can find application in cross-domain semantic parsing. In addition to pre-trained word embeddings, other language resources like paraphrase corpora (Ganitkevitch et al., 2013) can be incorporated into the paraphrase model to further facilitate domain adaptation. In this work we require a full mapping from logical form to canonical utterance, which could be costly for large domains. It is of practical interest to study the case where only a lexicon for mapping schema items to natural language is available. We have restrained ourselves to the case where domains are defined using the same formal language, and we look forward to evaluating the framework on domains of different formal languages when such datasets with canonical utterances become available.

Abstract

We introduce a new method for frame-semantic parsing that significantly improves the prior state of the art. Our model leverages the advantages of a deep bidirectional LSTM network which predicts semantic role labels word by word and a relational network which predicts semantic roles for individual text expressions in relation to a predicate. The two networks are integrated into a single model via knowledge distillation, and a unified graphical model is employed to jointly decode frames and semantic roles during inference. Experiments on the standard FrameNet data show that our model significantly outperforms existing neural and non-neural approaches, achieving a 5.7 F1 gain over the current state of the art, for full frame structure extraction.

1 Introduction

One way to represent meaning is through organization of semantic structures. Consider the following sentences "John sells Marry a car." and "Mary buys a car from John.". While having different syntactic structures, they express the same type of event that involves a buyer, a seller, and goods. Such meaning can be represented using semantic frames – structured representations that characterize events, scenarios, and the participants. Researchers have developed FrameNet (Baker et al., 1998; Fillmore et al., 2003), a large lexical database of English that comes with sentences annotated with semantic frames. It has been considered a valuable resource for Natural Language Processing and useful for studying tasks such as information extraction, machine translation, and question answering (Surdeanu et al., 2003; Shen and Lapata, 2007; Liu and Gildea, 2010).

Here we consider the task of automatic extraction of semantic frames as defined in FrameNet. This include *target identification* – identifying frame-evoking predicates, *frame identification* – identifying which frame each predicate evokes, and *semantic role labeling* (SRL) – identifying phrasal arguments of each evoked frame and labeling them with the frame's semantic roles. Consider the sentence "We decided to treat the patient with combination chemotherapy.". Here "decided" evokes the DECIDING frame and "treat" evokes the CURE frame. Each frame takes a set of arguments that fill the semantic roles of the frame, as illustrated below:

> [We$_{\text{COGNIZER}}$] **decided** [to treat the patient with combination chemotherapy$_{\text{DECISION}}$].
>
> [We$_{\text{HEALER}}$] decided to **treat** [the patient$_{\text{PATIENT}}$] [with combination chemotherapy$_{\text{TREATMENT}}$].

We address frame identification and semantic role labeling in this work.[1] Frame identification can be addressed as a word sense disambiguation problem, while semantic role labeling can be formulated as a structured prediction problem. We train different neural network models for these two problems, and interpret their outputs as factors in a graphical model for performing joint inference over the distribution of frames and semantic roles.

Specifically, our frame identification model is a simple multi-layer neural network that learns ap-

[1] We do not consider target identification due to the lack of consistent labeled data (Das et al., 2014).

Copenhagen, Denmark, September 7–11, 2017. ©2017 Association for Computational Linguistics

propriate feature representations for frame disambiguation. Our SRL model is an integrated model of an LSTM-based network that learns to predict semantic roles on a word-by-word basis and a multi-layer network that learns to directly predict semantic roles for individual text spans in relation to a given predicate. The sequential neural network is powerful for modeling sentence-level information while the relational neural network is good at capturing span-level dependencies between predicate and arguments. To leverage the power of these two networks, we transfer the knowledge in the sequential model, encoded as its predictive distributions. Specifically, we do this by training a single relational model with an objective that measures both its prediction accuracy with respect to the true semantic role labels, and its match to the probability distributions provided by the sequential model.

We evaluate our models for frame identification, SRL, and full structure extraction on the FrameNet 1.5 data. Our full model achieves 76.6 F1, a 5.7 absolute gain over the prior state of the art. We also evaluate our SRL model on CoNLL 2005. It demonstrates strong performance that is close to the best published results. Error analysis further confirms the benefits of integrating sequential and relational models and performing joint inference over frames and semantic roles.

2 Related Work

Research on automatic semantic structure extraction has been widely studied since the pioneering work of Gildea and Jurafsky (2002). This work focuses on extracting semantic frames defined in FrameNet (Baker et al., 1998), which includes predicting frame types and frame-specific semantic roles. Our model can be easily adapted to predict PropBank-style semantic roles (Palmer et al., 2005), where role labels are generic instead of frame-specific.

The core problem in semantic frame extraction is semantic role labeling (SRL). Earlier SRL systems employ linear classifiers which rely heavily on hand-engineered feature templates to represent argument structures (Johansson and Nugues, 2007; Das et al., 2010; Das, 2014). Recent work has exploited neural networks to learn better feature representations. Roth and Woodsend (2014) improves the feature-based system by adding word embeddings as features. Roth and Lapata (2016) further includes dependency path embeddings as features. FitzGerald et al. (2015) embeds the standard SRL features into a low-dimensional vector space using a feed-forward neural network and demonstrates state-of-the-art results on FrameNet.

Different neural network architectures have also been explored for SRL. Collobert et al. (2011) first applies a convolutional neural network to extract features from a window of words. Zhou and Xu (2015) employs a deep bi-directional LSTM (DB-LSTM) network and achieves state-of-the-art results on PropBank-style SRL. Recently, Swayamdipta et al. (2016) employs stack LSTMs (Dyer et al., 2015) for joint syntactic-semantic dependency parsing. He et al. (2017) recently proposed further improvements to the DB-LSTM architecture which significantly improve the state of the art results on PropBank SRL.

In order to enforce structural consistency, most existing work applies different types of structural constraints during inference. The inference problem are typically solved via Integer Linear Programming (ILP) (Punyakanok et al., 2008). Täckström et al. (2015) improves the inference efficiency with a dynamic programming algorithm that encodes tractable global constraints. Recently, Belanger et al. (2017) models SRL using end-to-end structured prediction energy networks and demonstrates benefits of accounting for complex structural dependencies during training. In this work, we explicitly encode structural constraints as factors in a graphical model, and adopt the Alternating Directions Dual Decomposition (AD^3) algorithm (Martins et al., 2011) for efficient inference.

3 Overview

We aim to extract frame-semantic structures from text. Each semantic frame contains a frame-evoking predicate, its frame type, the arguments of the predicate, and their semantic roles.

Both FrameNet (Baker et al., 1998) and PropBank (Palmer et al., 2005) provide sentences annotated with predicates and the semantic roles of arguments of the predicates, but there are some differences. In FrameNet, a semantic frame can be evoked by a set of lexical units. For example, the COMMERCE_BUY frame can be evoked by *buy.v*, *purchase.n*, and *purchase.v*. Each frame is also associated with a set of roles, some of which are core roles (necessary components) of the frame.

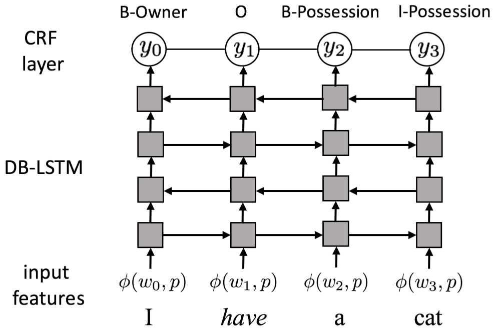

Figure 1: DB-LSTM network (four layers) with a CRF prediction layer. The network learns to predict a sequence of argument role labels given a sentence (e.g., "I have a cat") and a predicate (e.g., "have").

For example, the COMMERCE_BUY frame contains core roles such as BUYER and GOODS, and non-core roles such as MONEY and MEANS. In PropBank, a semantic frame is corresponding to a verb senses. Each verb sense is associated with a set of semantic roles. For example, the verb sense *buy.01* is associated with roles A0 (i.e., agent), A1 (i.e., patient), A2 (i.e., instrument), etc. The semantic roles in PropBank use generic labels. There are about 30 different role labels in total (vs $\sim 10^3$ role labels in FrameNet). Among them 7 are core role labels (A0-A5 and AA) and the rest are non-core (modifier) roles (e.g., the locative role LOC and the temporal role TMP).

In the rest of the paper, we first describe our models for SRL (§ 4), including a sequential neural model, a relational neural model, and the integration of the two. Then, we present our frame identification model (§ 5), followed by a joint inference algorithm for full frame-semantic structure extraction that enforces structural constraints among predicates and arguments (§ 6).

4 Semantic Role Labeling

Given a predicate and its frame, we seek to identify arguments of the predicate and their semantic roles in relation to the predicate's frame. Denote a predicate as p, its frame as f, and a sentence as x. We want to output a set of argument spans $A = \{a_1, ..., a_k\}$, where each a_i is labeled with a semantic role that takes values from a set of role labels $\mathcal{R}_f$ with respect to the frame f.

4.1 Sequential Neural Model

The SRL task can be formulated as a sequence labeling problem, where the semantic role labels are encoded using the "IOB" tagging scheme, as in (Collobert et al., 2011; Zhou and Xu, 2015), where "I" indicates the inside of a chunk, "B" indicates the beginning of a chunk, and "O" indicates being outside of a chunk.

We employ DB-LSTM, a deep bidirectional Long Short-Term Memory neural network with a Condidtional Random Field (CRF) layer introduced by Zhou and Xu (2015) for PropBank-style SRL. The architecture is illustrated in Figure 1. In this work, we adapt it to perform both FrameNet-style and PropBank-style SRL.

At each time step t, the DB-LSTM network is provided with a set of input features $\phi(w_t, p)$, including the current word w_t, the predicate word p, and a position mark that denotes whether the current word is in the neighborhood of the predicate (within a window of 5 words)[2]. Each word feature is associated with a parameter vector which is initialized using the pre-trained paraphrastic word embeddings (Wieting et al., 2015). The input representation at time step t is the concatenation of the above features. As proposed in (Zhou and Xu, 2015), we stack 8 layers of the LSTM unit to produce the hidden representation for each time step. Then, we employ a CRF layer on top to estimate the sequence-level label distributions.

During training, we minimize the negative conditional log-likelihood of N training examples. Each example consists of a sentence x, a predicate p, and a label sequence $\mathbf{y} = \{y_1, ..., y_n\}$, where n is the length of the sentence. The conditional probability is given by:

$$P_{seq}(\mathbf{y} \mid p, f; \boldsymbol{\theta}) = \frac{1}{Z_f} \exp\left(\sum_{t=1}^{n} C_{t,y_t} + \sum_{t=0}^{n} T_{y_t, y_{t+1}}\right) \tag{1}$$

where Z_f is a normalization constant depending on the frame f, as we only normalize over role label sequences that are compatible with the frame. For PropBank-style SRL, we simply drop the dependency on f and compute normalization over all possible role label sequences. C_{t,y_t} is the score output by DB-LSTM for assigning the t-th word

[2] We did not use the predicate context features as in Zhou and Xu (2015) since they did not improve performance in our implementation.

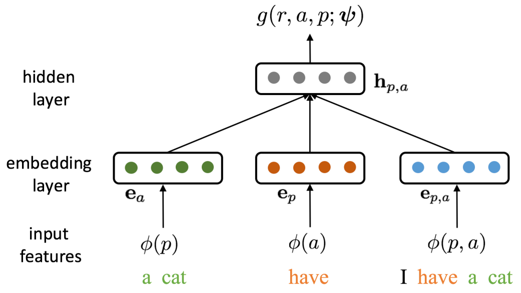

Figure 2: A relational network architecture. The network learns to predict a relation between a predicate p and an argument a given the predicate-argument pair and the sentence that contains it.

with label y_t and $T_{y_t,y_{t+1}}$ is the score of transitioning from label y_t to y_{t+1}. $\boldsymbol{\theta}$ denotes the model parameters, including the DB-LSTM parameters and the transition matrix T.

4.2 Relational Neural Model

An alternative way to formulate the SRL problem is to enumerate all possible argument spans for a given predicate and employ multi-class classification on every argument span. We describe how to obtain candidate argument spans in Section §7.2.

Denote a set of candidate argument spans as $\tilde{\mathcal{A}}$. For each argument span $a \in \tilde{\mathcal{A}}$, we seek to estimate the conditional probability given by:

$$P_{rel}(r \mid a, p, f; \boldsymbol{\psi}) = \frac{\exp(g(r, a, p; \boldsymbol{\psi}))}{\sum_{r' \in \mathcal{R}_f \cup \varnothing} \exp(g(r', a, p; \boldsymbol{\psi}))} \quad (2)$$

where $g(r, a, p; \boldsymbol{\psi})$ is a potential function for scoring the assignment of semantic role r to an argument span a with respect to predicate p, $\boldsymbol{\psi}$ denotes the model parameters, $\mathcal{R}_f$ is a set of valid semantic roles with respect to frame f and $\varnothing$ is an empty class that indicates invalid semantic roles.

We estimate g using a neural network as depicted in Figure 2. The inputs to the network are discrete features: $\phi(a)$ denotes argument-specific features, which include words within the argument span, the dependents of the argument's head, and their dependency labels; $\phi(p)$ denotes predicate-specific features, which include the predicate word, its dependents, and their dependency labels; $\phi(p, a)$ denotes predicate-argument relation features, which include the words between p and a and the lexicalized shortest dependency path.

We then map these features into a low dimensional space. Specifically, we compute an embedding of the argument features: $\mathbf{e}_a = [\bar{\mathbf{v}}_w^a; \bar{\mathbf{v}}_d^a; \bar{\mathbf{v}}_l^a]$, where $\bar{\mathbf{v}}_w^a \in \mathbb{R}^k$ is the average of argument word embeddings, $\bar{\mathbf{v}}_d^a \in \mathbb{R}^k$ is the average embedding of the argument's dependents, and $\bar{\mathbf{v}}_l^a \in \mathbb{R}^k$ is the average embedding of the corresponding dependency labels. Similarly, the embedding of the predicate features is: $\mathbf{e}_p = [\bar{\mathbf{v}}_w^p; \bar{\mathbf{v}}_d^p; \bar{\mathbf{v}}_l^p]$, which is the concatenation of the average embeddings for the predicate words, the predicate's dependents, and their dependency labels. For the relational features, we have $\mathbf{e}_{p,a} = [\bar{\mathbf{v}}_w^{pa}; \mathbf{v}_{path}]$, where $\bar{\mathbf{v}}_w^{pa} \in \mathbb{R}^k$ is the average embedding for words between p and a, and $\mathbf{v}_{path} \in \mathbb{R}^k$ is a dependency path embedding, which is the final hidden state of an LSTM network that operates over the dependency path between p and a, with the input at each time step being the concatenation of a dependency label embedding and a word embedding.

The feature embeddings are then integrated through a non-linear hidden layer:

$$\mathbf{h}_{p,a} = \text{ReLu}(\mathbf{W}_{p,a} \cdot [\mathbf{e}_a; \mathbf{e}_p; \mathbf{e}_{p,a}]) \quad (3)$$

where $\mathbf{W}_{p,a}$ is an $m \times 8k$ matrix and $\text{ReLu}(x) = \max(0, x)$. Finally, we compute the potential function: $g(r, a, p; \boldsymbol{\psi}) = \mathbf{w}_r^T \mathbf{h}_{p,a}$, where $\mathbf{w}_r \in \mathbb{R}^m$ is a weight vector to be learned.

During training, we minimize the negative conditional log-likelihood of the training examples, with the conditional probability for each example given by Eq. 2.

4.3 An Integrated Model

Our integrated model is essentially a relational neural model that is learned using the knowledge distilled from the sequential model.

Note that the sequential model estimates probabilities for semantic role label sequences over words instead of over text spans. These learned probabilities carry important information about how the sequential model learns to generalize. We identify them as the learned knowledge of the sequential model. To make use of such knowledge in the relational model, we first transform the sequence distributions into span-based distributions. Specifically, we derive the marginal distribution for any given span $a = (w_s, ..., w_t)$, $1 \leq s \leq t < n$, and a non-empty semantic role label r as:

$$\begin{aligned} &P_{seq}(r \mid a) = \\ &P_{seq}(y_s = B_r, ..., y_t = I_r, y_{t+1} \neq I_r \mid a) \end{aligned} \quad (4)$$

Here we drop the dependency on p, and f for brevity. B_r, I_r, and O denote the beginning, the inside, and the outside of the filler of role r respectively. The probability for an empty role is:

$$P_{seq}(r = \varnothing \mid a) = 1 - \sum_{r \in \mathcal{R}_f} P_{seq}(r \mid a) \quad (5)$$

After obtaining the span-based role distributions, we incorporate them into the training objective of a relational model $\tilde{P}_{rel}$ by adding a regularization term that minimizes the KL divergence:

$$L = -\log \tilde{P}_{rel}(r \mid a) + \beta KL(P_{seq} || \tilde{P}_{rel}) \quad (6)$$

which is equivalent to minimizing

$$-\log \tilde{P}_{rel}(r \mid a) + \beta \sum_{r} P_{seq}(r \mid a) \log \tilde{P}_{rel}(r \mid a)$$

where β is a weight parameter. We refer to $\tilde{P}_{rel}$ as the integrated model. At inference time, it computes the predictive distributions of semantic roles in the same way as a vanilla relational model.

5 Frame Identification

Our semantic role labeling model is conditioned on a predicate and its frame. We now describe how to estimate the probabilities of a frame f given a predicate p.

Denote $\mathcal{F}$ as a set of semantic frames, we learn to estimate the probability:

$$P_f(f \mid p) = \frac{\exp\left(u(f, p; \boldsymbol{\lambda})\right)}{\sum_{f' \in \mathcal{F}} \exp\left(u(f', p; \boldsymbol{\lambda})\right)} \quad (7)$$

The potential function $u(f, p; \boldsymbol{\lambda})$ is computed using a multi-layer neural network, whose architecture is similar to Figure 2. The input features are $\phi(p)$ as defined in §4.2. The embedding layer computes $\mathbf{e}_p$ as described above, and the hidden layer computes:

$$\mathbf{h}_p = \text{ReLu}(\mathbf{W}_p \cdot \mathbf{e}_p)$$

where $\mathbf{W}_p$ is an $m \times 3k$ matrix. The potential function is then estimated as $u(f, p; \boldsymbol{\lambda}) = \mathbf{w}_f^T \mathbf{h}_p$, where $\mathbf{w}_f \in \mathbb{R}^m$ is a weight vector to be learned. Training is done by minimizing the negative conditional log-likelihood of the training examples where the conditional probability for each example is given by Eq. 7.

6 Joint Inference

Finally, we want to jointly assign frames and roles to all predicates and their arguments.

Given a set of predicates $\mathcal{P} = \{p_1, ..., p_N\}$ and a set of candidate argument spans $\tilde{\mathcal{A}} = \{a_1, ..., a_M\}$, we optimize the following objective:

$$\underset{\text{s.t. } (\mathbf{f}, \mathbf{r}) \in \mathcal{Q}}{\arg\max} \sum_{j=1}^{N} P_f(f_j \mid p_j) \sum_{i=1}^{M} \tilde{P}_{rel}(r_i \mid a_i, p_j, f_j) \quad (8)$$

where $\mathbf{f}$ is a vector of frame assignments, $\mathbf{r}$ is a vector of role assignments, and $\mathcal{Q}$ is a constrained set of frame and role assignments.

We employ the standard structural constraints for SRL, including avoiding non-overlapping argument spans and repeated core roles for each frame. In addition, we introduce two constraints: one encodes the compatibility between frame types and semantic roles, for example, INSTRUMENT is not a valid role for the frame COMMERCIAL_TRANSACTION, and the other encodes type consistencies of semantic role fillers of different frames, e.g., the same named entity cannot play both a PERSON role and a VEHICLE role. We consider six common entity types (that are mutually exclusive): PERSON, LOCATION, WEAPON, VEHICLE, VALUE, and TIME.[3]

We solve the inference problem (8) using the AD^3 algorithm (Martins et al., 2011), which allows for more efficient constrained optimization than generic Integer Linear Programming solvers.

7 Experiment

7.1 Datasets

We evaluate our approach on semantic frame extraction using the FrameNet 1.5 release[4]. We use the same train/development/test split of the fully-annotated text documents as in previous work. We also include the partially-annotated exemplar sentences (i.e., each exemplar has only one annotated frame.) in FrameNet as training data.[5] We use the standard evaluation script that measures frame

[3] We simply check if the role name contains any of the entity type names like "person", "location". We plan to incorporate an automatic semantic typing model into our framework in future work.

[4] http://framenet.icsi.berkeley.edu

[5] Existing work also makes use of the exemplars, but mainly as a lexicon. We found that adding the exemplar sentences generally introduces a 3-4 F1 gain for FrameNet SRL.

structure extraction precision, recall and F1[6].

For PropBank-style SRL, we use the CoNLL2005 data set (Carreras and Màrquez, 2005) with the official scripts[7] for evaluation. It contains section 2-21 of WallStreet Journal (WSJ) data as training set, section 24 as development set and section 23 of WSJ concatenated with 3 sections from Brown corpus as the test set.

For data pre-processing, we parse all the sentences with the part-of-speech tagger and the dependency parser provided in the Stanford CoreNLP toolkit (Manning et al., 2014).

7.2 Argument candidate extraction

Existing work relied on either constituency syntax (Xue and Palmer, 2004) or dependency syntax (Täckström et al., 2015) to derive heuristic rules for extracting candidate arguments. Instead, we extract candidate arguments using a pre-trained sequential SRL model (described in § 4.1). Specifically, we extract the argument spans from the K-best semantic role label sequences output by the sequential model. We choose K from {5,10,20,50}. Increasing K will increase the recall of unlabeled arguments but lower the precision. We tune K based on the argument extraction performance of our relational model (in § 4.2) using the development data. In all our experiments, we set $K = 10$, which gives an unlabeled argument recall/precision of 89.6%/24.8% on FrameNet and 92.4%/29.4% on CoNLL2005.

7.3 Implementation details

All of our models are implemented using Theano on a single GPU. We set the embedding dimension k to 300 and the hidden dimension m to 100. We initialize the word embeddings using the pre-trained word embeddings from (Wieting et al., 2015) while randomly initializing the embeddings for out-of-vocabulary words and the embeddings for the dependency labels within $(-0.01, 0.01)$. All these embeddings are updated during the training process. We apply dropout to the embedding layer with rate 0.5, and train using Adam with default settings (Kingma and Ba, 2014). The weight parameter β in Eq. 6 is set to 1 in our experiments. All the models are trained for 50 epochs with early stopping based on development results.

Model	All	Ambiguous
Log-Linear Words	87.3	70.5
Log-Linear Embedding	86.7	70.3
Wsabie Embedding	**88.4**	73.1
Ours (Frame Only)	88.2	**75.7**

Table 1: Accuracy results on frame identification, including results on *all* predicates and *ambiguous* predicates in the FrameNet lexicon.

For all our experimental results, we perform statistical significance tests using the paired bootstrap test (Efron and Tibshirani, 1994) with 1000 bootstrap samples of the evaluated examples, and use $*$ to indicate statistical significance ($p < 0.05$) of the differences between our best model and our second best model.

7.4 FrameNet Results

Frame Identification. We first evaluate our frame identification model in § 5. For baselines, we consider the prior state-of-the-art approach Wsabie Embedding (Hermann et al., 2014), which learns feature representations based on word embeddings and dependency path embeddings using the Wsabie algorithm (Weston et al., 2011). We also include two strong baselines implemented in Hermann et al. (2014): Log-Linear Words and Log-Linear Embeddings, which are both log-linear models, one with standard linguistic features and one with embedding features. Table 1 shows the results.[8] We can see that our model in general gives competitive performance and it outperforms all the baselines on predicting frames for ambiguous predicates (i.e., seen with more than one possible frames in the FrameNet lexicon).

Semantic Role Labeling. Next, we evaluate our SRL models with gold-standard frames, so that we can focus on the performance for argument identification. Our SRL models include the sequential model described in § 4.1 (denoted as *Seq*); the relational model described in § 4.2 (denoted as *Rel*); and the integrated model described in § 4.3 (denoted as *Seq+Rel*).

Table 2 shows the results for argument span ex-

[6] http://www.cs.cmu.edu/~ark/SEMAFOR/eval/

[7] http://www.lsi.upc.edu/~srlconll/srl-eval.pl

[8] We consider the Full Lexicon evaluation setting and copy the results from the updated version of the paper from the author's website http://www.dipanjandas.com/pages/papers. Note that the set of ambiguous predicates we consider is different from the set used by Hermann et al. (2014). This is because we process the lexical units with the Stanford POS tagger.

Ours (Seq+Rel)	84.2	77.1	**80.5***

Table 3: Full structure extraction results on the FrameNet test set (with gold frames) in comparison to the results in Roth and Lapata (2015).

traction. Our baselines include SEMAFOR (Das et al., 2014)[9], a widely used frame-semantic parser for English, and SEMAFOR (BEST), an improved SEMAFOR system that is trained with heterogeneous resources (Kshirsagar et al., 2015). We can see that all of our models outperform these two systems in terms of F1, especially, our sequential model provides the best recall, our relation model provides the best precision, and our integrated model gives the best F1 score.

Table 3 shows results for full structure extraction (i.e., the accuracies of the frame-argument structure as a whole). We compare to the results reported in Roth and Lapata (2015). *Framat* is an open-source semantic role labeling tool provided by mate-tools (Björkelund et al., 2010), and *Framat+context* is an extension of *Framat* that uses additional context features. All of our models significantly outperform the baselines in F1. In particular, our integrated model achieves the best F1 score of 80.5%.

Full Semantic Structure Extraction. We now evaluate our models on full semantic frame extraction. Previous work implements the task in a two-stage pipeline: first apply a frame identification model to assign a frame to each predicate, and then apply a SRL model to assign a frame-specific role label or ∅ to each candidate argument span. We compare with previous work using four model variants: three are pipeline models that combine our frame identification model with each of our SRL models and *JointAll* is the joint model that simultaneously predicts frames and roles as described in § 6.

Table 4: Full structure extraction results on the FrameNet test set in comparison to the previously published results.

Table 4 compares our models with previously published results. The first block shows results from Roth and Lapata (2015) and the second block shows results from FitzGerald et al. (2015). All these previous methods implements a pipeline of frame identification and semantic role labeling. The first block uses SEMAFOR for frame identification and the second block uses the WSABIE model from Hermann et al. (2014). For the semantic role labeling step, *Hermann* is a standard log-linear classification model used in Hermann et al. (2014); *Täckström (Struct.)* is a graphical model with global factors (Täckström et al., 2015); *FitzGerald (Struct.)* is an improved version of the graphical model with non-linear potential functions instead of linear ones; *FitzGerald (Struct., PoE)* further employs an ensemble with the product-of-experts (PoE) (Hinton, 2002); and *FitzGerald (Local, PoE, Joint)* indicates the best reported results in FitzGerald et al. (2015) which uses local factors and additional training data from CoNLL 2005. We can see that our sequential model alone is already close to the state of the art. Our relational model demonstrates superior performance on precision, which confirms the benefit of modeling predicate-argument interactions at the span level. The integrated model further improves over the relational model in both precision and recall. Finally, by

joint inference of both frames and semantic roles, our model performs even better, achieving a 5.7 absolute F1 gain over the prior state of the art.

7.5 CoNLL Results

Table 5 shows the results of our SRL models on the CoNLL 2005 data. Our baselines include the best feature-based systems of Surdeanu et al. (2007), Toutanova et al. (2008), and Punyakanok et al. (2008), the recurrent neural network model (DB-LSTM) (Zhou and Xu, 2015), the graphical model with global factors (Täckström et al., 2015) and the improved versions that use neural network factors (FitzGerald et al., 2015). Note that our sequential model in this setting is essentially the same as the DB-LSTM model (Zhou and Xu, 2015) since all the frame-specific constraints are removed, except that we use simpler input features.[10] We observe a similar performance trend among our models. However, the performance gain introduced by our integrated model is relatively small compared to our FrameNet results. Note that the argument structures in CoNLL 2005 is much simpler and less diverse than the ones in FrameNet. This may lead to less complementary information captured by the sequential model and the relational model. Overall, our integrated model achieves comparable performance to the previously published results.

7.6 Analysis

We perform further analysis of our results on FrameNet to better understand our models.

We first look at how well our models perform on sentences of different lengths. In general, longer sentences tend to have more predicates and are more likely to contain complex long-range predicate-argument dependencies. We divide the FrameNet test set into 7 bins based on sentence lengths, each with length increased by 10, and the last bin contains sentences of length > 60. Figure 3 shows the F1 scores for full structure extraction for each bin. For all our models, performance tends to degrade as sentence length increases. Interestingly, our relational model consistently outperforms our sequential model at different sentence lengths, which demonstrates its robustness of handling relations of different ranges. The combination of the two models leads to consistent performance gains, and our final joint model performs the best across different sentence lengths.

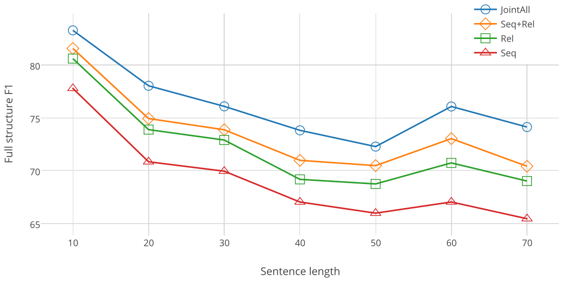

Figure 3: Full structure F1 on the FrameNet test set by the sentence length.

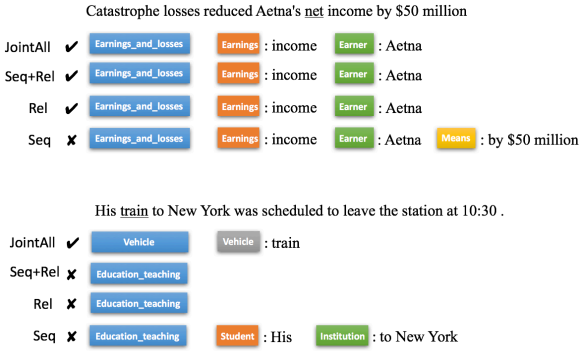

Catastrophe losses reduced Aetna's net income by $50 million

JointAll ✔ Vehicle Vehicle : train
Seq+Rel ✘ Education_teaching
Rel ✘ Education_teaching
Seq ✘ Education_teaching Student : His Institution : to New York

Figure 4: Examples of semantic frames output by different models.

Next, we analyze the errors made by different models. In general, our sequential model produces higher recall than the relational model and the integrated model, but it has lower precision. For example, for the first sentence in Figure 4, the sequential model mistakenly predicts "by $50 million" as a means to earn while both the relational and integrated models avoid this mistake. This

[10] Our reimplementation using the same feature set as Zhou and Xu (2015) did not achieve the same performance, see § 4.1 for details.

shows that performing sequential predictions over individual words has limitations. Although our relational models are good at reducing precision errors, they can be affected by frame identification errors if they are used in a pipeline. This is demonstrated by the second sentence in Figure 4, where only the *JointAll* model correctly predicts that the word "train" triggers a "Vehicle" frame. All the pipeline approaches mistakenly predict the "Education_teaching" frame in the first stage. In the second stage, the sequential model further extracts wrong semantic roles "Student" and "Institution". While the relational model and the integrated model extract no semantic roles, the frame prediction mistake remains.

8 Conclusion

We presented a new method for frame-semantic parsing that achieves the new state of the art results on standard FrameNet data. Our model integrates a sequential neural network into the learning of a relational neural network for more accurate span-based semantic role labeling. During inference, it jointly predicts frames and semantic roles using a graphical model with neural network factors. Empirical results demonstrate that our approach significantly outperforms existing neural and non-neural approaches on FrameNet data. Our model can also be adapted to perform PropBank-style SRL and it demonstrates comparable performance with the state of the art on CoNLL 2005 data.

Getting the Most out of AMR Parsing

Chuan Wang and **Nianwen Xue**
Brandeis University
{cwang24,xuen}@brandeis.edu

Abstract

This paper proposes to tackle the AMR parsing bottleneck by improving two components of an AMR parser: concept identification and alignment. We first build a Bidirectional LSTM based concept identifier that is able to incorporate richer contextual information to learn sparse AMR concept labels. We then extend an HMM-based word-to-concept alignment model with graph distance distortion and a rescoring method during decoding to incorporate the structural information in the AMR graph. We show integrating the two components into an existing AMR parser results in consistently better performance over the state of the art on various datasets.

1 Introduction

Abstract Meaning Representation (AMR) (Banarescu et al., 2013) is a semantic representation where the meaning of a sentence is encoded as a rooted, directed graph. A number of AMR parsers have been developed in recent years (Flanigan et al., 2014; Wang et al., 2015b; Artzi et al., 2015; Pust et al., 2015; Peng et al., 2015; Zhou et al., 2016; Goodman et al., 2016a), and the initial benefit of AMR parsing has been demonstrated in various downstream applications such as Information Extraction (Pan et al., 2015; Huang et al., 2016), Machine Comprehension (Sachan and Xing, 2016), and Language Generation (Flanigan et al., 2016b; Butler, 2016). However, AMR parsing parsing accuracy is still in the high 60%, as measured by the SMatch score (Cai and Knight, 2013), and a significant improvement is needed in order for it to positively impact a larger number of applications.

Previous research has shown that concept identification is the bottleneck to further improvement of AMR parsing. For example, JAMR (Flanigan et al., 2014), the first AMR parser, is able to achieve an F-score of 80% (close to the inter-annotator agreement of 83) if gold concepts are provided. Its parsing accuracy drops sharply to 62.3% when the concepts are identified automatically.

One of the challenges in AMR concept identification is data sparsity. A large portion of AMR's concepts are either word lemmas or sense-disambiguated lemmas drawn from Propbank (Palmer et al., 2005). Since the AMR Bank is relatively small, many of the concept labels in the development or test set only occur a few times or never appear in the training set. Werling et al. (2015) addresses this problem by defining a set of *generative* actions that maps words in the sentence to their AMR concepts and use a local classifier to learn these actions. Given such sparse data, making full use of contextual information is crucial to accurate concept labeling. Bidirectional LSTM has shown its success on many sequence labeling tasks since it is able to combine contextual information from both directions and avoid manual feature engineering. However, it is non-trivial to formalize concept identification as a sequence labeling problem because of the large concept label set. Inspired by Foland and Martin (2016; 2017), who first apply the Bidirectional LSTM to AMR concept identification by categorizing the large labels into a finite set of predefined types, we propose to address concept identification using Bidirectional LSTM with **Factored Concept Labels (FCL)**, where we re-group the concept label set based on their shared graph structure. This makes it possible for different concepts to be represented by one common label that captures the shared semantics of these concepts.

Proceedings of the 2017 Conference on Empirical Methods in Natural Language Processing, pages 1257–1268
Copenhagen, Denmark, September 7–11, 2017. ©2017 Association for Computational Linguistics

Accurate concept identification also crucially depends on the word-to-AMR-concept alignment. Since there is no manual alignment in the AMR annotation, typically either a rule-based or unsupervised aligner is applied to the training data to extract the mapping between words and concepts. This mapping will then be used as reference data to train concept identification models. The JAMR aligner (Flanigan et al., 2014) greedily aligns a span of words to graph fragments using a set of heuristics. While it can easily incorporate information from additional linguistic sources such as WordNet, it is not adaptable to other domains. Unsupervised aligners borrow techniques from Machine Translation and treat sentence-to-AMR alignment as a word alignment problem between a source sentence and its linearized AMR graph (Pourdamghani et al., 2014) and solve it with IBM word alignment models (Brown et al., 1993). However, the distortion model in the IBM models is based on the linear distance between source side words while the linear order of the AMR concepts has no linguistic significance, unlike word order in natural language. A more appropriate sentence-to-AMR alignment model should be one that takes the hierarchical structure of the AMR into account. We develop a Hidden Markov Model (HMM)-based sentence-to-AMR alignment method with a novel **Graph Distance** distortion model to take advantage of the structural information in AMR, and apply a structural constraint to re-score the posterior during decoding time.

We present experimental results that show incorporating these two improvements to CAMR (Wang et al., 2016), a state-of-the-art transition-based AMR parser, results in consistently better Smatch scores over the state of the art on various datasets. The rest of paper is organized as follows. Section 2 describes related work on AMR parsing. Section 3 describes our improved LSTM based concept identification model, and Section 4 describes our alignment method. We present experimental results in Section 5, and conclude in Section 6.

2 Related Work

Existing AMR parsers are either transition-based or graph-based. Transition-based AMR parsers (Wang et al., 2015b,a; Goodman et al., 2016a,b), focus on modeling the correspondence between the dependency tree and the AMR graph of a sentence by designing a small set of actions that transform the dependency tree into the AMR graph. Pust et al. (2015) formulates AMR parsing as a machine translation problem in which the sentence is the source language input and the AMR is the target language output. AMR parsing systems that focus on modeling the graph aspect of the AMR includes JAMR (Flanigan et al., 2014, 2016a; Zhou et al., 2016), which treats AMR parsing as a procedure for searching for the Maximum Spanning Connected Subgraphs (MSCGs) from an edge-labeled, directed graph of all possible relations. Parsers based on Hyperedge Replacement Grammars (HRG) (Chiang et al., 2013; Björklund et al., 2016; Groschwitz et al., 2015) put more emphasis on modeling the formal properties of the AMR graph. One practical implementation of HRG-based parsing is that of (Peng et al., 2015; Peng and Gildea, 2016). The adoption of Combinatory Categorical Grammar (CCG) in AMR parsing has also been explored in (Artzi et al., 2015; Misra and Artzi, 2016), where a number of extensions have been proposed to enable CCG to work on the broad-coverage AMR corpus.

More recently, Foland and Martin (2016; 2017) describe a neural network based model that decomposes the AMR parsing task into a series of subproblems. Their system first identifies the concepts using a Bidirectional LSTM Recurrent Neural Network (Hochreiter and Schmidhuber, 1997), and then locates and labels the arguments and attributes for each predicate, and finally constructs the AMR using the concepts and relations identified in previous steps. (Barzdins and Gosko, 2016) first applies the sequence-to-sequence model (Sutskever et al., 2014) typically used in neural machine translation to AMR parsing by simply treating the pre-order traversal of AMR as foreign language strings. (Peng et al., 2017) also adopts the sequence-to-sequence model for neural AMR parsing and focuses on reducing data sparsity in neural AMR parsing with categorization of the concept and relation labels. In contrast, (Konstas et al., 2017) adopts a different approach and tackles the data sparsity problem with a self-training procedure that can utilize a large set of unannotated external corpus. (Buys and Blunsom, 2017) design a generic transition-based system for semantic graph parsing and apply sequence-to-sequence framework to learn the transformation from natural language sequences to action sequences.

3 Concept Identification with Bidirectional LSTM

In this section, we first introduce how we categorize AMR concepts using **Factored Concept Labels**. We then integrate character-level information into a Bidirectional LSTM through Convolutional Neural Network (CNN)-based embeddings.

3.1 Background and Notation

Given a pair of AMR graph G and English sentence S, a look-up table M is first generated which maps a span of tokens to concepts using an aligner. Although there are differences among results generated by different aligners, in general, the aligned AMR concepts can be classified into the following types:

- PREDICATE. Concepts with sense tags, which are frames borrowed from Propbank, belong to this case. Most of the tokens aligned to this type are verbs and nouns that have their own argument structures.
- NON-PREDICATE. This type of concepts are mostly lemmatized word tokens from the original English sentences.
- CONST. Most of the numerical expressions in English sentences are aligned to this type, where AMR concepts are normalized numerical expressions.
- MULTICONCEPT. In this type, one or more word tokens in an English sentence are aligned to multiple concepts that form a sub-structure in an AMR graph. The most frequent case is named entity subgraphs. For example, in Figure 1, *"Mr. Vinken"* is aligned to subgraph `(p / person :name (m / name :op1 "Mr." :op2 "Vinken")`.

3.2 Factored Concept Labels

To be able to fit AMR's large concept label space into a sequence labeling framework, redefining the label set is necessary in order to make the learning process feasible. While it is trivial to categorize the PREDICATE, NON-PREDICATE, CONST cases, there is no straightforward way to deal with the MULTICONCEPT type. Foland and Martin (2016) only handle named entities, which constitute the majority of the MULTICONCEPT cases, where they adopt BIOES tags to detect the boundary and use an additional Bidirectional LSTM to learn the fine-grained named entity concept types. For other MULTICONCEPT cases, they only use the leaf concepts and ignore other parts of the subgraphs. Figure 2 shows the concept label distribution on development set of LDC2015E86, where we can see nearly half of the MULTICONCEPTcases are not named entities.

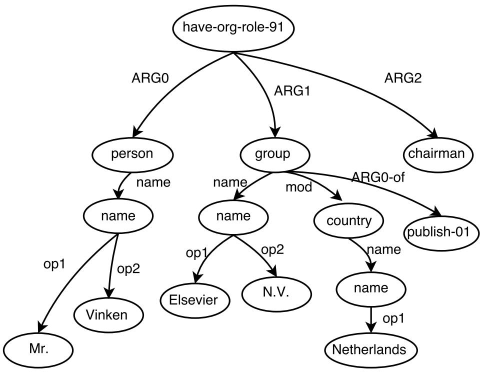

Figure 1: An example AMR graph for sentence: "*Mr. Vinken is chairman of Elsevier N.V., the Dutch publishing group.*".

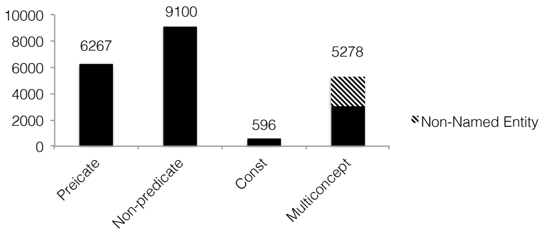

Figure 2: AMR concept label distribution for development set of LDC2015E86

Based on the observation that many of the MULTICONCEPT cases are actually similarly structured subgraphs that only differ in the lexical items, we choose to factor the lexical items out of the subgraph fragments and use the skeletal structure as the fine-grained labels, which we refer as **Factored Concept Label (FCL)**.

Figure 4 shows that although English words "visitor" and "worker" have been aligned to different subgraph fragments, after replacing the lexical items, in this case the leaf concepts `visit-01` and `work-01` with a placeholder "x", we are able to arrive at the same FCL. The strategy for determining the FCL for a word is simple: for each English word w and the subgraph s it aligns to, if the length of the longest overlapping substring be-

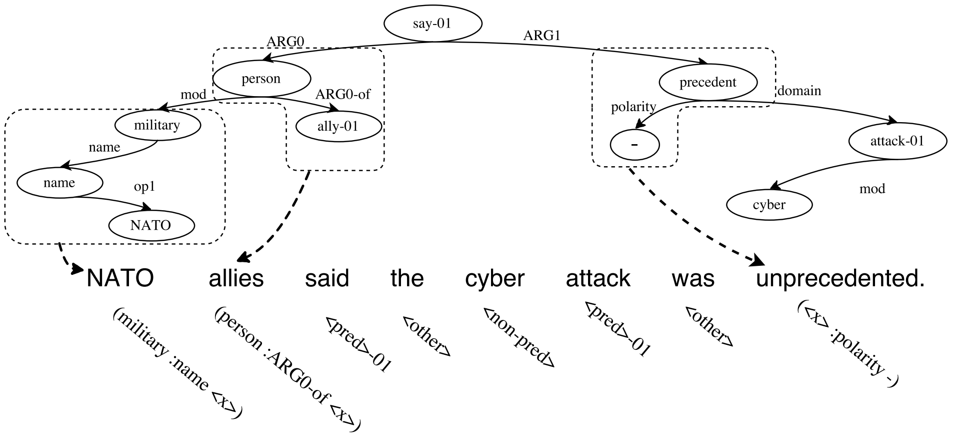

Figure 3: One example of generating FCL for sentence "*NATO allies said the cyber attack was unprecedented.*"

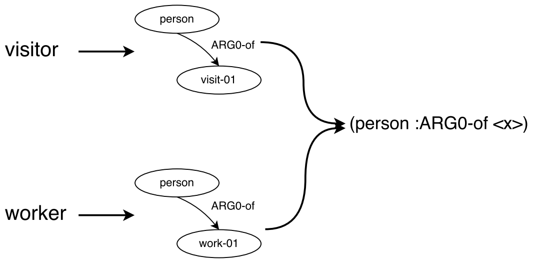

Figure 4: One example of generating FCL

tween w and the leaf concept c of s is greater than 4, we replace c with a placeholder.

Despite this simple strategy, our results show that it can capture a wide range of MULTICONCEPT cases while keeping the new label space manageable. While the named entity can be easily categorized using FCL, it can also cover some other common cases such as morphological expressions of negation (e.g., "inadequate") and comparatives (e.g., "happier"). Setting a frequency threshold to prune out the noisy labels, we are able to extract 91 canonical FCL labels on the training set. Our empirical results show that this canonical FCL label set can cover 96% of the MULTICONCEPT cases on the development set. Figure 3 gives one full example of FCLs generated for one sentence. For the PREDICATE cases, following (Foland and Martin, 2016), we only use the sense tag as its label.

We use label $\langle other\rangle$ to label stop words that do not map to AMR concepts. The MULTICONCEPT cases are handled by FCL. The FCL label set generated by this procedure can be treated as an abstraction of the original AMR concept label space, where it groups concepts that have similar AMR subgraphs into the same category.

3.3 CNN-based Character-level Embedding

After constructing the new label set with FCL, we set up a baseline Bidirectional LSTM using the concatenation of word and NER embeddings as the input. For each input word w and its NER tag t, their embeddings e_{w} and e_{t} are extracted from a word embedding matrix $W_{\text{wd}} \in \mathbb{R}^{d_{\text{wd}}\times|V_{\text{wd}}|}$ and a NER tag embedding matrix $W_{\text{t}} \in \mathbb{R}^{d_{\text{t}}\times|V_{\text{t}}|}$ respectively, where d_{wd} and d_{t} are the dimensions of the word and NER tag embedding matricies, $|V_{\text{wd}}|$ and $|V_{\text{t}}|$ are the sizes of the word and NER tag vocabulary.

Although this architecture is able to capture long-range contextual information, it fails to extract information originating from the word form itself. As we have discussed above, in some of the MULTICONCEPT cases the concepts are associated with the word forms themselves and won't benefit from its contextual information. For example, in "*unprecedented*", the prefix "*un*" itself already gives enough information to predict the FCL label $\langle x\rangle$: $polarity$ −, which indicates negative polarity. In order to incorporate such morphological and shape information, we choose to add a convolutional layer to extract character-level representations. A similar technique has been applied to Named Entity Recognition (Santos and Guimaraes, 2015; Chiu and Nichols, 2015) and we only provide a brief description of the architecture here. For a word w composed of characters $\{c_1, c_2, \ldots, c_l\}$, where l is the length of word w, we learn a character embedding matrix $W_{\text{c}} \in \mathbb{R}^{d_{\text{c}}\times|V_{\text{c}}|}$, where d_{c} is the character embedding dimension defined by the user and V_{c} is character vocabulary size. After retrieving the character embedding ch_i for each character c_{i} in word w, we obtain a sequence of vectors $\{ch_1, ch_2, \dots, ch_l\}$. This serves as the input to convolutional layer.

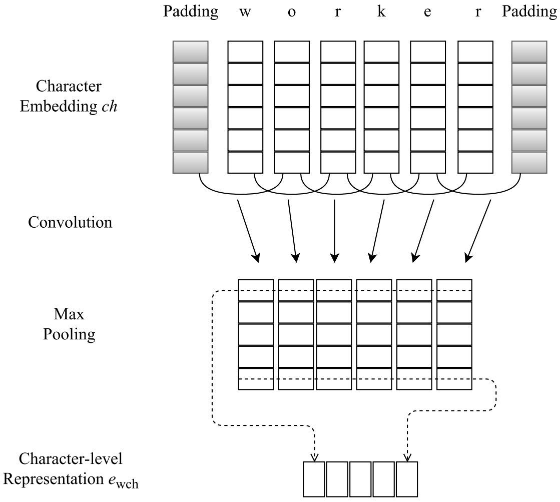

Figure 5: The architecture of the CNN-based character-level embedding.

The convolutional layer applies a linear transformation to the local context of a character in the input sequence, where the local context is parameterized by window size k. Here we define the local context of the character embedding ch_i to be:

$$f_i = (ch_{i-(k-1)/2}, \dots, ch_{i+(k-1)/2})^\top \quad (1)$$

The j-th element of the convolutional layer output vector e_{wch} is computed by element-wise max-pooling (Ranzato et al., 2007):

$$[e_{\text{wch}}]_j = \max_{1 \le i \le l} [W^0 f_i + b^0]_j \quad (2)$$

W^0 and b^0 are the parameters of the convolutional layer. And the output vector e_{wch} is the character level representation of the word w. The architecture of the model is shown in Figure 5.

The final input to the Bidirectional LSTM is the concatenation of three embeddings $[e_w, e_t, e_{\text{wch}}]$ for each word position.

4 Aligning an English Sentence to its AMR graph

Given an AMR graph G and English sentence $\boldsymbol{e} = \{e_1, e_2, \dots, e_i, \dots, e_I\}$, in order to fit them into the traditional word alignment framework, the AMR graph G is normally linearized using depth first search by printing each node as soon as it it visited. The re-entrance node is printed but not expanded to preserve the multiple mentions of concept. The relation (also called AMR role token) between concepts are preserved in the unsupervised aligner (Pourdamghani et al., 2014) because they also try to align relations to English words. We ignore the relations here since we focus on aligning concepts. Therefore the linearized concept sequences can be represented as $\boldsymbol{g} = \{g_1, g_2, \dots, g_j, \dots, g_J\}$. However, although this configuration makes it easy to adopt existing word alignment models, it also ignores the structural information in the AMR graph.

In this section, we proposes a method that incorporates the structural information in the AMR graph through a distortion model inside an HMM-based word aligner. We then further improve the model with a re-scoring method during decoding time.

4.1 HMM-based Aligner with Graph Distance Distortion

Given a sequence pair $(\boldsymbol{e}, \boldsymbol{g})$, the HMM-based word alignment model assumes that each source word is assigned to exactly one target word, and defines an asymmetric alignment for the sentence pair as $\boldsymbol{a} = \{a_1, a_2, \dots, a_i, \dots, a_I\}$, where each $a_i \in [0, J]$ is an alignment from source position i to target position a_i, $a_i = 0$ means that e_i is not aligned to any target words. Note that in the AMR to English alignment context, both the alignment and the graph structure is asymmetric, since we only have AMR graph annotation on in linearized AMR sequence g. Unlike the traditional word alignment for machine translation, here we will have different formulas for each translation direction. In this section, we only discuss the translation from English (source) to linearized AMR concepts (target) and we will discuss the AMR to English direction in the following section.

The HMM-based model breaks the generative alignment process into two factors:

$$P(\boldsymbol{e}, \boldsymbol{a} \mid \boldsymbol{g}) = \prod_{i=1}^{I} P_d(a_i \mid a_{i-1}, J) P_t(e_i | g_{a_i}) \quad (3)$$

where P_d is the distortion model and P_t is the translation model. Traditionally, the distortion probability $P_d(j \mid j', J)$ is modeled to depend only on the jump width $(j - j')$ (Vogel et al., 1996) and is defined as:

$$P_d(j \mid j', J) = \frac{ct(j - j')}{\sum_{j''=1}^{J} ct(j'' - j')} \quad (4)$$

where $ct(j - j')$ is the count of jump width. This formula simultaneously satisfies the normalization constraint and captures the *locality* assumption that words that are adjacent in the source sentence tend to align to words that are closer in the target sentence.

As the linear *locality* assumption does not hold among linearized AMR concepts, we choose instead to encode the distortion probability through graph distance, which is given by:

$$P_{\text{gd}}(j \mid j', G) = \frac{ct(d(j,j'))}{\sum_{j''} ct(d(j'',j'))} \tag{5}$$

The graph distance $d(j, j')$ is the length of shortest path on AMR graph G from concept j to concept j'. Note that we have to artificially normalize $P_{\text{gd}}(j \mid j', G)$, because unlike the linear distance between word tokens in a sentence, there can be multiple concepts that can have the same distance from the j'-th concept in the AMR graph, as pointed out in (Kondo et al., 2013).

During training, just like the original HMM-based aligner, an EM algorithm can be applied to update the parameters of the model.

4.2 Improved Decoding with Posterior Rescoring

So far, we have integrated the graph structure information into the forward direction (English to AMR). To also improve the reverse direction model (AMR to English), we choose to use the graph structure to rescore the posterior during decoding time.

Compared with Viterbi decoding, posterior thresholding has shown better results in word alignment tasks (Liang et al., 2006). Given threshold γ, for all possible alignments, we select the final alignment based on the following criteria:

$$\boldsymbol{a} = \{(i,j) : p(a_j = i \mid \boldsymbol{g}, \boldsymbol{e}) > \gamma\} \tag{6}$$

where the state probability $p(a_j = i \mid \boldsymbol{g}, \boldsymbol{e})$ is computed using the forward-backward algorithm. The forward algorithm is defined as:

$$\alpha_{j,i} \\ = \sum_{i'} \alpha_{j-1,i'} p(a_j = i \mid a_{j-1} = i') p(g_j \mid e_{a_j}) \tag{7}$$

To incorporate the graph structure, we rescale the distortion probability in reverse direction model as:

$$p_{\text{new}}(a_j = i \, | a_{j-1} = i') \\ = p(a_j = i \mid a_{j-1} = i')^{e^{\Delta d}} \tag{8}$$

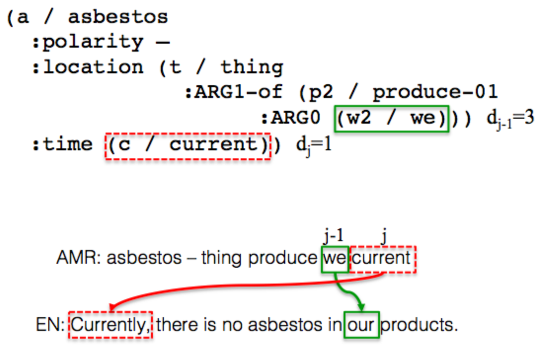
where the scaling factor $\Delta d = d_j - d_{j-1}$ is the graph depth difference between the adjacent AMR concepts g_j and g_{j-1}. We also apply the same procedure for the backward computation. Note that since the model is in reverse direction, the distortion $p(a_j = i \mid a_{j-1} = i')$ here is still based on English word distance, jump width.

This rescaling procedure is based on the intuition that after we have processed the last concept g_{j-1} in some subgraph, the next concept g_j's aligned English position i is not necessarily related to the last aligned English position i'. Figure 6 illustrates this phenomenon: Although `we` and `current` are adjacent concepts in linearized AMR sequence, they are actually far away from each other in the graph (with a graph depth difference of -2). However, the distortion based on the English word distance mostly tends to choose the closer word, which may yield a very low probability for our correct answer here (the jump width between "Currently" and "our" is -6). By applying the exponential scaling factor, we are able to reduce the differences between different distortion probabilities. On the contrary, when the distortion probability is reliable (the absolute value of the graph depth difference is small), the model chooses to trust the distortion and picks the closer English word.

The rescaling factor can be viewed as a selection filter for decoding, where it relies on the graph depth difference Δd to control the effect of learned distortion probability. Note that after the rescaling, the resulting distortion probability no longer satisfies the normalization constraint. However, we only apply this during decoding time and experiments show that the typical threshold $\gamma = 0.5$ still works well for our case.

4.3 Combining Both Directions

Empirical results show that combining alignments from both directions improve the alignment quality (DeNero and Klein, 2007; Och and Ney, 2003; Liang et al., 2006). To combine the alignments, we adopt a slightly modified version of posterior thresholding, *competitive thresholding*, as proposed in (DeNero and Klein, 2007), which tends to select alignments that form a contiguous span.



(a / asbestos
:polarity –
:location (t / thing
:ARG1-of (p2 / produce-01
:ARG0 (w2 / we))) d_{j-1}=3

j-1
j
AMR: asbestos – thing produce we current
EN: Currently, there is no asbestos in our products.

Figure 6: AMR graph annotation, linearized concepts for sentence "*Currently, there is no asbestos in our products*". The concept `we` in solid line is the $(j-1)$-th token in linearized AMR. It is aligned to English word "our" and its depth in graph d_{j-1} is 3. While the word distance-based distortion prefers an alignment near "our", the correct alignment needs a longer distortion.

5 Experiments

We first test the performance of our Bidirectional LSTM concept identifier and HMM-based aligner as standalone tasks, where we investigate the effectiveness of each component in AMR parsing. Then we report the final results by incorporating both components to CAMR (Wang et al., 2016). At the model development stage, we mainly use the dataset LDC2015E86 used in the SemEval Shared Task (May, 2016). Note that this dataset includes `:wiki` relations where every named entity concept is linked to its wikipedia entry. We remove this information in the training data throughout the development of our models. At the final testing stage, we add wikification using an off-the-shelf AMR wikifier (Pan et al., 2015) as a post-processing step. All AMR parsing results are evaluated using the Smatch (Cai and Knight, 2013) scorer.

5.1 Bidirectional LSTM Concept Identification Evaluation

In order to isolate the effects of our concept identifier, we first use the official alignments provided by SemEval. The alignment is generated by the unsupervised aligner described in (Pourdamghani et al., 2014). After getting the alignment table, we generate our FCL label set by filtering out noisy FCL labels that occur fewer than 30 times in the training data. The remaining FCL labels account for 96% of the MULTICONCEPT cases in the development set. Adding other labels that include PREDICATE, NON-PREDICATE and CONST gives us 116 canonical labels. UNK label is added to handle the unseen concepts.

In the Bidirectional LSTM, the hyperparameter settings are as follows: word embedding dimension $d_{wd} = 128$, NER tag embedding dimension $d_t = 8$, character embedding dimension $d_c = 50$, character level embedding dimension $d_{wch} = 50$, convolutional layer window size $k = 2$.

Input	P	R	F_1	Acc
word,NER	81.2	80.6	80.9	85.4
word,NER,CNN	83.3	82.7	83.0	87.0

Table 1: Performance of Bidirectional LSTM with different input.

Table 1 shows the performance on the development set of LDC2015E86, where the precision, recall and F-score are computed by treating $\langle other \rangle$ as the negative label and accuracy is calculated using all labels. We include accuracy here since correctly predicting words that don't invoke concepts is also important. We can see that utilizing CNN-based character level embedding yields an improvement of around 2 percentage points absolute for both F-score and accuracy, which indicates that morphological and word shape information is important for concept identification.

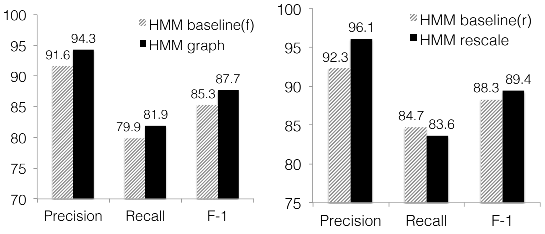
Impact on AMR Parsing In order to test the impact of our concept identification component on AMR parsing, we add the predicted concept labels as features to CAMR. Here is the detailed feature set we add to CAMR's feature templates. To clarify the notation, we refer the concept labels predicted by our concept identifier as c_{pred} and the candidate concept labels in CAMR as c_{cand}:

- `pred_label`. c_{pred} used directly as a feature.
- `is_eq_sense`. A binary feature of whether a c_{pred} and c_{cand} have the same sense (if applicable).

One reason why we choose to add the concept label and sense as features to predict the concept rather than using the predicted label to recover the concept directly is that the latter is not a straightforward process. For example, since we generalize all the predicates to a compact form `<pred-xx>`, for irregular verbs like "*became*" ⇒ `become-01`, simply stemming the inflected verb form will not give us the correct concept even if the sense is predicted correctly. However, since CAMR uses the alignment table to store all possible concept candidates for a word, adding our predicated label as a feature could potentially help the parser to choose the correct concept. In order to take full advantage of the predicted concept labels, we also extend CAMR so that it can discover candidate concepts outside of the alignment table. To achieve this, during the FCL label generation process, we first store the string-to-concept mapping as a template. For example, when we generate the FCL label `(person :ARG0-of <x>-01)` from “worker”, we also store the template `<x>er -> (person :ARG0-of <x>-01)`. Then during decoding time, we would enumerate every template and try to use the left hand side of the template (which is `<x>er`) as a regular expression to match current word. Once we find a match in all the template entries, we would substitute the placeholder in right hand side with the matched substring to get the candidate concept label. As a result, even we haven’t seen “teacher”, by matching teacher with the regular expression `(.⋆)er`, we could generate the correct answer `(person :ARG0-of teach-01)`. We refer this process as *unknown concept generation*. Table 2 summarizes the impact of our proposed methods on development set of LDC2015E86. We can see that by utilizing the unknown concept generation and features derived from c_{pred} , both precision and recall improve by about 1 percentage point, which indicates that the new feature brings richer information to the concept prediction model to help correctly score candidate concepts from the alignment table.

Parsers	P	R	F_1
CAMR (Wang et al., 2016)	72.3	61.4	66.5
CAMR-*gen*	72.1	62.0	66.6
CAMR-*gen*-c_{pred}	**73.6**	**62.6**	**67.6**

Table 2: Performance of AMR parsing with c_{pred} features without *wikification* on dev set of LDC2015E86. The first row is performance of the baseline parser. The second row adds unknown concept generation and the last row additionally extends the baseline parser with c_{pred} features.



(a) HMM forward

(b) HMM reverse

Figure 7: Our improved forward (graph) and reverse(rescale) model compared with HMM baseline on hand aligned development set.

5.2 HMM-based AMR-to-English Aligner Evaluation

To validate the effectiveness of our proposed alignment methods, we first evaluate our forward (English-to-AMR) and reverse (AMR-to-English) aligners against the baseline HMM word alignment model, which is the Berkeley aligner toolkit (DeNero and Klein, 2007). Then we combine the forward and reverse alignment results using competitive thresholding. We set the threshold γ to be 0.5 in the following experiments. To evaluate the alignment quality, we use 200 hand-aligned sentences from (Pourdamghani et al., 2014) split equally as the development and test sets. We process the English sentences by removing stop words, following similar procedure as in (Pourdamghani et al., 2014). When linearizing AMR graphs, we instead remove all the relations and only keep the concepts. For all models, we run 5 iterations of IBM Model 1 and 2 iterations of HMM on the whole dataset.

From Figure 7a, we can see that our graph-distance based model improves both the precision and recall by a large margin, which indicates the graph distance distortion better fits the English-to-AMR alignment task. For the reverse model, although our HMM rescaling model loses accuracy in recall, it is able to improve the precision by around 4 percentage points, which confirms our intuition that the rescoring factor is able to keep reliable alignments and penalize unreliable ones. We then combine our forward and reverse alignment result using competitive thresholding. Table 3 shows the combined result against hand-aligned dev and test sets.

Datasets	P	R	F_1
dev	97.7	84.3	90.5
test	96.9	84.6	90.3

Table 3: Combined HMM alignment result evaluation.

Dataset	Aligner	P	R	F_1
Dev	JAMR	73.6	62.6	67.6
	ISI	72.8	**64.6**	**68.4**
	Our HMM	**73.6**	63.6	68.2
Test	JAMR	71.6	61.3	66.0
	ISI	70.6	**62.7**	66.4
	Our HMM	**72.1**	62.5	**67.0**

Table 4: AMR parsing result (without *wikification*) with different aligner on development and test of LDC2015E86, where JAMR is the rule-based aligner, ISI is the modified IBM Model 4 aligner

Impact on AMR Parsing To investigate our aligner's contribution to AMR parsing, we replace the alignment table generated by the best performing aligner (the forward and reverse combined) in the previous section and re-train CAMR with the predicted concept label features included.

From Table 4, we can see that the unsupervised aligner (ISI and HMM) generally outperforms the JAMR rule-based aligner, and our improved HMM aligner is more consistent than the ISI aligner (Pourdamghani et al., 2014), which is a modified version of IBM Model 4.

5.3 Comparison with other Parsers

We first add the *wikification* information to the parser output using the off-the-shelf AMR wikifier (Pan et al., 2015) and compare results with the state-of-the-art parsers in 2016 SemEval Shared Task. We also report our result on the previous release (LDC2014T12), AMR annotation Release 1.0, which is another popular dataset that most of the existing parsers report results on. Note that the Release 1.0 annotation doesn't include *wiki* information.

Dataset	Parsers	P	R	F_1
SemEval Test	CAMR	70.3	63.1	66.5
	RIGA	-	-	67.2
	JAMR(2016a)	70	65	67
	Our parser	**71.7**	**64.9**	**68.1**
SemEval Blind Test	CAMR	67.4	57.3	62.0
	RIGA	68.0	57.0	62.0
	JAMR(2016a)	-	-	56
	Our parser	**68.2**	**59.5**	**63.6**

Table 5: Comparison with the winning systems in SemEval (**with** *wikification*) on test and blind test sets

CAMR and RIGA (Barzdins and Gosko, 2016) are the two best performing parsers that participated in SemEval 2016 shared task. While we use CAMR as our baseline system, the parser from RIGA is also based on a version of CAMR extended with a error-correction wrapper and an ensemble with a character-level neural sequence-to-sequence model. Our parser outperforms both systems by around 1.5 percentage points, where the improvement in recall is more significant, at around 2 percentage points.

Parsers	P	R	F_1
CAMR	71.3	62.2	66.5
(Zhou et al., 2016)	70	62	66
(Pust et al., 2015)	-	-	65.8
Our parser	**72.7**	**64.0**	**68.07**

Table 6: Comparison with the existing parsers on full test set of LDC2014T12

Table 6 shows the performance of our parser on the full test set of LDC2014T12. We include the previous best results on this dataset. The parser proposed in (Zhou et al., 2016) jointly learns the concept and relation through an incremental joint model. We also include the AMR parser by (Pust et al., 2015) that models AMR parsing as a machine translation task and incorporates various external resources. Our parser still achieves the best result without incorporating external resources other than the NER information.

6 Conclusion

In this paper, we presents work that improves AMR parsing performance by focusing on two components of the parser: concept identification and alignment. We first build a Bidirectional LSTM based concept identifier which is able to incorporate richer context and learn sparse concept labels. Then we extend the HMM-based word alignment model with a graph distance distortion and a rescoring method during decoding to incorporate the graph structure information. By integrating the two components into an existing AMR parser, our parser is able to outperform state-of-the-art AMR parsers and establish a new state of the art.

Abstract

We present a transition-based AMR parser that directly generates AMR parses from plain text. We use Stack-LSTMs to represent our parser state and make decisions greedily. In our experiments, we show that our parser achieves very competitive scores on English using only AMR training data. Adding additional information, such as POS tags and dependency trees, improves the results further.

1 Introduction

Transition-based algorithms for natural language parsing (Yamada and Matsumoto, 2003; Nivre, 2003, 2004, 2008) are formulated as a series of decisions that read words from a buffer and incrementally combine them to form syntactic structures in a stack. Apart from dependency parsing, these models, also known as shift-reduce algorithms, have been successfully applied to tasks like phrase-structure parsing (Zhang and Clark, 2011; Dyer et al., 2016), named entity recognition (Lample et al., 2016), CCG parsing (Misra and Artzi, 2016) joint syntactic and semantic parsing (Henderson et al., 2013; Swayamdipta et al., 2016) and even abstract-meaning representation parsing (Wang et al., 2015b,a; Damonte et al., 2016).

AMR parsing requires solving several natural language processing tasks; mainly named entity recognition, word sense disambiguation and joint syntactic and semantic role labeling.[1] Given the difficulty of building an end-to-end system, most prior work is based on pipelines or heavily dependent on precalculated features (Flanigan et al., 2014; Zhou et al., 2016; Werling et al., 2015; Wang et al., 2015b, inter-alia).

Inspired by Wang et al. (2015b,a); Goodman et al. (2016); Damonte et al. (2016) and Dyer et al. (2015), we present a shift-reduce algorithm that produces AMR graphs directly from plain text. Wang et al. (2015b,a); Zhou et al. (2016); Goodman et al. (2016) presented transition-based tree-to-graph transducers that traverse a dependency tree and transforms it to an AMR graph. Damonte et al. (2016)'s input is a sentence and it is therefore more similar (with a different parsing algorithm) to our approach, but their parser relies on external tools, such as dependency parsing, semantic role labeling or named entity recognition.

The input of our parser is plain text sentences and, through rich word representations, it predicts all actions (in a single algorithm) needed to generate an AMR graph representation for an input sentence; it handles the detection and annotation of named entities, word sense disambiguation and it makes connections between the nodes detected towards building a predicate argument structure. Even though the system that runs with just words is very competitive, we further improve the results incorporating POS tags and dependency trees into our model.

Stack-LSTMs[2] have proven to be useful in tasks related to syntactic and semantic parsing (Dyer et al., 2015, 2016; Swayamdipta et al., 2016) and named entity recognition (Lample et al., 2016). In this paper, we demonstrate that they can be effectively used for AMR parsing as well.

2 Parsing Algorithm

Our parsing algorithm makes use of a STACK (that stores AMR nodes and/or words) and a BUFFER that contains the words that have yet to be processed. The parsing algorithm is inspired from

[1] Check (Banarescu et al., 2013) for a complete description of AMR graphs.

[2] We use the dynamic framework of Neubig et al. (2017) to implement our parser.

Proceedings of the 2017 Conference on Empirical Methods in Natural Language Processing, pages 1269–1275
Copenhagen, Denmark, September 7–11, 2017.

the semantic actions presented by Henderson et al. (2013), the transition-based NER algorithm by Lample et al. (2016) and the arc-standard algorithm (Nivre, 2004). As in (Ballesteros and Nivre, 2013) the buffer starts with the root symbol at the end of the sequence. Figure 2 shows a running example. The transition inventory is the following:

- SHIFT: pops the front of the BUFFER and push it to the STACK.
- CONFIRM: calls a subroutine that predicts the AMR node corresponding to the top of the STACK. It then pops the word from the STACK and pushes the AMR node to the STACK. An example is the prediction of a propbank sense: From *occured* **to** *occur-01*.
- REDUCE: pops the top of the STACK. It occurs when the word/node at the top of the stack is complete (no more actions can be applied to it). Note that it can also be applied to words that do not appear in the final output graph, and thus they are directly discarded.
- MERGE: pops the two nodes at the top of the STACK and then it merges them, it then pushes the resulting node to the top of STACK. Note that this can be applied recursively. This action serves to get multiword named entities (e.g. *New York City*).
- ENTITY(label): labels the node at the top of the STACK with an entity label. This action serves to label named entities, such as *New York City* or *Madrid* and it is normally run after MERGE when it is a multi-word named entity, or after SHIFT if it is a single-word named entity.
- DEPENDENT(label,node): creates a new node in the AMR graph that is dependent on the node at the top of the STACK. An example is the introduction of a negative *polarity* to a given node: From *illegal* **to** (*legal, polarity* -).
- LA(label) and RA(label): create a left/right arc with the top two nodes at the top of the STACK. They keep both the head and the dependent in the stack to allow reentrancies (multiple incoming edges). The head is now a composition of the head and the dependent. They are enriched with the AMR label.
- SWAP: pops the two top items at the top of the STACK, pushes the second node to the front of the BUFFER, and pushes the first one back into the STACK. This action allows non-projective arcs as in (Nivre, 2009) but it also helps to introduce reentrancies. At oracle time, SWAP is produced when the word at the top of the stack is blocking actions that may happen between the second element at the top of the stack and any of the words in the buffer.

Figure 1 shows the parser actions and the effect on the parser state (contents of the stack, buffer) and how the graph is changed after applying the actions.

We implemented an oracle that produces the sequence of actions that leads to the gold (or close to gold) AMR graph. In order to map words in the sentences to nodes in the AMR graph we need to align them. We use the JAMR aligner provided by Flanigan et al. (2014).[3] It is important to mention that even though the aligner is quite accurate, it is not perfect, producing a F1 score of around 0.90. This means that most sentences have at least one alignment error which implies that our oracle is not capable of perfectly reproducing all AMR graphs. This has a direct impact on the accuracy of the parser described in the next section since it is trained on sequences of actions that are not perfect. The oracle achieves 0.895 F1 Smatch score (Cai and Knight, 2013) when it is run on the development set of the LDC2014T12.

The algorithm allows a set of different constraints that varies from the basic ones (not allowing impossible actions such as SHIFT when the buffer is empty or not generating arcs when the words have not yet been CONFIRMed and thus transformed to nodes) to more complicated ones based on the propbank candidates and number of arguments. We choose to constrain the parser to the basic ones and let it learn the more complicated ones.

3 Parsing Model

In this section, we revisit Stack-LSTMs, our parsing model and our word representations.

[3] We used the latest version of the aligner (Flanigan et al., 2016)

3.1 Stack-LSTMs

The **stack LSTM** is an augmented LSTM (Hochreiter and Schmidhuber, 1997; Graves, 2013) that allows adding new inputs in the same way as LSTMs but it also provides a POP operation that moves a pointer to the previous element. The output vector of the LSTM will consider the stack pointer instead of the rightmost position of the sequence.[4]

3.2 Representing the State and Making Parsing Decisions

The state of the algorithm presented in Section 2 is represented by the contents of the STACK, BUFFER and a list with the history of actions (which are encoded as Stack-LSTMs).[5] All of this forms the vector $\mathbf{s}_t$ that represents the state which s calculated as follows:

$$\mathbf{s}_t = \max\left\{\mathbf{0}, \mathbf{W}[\mathbf{st}_t; \mathbf{b}_t; \mathbf{a}_t] + \mathbf{d}\right\},$$

where $\mathbf{W}$ is a learned parameter matrix, $\mathbf{d}$ is a bias term and $\mathbf{st}_t$, $\mathbf{b}_t$,$\mathbf{a}_t$ represent the output vector of the Stack-LSTMs at time t.

Predicting the Actions: Our model then uses the vector $\mathbf{s}_t$ for each timestep t to compute the probability of the next action as:

$$p(z_t \mid \mathbf{s}_t) = \frac{\exp\left(\mathbf{g}_{z_t}^\top \mathbf{s}_t + q_{z_t}\right)}{\sum_{z' \in \mathcal{A}} \exp\left(\mathbf{g}_{z'}^\top \mathbf{s}_t + q_{z'}\right)} \quad (1)$$

where $\mathbf{g}_z$ is a column vector representing the (output) embedding of the action z, and q_z is a bias term for action z. The set $\mathcal{A}$ represents the actions listed in Section 2. Note that due to parsing constraints the set of possible actions may vary. The total number of actions (in the LDC2014T12 dataset) is 478; note that they include all possible labels (in the case of LA and RA) and the different dependent nodes for the DEPENDENT action

Predicting the Nodes: When the model selects the action CONFIRM, the model needs to decide the AMR node[6] that corresponds to the word at

[4] We refer interested readers to (Dyer et al., 2015) for further details.

[5] Word representations, input and hidden representations have 100 dimensions, action and label representations are of size 20.

[6] When the word at the top of stack is an out of vocabulary word, the system directly outputs the word itself as AMR node.

the top of the STACK, by using $\mathbf{s}_t$, as follows:

$$p(e_t \mid \mathbf{s}_t) = \frac{\exp\left(\mathbf{g}_{e_t}^{\top}\mathbf{s}_t + q_{e_t}\right)}{\sum_{e' \in \mathcal{N}} \exp\left(\mathbf{g}_{e'}^{\top}\mathbf{s}_t + q_{e'}\right)} \quad (2)$$

where $\mathcal{N}$ is the set of possible candidate nodes for the word at the top of the STACK. $\mathbf{g}_e$ is a column vector representing the (output) embedding of the node e, and q_e is a bias term for the node e. It is important to mention that this implies finding a propbank sense or a lemma. For that, we rely entirely on the AMR training set instead of using additional resources.

Given that the system runs two softmax operations, one to predict the action to take and the second one to predict the corresponding AMR node, and they both share LSTMs to make predictions, we include an additional layer with a *tanh* nonlinearity after $\mathbf{s}_t$ for each softmax.

3.3 Word Representations

We use character-based representations of words using bidirectional LSTMs (Ling et al., 2015b; Ballesteros et al., 2015). They learn representations for words that are orthographically similar. Note that they are updated with the updates to the model. Ballesteros et al. (2015) and Lample et al. (2016) demonstrated that it is possible to achieve high results in syntactic parsing and named entity recognition by just using character-based word representations (not even POS tags, in fact, in some cases the results with just character-based representations outperform those that used explicit POS tags since they provide similar vectors for words with similar/same morphosyntactic tag (Ballesteros et al., 2015)); in this paper we show a similar result given that both syntactic parsing and named-entity recognition play a central role in AMR parsing.

These are concatenated with pretrained word embeddings. We use a variant of the skip n-gram model provided by Ling et al. (2015a) with the LDC English Gigaword corpus (version 5). These embeddings encode the syntactic behavior of the words (see (Ling et al., 2015a)).

More formally, to represent each input token, we concatenate two vectors: a learned character-based representation ($\tilde{\mathbf{w}}_{\mathrm{C}}$); and a fixed vector representation from a neural language model ($\tilde{\mathbf{w}}_{\mathrm{LM}}$). A linear map ($\mathbf{V}$) is applied to the resulting vector and passed through a component-wise ReLU,

$$\mathbf{x} = \max\left\{\mathbf{0}, \mathbf{V}[\tilde{\mathbf{w}}_{\mathrm{C}}; \tilde{\mathbf{w}}_{\mathrm{LM}}] + \mathbf{b}\right\}.$$

where $\mathbf{V}$ is a learned parameter matrix, b is a bias term and $\mathbf{w}_{\mathrm{C}}$ is the character-based learned representation for each word, $\tilde{\mathbf{w}}_{\mathrm{LM}}$ is the pretrained word representation.

3.4 POS Tagging and Dependency Parsing

We may include preprocessed POS tags or dependency parses to incorporate more information into our model. For the POS tags we use the Stanford tagger (Toutanova et al., 2003) while we use the Dyer et al. (2015)'s Stack-LSTM parser trained on the English CoNLL 2009 dataset (Hajič et al., 2009) to get the dependencies.

POS tags: The POS tags are preprocessed and a learned representation $\mathbf{tag}$ is concatenated with the word representations. This is the same setting as (Dyer et al., 2015).

Dependency Trees: We use them in the same way as POS tags by concatenating a learned representation $\mathbf{dep}$ of the dependency label to the parent with the word representation. Additionally, we enrich the state representation $\mathbf{s}_t$, presented in Section 3.2. If the two words at the top of the STACK have a dependency between them, $\mathbf{s}_t$ is enriched with a learned representation that indicates that and the direction; otherwise $\mathbf{s}_t$ remains unchanged. $\mathbf{s}_t$ is calculated as follows:

$$\mathbf{s}_t = \max\left\{\mathbf{0}, \mathbf{W}[\mathbf{st}_t; \mathbf{b}_t; \mathbf{a}_t; \mathbf{dep}_t] + \mathbf{d}\right\},$$

where $\mathbf{dep}_t$ is the learned vector that represents that there is an arc between the two top words at the top of the stack.

4 Experiments and Results

We use the LDC2014T12 dataset[7] for our experiments. Table 1 shows results, including comparison with prior work that are also evaluated on the same dataset.[8]

[7] This dataset is a standard for comparison and has been used for evaluation in recent papers like (Wang et al., 2015a; Goodman et al., 2016; Zhou et al., 2016). We use the standard training/development/test split: 10,312 sentences for training, 1,368 sentences for development and 1,371 sentences held-out for testing.

[8] The first entry for Damonte et al. is calculated using a pretrained LDC2015 model, available at https://github.com/mdtux89/amr-eager, but evaluated on the LDC2014 dataset. This means that the score is not directly comparable with the rest. The second entry (0.64) for Damonte et al. is calculated by training their parser with the LDC2014 training set which makes it directly comparable with the rest of the parsers.

Table 1: AMR results on the LDC2014T12 dataset; Newsire section (left) and full (right). Rows labeled with OUR-PARSER show our results. POS indicates that the system uses preprocessed POS tags, DEP indicates that it uses preprocessed dependency trees, SRL indicates that it uses preprocessed semantic roles, NER indicates that it uses preprocessed named entitites. LM indicates that it uses a LM trained on AMR data and WordNet indicates that it uses WordNet to predict the concepts. Systems marked with * are pipeline systems that require a dependency parse as input. (WITH PRETRAINED-NO CHARS) shows the results of our parser without character-based representations. (NO PRETRAINED-WITH CHARS) shows results without pretrained word embeddings. (NO PRETRAINED-NO CHARS) shows results without character-based representations and without pretrained word embeddings. The rest of our results include both pretrained embeddings and character-based representations.

Our model achieves 0.68 F1 in the newswire section of the test set just by using character-based representations of words and pretrained word embeddings. All prior work uses lemmatizers, POS taggers, dependency parsers, named entity recognizers and semantic role labelers that use additional training data while we achieve competitive scores without that. Pust et al. (2015) reports 0.66 F1 in the full test by using WordNet for concept identification, but their performance drops to 0.61 without WordNet. It is worth noting that we achieved 0.64 in the same test set without WordNet. Wang et al. (2015b,a) without SRL (via Propbank) achieves only 0.63 in the newswire test set while we achieved 0.69 without SRL (and 0.68 without dependency trees).

In order to see whether pretrained word embeddings and character-based embeddings are useful we carried out an ablation study by showing the results of our parser with and without character-based representations (replaced by standard lookup table learned embeddings) and with and without pretrained word embeddings. By looking at the results of the parser without character-based embeddings but with pretrained word embeddings we observe that the character-based representation of words are useful since they help to achieve 2 points better in the Newswire dataset and 1 point more in the full test set. The parser with character-based embeddings but without pretrained word embeddings, the parser has more difficulty to learn and only achieves 0.61 in the full test set. Finally, the model that does not use neither character-based embeddings nor pretrained word embeddings is the worst achieving only 0.59 in the full test set, note that this model has no explicity way of getting any syntactic information through the word embeddings nor a smart way to handle out of vocabulary words.

All the systems marked with * require that the input is a dependency tree, which means that they solve a transduction task between a dependency tree and an AMR graph. Even though our parser starts from plain text sentences when we incorporate more information into our model, we achieve further improvements. POS tags provide small improvements (0.6801 without POS tags vs 0.6822 for the model that runs with POS tags). Dependency trees help a bit more achieving 0.6920.

5 Conclusions and Future Work

We present a new transition-based algorithm for AMR parsing and we implement it using Stack-LSTMS and a greedy decoder. We present competitive results, without any additional resources and external tools. Just by looking at the words, we achieve 0.68 F1 (and 0.69 by preprocessing dependency trees) in the standard dataset used for evaluation.

Acknowledgments

We thank Marco Damonte, Shay Cohen and Giorgio Satta for running and evaluating their parser in the LDC2014T12 dataset. We also thank Chuan Wang for useful discussions.

Abstract

Given a question and a set of answer candidates, answer triggering determines whether the candidate set contains any correct answers. If yes, it then outputs a correct one. In contrast to existing pipeline methods which first consider *individual* candidate answers separately and then make a prediction based on a threshold, we propose an end-to-end deep neural network framework, which is trained by a novel *group-level* objective function that directly optimizes the answer triggering performance. Our objective function penalizes three potential types of error and allows training the framework in an end-to-end manner. Experimental results on the WikiQA benchmark show that our framework outperforms the state of the arts by a 6.6% absolute gain under F_1 measure[1].

1 Introduction

Question Answering (QA) aims at automatically responding to natural language questions with direct answers (Heilman and Smith, 2010; Severyn and Moschitti, 2013; Yao et al., 2013; Berant and Liang, 2014; Yih et al., 2015; Sun et al., 2015; Miller et al., 2016; Sun et al., 2016). Most existing QA systems always output an answer for any question, no matter whether their answer candidate set contains correct answers or not (Feng et al., 2015; Severyn and Moschitti, 2015; Yang et al., 2016; Rao et al., 2016). In practice, however, this can greatly hurt user experience, especially when it is hard for users to judge answer correctness. In this paper, we study the critical yet under-addressed *Answer Triggering* (Yang et al., 2015) problem: Given a question and a set of answer candidates, determine whether the candidate set contains any correct answer, and if so, select a correct answer as system output.

The answer triggering problem can be logically divided into two sub-problems: $\mathbf{P}_1$: Build an *individual-level* model to rank answer candidates so that a correct one (if it exists) gets the highest score. $\mathbf{P}_2$: Make a *group-level* binary prediction on the existence of correct answers within the candidate set. Previous work (Yang et al., 2015; Jurczyk et al., 2016) attack the problem via a pipeline approach: First solve P_1 as a ranking task and then solve P_2 by choosing an optimal threshold upon the previous step's highest ranking score. However, the yielded answer triggering performance is far from satisfactory, with F_1 between 32% and 36%. An alternative pipeline approach is to first solve P_2 and then P_1, i.e., first determine whether there's a correct answer in the candidate set and then rank all candidates to find a correct one. However, as we will show using state-of-the-art Multiple Instance Learning (MIL) algorithms in Section 4, P_2 by itself is currently a very challenging task, partly because of the difficulty of extracting features from a set of candidate answers that are effective for answer triggering. Because both P_1 and P_2 performances are far from perfect, the above pipeline approaches also suffer from error propagation (Finkel et al., 2006; Zeng et al., 2015).

We propose Group-level Answer Triggering (GAT), an end-to-end framework for jointly optimizing P_1 and P_2. Our key contribution in GAT is a novel group-level objective function, which aggregates individual-level information and penalizes three potential error types in answer triggering as a group-level task. By optimizing this objective function, we can directly back-propagate the

[1] Our code is available at https://github.com/jiez-osu/answer-triggering.

Copenhagen, Denmark, September 7–11, 2017. ©2017 Association for Computational Linguistics

final answer triggering errors to the entire framework and learn all the parameters simultaneously. We conduct evaluation using the same dataset and measure as in previous work (Yang et al., 2015; Jurczyk et al., 2016), and our framework improves the F_1 score by **6.6%** (from 36.65% to 43.27%), compared with the state of the art.

2 Framework

Notations. Let i and j respectively be the index of question and answer candidate, $l_{i,j}$ be the binary label of the j-th answer candidate for question q_i, and l_i be the group label of the answer candidate set of q_i (1 if it contains any correct answer; 0 otherwise). $m_{i,j}$ denotes an individual-level matching score, measuring how likely question q_i can be correctly addressed by its j-th answer candidate.

The GAT framework is illustrated in Figure 1, which consists of three components: (1) ***Encoder***. Two separate encoders process questions and answer candidates respectively, mapping them from token sequences into two different vector spaces. (2) ***QA Matching***. For each question and answer candidate pair, we concatenate their encoded vectors, and pass it through a feed forward neural network with a binary softmax output layer. The output is an *individual-level* matching score, i.e., $m_{i,j}$. (3) ***Signed Max Pooling***. Max pooling is applied on all the matching scores in a candidate set. During training when each candidate is positively/negatively labeled on whether they can answer the question or not, we use the labels to divide the scores into two disjoint subsets and perform max pooling separately:

$$m_i^+ = \max_{j:l_{i,j}=1} m_{i,j}, \qquad m_i^- = \max_{j:l_{i,j}=0} m_{i,j},$$

where m_i^+ is the maximum score among correct answers (if there's any) and m_i^- is that among wrong ones. At testing time when labels are unavailable, it reduces to normal max pooling and pools a single score $m_i = \max_j m_{i,j}$. The answer triggering prediction is then made by comparing m_i with a predefined threshold (0.5) to decide whether to return the top-scored answer candidate to the user.

The GAT framework design is generic in that the Encoder component can be instantiated with different network architectures. In this paper, we implement it with Bidirectional RNNs (Bi-RNN) (Schuster and Paliwal, 1997) with GRU cells (Cho et al., 2014), and use the temporal average pooling over the hidden states as the encoding representation. We choose Bi-RNN mainly because of its good performance in many QA problems (Wang and Nyberg, 2015; Wang et al., 2016).

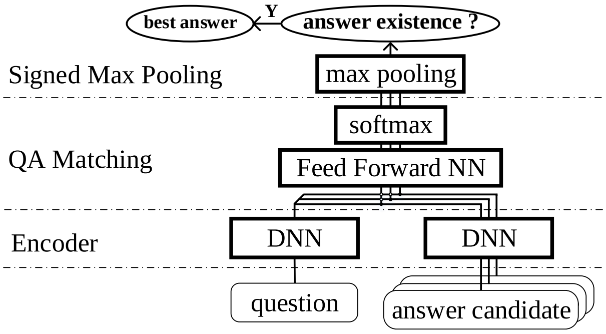

Figure 1: GAT: An end-to-end deep framework to be trained with a novel group-level objective function. Rounded rectangles at the bottom represent input data.

2.1 Learning

The cost function for negative groups (answer candidate sets without correct answers) and positive groups (those with correct answers) are treated differently. For each negative group, the highest QA matching score is penalized by a hinge loss:

$$O_1 = \frac{1}{N_{\text{neg}}} \sum_{i:\, l_i=0} \max(0, d^- - (0.5 - m_i^-)),$$

where the maximum matching score m_i^- is compared with 0.5, a fixed threshold for our framework. The variable d^- here, as well as d^+ and $d^\pm$ that will appear shortly after, are all margin hyperparameters. O_1 is normalized by N_{neg}, which is the number of negative groups (with $l_i = 0$). We use O_1 to reduce false-positive answer existence predictions by penalizing the top matching score that is not safely below the 0.5 threshold.

For a positive group, it is more complicated because answer triggering prediction can have the following two error types: (1) the top matching score is below the threshold, or (2) the top ranked answer candidate is a wrong answer. We design loss terms O_2 and O_3 to penalize these two types of error, respectively. O_2 is a hinge loss that penalizes the case where the highest score among the correct answers in a group is not large enough to signify answer existence. O_3 is to penalize the case where the highest score is obtained by an incorrect candidate answer. Formally:

$$O_2 = \frac{1}{N_{\text{pos}}} \sum_{i:\, l_i=1} \max(0, d^+ - (m_i^+ - 0.5))$$

$$O_3 = \frac{1}{N_{\text{pos}}} \sum_{i:\, l_i=1} \max(0, d^\pm - (m_i^+ - m_i^-))$$

Finally, the overall objective function in Equation 1 is a linear combination of the three loss terms and a standard ℓ_2-regularization. Θ denotes all the trainable parameters in the framework. α, β and λ are hyper-parameters.

$$\mathcal{O} = O_1 + \alpha O_2 + \beta O_3 + \lambda\|\Theta\|^2 \qquad (1)$$

2.2 A Naive Objective Baseline

For comparison, we provide an alternative objective formulation, which equivalently treats positive and negative groups, and does not explicitly penalize cases where an incorrect candidate answer obtains the highest QA matching score in a positive group.

$$\begin{aligned} O_2^* &= \frac{1}{N_{\text{pos}}} \sum_{i:\, l_i=1} \max(0, d^+ - (m_i - 0.5)) \\ O_1^* &= O_1; \quad \mathcal{O}^* = O_1^* + \alpha^* O_2^* + \lambda^* \|\Theta\|^2 \end{aligned} \qquad (2)$$

Here d^+ is a margin and α^*, λ^* are weights. We hypothesize this formulation will work worse than the objective in Equation 1, and will use experiments to verify it.

3 Experiments

3.1 Dataset

We use the WikiQA dataset (Yang et al., 2015) for evaluation. It contains 3,047 questions from Bing query logs, each associated with a group of candidate answer sentences from Wikipedia and manually labeled via crowdsourcing. Several intuitive features are also included in WikiQA: two word matching features (IDF-weighted and unweighted word-overlapping counts between questions and candidate answers, denoted as `Cnt`), the length of a question (`QLen`), and the length of a candidate answer (`SLen`). As in previous works, we also test the effect of these features, by combining them with other features as input into the Softmax layer in our framework. We use the standard 70% (train), 10% (dev), and 20% (test) split of WikiQA. We also use the same data pre-processing steps for fair comparison: Truncate questions and sentences to a maximum of 40-token long and initialize the 300-dimensional word vectors using pretrained word2vec embedding (Mikolov et al., 2013).

3.2 Implementation Details

We implement our full framework using TensorFlow (Abadi et al., 2016) and train it using the AdaDelta optimizer (Zeiler, 2012) with learning rate 0.1 and decay factor 0.95. Dropout is used during training to prevent overfitting. The default threshold in Signed Max Pooling is set at 0.5. We select the hyper-parameters using the dev set and set α=1.2, β=1.0, d^+=0.2, d^-=0.3, $d^\pm$=0.5, λ=$1e^{-4}$. The RNN's hidden state size is 200 in both directions. The feed-forward network in *QA Matching* has two layers of 400 hidden units.

3.3 Evaluation Metrics

We use precision, recall, and F_1, defined in the same way as in previous work. A question is treated as a positive case only if it contains one or more correct answers in its candidate set. For the prediction of a question, only the candidate with the highest matching score is considered. A true positive prediction shall meet two criteria: (1) the score is above a threshold (0.5 for our framework; tuned on dev set in other work), and (2) the candidate is labeled as a correct answer to the question.

3.4 Results

a. Comparison with Baselines

We evaluate the effectiveness of the proposed GAT framework by comparing with several baseline models. To the best of our knowledge, there has only been limited work so far on answer triggering, and they are the first two baselines below. (1) Yang et al. (2015) propose CNN-Cnt, which is a combination of the CNN model from Yu et al. (2014) and two `Cnt` features. We use their best reported result which is achieved when CNN-Cnt is combined with `QLen` features. (2) Jurczyk et al. (2016) extend the previous work with various network structures and add some more sophisticated features. Here we compare with their best model on WikiQA, which is a CNN model combined with carefully designed tree-matching features, extracted from expensive dependency parsing results. (3) We include a third **Naive** baseline where the objective function in Equation 2 is used to train our architecture in Figure 1. Due to space limits, we show its best result obtained among various feature combinations.

The results are summarized in Table 1.

We can see that GAT combined with `Cnt` features improves the F_1 score from Yang et al. (2015) and Jurczyk et al. (2016) by around **11.1%** and **6.6%** (from 32.17 and 36.65 to 43.27), which shows the effectiveness of our framework. We denote this configuration as our *full* framework. Through the comparison between Naive and GAT,

Model	Prec	Rec	F1
(Yang et al., 2015)	27.96	37.86	32.17
(Jurczyk et al., 2016)	29.43	48.56	36.65
Naive +`Cnt`	27.36	48.84	35.07
GAT	32.70	48.59	39.09
GAT +`Cnt` (Full)	33.54	60.92	**43.27**
GAT +`Cnt`+`QLen`	33.12	59.09	42.45
GAT +`Cnt`+`SLen`	28.03	64.60	39.10
GAT +`All`	31.35	58.82	40.90

Table 1: Results on the test set.

we can see that our proposed objective function has a great advantage over the Naive one which does not model the complexity of answer triggering for positive candidate sets. Different from Yang et al. (2015)'s results, combining with the `QLen` feature does not further improve the performance in our case, possibly because we choose Bi-RNN as our encoder, which may capture some question characteristics better than a length feature.

b. Framework Breakdown

Now we conduct further analysis in order to better understand the contribution of each component in our full framework. Since the code from (Yang et al., 2015) is available, we use it (rather than (Jurczyk et al., 2016)) to assist our analysis.

We first test a variant of our full framework by replacing the Encoder and QA Matching component with the CNN based model from (Yang et al., 2015)[2], denoted as **GAT** w/ CNN, and train it with our objective. From the first two rows in Table 2, we observe that: (1) Using our current design Bi-RNN and feed-foward NN improves from 35.03% to 43.27%, in comparison with the CNN based model, partly because their CNN only consists of one convolution layer and one average pooling layer. However, we leave more advanced encoder and QA matching design for future work, and anticipate that more complex CNN based models can achieve similar or better results than our current design, as in many other QA-related work (Hu et al., 2014; He and Lin, 2016). (2) Compared with the best result from (Yang et al., 2015) in Table 1, training the CNN based model end-to-end using our objective improves from 32.17% to 35.03%. *This directly shows an end-to-end learning strategy works better than the pipeline approach in (Yang et al., 2015).*

Now we detach the Encoder component **ENC** from our end-to-end full framework. To obtain semantic vectors of questions and candidate answers as input to the subsequent QA Matching component, we leverage Yang et al.(2015)'s released code to train the Encoder component (with CNN) through their well-tuned individual-level optimization, and use their learnt semantic vectors. Then our framework without ENC, i.e.,
-ENC, is trained and tested as before. We further detach the QA matching component **QAM** in a similar way: We directly use the matching score between a question and a candidate answer obtained by Yang et al. (2015), and concatenate it with `Cnt` features as input to the Softmax layer, which is our framework without ENC or QAM, denoted as **-ENC -QAM**, and trained by our group-level objective. By comparing them with our end-to-end frameworks on both dev and test sets, we can see that it is beneficial to jointly train the entire framework.

	Framework	F_1 score	
		dev	test
End-to-End	Full	44.63	**43.27**
	GAT w/ CNN	39.67	35.03
Pipeline	**-ENC**	39.13	33.42
	-ENC -QAM	38.69	33.20

Table 2: GAT framework breakdown. All variants are trained with our proposed objective function (Equation 1).

3.5 Error Analysis

We now demonstrate some typical mistake types made by our framework to inspire future improvements.

Q: *What city was the convention when Gerald Ford was nominated?*
A: *Held in Kemper arena in Kansas City , Missouri , the convention nominated president Gerald Ford for a full term, but only after narrowly defeating a strong challenge from former California governor Ronald Reagan.*

In this case, **A** is correct, but our framework made a false negative prediction. Although already being the highest ranked in a set of 4 candidate answers, **A** only got a score of 0.134, possibly due to its complicated semantic structure (attribute clause) and the extra irrelevant information (defeating Reagan).

Q: *What can SQL 2005 do?*
A1: *Microsoft SQL server is a relational database management system developed by Microsoft.*

[2] Where the QA matching score is obtained first through CNN encoding and then a bilinear model.

A2: *As a database , it is a software product whose primary function is to store and retrieve data as requested by other software applications, be it those on the same computer or those running on another computer across a [TRUNCATED END]*

The incorrect answer **A1** is ranked higher than the correct answer **A2**, both with scores above 0.5. This is a false positive case, with incorrect ranking as well. Possible reasons are that the detailed functionality of SQL explained in **A2** is hard to be captured and related to the question, and **A2** gets truncated to 40 tokens long in our experiments. On the other hand, the "database management system" phrase in **A1** sounds close to an explanation of functionality, if not carefully distinguished.

Both cases above show that the semantic relation between a question and its answer is hard to capture. For future research, more advanced models can be incorporated in the *Encoder* and *QA Matching* components of our framework.

4 Related Work

Answer Selection. Answer selection (a.k.a., answer sentence selection) is the task of assigning answer candidates with individual-level ranking scores given a question, which is similar to P1 defined in Section 1. Existing QA systems based on answer selection just select the top-scored candidate as answer, without considering the possibility that the true answer doesn't even exist. However, many neural network models recently explored in the answer existence literature (Hu et al., 2014; Wang and Nyberg, 2015; Feng et al., 2015) could be utilized for answer selection as well in the future. For example, Tan et al. (2016) explore the respective advantages of different network architectures such as Long Short-Term Memory Networks (LSTMs) and CNNs. They also develop hybrid models for answer selection. Various attention mechanisms have been proposed such as (Wang et al., 2016) for RNNs and (Yin et al., 2015; dos Santos et al., 2016) for CNNs. Answer selection is also formulated as a sentence similarity measurement problem (He and Lin, 2016; He et al., 2015) or a pairwise ranking problem as in (Severyn and Moschitti, 2015; Yang et al., 2016; Rao et al., 2016).

Multiple Instance Learning We have briefly mentioned MIL (Babenko et al., 2011; Amores, 2013; Cheplygina et al., 2015) in Section 1. Many MIL algorithms can not be directly applied for answer triggering, because individual-level annotations and predictions are often assumed unavailable and unnecessary in MIL (Maron and Lozano-Pérez, 1998; Babenko et al., 2011; Amores, 2013; Cheplygina et al., 2015), but not in the answer triggering setting, where the correctness of each answer candidate is annotated during training and needs to be predicted during testing. We experimented with two popular MIL algorithms that explicitly discriminate individual-level labels: MI-SVM(Andrews et al., 2003) and SbMIL (Bunescu and Mooney, 2007) implemented in one of the state-of-the-art MIL toolkits (Doran and Ray, 2014), where we represented each question/answer with encoder vectors as in Section 3.4. Unfortunately, both algorithms predict no correct answer exists for any question, possibly because the training data are biased towards negative groups and the input features are not effective enough. This indicates that using MIL for answer triggering is challenging and still open for future research.

5 Conclusion

In conclusion, we address the critical answer triggering challenge with an effective framework based on deep neural networks. We propose a novel objective function to optimize the entire framework end-to-end, where we focus more on the group-level prediction and take into account multiple important factors. In particular, the objective function explicitly penalizes three potential errors in answer triggering: (1) false-positive and (2) false-negative predictions of the existence of a correct answer, as well as (3) ranking incorrect answers higher than correct ones. We experimented with different objective function settings and show that our GAT framework outperforms the previous state of the arts by a remarkable margin.

Predicting Word Association Strengths

Abstract

This paper looks at the task of predicting word association strengths across three datasets; WordNet Evocation (Boyd-Graber et al., 2006), University of Southern Florida Free Association norms (Nelson et al., 2004), and Edinburgh Associative Thesaurus (Kiss et al., 1973). We achieve results of $r = 0.357$ and $\rho = 0.379$, $r = 0.344$ and $\rho = 0.300$, an $\rho = 0.292$ and $\rho = 0.363$, respectively. We find Word2Vec (Mikolov et al., 2013) and GloVe (Pennington et al., 2014) cosine similarities, as well as vector offsets, to be the highest performing features. Furthermore, we examine the usefulness of Gaussian embeddings (Vilnis and McCallum, 2014) for predicting word association strength, the first work to do so.

1 Introduction

Word embeddings such as Word2Vec (Mikolov et al., 2013) or GloVe (Pennington et al., 2014) have received increasing attention in the world of natural language processing and computational linguistics. Under such embeddings, the semantic relatedness of two words is generally taken to be the cosine similarity of their word vectors. Although this approach performs well for variety of applications, it is not without its limitations. First, it defines "relatedness" quite narrowly as the extent to which the two words appear in similar contexts. Second, it fails to capture how humans internally represent words (De Deyne et al., 2016b).

Word associations offer a more flexible view of semantic relatedness by leveraging "lexical knowledge acquired through world experience" (Nelson et al., 2004). While word embeddings capture distributional relationships, word associations are able to capture more nuanced relationships "which are based on human perception and experiences [and] are not reflected in common language usage." (Ma, 2013) For example, "yellow" is so closely associated with "banana" that many people would only specify a banana's colour if it is not yellow. This is backed up by De Deyne et al. (2016b) which found word associations performed better than word embeddings across a variety of semantic relatedness tasks.

Furthermore, word associations, unlike cosine similarities, are asymmetric; when presented with the word "beer", many people think of the word "glass" but when presented with the word "glass", few people think of the word "beer" (Ma, 2013). This directionality allows for more fine-grained exploration of semantic links, with applications in word similarity (Jabeen et al., 2013) and computational humour (Cattle and Ma, 2016).

Although several word association datasets exist, such as the Edinburgh Associative Thesaurus (EAT, Kiss et al., 1973), the University of South Florida Free Association Norms (USF, Nelson et al., 2004), or WordNet Evocation (Evocation, Boyd-Graber et al., 2006), their reliance on human annotations mean they all suffer from coverage issues relating to limited vocabularies or sparse connectivity (Cattle and Ma, 2016; De Deyne et al., 2016b). Although these issues would be somewhat alleviated by the creation of larger datasets, collecting human judgments for all possible word pairs is impractical. Therefore, the ability to predict association strengths between arbitrary word pairs represents the best solution to these coverage issues (Boyd-Graber et al., 2006).

Although the prediction of Evocation ratings has attracted some attention (Boyd-Graber et al., 2006; Hayashi, 2016), to the best of our knowledge this is the first work to focus on the prediction of USF or EAT strengths. As described in Sec-

Proceedings of the 2017 Conference on Empirical Methods in Natural Language Processing, pages 1283–1288
Copenhagen, Denmark, September 7–11, 2017.

tion 2, USF and EAT have several advantages over Evocation, such as the ability to work with ambiguous words instead of WordNet synsets. Following Hayashi (2016)'s work on Evocation prediction, we frame word association prediction as a supervised regression task and introduce several new and modified features, including the first use of Gaussian embeddings (Vilnis and McCallum, 2014) to better capture the asymmetric nature of word associations.

2 Previous Work

Word association has been used in psychological and psycholinguistic experiments for well over 100 years (Boyd-Graber et al., 2006; De Deyne and Storms, 2008). Word association datasets such as USF or EAT have typically framed word association as "a task that requires participants to produce the first word to come to mind that is related in a specified way to a presented cue" (Nelson et al., 2000). These datasets use *forward strengths*, the proportion of participants who produce a specific response, to "index the relative accessibility of related words in memory [for a given cue]" (Nelson et al., 2004).

This cue/response framework has several drawbacks. First, since forward strengths are relative, comparing strengths across different cue words is difficult. Second, both cues and responses are ambiguous, with each participant's responses being greatly influenced by how they chose to interpret a given cue. For example, someone responding to the cue "brother" with "monk" is considering a different sense of "brother" than someone who responds "sister" (Ma, 2013). As such, forward strengths are biased toward responses which presume more readily apparent cue word senses. Third, limiting participants to a single response can lead to weaker associations being underreported or omitted entirely.

Evocation solves the ambiguity issue by focusing on associations between WordNet synsets. Boyd-Graber et al. (2006) presented participants with randomly selected synset pairs and asked them to score how much the first synset *evoked* (i.e. brought to mind) the second. Unlike forward strengths, these Evocation ratings are absolute, meaning they can be directly compared across different cues. While randomly selecting synset pairs ensured that weaker associations would not be underreported, it did have the disadvantage that 67% of pairs were unanimously rated as having no connection (Boyd-Graber et al., 2006).

Despite attempts to address this spareness issue by expanding Evocation with data gathered from Amazon Mechanical Turk[1] (Nikolova et al., 2009) or word-sense disambiguated USF cue/response pairs (Ma, 2013), obtaining human judgments for all possible synset pairs is impractical. As such, the prediction of Evocation ratings presents the most promising solution to this coverage issue. Boyd-Graber et al. (2006) detailed a simple Evocation estimator which used a combination of WordNet structure-based features, WordNet definition-based features, and corpus-based word co-occurrence features. However, this approach is somewhat limited in that it frames Evocation prediction as a classification task, considering only five Evocation levels.

The main drawback of Evocation prediction as a classification task is that it is too coarse-grained to deal with very weak associations, such as those in remote triads (De Deyne et al., 2016a), or very slight variations in association strength, such as those useful for computational humour (Cattle and Ma, 2016). To this end, Hayashi (2016) framed Evocation prediction as a supervised regression task. They employed a combination of WordNet structure-based features, word embedding-based features, and lexical features and found that vector offsets, i.e. the mathematical difference between vectors, were a strong indicator of Evocation ratings.

While Evocation's use of unambiguous synsets is useful for many applications, it is not without its own drawbacks. First, it requires texts to be word sense disambiguated; a non-trivial task. Second, since humans do not conceptualize words as a discrete set of independent word senses, Evocation is unable to capture natural associations owing to homography, homophony, or polysemy (Ma, 2013). As such, despite their drawbacks, word associations may provide a more flexible, more holistic view of mental semantics.

By allowing participants to record more than one response, De Deyne and Storms (2008), and their derivative works De Deyne et al. (2013) and De Deyne et al. (2016b), were able to better represent weaker associations. However, this introduced its own set of problems as great care had to be taken to avoid chaining, i.e. responding to a

[1] https://mturk.com/

previous response instead of the cue, and retrieval inhibition. De Deyne and Storms (2008) frames word association collection as a continuous task, meaning not only that the vocabulary is ever growing but also that changes in associations over time can be observed and tracked. But despite the steps taken to improve the size and quality of their association dataset, practicality dictates that coverage issues cannot be completely eliminated.

3 System Definition

Our word association prediction system extends the method in Hayashi (2016) with several modifications to make it better suited to the USF and EAT datasets.

First, we modify Hayashi (2016)'s *lexVector*. Hayashi (2016) represent each word's part-of-speech (POS) using a one-hot encoded five dimensional vector (one of each POS in WordNet). Similarly, they represent each word's lexical category using a one-hot encoded 45 dimensional vector (one for each WordNet lexicographer file). This results in a 100 dimensional vector representing the POS and lexical categories of both the cue and the response. Since words in USF and EAT can be associated with multiple synsets and we want to be able to capture associations related to polysemy, instead using a one-hot encoding we employ count vectors specifying the number of synsets from each POS/lexical category each word belongs to.

Second, instead of computing Wu-Palmer similarity (WUP, Wu and Palmer, 1994) between a single synset pair, we compute it for all cue synset/response synset pairs and record the maximum and average values. Following Boyd-Graber et al. (2006) and Ma (2013), we also explored the use of path and Leacock-Chodorow (Leacock and Chodorow, 1998) similarities but found they did not add any advantage over WUP alone. We take a similar approach for adapting load and betweenness centralities (Barthelemy, 2004) as well as AutoExtend (AutoEx, Rothe and Schütze, 2015) similarity.

Third, we extend the notion of *dirRel*, introduced in Hayashi (2016) to leverage the semantic network structure of WordNet. Given a graph where nodes represent synsets and arcs represent WordNet relations such as hypernym/hyponym and holonym/meronym, *dirRel(s,t,k)* is the proportion of k-step neighbours of s that are also k-step neighbours of t. In the original formula, s and t are nodes representing a single synset. We instead consider a set of nodes S and a set of nodes T representing the set of synsets associated with the cue and response words, respectively, as shown in Equation 1. This may increase the probability that $|nb(S,k) \cap nb(T,k)| > 0$, a shortcoming of the original *dirRel* due to WordNet's "relatively sparse connective structure" (Hayashi, 2016).

$$dirRel(S,T,k) = \frac{|nb(S,k) \cap nb(T,k)|}{|nb(S,k)|} \quad (1)$$

Fourth, in addition to the Word2Vec (w2v) cosine similarity between cue/response pairs calculated using Google's pre-trained 300 dimension Word2Vec embeddings[2]. We also examine the effectiveness of Stanford's pre-trained 300 dimension GloVe embeddings[3].

Fifth, in order to better capture asymmetric word associations, we propose using Gaussian embeddings. Gaussian embeddings (Vilnis and McCallum, 2014) represent words not as a fixed point in vector space but as "potential functions", continuous densities in latent space; therefore, they are more suitable for capturing asymmetric relationships. More specifically, for each cue/response pair, we calculate both the KL-divergence and cosine similarities of their Gaussian embeddings. The embeddings have a dimensionality of 300 and are trained on English Wikipedia using the Word2Gauss[4] (w2g) and the hyperparameters reported by the developer[5]

Sixth, since cue and response words are not associated with a single synset, the AutoEx embeddings employed in Hayashi (2016) to compute vector offsets are not well suited for our task. Instead, we experiment with offsets calculated using w2v, GloVe, and w2g embeddings.

Finally, our 300 topic LDA model (Blei et al., 2003) was trained using Gensim[6] on full English Wikipedia instead of the subset of English Wikipedia used in Hayashi (2016).

Using the above features, we trained a multilayer perceptron for each of our three datasets; Evocation, USF, and EAT. In the case of Evocation, we discarded any synset information and

Table 2: Ablation performance after 50 epochs

simply use each synset's headword (e.g. given the sysnet *entity.n.01*, we only considered the word *entity*). Following the setup used in Hayashi (2016), all neural networks are trained using the Chainer[7] Python library with rectified linear units, dropout, and two hidden layers, each with 50% of the number of units in the input layer. All were trained on 80% of their respective dataset, with 20% held out for testing. Mean squared error was used as a loss function and optimization was performed using Adam algorithm (Kingma and Ba, 2014). To act as a baseline, we also reimplemented the system described in Hayashi (2016) and trained it on the same 80/20 split of Evocation as our system. In addition to the reported results, we also performed feature selection experiments using 20% of the training sets as validation.

4 Results and Discussion

The performance of individual features are reported in Table 1 while the results of our ablation experiments are reported in Table 2. For all experiments we report both the Pearson correlation coefficient (as r) and Spearman's rank correlation coefficient (as ρ).

The best performing single feature on Evocation and USF is w2v cosine similarity. However, its removal in the ablation test had little effect. This is likely due to redundancy between w2v and GloVe; not only does GloVe perform similarly to w2v but removing both features at the same time produced the largest drop in performance. It is unclear why word embedding cosine similarities in general performed relatively poorly on EAT. While the USF and EAT datasets are very similar, EAT does seem to contain a greater number of multi-word cues/responses which would not be in the word embedding vocabularies. In such cases, perhaps a multi-word embedding like Doc2Vec (Le and Mikolov, 2014) would be more appropriate. However, if this were indeed the issue, one would expect vector offsets to perform equally poorly. This is not the case, with GloVe offsets being the best performing single feature on EAT and the removal of w2v offsets causing the greatest drop in performance in the EAT ablation tests.

The results of our Hayashi (2016) implementation are roughly comparable to those reported in the original paper ($r = 0.374$, $\rho = 0.401$ compared to $r = 0.439$, $\rho = 0.400$). Our slightly lower Pearson's R may be due to differences in way we split our training and test data as well as due to randomness in the training process itself.

On Evocation, our system does not perform as well as Hayashi (2016). This is expected as we explicitly ignore any synset information and instead attempt to predict association strengths between word-sense ambiguous words. Despite this, our performance is not appreciably lower, indicating the fitness of our system.

The fact that we perform better on Evocation than either USF or EAT is quite interesting considering our system was designed with USF and EAT in mind. There are several possible explanations for this. First, as mentioned in Section 2, 67% of cue/response pairs in Evocation have a strength of zero. This uniformity in Evocation strengths may make them easier to predict. Second, due to the way USF and EAT were collected, there are no true zeros in the datasets. This lack of grounding

[7] http://chainer.org/

may skew the predictions. Third, this may be an indication that predicting associations in a word-sense ambiguous context is a harder task than predicting them in a word-sense disambiguated one. Boyd-Graber et al. (2006) explicitly told annotators to ignore associations based on polysemy or rhyme. It could be the case that these effects are more difficult to identify.

Another possible explanation for this relatively lower performance is a lack of bespoke features. For example, we heavily rely on WordNet-based features which make sense in a word-sense disambiguated context but are less suited for ambiguous contexts. In fact, removal of several of these features, such as betweenness or AutoEx similarity, seem to slightly improve performance. One explanation is that, despite noting in Section2 that word association strengths are influenced by word-sense frequencies, our system instead implicitly assumes all synsets are equally likely.

The most surprising finding was the poor performance of Gaussian embeddings overall, and KL-divergence in particular. Given the asymmetric nature of word associations, KL-divergence seemed to be a natural fit. However, it is vastly outperformed by even cosine similarity on the same set of embeddings. Despite this, the usefulness of Gaussian embeddings cannot be ruled out. While we used pre-trained embeddings for Word2Vec and GloVe, we had to train our own Gaussian embedding model. Not only were Word2Vec and GloVe trained on much larger corpora than Gaussian embedding's English Wikipedia, but the pre-trained embeddings likely underwent a greater degree of hyperparameter tuning.

5 Conclusions and Future Works

In this paper we explored the effectiveness of various features for predicting Evocation, USF, and EAT association strengths, finding GloVe and Word2Vec cosine similarities as well as vector offsets to be the most useful features. We also examined the effectiveness of Gaussian embeddings for capturing the asymmetric nature of word embeddings but found it to be less effective than traditional word embeddings.

Although we report a lower performance than that in Hayashi (2016), potentially indicating that predicting association strengths in word-sense ambiguous contexts is a harder task, we believe our results are a promising start. Training Gaussian embeddings on a larger corpus may lead to improved effectiveness. Future works should also consider incorporating word-sense frequencies or developing word-sense agnostic features, with a particular focus on asymmetric features.

Abstract

Recent advances in RST discourse parsing have focused on two modeling paradigms: (a) high order parsers which jointly predict the tree structure of the discourse and the relations it encodes; or (b) linear-time parsers which are efficient but mostly based on local features. In this work, we propose a linear-time parser with a novel way of representing discourse constituents based on neural networks which takes into account global contextual information and is able to capture long-distance dependencies. Experimental results show that our parser obtains state-of-the art performance on benchmark datasets, while being efficient (with time complexity linear in the number of sentences in the document) and requiring minimal feature engineering.

Figure 1: Example text (bottom) composed of two sentences (three EDUs) and its RST discourse tree representation (top).

1 Introduction

The computational treatment of discourse phenomena has recently attracted much attention, due to their increasing importance for potential applications. Knowing how text units can be composed into a coherent document and how they relate to each other e.g., whether they express contrast, cause, or elaboration, can usefully aid downstream tasks such summarization (Yoshida et al., 2014), question answering (Chai and Jin, 2004), and sentiment analysis (Somasundaran, 2010).

Rhetorical Structure Theory (RST, Mann and Thompson 1988), one of the most influential frameworks in discourse processing, represents texts by trees whose leaves correspond to Elementary Discourse Units (EDUs) and whose nodes specify how these and larger units (e.g., multi-sentence segments) are linked to each other by rhetorical relations. Discourse units are further characterized in terms of their importance in text: nuclei denote central segments, whereas satellites denote peripheral ones. Figure 1 shows an example of a discourse tree representing two sentences with three EDUs (e_1, e_2, and e_3). EDUs e_1 and e_2 are connected with a mononuclear relation (i.e., *Consequence*), where e_1 is the nucleus and e_2 the satellite (indicated by the left pointing arrow in the figure). Span $e_{1:2}$ is related to e_3 via *List*, a multi-nuclear relation, expressing the fact that both spans are equally important and therefore both nucleus.

Given such tree-based representations of discourse structure, it is not surprising that RST-style document analysis is often viewed as a parsing task. State-of-the-art performance on RST parsing is achieved by cubic-time parsers (Li, Li, and Hovy, 2014; Li, Li, and Chang, 2016), with $O(n^3)$ time complexity (where n denotes the number of sen-

Proceedings of the 2017 Conference on Empirical Methods in Natural Language Processing, pages 1289–1298
Copenhagen, Denmark, September 7–11, 2017. ©2017 Association for Computational Linguistics

tences in the document). These systems model the relations between all possible adjacent discourse segments and use a CKY-style algorithm to generate a global optimal tree. The high order complexity renders such parsers inefficient in practice, especially when processing large documents. As a result, more efficient linear-time discourse parsers have been proposed (Feng and Hirst, 2014; Ji and Eisenstein, 2014) which make local decisions and model the structure of the discourse and its relations separately. In this case, features are extracted from a local context (i.e., a small window of discourse constituents) without considering document-level information, which has been previously found useful in discourse analysis (Feng and Hirst, 2012).

In this paper, we propose a simple and efficient linear-time discourse parser with a novel way of learning contextual representations for discourse constituents. To guarantee linear-time complexity, we use a two-stage approach: we first parse each sentence in a document into a tree whose leaves correspond to EDUs, and then parse the document into a tree whose leaves correspond to already preprocessed sentences. The feature learning process for both stages is based on neural network models. At the sentence level, Long-Short Term Memory Networks (LSTMs; Hochreiter and Schmidhuber 1997) learn representations for EDUs and larger constituents, whereas at the document level, LSTMs learn representations for entire sentences. Treating a sentence as a sequence of EDUs and a document as a sequence of sentences allows to incorporate important contextual information on both levels capturing long-distance dependencies.

Recurrent neural networks excel at modeling sequences, but cannot capture hierarchical structure which is important when analyzing multi-sentential discourse. We therefore adopt a more structure-aware representation at the document level which we argue is complementary to the flat representations obtained from the LSTM. We represent documents as trees using recursive neural networks (Socher et al., 2012). Experimental evaluation on the RST Treebank shows that our parser yields comparable performance to previous linear-time systems, without requiring extensive manual feature engineering and improves upon related neural models (Li et al., 2014, 2016) on discourse relation classification, while being more efficient.

The rest of this paper is organized as follows. We overview related work in the following section. We describe the general flow of our parser in Section 3 and provide details on our parsing algorithm and feature learning method in Section 4. Experimental results are reported in Section 5. Section 7 concludes the paper.

2 Related Work

Recent advances in discourse modeling have greatly benefited from the availability of resources annotated with discourse-level information such as the RST Discourse Treebank (RST-DT; Carlson et al. 2003) and the Penn Discourse Treebank (PDTB, Prasad et al. 2008). In this work, we focus on RST-style discourse parsing, where a tree representation is derived for an entire document. In PDTB, discourse relations are annotated mostly between adjacent sentences and no global tree structure is provided.

Early approaches to discourse parsing (Marcu, 2000; LeThanh et al., 2004) have primarily focused on overt discourse markers (or cue words) and used a series of rules to derive the discourse tree structure. Soricut and Marcu (2003) employed a standard bottom-up chart parsing algorithm with syntactic and lexical features to conduct sentence-level parsing. Baldridge and Lascarides (2005) and Sagae (2009) used probabilistic head-driven parsing techniques. Subba and Di Eugenio (2009) were the first to incorporate rich compositional semantics into sentence- and document-level discourse parsing.

HILDA (Hernault et al., 2010) has been one of the most influential document-level discourse parsers paving the way for many machine learning-based models. HILDA parses a document pre-segmented into EDUs with two support vector machine classifiers working iteratively in a pipeline. At each iteration, a binary SVM predicts which adjacent units should be merged and then a multi-class SVM predicts their discourse relation. Subsequent work (Feng and Hirst, 2014; Joty et al., 2013) has shown that two-stage systems are not only efficient but can also achieve competitive performance. CKY-based parsers which guarantee globally optimal results have also been developed (Joty et al., 2013; Li et al., 2014).

Ji and Eisenstein (2014) were the first to apply neural network models to RST discourse parsing; their shift-reduce parser uses a feedforward neural network to learn the representations of the transition stack and queue. Li et al. (2014) proposed a CKY-based parser which uses recursive neural networks to learn representations for EDUs and their composition during the tree-building process. More recently, Li et al. (2016) designed a CKY-based parser which uses LSTMs to model text spans and a tensor-based transformation to compose adjacent spans.

Our own work joins others (Feng and Hirst, 2014; Joty et al., 2013) in adopting a two-stage architecture for our discourse parser. However, rather than considering each discourse constituent independently, we learn contextually-aware representations capturing long-range dependencies across sentences and documents. Discourse constituents at all levels are modeled with recurrent neural networks adopting a relatively simple, yet efficient, architecture compared to previously proposed neural systems (Li et al., 2016). Finally, we experimentally assess whether sequence-based representations are expressive enough by comparing them to those obtained (with recursive neural networks) from structured inputs.

3 Discourse Parser Overview

In RST discourse parsing, a document is first segmented into EDUs and a parser then builds a discourse tree with the EDUs as leaves. The first subtask is considered relatively easy with state-of-art accuracy at above 90% (Hernault et al., 2010). As a result, recent research focuses on the second subtask and often uses manual EDU segmentation.

Joty et al. (2013) found that a two-stage parsing strategy, which separates intra-sentential from multi-sentential parsing, has some advantages for document-level discourse parsing, since the distribution of discourse relations and useful features are different in the two stages. Based on their findings, our model also follows a two-stage approach and is composed by two components: an *intra-sentential parser* and a *multi-sentential parser*. Given a document pre-segmented into EDUs, our intra-sentential parser first builds a sentence-level discourse tree for individual sentences. Then, our multi-sentential parser creates a discourse tree for the entire document.

To guarantee linear-time complexity, both parsers adopt a greedy bottom-up tree-building process (Hernault et al., 2010) and are based on two conditional random field (CRF) models, one for creating discourse structure and another one for assigning relations. The intra-sentential parser considers adjacent EDUs and decides whether they should be connected (based on the scores predicted by the first CRF) and their relation (based on predictions of the second CRF). The multi-sentential parser follows the same procedure while operating over sentences.

The CRFs employ feature representations which we obtain using neural networks. Specifically, discourse constituents at all levels are modeled with recurrent neural networks (see Section 4.2 for details). In addition, for inter-sentential constituents, we complement the flat text span representation with recursive neural networks (see Section 4.4). We argue that the combination is advantageous; a sequential text span representation is in principle unsuitable for capturing hierarchical discourse structure, whereas a tree-based representation can be more precise, albeit less robust (due to the accumulation of errors from the recursive tree-building process).

4 Parsing Model

4.1 Intra-sentential Parser

To parse a sentence, we start with EDUs, which can be viewed as discourse constituents at the first level. As mentioned earlier, our intra-sentential parser is based on two linear-chain CRFs, the structure CRF decides which pair of constituents should be merged at the current level and the relation CRF assigns discourse relations to non-leaf constituents. For example, let $C_1 = \{e_1, e_2, \cdots, e_m\}$ denote a sentence with a sequence of EDUs, where e_i is the i^{th} EDU in the sentence. Suppose the structure CRF decides to merge together e_2 and e_3, then the next-level sequence is $C_2 = \{e_1, e_{2:3}, e_4, \cdots, e_m\}$ and the relation CRF will assign a discourse relation to $e_{2:3}$, the only non-leaf constituent so far. This process iterates until all EDUs are merged and a discourse subtree is generated for the entire sentence.

A linear-chain CRF for intra-sentential discourse parsing is shown in Figure 2. Here, $C = \{c_0, \cdots, c_t, \cdots, c_n\}$ are observed discourse constituents and $L = \{l_1, \cdots, l_t, \cdots, l_n\}$ are hidden structure nodes; label $l_t \in \{1, 0\}$ denotes whether constituents c_t and c_{t+1} should be connected. Our model differs from standard linear-chain CRFs in that the score between adjacent hidden nodes is not calculated based on a transition matrix, but is learned from observations instead. Specifically,

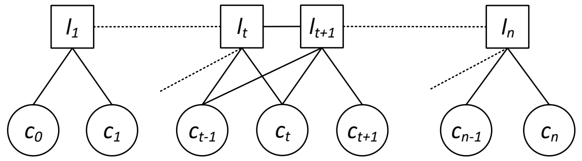

Figure 2: Intra-sentential structure CRF with pairwise modeling.

given a constituent sequence C, the probability of forming the structure sequence Y^{str} is written as:

$$p(Y^{str}|C) = \frac{1}{Z}\prod_{t=1}^{n} exp(u_t^{str} + b_{t,t+1}^{str}) \quad (1)$$

$$u_t^{str} = \theta(c_t, c_{t+1}, y_t) \quad (2)$$

$$b_{t,t+1}^{str} = \gamma(c_{t-1}, c_t, c_{t+1}, y_t, y_{t+1}) \quad (3)$$

where the u_t^{str} represents the unary potential score of structure node $l_t = y_t$, depending on constituents c_t and c_{t+1}. The binary potential score $b_{t,t+1}^{str}$ for $s_t = y_t, s_{t+1} = y_{t+1}$ is calculated based on c_{t-1}, c_t and c_{t+1}. The binary potential provides information for discriminating between $s_t = 0, s_{t+1} = 1$ and $s_t = 1, s_{t+1} = 0$. Also, we impose the constraint that one constituent can be merged with at most one other adjacent constituent.

Figure 3 depicts the relation CRF for intra-sentential parsing. Similar to the structure CRF, $C = \{c_0, \cdots, c_t, \cdots, c_n\}$ are observed constituents and $R = \{r_1, \cdots, r_t, \cdots, r_n\}$ hidden nodes, corresponding to discourse relations. The CRF will assign a relation to a non-leaf constituent c_t based on its right and left children, $c_{t,L}$ and $c_{t,R}$, respectively. If a constituent is a single EDU, we force its hidden node to be the special label *LEAF*, whereas hidden nodes for constituents which are the product of merging cannot be *LEAF*. Given a sequence of constituents C, the probability of the relation label sequence Y^{rel} can be written as:

$$p(Y^{rel}|C) = \frac{1}{Z}\prod_{t=1}^{n} exp(u_t^{rel} + b_{t,t+1}^{rel}) \quad (4)$$

$$u_t^{rel} = \theta(c_t, y_t) \quad (5)$$

$$b_{t,t+1}^{rel} = \gamma(c_t, c_{t+1}, y_t, y_{t+1}) \quad (6)$$

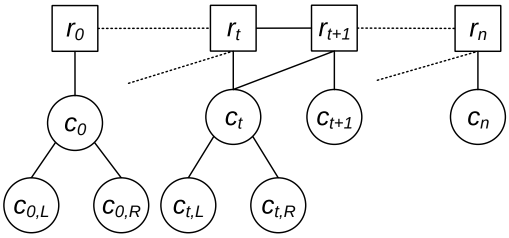

Figure 3: Intra-sentential relation CRF with pairwise modeling.

4.2 Intra-sentential Feature Learning

Instead of adopting a high order parsing model, we use neural networks to capture contextual information and recover the meaning of discourse constituents. Aside from modeling long distance dependencies, our representation learning process alleviates the need for elaborate feature engineering and selection. Our approach is based on LSTMs (Hochreiter and Schmidhuber, 1997) which have recently emerged as a popular architecture for modeling sequences and have been successfully applied to a variety of tasks ranging from machine translation (Sutskever et al., 2014), to speech recognition (Graves et al., 2013), and image description generation (Vinyals et al., 2015b). LSTMs have also been incorporated into syntactic parsing in a variety of ways (Vinyals et al. 2015a; Kiperwasser and Goldberg 2016; Dyer et al. 2015, *inter alia*). Of particular relevance to this work is LSTM-minus, a method for learning embeddings of text spans, which has achieved competitive performance in both dependency and constituency parsing (Wang and Chang, 2016; Cross and Huang, 2016). We describe below how we extend this method which is based on subtraction between LSTM hidden vectors to discourse parsing.

We represent each sentence as a sequence of word embeddings $[\boldsymbol{w}_{sos}, \boldsymbol{w}_1, \cdots, \boldsymbol{w}_i, \cdots, \boldsymbol{w}_n, \boldsymbol{w}_{eos}]$ and insert a special embedding w_E to indicate the boundaries of EDUs. We run a bidirectional LSTM over the sentence and obtain the output vector sequence $[\boldsymbol{h}_0, \cdots, \boldsymbol{h}_i, \cdots, \boldsymbol{h}_t]$, where $\boldsymbol{h}_i = [\overrightarrow{\boldsymbol{h}}_i, \overleftarrow{\boldsymbol{h}}_i]$ is the output vector for the i^{th} word, and $\overrightarrow{\boldsymbol{h}}_i$ and $\overleftarrow{\boldsymbol{h}}_i$ are the output vectors from the forward and backward directions, respectively. We represent a constituent c from position a to b with a span vector $\boldsymbol{sp}$ which is the concatenation of the vector differences $\overrightarrow{\boldsymbol{h}}_{b+1} - \overrightarrow{\boldsymbol{h}}_a$ and $\overleftarrow{\boldsymbol{h}}_{a-1} - \overleftarrow{\boldsymbol{h}}_b$:

$$\boldsymbol{sp} = [\overrightarrow{\boldsymbol{h}}_{b+1} - \overrightarrow{\boldsymbol{h}}_a, \overleftarrow{\boldsymbol{h}}_{a-1} - \overleftarrow{\boldsymbol{h}}_b] \quad (7)$$

As illustrated in Figure 4, spans are represented using output from both backward and forward LSTM components. Intuitively, this allows to obtain representations for EDUs and larger constituents in context, as embeddings are learned based on in-

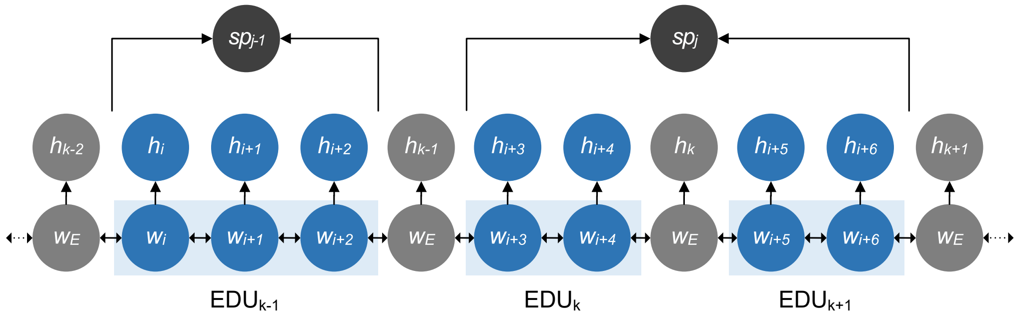

Figure 4: Modeling discourse constituents by LSTM-minus features. The feature vector $\boldsymbol{sp}_j$ for a constituent covering EDU$_k$ and EDU$_{k+1}$ is $[\overrightarrow{\boldsymbol{h}}_{k+1} - \overrightarrow{\boldsymbol{h}}_{i+3}, \overleftarrow{\boldsymbol{h}}_{k-1} - \overleftarrow{\boldsymbol{h}}_{i+6}]$. Blue nodes indicate word embeddings and LSTM outputs for words, while gray nodes represent EDU separators. Black nodes are learned LSTM-minus features for constituents.

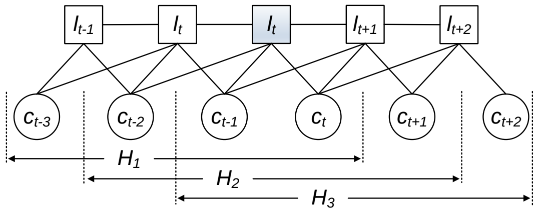

Figure 5: Multi-sentential structure CRF with sliding-window. The window size is 3, H_1, H_2, and H_3 denote the windows for predicting s_t, which is highlighted by the shaded rectangle.

formation from the span itself and the words surrounding it.

The structure CRF model calculates the unary potential score u_t^{str} and the binary potential score $b_{t,t+1}^{str}$ based on the span vector as follows:

$$\boldsymbol{u}_t^{str} = \boldsymbol{W}_u^{str}[\boldsymbol{sp}_j, \boldsymbol{sp}_{j+1}] \tag{8}$$

$$\boldsymbol{b}_{t,t+1}^{str} = \boldsymbol{W}_b^{str}[\boldsymbol{sp}_{j-1}, \boldsymbol{sp}_j, \boldsymbol{sp}_{j+1}] \tag{9}$$

where $\boldsymbol{sp}_j$ is the span vector for the j^{th} constituent in the current sequence; and $\boldsymbol{W}_u^{str} \in \mathbb{R}^{d\times 2}, \boldsymbol{W}_b^{str} \in \mathbb{R}^{d\times 4}$ are weight matrices. $\boldsymbol{b}_t^{str}$ is reshaped into a 2×2 matrix, where the $(i, j)^{th}$ entry indicates the score of the transition from label i to label j between constituent c_t and c_{t+1}.

Analogously, unary and binary potential scores for the relation CRF are calculated as:

$$\boldsymbol{u}_t^{rel} = \boldsymbol{W}_u^{rel}[\boldsymbol{sp}_{j,L}, \boldsymbol{sp}_{j,R}] \tag{10}$$

$$\boldsymbol{b}_{t,t+1}^{rel} = \boldsymbol{W}_b^{rel}[\boldsymbol{sp}_{j,L}, \boldsymbol{sp}_{j,R}, \boldsymbol{sp}_{j+1,L}, \boldsymbol{sp}_{j+1,R}] \tag{11}$$

where $\boldsymbol{sp}_{j,L}$ and $\boldsymbol{sp}_{j,R}$ are span vector representations for the left and right child of the j^{th} constituent; $\boldsymbol{W}_u^{rel} \in \mathbb{R}^{d\times n_r}, \boldsymbol{W}_b^{rel} \in \mathbb{R}^{d\times n_r^2}$, and n_r is the number of discourse relations; $\boldsymbol{b}_t^{rel}$ is also reshaped into a $n_r \times n_r$ matrix. For a constituent that is a single EDU, $\boldsymbol{sp}_{j,R}$ and $\boldsymbol{sp}_{j+1,R}$ are special vectors $\boldsymbol{w}_{LEAF_L}$ and $\boldsymbol{w}_{LEAF_R}$.

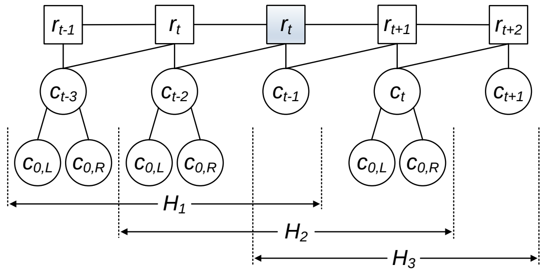

Figure 6: Multi-sentential relation CRF with sliding-window. The window size is 3, H_1, H_2 and H_3 denote the windows for predicting r_t, which highlighted by the shaded rectangle.

4.3 Multi-sentential Parser

The multi-sentential discourse parser treats sentences as the smallest possible discourse units, following a process similar to the intra-sentential model. Unfortunately, it is practically unfeasible to model all constituents with one CRF when processing entire documents. The forward-backward algorithm for calculating the CRF normalization factor on a sequence with T units has time complexity $O(TM^2)$, where M is the number of labels, leading to $O(T^2M^2)$ time for parsing a document.

We therefore modify the two CRFs into sliding-window versions. Specifically, at each level, when decoding a constituent sequence, for each hidden structure node l_i or relation node r_i, we find all windows of constituents that contain the hidden node, and set the hidden node's label according to the window with the maximum joint probability.

We present the modified sliding-window CRFs in Figure 5 (structure) and Figure 6 (relation).

4.4 Multi-sentential Feature Learning

For multi-sentential parsing, we also use the LSTM-minus method to model constituents, however, the minimum units here are sentences rather than EDUs. We represent individual sentences with the same bidirectional LSTM used for intra-sentential parsing. For sentence s_i, the LSTM output vector of the first token $\boldsymbol{h}_0$ and the last token $\boldsymbol{h}_n$ are taken to form the sentence representation $\boldsymbol{v}_i$:

$$\boldsymbol{v}_i = [\boldsymbol{h}_0, \boldsymbol{h}_n] \tag{12}$$

In order to capture additional contextual information, we then build another bidirectional LSTM over a sequence of sentence vectors. We learn representations for constituents (aka text spans within a document) with the LSTM-minus method and use $\boldsymbol{fl}$ to denote the resulting vectors. Although this flat representation is relatively straightforward to obtain, it is perhaps overly simplistic for modeling documents where the number of sentences can be relative large. Moreover, it is not clear that it is discriminating enough for modeling relations between constituents. Such relations follow structural regularities (e.g., they can be asymmetric or symmetric, left- or right-branching) which cannot be captured when adopting a sequence-based document view.

To inject structural knowledge in our representation, we also model constituents as subtrees with recursive neural networks (Socher et al., 2012). The latter operate over tree structures which we obtain during training from the RST Discourse Treebank (Carlson et al., 2003). The representation for each parent is computed based on its children iteratively, in a bottom-up fashion. More formally, let vectors $\boldsymbol{h}_L$ and $\boldsymbol{h}_R$ denote the left and right children of constituent c and dis their rhetorical relation. The vector for parent c is:

$$\boldsymbol{h}_c = \tanh(\boldsymbol{W}_{dis}[\boldsymbol{h}_L, \boldsymbol{h}_R] + \boldsymbol{b}_{dis}) \tag{13}$$

where $[\boldsymbol{h}_L, \boldsymbol{h}_R]$ is the concatenation of the children representations $\boldsymbol{h}_L \in \mathbb{R}^d$ and $\boldsymbol{h}_R \in \mathbb{R}^d$, $\boldsymbol{W}_{dis} \in \mathbb{R}^{2d\times d}$, and $\boldsymbol{b}_{dis} \in \mathbb{R}^d$ is the bias vector. We henceforth use the term tree vector $\boldsymbol{tr}$ to refer to the representation in Equation (13) since constituents are now subtrees in a document-wide discourse tree.

In multi-sentential parsing, the span vector $\boldsymbol{sp}$ now becomes the concatenation of the flat vector $\boldsymbol{fl}$ and the tree vector $\boldsymbol{tr}$:

$$\boldsymbol{sp} = [\boldsymbol{fl}, \boldsymbol{tr}] \tag{14}$$

The representation above, attempts to capture richer semantic features during the tree building process while benefiting from the robustness afforded by the flat LSTM-based text spans. An example of this representation is given in Figure 7.

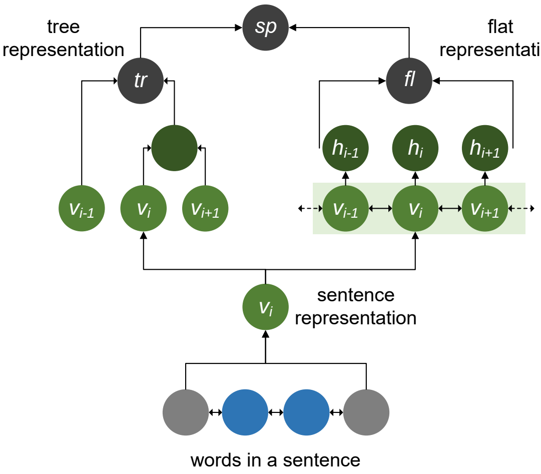

Figure 7: Document-level constituents with LSTM-minus features. Blue nodes are LSTM outputs for words, light green nodes represent vectors for sentences, dark green nodes are LSTM outputs for sentences, and black nodes are learned constituent representations.

Unary and binary potential scores for the structure and relation CRFs are calculated as in intra-sentential parsing (see Section 4.2).

4.5 Training

We first train the intra-sentential parser and use the learned LSTM as a component of the multi-sentential parser. During training, we maximize the log-likelihood of the correct label sequence Y given a constituent sequence C, which is $p(Y^{str}|C)$ for the structure CRFs and $p(Y^{rel}|C)$ for the relation CRFs. Stochastic gradient descent with momentum is used to update the parameters of the network. In our experiments, the momentum is set to 0.9 and the learning rate is 0.001. The LSTMs in our paper have one hidden layer.

5 Experimental Setup

In this section we present our experimental setup for assessing the performance of the discourse parser described above. We give details on the datasets we used, evaluation protocol, and model training.

Evaluation We evaluated our model on the RST Discourse Treebank (RST-DT; Carlson et al. 2003), which is partitioned into 347 documents for training and 38 documents for testing. Following previous work (Joty et al., 2013; Li et al., 2016), we converted non-binary relations into a cascade of right-branching binary relations.

Predicted RST-trees are typically evaluated by computing F1 against gold standard trees (Marcu, 2000). Evaluation metrics for RST-style discourse parsing include: (a) *span* (S) which measures whether the predicted subtrees match the goldstandard; (b) *nucleus* (N) which measures whether subtrees have the same nucleus as in the goldstandard and (c) *relation* (R) which measures whether discourse relations have been identified correctly. The three metrics are interdependent, errors on the span metric propagate to the nuclearity metric, and in turn to the relation metric. Following other RST-style discourse parsing systems (Hernault et al., 2010), we evaluate the relation metric using 18 coarse-grained relation classes, and with nuclearity attached, we have a total of 41 distinct relations.[1] Since EDU segmentation falls outside the scope of this work, we evaluate our system on gold-standard EDUs. Comparison systems are also assessed in the same setting.

Training Details Word embeddings were pretrained with the Gensim[2] implementation of word2vec (Mikolov et al., 2013) on the English GigaWord corpus (with case left intact). The dimensionality of the word embeddings was set to 50. Following Li et al. (2016), the embeddings were fine-tuned using a mapping matrix $\boldsymbol{W} \in \mathbb{R}^{50\times 50}$ trained with the following criterion:

$$\min_{\boldsymbol{W},\boldsymbol{b}} \|\boldsymbol{LT}_{tuned} - \boldsymbol{LT}_{pre}\boldsymbol{W} + \boldsymbol{b}\| \qquad (15)$$

where $\boldsymbol{LT}_{tuned}$, and $\boldsymbol{LT}_{pre}$ are lookup tables for fine-tuned and pre-trained word embeddings in the training set. Matrix W can be subsequently used to to estimate fine-tuned embeddings for words in the test set.

Tokenization, POS tagging and sentence splitting were performed using the Stanford CoreNLP toolkit (Manning et al., 2014). All neural network parameters were initialized randomly with Xavier's initialization (Glorot and Bengio, 2010). The hyper-parameters are tuned by cross-validation on the training set.

CIDER	S	N	R
Tree Span	79.5	68.1	56.6
Flat Span (−minus)	82.7	69.3	55.6
Flat Span (+minus)	83.6	70.1	55.4
Tree + Flat Span (+minus)	83.6	71.1	57.3

Table 1: CIDER performance using different constituent representations (RST-DT test set).

Additional Features Most existing state-of-the-art systems rely heavily on handcrafted features (Hernault et al., 2010; Feng and Hirst, 2014; Joty et al., 2013) some of which have been also proved helpful in neural network models (Li et al., 2014, 2016). In our experiments, we use the following basic features which have been widely adopted in various discourse parsing models: (1) the first three words and the last two words of each constituent; (2) the POS tags of the first three words and the last two words of each constituent; (3) the number of EDUs; and (4) the number of tokens of each constituent. We concatenate these features with the constituent vectors learned by our neural networks, and train new CRF models.

6 Results

In this paper we have presented two views for modeling discourse constituents, namely as trees or sequences. We experimentally assessed whether these two views are overlapping or complementary. Table 1 reports the performance of our parser which we call CIDER (as a shorthand for **C**ontextually **I**nformed **D**iscourse Pars**er**) without the additional features introduced in Section 5. The first row presents a version of CIDER based solely on tree span representations. In the second row, CIDER uses flat representations without LSTM minus features. Specifically, each constituent is represented as the average of the LSTM outputs within it. In the third row, CIDER's representations are computed with the LSTM minus method, while the fourth row shows results for the full system.

As can be seen, on the span (S) metric, CIDER with flat span representations is much better than CIDER with tree span representations; on the nuclearity (N) metric tree representations are still inferior to flat representations but the performance

[1] For calculating the binary potential scores, 41 relations will lead to a large number of parameters; to avoid this, we only use 18 relations without nuclearity.

Discourse Parsers	S	N	R	Speed
Ji and Eisenstein (2014)	82.1	71.1	61.6	0.21
Feng and Hirst (2014)	85.7	71.0	58.2	9.88
Heilman and Sagae (2015)	83.5	68.1	55.1	0.40
CIDER (−AF)	83.6	71.1	57.3	3.80
CIDER (+AF)	85.0	71.1	59.0	3.80
Li et al. (2014)	84.0	70.8	58.6	26.00
Li et al. (2016)	85.8	71.7	58.9	–
Human	88.7	77.7	65.8	–

Table 2: Comparison with state-of-the-art systems (RST-DT test set). Speed indicates the average number seconds taken to parse a document.

gap is narrower, whereas on the the relation (R) metric, tree span representations are superior. We believe this can be explained by the fact that relation identification relies on more semantic information while span identification relies on more shallow features, like the beginning and the end of the span (Ji and Eisenstein, 2014). Span features based on the LSTM minus method bring improvements over vanilla LSTM representations on the span and nuclearity metrics. Perhaps unsurprisingly, the combination of span and tree representations achieves the best results overall.

In Table 2, we compare our system with several state-of-the-art discourse parsers, which can be classified in two groups depending on their time complexity. Linear-time systems (first block in the table) include two transition-based parsers (Ji and Eisenstein, 2014; Heilman and Sagae, 2015) and one CRF-based parser (Feng and Hirst, 2014), whereas cubic-time parsers (second block) include two neural network models (Li, Li, and Hovy, 2014; Li, Li, and Chang, 2016). CIDER falls in the first group as it is a liner-time parser, while it shares with parsers in the second group the use of neural architectures for automated feature extraction. We report CIDER scores with and without the additional features (AF) discussed in the previous section. As an upper bound, we also report inter-annotator agreement on the discourse parsing task (last row in the table).

Amongst linear-time systems, our parser achieves comparable results on the span and relation metric, and best performance on the nuclearity metric. Note that the three metrics evaluate different aspects of a discourse parser, and CIDER achieves the most balanced results across all metrics. As far as other comparison systems are concerned, Ji and Eisenstein (2014) employ a shift-reduce discourse parser. They represent EDUs with word-count vectors and use a projection matrix to combine them into text spans. A support vector machine classifier is used to decide the actions of the parser. Heilman and Sagae (2015) also adopt a shift-reduce approach and use multi-class logistic regression to select the best parsing action. Their classifier considers a variety of lexical, syntactic, and positional features. Feng and Hirst's (2014) system is closest to ours in their use of linear-chain CRFs, but their features are mainly extracted from local constituents. Furthermore, they adopt a post-editing method which modifies the discourse trees their parser creates with height features.

With regard to previously proposed cubic-time systems, CIDER outperforms Li et al. (2014) across all metrics. Their CYK-based parser adopts a recursive deep model for composing EDUs hierarchically together with several additional features to boost performance. CIDER performs slightly worse on span and nuclearity compared to Li et al. (2016), but is better at identifying relations. Their system uses an attention-based hierarchical neural network for modeling text spans and a tensor-based transformation for combining two spans. A CKY-like algorithm is used to generate the discourse tree structure. In comparison, CIDER is conceptually simpler, and more efficient.

We used paired bootstrap re-sampling (Efron and Tibshirani, 1993) to assess whether differences in performance are statistically significant. CIDER is significantly better than Feng and Hirst's 2014 system on the relation metric ($p < 0.05$); it is also significantly better ($p < 0.05$) than Heilman and Sagae (2015) on all three metrics and better than Ji and Eisenstein (2014) on the span metric. Compared to Li et al. (2014), CIDER is significantly better on the span and relation metrics ($p < 0.05$). Unfortunately, we cannot perform significance tests against Li et al. (2016) as we do not have access to the output of their system.

We also evaluated the speed of CIDER and comparison discourse parsers on a platform with Intel Core-i5-7200U CPU at 2.50GHz. We report the average number of seconds taken to parse a document in the RST-DT test set. The times shown in Table 2 do not include pre-processing, which for CIDER is only part-of-speech tagging, whereas all other linear-time systems rely on a syntactic parser. As can be seen CIDER is quite efficient compared to related systems (Feng and Hirst, 2014;

Heilman and Sagae, 2015) whilst requiring less feature engineering.

7 Conclusions

In this paper we described CIDER, a simple and efficient discourse parser which adopts a two-stage parsing strategy, whilst exploiting a more global feature space. We proposed a novel way to learn contextually informed representations of constituents with the LSTM minus method, at the sentence and document level. We also demonstrated that flat representations of text spans can be usefully complemented with tree-based ones leading to a more accurate characterization of discourse relations. Experimental results showed that CIDER performs on par with the state of the art (Li et al., 2016), despite the greedy parsing algorithm and relatively simple neural architecture. In the future, we would like to improve parsing accuracy by leveraging unlabeled text rather than relying exclusively on human annotated training data.

Abstract

We present a novel multi-task attention-based neural network model to address implicit discourse relationship representation and identification through two types of representation learning, an attention-based neural network for learning discourse relationship representation with two arguments and a multi-task framework for learning knowledge from annotated and unannotated corpora. The extensive experiments have been performed on two benchmark corpora (i.e., PDTB and CoNLL-2016 datasets). Experimental results show that our proposed model outperforms the state-of-the-art systems on benchmark corpora.

1 Introduction

The task of implicit discourse relation (or rhetorical relation) identification is to recognize how two adjacent text spans without explicit discourse marker (i.e., connective, e.g., *because* or *but*) between them are logically connected to one another (e.g., *cause* or *contrast*). It is considered to be a crucial step for discourse analysis and language generation and helpful to many downstream NLP applications, e.g., QA, MT, sentiment analysis, machine comprehension, etc.

With the release of PDTB 2.0 (Prasad et al., 2008), lots of work has been done for discourse relation identification on natural (i.e., genuine) discourse data (Pitler et al., 2009; Lin et al., 2009; Wang et al., 2010; Zhou et al., 2010; Braud and Denis, 2015; Fisher and Simmons, 2015) with the use of traditional NLP linguistically informed features and machine learning algorithms. Recently, more and more researchers resorted to neural networks for implicit discourse recognition (Zhang et al., 2015; Chen et al., 2016; Liu et al., 2016b; Qin et al., 2016a; Liu and Li, 2016; Braud and Denis, 2016; Wu et al., 2016). Meanwhile, to alleviate the shortage of labeled data, researchers explored multi-task learning with the aid of unannotated data for implicit discourse recognition either in traditional machine learning framework (Collobert and Weston, 2008; Lan et al., 2013) or recently in neural network framework (Wu et al., 2016; Liu et al., 2016b).

In this work, we present a novel multi-task attention-based neural network to address implicit discourse relationship representation and recognition. It performs two types of representation learning at the same time. An attention-based neural network conducts discourse relationship representation learning through interaction between two discourse arguments. Meanwhile, a multi-task learning framework leverages knowledge from auxiliary task to enhance the performance of main task. Furthermore, these two types of learning are integrated into one neural network framework and work together to maximize the overall performance.

The contributions of this work are listed as follows.

- We propose a multi-task attention-based neural network model to address implicit discourse relationship representation and recognition, which benefits from both the interaction between discourse arguments and the interaction between different learning tasks;
- Our method achieves the best results on two benchmark corpora in comparison with the state-of-the-art systems so far.

The organization of this work is as follows. Section 2 describes the proposed novel multi-task neural network. Section 3 introduces the exper-

Proceedings of the 2017 Conference on Empirical Methods in Natural Language Processing, pages 1299–1308
Copenhagen, Denmark, September 7–11, 2017. ©2017 Association for Computational Linguistics

imental settings in detail. Section 4 reports the comprehensive experimental results on two benchmark corpora. Section 5 summarized related work. Finally, Section 6 concludes this work.

2 Multi-task Attention-based Neural Networks Models

2.1 Motivation

The idea of learning two types of interactive knowledge from arguments and from multi-tasks is motivated by the following observations and analysis.

On the one hand, to recognize the discourse relationships, our system needs to understand the meaning of each argument and infer the discourse sense transferred between two arguments (denoted as *Arg*-1 and *Arg*-2). Learning the semantic representation of each argument (sentence) has been studied with the use of many neural network models and their variants (e.g., CNN, RNN, LSTM, Bi-LSTM, ect). However, learning the complicated and various types of discourse relationships between arguments may not be performed by simply summing up or concatenating two argument representations. We analyze the discourse with contrast relationship and find that the contrast information may result from different parts of sentence, e.g., tenses (e.g., previous vs. now), entities (their vs our), or even the whole arguments, etc. Therefore, in order to learn the relationship representation between two arguments, we propose an attention mechanism that can select out the most important part from two arguments and perform the information interaction between two arguments.

On the other hand, one common issue involved in implicit discourse relationship identification is the lack of labeled data. In this work, we state that the relevant information from unlabelled data might be helpful and we present a novel multi-task learning framework. In contrast with previous multi-task learning framework in traditional machine learning, we improve multi-task learning framework with representation learning for better discourse relationship representation.

Inspired by the above considerations, we present a novel multi-task attention-based neural network model by integrating attention mechanism with multi-task learning for information interaction between arguments and between tasks.

2.2 Learning Discourse Representation

To learn the semantic representation of each argument in discourse, a lot of neural network models and their variants have been proposed, such as, convolutional neural network (CNN), recurrent neural network (RNN) and so on. As a variant of RNN, long-short term memory (LSTM) neural network specifically addresses the issue of learning long-term dependencies and is good at modeling over a sequence of words with consideration of the contextual information. Therefore, in this work we adopt LSTM to model discourse argument.

2.2.1 LSTM for Argument Representation

Figure 1 shows the traditional LSTM model for representation learning of arguments. First of all, through the embedding layer, we associate each word w in the vocabulary with a vector representation $\boldsymbol{x}_w \in \mathbb{R}^{d_w}$. Let $\boldsymbol{x}_i^1$ ($\boldsymbol{x}_i^2$) be the i-th word vector in *Arg*-1 (*Arg*-2), then these two discourse arguments are represented as:

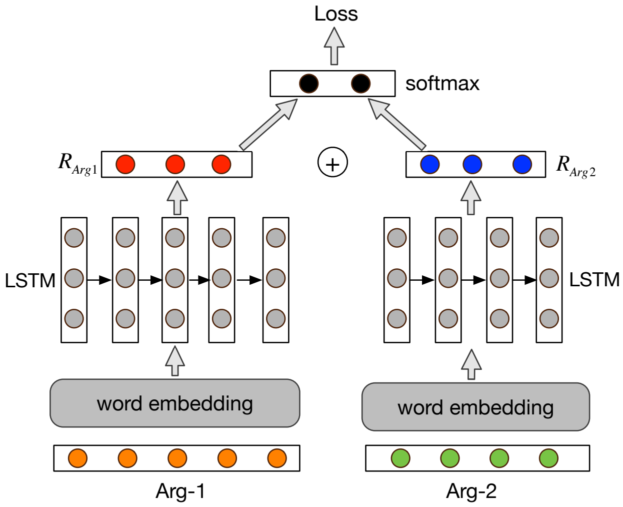

Figure 1: LSTM for discourse argument pair representation learning.

$$Arg\text{-}1\text{: } [\boldsymbol{x}_1^1, \boldsymbol{x}_2^1, \cdots, \boldsymbol{x}_{L_1}^1] \quad (1)$$

$$Arg\text{-}2\text{: } [\boldsymbol{x}_1^2, \boldsymbol{x}_2^2, \cdots, \boldsymbol{x}_{L_2}^2] \quad (2)$$

where *Arg*-1 (*Arg*-2) has L_1 (L_2) words.

Given the word representations of the argument $[\boldsymbol{x}_1, \boldsymbol{x}_2, \cdots, \boldsymbol{x}_L]$ as the input sequence, an LSTM computes the state sequence $[\boldsymbol{h}_1, \boldsymbol{h}_2, \cdots, \boldsymbol{h}_L]$ for each time step i using the following formulation:

$$\boldsymbol{i}_i = \sigma(\boldsymbol{W}_i[\boldsymbol{x}_i, \boldsymbol{h}_{i-1}] + \boldsymbol{b}_i) \tag{3}$$
$$\boldsymbol{f}_i = \sigma(\boldsymbol{W}_f[\boldsymbol{x}_i, \boldsymbol{h}_{i-1}] + \boldsymbol{b}_f) \tag{4}$$
$$\boldsymbol{o}_i = \sigma(\boldsymbol{W}_o[\boldsymbol{x}_i, \boldsymbol{h}_{i-1}] + \boldsymbol{b}_o) \tag{5}$$
$$\tilde{\boldsymbol{c}}_i = tanh(\boldsymbol{W}_c[\boldsymbol{x}_i, \boldsymbol{h}_{i-1}] + \boldsymbol{b}_c) \tag{6}$$
$$\boldsymbol{c}_i = \boldsymbol{i}_i \odot \tilde{\boldsymbol{c}}_i + \boldsymbol{f}_i \odot \boldsymbol{c}_{i-1} \tag{7}$$
$$\boldsymbol{h}_i = \boldsymbol{o}_i \odot tanh(\boldsymbol{c}_i) \tag{8}$$

where [ ] means the concatenation operation of vectors, σ denotes the sigmoid function and $\odot$ denotes element-wise product. Besides, $\boldsymbol{i}_i$, $\boldsymbol{f}_i$, $\boldsymbol{o}_i$ and $\boldsymbol{c}_i$ denote the input gate, forget gate, output gate and memory cell, respectively. Moreover, we also use bidirectional LSTM (Bi-LSTM) which is able to capture the context from both past and future rather than LSTM which only considers the context information from the past. Therefore, at each position i of the sequence, we obtain two states $\overrightarrow{\boldsymbol{h}}_i$ and $\overleftarrow{\boldsymbol{h}}_i$, where $\overrightarrow{\boldsymbol{h}}_i, \overleftarrow{\boldsymbol{h}}_i \in \mathbb{R}^{d_h}$. Then we concatenate them to get the intermediate state, i.e. $\boldsymbol{h}_i = [\overrightarrow{\boldsymbol{h}}_i, \overleftarrow{\boldsymbol{h}}_i]$. After that, we sum up the sequence states $[\boldsymbol{h}_1, \boldsymbol{h}_2, \cdots, \boldsymbol{h}_L]$ to get the representations of *Arg*-1 and *Arg*-2 respectively as follows:

$$\boldsymbol{R}_{Arg_1} = \sum_{i=1}^{L_1} \boldsymbol{h}_i^1 \tag{9}$$

$$\boldsymbol{R}_{Arg_2} = \sum_{i=1}^{L_2} \boldsymbol{h}_i^2 \tag{10}$$

Finally we concatenate the two argument representations $\boldsymbol{R}_{Arg_1}$ and $\boldsymbol{R}_{Arg_2}$ as the argument pair representation, i.e., $\boldsymbol{R}_{pair} = [\boldsymbol{R}_{Arg_1}, \boldsymbol{R}_{Arg_2}]$.

Clearly, in this way, there is no any correlation and interaction between the two arguments. That is, whatever the types of discourse relationship they hold, the argument pair representation $\boldsymbol{R}_{pair}$ is independent from $\boldsymbol{R}_{Arg_1}$ or $\boldsymbol{R}_{Arg_2}$.

2.2.2 Attention Neural Network for Relationship Representation

In order to effectively capture the complicated and various types of relationships between arguments, we proposed a novel attention-based neural network model shown in Figure 2.

To do it, we first compute the match between $\boldsymbol{R}_{Arg_1}$ ($\boldsymbol{R}_{Arg_2}$) and each state $\boldsymbol{h}_i^2$ ($\boldsymbol{h}_i^1$) of *Arg*-2 (*Arg*-1) by taking the inner product followed by a softmax as follows:

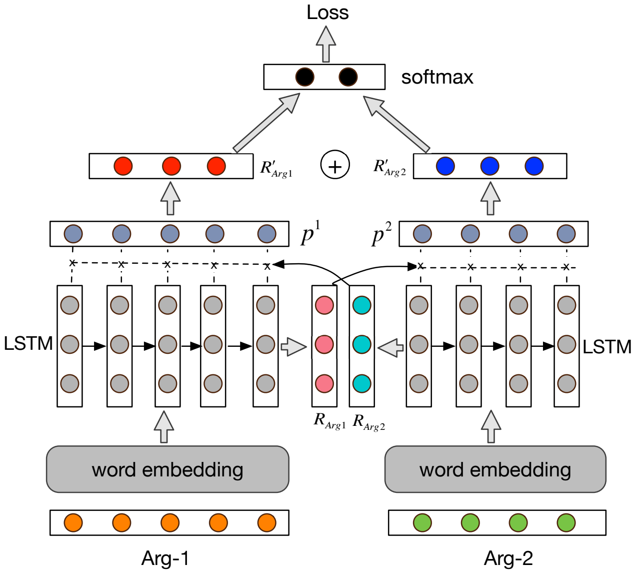

Figure 2: Attention Neural Network for representation learning of arguments.

$$p_i^1 = \text{Softmax}(\boldsymbol{R}_{Arg_2}^T \boldsymbol{h}_i^1) \tag{11}$$
$$p_i^2 = \text{Softmax}(\boldsymbol{R}_{Arg_1}^T \boldsymbol{h}_i^2) \tag{12}$$

where $\text{Softmax}(z_i) = e^{z_i} / \sum_j e^{z_i}$. Here $\boldsymbol{p}$ is an attention (probability) vector over the inputs and can be viewed as the weights of the words measuring to what degree our model should pay attention to. It is worth noting that $\boldsymbol{p^1}$ and $\boldsymbol{p^2}$ are determined by $\boldsymbol{R}_{Arg_2}$ and $\boldsymbol{R}_{Arg_1}$ respectively, which means the representation of one argument depends on the representation of the other.

Next, we sum over the state $\boldsymbol{h}_i$ weighted by the attention vector $\boldsymbol{p}$ to compute the new representations for *Arg*-1 and *Arg*-2 respectively as below:

$$\boldsymbol{R}'_{Arg_1} = \sum_{i=0}^{L_1} \boldsymbol{h}_i^1 p_i^1 \tag{13}$$

$$\boldsymbol{R}'_{Arg_2} = \sum_{i=0}^{L_2} \boldsymbol{h}_i^2 p_i^2 \tag{14}$$

The representation of *Arg*-2 ($\boldsymbol{R}_{Arg_2}$) is used to compute the weights of words in *Arg*-1 (i.e., $\boldsymbol{p^1}$) and $\boldsymbol{R}_{Arg_1}$ is used to compute the weights of words in *Arg*-2 (i.e., $\boldsymbol{p^2}$). In this way, the new representations of the two arguments interact with each other. Therefore, this attention mechanism enables our model to focus on specific spans in the two arguments, which is crucial to recognize the discourse relations. We then concatenate $\boldsymbol{R}'_{Arg_1}$

and $\boldsymbol{R}'_{Arg_2}$ to get the argument pair representation $\boldsymbol{R}_{pair} = [\boldsymbol{R}'_{Arg_1}, \boldsymbol{R}'_{Arg_2}]$.

Finally, we feed the argument pair vector $\boldsymbol{R}_{pair}$ to a fully-connected softmax layer which outputs the probabilities of different classes for the classification task. Here we choose the cross-entropy loss between the outputs of the softmax layer and the ground-truth class labels as our loss function.

2.3 Multi-task Attention-based Neural Networks

The model presented in Section 2.2 can perform implicit discourse relation recognition in itself. However, similar with many models in deep learning, one big issue is the lack of labeled data. Therefore, we propose a multi-task attention-based neural network by integrating the aforementioned model into a multi-task learning framework to address the implicit discourse relation recognition with the aid of large amount of unlabelled data. Figure 3 shows the general framework of our proposed multi-task attention-based neural network model.

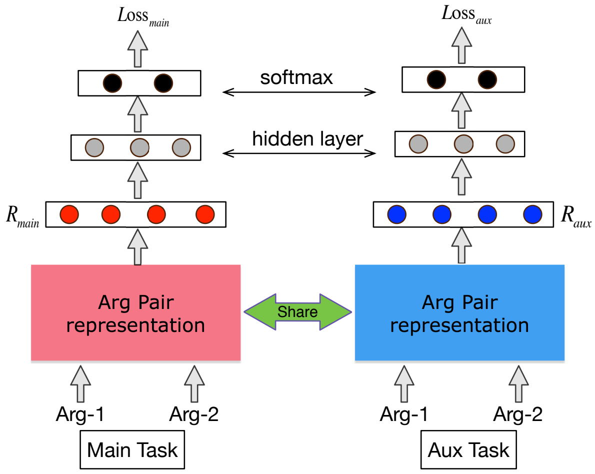

Figure 3: The framework of our proposed multi-task attention-based neural network model.

We use the aforementioned attention-based neural network to map the argument pair into a low-dimensional vector ($\boldsymbol{R}_{pair}$) denoted as `Arg Pair representation` component in Figure 3. Under the multi-task learning framework, the parameters of the `Arg Pair representation` components are shared between the main task and the auxiliary tasks. We denote $\boldsymbol{R}_{main}$ and $\boldsymbol{R}_{aux}$ as the representations of argument pair for main and auxiliary tasks, respectively. And we add a hidden layer after $\boldsymbol{R}_{main}$ and $\boldsymbol{R}_{aux}$ to learn the task-specific representations followed by the softmax layers used to compute the loss of the main task ($Loss_{main}$) and the loss of the auxiliary task ($Loss_{aux}$), respectively.

Regarding the strategy of sharing knowledge learnt from auxiliary to main task, we propose the following three methods.

2.3.1 Equal Share

A simple and straightforward way is to equally share the knowledge learned from main task and auxiliary task. Therefore, the total loss of the multi-task neural network is calculated as:

$$Loss = Loss_{main} + Loss_{aux} \tag{15}$$

where $Loss_{aux}$ has the same weight as $Loss_{main}$.

2.3.2 Weighted Share

Another method is to give different weights to the main and auxiliary task as below:

$$Loss = Loss_{main} + w * Loss_{aux} \tag{16}$$

where $w \in (0, 1]$ is a weight parameter. Clearly, a lower value of w means less importance of auxiliary task.

2.3.3 Sigmoid (Gated) Interaction

The above two ways of sharing knowledge actually have no deep interaction between the main and auxiliary tasks. They only share equal or weighted contributions from tasks to final result. Therefore, we propose a model that can perform interaction between tasks, which is shown in Figure 4.

We introduce two important parameters $\boldsymbol{W}_{inter} \in \mathbb{R}^{d_{pair} \times d_{pair}}$ and $\boldsymbol{b}_{inter} \in \mathbb{R}^{d_{pair}}$ (d_{pair} is the length of the argument pair representation vector $\boldsymbol{R}_{pair}$) to fulfil the interaction between main and auxiliary tasks. As shown in the following Formula (17) and (18), the new representation of argument pair $\boldsymbol{R}'_{main}$ is updated by the combination of $\boldsymbol{W}_{inter}$ and $\boldsymbol{R}_{aux}$ using a Sigmoid function.

$$\boldsymbol{R}'_{main} = \boldsymbol{R}_{main} \odot \sigma(\boldsymbol{W}_{inter}\boldsymbol{R}_{aux} + \boldsymbol{b}_{inter}) \tag{17}$$

$$\boldsymbol{R}'_{aux} = \boldsymbol{R}_{aux} \odot \sigma(\boldsymbol{W}_{inter}\boldsymbol{R}_{main} + \boldsymbol{b}_{inter}) \tag{18}$$

$\boldsymbol{W}_{inter}$ and the Sigmoid function (σ) work together to make information interacted between two tasks and select useful relevant information out of the opposite tasks as well. Clearly, $\boldsymbol{W}_{inter}$ is

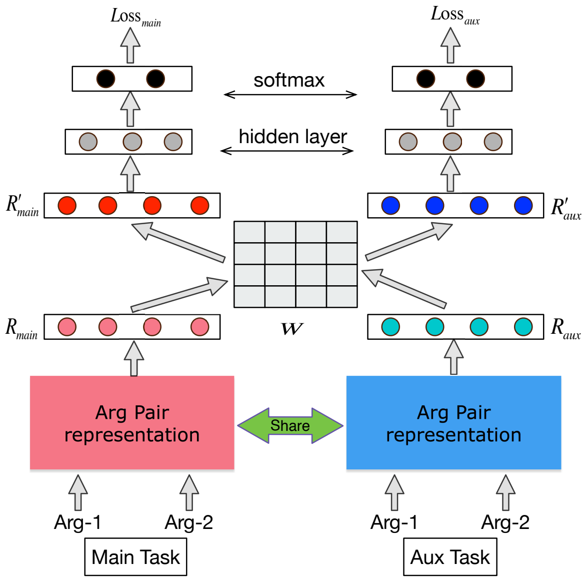

Figure 4: Sigmoid (Gated) interaction shared in multi-task framework (GShare).

a parameter to be trained. This mechanism acts as a gate to determine how much the information would pass through to the final result. Therefore, under the framework of multi-task and gated mechanism, the main and auxiliary tasks are capable of not only sharing the parameters of learning argument pair representation but also interacting the representations learning from each other.

2.4 Parameter Learning

We tried various settings of word embeddings trained on the BLLIP corpus with different dimensions d_{WE} = [50, 100, 150, 200] by *word2vec tool*[1] and finally set dimensionality as 50 based on the results on development set. we also explored the hidden state d_h = [50, 100, 150, 200] and the size of hidden layer in multi-task framework $d_{multi-task}$ = [50, 80, 120, 150]. Finally, for binary classification and four way classification on PDTB, we chose $d_h = 50$ and $d_{multi-task} = 80$. For multi-class classification on CoNLL-2016, we chose $d_h = 100$ and $d_{multi-task} = 120$. We applied dropout to the penultimate layer and set the dropout rate as 0.5. These parameters remain the same in experiments except the share weight w varies which will be discussed later. We chose the cross-entropy loss as loss function and adopted AdaGrad (Duchi et al., 2011) with a learning rate of 0.001 and a minibatch size of 64 to train the model.

3 Experiment Settings

3.1 Datasets

We adopted three corpora: PDTB 2.0 and CoNLL-2016 datasets are annotated for discourse relation recognition evaluation, and the BLLIP corpus is unlabeled and used as auxiliary task.

PDTB 2.0 is the largest annotated corpus of discourse relations, which contains 2, 312 Wall Street Journal (WSJ) articles. The sense label of discourse relations is hierarchically with three levels, i.e., class, type and sub-type. The top level contains four major semantic classes: Comparison (denoted as Comp.), Contingency (Cont.), Expansion (Exp.) and Temporal (Temp.). For each class, a set of types is used to refine relation sense. The set of subtypes is to further specify the semantic contribution of each argument. We focus on the top level (class) relations. Following (Pitler et al., 2009), we used sections 2-20 as training set, sections 21-22 as test set, and sections 0-1 as development set. Table 1 summarizes the statistics of four top level implicit discourse relations in PDTB.

Relation	Train	Dev	Test
Comp.	1942	197	152
Cont.	3342	295	279
Exp.	7004	671	574
Temp.	760	64	85

Table 1: The statistics of four top level implicit discourse relations in PDTB 2.0.

The CoNLL-2016 Shared Task focuses on shallow discourse parsing, which provides two test datasets, i.e., one from PDTB section 23 denoted as CoNLL-Test set, and the other from a similar source and domain (English Wikinews[2]) denoted as CoNLL-Blind test set. Different from the sense labels in PDTB, the CoNLL-Test set has three sense levels and the EntRel label. Moreover, it merges several labels in the original annotation to reduce some sparsity without losing too much of the utility and the semantics of the sense.

BLLIP The North American News Text (Complete) is used as unlabeled data source to generate synthetic labeled data for auxiliary task. We remove the explicit discourse connectives from raw texts and grant the explicit relations as the synthetic implicit relations. We obtain a resulting corpus with 100, 000 implicit relations by random sampling.

[1] http://www.code.google.com/p/word2vec

[2] https://en.wikinews.org/

3.2 Evaluation Measures

We adopt precision (*P*), recall (*R*) and their harmonic mean, i.e., F_1 for performance evaluation. We also report accuracy for direct comparison with previous works.

4 Results and Discussion

4.1 Results on PDTB in multiple binary classification

To be consistent with previous work, we first perform multiple binary classification (one-versus-other) on the four top level classes in PDTB. Several previous studies merged EntRel with Expansion, which is also explored in our study and noted as Exp+. Table 2 shows the results of our proposed three models in terms of F_1 (%) on PDTB using multiple binary classification, where STL means single task learning, *Eshare*, *Wshare* and *Gshare* denote the equal share, weighted share and gated interaction share under multi-task framework respectively, *Imp* denotes the standard implicit relations dataset in PDTB (similarly, *Imp* denotes standard implicit relations dataset in the CoNLL dataset when we perform experiments on the CoNLL dataset) used for training, *Exp* denotes all explicit relations in sections 00-24 in PDTB (similarly, all explicit relations in the CoNLL dataset when we perform experiments on the CoNLL dataset), and *BLLIP* denotes the synthetic implicit relations extracted from BLLIP. For example, *Imp* + *BLLIP* indicates that *Imp* is used for main task and *BLLIP* is for auxiliary task.

The first three rows in Table 2 list the results of LSTM, Bi-LSTM and attention neural network in the single task learning (STL) framework, which act as baselines for comparison with multi-task learning. We see that Bi-LSTM achieve slightly better performance than LSTM, which is consistent with previous work as Bi-LSTM considers the forward and backward direction contextual information while LSTM only considers the forward information. Compared with LSTM and Bi-LSTM, the attention neural network achieves much better performance. This indicates the effectiveness of attention mechanism for capturing the interaction between discourse arguments, which is crucial for relationship representation.

Generally, under the multi-task neural network framework, the three proposed multi-task neural networks, i.e., *Eshare*, *Wshare* and *Gshare*, outperform the single task learning methods. Comparing with *Eshare* and *Wshare*, we see that using a low value of w is able to boost the performance and reduce the negative influence brought by auxiliary task. We then use the best w value in *Wshare* to construct the loss of *Gshare* and the *Gshare* achieves the best performance among all methods through information interaction between main and auxiliary tasks.

Comparing *Imp* + *Exp* with *Imp* + *BLLIP*, we see that using *Exp* as auxiliary task achieves lower performance than using *BLLIP* and even hurts the performance compared with the single task. The possible reasons may result from (1) there is difference between explicit and implicit discourse relations and (2) the size of *Exp* dataset is much smaller than that of *BLLIP* and thus it is not large enough to boost the performance.

4.2 Results on PDTB and CoNLL-2016 in multi-class classification

We also perform multi-class classification on PDTB and CoNLL-2016. That is, a four-way classification on the four top-level classes in PDTB and a 15-way classification on the 15 sense labels in CoNLL dataset. Table 3 shows the results of multi-class classification on PDTB and CoNLL-2016 corpora in terms of accuracy (%) and macro-averaged F_1 (%).

The results of multi-class classification are consistent with the results of binary classification. First, the attention neural network achieves better performance than LSTM and Bi-LSTM. Second, the multi-task learning methods outperform the single-task learning method. Thrid, the *Gshare* method achieves the best performance.

4.3 Comparison with the state-of-the-art Systems

Table 4 lists the performance of our best model with the reported state-of-the-art systems on PDTB and CoNLL-2016. We see that our model achieves F_1 improvements of 1.64% on Cont., 0.97% on Exp., and 1.35% on Exp.+ against the best reported systems in binary classification. And in multi-class classification, our model also achieves the best performance of F_1 in four-way classification and accuracy in CoNLL-2016 Blind test set, which indicates that our model has good generality.

Specially, (Liu et al., 2016b) and (Liu and Li, 2016) listed in Table 4, which adopted neural network-based multi-task framework, are quite

		Comp.	Cont.	Exp.	Exp+	Temp

Table 4: Comparison with the state-of-the-art systems reported on PDTB and CoNLL-2016, where - means N.A.

relevant to this work. (Liu et al., 2016b) presented a multi-task neural network, which considered information sharing between the main and auxiliary task. Different from their work, our work integrates the attention-based interaction between arguments and the multi-task based interaction between tasks into the final model. This is the main reason why our model achieves better performance in all types of relations, which shows the effectiveness of integrating gated mechanism into multi-task framework. Besides, (Liu and Li, 2016) used a complicated multi-level attention mechanism and the performance of our attention neural network in the single task is comparable to their results. Our multi-task attention model achieves better performance in most types with the aid of multi-task framework.

Besides, our previous work in (Lan et al., 2013) listed in Table 4, also presented a multi-task framework with traditional machine learning method to address implicit discourse recognition using BLLIP to obtain synthetic data. Clearly, under neural network-based multi-task framework, the attention and gated mechanism significantly improved the results and outperformed traditional machine learning method in all types of relations.

4.4 Effects of parameters w

Figure 5 shows the performance of four binary classification on four top level classes influenced by different share weights w in *Wshare* multi-task framework. We see that the best performance is achieved when we use a lower value of w. This

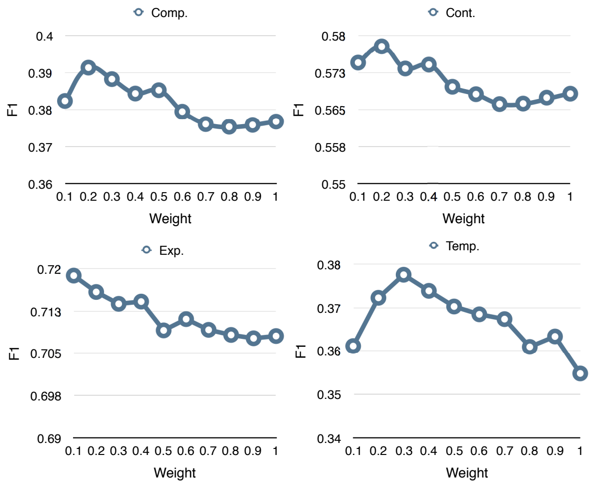

Figure 5: Results of top level implicit discourse relations in PDTB 2.0 with different weights w.

indicates that a low value of w can boost performance and reduce the negative influence brought by auxiliary task and enable our model to pay more attention to the main task.

5 Related Work

5.1 Implicit Discourse

With the release of PDTB 2.0, a number of studies performed discourse relation recognition on natural (i.e., genuine) discourse data with the use of traditional NLP techniques to extract linguistically informed features and traditional machine learning algorithms (Pitler et al., 2009; Lin et al., 2009; Wang et al., 2010; Braud and Denis, 2015; Fisher and Simmons, 2015).

Later, to make a full use of unlabelled data, several studies performed multi-task or unsupervised learning methods (Lan et al., 2013; Braud and Denis, 2015; Fisher and Simmons, 2015; Rutherford and Xue, 2015).

Recently, with the development of deep learning, researchers resorted to neural networks methods (Ji and Eisenstein, 2015; Zhang et al., 2015; Chen et al., 2016; Liu et al., 2016b; Qin et al., 2016a; Liu and Li, 2016; Braud and Denis, 2016; Wu et al., 2016).

5.2 Multi-task learning

Multi-task learning framework adopts traditional machine learning with human-selected effective knowledge and the shared part is integrated into the cost function to prefer the main task learning. (Collobert and Weston, 2008) proposed a multi-task neural network trained jointly on the relevant tasks using weight-sharing (sharing the word embeddings with tasks). (Liu et al., 2016a) proposed the multi-task neural network by modifying the recurrent neural network for text classification tasks. (Lan et al., 2013) present a multi-task learning based system which can effectively use synthetic data for implicit discourse relation recognition. (Wu et al., 2016) use bilingually-constrained synthetic implicit data for implicit discourse relation recognition a multi-task neural network. (Liu et al., 2016b) propose a convolutional neural network embedded multi-task learning system to improve the performance of implicit discourse identification.

5.3 Deep learning with Attention

Recently deep learning with attention has been widely adopted by NLP researchers. (Zhou et al., 2016) proposed an attention-based Bi-LSTM for relation classification. (Wang et al., 2016c) proposed an attention-based LSTM for aspect-level sentiment classification. (Tan et al., 2016) proposed a attentive LSTMs for Question Answer Matching. (Wang et al., 2016a) proposed an inner attention based RNN (add attention information before RNN hidden representation) for Answer Selection in QA. (Wang et al., 2016b) proposed multi-level attention CNNs for relation classification. (Yin et al., 2016) proposed an attentive convolutional neural network for QA.

6 Concluding Remarks

We present a novel multi-task attention-based neural network model for implicit discourse relationship representation and identification. Our method captures both the discourse relationships through interactions between discourse arguments and the complementary knowledge through interactions between annotated and unannotated data. The experimental results showed that our proposed model outperforms the state-of-the-art systems on two benchmark corpora.

Chinese Zero Pronoun Resolution with Deep Memory Network

Qingyu Yin, Yu Zhang, Weinan Zhang, Ting Liu[*]
Research Center for Social Computing and Information Retrieval
Harbin Institute of Technology, China
{qyyin, yzhang, wnzhang, tliu}@ir.hit.edu.cn

Abstract

Existing approaches for Chinese zero pronoun resolution typically utilize only syntactical and lexical features while ignoring semantic information. The fundamental reason is that zero pronouns have no descriptive information, which brings difficulty in explicitly capturing their semantic similarities with antecedents. Meanwhile, representing zero pronouns is challenging since they are merely gaps that convey no actual content. In this paper, we address this issue by building a deep memory network that is capable of encoding zero pronouns into vector representations with information obtained from their contexts and potential antecedents. Consequently, our resolver takes advantage of semantic information by using these continuous distributed representations. Experiments on the OntoNotes 5.0 dataset show that the proposed memory network could substantially outperform the state-of-the-art systems in various experimental settings.

1 Introduction

A zero pronoun (ZP) is a gap in a sentence, which refers to an entity that supplies the necessary information for interpreting the gap (Zhao and Ng, 2007). A ZP can be either anaphoric if it corefers to one or more preceding noun phrases (antecedents) in the associated text, or non-anaphoric if there are no such noun phrases. Below is an example of ZPs and their antecedents, where "ϕ" denotes the ZP.

[警方] 表示 他们 自杀 的 可能性 很高，不过 ϕ_1 也 不 排除 ϕ_2 有 他杀 的 可能。

([The police] said that they are more likely to commit suicide, but ϕ_1 could not rule out ϕ_2 the possibility of homicide.)

In this example, the ZP "ϕ_1" is an anaphoric ZP that refers to the antecedent "警方/The police" while the ZP "ϕ_2" is non-anaphoric. Unlike overt pronouns, ZPs lack grammatical attributes such as gender and number that have been proven to be essential in pronoun resolution (Chen and Ng, 2014a), which makes ZP resolution a more challenging task than overt pronoun resolution.

Automatic Chinese ZP resolution is typically composed of two steps, i.e., anaphoric zero pronoun (AZP) identification that identifies whether a ZP is anaphoric; and AZP resolution, which determines antecedents for AZPs. For AZP identification, state-of-the-art resolvers use machine learning algorithms to build AZP classifiers in a supervised manner (Chen and Ng, 2013, 2016). For AZP resolution, literature approaches include unsupervised methods (Chen and Ng, 2014b, 2015), feature-based supervised models (Zhao and Ng, 2007; Kong and Zhou, 2010), and neural network models (Chen and Ng, 2016). Neural network models for AZP resolution are of growing interest for their capacity to learn task-specific representations without extensive feature engineering and to effectively exploit lexical information for ZPs and their candidate antecedents in a more scalable manner than feature-based models.

Despite these advantages, existing supervised approaches (Zhao and Ng, 2007; Chen and Ng, 2013, 2016) for AZP resolution typically utilize only syntactical and lexical information through features. They overlook semantic information that is regarded as an important factor in the resolution of common noun phrases (Ng, 2007). The fundamental reason is that ZPs have no descriptive information, which results in difficulty in calculating semantic similarities and relatedness scores

between the ZPs and their antecedents. Therefore, the proper representations of ZPs are required so as to take advantage of semantic information when resolving ZPs. However, representing ZPs is challenging because they are merely gaps that convey no actual content.

One straightforward method to address this issue is to represent ZPs with supplemental information provided by some available components, such as contexts and candidate antecedents. Motivated by Chen and Ng (2016) who encode a ZP's lexical contexts by utilizing its preceding word and governing verb, we notice that a ZP's context can help to describe the ZP itself. As an example of its usefulness, given the sentence "ϕ taste spicy", people may resolve the ZP "ϕ" to the candidate antecedent "red peppers", but can hardly regard "my shoes" as its antecedent, because they naturally look at the ZP's context "taste spicy" to resolve it ("my shoes" cannot "taste spicy"). Meanwhile, considering that the antecedents of a ZP provide the necessary information for interpreting the gap (ZP), it is a natural way to express a ZP by its potential antecedents. However, only some subsets of candidate antecedents are needed to represent a ZP[1]. To achieve this goal, a desirable solution should be capable of explicitly capturing the importance of each candidate antecedent and using them to build up the representation for the ZP.

In this paper, inspired by the recent success of computational models with attention mechanism and explicit memory (Sukhbaatar et al., 2015; Tang et al., 2016; Kumar et al., 2015), we focus on AZP resolution, proposing the zero pronoun-specific memory network (**ZPMN**) that is competent for representing a ZP with information obtained from its contexts and candidate antecedents. These representations provide our system with an ability to take advantage of semantic information when resolving ZPs. Our **ZPMN** consists of multiple computational layers with shared parameters. With the underlying intuition that not all candidate antecedents are equally relevant for representing the ZP, we develop each computational layer as an attention-based model, which first learns the importance of each candidate antecedent and then utilizes this information to calculate the continuous distributed representation of the ZP. The attention weights over candidate antecedents with respect to the ZP's representation obtained by the last layer are regarded as the ZP coreference classification result. Given that every component is differentiable, the entire model could be efficiently trained end-to-end with gradient descent.

We evaluate our method on the Chinese portions of the OntoNotes 5.0 corpus by comparing with the baseline systems in different experimental settings. Results show that our approach significantly outperforms the baseline algorithms and achieves state-of-the-art performance.

2 Zero Pronoun-specific Memory Network

We describe our deep memory network approach for AZP resolution in this section. We first give an overview of our model and then describe its components. Finally, we present the training and initialization details.

2.1 An Overview of the Method

In this part, we present an overview of the zero pronoun-specific memory network (**ZPMN**) for AZP resolution. Given an AZP zp, we first extract a set of candidate antecedents. Following Chen and Ng (2016), we regard all and only those maximal or modifier noun phrases (NPs) that precede zp in the associated text and are at most two sentences away from it, to be its candidate antecedents. Suppose k candidate antecedents are extracted, our task is to determine the correct antecedent of zp from its candidate antecedent set $\mathcal{A}(zp) = \{c_1, c_2, ..., c_k\}$.

Specifically, these candidate antecedents are represented in form of vectors $\{v_{c_1}, v_{c_2}, ..., v_{c_k}\}$, which are stacked and regarded as the external memory $mem \in \mathbb{R}^{l \times k}$, where l is the dimension of v_c. Meanwhile, we represent each word as a continuous and real-valued vector, which is known as word embedding (Bengio et al., 2003). These word vectors can be randomly initialized, or be pre-trained from text corpus with learning algorithms (Mikolov et al., 2013; Pennington et al., 2014). In this work, we adopt the latter strategy since it can better exploit the semantics of words. All the word vectors are stacked in a word embedding matrix $L_w \in \mathbb{R}^{d \times |V|}$, where d is the dimension of the word vector and $|V|$ is the size of the word vocabulary. The embedding of word w is

[1] A common way to do this task is to first extract a set of candidate antecedents, and then select antecedents from the candidate set. Therefore, only those candidates who are possibly the correct antecedent of the given ZP are suitable for interpreting it.

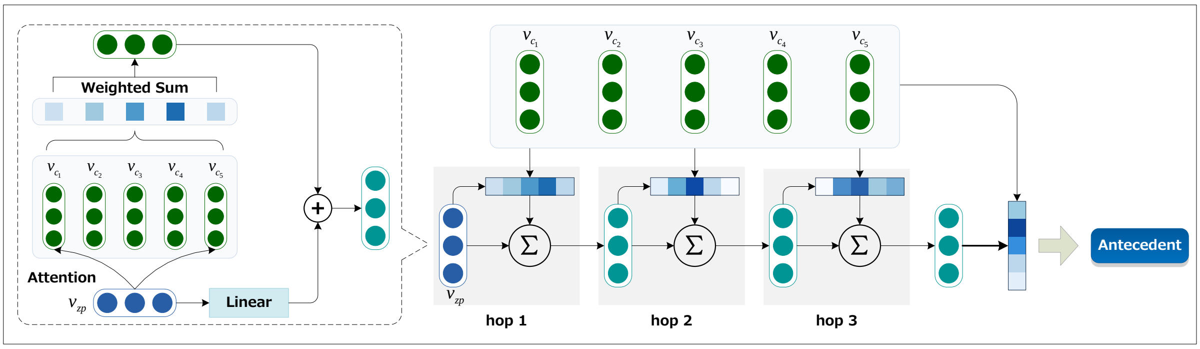

Figure 1: Illustration of the zero pronoun-specific memory network with three computational layers (hops). v_{zp} and v_c denote the vector representation of an AZP and its candidate antecedents. The left part in dashed box shows the details of the first hop.

notated as $e \in \mathbb{R}^{d \times 1}$, which is the column in L_w.

An illustration of **ZPMN** is given in Figure 1, which is inspired by the memory network utilized in question answering (Sukhbaatar et al., 2015). Our model consists of multiple computational layers, each of which contains an attention layer and a linear layer. First, we represent the AZP zp by utilizing its contextual information, that is, proposing the ZP-centered LSTM that encodes zp into its distributed vector representation (i.e. v_{zp} in Figure 1). We then regard v_{zp} as the initial representation of zp, and feed it as the input to the first computational layer (hop 1). In the first computational layer, we calculate the attention weight across the AZP for each candidate antecedent, by which our model adaptively selects important information from the external memory (candidate antecedents). The output of the attention layer and the linear transformation of v_{zp} are summed together as the input of to the next layer (hop 2).

We stack multiple hops by repeating the same process for multiple times in a similar manner. We call the abstractive information obtained from the external memory the "*key extension*" of the AZP. Note that the attention and linear layer parameters are shared in different hops. Regardless of the number of hops the model employs, they utilize the same number of parameters. Finally, after going through all the hops, we regard the attention weight of each candidate antecedent with respect to the AZP representation generated by the last hop as the probability that the candidate antecedent is the correct antecedent, and predict the highest-scoring (most probable) one to be the antecedent of the given AZP.

2.2 Modeling Zero Pronouns by Contexts

A vector representation of AZP is required when computing the **ZPMN**. As aforementioned, a ZP contains no actual content, it is therefore needed to employ some supplemental information to generate its initial representation. To achieve this goal, we develop the ZP-centered LSTM that encodes an AZP into a vector representation by utilizing its contextual information.

Admittedly, one efficient method to model a variable-length sequence of words (context words) is to utilize a recurrent neural network (Elman, 1991). A recurrent neural network (RNN) stores the sequence history in a real-valued history vector, which captures information of the whole sequence. LSTM (Hochreiter and Schmidhuber, 1997) is one of the classical variations of RNN that mitigate the gradient vanish problem of RNN. Assuming $x = \{x_1, x_2, ..., x_n\}$ is an input sequence, each time step t has an input x_t and a hidden state h_t. The internal mechanics of the LSTM is defined by:

$$i_t = \sigma(W^{(i)} \cdot [x_t; h_{t-1}] + b^{(i)}) \quad (1)$$

$$f_t = \sigma(W^{(f)} \cdot [x_t; h_{t-1}] + b^{(f)}) \quad (2)$$

$$o_t = \sigma(W^{(o)} \cdot [x_t; h_{t-1}] + b^{(o)}) \quad (3)$$

$$\tilde{C}_t = tanh(W^{(c)} \cdot [x_t; h_{t-1}] + b^{(c)}) \quad (4)$$

$$C_t = i_t \odot \tilde{C}_t + f_t \odot C_{t-1} \quad (5)$$

$$h_t = o_t \odot tanh(C_t) \quad (6)$$

where $\odot$ is an element-wise product and $W^{(i)}$, $b^{(i)}$, $W^{(f)}$, $b^{(f)}$, $W^{(o)}$, $b^{(o)}$, $W^{(c)}$, and $b^{(c)}$ are the parameters of the LSTM network.

Intuitively, the words near an AZP generally contain richer information to express it. To bet-

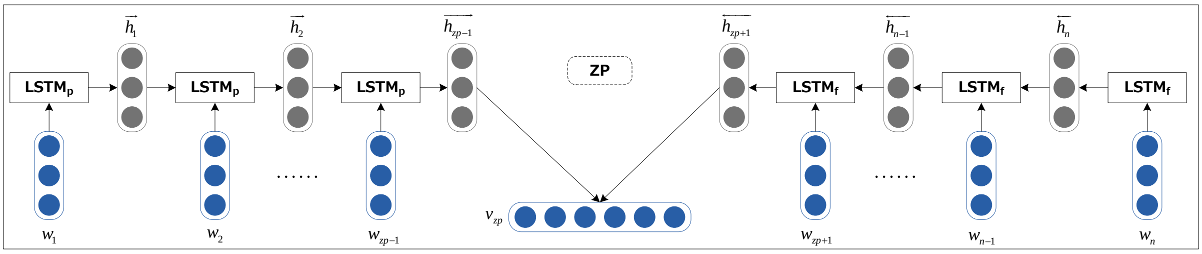

Figure 2: ZP-centered LSTM for encoding the AZP by its context words. w_i means the i-th word in the sentence, w_{zp-i} is the i-th last word before the ZP and w_{zp+i} is the i-th word behind the ZP.

ter utilize the information of words surrounding the AZP, on the basis of the traditional LSTM, we propose the ZP-centered LSTM to encode the AZPs. A graphical representation of this model is displayed in Figure 2. Specifically, the ZP-centered LSTM contains two standard LSTM neural networks, i.e., the LSTM$_p$ that encodes the preceding context of the AZP in a left-to-right manner, and the LSTM$_f$ that models the following context in the reverse direction. Ideally, the ZP-centered LSTM models the preceding and following contexts of the AZP separately, so that the words near the AZP are regarded as the last hidden units and could contribute more in representing the AZP. Afterward, we obtain the representation of the AZP by concatenating the last hidden vectors of LSTM$_p$ and LSTM$_f$, which summarizes the useful contextual information centered around the AZP. Averaging or summing the last hidden vectors of LSTM$_p$ and LSTM$_f$ could also be attempted as alternatives. We regard it as the initial vector representation of the AZP and feed it to the first computational layer to go through the remaining procedures of our system.

2.3 Generating the External Memory

We describe our method for generating the external memory in this subsection. For a given AZP, a set of noun phrases (NPs) is extracted as its candidate antecedents. Specifically, we generate the external memory by utilizing these candidate antecedents. One way to encode an NP candidate is to utilize its head word embedding (Chen and Ng, 2016). However, this method has a major drawback of not utilizing contextual information that is essential for representing a phrase. Besides, some approaches (Socher et al., 2013; Sun et al., 2015) encode a phrase by utilizing the average word embedding it contains. We argue that such an averaging operation simply treats all the words in a phrase equally, which is inaccurate because some words might be more informative than others.

A helpful property of LSTM is that it could keep useful history information in the memory cell by exploiting input, output and forget gates to decide how to utilize and update the memory of previous information. Given a sequence of words $\{w_1, w_2, ..., w_n\}$, previous research (Sutskever et al., 2014) utilizes the last hidden vector of LSTM to represent the information of the whole sequence. For word w_t in a sequence, its corresponding hidden vector h_t can capture useful information before and including w_t.

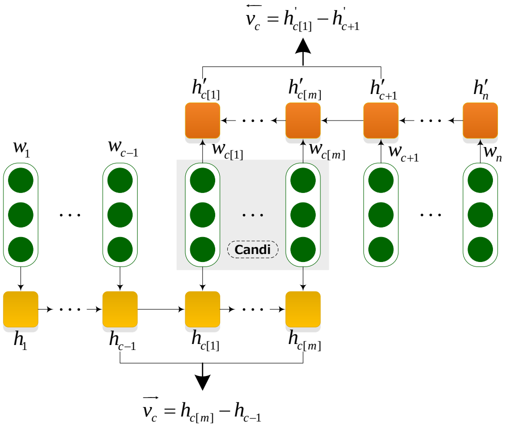

Figure 3: Illustration for modeling a candidate antecedent through its context and content words. *Candi* represents the candidate antecedent. Suppose the candidate antecedent contains m words, $w_{c[j]}$ denotes its j-th word. w_i is the i-th word in the sentence, and $w_{c+1(-1)}$ is the word appears immediately after (before) the candidate antecedent.

Inspired by this, we propose a novel method to produce representations of the candidate antecedents by utilizing both their contexts and content words. Specifically, we use the subtraction between LSTM hidden vectors to encode the candidate antecedents, as illustrated in Figure 3. Given a candidate antecedent c with m words, two standard LSTM neural networks are employed for encoding c in the forward and backward direction, respectively. For the forward LSTM, we extract a sequence of words related with c in a left-to-right manner, i.e., $\{w_1, w_2, ..., w_{c-1}, w_{c[1]}, ..., w_{c[m]}\}$. Subsequently, the forward vector representation of c can be calculated as $\overrightarrow{v_c} = h_{c[m]} - h_{c-1}$, where $h_{c[m]}$ and h_{c-1} indicate the hidden vectors of the forward LSTM corresponding to $w_{c[m]}$ and w_{c-1}, respectively. Meanwhile, the backward LSTM models a sequence of words that are extracted in the reverse direction, that is, $\{w_n, w_{n-1}, ..., w_{c+1}, w_{c[m]}, ..., w_{c[1]}\}$. We then perform the similar operation, computing the backward representation of c as $\overleftarrow{v_c} = h'_{c[1]} - h'_{c+1}$, where $h'_{c[1]}$ and h'_{c+1} indicate the hidden vectors of the backward LSTM corresponding to $w_{c[1]}$ and w_{c+1}. Finally, we concatenate these two vectors together as the ultimate vector representation of c, $v_c = \overrightarrow{v_c} || \overleftarrow{v_c}$.

This method enables our model to encode a candidate antecedent by the information both outside and inside the phrase, which provides our model a strong ability to access to sentence-level information when modeling the candidate antecedents. In this manner, we generate the vector representations of the candidate antecedents, and regard them as the external memory, i.e., $mem = \{v_{c_1}, v_{c_2}, ..., v_{c_k}\}$.

2.4 Attention Mechanism

In this part, we introduce our attention mechanism. This strategy has been widely used in many nature language processing tasks, such as factoid question answering (Hermann et al., 2015), entailment (Rocktäschel et al., 2015) and disfluency detection (Wang et al., 2016). The basic idea of attention mechanism is that it assigns a weight/importance to each lower position when computing an upper-level representation (Bahdanau et al., 2015). With the underlying intuition that not all candidate antecedents are equally relevant for representing the AZP, we employ the attention mechanism as to dynamically align the more informative candidate antecedents from the external memory, $mem = \{v_{c_1}, v_{c_2}, ..., v_{c_k}\}$ with regard to the given AZP, and use them to build up the representation of the AZP.

As shown in Chen and Ng (2016), traditional hand-crafted features are crucial for the resolver's success since they capture the syntactic, positional and other relationships between an AZP and its candidate antecedents. Therefore, to evaluate the importance of each candidate antecedent in a comprehensive manner, following Chen and Ng (2016) who encode hand-crafted features as inputs to their network, we integrate a set of features that are utilized in Chen and Ng (2016), in the form of vector ($v^{(feature)}$) into our attention model. For each multi-valued feature, we convert it into a corresponding set of binary-valued features[2].

Specifically, for the t-th candidate antecedent in the memory, v_{c_t}, taking the vector representation of the AZP v_{zp} and the corresponding feature vector $v_t^{(feature)}$ as inputs, we compute the attention score as $\alpha_t = G(v_{c_t}, v_{zp}, v_t^{(feature)})$. The scoring function G is defined by:

$$s_t = tanh(W^{(att)} \cdot [v_{c_t}; v_{zp}; v_t^{(feature)}] + b^{(att)}) \tag{7}$$

$$\alpha_t = \frac{exp(s_t)}{\sum_{t'=1}^{k} exp(s_{t'})} \tag{8}$$

where $W^{(att)}$ and $b^{(att)}$ are the attention parameters and k indicates the number of candidate antecedents. After obtaining the attention scores for all the candidate antecedents $\{a_1, a_2, ..., a_k\}$, our attention layer outputs a continuous vector vec that is computed as the weighted sum of each piece of memory in mem:

$$vec = \sum_{i=1}^{k} \alpha_i v_{c_i} \tag{9}$$

2.5 Training Details

We initialize our word embeddings with 100 dimensional ones produced by the $word2vec$ toolkit (Mikolov et al., 2013) on the Chinese portion of the training data from the OntoNotes 5.0 corpus. We randomly initialize the parameters from a uniform distribution $U(-0.03, 0.03)$ and minimize the training objective using stochastic gradient descent with learning rate equals to 0.01. In addition, to regularize the network, we apply L2 regularization to the network weights and dropout with a rate of 0.5 on the output of each hidden layer.

[2] If one feature has k different values, we will convert it into k binary features.

The model is trained in a supervised manner by minimizing the cross-entropy error of ZP coreference classification. Suppose the training set contains N AZPs $\{zp_1, zp_2, ..., zp_N\}$. Let $\mathcal{A}(zp_i)$ denote the set of candidate antecedents of an AZP zp_i, and $P(c|zp_i)$ represents the probability of predicting candidate c as the antecedent of zp_i (i.e., the attention weight of candidate antecedent c with respect to the AZP representation generated by the last hop), the loss is given by:

$$loss = -\sum_{i=1}^{N} \sum_{c \in \mathcal{A}(zp_i)} \delta(zp_i, c) log(P(c|zp_i)) \tag{10}$$

where $\delta(zp, c)$ is 1 or 0, indicating whether zp and c are coreferent.

3 Experiments

3.1 Experimental Setup

Datasets: Following Chen and Ng (2016, 2015), we run experiments on the Chinese portion of the OntoNotes Release 5.0 dataset[3] used in the CoNLL 2012 Shared Task (Pradhan et al., 2012). The dataset consists of three parts, i.e., a training set, a development set and a test set. Since only the training set and the development set contain ZP coreference annotations, we train our model on the training set and utilize the development set for testing purposes. Meanwhile, we reserve 20% of the training set as a held-out development set for tuning the hyperparameters of our network. The same experimental data setting is utilized in the baseline system (Chen and Ng, 2016). Table 1 shows the statistics of our corpus. Besides, documents in the datasets come from six sources, i.e., broadcast news (BN), newswires (NW), broadcast conversations (BC), telephone conversations (TC), web blogs (WB) and magazines (MZ).

	Documents	Sentences	Words	AZPs
Training	1,391	36,487	756K	12,111
Test	172	6,083	110K	1,713

Table 1: Statistics on the training and test corpus.

Evaluation metrics: Same as previous studies on Chinese ZP resolution (Zhao and Ng, 2007; Chen and Ng, 2016), we use three metrics to evaluate the quality of our model: recall, precision and F-score (denoted as R, P and F, respectively).

Experimental settings: We employ three Chinese ZP resolution systems as our baselines, i.e., Zhao and Ng (2007); Chen and Ng (2015, 2016). Consistent with Chen and Ng (2015, 2016), three experimental settings are designed to evaluate our approach. In Setting 1, we directly employ the gold syntactic parse trees and gold AZPs that are obtained from the OntoNotes dataset. In Setting 2, we utilize gold syntactic parse trees and system (automatically identified) AZPs[4]. In Setting 3, we employ system AZP and system syntactic parse trees that obtained through the Berkeley parser[5], which is the state-of-the-art parsing model.

3.2 Experimental Results

Table 2 shows the experimental results of the baseline systems and our model on entire test set. Our approach is abbreviated to ZPMN (k), where k indicates the number of hops. The best methods in each of the three experimental settings are in **bold** text. From Table 2, we can observe that our approach outperforms all previous baseline systems by a substantial margin. Meanwhile, among all our models from single hop to six hops, using more computational layers could generally lead to better performance. The best performance is achieved by the model with six hops under experimental Setting 1 and 2, and with four hops in experimental Setting 3. Furthermore, the **ZPMN** (with six hops) significantly outperforms the state-of-the-art baseline system (Chen and Ng, 2016) under three experimental settings by 2.7%, 2.7%, and 3.9% in terms of overall F-score[6], respectively. In all words, our model is an extremely strong performer and substantially outperforms baseline methods, which demonstrate the efficiency of the proposed zero pronoun-specific memory network.

It is well accepted that computational models that are composed of multiple processing layers could learn representations of data with multiple levels of abstraction (LeCun et al., 2015). In our approach, multiple computation layers allow the model to learn representations of AZPs with multiple levels of abstraction generated by candidate antecedents. Each layer/hop retrieves important candidate antecedents, and transforms the repre-

Table 3: Experimental results on each source of test data. The strongest F-score in each row is in **bold**.

sentation at previous level into a representation at a higher, slightly more abstract level. We regard this representation as the "*key extension*" of the AZP, by which our model learns to encode the AZP in an efficient manner.

For per-source results, we conduct experiments by comparing the **ZPMN** (with six hops) with the state-of-the-art baseline system (Chen and Ng, 2016) on six sources of test data, as shown in Table 3. The rows in Table 3 are the experimental results from different sources under the three experimental settings. In experimental Settings 1 and 3, **ZPMN** improves results further across all the six sources of data. Under experimental Setting 2, our model outperforms the baseline system in five of the six sources of data, only slightly underperforms in source TC. All these prove that our approach achieves a considerable improvement in Chinese ZP resolution.

Moreover, to evaluate the effectiveness of our methods for modeling the AZP and candidate antecedents proposed in Section 2.2 and 2.3, we compare with three models that are all simplified versions of the **ZPMN**, namely, **ZPContextFree** where an AZP is initially represented by its governing verb and preceding word; **AntContentAvg** where the candidate antecedents are encoded by their averaged content word embeddings; and **AntContentHead** where each candidate antecedent is represented by the embedding of its head word. To make comparison as fair as possible, we keep the other parts of these models unchanged from the **ZPMN** with six computational layers (hop 6). To minimize the external influence, we run experiments under experimental Setting 1 (gold parse and gold AZPs). Table 4 shows the results.

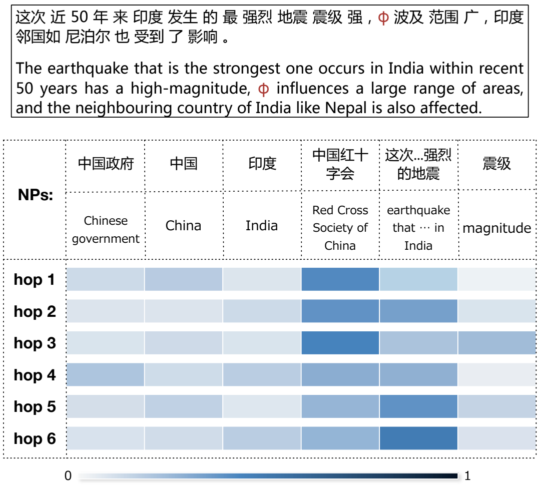
	R	P	F
ZPContextFree	53.5	53.8	53.6
AntContentAvg	52.6	52.9	52.7
AntContentHead	53.8	54.1	53.9
ZPMN (hop 6)	54.8	55.1	**54.9**

Table 4: Experimental results of different models.

With an intuition that contexts of an AZP provide more sufficient information than only a few specific of words in expressing the AZP, the performance of **ZPContextFree** is unsurprisingly worse than that of the **ZPMN**, which reflects the effects of the ZP-centered LSTM proposed to generate the initial representation for the AZP. In addition, the performance of **AntContentAvg** is relatively low. We attribute this to the model assigning the same importance to all the content words in a phrase, which causes difficulty for the model to capture informative words in a candidate antecedent. Meanwhile, **AntContent-**

Head only models limited information when encoding candidate antecedents, thereby underperforms the **ZPMN** whose external memory contains sentence-level information both outside and inside the candidate antecedents. These demonstrate the utility of the method for modeling candidate antecedents.

3.3 Attention Model Visualization



这次 近 50 年 来 印度 发生 的 最 强烈 地震 震级 强，φ 波及 范围 广，印度 邻国如 尼泊尔 也 受到 了 影响 。

The earthquake that is the strongest one occurs in India within recent 50 years has a high-magnitude, φ influences a large range of areas, and the neighbouring country of India like Nepal is also affected.

Figure 4: Example of attention weights in different hops. ZP is denoted as ϕ. The rows show the attention weights of candidates in each hop. Darker color means higher weight.

To obtain a better understanding of our deep memory network, we visualize the attention weights of the **ZPMN**, as is shown in Figure 4. We can observe that in the first three hops, the fourth candidate "中国红十字会/Red Cross Society of China" gains a higher attention weight than the others. Nevertheless, in hop 5 and 6, the attention weight of "这次...强烈的地震/the earthquake that ... in India" increases and the model finally predicts it correctly as the antecedent. This case illustrates the effects of multiple hops.

4 Related Work

4.1 Zero Pronoun Resolution

Chinese zero pronoun resolution. Early studies utilize heuristic rules to resolve ZPs in Chinese (Converse, 2006; Yeh and Chen, 2007). More recently, supervised approaches have been vastly explored. Zhao and Ng (2007) first present a machine learning approach to identify and resolve ZPs. By employing the J48 decision tree algorithm, various kinds of features are integrated into their model. Kong and Zhou (2010) develop a kernel-based approach, employing context-sensitive convolution tree kernels to model syntactic information. Chen and Ng (2013) further extend the study of Zhao and Ng (2007) by proposing several novel features and introducing the coreference links between ZPs. Despite the effectiveness of feature engineering, it is labor intensive and highly relies on annotated corpus. To handle these weaknesses, Chen and Ng (2014b) propose an unsupervised method. They first recover each ZP into ten overt pronouns and then apply a ranking model to rank the antecedents. Chen and Ng (2015) propose an end-to-end unsupervised probabilistic model, utilizing a salience model to capture discourse information. In recent years, Chen and Ng (2016) develop a deep neural network approach to learn useful task-specific representations and effectively exploit lexical features through word embeddings. Different from previous studies, in this work, we propose a novel memory network to perform the task. By encoding ZPs and candidate antecedents through the composition of texts based on the representation of words, our model benefits from the semantic information when resolving the ZPs.

Zero pronoun resolution for other languages. There have been various studies on ZP resolution for other languages besides Chinese. Ferrández and Peral (2000) propose a set of hand-crafted rules for resolving ZPs in Spanish texts. Recently, supervised approaches have been widely exploited for ZP resolution in Korean (Han, 2006), Italian (Iida and Poesio, 2011) and Japanese (Isozaki and Hirao, 2003; Iida et al., 2006, 2007; Imamura et al., 2009; Sasano and Kurohashi, 2011; Iida and Poesio, 2011; Iida et al., 2015). Iida et al. (2016) propose a multi-column convolutional neural network for Japanese intra-sentential subject zero anaphora resolution, where both the surface word sequence and dependency tree of a target sentence are exploited as clues in their model.

4.2 Attention and Memory Network

Attention mechanisms have been widely used in many studies and have achieved promising performances on a variety of NLP tasks (Rocktäschel et al., 2015; Rush et al., 2015; Liu et al., 2017). Recently, the memory network has been proposed and applied to question answering task (Weston et al., 2014), which is defined to have four components: input (I), generalization (G), output (O) and response (R). After then, memory networks have been adopted in many other NLP tasks, such as aspect sentiment classification (Tang et al., 2016), dialog systems (Dodge et al., 2015), and information extraction (Xiaocheng et al., 2017).

5 Conclusion

In this study, we propose a novel zero pronoun-specific memory network that is capable of encoding zero pronouns into the vector representations with supplemental information obtained from their contexts and candidate antecedents. Consequently, these continuous distributed vectors provide our model with an ability to take advantage of the semantic information when resolving zero pronouns. We evaluate our method on the Chinese portion of OntoNotes 5.0 dataset and report substantial improvements over the state-of-the-art systems in various experimental settings.

How much progress have we made on RST discourse parsing? A replication study of recent results on the RST-DT

Mathieu Morey and **Philippe Muller** and **Nicholas Asher**

Abstract

This article evaluates purported progress over the past years in RST discourse parsing. Several studies report a relative error reduction of 24 to 51% on all metrics that authors attribute to the introduction of distributed representations of discourse units. We replicate the standard evaluation of 9 parsers, 5 of which use distributed representations, from 8 studies published between 2013 and 2017, using their predictions on the test set of the RST-DT. Our main finding is that most recently reported increases in RST discourse parser performance are an artefact of differences in implementations of the evaluation procedure. We evaluate all these parsers with the standard Parseval procedure to provide a more accurate picture of the actual RST discourse parsers performance in standard evaluation settings. Under this more stringent procedure, the gains attributable to distributed representations represent at most a 16% relative error reduction on fully-labelled structures.

1 Introduction

While several theories of discourse structure for text exist, discourse parsing work has largely concentrated on Rhetorical Structure Theory (RST) (Mann and Thompson, 1988) and the RST Discourse Treebank (RST-DT) (Carlson et al., 2003), which is the largest corpus of texts annotated with full discourse structures. The RST-DT, annotated in the style of RST, consists of 385 news articles from the Penn Treebank, split into a training and test sets of 347 and 38 documents.The standard evaluation procedure for RST discourse parsing, RST-Parseval, proposed by Marcu (2000), adapts the Parseval procedure for syntactic parsing (Black et al., 1991). RST-Parseval computes scores on discourse structures with no label (S for Span) or labelled with nuclearity (N), relation (R) or both (F for Full). The semantic nature of discourse relations makes discourse parsing a difficult task. However, the recent introduction of distributed representations of discourse units has seemingly led to significant improvements, with a claimed relative error reduction of 51% on fully labelled structures. As part of a broader study of methods and evaluation metrics for discourse parsing, we collected predictions from nine RST discourse parsers and reimplemented RST-Parseval. In section 2, we present these RST parsers and report their published scores on RST-Parseval. In section 3, we replicate their evaluation and show that most of the heterogeneity in performance across RST parsers arises from differences in their evaluation procedures. In section 4, we replace RST-Parseval with the standard Parseval procedure and obtain a more accurate picture of the actual performance of RST parsers.

2 A sample of RST discourse parsers

Almost all RST discourse parsers are evaluated on the test section of the RST-DT using manually segmented Elementary Discourse Units (EDUs). We contacted by email the main or corresponding author of each recently (2013–2017) published, text-level RST discourse parser evaluated in this setting and asked the authors to provide us with the predictions they used in their study or a procedure that would enable us to reproduce identical or at least similar predictions. When our attempts were unsuccessful we tried to reproduce similar predictions from published materiel (source code, binaries, model). We managed to obtain or reproduce predictions for 9 parsers from 8 studies. The first parser, denoted **HHN16 HILDA**, is a reimplementation (Hayashi et al., 2016) of the classic, bottom-up, greedy HILDA parser with a linear SVM model (Hernault et al., 2010) ; this parser serves as a reference point to evaluate the progress made by more recent parsers. **SHV15**

Proceedings of the 2017 Conference on Empirical Methods in Natural Language Processing, pages 1319–1324
Copenhagen, Denmark, September 7–11, 2017. ©2017 Association for Computational Linguistics

D is a variant of the HILDA parser with different models (perceptron for attachment of discourse units, logistic regression for relation labelling) and a slightly different feature set adapted to use predicted syntactic dependency trees (Surdeanu et al., 2015). **JCN15 1S-1S** is a two stage (sentence-then document-level) CKY chart parser with Dynamic Conditional Random Field (DCRF) models, in its 1 sentence - 1 subtree (1S-1S) variant that builds a document-level RST tree on top of sentence-level subtrees built for each sentence independently (Joty et al., 2013, 2015). **FH14** ***g*****CRF** is a two stage (sentence- then document-level) bottom-up, greedy parser with linear-chain CRF models (Feng and Hirst, 2014). We use the version of the parser available on the author's webpage, that lacks post-editing and contextual features. **BPS16** is a sequence-to-sequence parser, heuristically constrained to build trees, with a hierarchical neural network model (hierarchical bi-LSTM) (Braud et al., 2016). **LLC16** is a CKY chart parser with a hierarchical neural network model (attention-based hierarchical bi-LSTM) (Li et al., 2016). **BCS17 mono, BCS17 cross+dev** are two variants of a transition-based parser that uses a feed-forward neural network model (Braud et al., 2017). **JE14 DPLP** is a shift-reduce parser that uses an SVM model (Ji and Eisenstein, 2014). We use predictions provided by the author, from an improved, unpublished version of the parser.

The first four parsers (HHN16 HILDA, SHV15 D, JCN15 1S-1S, FH14 *g*CRF) use, as features, only localist representations of the input and parsing state, i.e. surface-form and syntactic information: length of discourse units (DUs), distance between DUs, n-grams of words and POS tags, relations of syntactic dominance between DUs... The last five parsers (BPS16, LLC16, BCS17 mono and cross+dev, JE14 DPLP concat) build distributed representations of DUs, complemented with a subset of localist representations.

The authors used various implementations of RST-Parseval, but all applied a right-heavy binarization procedure to the reference RST trees: Each node of arity greater than 2 is replaced with a right-branching cascade of binary nodes. In the publications, the tables of results provide a unique score for labeled structures, corresponding to either the R or F metric, with no explicit distinction. The F_1 scores published in the literature for the parsers in our sample are reported in Table 1, where an en-dash (–) indicates missing scores. We also report the scores of human agreement, computed and reported by Joty (2015), over the doubly annotated subset of the RST-DT consisting of 53 documents (48 from train, 5 from test).

parser	**S**	**N**	**R** or **F**
HHN16 HILDA	82.6	66.6	54.2
SHV15 D	–	–	55.2
JCN15 1S-1S	82.6	68.3	55.8
FH14 *g*CRF	84.9	69.9	57.2
BPS16	83.6	69.8	55.1
LLC16	**85.8**	71.1	58.9
BCS17 mono	85.0	72.3	60.1
BCS17 cross+dev	85.1	**73.1**	61.4
JE14 DPLP concat	82.1	71.1	**61.6**
human	88.7	77.7	65.8

Table 1: Published F_1 scores.

The parsers in the second group seem to perform markedly better than the parsers in the first group, especially on the hardest subtasks of predicting (partly or fully) labelled structures (N and R or F). Collectively, the parsers in the second group claim absolute improvements over the parsers in the first group by 0.9, 3.2 and 4.2 points, corresponding to a relative error reduction of 24% on S, 41% on N and 51% on R or F, compared to human agreement. While discourse parsing is a difficult, semantic task with relatively little annotated training data, authors attribute these significant gains to the capacity of distributed representations to capture latent semantic information and generalize over a long tail of alternative surface forms. As a preliminary step towards probing these claims, we replicated the evaluation of these parsers' predictions.

3 Evaluation

We collected or reproduced predictions from each parser and replicated the evaluation procedure [1]. The predictions came in various formats: bracketed strings as in the RST-DT, lists of span descriptions, trees or lists of attachment decisions. We wrote custom functions to load and normalize the predictions from each parser into RST trees. While we favor evaluating against the original,

[1] The source code and material are available at https://github.com/irit-melodi/rst-eval

non binarized reference RST trees, we conformed in this replicative study to the de facto standard in the RST parsing literature: We transformed the reference RST trees into right-branching binary trees and used these binary trees as reference in all our evaluation procedures. We also examined the source code from the evaluation procedures provided by the authors to determine whether the published scores corresponded to the R or F metric. In so doing we noticed a potentially important discrepancy in the various implementations of the RST-Parseval procedure: the implementations used to evaluate the parsers in the first group compute **micro-averaged** F_1 scores, as is standard practice in the syntactic parsing community, whereas the implementations used to evaluate the parsers in the second group compute **macro-averaged** F_1 scores across documents. The micro-averaged F_1 score is computed globally over the predicted and reference spans from all documents ; the macro-averaged F_1 score across documents is the average of F_1 scores computed independently for each document.

We implemented both strategies and report the corresponding scores in two separate tables. Parsers originally evaluated with micro-averaging scores are in the top half of each table, parsers originally evaluated with macro-averaged scores in the bottom half. An asterisk (*) marks parsers for which we reproduced predictions using code and material made available by the authors, although the experimental settings are not guaranteed to match exactly those from the original study. A double asterisk (**) marks a parser for which we used predictions generated by the author using an improved, unpublished version of the parser posterior to the original study. Lines with no asterisk in Tables 2 to 4 correspond to parsers whose authors sent us their original predictions. Replicated scores expected to match scores in Table 1 are underlined.

parser	S	N	R	F
HHN16 HILDA	82.6	66.6	54.6	54.3
SHV15 D *	82.6	67.1	55.4	54.9
JCN15 1S-1S	82.6	68.3	55.8	55.4
FH14 *g*CRF *	**84.3**	**69.4**	56.9	56.2
BPS16	79.7	63.6	47.7	47.5
LLC16	82.2	66.5	51.4	50.6
BCS17 mono	81.0	67.7	55.7	55.3
BCS17 cross+dev	81.3	68.1	56.3	56.0
JE14 DPLP **	82.0	68.2	**57.8**	**57.6**
human	88.3	77.3	65.4	64.7

Table 2: Micro-averaged F_1 scores.

Table 2 contains the micro-averaged F_1 scores on each metric (S, N, R, F). As expected, parsers in the first group obtain micro-averaged scores equal or close to their published scores reported in Table 1. More strikingly, the micro-averaged scores for the parsers in the second group are much lower than their published scores [2] and most of their claimed advantages over the parsers in the first group has vanished. On S and N, parsers in the second group do not improve over parsers in the first group ; on R and F the best parser in the second group provides an absolute improvement of 0.9 and 1.4 points. This improvement corresponds to a relative error reduction of 11% on R and 16% on F, much lower than the 51% claimed in the literature. [3]

parser	S	N	R	F
HHN16 HILDA	85.9	72.1	60.0	59.4
SHV15 D *	85.1	71.1	59.8	59.1
JCN15 1S-1S	85.7	73.0	60.9	60.2
FH14 *g*CRF *	**87.0**	**74.1**	61.1	60.5
BPS16	83.6	69.8	55.4	55.1
LLC16	85.4	70.8	58.4	57.6
BCS17 mono	85.0	72.3	60.8	60.1
BCS17 cross+dev	85.1	73.1	61.6	61.4
JE14 DPLP **	85.0	71.6	**62.0**	**61.9**
human	89.6	78.3	66.7	65.3

Table 3: Macro-averaged F_1 scores.

Table 3 contains the macro-averaged F_1 scores. Parsers in the first group obtain macro-averaged scores markedly higher than the micro-averaged scores from Table 2. Parsers in the second group obtain macro-averaged scores that are equal or close to the published scores reported in Table 1, which confirms our analysis of the source code of their evaluation procedures. The global picture on

[2] The milder decrease of the DPLP scores, especially on S, is directly attributable to improvements in the latest, unpublished version of the parser.

[3] Our replicated scores for human agreement are 0.4 points lower than those published on S, N, R, possibly due to different approaches in handling divergences in EDU segmentation on the doubly annotated subset of documents.

macro-averaged scores is consistent with that on micro-averaged scores: On S and N, parsers in the second group do not improve over parsers the first group and the best parser brings an absolute improvement of 0.9 and 1.4 points on R and F. On each metric, the two lowest scores are obtained by parsers from the second group.

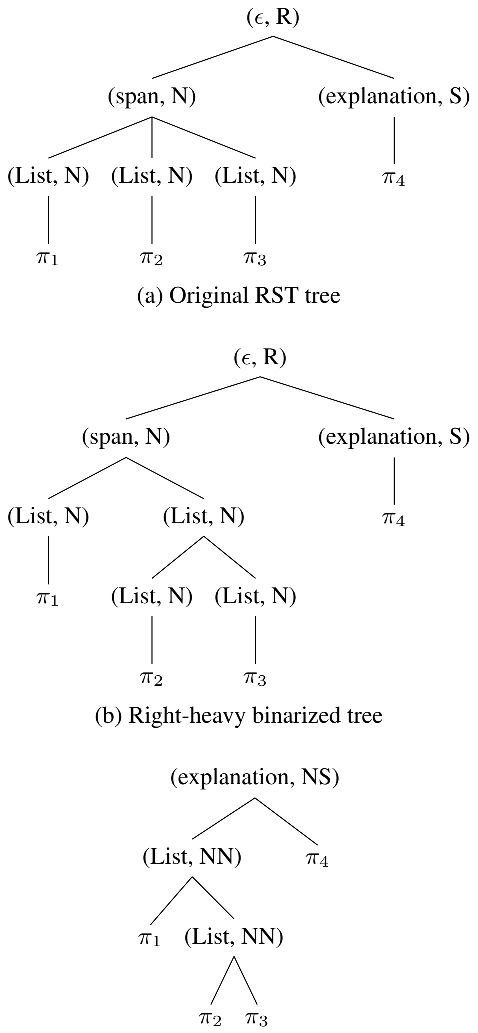
To sum up, parsers in the first group have identical scores in Tables 1 and 2, except for slight differences between our evaluation procedure and the authors', or between the predictions used in our evaluation compared to the original study. The second group of parsers have identical scores in Tables 1 and 3, modulo the same factors. The (exactly or nearly) matching entries between Tables 1, 2 and 3, underlined in Tables 2 and 3, are evidence of the two averaging strategies (micro in Table 2, macro in Table 3) used by the authors in their publications (Table 1). A comparison between Tables 2 and 3 reveals that the averaging strategy similarly affects both groups of parsers. As a result, the performance level among recent RST discourse parsers is much more homogeneous than the situation depicted in the literature. The distributed representations of DUs computed and used in JE14 DPLP (Ji and Eisenstein, 2014) and possibly BCS17 cross+dev (Braud et al., 2017) plausibly capture semantic information that helps with predicting discourse relations and structure, but the current experimental results do not provide a similarly strong support for BPS16 (Braud et al., 2016), LLC16 (Li et al., 2016) and BCS17 mono (Braud et al., 2017).

More generally, it is important that authors compute and report scores that accord with standard practice, unless duly motivated. The standard practice in syntactic parsing is to report micro-averaged scores for overall performance, often complemented with macro-averaged scores over classes to gain valuable insight into the average performance of parsers across labels, especially infrequent ones. Early work in RST discourse parsing follows this practice, reporting micro-averaged scores for global performance, plus distinct scores for each relation class or macro-averaged scores over all relation classes (Hernault et al., 2010; Feng and Hirst, 2014). The latter should not be confused with the scores published for BPS16, LLC16, BCS17 (mono, cross+dev) and JE14 DPLP, which are macro-averaged over documents.

4 Elements for a fairer evaluation

RST-Parseval crucially relies on an encoding of RST trees into constituency trees such that the rhetorical relation names are placed on the children nodes, and the nuclei of mononuclear relations are conventionally labelled SPAN. RST-Parseval resembles the original Parseval, except it considers a larger set of nodes to collect all nuclearity and relation labels in this encoding: the root node (whose label and nuclearity are fixed by convention) is excluded and the leaves, the EDUs, are included. On the one hand, RST-Parseval can handle discourse units of arity greater than 2, in particular those consisting of a nucleus independently modified by two satellites through distinct mononuclear relations. This avoids introducing discourse units that were not part of the original annotation, which a preliminary binarization of trees would have induced. On the other hand, RST-Parseval considers approximately twice as many nodes as the original Parseval would on binarized trees (at most $2n - 2$ nodes for n EDUs, compared to $n - 1$ attachments in a binary tree), and the relation labels of most nuclei are redundant with the nuclearity of a node and its sister (SPAN for a nucleus whose sisters are satellites, and the same label as its sisters for a nucleus whose sisters are nuclei). Both aspects artificially raise the level of agreement between RST trees, especially when using manual EDU segmentation.

However, all the parsers in our sample except (Sagae, 2009; Heilman and Sagae, 2015) predict binary trees over manually segmented EDUs and evaluate them against right-heavy binarized reference trees. In this setting, Marcu's encoding of RST trees RST-Parseval are no longer motivated. We can thus revert to using the standard Parseval procedure on a representation of binary RST trees where each internal node is a labelled attachment decision to obtain a more accurate evaluation of RST parser performance. Figure 1 represents (a) an original RST tree using Marcu's encoding, (b) its right-heavy binarized version, (c) the tree of labelled attachment decisions for the right-heavy binarized tree. To the best of our knowledge, we are the first to explicitly use an evaluation procedure for RST parsing closer to the original Parseval for syntax, although the trees of labelled attachment decisions we use directly correspond to the trees built by many RST parsers, eg. shift-reduce parsers. Table 4 provides the micro-averaged F_1



(a) Original RST tree

(b) Right-heavy binarized tree

(c) Labelled attachment decisions for the right-heavy binarized tree

Figure 1: Original RST tree, right-heavy binarization and labelled attachment decisions

scores for the parsers in our sample, using Parseval.

Parseval is more stringent than RST-Parseval, with the best system obtaining 46.3 on fully labelled structures (F). Parsers in the first group are competitive with parsers in the second group, outperforming them on S and to a lesser extent on N. Parsers in the second group reduce relative error by 8% on R and 16% on F, much lower than the published figures in the literature.

5 Conclusion

We replicated standard evaluation procedures in RST discourse parsing for 9 parsers and showed that most gains reported in recent publications are an artefact of implicit differences in evaluation procedures. We also showed how to use the standard Parseval procedure instead of Marcu's adaptation RST-Parseval, which artificially raises scores. Overall, the recent gains attributable to distributed representations represent at most a relative error reduction of 16%. Our study reveals an urgent need for the RST discourse parsing community to re-examine and standardize their evaluation procedures.

Abstract

In this paper, we address the problem of predicting one of three functions for the English pronoun 'it': anaphoric, event reference or pleonastic. This disambiguation is valuable in the context of machine translation and coreference resolution. We present experiments using a MAXENT classifier trained on gold-standard data and self-training experiments of an RNN trained on silver-standard data, annotated using the MAXENT classifier. Lastly, we report on an analysis of the strengths of these two models.

1 Introduction

We address the problem of disambiguating the English pronoun 'it', which may function as a pleonastic, anaphoric, or event reference pronoun. As an *anaphoric* pronoun, 'it' corefers with a noun phrase (called the *antecedent*), as in example (1):

(1) I have a bicycle. It is red.

Pleonastic pronouns, in contrast, do not refer to anything but are required to fill the subject position in many languages, including English, French and German:

(2) It is raining.

Event reference pronouns are anaphoric, but instead of referring to a noun phrase, they refer to a verb, verb phrase, clause or even an entire sentence, as in example (3):

(3) He lost his job. It came as a total surprise.

We propose the identification of the three usage types of *it*, namely anaphoric, event reference, and pleonastic, with a single system. We present several classification experiments which rely on information from the current and previous sentences, as well as on the output of external tools.

2 Related Work

Due to its difficulty, proposals for the identification and the subsequent resolution of abstract anaphora (i.e., event reference) are scarce (Eckert and Strube, 2000; Byron, 2002; Navarretta, 2004; Müller, 2007). The automatic detection of instances of pleonastic 'it', on the other hand, has been addressed by the non-referential 'it' detector NADA (Bergsma and Yarowsky, 2011), and also in the context of several coreference resolution systems, including the Stanford sieve-based coreference resolution system (Lee et al., 2011).

The coreference resolution task focuses on the resolution of nominal anaphoric pronouns, de facto grouping our event and pleonastic categories together and discarding both of them. The coreference resolution task can be seen as a two-step problem: *mention* identification followed by *antecedent* identification. Identifying instances of pleonastic 'it' typically takes place in the mention identification step. The recognition of event reference 'it' is, however, to our knowledge not currently included in any such systems, although from a linguistic point of view, event instances are also referential (Boyd et al., 2005). As suggested by Lee et al., (2016), it would be advantageous to incorporate event reference resolution in the second step.

In the context of machine translation, work by Le Nagard and Koehn (2010); Novák et al. (2013); Guillou (2015) and Loáiciga et al. (2016) have also considered disambiguating the function of the pronoun 'it' in the interest of improving pronoun translation into different languages.

3 Disambiguating ‘it’

3.1 Labeled Data

The ParCor corpus (Guillou et al., 2014) and *DiscoMT2015.test* dataset (Hardmeier et al., 2016) were used as gold-standard data. Under the ParCor annotation scheme, which was used to annotate both corpora, pronouns are manually labeled according to their function: anaphoric, event reference, pleonastic, etc. For all instances of ‘it’ in the corpora, we extracted the sentence-internal position of the pronoun, the sentence itself, and the two previous sentences. All examples were shuffled before the corpus was divided, ensuring a balanced distribution of the classes (Table 1).

The pronouns ‘this’ and ‘that’, when used as event reference pronouns, may often be used interchangeably with the pronoun ‘it’ (Guillou, 2016). We therefore automatically substituted all instances of event reference ‘this’ and ‘that’ with ‘it’ to increase the number of training examples.

Data set	Event	Anaphoric	Pleonastic	Total
Training	504	779	221	1,504
Dev	157	252	92	501
Test	169	270	62	501
Total	830	1,301	375	2,506

Table 1: Distribution of classes in the data.

3.2 Baselines

We provide two different baselines (MC and LM Baseline in Table 2). The first is a setting in which all instances are assigned to the majority class *it-anaphoric*. The second baseline system is a 3-gram language model built using KenLM (Heafield, 2011) and trained on a modified version of the annotated corpus in which every instance of ‘it’ is concatenated with its function (e.g. ‘it-event’). At test time, the ‘it’ position is filled with each of the three it-function labels in turn, the language model is queried, and the highest scoring option is chosen.

3.3 Features

We designed features to capture not only the token context, but also the syntactic and semantic context preceding the pronouns and, where appropriate, their antecedents/referents, as well as the pronoun head. We used the output of the POS tagger and dependency parser of Bohnet et al. (2013)[1], and of the TreeTagger lemmatizer (Schmid, 1994) to extract the following information for each training example:

Token context (tok) **1.** Previous three tokens and next two tokens. This includes words, punctuation and the tokens in the previous sentence when the ‘it’ occupies the first position of the current sentence. **2.** Lemmas of the next two tokens.

Pronoun head (hea) **3.** Head word and its lemma. Most of the time the head word is a verb. **4.** If the head verb is copular, we include its complement head and not the verb itself (for the verbs *be*, *appear*, *seem*, *look*, *sound*, *smell*, *taste*, *feel*, *become* and *get*). **5.** Whether the head word takes a ‘that’ complement (verbs only). **6.** Tense of head word (verbs only), computed as described by Loáiciga et al. (2014).

Syntactic context (syn) **7.** Whether a ‘that’ complement appears in the previous sentence. **8.** Closest NP head to the left and to the right. **9.** Presence or absence of extraposed sentential subjects as in ‘*So it’s difficult to attack malaria from inside malarious societies, [...].* **10.** Closest adjective to the right.

Semantic context (sem) **11.** VerbNet selectional restrictions of the verb. VerbNet (Kipper et al., 2008) specifies 36 types of argument that verbs can take. We limited ourselves to the values of *abstract*, *concrete* and *unknown*. **12.** Likelihood of head word taking an event subject (verbs only). An estimate of the likelihood of a verb taking a event subject was computed over the Annotated English Gigaword v.5 corpus (Napoles et al., 2012). We considered two cases favouring event subjects that may be identified by exploiting the parse annotation of the Gigaword corpus. The first case is when the subject is a gerund and the second case is composed of ‘this’ pronoun subjects. **13.** Non-referential probability assigned to the instance of ‘it’ by NADA (Bergsma and Yarowsky, 2011).

3.4 MaxEnt

The MaxEnt classifier is trained using the Stanford Maximum Entropy package (Manning and Klein, 2003) with all of the features described above. We also experimented with other features and options. For features 1 and 2, a window

Table 2: Comparison of baselines and classification results.

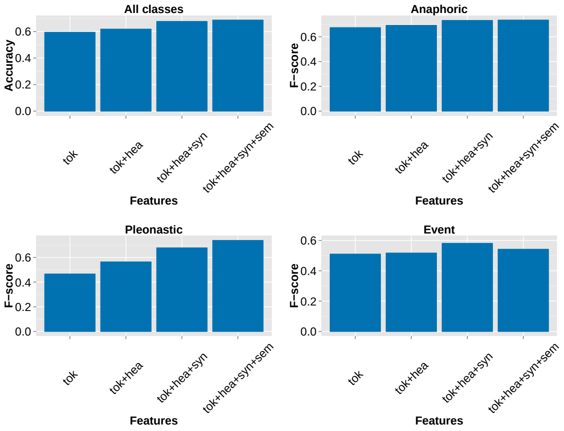

Figure 1: Feature ablation – MaxEnt system.

of three tokens showed a degradation in performance. For feature 8, adding one of the 26 WordNet (Princeton University, 2010) types of nouns had no effect. The feature combination of noun and adjectives to the left or right also had no effect. Feature ablation tests revealed that while combining all features is beneficial for the prediction of the anaphoric and pleonastic classes, the same is not true for the event class. In particular, the inclusion of semantic features, which we designed as indicators of event*ness*, appears to be harmful (Figure 1).

3.5 Unlabeled Data

Given the small size of the gold-standard data, and with the aim of gaining insight from unstructured and unseen data, we used the MaxEnt classifier to label additional data from the pronoun prediction shared task at WMT16 (Guillou et al., 2016). This new *silver-standard* training corpus comprises 1,101,922 sentences taken from the Europarl (3,752,440 sentences), News (344,805 sentences) and TED talks (380,072 sentences) sections of the shared task training data.

3.6 RNN

Our second system is a bidirectional recurrent neural network (RNN) which reads the context words and then makes a decision based on the representations that it builds. Concretely, it consists on word-level embeddings of size 90, two layers of Gated

REFERENCE RELATIONSHIP	MAXENT	RNN-COMBINED
(1) NP antecedent in previous 2 sentences *e.g. The infectious disease that's killed more humans than any other is* ***malaria****. It's carried in the bites of infected mosquitos, and* ***it****'s probably our oldest scourge.*	***(191/248)** **0.770**	(136/248) 0.548
(2) VP antecedent in previous 2 sentences *e.g. And there's hope in this next section, of this brain section of somebody else with M.S., because what it illustrates is, amazingly, the brain can* ***repair itself****. It just doesn't do* ***it*** *well enough.*	(25/38) 0.658	**(27/38)** **0.711**
(3) NP or VP antecedent further away in the text (not in snippet) *e.g. It has spread. It has more ways to evade attack than we know.* ***It****'s a shape-shifter, for one thing.*	(28/47) 0.596	(28/47) 0.596
(4) Sentential or clausal antecedent e.g. ***Pension systems have a hugely important economic and social role and are affected by a great variety of factors. It*** *has been reflected in EU policy on pensions, which has become increasingly comprehensive over the years.*	(52/88) 0.591	***(66/88)** **0.750**
(5) Pleonastic constructions *e.g. And* ***it*** *seemed to me that there were three levels of acceptance that needed to take place.*	(43/59) 0.729	(42/59) 0.728
(6) Ambiguous between event and anaphoric *e.g. Today, multimedia is a desktop or living room experience, because the apparatus is so clunky .* ***It*** *will change dramatically with small, bright, thin, high-resolution displays.*	(3/12) 0.250	**(7/12)** **0.583**
(7) Ambiguous between event and pleonastic *e.g. I did some research on how much it cost, and I just became a bit obsessed with transportation systems. And* ***it*** *began the idea of an automated car.*	**(2/5)** **0.400**	(1/5) 0.200
(8) Annotation errors *e.g. Youth unemployment is particularly worrying in* ***it*** *context, as the lost opportunity for jobless young people to develop professional skills is likely to translate into lower productivity and lower earnings over a longer period of time.*	(0/4) –	(0/4) –

Table 3: Accuracy scores of the systems in different portions of the test-set. For each category, we test whether MAXENT is better or worse than RNN-COMBINED. A * indicates significance at $p < 0.001$ using McNemar's χ^2 test.

Recurrent Units (GRUs) of size 90 as well, and a final softmax layer to make the predictions. The network uses a context window of 50 tokens both to the left and right of the 'it' to be predicted. The features described above are also fed to the network in the form of one-hot vectors. The system uses the *adam* optimizer and the categorical cross-entropy loss function. We chose this architecture following the example of Luotolahti et al. (2016), who built a system for the related task of cross-lingual pronoun prediction.

4 Discussion

We report all of the results in Table 2. MAXENT and RNN-GOLD are trained on the gold-standard data only. RNN-SILVER is trained on the silver-standard data (annotated using the MAXENT classifier). RNN-COMBINED is trained on both the silver-standard and gold-standard data.

The MAXENT and RNN models show improvements, albeit small for the it-event class, over the baseline systems. Since they are trained on the same gold-standard data, one would expect RNN-GOLD to perform similarly to MAXENT. However, in the case of the RNN-gold, the 50 tokens window may actually not have enough words to be filled with, because the gold-standard data is composed of the sentence with the it-pronoun and the three previous sentences, which in addition tend to be short. For the RNN-SILVER system this is not a problem, since the sentences of interest have not been taken out of their original context, fully exploiting the RNN capacity to learn the entirety of the context window they are presented with, even if the data is noisy. As expected, RNN-COMBINED performs better than RNN-GOLD and RNN-SILVER. Although it does not perform overwhelmingly better than MAXENT, there are gains in precision for the it-anaphoric class, and in recall for the it-pleonastic and it-event classes, suggesting that the system benefits from the inclusion of gold-standard data.

With the two-fold goal of gaining a better understanding of the difficulties of the task and strengths of the systems, we re-classified the test set in a stratified manner. We present the systems with seven scenarios reflecting the different types of reference relationships observed in the corpora (Table 3). Our scenarios are exhaustive, thus some only have few examples. The analysis reveals that the MAXENT is a better choice for nominal reference (case (1), mostly *it-anaphoric*) whereas the RNN-COMBINED system is better at identifying difficult antecedents such as cases (4) and (6). RNN-COMBINED performs slightly better at detecting verbal antecedents, case (2), while both systems perform similarly at learning pleonastic instances (5) or when the antecedent is not in the snippet (3). Finally, we found 4 instances of annotation errors (8). These correspond to some of the automatically substituted cases of 'this'/'that' with 'it', for which the 'this'/'that' should not have been marked as a pronoun by the human annotator in the first place. Case (8) is not taken into account in the evaluation.

Taking the complete test set, we found that the MAXENT system performs better than the RNN-COMBINED system in absolute terms ($\chi^2 = 50.8891, p < 0.001$), but this is because case (1) is the most frequent one, which is also the case the MAXENT system is strongest at.

5 Conclusions and Future Work

We have shown that distinguishing between nominal anaphoric and event reference realizations of 'it' is a complex task. Our results are promising, but there is room for improvement. The self-training experiment demonstrated the benefit of combining gold-standard and silver-standard data.

We also found that the RNN-COMBINED system is better at handling difficult and ambiguous referring relationships, while the MAXENT performed better for the nominal anaphoric case, when the antecedent is close. Since the two models have different strengths, in future work we plan to enrich the training data with re-training instances from the silver data where the two systems agree, in order to reduce the amount of noise, following the example of Jiang et al. (2016).

Ultimately, we aim towards integrating the it-prediction system within a full machine translation pipeline and a coreference resolution system. In the first case, the different translations of pronoun 'it' can be constrained according to their function. In the second case, the performance of a coreference resolution system vs a modified version using the three-way distinction can be measured.

Abstract

Selectional preferences have long been claimed to be essential for coreference resolution. However, they are mainly modeled only implicitly by current coreference resolvers. We propose a dependency-based embedding model of selectional preferences which allows fine-grained compatibility judgments with high coverage. We show that the incorporation of our model improves coreference resolution performance on the CoNLL dataset, matching the state-of-the-art results of a more complex system. However, it comes with a cost that makes it debatable how worthwhile such improvements are.

1 Introduction

Selectional preferences have long been claimed to be useful for coreference resolution. In his seminal work on "Resolving Pronominal References" Hobbs (1978) proposed a semantic approach that requires reasoning about the "demands the predicate makes on its arguments." For example, selectional preferences allow resolving the pronoun *it* in the text *"The Titanic hit an iceberg. It sank quickly."* Here, the predicate *sink* 'prefers' certain subject arguments over others: It is plausible that a ship sinks, but implausible that an iceberg does.

Work on the automatic acquisition of selectional preferences has shown considerable progress (Dagan and Itai, 1990; Resnik, 1993; Agirre and Martinez, 2001; Pantel et al., 2007; Erk, 2007; Ritter et al., 2010; Van de Cruys, 2014). However, today's coreference resolvers (Martschat and Strube, 2015; Wiseman et al., 2016; Clark and Manning, 2016a, i.a.) capture selectional preferences only implicitly at best, e.g., via a given mention's dependency governor and other contextual features.

Since negative results do not often get reported, there is no clear evidence in the literature regarding the non-utility of particular knowledge sources. Consequently, an absence of the explicit modeling of selectional preferences in the recent literature is an indicator that incorporating this knowledge source has not been very successful for coreference resolution.

More than ten years ago, Kehler et al. (2004) declared the "non-utility of predicate-argument structures for pronoun resolution" and observed that minor improvements on a small dataset were due to fortuity rather than selectional preferences having captured meaningful world knowledge relations.

The claim by Kehler et al. (2004) is based on selectional preferences extracted from a, by current standards, small number of 2.8m predicate-argument pairs. Furthermore, they employ a simple (linear) maximum entropy classifier, which requires manual definition of feature combinations and is unlikely to fully capture the complex interaction between selectional preferences and other coreference features. Therefore, it is worth revisiting how a better selectional preference model affects the performance of a more complex coreference resolver.

In this work, we propose a fine-grained, high-coverage model of selectional preferences and study its impact on a state-of-the-art, non-linear coreference resolver. We show that the incorporation of our selectional preference model improves the performance. However, it is debatable whether such small improvements, that cost notable extra time or resources, are advantageous.

2 Modeling Selectional Preferences

The main design choice when modeling selectional preferences is the selection of a relation inventory, i.e. the concepts and entities that can be relation arguments, and the semantic relationships that hold between them.

Prior work has studied many relation inventories. Predicate-argument statistics for word-word pairs (*eat, food*)[1] are easy to obtain but do not generalize to unseen pairs (Dagan and Itai, 1990). Class-based approaches generalize via word-class pairs (*eat, /nutrient/food*) (Resnik, 1993) or class-class pairs (*/ingest, /nutrient/food*) (Agirre and Martinez, 2001), but require disambiguation of words to classes and are limited by the coverage of the lexical resource providing such classes (e.g. WordNet).

Other possible relation inventories include semantic representations such as FrameNet frames and roles, event types and arguments, or abstract meaning representations. While these semantic representations are arguably well-suited to model meaningful world knowledge relationships, automatic annotation is limited in speed and accuracy, making it difficult to obtain a large number of such "more semantic" predicate-argument pairs. In comparison, syntactic parsing is both fast and accurate, making it trivial to obtain a large number of accurate, albeit "less semantic" predicate-argument pairs. The drawback of a syntactic model of selectional preferences is susceptibility to lexical and syntactic variation. For example, *The Titanic sank* and *The ship went under* differ lexically and syntactically, but would have the same or a very similar representation in a semantic framework such as FrameNet.

Our model of selectional preferences (Figure 1) overcomes this drawback via distributed representation of predicate-argument pairs, using (syntactic) dependencies that were specifically designed for semantic downstream tasks, and by resolving named entities to their fine-grained entity types.

Distributed representation. Inspired by Structured Vector Space (Erk and Padó, 2008), we embed predicates and arguments into a low-dimensional space in which (representations of) predicate slots are close to (representations of) their plausible arguments, as should be arguments that tend to fill the same slots of similar predicates, and predicate slots that have similar arguments. For example, *captain* should be close to *pilot*, *ship* to *airplane*, the subject of *steer* close to both *captain* and *pilot*, and also to, e.g., the subject of *drive*. Such a space allows judging the plausibility of unseen predicate-argument pairs.[2]

We construct this space via dependency-based word embeddings (Levy and Goldberg, 2014). To see why this choice is better-suited for modeling selectional preferences than alternatives such as word2vec (Mikolov et al., 2013) or GloVe (Pennington et al., 2014), consider the following example:

$$\begin{array}{ccccc} \text{captain} & \xleftarrow{\text{nsubj}} & \text{steers} & \xrightarrow{\text{dobj}} & \text{ship} \\ :: & & & & :: \\ \text{pilot} & \xleftarrow{\text{nsubj}} & \text{steers} & \xrightarrow{\text{dobj}} & \text{airplane} \end{array}$$

Here, *captain* and *ship*, have high syntagmatic similarity, i.e., these words are semantically related and tend to occur close to each other. This also holds for *pilot* and *airplane*. In contrast, *captain* and *pilot*, as well as *ship* and *airplane* have high paradigmatic similarity, i.e., they are seman-

[1] Examples due to Agirre and Martinez (2001).

[2] Prior work generalizes to unseen predicate-argument pairs via WordNet synsets (Resnik, 1993), a generalization corpus (Erk, 2007), or tensor factorization (Van de Cruys, 2010). Closest to our approach is neural model by Van de Cruys (2014), which, however, has much lower coverage since it is limited to 7k verbs and 30k arguments.

tically similar and occur in similar contexts. A model of selectional preferences requires paradigmatic similarity: The representations of *captain* and *pilot* in such a model should be similar, since they both can plausibly fill the subject slot of the predicate *steer*. Due to their use of linear context windows, word2vec and GloVe capture syntagmatic similarity, while dependency-based embeddings capture paradigmatic similarity (cf. Levy and Goldberg, 2014).

Enhanced++ dependencies. Due to distributed representation, our model generalizes over syntactic variation such as active/passive alternations: For example, *steer@dobj*[3] is highly similar to *steer@nsubjpass* (see Appendix for more examples). To further mitigate the effect of employing syntax as a proxy for semantics, we use Enhanced++ dependencies (Schuster and Manning, 2016). Enhanced++ dependencies aim to support semantic applications by modifying syntactic parse trees to better reflect relations between content words. For example, the plain syntactic parse of the sentence *Both of the girls laughed* identifies *Both* as subject of *laughed*. The Enhanced++ representation introduces a subject relation between *girls* and *laughed*, which allows learning more meaningful selectional preferences: Our model should learn that girls (and other humans) laugh, while learning that an unspecified *both* laughs is not helpful.

Fine-grained entity types. A good model of selectional preferences needs to generalize over named entities. For example, having encountered sentences like *The Titanic sank*, our model should be able to judge the plausibility of an unseen sentence like *The RMS Lusitania sank*. For popular named entities, we can expect the learned representations of *Titanic* and *RMS Lusitania* to be similar, allowing our model to generalize, i.e., it can judge the plausibility of *The RMS Lusitania sank* by virtue of the similarity between *Titanic* and *RMS Lusitania*. However, this will not work for rare or emerging named entities, for which no, or only low-quality, distributed representations have been learned. To address this issue, we incorporate fine-grained entity typing (Ling and Weld). For each named entity encountered during training, we generate an additional training instance by replacing the named entity with its entity type, e.g. *(Titanic, sank@nsubj)* yields *(/product/ship, sank@nsubj)*.

3 Implementation

We train our model by combining term-context pairs from two sources. Noun phrases and their dependency context are extracted from GigaWord (Parker et al., 2011) and entity types in context from Wikilinks (Singh et al., 2012). Term-context pairs are obtained by parsing each corpus with the Stanford CoreNLP dependency parser (Manning et al., 2014). After filtering, this yields ca. 1.4 billion phrase-context pairs such as *(Titanic, sank@nsubj)* from GigaWord and ca. 12.9 million entity type-context pairs such as *(/product/ship, sank@nsubj)* from Wikilinks. Finally, we train dependency-based embeddings using the generalized word2vec version by Levy and Goldberg (2014), obtaining distributed representations of selectional preferences. To identify fine-grained types of named entities at test time, we first perform entity linking using the system by Heinzerling et al. (2016), then query Freebase (Bollacker et al., 2008) for entity types and apply the mapping to fine-grained types by Ling and Weld.

The plausibility of an argument filling a particular predicate slot can now be computed via the cosine similarity of their associated embeddings. For example, in our trained model, the similarity of *(Titanic, sank@nsubj)* is 0.11 while the similarity of *(iceberg, sank@nsubj)* is -0.005, indicating that an iceberg sinking is less plausible.

4 Do Selectional Preferences Benefit Coreference Resolution?

We now investigate the effect of incorporating selectional preferences, implicitly and explicitly, in coreference resolution.

Figure 2 shows the selectional preference similarity of 10.000 coreferent and 10.000 non-coreferent mention pairs sampled randomly from the CoNLL 2012 training set. As we can see, while coreferent mention pairs are more similar than non-coreferent mention pairs according to the selectional preference similarity, there is not a direct relation between the similarity values and the coreferent relation. This indicates that coreference does not have a linear relation to the selectional preference similarities. However, it is worth investigating how these similarity values affect the overall performance when they are combined with

[3] In this work, a predicate's argument slots are denoted *predicate@slot*.

other knowledge sources in a non-linear way.

We select the ranking model of deep-coref (Clark and Manning, 2016b) as our baseline. deep-coref is a neural model that combines the input features through several hidden layers. *Baseline* in Table 1 reports our baseline results on the CoNLL 2012 test set. The results are reported using *MUC* (Vilain et al., 1995), B^3 (Bagga and Baldwin, 1998), *CEAF$_e$* (Luo, 2005), the average F_1 score of these three metrics, i.e. CoNLL score, and *LEA* (Moosavi and Strube, 2016b). deep-coref includes the embeddings of the dependency governor of mentions. Combined with the relative position of a mention to its governor, deep-coref may be able to implicitly capture selectional preferences to some extent. *−gov* in Table 1 represents deep-coref performance when governors are not incorporated. As we can see, the exclusion of the governor information does not affect the performance. This result shows that the implicit modeling of selectional preferences does not provide any additional information to the coreference resolver.

	MUC	B^3	CEAF$_e$	CoNLL	LEA
	development

+embedding	74.53	63.41	59.03	65.66	59.69
+binned sim.	74.85	63.64	59.21	65.90	59.98

Table 2: Incorporating the selectional preference model as new embeddings (+embedding) vs. as new pairwise features (+binned sim.).

For each mention, we consider (1) the whole mention string, (2) the whole mention string without articles, (3) mention head, (4) context representation, i.e. governor@dependency-relation, and (5) entity types if the mention is a named entity. We obtain an embedding for each of the above properties if they exist in the selectional preference model, otherwise we set them to unknown.

For each (antecedent, anaphor) pair, we consider all the acquired embeddings of anaphor and antecedent. We try two different ways of incorporating this knowledge into deep-coref including: (1) incorporating the computed embeddings directly as a new set of inputs, i.e. +*embedding* in Table 2. We add a new hidden layer on top of the new embeddings and combine its output with outputs of the hidden layers associated with other sets of inputs; and (2) computing a similarity value between all possible combinations of the antecedent-anaphor acquired embeddings and then binarizing all similarity values, i.e. +*binned sim.* in Table 2.

Providing selectional preference embeddings directly to deep-coref adds more complexity to the baseline coreference resolver. Yet, it performs on-par with +*binned sim.* on the development set and generalizes worse on the test set. +*SP* in Table 1 is the performance of +*binned sim.* on the test set. As we can see from the results, adding selectional

Table 4: Differences in the number of recall and precision errors on the CoNLL'12 test set in comparison to the baseline.

preferences as binary features improves over the baseline.

Reinforce in Table 1 presents the results of the reward-rescaling model of Clark and Manning (2016a) that are so far the highest reported results on the official test set. The reward rescaling model of Clark and Manning (2016a) casts the ranking model of Clark and Manning (2016b) in the reinforcement learning framework which considerably increases the training time, from two days to six days in our experiments.

We analyze how our selectional preference model affects the resolution of various types of mentions. We use Martschat and Strube (2014)'s toolkit [4] to perform recall and error analyses. The differences in the number of recall and precision errors in *+SP* compared to *baseline* on the test set are reported in Table 4.

By using our selectional preference features, the number of recall errors decreases for all types of mentions. The recall error reduction is more prominent for pronouns. On the other hand, the number of precision errors increases for all types of mentions. The increase in the precision error is the highest for common nouns. Overall, *+SP* creates about 260 more links than *baseline*.

Table 3 lists a few examples from the development set in which *+SP* creates a link that *baseline* does not. It also includes the similarity that has a high value for the linked mentions and probably is the reason for creating the link. For instance, in the first example, based on our model, similarity(*impact@nsubj,shows@nsubj*) is known and it is also higher than similarity(*impact@dobj,shows@nsubj*).

In order to estimate a higher bound on the expected performance boost, we run the *baseline* and *+SP* models only on anaphoric mentions. By using anaphoric mentions, the performance improves by one percent, based on both the CoNLL score and *LEA*. This result indicates that the incorporation of selectional preferences creates many links for non-anaphoric mentions, which in turn decreases precision. Therefore, the overall performance does not improve substantially when system mentions are used. deep-coref incorporates anaphoricity scores at resolution time. One possible way to further improve the results of *+SP* is to incorporate anaphoricity scores at the input level. In this way, the coreference resolver could learn to use selectional preferences mainly for mentions that are more likely to be anaphoric. However, given that the F_1 score of current anaphoricity determiners or singleton detectors is only around 85 percent (Moosavi and Strube, 2016a, 2017), the effect of using system anaphoricity scores might be small.

5 Conclusions

We introduce a new model of selectional preferences, which combines dependency-based word embeddings and fine-grained entity types. In order to be effective, a selectional preference model should (1) have a high coverage so it can be used for large datasets like CoNLL, and (2) be combined with other knowledge sources in a non-linear way. Our selectional preference model slightly improves coreference resolution performance, but considering the extra resources that are required to train the model, it is debatable whether such small improvements are advantageous for solving coreference.

Abstract

Topic segmentation plays an important role for discourse parsing and information retrieval. Due to the absence of training data, previous work mainly adopts unsupervised methods to rank semantic coherence between paragraphs for topic segmentation. In this paper, we present an intuitive and simple idea to automatically create a "quasi" training dataset, which includes a large amount of text pairs from the same or different documents with different semantic coherence. With the training corpus, we design a symmetric CNN neural network to model text pairs and rank the semantic coherence within the learning to rank framework. Experiments show that our algorithm is able to achieve competitive performance over strong baselines on several real-world datasets.

1 Introduction

The goal of topic segmentation is to segment a document into several topically coherent parts, with different parts corresponding to different topics. Topic segmentation enables better understanding of document structure, and makes long document much easier to navigate. It also provides helpful information for tasks such as information retrieval, topic tracking etc (Purver, 2011).

Due to the lack of large scale annotated topic segmentation dataset, previous work mainly focus on unsupervised models to measure the coherence between two textual segments. The intuition behind unsupervised models is that two adjacent segments from the same topic are more coherent than those from different topics. Under this intuition, one direction of research attempts to measure coherence by computing text similarity. The typical methods include *TextTiling* (Hearst, 1997) and its variants, such as *C99* (Choi, 2000), *TopicTiling* (Riedl and Biemann, 2012b) etc. The other direction of research develops topic modeling techniques to explore topic representation of text and topic change between textual segments (Yamron et al., 1998; Eisenstein and Barzilay, 2008; Riedl and Biemann, 2012a; Du et al., 2013; Jameel and Lam, 2013). With carefully designed generative process and efficient inference algorithm, topic models are able to model coherence as latent variables and outperform lexical similarity based models.

Though unsupervised models make progress in modeling text coherence, they mostly suffer from one of the following two limitations. First, it is not precise to measure coherence with text similarity, since text similarity is just one aspect to influence coherence. Second, many assumptions and manually set parameters are usually involved in the complex modeling techniques, due to the absence of supervised information. To overcome aforementioned limitations, we prefer to directly model the text coherence by exploring possible supervised information. Then, we can learn a function $f(s1, s2)$ which takes two textual segments $s1$ and $s2$ as input, and directly measure their semantic coherence.

As we know, it is hard to directly compile and collect a large number of samples with coherence scores labeling. Here we propose an intuitive and simple strategy to automatically create a "quasi" training corpus for supervision. It is a common sense that the original documents written by human are generally more coherent than a patchwork of sentences or paragraphs randomly extracted from different documents. In such cases, two textual segments from the same document are more coherent than those from different documents, and two segments from the same paragraph

Proceedings of the 2017 Conference on Empirical Methods in Natural Language Processing, pages 1340–1344
Copenhagen, Denmark, September 7–11, 2017. ©2017 Association for Computational Linguistics

are more coherent than those from different paragraphs. Then, we can get a large set of text pairs with partial ordering relations, which denote some text pairs are more coherent than other text pairs. With these ordering information, we propose to apply the learning to rank framework to model the semantic coherence function $f(s1, s2)$, based on which topic boundaries are identified.

The next key problem is how to model and represent text pairs. It is fortunate that neural networks have emerged as a powerful tool for modeling text pairs (Lu and Li, 2013; Severyn and Moschitti, 2015; Yin et al., 2015; Hu et al., 2014), freeing us from feature engineering. In this paper, we develop a symmetric convolutional neural network (CNN) framework, whose main idea is to jointly model text representation and interaction between texts. With our acquired large amount of training data, our CNN-based method is capable of reasonably rank semantic coherence and further conduct topic segmentation.

2 Model

2.1 Coherence Ordering between Text Pairs

In our work, we define $f(s1, s2)$ as a function, which returns a real number as semantic coherence score of the text pair <s1,s2>. To model $f(s1, s2)$ of any text pair, we aim to explore the partial ordering relations of coherence between different text pairs, since it is hard to get a corpus with labeled coherence scores.

Next, we exploit the two types of ordering relations stated in Section 1. To formalize, we notate a collection of documents as D. Each document $d_i \in D$ consists of several paragraphs, and each paragraph $p_j \in d_i$ consists of several sentences. We use $T_{ij}^{s:(s+k)}$ to represent a text segment covering k sentences starting from the s-th sentence in document d_i's j-th paragraph. To make symbols less cluttered, we omit k and simply use T_{ij}^{s} for the same meaning. A text pair $< T_{ij}^{s}, T_{i'j'}^{s'} >$ is a tuple of two text segments.

The first one ordering relation is: coherence score of a text pair from different documents is lower than that from the same document. Formally, its mathematical expression is shown below:

$$f(< T_{i\cdot}^{\cdot}, T_{i'\cdot}^{\cdot} >) < f(< T_{jm}^{\cdot}, T_{jm'}^{\cdot} >), \quad i \neq i', m \neq m' \tag{1}$$

where dot $\cdot$ means arbitrary value.

The second one is: coherence score of text pair from different paragraphs is lower than those from the same paragraph, as represented below.

$$f(< T_{ip}^{\cdot}, T_{ip'}^{\cdot} >) < f(< T_{jq}^{n}, T_{jq}^{n+k} >), p \neq p' \tag{2}$$

As our defined relations are partially ordering, they have the properties of reflexivity, transitivity, and antisymmetry, Then we can easily infer that coherence score of a text pair from different documents is also lower than that from the same paragraph.

2.2 Learning to Rank Semantic Coherence

Learning to rank is a widely used learning framework in the field of information retrieval (Liu et al., 2009). There are generally three formulations (Li, 2011): *pointwise ranking*, *pairwise ranking*, and *listwise ranking*. The goal is to learn a ranking function $f(\mathbf{w}, tp_i) \to y_i$ where tp_i denotes a text pair <s1,s2>. f maps tp_i to a real value y_i which is semantic coherence score in this paper, $\mathbf{w}$ is weight vector. We examine both *pointwise ranking* and *pairwise ranking* methods, *listwise ranking* is not naturally fit for our task, so it is not discussed here.

2.2.1 Pointwise Ranking

For pointwise formulation, $y_i = f(\mathbf{w}, tp_i) \in [0, 1]$ computes inner product between weight vector $\mathbf{w}$ and text pair tp_i's representation vector $\mathbf{h_i}$. Here we apply a $sigmoid$ non-linearity function.

$$y_i = \sigma(\mathbf{w} \cdot \mathbf{h_i}) \tag{3}$$

Representation vectors $\mathbf{h_i}$ of the text pair can be jointly learned through a neural network, which will be introduced in next subsection.

To conform to the partial ordering relations, we score each training instance tp_i as follows.

$$y_i^* = \begin{cases} 0, & \text{If } tp_i \text{ comes from different documents.} \\ 1, & \text{If } tp_i \text{ comes from same paragraph.} \\ \alpha, & \text{If } tp_i \text{ comes from different paragraphs.} \end{cases}$$

where $0 < \alpha < 1$ and α is a hyper-parameter chosen to maximize performance on validation dataset.

With N training instances, we formulate the coherence scoring as a regression problem and use cross entropy as loss function:

$$\min -\frac{1}{N}\sum_{i=1}^{N}(y_i \log y_i^* + (1-y_i)\log(1-y_i^*)) \tag{4}$$

Generally speaking, *pointwise ranking* is simple, scalable and efficient to train.

2.2.2 Pairwise Ranking with Sampling

Pairwise formulation explicitly compares each pair of training instance and requires a minimal margin ϵ between their ranking score.

$$f(\mathbf{w}, tp_i) > f(\mathbf{w}, tp_j) + \epsilon \quad (5)$$

Here, the text pair tp_i has a higher ranking score than tp_j, and $y_i = f(\mathbf{w}, tp_i) \in (-\infty, +\infty)$. Without loss of generality, we set $\epsilon = 1$ and use squared hinge loss as optimization function.

$$\min \ -\frac{1}{M}\sum_{i,j} max(0, 1 + y_j - y_i)^2 \quad (6)$$

where M is the number of pairs we need to compare. As we can see, in our problem setting, $M \approx N^2$, which makes M an extremely large number when $N \approx 10^5$.

To make training feasible, we adopt a straightforward sampling mechanism, which randomly samples pairs from different groups to construct a mini-batch on the fly during training.

Pairwise ranking is reported to have better performance than *pointwise ranking*, but it is less efficient to train.

2.3 Semantic Coherence Neural Network

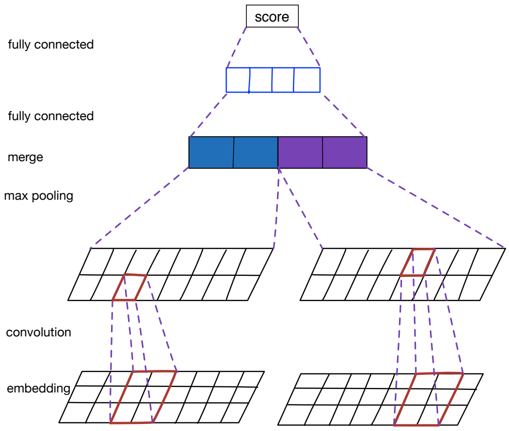

Figure 1: Semantic Coherence Neural Network

To model the text pair instances, we develop a symmetric convolutional neural network (CNN) architecture, as shown in Figure 1. Our model consists of two symmetric CNN models, and the two CNNs share their network configuration and parameters. Each CNN converts one text into a low-dimensional representation, and two generated text representation vectors are finally concatenated and fed into the scoring layer to get a real value as the coherence score.

2.4 Inference

At test time, coherence scores between any two adjacent paragraphs are computed. $T - 1$ paragraph boundaries with lowest semantic coherence score are chosen as topic boundaries, where T is ground-truth number of topics.

This inference procedure is computationally efficient. Unlike *TextTiling*, it doesn't need to calculate a so-called "depth score".

3 Experiments

3.1 Experimental Setup

Data In order to train our ranking neural network, we use full *English Wikipedia dump*, which consists of more than 5 million documents, to automatically construct text pairs.

For performance evaluation, we use topic segmentation dataset from (Jeong and Titov, 2010)[1]. This dataset consists of 864 manually labeled documents from four different areas, as shown in Table 1.

	News	*Lecture*	*Report*	*Biography*
#documents	184	120	160	400

Table 1: Overview of four datasets.

Baselines To compare with our method, *TextTiling* (Hearst, 1997), *TopicTiling* (Riedl and Biemann, 2012b) and *BayesSeg* (Eisenstein and Barzilay, 2008) are adopted as three baselines. We use open source implementations of *TextTiling*[2] and *TopicTiling*[3], and results of *BayesSeg* are from (Jeong and Titov, 2010).

Hyperparameters Our neural network implementation is based on *Tensorflow* (Abadi et al., 2015). We use pre-trained 50 dimensional *Glove* vectors (Pennington et al., 2014)[4] for word embeddings initialization. Each text pair consists of 2 text segments, and each text segment consists of

[1] We do not compare with *MultiSeg* model proposed by (Jeong and Titov, 2010), since our model is for single-document topic segmentation while *MultiSeg* is for multi-document topic segmentation.

Ours-point-static	**0.173**	**0.175**	**0.587**	0.176	**0.179**	**0.608**	**0.240**	**0.241**	**0.529**	0.216	0.219	**0.479**

Table 2: Experimental results. (a) *Ours-pair-finetune* is pairwise ranking model with word embedding fine-tuning. (b) *Ours-point-static* is pointwise ranking model without word embedding fine-tuning, etc.

no more than 3 sentences. Stop words and digits are removed from input text, and all words are converted to lowercase. We pad input sequence to 40 tokens. In order to capture information of different granularity, convolution window size of both 2 and 3 are used, with 64 filters for each window size. L2 regularization coefficient is set to 0.001. *Adam* algorithm (Kingma and Ba, 2014) is used for loss function minimization. We set α to 0.7 for *pointwise ranking*.

Evaluation System performance is evaluated according to three metrics: P_k (Beeferman et al., 1999), WindowDiff(WD) (Pevzner and Hearst, 2002) and $F1$ score. P_k and WD are calculated based on sliding windows, and can assign partial score to incorrect segmentation. Note that P_k and WD are penalty metrics, smaller value means better performance.

3.2 Results and Analysis

Experimental results are shown in Table 2. Our proposed model is examined in 4 different settings, including whether to use *pointwise ranking* or *pairwise ranking* algorithm, and whether to fine-tune word embeddings or not. The best model *Ours-pointwise-static* is able to achieve better or competitive performance compared to *BayesSeg* and *TopicTiling* according to all three metrics, especially on *News* dataset. *TopicTiling* is reported to perform well on heuristically constructed dataset (Riedl and Biemann, 2012b), but behave mediocre on manually labeled dataset in our experiments.

One interesting phenomenon is that fine-tuned word embeddings has negative impact on overall performance, which is generally not the case in many NLP tasks. The reason may be that our task involves domain adaptation, and word embeddings should generalize well across different domains rather than adapt to *Wikipedia* text. Though our proposed sampling mechanism enables easier training of *pairwise ranking* model, it inevitably loses some ordering information, which makes *pairwise ranking* model perform slightly worse than *pointwise ranking* model.

Text Pair	Score
A: A variety of techniques have been directed toward the study of blood group antibodies. **B:** If I'd work on my place-kicking he thought he could use me.	0.022
A: A second miracle is required for her to proceed to canonization. **B:** Mother Teresa inspired a variety of commemorations.	0.587
A: Plants have an amazing ability to respond to stimuli from their environment. **B:** These responses to environmental factors are known as tropisms.	0.861

Table 3: Coherence Score between Text Pairs.

To illustrate what the model has learned, we show some typical examples of coherence score for text pair **<A**,**B>** in Table 3. There is almost no lexical overlap for all the three text pairs, cosine similarity between one-hot vectors would surely fail to rank them, even though *"canonization"* and *"commemorations"*, *"respond"* and *"responses"*, *"environment"* and *"environmental"* are closely related semantically. As we expect, our proposed model is able to capture such semantic relatedness and assign reasonable score to each text pair, which is a key to topic boundary detection.

4 Conclusion

This paper proposes a novel approach for topic segmentation by learning to rank semantic coherence. Symmetric convolutional neural network is used for text pair modeling. Training data can be automatically constructed from unlabeled documents, and no labeled data is needed. Experiments show promising performance on dataset from various domains.

GrASP: Rich Patterns for Argumentation Mining

Eyal Shnarch **Ran Levy*** **Vikas Raykar**‡ **Noam Slonim**
IBM Research - Haifa, Israel
‡IBM Research - Bangalore, India

Abstract

We present the GrASP algorithm for automatically extracting patterns that characterize subtle linguistic phenomena. To that end, GrASP augments each term of input text with multiple layers of linguistic information. These different facets of the text terms are systematically combined to reveal rich patterns. We report highly promising experimental results in several challenging text analysis tasks within the field of Argumentation Mining. We believe that GrASP is general enough to be useful for other domains too.

1 Introduction

Many standard text analysis tasks can be addressed relatively well while exploiting simple textual features, e.g., Bag-Of-Words representation and Naive Bayes for document classification (McCallum and Nigam, 1998). However, the identification of more subtle linguistic phenomena, that are further reflected via relatively short texts – as opposed to whole documents – may require a wider spectrum of linguistic features.

The main contribution of this work is in outlining a simple method to automatically extract rich linguistic features in the form of patterns, and demonstrate their utility on tasks related to *Argumentation Mining* (Mochales Palau and Moens, 2009), although we believe that the proposed approach is not limited to this domain.

Argumentation mining involves automatically identifying argumentative structures within a corpus – e.g., claims or conclusions, and evidence instances or premises – as well as their interrelations. For instance, each of the following sentences includes a *claim* for a **[topic]**.

1. Opponents often argue that *the open primary is unconstitutional.* **[Open Primaries]**
2. Prof. Smith suggested that *affirmative action devalues the accomplishments of the chosen.* **[Affirmative Action]**
3. The majority stated that *the First Amendment does not guarantee the right to offend others.* **[Freedom of Speech]**

These sentences share almost no words in common, however, they are similar at a more abstract level. A human observer may notice the following underlying common structure, or *pattern*: `[someone][argue/suggest/state][that]` `[topic term][sentiment term]`

We present GrASP, standing for GReedy Augmented Sequential Patterns, an algorithm that aims to automatically capture such underlying structures of the given data. Table 1 shows the pattern that GrASP may find for the above examples, along with its matches in those texts. Such patterns can then be used to detect the existence of the phenomenon in new texts.

The algorithm starts with augmenting the terms of the input with various layers of *attributes*, such as hypernyms from WordNet (Fellbaum, 1998), named entity types, and domain knowledge (Section 3.1). This multi-layered representation enables GrASP to consider many facets of each term. Next, it finds the most indicative attributes (Section 3.2) and iteratively grows patterns by blending information from different attributes (Section 3.3). A greedy step is performed at the end of each iteration, when the algorithm only keeps the top *k* patterns, ranked by their predictive power. This results with a set of cross-layered patterns whose match in a given text instance suggests the appearance, or the non-appearance, of the target phenomenon.

Researchers can add layers of attributes of different kinds without being worried about which of

[*] First two authors contributed equally.

[noun]		[express]	[that]		[noun,topic]		[sentiment]	
Opponents	often	argue	that	the	open primary	is	unconstitutional	.
Prof. Smith		suggested	that		affirmative action		devalues	the ...
The majority		stated	that	the	First Amendment	does not guarantee ... to	offend	others.

Table 1: Claim sentences aligned by their common underlying pattern. [express] stands for all its (in)direct hyponyms, and [noun,topic] means a noun which is also related to the topic.

them are useful for the detection of the target phenomenon, and how to combine them. GrASP performs feature selection while generating complex patterns out of these attributes that best capture aspects of the target phenomenon.[1]

In experiments over different argumentation mining tasks, we show that GrASP outperforms classical techniques, and boosts full argumentation mining systems when added to them.

2 Background

While some aspects of GrASP were considered in the past, to the best of our knowledge, no prior work has presented a framework that allows users to: (i) easily add any type of attribute to the pattern alphabet, and (ii) consider **all** attributes when searching for patterns. GrASP provides a framework to integrate information from different layers, choosing the best combination to produce highly expressive patterns.

The alphabet of Hearst (1992) patterns is mainly stop words and noun-phrase tags, while Snow et al. (2004) add syntactic relations. Yangarber et al. (2000) consider a larger set of attributes (e.g., named entities, numeric expressions), however they commit to one generalization of each term. In contrast, we do not limit our alphabet and systematically consider all attributes of each term.

Riloff and Wiebe (2003) start with a small set of syntactic templates, composed of a single syntactic relation and a single POS tag, to learn a variety of lexicalized patterns that match these templates. RAPIER (Califf and Mooney, 2003) constraints are similar to our attributes, but are basic (surface form, POS tag, and hypernyms only), and expanding them will exponentially increase its complexity. In contrast, adding attributes to GrASP only increment runtime linearly (see Section 3.2).

To summarize, prior works usually have a basic alphabet and commit to one rule to generalize each term. Commonly, they do not allow gaps between their elements, nor assigning several attributes to a single element of the pattern.

Such characteristics are presented in *sequential patterns* (Agrawal and Srikant, 1995) which are mainly used for data mining and rarely for unstructured text (Jindal and Liu, 2006). GrASP also has these characteristics, and in addition it can learn *negative* patterns, indicating that the examined text *does not* contain the target phenomenon.

The phenomena we target are from the area of Argumentation Mining (see Lippi and Torroni (2016) for a survey). We focus on open-domain argument extraction. In this context, Levy et al. (2014) detect claims relevant to a debatable topic, Lippi and Torroni (2015) defined the context-*independent* claim detection task, and Rinott et al. (2015) introduced the context dependent evidence detection task (which is further split into different types of evidence, e.g., a *study* that supports a claim or a relevant *expert* testimony). These tasks aim to capture a subtle and rare linguistic phenomenon within large corpora, hence are suitable for demonstrating the potential of GrASP.

3 The GrASP Algorithm

The algorithm depicted in Algorithm 1. Its input is a set of positive and negative examples for the target phenomenon. The output is a ranked list of patterns, aiming to indicate the presence – or absence – of this phenomenon. In the following, a pattern is considered to be *matched* in a text iff all its elements are found in it, in the specified order, possibly with gaps between them, within a window of size w.

3.1 Multi-Layered Term Representations

Consider the verbs (argue/suggest/state) in the examples in Section 1. Using the POS tag *verb* to generalize them will end up with an overly general representation, while their hypernym, *express*, offers a better level of generalization.

Aiming to formalize this intuition, we start by augmenting each term in the input with a variety of linguistic *attributes* such as its POS tag, its syntac-

         $chooseTopK(patterns \cup current, k_2)$
14 return patterns
```

tic relation in a parse tree, and semantic attributes such as its hypernyms, WordNet superclasses, indications whether it is a named entity, and whether it bears a sentiment.[2] This attributes set can serve as a starting point for many text analysis tasks.

In addition, GrASP allows to add task-specific attributes. Thus, for context-dependent arguments detection we add boolean attributes indicating whether the term is related to the topic, whether it appears in a lexicon characterizing argumentative texts, or in a lexicon characterizing the topic.[3]

After augmentation, the representation of *argue*, from the first example, is: `[argue, VB, hypernyms={present, state, express}, in claim lexicon, root node, supeclass = communication]`.

3.2 Defining the Patterns Alphabet

The augmented representation, described above, is the first step (line 1 in Algorithm 1). Next, we define the alphabet of attributes that will be used to compose longer patterns (lines 2–3). To that end, we first discard non-frequent attributes that are matched in less than t_1 of all input examples.

Then, we sort all remaining attributes by their information gain (Mitchell, 1997) with the label, and select the top k_1 attributes. We discard redundant attributes whose correlation to some previously selected attribute is above t_2, measured by the normalized mutual information (Cover and Thomas, 2006). The selected k_1 attributes constitute the *alphabet* of the algorithm, or "patterns" of length 1. Note that considering additional attributes only affects this first iteration, and only increases it linearly.

3.3 Growing Patterns

Learning longer patterns is done by iteratively growing patterns selected in previous iterations, keeping only the most indicative ones (lines 6–13). We apply two methods for growing a pattern, p (e.g., `[noun]`) w.r.t. an attribute a (e.g., *obj*): (i) grow right – add a as another term in the pattern (i.e., `[noun][obj]`); (ii) grow inside – add a as another attribute to the last term of p, making it more specific (i.e., `[noun, obj]`). After each iteration (line 13), the top k_2 patterns are kept (after sorting by information gain and discarding redundant ones). Iterations continue till reaching *maxLen*.

Since GrASP relies on information gain for sorting, it can identify indicative *negative* patterns, implying that the target phenomenon is *less likely* to be presented in the examined example if such patterns were matched in it.

GrASP can be seen as a simple formal interface, allowing the user to examine a wide range of information sources letting the algorithm to select and combine them all and come up with the most useful patterns.

4 Evaluation and Results

In the following experiments we used a logistic regression classifier on top of the extracted patterns. Each pattern is used as a binary feature, which receives value of 1 iff it is matched in the candidate.

To demonstrate the robustness of the this approach, in all experiments we report the results of a single configuration of GrASP parameters, selected based on a quick analysis over a small portion of the claim-sentence detection data (task (a) below).[4] Specifically, we used minimal frequency threshold $t_1 = 0.005$, correlation threshold $t_2 = 0.5$, size of the alphabet $k_1 = 100$, number of patterns in the output $k_2 = 100$, maximal pattern length *maxLen* $= 5$, and window size $w = 10$.

This configuration is by no means the optimal one, and we saw that by carefully tuning the parameters per task, results were improved.

[2] We used OpneNLP POS tagger, Stanford NER, McCord and Bernth (2010) parser, WordNet superclasses, and the lexicon in Hu and Liu (2004) for sentiment words.

[3] We utilize existing lexicons, learning them is out of the scope of this work.

[4] We randomly chose 10 topics. The performance over them was somewhat inferior to that over all 58 topics.

	(a) Claim sentence			(b) Expert evidence			(c) Study evidence		
system	P@5	P@10	P@20	P@5	P@10	P@20	P@5	P@10	P@20

4.1 Direct Evaluation

We consider three context-dependent argumentation mining tasks: (a) Claim sentence detection (Levy et al., 2014), (b) Expert evidence detection, and (c) Study evidence detection. The latter two tasks are described in Rinott et al. (2015), where the goal is to detect sentences that can be used as an evidence to support/contest the topic.[5]

The benchmark data for these tasks was extracted from the data released by Rinott et al. (2015), consisting of 547 Wikipedia articles in which claims and evidence instances were manually annotated, in the context of 58 debatable topics. In all tasks the data is highly skewed towards negative examples (only 2.5% of 80.5K instances are positives in task (a), 4% of 55.6K in task (b), and 3.7% of 31.8K in task (c)), making these tasks especially challenging.

As (Levy et al., 2014; Rinott et al., 2015) we use a leave-one-topic-out schema; training over 57 topics, testing over the left out topic.

Our group develops debate supportive technologies which can assist humans to reason, make decisions, or persuade others.[6] Since in this scenario humans mainly consider top results (similar to information retrieval), precision is more relevant than recall. Thus, we report the macro-averaged Precision@K, where $K \in \{5, 10, 20\}$.

We considered the following baselines:

Naive Bayes: over BOW representation, discarding unigrams which appear less than 10 times.

Basic Patterns: a baseline that reflects common practices in the literature where a pattern is a consecutive ordered list of stop words or POS tags. We add a symbol for topic match (for the context-dependent tasks). A brute force process generates all possible patterns up to size *maxLen* and selects top k by the same procedure as GrASP. For each task we report the best results obtained with $k \in \{50, 100, .., 400\}$.

Convolutional Neural Network (CNN): following (Kim, 2014; Vinyals and Le, 2015) we used CNN whose input is a concatenation of the topic and the candidate.[7] The final state vector is fed to a LR soft-max layer. Cross-entropy loss function was used for training. The embedding layer was initialized using word2vec vectors (Mikolov et al., 2013). Hyper-parameters were tuned on the same portion of the dataset as used by GrASP for tuning.

For these baselines, we are not aware of available methods to incorporate GrASP multi-layered representation.

GrASP alphabet: a simplified version of GrASP which uses the chosen alphabet, or "patterns" of length 1. This baseline does utilize all the information available for GrASP.

Table 2 shows that *Naive Bayes* performance is the lowest, demonstrating that a simple representation is not sufficient for such complex tasks. Using *Basic patterns* yields better performance, and *CNN* performs even better. *GrASP alphabet* outperforms CNN, indicating the potential of explicitly incorporating linguistic information. Finally, using the patterns extracted by *GrASP* outperforms all other methods, emphasizing the added value of constructing patterns over the initial contribution of the multi-layered representation.

GrASP provides an easy way to analyze the importance of each attribute by inspecting its score at the end of the first iteration, the one which determines the alphabet. For example, *PERCENT* score was very high in the alphabet for Study evidence patterns (task b), and *Person* and *Organization* were ranked high in the alphabet of the Expert evidence (task c). Still, these three named enti-

[5] We did not examine the Anecdotal type due to the small size of the available benchmark data.

[6] for more details see IBM Debating Technologies.

[7] RNN, LSTM (Hochreiter and Schmidhuber, 1997) and GRU (Cho et al., 2014) were also considered but resulted with inferior performance.

system	P@5	P@10	P@20	P@50	R@50
Levy14	–	–	–	18	40
Levy14-rep	30.9	27.3	23.5	17.6	38.4
GrASP	32.7	30	23.9	17.5	36.2
Combined	**40***	**32.4***	**28***	**20.2***	**43.2***

Table 3: Adding GrASP to a full claim detection system. Significant results in comparison to Levy14-rep are marked by * (paired t-test with $p < 0.02$).

ties were not selected as part of the alphabet for Claim sentences (task a) – reflecting the importance of *PERCENT* in sentences describing studies and their numeric results, and the importance of authoritative source (either *Person* or *Organization*) in evidence based on expert testimonies.

For task (a) we performed two ablation tests, each of them yielded a decrease in performance: (i) not limiting the match of a pattern in a window (a decrease of 10.3 for P@5 and 2.8 for P@20), and (ii) not enforcing the order defined by the pattern (a decrease of 7.6 for P@5 and 2.8 for P@20).

4.2 Indirect Evaluation

In this evaluation we add GrASP patterns as additional features to the full claim detection system of Levy et al. (2014) to inspect their contribution. This evaluation is performed on a second claim detection benchmark (on which they have reported results), released by Aharoni et al. (2014) (1,387 annotated claims associated with 33 topics).

The system of Levy et al. (2014) is comprised of a cascade of three components; (i) detecting sentences which contain claims, (ii) identifying the exact boundaries of the claim part within the sentence, and (iii) ranking the claim candidates. Each of these components applies a classifier over dedicated features. Results were reported for the full cascade and for the first component, which is our task (a). For an idea on how to adapt GrASP for the claim boundaries detection task, see Section 5.

Table 3 presents measures reported in Levy et al. (2014) (right hand side) as well as additional measures which reflect the focus of this work on the precision of the top ranked candidates (performance of all systems on P@200 and R@200 were comparable and were omitted due to space limitations). The system of Levy et al. (2014), denoted *Levy14*, and our reproduction of it, denoted *Levy14-rep*, obtained comparable results.[8]

Evidently, utilizing GrASP patterns alone achieve similar performance as Levy14-rep. Considering the fact that Levy14-rep is a full system, tailored for claim detection via a lengthy feature engineering process, these results, obtained using only GrASP patterns, are promising. Adding GrASP features to Levy14-rep, denoted *Combined*, we observe a significant improvement, demonstrating their complementary value.

5 Discussion

GrASP extracts rich patterns that characterize subtle linguistic phenomena. It exploits a wide variety of information layers in a unified manner, identifying the most discriminative attributes for the given task, and greedily composes them into patterns. We demonstrated GrASP significant impact on several argumentation mining tasks.

As this was not the focus of this work, we chose standard statistical criteria to sort the candidate patterns and to filter redundant ones. Considering other criteria, and also more sophisticated search strategies to explore the huge space of possible patterns, is left for future work.

In addition to their value in classification tasks, the patterns revealed by GrASP are easy to interpret, in contrast to alternative techniques, like Deep Learning. Thus, these patterns can provide researchers with additional insights regarding the target phenomenon. These insights can be integrated back to by considering additional attributes to be explored in subsequent runs. Thus, GrASP can significantly expedite the research process, especially when addressing novel tasks.

Finally, we would like to hint on a sequel work that demonstrates how GrASP can be easily modified to address another important task – detecting the claim boundaries within its surrounding sentence (see italic text in the examples in Section 1). To cope with this unique task, we enhance the term representation (Section 3.1), by tripling each attribute a to distinguish between its appearance before (`PRE-a`), within (`IN-a`), or after (`POST-a`) the candidate claim boundaries. With this change only, GrASP was able to identify patterns for this new task, that were used to indicate the boundaries of a claim with promising preliminary results.

Acknowledgments

The authors thank Matan Ninio for giving the algorithm its catchy name.

[8] We reproduced their work to perform significant test and report the additional measures.

Patterns of Argumentation Strategies across Topics

Khalid Al-Khatib Henning Wachsmuth Matthias Hagen Benno Stein
Faculty of Media, Bauhaus-Universität Weimar, Germany
<firstname>.<lastname>@uni-weimar.de

Abstract

This paper presents an analysis of argumentation strategies in news editorials within and across topics. Given nearly 29,000 argumentative editorials from the New York Times, we develop two machine learning models, one for determining an editorial's topic, and one for identifying evidence types in the editorial. Based on the distribution and structure of the identified types, we analyze the usage patterns of argumentation strategies among 12 different topics. We detect several common patterns that provide insights into the manifestation of argumentation strategies. Also, our experiments reveal clear correlations between the topics and the detected patterns.

1 Introduction

Most current research in computational argumentation addresses argument mining, i.e., the identification of pro and con arguments in a text. Computational approaches that study how to deliver the arguments *persuasively* are still scarce — despite the importance of such studies for envisaged applications that deal with the synthesis of effective argumentation, such as debating systems.

Many studies have indicated that it is important to follow a specific *strategy* of how to deliver arguments in order to achieve persuasion in argumentative texts, and they proposed models for possible strategies. A recent work in this direction models the argumentation strategy of a text as an author's decision on what types of *evidence* to include in the text as well as on how to order them (Al-Khatib et al., 2016). This is in line with studies in communication theory, where many experiments have been conducted on the persuasiveness of different evidence types (Hornikx, 2005) and their combinations (Allen and Preiss, 1997).

Based on the model of Al-Khatib et al. (2016), the paper at hand investigates the usage patterns of argumentation strategies within and across topics. The study is rooted in our hypotheses that (1) effective strategies for synthesizing an argumentative text can be derived from the analysis of existing strategies that humans use in high-quality texts, and (2) the decision for preferring one strategy over another is affected by several text characteristics such as genre, provenance, and *topic*.

We approach our study within three steps. Starting from a collection of argumentative news editorials, we (1) categorize the editorials into n topics, (2) identify the evidence types (*statistics, testimony, anecdote*) in each editorial, and (3) analyze the selection and ordering of evidence types within editorials across topics. The output of these steps will be beneficial for synthesizing an effective argumentative text for a given topic (see Figure 1). The first two steps are carried out with supervised learning based on selected linguistic features, whereas the third step quantifies the distribution of evidence types and their *flows* (Wachsmuth et al., 2015).

To evaluate our approach, experiments are conducted on 28,986 editorials extracted from the *New York Times (NYT) Annotated Corpus* (Sandhaus, 2008). We automatically categorize these editorials into 12 coarse-grained topics (such as economics, arts, health, etc.). Our results expose significant differences in the distribution of evidence types across the 12 topics. Furthermore, they discriminate a number of flows of evidence types which are common in editorials. Both results provide insights into what patterns of argumentation strategies exist in editorials across different topics.

To foster future research on evidence identification and argumentation strategies, the topic categorization of all editorials as well as the developed evidence classifier are publicly available at http://www.webis.de.

2 Topic Categorization

The NYT Annotated Corpus comprises about 1.8 million articles published by the New York Times between 1987 and 2007. The corpus covers several types of articles that mainly categorized into 12 topics (the topics are given in Table 3) according to which section or sub-section the article is placed into in the news portal's hierarchy. Each article comes with 48 metadata tags that were assigned manually or semi-automatically by employees of the NYT. The tags cover several types of information such as *types of material* (e.g., review, editorial, etc.) and *taxonomic classifiers* (the hierarchy of articles section), among others.

All 28,986 articles tagged as "editorial" are used in our analysis. However, identifying an editorial's topic is not straightforward: While the NYT classifies the topic of most non-editorial articles, only 6% of all editorials are provided with topic information. The remaining 94% are labeled as "opinion". Analyzing the corpus, we observed that several tags include terms that describe the content of an article, such as "global warming". Some terms even include the topic itself, such as "Politics and Government". Thus, we exploited these tags to develop a standard supervised classifier for the topic categorization of editorials. In particular, we trained the classifier on all 1.29 million non-editorial articles that are assigned a topic, and then used it to classify editorials with unknown topic.

We used the default configuration of the Weka Naïve Bayes multinomial model with unigram features (Hall et al., 2009), as related studies suggest that this classifier performs particularly well in topic categorization (Husby and Barbosa, 2012). Since articles may have more than one topic, we label each article with all topics given a probability of at least 0.3 by the classifier. This threshold has been selected based on the training data.

The 6% of editorials, which are provided with "topic" labels in the corpus, were used for testing the effectiveness of our topic classifier. The classifier obtained an accuracy of 0.82 on these articles.

3 Evidence Identification

This section describes and evaluates our approach for identifying evidence types in an editorial.

All experiments are based on the corpus of Al-Khatib et al. (2016), which contains 300 editorials from three news portals: The Guardian, Al Jazeera, and Fox News. Each of these editorials is separated into argumentative segments, and every segment is labeled with one of six types. Three types refer to evidence: (1) *statistics*, where the segment states or quotes the results or conclusions of quantitative research, studies, empirical data analyses, or similar, (2) *testimony*, where the segment states or quotes that a proposition was made by some expert, authority, witness, group, organization, or similar, and (3) *anecdote*, where the segment states personal experience of the author, a concrete example, an instance, a specific event, or similar. We use the labels of all three evidence types, whereas we consider all remaining types in the corpus (e.g., *assumption*) as belonging to the type *other*.

Each segment in the corpus spans one sentence or less. Accordingly, it is possible that a sentence includes multiple types (e.g., *testimony* and *statistics*), although the proportion of such sentences is very low (less than 5%). We hence decided to simplify the task by identifying only one type for each sentence; in case a sentence has more than one type, we favor evidence types over *other*, and less frequent evidence types over more frequent ones.

Thereby, we avoid dealing with argumentative text segmentation and multi-type classification.

For identifying evidence types, we rely on supervised learning. The task is similar to tasks concerned with the pragmatic level of text, such as language function analysis (Wachsmuth and Bujna, 2011) or speech act classification (Ferschke et al., 2012). We employ several features that capture the content, syntax, style, and semantics of a sentence. Some of them have been used for the mentioned tasks, others are tailored to our task—based on our inspection of the training set of the corpus.

Lexical Features Previous work on speech acts classification showed a strong positive impact of lexical features, e.g., (Jeong et al., 2009). In case of evidence types, words such as "study" and "find" are indicators for *statistics*,"according" and "states" for *testimony*, and "example" and "year" for *anecdote*, for instance. We represent this feature type as the frequency of word unigrams, bigrams, and trigrams. We also consider punctuation and digits in our features; quotes play an important role for *testimony*, numbers for *statistics*.

Style Features We hypothesize that texts with different evidence types show specific style characteristics. To test this, we use character 1–3-grams, chunk 1–3-grams, function word 1–3-grams, and the first 1–3 tokens in a sentence. Similarly, we expect *anecdote* and *testimony* sentences to be longer than *statistics*, which we capture by the number of characters, syllables, tokens, and phrases in a sentence. Moreover, we assess whether a sentence is the first, second, or last within a paragraph.

Syntactic Features Syntax plays a role in different linguistic tasks. For evidence type identification, narrative tenses may be indicators of anecdotes, for instance. We model syntax simply via the frequencies of part of speech tag 1–3-grams.

Semantic Features We use the frequency of person, location, organization, and misc entities, as well as the proportion of each of these entity types. In many cases, a sentence with evidence refers to specific entities (e.g., a scientific lab in *statistics*). Also, we use the mean SentiWordNet score of the words in a sentence, once for the word's first sense and once for its average sense (Baccianella et al., 2010). Moreover, we compute the frequency of each word class of the *General Inquirer* (`http://www.wjh.harvard.edu/~inquirer`).

In our experiments, the sequential minimal optimization (SMO) implementation of support vector machines from Weka performed best among several models on the validation set of the given corpus. There, SMO achieved the highest results for a cost hyperparameter value of 5, which we then used to evaluate SMO on the test set.

#	Feature Type	Accuracy	F_1-Score
1	Lexical features	0.76	0.73
2	Style features	0.74	0.70
3	Syntactic features	0.74	0.71
4	Semantics features	0.71	0.67

Anecdote	0.55	0.47	0.51
Other	0.84	0.90	0.87

Table 2: Precision, recall, and F_1-Score for all four classes in the identification of evidence types.

Results Table 1 shows the effectiveness of our classifier in terms of accuracy and weighted average F_1-score for each single feature type as well as for the complete feature set. In general, lexical features are the most discriminative, closely followed by the syntax features. All feature types contribute to the effectiveness of the complete feature set. Table 2 shows the precision, recall, and F_1-score values for classifying each of the three evidence types as well as the class *other*. The classifier achieved the highest F_1-score for *other*, followed by *testimony*, *anecdote*, and *statistics* respectively.

Error Analysis The classifier has a small tendency towards labeling sentences with the majority class *other*. However, sampling the training set yielded worse results for all classes. Overall, the task is challenging, and the results we obtained are in line with those that have been reported in speech act classification. Also, the decision to classify each sentence with one of the evidence classes (to avoid segmentation) may render the type identification itself harder. For example, some features such as quotation marks can be helpful to identify *testimony*. However, if some *testimony* evidence covers several sentences, the ones which are between the first and the last sentences might be difficult to be identified as part of the *testimony*.

4 Argumentation Strategy Analysis

In this section, we analyze strategy patterns across editorials of 12 topics, exploring the selection and ordering based on the distribution and sequential flows of evidence types respectively.

To this end, we applied our topic and evidence type classifiers to all given 28,986 NYT editorials. As the analysis of argumentation strategies depends strongly on the effectiveness of evidence type identification, we consider the impact of classification errors in the analysis results as follows. For each evidence type t in dataset d, we compute a confidence interval $[lower\ bound, upper\ bound]$ for the n sentences that the classifier labels with t. The interval is derived from the precision and recall of our classifier for type t (determined on the ground truth): We compute the lower bound as $n \cdot precision(t)$ and the upper bound as $n/recall(t)$.

Based on the mean of $lower\ bound$ and $upper\ bound$, we perform a significance test among the evidence type distribution across topics. In particular, we use the chi-square statistical method with a significance level of 0.001. For the sequential flows, however, a consideration of the impact of misclassified sentences seems unreliable: As each editorial is represented by only one flow, the 60 editorials in the test set of Al-Khatib et al. (2016) are not enough for computing precision and recall. In contrast, we again use chi-square with a significance level of 0.001 for specifying significant differences among the flows.

Distribution of Evidence Types Altogether, the given 28,986 editorials contain 669,092 sentences whose type we classified. As Table 3 shows, the most frequent type is *other* (64.4%) according to our classifier, followed by *anecdote* (24.9%), *testimony* (7.7%), and *statistics* (3.0%).

In terms of the performed chi-squared tests, all pairs of topic-specific type distributions in Table 3 are significantly different from each other with only one exception: *arts* and *religion*. This results strongly support the hypothesis that topic influences the usage of evidence types. For anecdotes, the values of both *science* and *technology* differ not significantly from *all*. For testimony, *law* does not differ significantly from *all*, and for statistics, the analog holds for *science* and *sports*.

The highest relative frequency of anecdotes is observed for *arts* (31.6%) and *religion* (31.1%), followed by *sports* (31.1%). Matching intuition, authors of *arts* and *religion* editorials add much testimony evidence (11.3% and 10.8% respectively). In contrast, anecdotes and testimony are clearly below the average for *health*, while statistics play a more important role there with 4.9%, the second highest percentage after *economy* (5.0%).

Sequential Flows of Evidence Types Following related research (Wachsmuth et al., 2015), we designate the *flow* here as a sequential representation of all evidence types in an editorial. Following one the flow generalizations proposed by Wachsmuth et al. (2015), we abstract flows considering only changes of evidence types. For example, the flow (AN, AN, TE) for an editorial will be abstracted into (AN, TE). Such an abstraction produces more frequent and thus reliable patterns. Table 4 lists the resulting *evidence change flows* that are most common among all editorials.

The most frequent flow is (AN), representing 16.6% of all editorials across topics. This means that about one sixth of all editorials contain only this evidence type. The frequency of (AN) ranges from 9.3% (*education*) to 26.7% (*style*), revealing the varying importance of anecdotes in editorials of different topics. The frequency of (AN, TE, AN) is more stable across topics; only *health* and *technology* show notably lower values there (8.8% and 9.5% respectively). For *technology*, the percentage is much above the average for some other flows based on AN and TE, such as (AN, TE) (10.7% vs. 6.9%) and (TE, AN) (4.3% vs. 2.6%). Hence, the ordering of evidence seems to make a difference.

#	Evidence Change Flow	All	Arts	Econ.	Edu.	Envir.	Health	Law	Polit.	Relig.	Science	Sports	Style	Tech.
1	(AN)	**16.6**	16.0	13.5	**9.3**	21.3	17.4	17.4	16.2	11.9	20.4	21.8	**26.7**	20.9

5	(AN, TE, AN, TE, AN)	5.3	8.4	3.4	4.3	3.9	2.4	6.4	6.3	7.0	3.1	4.6	3.5	6.6
6	(AN, TE, AN, TE)	4.9	6.2	3.3	4.9	3.5	3.2	5.3	5.7	8.2	4.0	4.8	4.0	4.3
7	(TE, AN)	**2.6**	2.4	2.2	2.3	1.7	2.5	1.8	3.0	<0.5	2.2	2.4	2.3	**4.3**
8	(AN, ST)	2.2	0.7	3.8	1.9	3.1	4.3	2.4	1.5	1.2	3.1	1.9	2.0	1.6
9	(AN, TE, AN, TE, AN, TE)	2.2	2.9	1.3	1.8	1.2	1.1	2.8	2.8	2.9	0.7	1.3	1.7	1.4
10	(AN, TE, AN, TE, AN, TE, AN)	2.0	4.3	1.5	1.8	0.8	1.0	1.9	2.3	5.8	1.3	1.6	1.7	1.4
11	(TE, AN, TE, AN)	1.8	2.2	0.9	2.5	0.7	1.0	1.5	2.3	2.1	0.7	1.8	1.4	1.0
12	(AN, ST, AN, TE, AN)	1.4	0.9	1.8	1.6	2.4	1.2	0.9	1.3	0.8	2.2	1.8	1.3	0.6
13	(ST, AN)	1.3	<0.5	2.2	1.0	1.3	2.8	1.2	0.9	<0.5	2.0	0.7	1.4	2.3
14	(TE, AN, TE)	1.3	1.4	0.8	1.4	0.7	0.9	1.1	1.6	2.1	1.5	<0.5	0.6	1.9
15	(AN, ST, AN, TE)	1.2	0.7	1.6	1.5	2.0	1.5	1.4	1.0	1.2	0.9	1.3	0.9	1.4

Table 4: Relative frequency of the top 15 evidence change flows in all editorials and in those of each topic, given in percent. In the flows, the type *Other* is ignored. Values discussed in Section 4 are in bold.

In accordance with literature on argumentation in editorials (van Dijk, 1995), many common flows start with an anecdote and end with one. While testimony occurs most often between the anecdotes, the fourth most frequent flow is (AN, ST, AN) (5.3%). This flow occurs particularly often in editorials about *environment* (8.6%), even though statistics are not that frequent in these editorials (see Table 4) — and similar holds for (AN, ST). Such observations emphasize the role of topic on ordering decisions in argumentation strategies.

5 Related Work

In addition to the work on argumentation strategies in editorials (Al-Khatib et al., 2016) that we have discussed in Section 3, several approaches have been proposed for modeling and identifying the types or roles of argumentative units. For instance, Stab and Gurevych (2014) distinguish premises from claims and major claims, and Park and Cardie (2014) unverifiable from verifiable statements.

In this line of research, Rinott et al. (2015) have proposed a supervised learning model for identifying context-dependent evidence in Wikipedia articles. While the authors target the same evidence types that we consider in our work, they approach a different task. In particular they classify only evidence that is *related to given claims*. Hence, a comparison of their effectiveness results with ours would be meaningless. Moreover, some of their features rely on resources that are not publicly available (e.g., lexicons), which is why could not resort to their approach or compare it to ours.

The NYT Annotated Corpus has been analyzed in several papers. Among others, Li et al. (2016) and Hong and Nenkova (2014) used the metadata tag *abstract*, which contains a manually created article summary. Other tags, such as those for people, locations, and organizations mentioned in an article, have been used by Dunietz and Gillick (2014).

6 Conclusion

This paper has studied argumentation strategies in news editorials of different topics. We have observed varying distributions of evidence types across the topics as well as varying sequential flows of these types. Overall, our analysis has revealed several patterns of how authors argue in news editorials, and how the topic influences such patterns. We believe that the obtained results provide valuable insights for research on the synthesis of effective argumentative texts.

Besides text synthesis, we consider this study as beneficial for argument mining as well as for the topic categorization of argumentative texts. It provides insights and empirical results on prior knowledge regarding distributional and structural probabilities for evidence usage among topics. Our findings can be incorporated into unsupervised classification models (Hu et al., 2015).

In future work, we plan to investigate argumentation strategies across different genres and provenances. Also, we will further explore whether there are important types of evidence in editorials and similar texts that we have not considered in this paper so far, such as analogies.

Abstract

We study the helpful product reviews identification problem in this paper. We observe that the evidence-conclusion discourse relations, also known as *arguments*, often appear in product reviews, and we hypothesise that some *argument*-based features, e.g. the percentage of argumentative sentences, the evidences-conclusions ratios, are good indicators of helpful reviews. To validate this hypothesis, we manually annotate arguments in 110 hotel reviews, and investigate the effectiveness of several combinations of argument-based features. Experiments suggest that, when being used together with the argument-based features, the state-of-the-art baseline features can enjoy a performance boost (in terms of F1) of 11.01% in average.

1 Introduction

Product reviews have significant influences on potential customers' opinions and their purchase decisions (Chatterjee, 2001; Chen et al., 2004; Dellarocas et al., 2004). Instead of reading a long list of reviews, customers usually are only willing to view a handful of *helpful reviews* to make their purchase decisions. In other words, helpful reviews have even greater influences on the potential customers' decision-making processes and thus on the sales; as a result, the automatic identification of helpful reviews has received considerable research attentions in recent years (Kim et al., 2006; Liu et al., 2008; Mudambi, 2010; Xiong and Litman, 2014; Martin and Pu, 2014; Yang et al., 2015, 2016).

Existing works on helpful reviews identification mostly focus on designing efficient features. Widely used features include *external features*, (e.g. date (Liu et al., 2008), product rating (Kim et al., 2006) and product type (Mudambi, 2010)) and *intrinsic features* (e.g. semantic dictionaries (Yang et al., 2015) and emotional dictionaries (Martin and Pu, 2014)). Compared to external features, intrinsic features can provide some insights and explanations for the prediction results, and support better cross-domain generalisation. In this work, we investigate a new form of intrinsic features: the *argument* features.

An argument is a basic unit people use to persuade their audiences to accept a particular state of affairs (Eckle-Kohler et al., 2015). An argument usually consists of a *claim* (also known as *conclusion*) and some *premises* (also known as *evidences*) offered in support of the claim. For example, consider the following review excerpt: "*The staff were amazing, they went out of their way to help us*"; the texts before the comma constitute a claim, and the texts after the comma give a premise supporting the claim. Argumentation mining (Moens, 2013; Lippi and Torroni, 2016) receives growing research interests in various domains (Palau and Moens, 2009; Contractor et al., 2012; Park and Cardie, 2014; Madnani et al., 2012; Kirschner et al., 2015; Wachsmuth et al., 2014, 2015). Recent advances in automatic arguments identification (Stab and Gurevych, 2014), has stimulated the usage of argument features in multiple domains, e.g. essay scoring (Wachsmuth et al., 2016) and online forum comments ranking (Wei12 et al., 2016).

The motivation of this work is a hypothesis that, the helpfulness of a review is closely related to some argument-related features, e.g. the percentage of argumentative sentences, the average number of premises in each argument, etc. To validate our hypothesis, we manually annotate arguments in 110 hotel reviews so as to use

Proceedings of the 2017 Conference on Empirical Methods in Natural Language Processing, pages 1358–1363
Copenhagen, Denmark, September 7–11, 2017.

these “ground truth” arguments to testify the effectiveness of argument-based features for detecting helpful hotel reviews. Empirical results suggest that, for four baseline feature sets we test, their performances can be improved, in average, by 11.01% in terms of F1-score and 10.40% in terms of AUC when they are used together with some argument-based features. Furthermore, we use the effective argument-based features to give some insights into which product reviews are more helpful.

2 Corpus

We use the Tripadvisor hotel reviews corpus built by (O’Mahony and Smyth, 2010) to test the performance of our helpful reviews classifier. Each entry in this corpus includes the review texts, the number of people that have viewed this review (denoted by Y) and the number of people that think this review is helpful (denoted by X).

We randomly sample 110 hotel reviews from this corpus to annotate the “ground truth” argument structures [1]. In line with (Wachsmuth et al., 2015), we view each sub-sentence in the review as a *clause* and ask three annotators independently to annotate each clause as one of the following seven argument components:

Major Claim: a summary of the main opinion of a review. For instance, *“I have enjoyed the stay in the hotel”, “I am sad to say that i am very disappointed with this hotel”*;

Claim: a subjective opinion on a certain aspect of a hotel. For example, *“The staff was amazing”, “The room is spacious”*;

Premise: an objective reason/evidence supporting a claim. For instance, *“The staff went out of their way to help us”*, it supports the first example claim above; *“We had a sitting room as well as a balcony”*, it supports the second example claim above;

Premise Supporting an Implicit Claim (PSIC): an objective reason/evidence that supporting an *implicit claim*, which does appear in review. For instance, *“just five minutes’ walk to the down town”* supports some implicit claims like *“the location of the hotel is good”*, although this implicit claims has never appeared in the review;

Background: an objective description that does not give direct opinions but provides some background information. For example, *“We checked into this hotel at midnight”, “I stayed five nights at this hotel because i was attending a conference at the hotel”*;

Component Type	Number	Kappa
Major claim	143	0.86
Claim	581	0.77
Premise	206	0.65
PSIC	121	0.94
Background	80	0.89
Recommendation	70	1.00
Non-argumentative	145	0.78

Table 1: The number and Fleiss’ kappa for each argument component type we annotate.

Recommendation: a positive or negative recommendation for the hotel. For instance, *“I would definitely come to this hotel again the next time I visit London”, “Do not come to this hotel if you look for some clean places to live”*;

Non-argumentative: for all the other clauses.

We use the Fleiss’ kappa metric (Fleiss, 1971) to evaluate the quality of the obtained annotations, and the results are presented in Table 1. We can see that the lowest Kappa scores (for Premise) is still above 0.6, suggesting that the quality of the annotations are *substantial* (Landis and Koch, 1977); in other words, there exist little noises in the ground truth argument structures. We aggregate the annotations using majority voting.

3 Features

In line with (Yang et al., 2015), we consider the helpfulness as an intrinsic characteristic of product reviews, and thus only consider the following four intrinsic features as our baseline features.

Structural features (**STR**) (Kim et al., 2006; Xiong and Litman, 2014): we use the following structural features: total number of tokens, total number of sentences, average length of sentences, number of exclamation marks, and the percentage of question sentences.

Unigram features (**UGR**) (Kim et al., 2006; Xiong and Litman, 2014): we remove all stopwords and non-frequent words ($tf < 3$) to build the unigram vocabulary. Each review is represented by the vocabulary with *tf-idf* weighting for each appeared term.

Emotional features (**GALC**) (Martin and Pu, 2014): the Geneva Affect Label Coder (GALC) dictionary proposed by (Scherer, 2005) defines 36 emotion states distinguished by words. We build a

[1] The annotated corpus can be obtained by contacting the first author

real feature vector with the number of occurrences of each emotional word plus one additional dimension for the number of non-emotional words.

Semantic features (**INQUIRER**) (Yang et al., 2015): the General Inquirer (INQUIRER) dictionary proposed by (Stone et al., 1962) maps each word to some semantic tags, e.g. word *absurd* is mapped to tags NEG and VICE; similar to the GALC features, the semantic features include the number of occurrences of each semantic tag.

3.1 Argument-based Features

The argument-based features can have different granularity: for example, the number of argument components can be used as features, and the number of tokens (words) in the argument components can also be used as features. We consider four granularity of argument features, detailed as follows.

Component-level argument features. A natural feature that we believe to be useful is the ratio of different argument component numbers. For example, we may be interested in the ratio between the number of premises and that of claims; a high ratio suggests that there are more premises supporting each claim, indicating that the review gives many evidences. To generalise this component ratio feature, we propose *component-combination ratio* features: we compute the ratios between any two argument components combinations. For example, we may be interested in the ratio between the number of MajorClaim+Claim+Premise and that of Background+Non-argumentative. As there are 7 types of labels, the number of possible combinations is $2^7 - 1 = 127$, and thus the possible number of combination ratio pairs is $127 \times 126 = 16002$. In other words, the component-level feature is a 16002-dimensional real vector.

Token-level argument features. In a finer-granularity, we consider the number of tokens in argument components to build features: for example, suppose a review has only two claims, one has 10 words and the other has 5 words; we may want to know the average number of words contained in each claim, the total number of words in claims, etc. In total, for each argument component type, we consider 5 types of token-level statistics: the total number of words in the given component type, the length (in terms of word) of the shortest/longest component of the given type, and the mean/variance of the number of words in each component of the given type. Thus, there are in total $7 \times 5 = 35$ features to represent the token-level statistics.

In addition, the ratio of some token-level statistics may also be of interests: for example, given a review, we may want to know the ratio between the number of words in Claims+MajorClaims and that in Premises. Thus, the combination ratio can also be applied here. We consider only the combination ratio for two statistics: the total number of words and the average number of words in each component-combination; hence, there are $16002 \times 2 = 32004$ dimensions for the combination ratio for the statistics. In total, there are $32004 + 35 = 32039$ dimensions for the token-level argument features.

Letter-level argument features. In the finest-granularity, we consider the letter-level features, which may give some information the token-level features do not contain: for example, if a review has a big number of letters and a small number of words, it may suggests that many long and complex words are used in this review, which, in turn, may suggests that the linguistic complexity of the review is relative high and the review may gives some very professional opinions. Similar to the token-level features above, we design 5 types of statistics and their combination ratios. Thus, the dimension for the letter-level features is the same to that of the token-level features.

Position-level argument features. Another dimension to consider argument features is the positions of argument components: for example, if the major claims of a review are all at the very beginning, we may think that readers can more easily grasp the main idea of the review and, thus, the review is more likely to be helpful. For each component, we use a real number to represent its position: for example, if a review has 10 sub-sentences (i.e. clauses) in total and the first sub-sentence the component overlaps is the second sub-sentence, then the position for this component is $2/10 = 0.2$. For each type of argument component, we may be interested in some statistics for its positions: for example, if a review has several premises, we may want to know the location of the earliest/latest appearance of premises, the average position of all premises and its variance, etc. Similar to the token- and letter-level features, we design the same number of features for position-

	Accuracy	Precision	Recall	F1-score	AUC

level features.

4 Experiments

Following (O'Mahony and Smyth, 2010; Martin and Pu, 2014), we model the helpfulness prediction task as a classification problem; thus, we use accuracy, precision, recall, macro F1 and area under the curve (AUC) to as evaluation metrics. Similar to (O'Mahony and Smyth, 2010), we consider a review as helpful if and only if at least 75% opinions for the review are positive, i.e. $X/Y \geq 0.75$ (see X and Y in Sect. 2). For the features whose number of dimensions is more than 10k (i.e. the UGR features and argument-based features), to reduce their dimensions and to improve the performance, we only use the positive-information-gain features in these feature sets. In line with most existing works on helpfulness prediction (Martin and Pu, 2014; Yang et al., 2015), we use the LibSVM (Chang and Lin, 2011) as our classifier.

The performances of different features are presented in Table 2. Each number in the table is the average performance in 10-fold cross-validation tests. From the table we can see that, when being used together with the argument-based features, either of the four baseline features enjoys a performance boost in terms of all metrics we consider. To be more specific, in terms of accuracy, precision, recall, F1 and AUC, the average improvement for the baseline features are 4.33%, 10.30%, 4.32%, 11.01% and 10.40%, respectively. However, we observe that the precision of UGR+AF, although gives the second highest score among all feature combinations, is lower than that of UGR; we leave it for future work. Also, we notice that when using the argument-based features alone, its performance (in terms of Precision, F1 and AUC) is superior to those of STR, GALC and INQUIRER, and is only inferior to UGR. However, a major drawback of the UGR feature is its huge and document-dependent dimensionality, while the dimensionality of argument-based features is fixed, regardless of the size of the input documents. Moreover, the UGR features are sparse and problematic in online learning. To summarise, compared with the other state-of-the-art features, argument-based features are effective in identifying helpful reviews, and can represent some complementary information that cannot be represented in other features.

5 What Makes a Review Helpful ?

Argument-based features can not only improve the performance of review helpfulness identification, but also can be used to interpret what makes a review helpful. We analyse the information gain ranking of the argument-based features and find that, among all the positive-information-gain argument features, 36% are from the token-level argument feature set, and 29% are from the letter-level argument feature set, suggesting that these two feature sets are most effective in identifying helpful reviews. Among all the token-level argument features with positive information gain, 69% are ratios of sum of token number between component-combinations, and the remaining are ratios of the mean token numbers between component-combinations. We interpret this observation as follows: given a review, the larger number of tokens it contains, and the more likely the review is helpful. In fact, helpful reviews are tend to occur in those long reviews, which generally provide with more experiences and comments about the product being reviewed. Among all the letter-level argument features, around three-quarters are ratios of the sum of the number of letters between component-combinations. This observation, again, suggests that the length of reviews plays an important role in the review helpfulness identification.

Moreover, among all the argument-based features with positive information gain values, a quarter of features are the position-level argument feature. This is because the position of each argument component influences the logic flow of reviews, which, in turn, influences the readability, convincingness and helpfulness of the reviews. This information can hardly be represented by all the baseline features we considered, and we believe this explains why the performances of the baseline features are improved when being used together with the argument-based features. However, among all the argument-based features with positive information gain values, only 10% are the component-level argument feature. This indicates that compared to three finer-granularity argument features above, the component-level argument feature provides less useful information in review helpfulness identification.

6 Conclusion and Future Work

In this work, we propose a novel set of intrinsic features of identifying helpful reviews, namely the *argument*-based features. We manually annotate 110 hotel reviews, and compare the performances of argument-based features with those of some state-of-the-art features. Empirical results suggest that, argument-based features include some complementary information that the other feature sets do not include; as a result, for each baseline feature, the performance (in terms of various metrics) of jointly using this feature and argument-based features is higher than using this baseline feature alone. In addition, by analysing the effectiveness of different argument-based features, we give some insights into which reviews are more likely to be helpful, from an argumentation perspective.

For future work, an immediate next step is to explore the usage of automatically extracted arguments in helpful reviews identification: in this work, all argument-based features are based on manually annotated arguments; deep-learning based argument mining (Li et al., 2017; Eger et al., 2017) has produced some promising results recently, and we plan to investigate whether the automatically extracted arguments can be used to identify helpful reviews, and how the errors made in the argument extraction stage will influence the performance of helpful reviews identification. We also plan to investigate the effectiveness of argument-based features in other domains.

Here's My Point: Joint Pointer Architecture for Argument Mining

Peter Potash, Alexey Romanov, Anna Rumshisky

Abstract

In order to determine argument structure in text, one must understand how individual components of the overall argument are linked. This work presents the first neural network-based approach to link extraction in argument mining. Specifically, we propose a novel architecture that applies Pointer Network sequence-to-sequence attention modeling to structural prediction in discourse parsing tasks. We then develop a joint model that extends this architecture to simultaneously address the link extraction task and the classification of argument components. The proposed joint model achieves state-of-the-art results on two separate evaluation corpora, showing far superior performance than the previously proposed corpus-specific and heavily feature-engineered models. Furthermore, our results demonstrate that jointly optimizing for both tasks is crucial for high performance.

1 Introduction

An important goal in argument mining is to understand the structure in argumentative text (Persing and Ng, 2016; Peldszus and Stede, 2015; Stab and Gurevych, 2016; Nguyen and Litman, 2016). One fundamental assumption when working with argumentative text is the presence of Arguments Components (ACs). The types of ACs are generally characterized as a *claim* or a *premise* (Govier, 2013), with premises acting as support (or possibly attack) units for claims (though some corpora have further AC types, such as *major claim* (Stab and Gurevych, 2016, 2014b)).

The task of processing argument structure encapsulates four distinct subtasks (our work focuses on subtasks 2 and 3): (1) Given a sequence of tokens that represents an entire argumentative text, determine the token subsequences that constitute non-intersecting ACs; (2) Given an AC, determine the type of AC (*claim*, *premise*, etc.); (3) Given a set/list of ACs, determine which ACs have directed links that encapsulate overall argument structure; (4) Given two linked ACs, determine whether the link is a supporting or attacking relation. This can be labeled as a 'micro' approach to argument mining (Stab and Gurevych, 2016). In contrast, there have been a number of efforts to identify argument structure at a higher level (Boltuzic and Šnajder, 2014; Ghosh et al., 2014; Cabrio and Villata, 2012), as well as slightly re-ordering the pipeline with respect to AC types (Rinott et al., 2015)).

There are two key assumptions our work makes going forward. First, we assume subtask 1 has been completed, i.e. ACs have already been identified. Second, we follow previous work that assumes a tree structure for the linking of ACs (Palau and Moens, 2009; Cohen, 1987; Peldszus and Stede, 2015; Stab and Gurevych, 2016). Specifically, a given AC can only have a single outgoing link, but can have numerous incoming links. Furthermore, there is a 'head' component that has no outgoing link (the top of the tree). Depending on the corpus (see Section 4), an argument structure can be either a single tree or a forest, consisting of multiple trees. Figure 1 shows an example that we will use throughout the paper to concretely explain how our approach works. First, the left side of the figure presents the raw text of a paragraph in a persuasive essay (Stab and Gurevych, 2016), with the ACs contained in square brackets. Squiggly vs straight underlining differentiates between claims and premises, respectively. The ACs have been annotated as to how they are linked, and the right side of the figure reflects this structure. The argument

Proceedings of the 2017 Conference on Empirical Methods in Natural Language Processing, pages 1364–1373
Copenhagen, Denmark, September 7–11, 2017. ©2017 Association for Computational Linguistics

First, [cloning will be beneficial for many people who are in need of organ transplants]$_{AC1}$. In addition, [it shortens the healing process]$_{AC2}$. Usually, [it is very rare to find an appropriate organ donor]$_{AC3}$ and [by using cloning in order to raise required organs the waiting time can be shortened tremendously]$_{AC4}$.

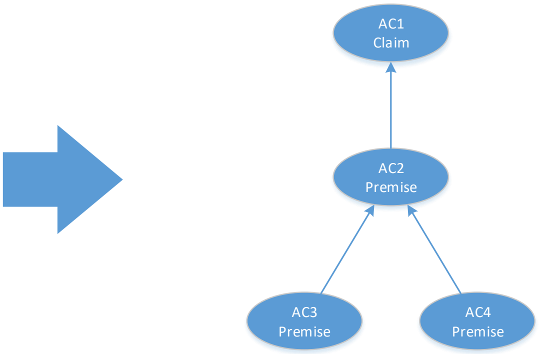

Figure 1: An example of argument structure with four ACs. The left side shows raw text that has been annotated for the presence of ACs. Squiggly or straight underlining means an AC is a *claim* or *premise*, respectively. The ACs in the text have also been annotated for links to other ACs, which is shown in the right figure. ACs 3 and 4 are *premises* that link to another *premise*, AC2. Finally, AC2 links to a *claim*, AC1. AC1 therefore acts as the central argumentative component.

structure with four ACs forms a tree, where AC2 has two incoming links, and AC1 acts as the head, with no outgoing links. We also specify the *type* of AC, with the head AC marked as a *claim* and the remaining ACs marked as *premises*. Lastly, we note that the order of argument components can be a strong indicator of how components should relate. Linking to the first argument component can provide a competitive baseline heuristic (Peldszus and Stede, 2015; Stab and Gurevych, 2016).

Given the above considerations, we propose that sequence-to-sequence attention modeling, in the spirit of a Pointer Network (PN) (Vinyals et al., 2015b), can be effective for predicting argument structure. To the best of our knowledge, a clean, elegant implementation of a PN-based model has yet to be introduced for discourse parsing tasks. A PN is a sequence-to-sequence model (Sutskever et al., 2014) that outputs a distribution over the encoding indices at each decoding timestep. More generally, it is a recurrent model with attention (Bahdanau et al., 2014), and we claim that as such, it is promising for link extraction because it inherently possesses three important characteristics: (1) it is able to model the sequential nature of ACs, (2) it constrains ACs to have a single outgoing link, thus partly enforcing the tree structure, and (3) the hidden representations learned by the model can be used for jointly predicting multiple subtasks. Furthermore, we believe the sequence-to-sequence aspect of the model provides two distinct benefits: (1) it allows for two separate representations of a single AC (one for the source and one for the target of the link), and (2) the decoder network-could learn to predict correct sequences of linked indices, which is a second recurrence over ACs. Note that we also test the sequence-to-sequence architecture against a simplified model that only uses hidden states from an encoding network to make predictions (see Section 5).

The main technical contribution of our work is a joint model that simultaneously predicts links between ACs and determines their *type*. Our joint model uses the hidden representation of ACs produced during the encoding step (see Section 3.4). While PNs were originally proposed to allow a variable length decoding sequence, our model differs in that it decodes for the same number of timesteps as there are inputs. This is a key insight that allows for a sequence-to-sequence model to be used for structural prediction. Aside from the partial assumption of tree structure in the argumentative text, our models do not make any additional assumptions about the AC types or connectivity, unlike the work of Peldszus (2014). Lastly, in respect to the broad task of parsing, our model is flexible because it can easily handle non-projective, multi-root dependencies. We evaluate our models on the corpora of Stab and Gurevych (2016) and Peldszus (2014), and compare our results with the results of the aformentioned authors. Our results show that (1) joint modeling is imperative for competitive performance on the link extraction task, (2) the presence of the second recurrence improves performance over a non-sequence-to-sequence model, and (3) the joint model can outperform models with heavy feature-engineering and corpus-specific constraints.

2 Related Work

Palau and Moens (2009) is an early work in argument mining, using a hand-crafted Context-Free Grammar to determine the structure of ACs in a corpus of legal texts. Lawrence et al. (2014) leverage a topic modeling-based AC similarity to uncover tree-structured arguments in philosophical texts. Recent work offers data-driven approaches to the task of predicting links between ACs. Stab and Gurevych (2014b) approach the task as a binary classification problem. The authors train an SVM with various semantic and structural features. Peldszus and Stede have also used classification models for predicting the presence of links (2015). The first neural network-based model for argumentation mining was proposed by Laha and Raykar (2016), who use two recurrent networks in end-to-end fashion to classify AC types.

Various authors have also proposed to jointly model link extraction with other subtasks from the argument mining pipeline, using either an Integer Linear Programming (ILP) framework (Persing and Ng, 2016; Stab and Gurevych, 2016) or directly feeding previous subtask predictions into a tree-based parser. The former joint approaches are evaluated on an annotated corpus of persuasive essays (Stab and Gurevych, 2014a, 2016), and the latter on a corpus of microtexts (Peldszus, 2014). The ILP framework is effective in enforcing a tree structure between ACs when predictions are made from otherwise naive base classifiers.

Recurrent neural networks have previously been proposed to model tree/graph structures in a linear manner. Vinyals et al. (2015c) use a sequence-to-sequence model for the task of syntactic parsing. Bowman et al. (2015) experiment on an artificial entailment dataset that is specifically engineered to capture recursive logic (Bowman et al., 2014). Standard recurrent neural networks can take in complete sentence sequences and perform competitively with a recursive neural network. Multi-task learning for sequence-to-sequence has also been proposed (Luong et al., 2015), though none of the models used a PN for prediction.

In the field of discourse parsing, the work of Li et al. (2016) is the only work, to our knowledge, that incorporates attention into the network architecture. However, the attention is only used in the process of creating representations of the text itself. Attention is *not* used to predict the overall discourse structure. In fact, the model still relies on a binary classifier to determine if textual components should have a link. Arguably the most similar approach to ours is in the field of dependency parsing (Cheng et al., 2016). The authors propose a model that performs 'queries' between word representations in order to determine a distribution over potential headwords.

3 Proposed Approach

In this section, we describe our approach to using a sequence-to-sequence model with attention for argument mining, specifically, identifying AC types and extracting the links between them. We begin by giving a brief overview of these models.

3.1 Pointer Network

A PN is a sequence-to-sequence model (Sutskever et al., 2014) with attention (Bahdanau et al., 2014) that was proposed to handle decoding sequences over the encoding inputs, and can be extended to arbitrary sets (Vinyals et al., 2015a). The original motivation for a pointer network was to allow networks to learn solutions to algorithmic problems, such as the traveling salesperson and convex hull problems, where the solution is a sequence over input points. The PN model is trained on input/output sequence pairs (E, D), where E is the source and D is the target (our choice of E,D is meant to represent the encoding, decoding steps of the sequence-to-sequence model). Given model parameters Θ, we apply the chain rule to determine the probability of a single training example:

$$p(D|E;\Theta) = \prod_{i=1}^{m(E)} p(D_i|D_1, ..., D_{i-1}, E; \Theta) \tag{1}$$

where the function m signifies that the number of decoding timesteps is a function of each individual training example. We will discuss shortly why we need to modify the original definition of m for our application. By taking the log-likelihood of Equation 1, we arrive at the optimization objective:

$$\Theta^* = \arg\max_{\Theta} \sum_{E,D} \log p(D|E;\Theta) \tag{2}$$

which is the sum over all training example pairs.

The PN uses Long Short-Term Memory (LSTM) (Hochreiter and Schmidhuber, 1997) for sequential modeling, which produces a hidden layer h at each encoding/decoding timestep. In practice, the PN has two separate LSTMs, one for

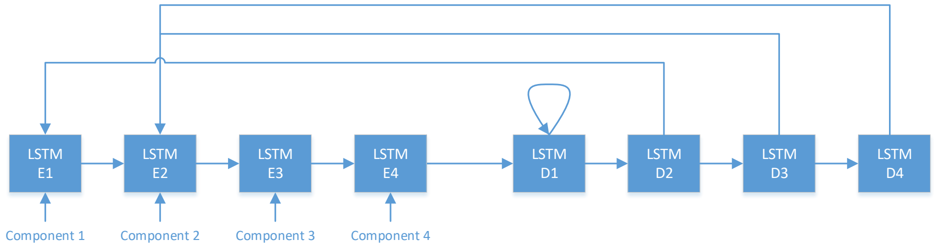

Figure 2: Applying a Pointer Network to the example paragraph in Figure 1 with LSTMs unrolled over time. Note that D1 points to itself to denote that it has not outgoing link and is therefore the head of a tree.

encoding and one for decoding. Thus, we refer to encoding hidden layers as e, and decoding hidden layers as d.

The PN uses a form of content-based attention (Bahdanau et al., 2014) to allow the model to produce a distribution over input elements. This can also be thought of as a distribution over input indices, wherein a decoding step 'points' to the input. Formally, given encoding hidden states $(e_1, ..., e_n)$, the model calculates $p(D_i|D_1, ..., D_{i-1}, E)$ as follows:

$$u^i_j = v^T \tanh(W_1 e_j + W_2 d_i) \quad (3)$$

$$p(D_i|D_1, ..., D_{j-1}, E) = softmax(u^i) \quad (4)$$

where matrices W_1, W_2 and vector v are parameters of the model (along with the LSTM parameters used for encoding and decoding). In Equation 3, prior to taking the dot product with v, the resulting transformation can be thought of as creating a joint hidden representation of inputs i and j. Vector u^i in equation 4 is of length n, and index j corresponds to input element j. Therefore, by taking the softmax of u^i, we are able to create a distribution over the input.

3.2 Link Extraction as Sequence Modeling

A given piece of text has a set of ACs, which occur in a specific order in the text: $(C_1, ..., C_n)$. Therefore, at encoding timestep i, the model is fed a representation of C_i. Since the representation is large and sparse (see Section 3.3 for details on how we represent ACs), we add a fully-connected layer before the LSTM input. Given a representation R_i for AC C_i, the LSTM input A_i is calculated as:

$$A_i = \sigma(W_{rep} R_i + b_{rep}) \quad (5)$$

where W_{rep}, b_{rep} in turn become model parameters, and σ is the sigmoid function[1]. Similarly, the decoding network applies a fully-connected layer with sigmoid activation to its inputs, see Figure 3. At encoding step i, the encoding LSTM produces hidden layer e_i, which can be thought of as a hidden representation of AC C_i.

In order to make sequence-to-sequence modeling applicable to the problem of link extraction, we explicitly set the number of decoding timesteps to be equal to the number of input components. Using notation from Equation 1, the decoding sequence length for an encoding sequence E is simply $m(E) = |\{C_1, ..., C_n\}|$, which is trivially equal to n. By constructing the decoding sequence in this manner, we can associate decoding timestep i with AC C_i.

From Equation 4, decoding timestep i will output a distribution over input indices. The result of this distribution will indicate to which AC component C_i links. Recall there is a possibility that an AC has no outgoing link, such as if it's the root of the tree. In this case, we state that if AC C_i does not have an outgoing link, decoding step D_i will output index i. Conversely, if D_i outputs index j, such that j is not equal to i, this implies that C_i has an outgoing link to C_j. For the argument structure in Figure 1, the corresponding decoding sequence is $(1, 1, 2, 2)$. The topology of this decoding sequence is illustrated in Figure 2. Observe how C_1 points to itself since it has no outgoing link.

Finally, we note that we have a Bidirectional LSTM (Graves and Schmidhuber, 2005) as the encoder, unlike the model proposed by Vinyals et al. (2015b). Thus, e_i is the concatenation of forward and backward hidden states $\overrightarrow{e}_i$ and $\overleftarrow{e}_{n-i+1}$, produced by two separate LSTMs. The decoder remains a standard forward LSTM.

3.3 Representing Argument Components

At each timestep of the encoder, the network takes in a representation of an AC. Each AC is itself

[1] We also experimented with relu and elu activations, but found sigmoid to yield the best performance.

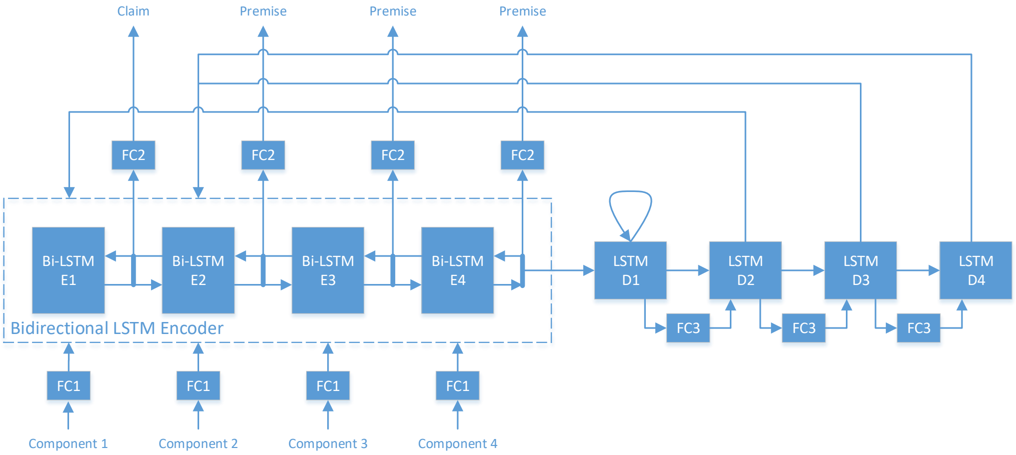

Figure 3: Architecture of the joint model applied to the example in Figure 1. Note that D1 points to itself to denote that it has not outgoing link and is therefore the head of a tree.

a sequence of tokens, similar to the Question-Answering dataset from Weston et al. (2015). We follow the work of Stab and Gurevych (2016) and focus on three different types of features to represent our ACs: (1) Bag-of-Words of the AC; (2) Embedding representation based on GloVe embeddings (Pennington et al., 2014), which uses average, max, and min pooling across the token embeddings; (3) Structural features: Whether or not the AC is the first AC in a paragraph, and whether the AC is in an opening, body, or closing paragraph. See Section 6 for an ablation study of the proposed features.

3.4 Joint Neural Model

Up to this point, we focused on the task of extracting links between ACs. However, recent work has shown that joint models that simultaneously try to complete multiple aspects of the subtask pipeline outperform models that focus on a single subtask (Persing and Ng, 2016; Stab and Gurevych, 2014b; Peldszus and Stede, 2015). Therefore, we will modify the single-task architecture so that it would allow us to perform AC classification (Kwon et al., 2007; Rooney et al., 2012) together with link prediction. Knowledge of an individual subtask's predictions can aid in other subtasks. For example, *claims* do not have an outgoing link, so knowing the type of AC can aid in the link prediction task. This can be seen as a way of regularizing the hidden representations from the encoding component (Che et al., 2015).

At each timestep, predicting AC type is a straightforward classification task: given AC C_i, we need to predict whether it is a *claim*, *premise*, or possibly *major claim*. More generally, this is another sequence modeling problem: given input sequence E, we want to predict a sequence of argument types T. For encoding timestep i, the model creates hidden representation e_i. This can be thought of as a representation of AC C_i. Therefore, our joint model will simply pass this representation through a fully-connected layer as follows:

$$z_i = W_{cls}e_i + b_{cls} \tag{6}$$

where W_{cls}, b_{cls} become elements of the model parameters, Θ. The dimensionality of W_{cls}, b_{cls} is determined by the number of classes. Lastly, we use softmax to form a distribution over the possible classes.

Consequently, the probability of predicting the component type at timestep i is defined as:

$$p(T_i|E_i;\Theta) = softmax(z_i) \tag{7}$$

Finally, combining this new prediction task with Equation 2, we arrive at the new training objective:

$$\begin{aligned}\Theta^* = \arg\max_{\Theta} \alpha \sum_{E,D} \log p(D|E;\Theta) \\ +(1-\alpha)\sum_{E} \log p(T|E;\Theta)\end{aligned} \tag{8}$$

which simply sums the costs of the individual prediction tasks, and the second summation is the cost for the new task of predicting AC type. $\alpha \in [0,1]$ is a hyperparameter that specifies how we weight the two prediction tasks in our cost function. The architecture of the joint model, applied to our ongoing example, is illustrated in Figure 3.

4 Experimental Design

As we have mentioned, our work assumes that ACs have already been identified. The order of ACs corresponds directly to the order in which the ACs appear in the text. We test the effectiveness of our proposed model on a dataset of persuasive essays (PEC) (Stab and Gurevych, 2016), as well as a dataset of microtexts (MTC) (Peldszus, 2014). The feature space for the PEC has roughly 3,000 dimensions, and the MTC feature space has between 2,500 and 3,000 dimensions, depending on the data split. The PEC contains a total of 402 essays, with a frozen set of 80 essays held out for testing. There are three AC types in this corpus: *major claim*, *claim*, and *premise*. In this corpus, individual structures can be either trees or forests. Also, in this corpus, each essay has multiple paragraphs, and argument structure is only uncovered within a given paragraph. The MTC contains 112 short texts. Unlike the PEC, each text in this corpus is itself a complete example, as well as a single tree. Since the dataset is small, the authors have created 10 sets of 5-fold cross-validation, reporting the the average across all splits for final model evaluation. This corpus contains only two types of ACs: *claim* and *premise*. Note that link prediction is directed, i.e., predicting a link between the pair $C_i, C_j (i \neq j)$ is different than C_j, C_i.

We implement our models in TensorFlow (Abadi et al., 2015). We use the following parameters: hidden input dimension size 512, hidden layer size 256 for the bidirectional LSTMs, hidden layer size 512 for the LSTM decoder, α equal to 0.5, and dropout (Srivastava et al., 2014) of 0.9. We believe the need for such high dropout is due to the small amounts of training data (Zarrella and Marsh, 2016), particularly in the MTC. All models are trained with Adam optimizer (Kingma and Ba, 2014) with a batch size of 16. For a given training set, we randomly select 10% to become the validation set. Training occurs for 4,000 epochs. Once training is completed, we select the model with the highest validation accuracy (on the link prediction task) and evaluate it on the held-out test set. At test time, we take a greedy approach and select the index of the probability distribution (whether link or type prediction) with the highest value.

5 Results

The results of our experiments are presented in Tables 1 and 2. For each corpus, we present f1 scores for the AC type classification experiment, with a macro-averaged score of the individual class f1 scores. We also present the f1 scores for predicting the presence/absence of links between ACs, as well as the associated macro-average between these two values.

We implement and compare four types of neural models: 1) The previously described joint model from Section 3.4 (called Joint Model in the tables); 2) The same as 1), but without the fully-connected input layers (called Joint Model No FC Input in the table); 3) The same as 1), but the model only predicts the link task, and is therefore not optimized for type prediction (called Single-Task Model in the table); 4) A non-sequence-to-sequence model that uses the hidden layers produced by the BLSTM encoder with the same type of attention as the joint model (called Joint Model No Seq2Seq in the table). That is, d_i in Equation 3 is replaced by e_i.

In both corpora we compare against the following previously proposed models: Base Classifier (Stab and Gurevych, 2016) is a feature-rich, task-specific (AC type or link extraction) SVM classifier. Neither of these classifiers enforce structural or global constraints. Conversely, the ILP Joint Model (Stab and Gurevych, 2016) provides constraints by sharing prediction information between the base classifiers. For example, the model attempts to enforce a tree structure among ACs within a given paragraph, as well as using incoming link predictions to better predict the type class *claim*. For the MTC only, we also have the following comparative models: Simple (Peldszus and Stede, 2015) is a feature-rich logistic regression classifier. Best EG (Peldszus and Stede, 2015) creates an Evidence Graph (EG) from the predictions of a set of base classifiers. The EG models the potential argument structure, and offers a global optimization objective that the base classifiers attempt to optimize by adjusting their individual weights. Lastly, MP+p (Peldszus and Stede, 2015) combines predictions from base classifiers with a Minimum Spanning Tree Parser (MSTParser).

6 Discussion

First, we point out that the joint model achieves state-of-the-art on 10 of the 13 metrics in Tables 1 and 2, including the highest results in all metrics on the PEC, as well as link prediction on the MTC. The performance on the MTC is very en-

	Type prediction				Link prediction		
Model	Macro f1	MC f1	Cl f1	Pr f1	Macro f1	Link f1	No Link f1
Base Classifier	.794	.891	.611	.879	.717	.508	.917

Joint Model	**.849**	**.894**	**.732**	**.921**	**.767**	**.608**	**.925**

Table 1: Results on the Persuasive Essay corpus. All models we tested are joint models, except for the Single-Task Model model, which only predicts links. All model have a fully-connected input layer, except for the row titled 'Joint Model No FC Input'. See Section 5 for a full description of the models.

	Type prediction			Link prediction		
Model	Macro f1	Cl f1	Pr f1	Macro f1	Link f1	No Link f1
Simple	.817	-	-	.663	.478	.848
Best EG	**.869**	-	-	.693	.502	.884
MP+p	.831	-	-	.720	.546	.894
Base Classifier	.830	.712	.937	.650	.446	.841
ILP Joint Model	.857	.770	.943	.683	.486	.881
Joint Model	.813	.692	.934	**.740**	**.577**	**.903**

Table 2: Results on the Microtext corpus.

couraging for several reasons. First, the fact that the model can perform so well with only a hundred training examples is rather remarkable. Second, although we motivate the use of an attention model due to the fact that it partially enforces a tree structure, other models we compare against explicitly contain further constraints (for example, only premises can have outgoing links). Moreover, the MP+p model directly enforces the single tree constraint unique to the microtext corpus (the PEC allows forests). Even though the joint model does not have the tree constraint directly encoded, it able to learn the structure effectively from the training examples so that it can outperform the Mp+p model for link prediction. As for the other neural models, the joint model with no seq2seq performs competitively with the ILP joint model on the PEC, but trails the performance of the joint model. We believe this is because the joint model is able to create two different representations for each AC, one each in the encoding/decoding state, which benefits performance in the two tasks. We also believe that the joint model benefits from a second recurrence over the ACs, modeling the tree/forest structure in a linear manner. Conversely, the joint model with no seq2seq must encode information relating to type as well as link prediction in a single hidden representation. On one hand, the joint model no seq2seq outperforms the ILP model on link prediction, yet it is not able to match the ILP joint model's performance on type prediction, primarily due to the poor performance on predicting the *major claim* class. Another interesting outcome is the importance of the fully-connected layer before the LSTM input. This extra layer seems to be crucial for improving performance on this task. The results dictate that even a simple fully-connected layer with sigmoid activation can provide a useful dimensionality reduction step. Finally, and arguably most importantly, the single-task model, only optimized for link prediction, suffers a large drop in performance, conveying that the dual optimization of the joint model is vital for high performance in the link prediction task. We believe this is because the joint optimization creates more expressive representations of the ACs, which capture the natural relation between AC type and AC linking.

Table 3 shows the results of an ablation study for AC feature representation. Regarding link prediction, BOW features are clearly the most important, as their absence results in the highest drop in performance. Conversely, the presence of structural features provides the smallest boost in performance, as the model is still able to record state-

	Type prediction				Link prediction		
Model	Macro f1	MC f1	Cl f1	Pr f1	Macro f1	Link f1	No Link f1
No structural	.808	.824	.694	.907	.760	.598	.922
No BOW	.796	.833	.652	.902	.728	.543	.912
No Embeddings	.827	.874	.695	.911	.750	.581	.918
Only Avg Emb*	.832	.873	.717	.917	.751	.583	.918
Only Max Emb*	.843	.874	**.732**	**.923**	.766	**.608**	.924
Only Min Emb*	.838	.878	.719	.918	.763	.602	.924
All features	**.849**	**.894**	**.732**	.921	**.767**	**.608**	**.925**

Table 3: Feature ablation study. * indicates that both BOW and Structural are present, as well as the stated embedding type.

	Type prediction				Link prediction		
Bin	Macro f1	MC f1	Cl f1	Pr f1	Macro f1	Link f1	No Link f1
$1 \leq len < 4$	.863	.902	.798	.889	.918	.866	.969
$4 \leq len < 8$	.680	.444	.675	.920	.749	.586	.912
$8 \leq len < 12$	.862*	.000*	.762	.961	.742	.542	.941

Table 4: Results of binning test data by length of AC sequence. * indicates that this bin does not contain any *major claim* labels, and this average only applies to *claim* and *premise* classes. However, we do not disable the model from predicting this class: the model was able to avoid predicting this class on its own.

of-the-art results compared to the ILP Joint Model. This shows that the Joint Model is able to capture structural cues through sequence modeling and semantics. When considering type prediction, both BOW and structural features are important, and it is the embedding features that provide the least benefit. The ablation results also provide an interesting insight into the effectiveness of different pooling strategies for using individual token embeddings to create a multi-word embedding. The popular method of averaging embeddings (which is used by Stab and Gurevych (2016) in their system) is in fact the worst method, although its performance is still competitive with the previous state-of-the-art. Conversely, max pooling results are on par with the joint model results in Table 1.

Table 4 shows results on the PEC test set with the test examples binned by sequence length. First, it is not surprising to see that the model performs best when the sequences are the shortest (for link prediction; type prediction actually sees the worst performance in the middle bin). As the sequence length increases, the accuracy on link prediction drops. This is possibly due to the fact that as the length increases, a given AC has more possibilities as to which other AC it can link to, making the task more difficult. Conversely, there is actually a rise in no link prediction accuracy from the second to third row. This is likely due to the fact that since the model predicts at most one outgoing link, it indirectly predicts no link for the remaining ACs in the sequence. Since the chance probability is low for having a link between a given AC in a long sequence, the no link performance is actually better in longer sequences. The results of the length-based binning could also potentially give insight into the poor performance on the type prediction task in the MTC. Since the arguments in the MTC average 5 ACs, they would be in the second bin (row 2) of Table 4. The *claim* and *premise* f1 scores for this bin are similar to those from the same system's performance on the MTC.

7 Conclusion

In this paper we have proposed how to use a joint sequence-to-sequence model with attention (Vinyals et al., 2015b) to both extract links between ACs and classify AC type. We evaluate our models on two corpora: a corpus of persuasive essays (Stab and Gurevych, 2016), and a corpus of microtexts (Peldszus, 2014). The Joint Model records state-of-the-art results on the persuasive essay corpus, as well as achieving state-of-the-art results for link prediction on the microtext corpus. The results show that jointly modeling the two prediction tasks is critical for high performance. Future work can attempt to learn the AC representations themselves, such as in Kumar et al. (2015).

Lastly, future work can integrate subtasks 1 and 4 into the model. The representations produced by Equation 3 could potentially be used to predict link type, i.e. supporting or attacking (the fourth subtask in the pipeline). In addition, a segmenting technique, such as the one proposed by Weston et al. (2014), can accomplish subtask 1.

Identifying *attack* and *support* argumentative relations using deep learning

Oana Cocarascu and **Francesca Toni**
Department of Computing
Imperial College London

Abstract

We propose a deep learning architecture to capture argumentative relations of *attack* and *support* from one piece of text to another, of the kind that naturally occur in a debate. The architecture uses two (unidirectional or bidirectional) Long Short-Term Memory networks and (trained or non-trained) word embeddings, and allows to considerably improve upon existing techniques that use syntactic features and supervised classifiers for the same form of (relation-based) argument mining.

1 Introduction

Argument Mining (AM) is a relatively new research area which involves, amongst others, the automatic detection in text of arguments, argument components, and relations between arguments (see (Lippi and Torroni, 2016) for an overview). We focus on a specific type of AM, referred to as *Relation-based AM* (Carstens and Toni, 2015), which has recently received attention by several researchers (e.g. see (Bosc et al., 2016; Carstens and Toni, 2017)). This type of AM aims at identifying argumentative relations of *attack* and *support* between natural language arguments in text, by classifying pairs of pieces of text as belonging to *attack*, *support* or *neither attack nor support* relations. For example, consider the three texts taken from Carstens and Toni (2015):

t_1: *'We should grant politicians immunity from prosecution'*

t_2: *'Giving politicians immunity allows them to focus on performing their duties'*

t_3: *'The ability to prosecute politicians is the ultimate protection against abuse of power'*

Here t_2 *supports* t_1, t_3 *attacks* t_1, and t_2 and t_3 *neither attack nor support* one another.

Relation-based AM is useful, for example, to pave the way towards identifying accepted opinions (Bosc et al., 2016) or divisive issues (Konat et al., 2016) within debates.

We propose a deep learning architecture for Relation-based AM based on Long-Short Term Memory (LSTM) networks (Hochreiter and Schmidhuber, 1997; Schuster and Paliwal, 1997). Within the architecture, each input text is fed, as a (trained or non-trained) 100-dimensional GloVe embedding (Pennington et al., 2014), into a (unidirectional or bidirectional) LSTM which produces a vector representation of the text independently of the other text being analysed. The two vectors are then merged (using element-wise sum or concatenation) and the resulting vector is fed to a softmax classifier which predicts whether the pair of input texts belongs to the *attack*, *support* or *neither* relations. The input texts may be at most 50 words long, but are not restricted to single sentences.

We experimented with several instances of the architecture and achieved 89.53% accuracy and 89.07% F_1 using unidirectional LSTMs and concatenation as the merge layer, considerably outperforming feature-based supervised classifiers used in the studies which presented the corpus we also use (Carstens and Toni, 2015, 2017).

The remainder of the paper is organised as follows. In Section 2 we discuss related work and the corpus we use. In Section 3 we describe our deep learning architecture and report experiments and results in Section 4. We conclude the paper and propose directions for future work in Section 5.

2 Background

2.1 Recurrent Neural Networks

Recurrent Neural Networks (RNNs) (Elman, 1990; Mikolov et al., 2010) are a type of neural networks in which the hidden layer is connected to itself so that the previous hidden state is used along with the input at the current step. RNNs tend to suffer from the vanishing gradients problem (Bengio et al., 1994) while trying to capture long-term dependencies.

LSTM models (Hochreiter and Schmidhuber, 1997), a type of RNNs, address this problem by introducing memory cells and gates into networks. LSTMs use memory cells to store contextual information and three types of gates (input, forget, and output gates) that determine which information needs to be added or removed to learn long-term dependencies within a sequence.

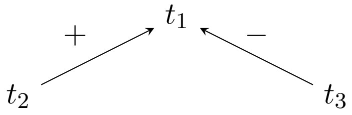
One problem with RNNs/LSTMs in natural language processing is that they do not make use of the information of future words. Bidirectional RNNs/LSTMs (BiRNNs/BiLSTMs) (Schuster and Paliwal, 1997) solve this problem by using both previous and future words while processing the input sequence with two RNNs: one in the forward and one in the backward direction, resulting in two vectors for each input.

2.2 Related work

Identifying relations between texts has recently received a great deal of attention, e.g. in Argument Mining (AM) (see (Lippi and Torroni, 2016) for a recent overview). In particular, *Relation-based AM* (Carstens and Toni, 2015) aims to automatically identify argumentative relations to create Bipolar Argumentation Frameworks (BAFs) (Cayrol and Lagasquie-Schiex, 2005).

BAFs are triples $\langle AR, attacks, supports\rangle$ consisting of a set of arguments AR and two binary relations $attacks$ and $supports$ between arguments.

The example texts introduced in Section 1 form a BAF with $AR = \{t_1, t_2, t_3\}$ and $attacks$, $supports$ given graphically (as -, + respectively) as follows:



Carstens and Toni (2017) obtained 61.8% accuracy and 62.1% F_1 on a news articles using Support Vector Machines (SVMs) and features such as distance measures, word overlap, sentence metrics and occurences of sentiment words.

Bosc et al. (2016) used a corpus consisting of tweets to determine *attack* and *support* relations between tweets. Using an encoder-decoder architecture and two LSTMs (the second LSTM initialised with the last hidden state of the first LSTM), they obtained negative results (0.2 F_1 for *support* and 0.16 F_1 for *attack*).

Other works in AM use deep learning models to determine relations between arguments, but of a different kind than in our work. Notably, Habernal and Gurevych (2016) experimented with LSTM models extended with an attention mechanism and a convolution layer over the input pairs to determine whether an input argument is more convincing than the other input argument. Thus, their focus is on determining a “more convincing than” relation, rather than *attack* and *support* argumentative relations, between arguments.

Several authors used neural network models for tasks related to the form of AM we consider. Yin et al. (2016) proposed three attention mechanisms for Convolutional Neural Networks to model pairs of sentences in tasks such as textual entailment and answer selection, whereas dos Santos et al. (2016) proposed a two-way attention mechanism to jointly learn the representation of two inputs in an answer selection setting.

Bowman et al. (2015) used stacked LSTMs to determine entailment, neutral and contradiction relations amongst sentence pairs using the SNLI (Stanford Natural Language Inference) corpus, with the bottom layer taking as input the concatenation of the input sentences. Recognising textual entailment between two sentences was also addressed in (Rocktäschel et al., 2015) which used LSTMs and a word-by-word neural attention mechanism on the SNLI corpus.

Liu et al. (2016) proposed two models capturing the interdependencies between the two parallel LSTMs encoding two input sentences for the tasks of recognising textual entailment and matching questions and answers. Further, Koreeda et al. (2016) used a BiRNN with a word-embedding-based attention model to determine whether a piece of an evidence supports a claim that a phrase promotes or suppresses a value, using a dataset of 1000 pairs.

2.3 Dataset

Determining relations between any texts can be seen as a three-class problem, with labels $L = \{attack, support, neither\}$. We used a dataset covering various topics such as movies, technology and politics[1], where *attack* relations represent 31% of the dataset, *support* relations represent 32% of the dataset and *neither* relations represent 37% of the dataset.

We have also explored the use of other corpora (e.g. the SNLI corpus (Bowman et al., 2015) and Araucaria in AIFdb[2]) that we ultimately decided not to include due to their structure not being directly amenable to our analysis.

3 Architecture

Figure 1 summarises the deep learning architecture that we use for predicting which relation from $L = \{attack, support, neither\}$ holds between the first and the second texts in any input pair.

We do not limit input texts to be single sentences, but limit them to 50 words (as this is the average text length in our corpus): inputs whose size is smaller than this threshold are padded with zeros at the end to give sequences of exactly 50 words. The input texts are (separately) embedded as 100-dimensional GloVe vectors (Pennington et al., 2014), with the words that do not appear in the vectors being treated as unknown. As we will see in Section 4, we experimented with the pre-trained word representations (freezing the weights during learning) as well as learning the weights.

The architecture relies upon two parallel LSTMs to model the two texts separately. We experimented with both unidirectional and bidirectional LSTMs (see Section 4). In both cases, we set the LSTM dimension to 32, as this proved to be the best, amongst alternatives (64, 100, 128), for mitigating overfitting. In addition, our LSTMs use a Rectified Linear Unit (ReLU) activation, each returning a vector of dimension 32.

Each LSTM network produces a vector representation of the input text, independently of the other text being analysed. The two vectors are then merged and the resulting vector fed to a softmax classifier which predicts the label for the relation between the first and the second input texts. As we will see in Section 4, we experimented with two types of merge layer: *sum*, which performs element-wise sum, and *concat*, which performs tensor concatenation.

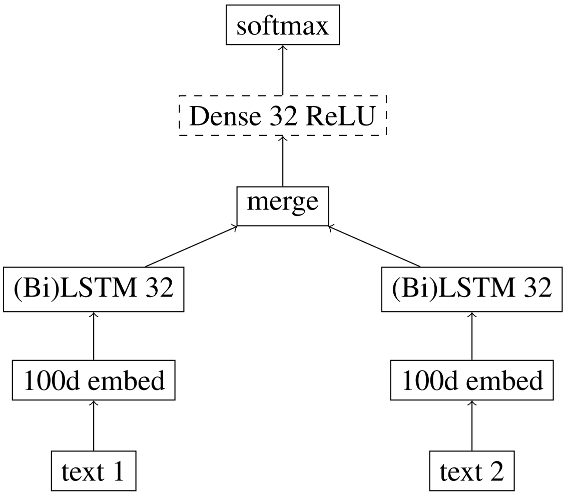


Figure 1: Our architecture: two (unidirectional or bidirectional) LSTMs are run with one text each. The dashed layer (Dense 32 ReLU) is optional.

Hyper-parameter	Value	Hyper-parameter	Value
Dropout	0.2	LSTM size	32
Embedding size	100	Dense size	32
Sequence length	50	Batch size	128

Table 1: Hyper-parameters for our (Bi)LSTMs.

After the merge layer, our architecture incorporates an optional dense feedforward layer. Our experiments (see Section 4) included testing whether the inclusion of this layer has an impact on the results. Again, we chose the dimension (32) as it proved better for mitigating overfitting than alternatives that we tried (64).

The values for the hyper-parameters used in our experiments (see Section 4) are summarised in Table 1. We used a mini-batch size of 128 and cross-entropy loss. To avoid overfitting, we applied dropout before the merge layer with probability 0.2, but not on the recurrent units. The hyper-parameters were optimised using the Adam method (Kingma and Ba, 2014) with learning rate 0.001, which turned out to give better performances than alternative optimisers we tried (Adagrad, Adadelta and RMSprop).

4 Results

We trained for 50 epochs or until the performance on the development set stopped improving, in order to avoid overfitting. The development set was 20% of the training dataset in the 10-fold cross-validation setup. In more detail, we run 10 stratified fold cross-validation for 5 times (so that each fold is a good representative of the whole). We report the average results of the 5x10 fold cross-validation in Table 2. As baseline, we used Logistic Regression (LR) and unigrams obtained from concatenating the two input texts.

We experimented with using BiLSTMs and unidirectional LSTMs with the two types of merge layers and using non-trained embeddings, namely pre-trained word representations (freezing the weights during learning), or trained embeddings, learning the weights during training.

We achieved 89.53% accuracy and 89.07% F_1 by concatenating the output of the two separate LSTMs. Unexpectedly, BiLSTMs performed worse than LSTMs (Table 2 only includes the best performing BiLSTM instance of the architecture, using concatenation and the feedforward layer). We believe this is because of the size of the dataset and that this effect could be diminished by acquiring more data. For the LSTM model with trained embeddings, the accuracy varied between 84.84% and 90.02%. Concatenating the LSTMs' output vectors yields better performance than performing element-wise sum of the vectors. We believe this is because this allows the system to encode more features, allowing the network to use more information.

Using the default, pre-trained word embeddings yields worse results compared to the baseline. We believe this is because the quality of word embeddings is dependent on the training corpora.[3] Training the word embeddings results in better performance compared to the baseline with improvements of up to 12% in accuracy and up to 11.5% in F_1.

In all cases, training the word embeddings results in dramatic improvements compared to freezing the embedding weights during learning, varying from 9.9% to 21.3% increase in accuracy and up to 25% in F_1. We also report the standard deviation of our models with trained embeddings. This shows that our best models (LSTMs with a concatenation layer) are stable and perform consistently on the task considered. Using One-Way ANOVA, the result is significant at $p < 0.05$ (the f-ratio value is 145.45159, the p-value is $<$ 0.00001).

5 Conclusion

We proposed a deep learning architecture based on Long Short-Term Memory (LSTM) networks to capture the argumentative relation of *attack* and *support* between any two texts. Our architecture uses two (unidirectional or bidirectional) LSTMs to analyse separately two 100-dimensional (non-trained or trained) GloVe vectors representing the two input texts. The outputs of the two LSTMs are then concatenated and fed to a softmax classifier to predict the relation between the input texts.

Our unidirectional LSTM model with trained embeddings and a concatenation layer achieved 89.53% accuracy and 89.07% F_1. The results indicate that LSTMs may be better suited for Relation-based Argument Mining at least for non-micro texts (Bosc et al., 2016) than standard classifiers as used in e.g. Carstens and Toni (2017), as LSTMs are better at capturing long-term dependencies between words and they operate over sequences, as found in text.

In future work, we plan to test our model on corpora such as the Language of Opposition from AIFdb[4] (by converting the finer-grained relation types used in this corpus to argumentative relations of the kind we considered), on datasets proposed for different tasks (e.g. identifying textual entailment could be seen as identifying support) and thus possibly use the corpus proposed by Bowman et al. (2015), as well as the twitter dataset of Bosc et al. (2016) once it becomes publicly available. Also, attack and support relations of the kind we have considered in this paper may be seen as special types of discourse relations (Teufel et al., 1999; Lin et al., 2009). It would be interesting to see whether any corpora for identifying discourse relations could be useful for furthering our experimentation. Finally, we plan to incorporate an attention-based mechanism as well as additional features (e.g. extracted through sentiment analysis) to determine which parts of the texts are most relevant in identifying attack and support.

[3] Pennington et al. (2014) computed the 100-dimensional GloVe embeddings on a a dump of English Wikipedia pages from 2014 consisting of 400k words.

Abstract

The input to a neural sequence-to-sequence model is often determined by an up-stream system, e.g. a word segmenter, part of speech tagger, or speech recognizer. These up-stream models are potentially error-prone. Representing inputs through word lattices allows making this uncertainty explicit by capturing alternative sequences and their posterior probabilities in a compact form. In this work, we extend the TreeLSTM (Tai et al., 2015) into a LatticeLSTM that is able to consume word lattices, and can be used as encoder in an attentional encoder-decoder model. We integrate lattice posterior scores into this architecture by extending the TreeLSTM's child-sum and forget gates and introducing a bias term into the attention mechanism. We experiment with speech translation lattices and report consistent improvements over baselines that translate either the 1-best hypothesis or the lattice without posterior scores.

1 Introduction

In many natural language processing tasks, we will require a down-stream system to consume the input of an up-stream system, such as word segmenters, part of speech taggers, or automatic speech recognizers. Among these, one of the most prototypical and widely used examples is speech translation, where a down-stream translation system must consume the output of an up-stream automatic speech recognition (ASR) system.

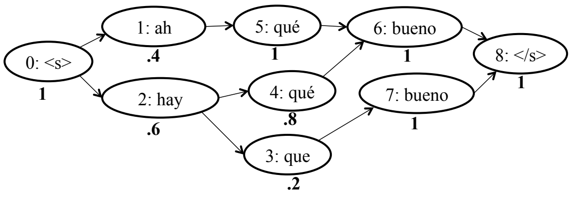

Figure 1: A lattice with 3 possible paths and posterior scores. Translating the whole lattice potentially allows for recovering from errors in its 1-best hypothesis.

Previous research on traditional phrase-based or tree-based statistical machine translation have used word lattices (e.g. Figure 1) as an effective tool to pass on uncertainties from a previous step (Ney, 1999; Casacuberta et al., 2004). Several works have shown quality improvements by translating lattices, compared to translating only the single best upstream output. Examples include translating lattice representations of ASR output (Saleem et al., 2004; Zhang et al., 2005; Matusov et al., 2008), multiple word segmentations, and morphological alternatives (Dyer et al., 2008).

Recently, neural sequence-to-sequence (seq2seq) models (Kalchbrenner and Blunsom, 2013; Sutskever et al., 2014; Bahdanau et al., 2015) have often been preferred over the traditional methods for their strong empirical results and appealing end-to-end modeling. These models force us to rethink approaches to handling lattices, because their recurrent design no longer allows for efficient lattice decoding using dynamic programming as was used in the earlier works.

As a remedy, Su et al. (2017) proposed replacing the sequential encoder by a lattice encoder to obtain a lattice-to-sequence (lat2seq) model. This is achieved by extending the encoder's Gated Recurrent Units (GRUs) (Cho et al., 2014) to be conditioned on multiple predecessor paths. The authors demonstrate improvements in Chinese-to-English translation by translating lattices that combine the output of multiple word segmenters, rather than a single segmented sequence.

Proceedings of the 2017 Conference on Empirical Methods in Natural Language Processing, pages 1380–1389
Copenhagen, Denmark, September 7–11, 2017. ©2017 Association for Computational Linguistics

However, this model does not address one aspect of lattices that we argue is critical to obtaining good translation results: their ability to encode the certainty or uncertainty of the paths through the use of posterior scores. Specifically, we postulate that these scores are essential for tasks that require handling lattices with a considerable amount of erroneous content, such as those produced by ASR systems. In this paper, we propose a lattice-to-sequence model that accounts for this uncertainty. Specifically, our contributions are as follows:

- We employ the popular child-sum TreeLSTM (Tai et al., 2015) to derive a lattice encoder that replaces the sequential encoder in an attentional encoder-decoder model. We show empirically that this approach yields only minor improvements compared to a baseline fine-tuned on sequential ASR outputs. This finding stands in contrast to the positive results by Su et al. (2017), and by Ladhak et al. (2016) on a lattice classification task, and suggests higher learning complexity of our speech translation task.
- We hypothesize that lattice scores are crucial in aiding training and inference, and propose several techniques for integrating lattice scores into the model: (1) We compute *weighted child-sums*,[1] where hidden units in the lattice encoder are conditioned on their predecessor hidden units such that predecessors with low probability are less influential on the current hidden state. (2) We bias the TreeLSTM's *forget gates* for each incoming connection toward being more forgetful for predecessors with low probability, such that their cell states become relatively less influential. (3) We *bias the attention mechanism* to put more focus on source embeddings belonging to nodes with high lattice scores. We demonstrate empirically that the third proposed technique is particularly effective and produces strong gains over the baseline. According to our knowledge, this is the first attempt of integrating lattice scores already at the *training stage* of a machine translation model.
- We exploit the fact that our lattice encoder is a strict generalization of a sequential encoder by *pre-training* on sequential data, obtaining faster and better training convergence on large corpora of parallel sequential data.

We conduct experiments on the Fisher and Callhome Spanish–English Speech Translation Corpus (Post et al., 2013) and report improvements of 1.4 BLEU points on Fisher and 0.8 BLEU points on Callhome, compared to a strong baseline optimized for translating 1-best ASR outputs. We find that the proposed integration of lattice scores is crucial for achieving these improvements.

2 Background

Our work extends the seminal work on attentional encoder-decoder models (Kalchbrenner and Blunsom, 2013; Sutskever et al., 2014; Bahdanau et al., 2015) which we survey in this section.

Given an input sequence $\boldsymbol{x} = (x_1, x_2, \ldots, x_N)$, the goal is to generate an appropriate output sequence $\boldsymbol{y} = (y_1, y_2, \ldots, y_M)$. The conditional probability $p(\boldsymbol{y} \mid \boldsymbol{x})$ is estimated using parameters trained on a parallel corpus, e.g. of sentences in the source and target language in a translation task. This probability is factorized as the product of conditional probabilities of each token to be generated: $p(\boldsymbol{y} \mid \boldsymbol{x}) = \prod_{t=1}^{M} p(y_t \mid \boldsymbol{y}_{<t}, \boldsymbol{x})$. The training objective is to estimate parameters θ that maximize the log-likelihood of the sentence pairs in a given parallel training set D: $J(\theta) = \sum_{(\boldsymbol{x},\boldsymbol{y})\in D} \log p(\boldsymbol{y} \mid \boldsymbol{x}; \theta)$.

2.1 Encoder

In our baseline model, the encoder is a bi-directional recurrent neural network (RNN), following (Bahdanau et al., 2015). Here, the source sentence is processed in both the forward and backward directions with two separate RNNs. For every input x_i, two hidden states are generated as

$$\overrightarrow{\mathbf{h}}_i = \mathrm{LSTM}\left(E_{\mathit{fwd}}(x_i), \overrightarrow{\mathbf{h}}_{i-1}\right) \qquad (1)$$

$$\overleftarrow{\mathbf{h}}_i = \mathrm{LSTM}\left(E_{\mathit{bwd}}(x_i), \overleftarrow{\mathbf{h}}_{i+1}\right), \qquad (2)$$

where E_{fwd} and E_{bwd} are source embedding lookup tables. We opt for long short-term memory (LSTM) (Hochreiter and Schmidhuber, 1997) recurrent units because of their high performance and in order to later take advantage of the TreeLSTM extension (Tai et al., 2015). We stack multiple LSTM layers and concatenate the final layer into the final source hidden state $\mathbf{h}_i = \overrightarrow{\mathbf{h}}_i \mid \overleftarrow{\mathbf{h}}_i$, where layer indices are omitted for simplicity.

2.2 Attention

We use an attention mechanism (Luong et al., 2015) to summarize the encoder outputs into a

[1] This is reminiscent of the weighted pooling strategy by Ladhak et al. (2016) for spoken utterance classification.

fixed-size representation. At each decoding time step j, a context vector $\mathbf{c}_j$ is computed as a weighted average of the source hidden states: $\mathbf{c}_j = \sum_{i=1}^{N} \alpha_{ij}\mathbf{h}_i$. The normalized attentional weights α_{ij} measure the relative importance of the source words for the current decoding step and are computed as a softmax with normalization factor Z summing over i:

$$\alpha_{ij} = \frac{1}{Z}\exp\left(\mathrm{s}\left(\mathbf{s}_{j-1}, \mathbf{h}_i\right)\right) \tag{3}$$

$\mathrm{s}(\cdot)$ is a feed-forward neural network with a single layer that estimates the importance of source hidden state $\mathbf{h}_i$ for producing the next target symbol y_j, conditioned on the previous decoder state $\mathbf{s}_{j-1}$.

2.3 Decoder

The decoder creates output symbols one by one, conditioned on the encoder states via the attention mechanism. It contains another LSTM, initialized using the final encoder hidden state: $\mathbf{s}_0 = \mathbf{h}_N$. The decoding at step j assumes a special start-of-sequence symbol y_0 and is computed as $\mathbf{s}_j = \mathrm{LSTM}\left(E_{trg}(y_{j-1}), \mathbf{s}_{j-1}\right)$, and then $\tilde{\mathbf{s}}_t = \tanh(W_{hs}[\mathbf{s}_j; \mathbf{c}_j] + \mathbf{b}_{hs})$ The conditional probability that the j-th target word is generated is: $p(y_j \mid \boldsymbol{y}_{<j}, \boldsymbol{x}) = \mathrm{softmax}(W_{so}\tilde{\mathbf{s}}_t + \mathbf{b}_{so})$. Here, E_{trg} is the target embedding lookup table, W_{hs} and W_{so} are weight matrices, and $\mathbf{b}_{hs}$ and $\mathbf{b}_{so}$ are bias vectors.

During decoding beam search is used to find an output sequence with high conditional probability.

3 Attentional Lattice-to-Sequence Model

The seq2seq model described above assumes sequential inputs and is therefore limited to taking a single output of an up-stream model as input. Instead, we wish to consume lattices to carry over uncertainties from an up-stream model.

3.1 Lattices

Lattices (e.g. Figure 1) represent multiple ambiguous or competing sequences in a compact form. They are a more efficient alternative to enumerating all hypotheses as an n-best list, as they allow for avoiding redundant computation over subsequences shared between multiple hypotheses. Lattices can either be produced directly, e.g. by an ASR dumping its pruned search space (Post et al., 2013), or can be obtained by merging several n-best sequences (Dyer et al., 2008; Su et al., 2017).

A word lattice $\mathcal{G} = \langle V, E\rangle$ is a directed, connected, and acyclic graph with nodes V and edges E. $V{\subset}\mathbb{N}$ is a node set, and $(k,i){\in}E$ denotes an edge connecting node k to node i. $C(i)$ denotes the set of predecessor nodes for node i. We assume that all nodes follow a topological ordering, such that $k{<}i \; \forall \; k{\in}C(i)$. Each node i is assigned a word label $w(i)$. [2] Every lattice contains exactly one start-of-sequence node with only outgoing edges, and exactly one end-of-sequence node with only incoming edges.

3.2 Lattices and the TreeLSTM

One thing to notice here is that lattice nodes can have multiple predecessor states. In contrast, hidden states in LSTMs and other sequential RNNs are conditioned on only one predecessor state ($\tilde{h}_j$ in left column of Table 1), rendering standard RNNs unsuitable for the modeling of lattices. Luckily Tai et al. (2015)'s TreeLSTM, which was designed to compose encodings in trees, is also straightforward to apply to lattices; the TreeLSTM composes multiple child states into a parent state, which can also be applied to lattices to compose multiple predecessor states into a successor state. Table 1, middle column, shows the TreeLSTM in its child-sum variant that supports an arbitrary number of predecessors. Conditioning on multiple predecessor hidden states is achieved by simply taking their sum as $\tilde{\mathbf{h}}_i$. Cell states from multiple predecessor are each passed through their own forget gates $\mathbf{f}_{jk}$ and then summed.

Encoding a lattice results in one hidden state for each lattice node. Our lat2seq framework uses this network as encoder, computing the attention over all lattice nodes.[3] In other words we replace (1) by the following:

$$\overrightarrow{\mathbf{h}}_i = \mathrm{LatticeLSTM}\left(\mathbf{x}_i, \{\overrightarrow{\mathbf{h}}_k \mid k{\in}C(i)\}\right) \tag{4}$$

Similarly, we encode the lattice in backward direction and replace (2) accordingly. Figure 2 illustrates the result. The computational complexity of the encoder is $\mathcal{O}(|V| + |E|)$, i.e. linear in the number of nodes plus number of edges in the graph. The complexity of the attention mechanism is $\mathcal{O}(|V|M)$, where M is the output sequence

[2] It is perhaps more common to think of each edge representing a word, but we will motivate why we instead assign word labels to nodes in §3.3.

[3] This is similar in spirit to Eriguchi et al. (2016) who used the TreeLSTM in an attentional tree-to-sequence model.

	Sequential LSTM	TreeLSTM	Proposed LatticeLSTM

length. $|V|$ depends on both the expected input sentence length and the lattice density.

3.3 Node-labeled Lattices

At this point we take a step back to motivate our choice of assigning word labels to lattice nodes, which is in contrast to the prior work by Ladhak et al. (2016) and Su et al. (2017) who assign word labels to edges. Recurrent states in edge-labeled lattice encoders are conditioned not only on multiple predecessor states, but must also aggregate words from multiple incoming edges. This implies that hidden units may represent more than one word in the lattice. Moreover, in the edge-labeled case hidden units that are in the same position in forward and backward encoders represent different words, but are nevertheless concatenated and attended to jointly. For these reasons we find our approach of encoding word-labeled lattices more intuitively appealing when used as input to an attentional decoder, although empirical justification is beyond the scope of this paper. We also note that it is easy to convert an edge-labeled lattice into a node-labeled lattice using the line-graph algorithm (Hemminger and Beineke, 1978), which we utilize in this work.

4 Integration of Lattice Scores

This section describes the key technical contribution of our work: integration of lattice scores encoding input uncertainty into the lat2seq framework. These lattice scores assign different probabilities to competing paths, and are often provided by up-stream statistical models. For example, an ASR may attach posterior probabilities that capture acoustic evidence and linguistic plausibility of words in the lattice. In this section, we describe our method, first explaining how we normalize scores to a format that is easily usable in our method, then presenting our methods for incorporating these scores into our encoder calculations.

4.1 Lattice Score Normalization

Lattice scores that are obtained from upstream systems (such as ASR) are typically given in forward-normalized fashion, interpreted as the probability

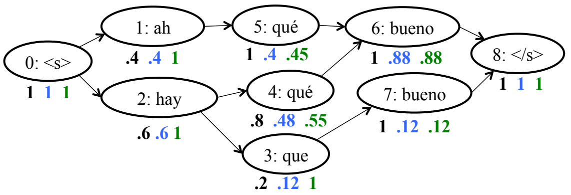

Figure 3: Lattice with forward-normalized, marginal, and backward-normalized scores.

of a node given its predecessor. Here, outgoing edges sum up to one, as illustrated in Figure 1. However, in some of our methods it will be necessary that scores be normalized in the backward direction, so that the weights from incoming connections sum up to one, or globally normalized, so that the probability of the node is the marginal probability of all the paths containing that node.

Let $w_{f,i}$, $w_{m,i}$, $w_{b,i}$ denote forward-normalized, marginal, and backward-normalized scores for node i respectively, illustrated in Figure 3. Given $w_{f,i}$, we can compute marginal probabilities recursively as $w_{m,i} = \sum_{k \in C(i)} w_{m,k} \cdot w_{f,i}$ by using the forward algorithm (Rabiner, 1989). Then, we can normalize backward using $w_{b,i} = \frac{w_{m,i}}{\sum_{k \in C'(i)} w_{m,k}}$, where $C'(i)$ denotes the successors of node i. All 3 forms are employed in the sections below.

Furthermore, when integrating these scores into the lat2seq framework, it is desirable to maintain flexibility over how strongly they should impact the model. For this purpose, we introduce a peakiness coefficient S. Given a lattice score $w_{b,i}$ in backward direction, we compute $w_{b,i}^{S}/Z_i$. $Z_i = \sum_{k \in C(i)} w_{b,k}$ is a re-normalization term to ensure that incoming connections still sum up to one. In the forward direction, we compute $w_{f,i}^{S}/Z_i$ and normalize analogously over outgoing connections. Setting $S=0$ amounts to ignoring the scores by flattening their distribution, while letting $S \to \infty$ puts emphasis solely on the strongest nodes. S can be optimized jointly with the other model parameters via back-propagation during model training.

4.2 Integration Approaches

We suggest three methods to integrate these scores into our lat2seq model, with equations shown in the right column of Table 1. These methods can optionally be combined, and we conduct an ablation study to assess the effectivity of each method in isolation (§5.3).

The first method consists of computing a weighted child-sum (WCS), using lattice scores as weights when composing the hidden state $\tilde{\mathbf{h}}_i$. This is based on the intuition that predecessor hidden states with high lattice weights should have a higher influence on their successor than states with low weights. The precise formulas for WCS are shown in (5).

The second method biases the forget gate $\mathbf{f}_{ik}$ for each predecessor cell state such that predecessors with high lattice score are more likely to pass through the forget gate (BFG). The intuition for this is similar to WCS; the composed cell state is more highly influenced by cell states from predecessors with high lattice score. BFG is implemented by introducing a bias term inside the sigmoid as in (6).

In the cases of both WCS and BFG, all hidden units have their own independent peakiness. Thus $\mathbf{S}_h$ and $\mathbf{S}_f$ are vectors, applied element-wise after broadcasting the lattice score. The renormalization terms $\mathbf{Z}_{h,k}$ and $\mathbf{Z}_{f,k}$ are also vectors and are applied element-wise. We use backward-normalized scores $w_{b,i}$ for the forward-directed encoder, and forward-normalized scores $w_{f,i}$ for the backward-directed encoder.

In the third and final method, we bias the attentional weights (BATT) to put more focus on lattice nodes with high lattice scores. This can potentially mitigate the problem of having multiple contradicting lattice nodes that may confuse the attentional decoder. BATT is computed by introducing a bias term to the attention as in (7). Attentional weights are scalars, so here the peakiness S_a is also a scalar. We drop the normalization term, relying instead on the softmax normalization. Both BFG and BATT use the logarithm of lattice scores so that values will still be in the probability domain after the softmax or sigmoid is computed.

4.3 Pre-training

Finally, note that our lattice encoder is a strict generalization of a sequential encoder. To reduce the computational burden, we exploit this fact and perform a two-step training process where the model is first *pre-trained* on sequential data, then *fine-tuned* on lattice data.[4] The pre-training, like standard training for neural machine translation (NMT), allows for efficient training using mini-batches, and also allows for training on standard text corpora for which we might not have lat-

[4] For the sequential data, we set all confidence scores to 1.

tices available. The fine-tuning is then performed on parallel data with lattices on the source side. This is much slower[5] than the pre-training because the network structure changes from sentence to sentence, preventing us from using efficient minibatched calculations. However, fine-tuning for only a small number of iterations is generally sufficient, as the model is already relatively accurate in the first place. In practice we found it important to use minibatches when fine-tuning, accumulating gradients over several examples before performing parameter updates. This provided negligible speedups but greatly improved optimization stability.

At test time, the model is able to translate both sequential and lattice inputs and can therefore be used even in cases where no lattices are available, at potentially diminished accuracy.

5 Experiments

5.1 Setting

We conduct experiments on the Fisher and Callhome Spanish–English Speech Translation Corpus (Post et al., 2013), a corpus of Spanish telephone conversations that includes automatic transcripts and lattices. The Fisher portion consists of telephone conversations between strangers, while the Callhome portion contains telephone conversations between relatives or friends. The training data size is 138,819 sentences (Fisher/Train), and 15,000 sentences (Callhome/Train). Held-out testing data is shown in Table 2. ASR word error rates (WER) are relatively high, due to the spontaneous speaking style and challenging acoustics. Lattices contain on average 3.4 (Fisher/Train) or 4.5 (Callhome/Train) times more words than the corresponding reference transcripts.

For preprocessing, we tokenized and lowercased source and target sides. We removed punctuation from the reference transcripts on the source side for consistency with the automatic transcripts and lattices. All models are pre-trained and fine-tuned on Fisher/Train unless otherwise noted. Our source-side vocabulary contains all words from the automatic transcripts for Fisher/Train, replacing singletons by an unknown word token, totaling 14,648 words. Similarly, on the target side we used all words from the reference translations of Fisher/Train, replacing singletons by the unknown word, yielding 10,800 words in total.

	1-best WER	oracle WER	# sent.
Fisher/Dev	41.3	19.3	3,979
Fisher/Dev2	40.0	19.4	3,961
Fisher/Test	36.5	16.1	3,641
Callhome/Devtest	64.7	36.4	3,966
Callhome/Evltest	65.3	37.9	1,829

Table 2: Development data statistics. Average sentence length is between 11.8 and 13.1.

Our implementation is based on lamtram (Neubig, 2015) and the DyNet (Neubig et al., 2017a) toolkit. We use the implemented attentional model with default parameters: a layer size of 256 per encoder direction and 512 for the decoder. Word embedding size was also set to 512. We used two encoder layers and two decoder layers for better baseline performance. For the sequential baselines, the LSTM variant in the left column of Table 1 was employed. We initialized the forget gate biases to 1 as recommended by Jozefowicz et al. (2015).

We used Adam (Kingma and Ba, 2014) for training, with an empirically determined initial learning rate of 0.001 for pre-training and 0.0001 for fine-tuning. We halve the learning rate when the dev perplexity (on Fisher/Dev) gets worse. Pre-training and fine-tuning on 1-best sequences is performed until convergence, and training on lattices is performed for 2 epochs to keep experimental effort manageable. On Fisher/Train, this took 3-4 days on a fast CPU.[6] Minibatch size was 1000 target words for pre-training, and 20 sentences for lattice training. Unless otherwise noted, we employed all three proposed lattice score integration approaches, and optimized peakiness coefficients jointly during training. We repeat training 3 times with different random seeds for parameter initialization and data shuffling, and report averaged results. We set the decoding beam size to 5.

[5] Our implementation processed sequential inputs about 75 times faster than lattice inputs during training, and overall fine-tuning convergence was 15 times faster. Decoding was only 1.2 times slower when using lattice inputs. Note that recently proposed approaches for autobatching (Neubig et al., 2017b) may considerably speed up lattice training.

[6] For comparison, we tried training on lattices from scratch, which took 9 days (6 epochs) to converge at a dev perplexity that was 10% worse than with the pre-training plus fine-tuning strategy. We also confirmed BLEU scores to be much inferior without pretraining.

5.2 Main Results

We compare 4 systems: Performing pre-training on the sequential reference transcripts only (R), fine-tuning on 1-best transcripts (R+1), fine-tuning on lattices without scores (R+L), and fine-tuning on lattices including lattice scores (R+L+S). At test time, we try references, lattice oracles,[7] 1-best transcripts, and lattices as inputs to all 4 systems. The former 2 experiments give upper bounds on achievable translation accuracy, while the latter 2 correspond to a realistic setting. Table 3 shows the results on Fisher/Dev2 and Fisher/Test.

Before even considering lattices, we can see that 1-best fine-tuning boosted BLEU scores quite impressively (1-best/R vs. 1-best/R+1), with gains of 1.3 and 0.7 BLEU points. This stands in contrast to Post et al. (2013) who find the 1-best transcripts not to be helpful for training a hierarchical machine translation system. Possible explanations are learning from repeating error patterns, and improved robustness to erroneous inputs. On top of these gains, our proposed set-up (lattice/R+L+S) improve BLEU scores by another 1.4. Removing the lattice scores (lattice/R+L) diminishes the results and performs worse than the 1-best baseline (1-best/R+1), indicating that the proposed lattice score integration is crucial for good performance. This demonstrates a clear advantage of our proposed method over that of Su et al. (2017).

As can be seen in the table, models fine-tuned on lattices show reasonable performance for both lattice and sequential inputs (1-best/R+L, lattice/R+L, 1-best/R+L+S, lattice/R+L+S). This is not surprising, given that the lattice training data includes lattices of varying density, including lattices with very few paths or even only one path. On the other hand, without fine-tuning on lattices, using lattices as input performs poorly (lattice/R and lattice/R+1). A closer look revealed that translations were often too long, potentially because implicitly learned mechanisms for length control were not ready to handle lattice inputs.

Table 3 reports perplexities for Fisher/Dev2. Unlike the corresponding BLEU scores, the lattice encoder appears stronger than the 1-best baseline in terms of perplexity even without lattice scores (lattice/R+L vs. 1-best/R+1). To understand this better, we computed the average entropy of the decoder softmax, a measure of how much confusion there is in the decoder predictions, independent of whether it selects the correct answer or not. Over the first 100 sentences, this value was 2.24 for 1-best/R+1, 2.39 for lattice/R+L, and 2.15 for lattice/R+L+S. This indicates that the decoder is more confused for lattices without scores, while integrating lattice scores removes this problem. These numbers also suggest that it may be possible to obtain further gains using methods that stabilize the decoder.

5.3 Ablation Experiments

Next, we conduct an ablation study to assess the impact of the three proposed extensions for integrating lattice scores (§4.2). We train models with different peakiness coefficients S, either ignoring lattices scores by fixing S=0, using lattice scores as-is by fixing S=1, or optimizing S during training. Table 4 shows the results. Overall, joint training of S gives similar results as fixing S=1, but both clearly outperform fixing S=0. Removing confidences (setting S=0) in one place at a time reveals that the attention mechanism is clearly the most important point of integration, while gains from the integration into child-sum and forget gate are smaller and not always consistent.

We also analyzed what peakiness values were actually learned. We found that all 3 models that we trained for the averaging purposes converged to S_a=0.62. $\mathbf{S}_h$ and $\mathbf{S}_f$ had per-vector means between 0.92 and 1.0, at standard deviations between 0.02 and 0.04. We conclude that while the peakiness coefficients were not particularly helpful in our experiments, stable convergence behavior makes them safe to use, and they might be helpful on other data sets that may contain lattice scores of higher or lower reliability.

5.4 Callhome Experiments

In this experiment, we test a situation in which we have a reasonable amount of sequential data available for pre-training, but only a limited amount of lattice training data for the fine-tuning step. This may be a more realistic situation, because speech translation corpora are scarce. To investigate in this scenario, we again pre-train our models on Fisher/Train, but then fine-tune them on the 9 times smaller Callhome/Train portion of the corpus. We fine-tune for 10 epochs, all other settings are as before. We use Callhome/Evltest for testing. Table 5 shows the results. The trends are consistent to §5.2: The proposed model (lattice/R+L+S) outperforms the 1-best baseline (1-best/R+1) by

0.8 BLEU points, which in turn beats the pre-trained system (1-best/R) by 1.5 BLEU points. Including the lattice scores is clearly beneficial, although lattices without scores also improve over 1-best inputs in this experiment.

5.5 Impact of Lattice Quality

Next, we analyze the impact of using lattices and lattice scores as the ASR WER changes. We concatenate all test data from Table 2 and divide the result into bins according to the 1-best WER. We sample 1000 sentences from each bin, and compare BLEU scores between several models.

The results are shown in Figure 4. For very good WERs, lattices do not improve over 1-best inputs, which is unsurprising. In all other cases, lattices are helpful. Lattice scores are most beneficial for moderate WERs, and not beneficial for very high WERs. We speculate that for high WERs, the lattice scores tend to be less reliable than for lower WERs.

6 Conclusion

We investigated translating uncertain inputs from an error-prone up-stream component using a neu-

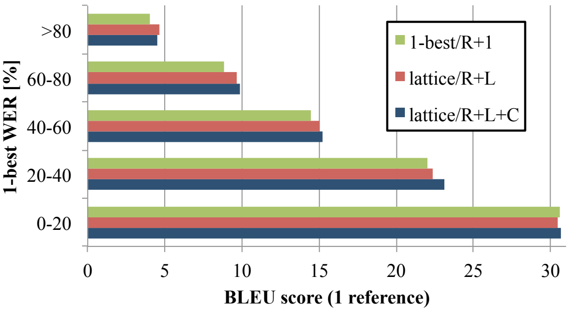

Figure 4: BLEU score over varying 1-best WERs.

ral lattice-to-sequence model. Our proposed model takes word lattices as input and is able to take advantage of lattice scores. In our experiments in a speech translation task we find consistent improvements over translating 1-best transcriptions and that consideration of lattice scores, especially in the attention mechanism, is crucial for obtaining these improvements.

Promising avenues for future work are investigating consensus networks (Mangu et al., 2000) for potential gains in terms of speed or quality as compared to lattice inputs, explicitly dealing with rare or unknown words in the lattice, and facilitating GPU training via autobatching (Neubig et al., 2017b).

Abstract

Neural machine translation (NMT) has achieved notable success in recent times, however it is also widely recognized that this approach has limitations with handling infrequent words and word pairs. This paper presents a novel memory-augmented NMT (M-NMT) architecture, which stores knowledge about how words (usually infrequently encountered ones) should be translated in a memory and then utilizes them to assist the neural model. We use this memory mechanism to combine the knowledge learned from a conventional statistical machine translation system and the rules learned by an NMT system, and also propose a solution for out-of-vocabulary (OOV) words based on this framework. Our experiments on two Chinese-English translation tasks demonstrated that the M-NMT architecture outperformed the NMT baseline by 9.0 and 2.7 BLEU points on the two tasks, respectively. Additionally, we found this architecture resulted in a much more effective OOV treatment compared to competitive methods.

1 Introduction

Neural Machine Translation (NMT) has been shown to have highly promising performance, particularly when a large amount of training data is available (Wu et al., 2016; Johnson et al., 2016; Mi et al., 2016). Although there are different model architectures (Sutskever et al., 2014; Bahdanau et al., 2015), the common principle behind the NMT approach is the same: encoding the meaning of the input into a concept space and performing translation based on this encoding. This 'meaning encoding' principle leads to a deeper understanding and learning of the translation rules, and hence a better translation than conventional statistic machine translation (SMT) that considers only surface forms, i.e., words and phrases (Koehn et al., 2003).

src.	人类共有二十三对染色体。
ref.	Humans have 23 pairs of chromosomes.
NMT	There are 23-year history of human history.

Table 1: An example of Chinese-to-English 'meaning drift' with NMT.

Despite positive results obtained so far, a particular problem of the NMT approach is that it has a tendency towards overfitting to frequent observations (words, word co-occurrences, translation pairs, etc.), but overlooking special cases that are not frequently observed. For example, NMT is good at learning translation pairs that are frequently observed, and can make use of them well at run-time, but for low-frequency pairs in the training data, the system may 'forget' to use them when they should be. Unfortunately, rare words are inevitable for all translation tasks due to Zipf's law, and indeed they are often the most important parts of a sentence, e.g., domain-specific entity names. Table 1 shows an example, where the word '染色体(chromosomes)' is an infrequent word. As the system does not know (or has effectively 'forgotten') this keyword, it does not translate correctly, and an irrelevant translation is produced, leading to the phenomenon of 'meaning drift'. This weakness with regard to infrequent words/pairs with NMT has been noticed by a number of researchers, and some studies have been conducted to address this problem, e.g., Luong et al. (2014); Cho et al. (2014); Li et al. (2016); Arthur et al. (2016); Bentivogli et al. (2016); Zhang et al. (2017).

Proceedings of the 2017 Conference on Empirical Methods in Natural Language Processing, pages 1390–1399
Copenhagen, Denmark, September 7–11, 2017. ©2017 Association for Computational Linguistics

Superficially, this problem appears to be caused by the imperfect embeddings of infrequent words or the limited vocabulary size of NMT systems, but we argue that the deeper reason should be attributed to the nature of neural models: the translation function, represented by various neural networks, is shared amongst all of the translation pairs, so high-frequency and low-frequency pairs impact each other by adapting their shared parameters. Due to the overwhelming proportion of high-frequency pairs in the training data, the resulting trained model will naturally be much more focused on these frequently observed pairs. More seriously, because the translation function is smooth, infrequent pairs tend to be wrongly seen as noise in the training process and so are largely ignored by the model.

In contrast to this, the conventional SMT approach is based on statistics of words and/or phrases, which, in principle, is a symbolic method that uses a discrete model and involves little parameter sharing. The discrete model means that no matter how infrequently a pair occurs, its probability cannot be smoothed out, and the lack of shared parameters means that the frequent words or pairs have much less impact on infrequent words or pairs. Essentially, SMT memorizes as many of the observed patterns as possible, usually using a phrase table.

The respective advantages of SMT and NMT suggest that neither the pure neural approach nor the pure symbolic approach can provide a complete solution for machine translation, and a combined system that exploits the advantages of both approaches would be ideal. This idea has been adopted in early research into neural-based MT methods, where neural models were utilized to improve SMT performance (Zhang et al., 2015). However, this seems to be counterintuitive, as intuitively learning general rules should be the first step, rather than first memorizing special cases and then learning general rules. This suggests that the combined system should be primarily based on the neural architecture, with symbolic knowledge as a complementary support.

This paper presents such a neural-symbolic architecture, which involves a neural model component to deal with frequently seen patterns, and a memory component to provide knowledge for infrequently used words and pairs. More specifically, each memory element stores a source-target pair, specifying that a word defined by the source part should be translated to the word defined by the target part. This knowledge is then used to improve the neural model. This is analogy to an experienced translator, who can work well in most cases using their own knowledge (i.e. the neural model aspect), but for unfamiliar and uncommon words that they have little experience of, they will still need to refer to a dictionary (i.e., the memory). This proposed memory-augmented NMT, or M-NMT, is therefore arguably much more similar to human translators than either NMT or SMT.

2 Attention-based NMT

Before introducing our M-NMT architecture, we will give a brief review of our implementation of the attention-based RNN model first presented by Bahdanau et al. (2015). This model is regarded as the state-of-the-art model and will be used as the baseline system in this study. Additionally, the neural model component of the M-NMT architecture uses the same attention-based RNN model, as being presented in the following.

The attention-based RNN model is based on an encoder-decoder frame, where the input word sequence $[x_1, x_2, ...]$ in the source language is embedded as a sequence of hidden states $[h_1, h_2, ...]$ by a bi-directional RNN with GRU as the hidden units, and another RNN is used to produce the target sentence $[y_1, y_2, ...]$. To force the generation to focus on a particular segment of the input at each generation step, Bahdanau et al. (2015) proposed an attention mechanism. Specifically, when generating the i-th target word, the attention factor of the j-th source word (and its neighbors, precisely) is measured by the relevance between the current hidden state of the decoder, denoted by s_{t-1}, and the hidden state of the encoder at the j-th word h_j. This can be calculated by any similarity function, but a multiple layer perceptron (MLP) is often used, given by:

$$\alpha_{ij} = \frac{e_{ij}}{\sum e_{ik}}; \quad e_{ij} = a(s_{i-1}, h_j)$$

where $a(\cdot, \cdot)$ is the MLP-based relevance function, and α_{ij} is the attention factor of x_j at decoding step i. The semantic content that the decoder focuses on, i.e. attended content, is then derived by:

$$c_i = \sum \alpha_{ij} h_j.$$

The decoder updates the hidden state with a recurrent function f_d, formulated by:

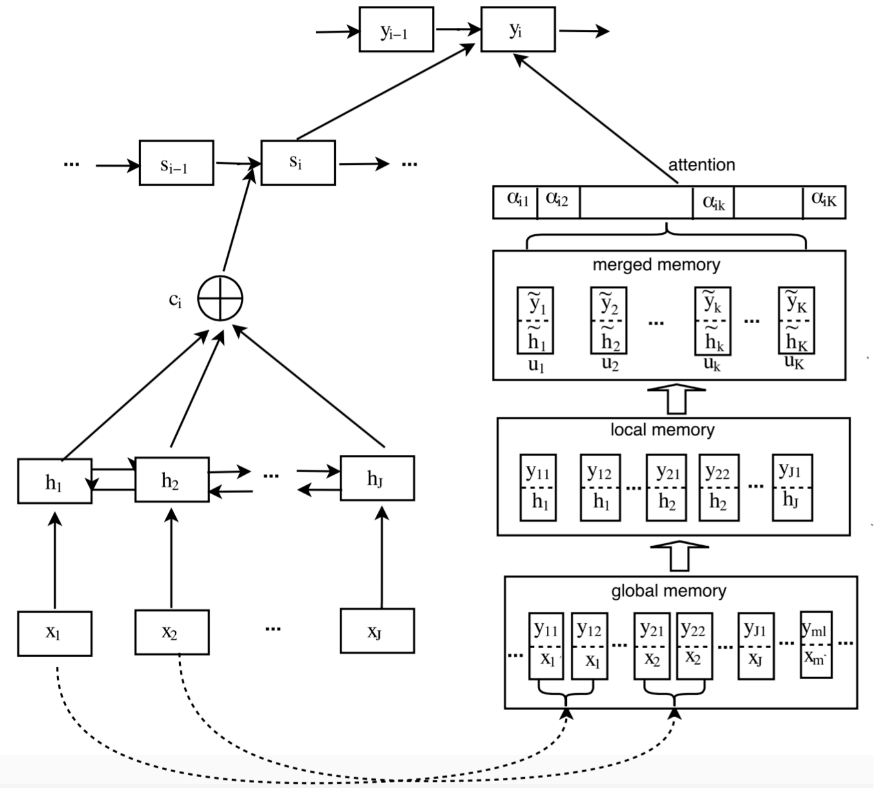

Figure 1: The structure of the M-NMT architecture.

$$s_i = f_d(y_{i-1}, s_{i-1}, c_i), \qquad (1)$$

and the next word y_i is generated according to the following posterior:

$$p(y_i) = \sigma(y_i^T W z_i) \qquad (2)$$

where $\sigma(\cdot)$ is the softmax function, W is a parameter matrix for word vector projection. The intermediate variable z_i is computed by a neural net with a single maxout hidden layer g, given by:

$$z_i = g(y_{i-1}, s_{i-1}, c_i).$$

We used Tensorflow to implement this model, and the training recipe largely followed the seminal paper of Bahdanau et al. (2015).

3 Memory-Augmented NMT

This section presents the M-NMT architecture. We first introduce the model, and then describe how the memory is constructed.

3.1 The Architecture

The M-NMT architecture is illustrated in Figure 1. It involves two components: the model and the memory components. The model component is a typical attention-based RNN model as presented in Section 2, which is regarded as being good at dealing with frequent words and pairs, and the memory component provides knowledge for infrequent words and pairs that are not easy for the neural model component to learn. The outputs of the two components are combined to produce a final consolidated translation.

3.2 Memory Elements

We define each item of memory as a mapping from a word in the source language to its translation in the target language. If there are multiple translations for a word, then several of the best will be added to the memory according to the probability of the translation, until the maximum number of target words is reached. A memory element can be formally written by:

$$u_{jl} = \begin{bmatrix} y_{jl} \\ x_j \end{bmatrix}$$

where y_{jl} is the l-th translation of word x_j. This mapping will be saved as a memory element and will be used during translation. We refer to this memory as the *global memory*, which is static during all the running time. The global memory is shown on the bottom-right of Figure 1.

To translate an input sentence, the memory elements the source words of which are in the input sentence are selected to form a *local memory*. This is shown in the right-middle of Figure 1. In order to include the context information in the local memory, the source part x_j is replaced by its annotation h_j:

$$u_{jl} = \begin{bmatrix} y_{jl} \\ h_j \end{bmatrix}$$

A consequence of the source encoding is that if a source word occurs multiple times in the sentence, all the occurrences should be put into the local memory, with different h_j to distinguish the context of each. Finally, the local memory is compressed as follows. For each distinct target word $\tilde{y}_k$ in the local memory, all the elements with $\tilde{y}_k$ as the target are merged into a single element u_k, for which the source part is the average of the source part of all the elements to be merged, given by:

$$u_k = \begin{bmatrix} \tilde{y}_k \\ \tilde{h}_k \end{bmatrix} = \begin{bmatrix} \tilde{y}_k \\ \sum_j p(x_j|\tilde{y}_k)h_j \end{bmatrix}; \ \forall \tilde{y}_k \in \{y_{jl}\} \quad (3)$$

where $p(x_j|\tilde{y}_k)$ means the probability that x_j is translated into $\tilde{y}_k$ and can be obtained from either a human-defined dictionary or the dictionary of an SMT system.

3.3 Memory Attention

In order to use the information stored in the memory to improve NMT, we need to pick up appropriate elements from the local memory at each translation step. A similar attention mechanism as in the neural model is designed. Denote the attention factor of each memory element u_k at each translation step i by α^m_{ik}, and assume it is derived from a relevance function e^m_{ik}:

$$\alpha^m_{ik} = \frac{e^m_{ik}}{\sum_{k=1}^{K} e^m_{ik}},$$

where K is the number of target words in the merged memory. The relevance function can be changed, but in this study, we use a simple design:

$$e^m_{ik} = (v^m)^\top tanh(W^m_s s_{i-1} + W^m_u u_k + W^m_y y_{i-1}) \quad (4)$$

where $tanh(\cdot)$ is the hyperbolic function, s_{i-1} is the current state of the decoder of the neural model, and y_{i-1} is the generated word in the previous step. The parameters of the memory attention mechanism include $\theta^m = \{v^m, W^m_s, W^m_u, W^m_y\}$, as defined in Eq. 4.

The attention factor α^m_{ik} can be used in different ways, here they are simply treated as the posterior to predict the next word to generate. Since the normalization is over all the target words in the local memory rather than the full vocabulary, treating α^m_{ik} as the posterior of all words is only an approximation, but was found in our experiments to be a good solution. This memory-based posterior is combined with the posterior of the neural model, resulting in a consolidated posterior, given by:

$$\tilde{p}(y_i) = \beta\alpha^m_{ik} + (1-\beta)p(y_i)$$

where $p(y_i)$ is the posterior produced by the neural model, as shown in Eq. 2, and β is a predefined interpolation factor. Here α^m_{ik} corresponds to the attention to the same word in the merged memory as the predicted word y_i. This simple posterior combination indicates the flexibility of the M-NMT architecture. Existing knowledge can be compiled into the local memory to improve model-based prediction, or if no knowledge is available, the system will rely on conventional NMT.

An advantage of this simple combination is that the memory component can be trained independently of the neural model. We set the objective of the training is to let the memory attention as accurate as possible. Given the n-th training sequence, at each translation step i, the target attention should be 1 on the current word y^n_i and 0 elsewhere. The objective function therefore can be written as the cross entropy between the target attention and the output of the attention function, given as follows:

$$L(\theta) = \sum_n \sum_i log(\alpha^m_{ik^n_i})$$

where k^n_i is the position of y^n_i in the merged memory. The optimization is conducted with respect to the parameters θ^m. The optimization algorithm is the stochastic gradient descent (SGD) with AdaDelta to adjust the learning rate (Zeiler, 2012).

It should be noted that joint training of the memory and the model is possible, but it requires a large amount of GPU memory and risks overfitting. Therefore, we only train the memory, with the model component unchanged. Efficient model-memory joint training is beyond the scope of this paper and can be investigated in future work. Particularly, the parameter β could be optimized to balance the contribution from the model part and the memory part, but constrains have to be carefully settled to avoid overfitting to the training data.

3.4 Memory for SMT Integration

The M-NMT architecture is a flexible framework that provides extra knowledge to the conventional model-based NMT. If the knowledge is generated by a conventional SMT system, it is essentially an elegant combination of SMT and NMT. In this work, we use the translation dictionary produced by an SMT system as the knowledge to create the memory, which involves first aligning the training sentence pairs using the GIZA++ toolkit (Och and Ney, 2003) in both directions, and applying the "intersection" refinement rules (Koehn et al., 2003) to get a single one-to-one alignment for each sentence pair, and then extracting the translation dictionary based on these alignments. We can see the dictionary as the phrase pairs of the length 1 and leave the phrase pairs longer than 1 as future work.

The key information provided by the dictionary is the conditional probability that a source and a target word are translated to each other. This information is used twice during local memory construction. Firstly, the conditional $p(y_{jl}|x_j)$ is used to select the most possible target words y_{jl} to participate the local memory, and secondly, the conditional $p(x_j|\tilde{y}_k)$ is used to merge the elements whose target words are $\tilde{y}_k$, as shown in Eq. 3.

3.5 Memory for OOV Treatment

The memory also provides a flexible way to address OOV words. OOV words can be defined in multiple ways, but here we focus on true OOVs that are totally new in both bilingual and monolingual data (i.e. rare words that are not present in any training data). One example is when a model is migrated to a specific domain. To address these OOVs, we firstly need a manually defined dictionary to specify how an OOV word should be translated, where the target word could be either an in-vocabulary word or an OOV.

This dictionary will be used as the knowledge to construct the local memory at run-time. Specifically, if an OOV word is encountered on either the source or target side during local memory construction, the vector of a similar word is borrowed to represent the OOV word. Since the words are totally new, the similar word has to be defined manually. To avoid any confusion with other words, the selected similar word should not appear in the existing input sequence if the OOV is in the source side, and should not match any target words in the existing local memory. To achieve this, several candidates have to be pre-defined for each OOV, so that alternative choices are available at run-time. A problem of this approach is that the vocabulary of the neural model is fixed, so cannot output probabilities for OOV words. To solve this, we let the selected similar word entirely overwritten by the OOV word, and any prediction for the similar word will be 're-directed' to the OOV word.

4 Related Work

The idea of memory augmentation was inspired by recent advances in the neural Turing machine (Graves et al., 2014, 2016) and memory network (Weston et al., 2014). These new models equip neural networks with an external memory that can be accessed and manipulated via some trainable operations. The memory idea has been utilized in NMT. For example, Wang et al. (2016) used a memory to extend the state of the decoder RNN in the attention-based NMT. In this case, the contribution of the memory is to provide temporary variables to assist RNN decoding. In contrast, our work uses memory to store knowledge. The memory in Wang et al.'s work could be considered to be note paper, while the memory in our work is more like a dictionary.

The idea of combining SMT and NMT was adopted by early NMT research, but these combinations were mostly based on the SMT framework, as discussed in depth in the review paper from Zhang et al. (2015). Cohn et al. (2016) proposed to enhance the attention-based NMT by using some structural knowledge from a word-based alignment model. The focus of their work was to use the extra knowledge to produce a better attention. In contrast, our work promotes the target words directly using the word mapping stored in the memory. Arthur et al. (2016) proposed to involve lexical knowledge to assist with translation, particularly for low-frequency words. This is similar to our proposed idea, with the key difference that their work uses the attention information to select the target words, while ours trains a separate attention, based on both the source and target words.

Regarding handling OOV words, Jean et al. (2015) presented an efficient training method to support a larger vocabulary, which helps alleviate the OOV problem significantly. Stahlberg et al. (2016) used SMT to produce candidate results in the form of lattice and NMT to re-score the results. As SMT uses a larger vocabulary than NMT, some OOV words can be retained. Sennrich et al. (2016) proposed a subword approach, where OOV words are expected to be spelled out by subword units. Luong et al. (2014) proposed a post-processing approach that learns the position of the source word when an UNK symbol is produced during decoding. By this position information, the UNK symbol (unknown words) can be replaced by the correct translation using a lexical table. Li et al. (2016) proposed a replace-and-restore approach that replaces infrequent words with similar words before the training and decoding, and restores rare words and their target words, obtained from a lexical table. Compared to the work of (Luong et al., 2014) and (Li et al., 2016), which relies on post-processing, our M-NMT approach is more like pre-processing. This means that the required information for OOV words is prepared before decoding. This seems more flexible than the post-processing methods, as we can easily deal with multiple targets for OOVs, by letting the decoder select which target is the most appropriate. Nevertheless, we do share the same idea of using similar words as in (Li et al., 2016), which we think is inevitable if the OOV words are totally new.

5 Experiments

5.1 Data

The experiments were conducted for Chinese-English translation using two datasets, the relatively small IWSLT dataset, and the much larger NIST dataset. As we will see, the NMT and SMT approaches exhibit different behaviours on these two datasets, and the memory-augmentation approach offers different contributions to them.

The IWSLT corpus The training data consists of 44K sentences from the tourism and travel domain. The development set was composed of the ASR devset 1 and devset 2 from IWSLT 2005, and testing used the IWSLT 2005 test set.

The NIST corpus The training data consists of 1M sentence pairs with 19M source tokens and 24M target tokens from the LDC corpora of LDC2002E18, LDC2003E07, LDC2003E14, and Hansard's portion of LDC2004T07, LDC2004T08 and LDC2005T06. We use the NIST 2002 test set as the development set and the NIST 2003 test set as the test set.

Memory data To construct the memory, we used the GIZA++ toolkit (Koehn et al., 2003) to align the training data in both directions, and kept the word pairs that appeared in the phrase tables of both directions. The global memory size is $80K$ for the IWSLT task, and $500K$ for the NIST task. These word pairs were then filtered according to the conditional probability $p(w_t|w_s)$ where w_s and w_t are source and target language words, respectively. For each w_s, at most two candidates of w_t were retained.

5.2 Systems

We used a conventional SMT system and an attention-based RNN NMT system as the baselines, and investigated a variety of M-NMT architectures.

SMT baseline: For the SMT system (denoted by *Moses*), Moses (Koehn et al., 2007), a state-of-the-art open-source toolkit, was used. The default configuration was used where the phrase length was 7 and the following features were employed: relative translation frequencies and lexical translation probabilities on both directions, distortion distance, language model and word penalty. For the language model, the KenLM toolkit (Heafield, 2011) was used to build a 5-gram language model (with the Keneser-Ney smoothing) on the target side of the training data.

NMT baseline: For NMT, we reproduced the attention-based RNN model proposed by Bahdanau et al. (2015), which is denoted by *NMT*. The implementation was based on Tensorflow[1]. We compared our implementations with a public implementation using Theano[2], and achieved comparable (even slightly better) performances on the same data sets with the same parameter settings.

M-NMT system: The M-NMT system was implemented by combining the memory structure and the NMT system. The model part is the same as the NMT baseline, while the attention function of

[1] https://www.tensorflow.org/

System	Attending	Attended
M-NMT(s, u^y)	s_{i-1}	$u_k(y)$
M-NMT(s, u^{xy})	s_{i-1}	$u_k(x), u_k(y)$
M-NMT(sy, u^y)	s_{i-1}, y_{i-1}	$u_k(y)$
M-NMT(sy, u^{xy})	s_{i-1}, y_{i-1}	$u_k(x), u_k(y)$

Table 2: M-NMT systems with different configurations.

the memory part was trained. During the training, if the target word is an UNK symbol, or the target word is not in the memory (due to the limited word pairs in the memory), this word is simply skipped from back-propagation. This skipping is important as it avoids bias caused by the large amount of UNK symbols. The trained M-NMT system can be readily used to deal with OOV words, without any re-training.

For M-NMT, the complete form of the relevance function for memory attention is $e^m_{ik}(s_{i-1}, y_{i-1}, u_k)$. Of these, s_{i-1} and y_{i-1} are 'attending factors' that represent the information used 'to attend', while u_k, which consists of a source part $u_k(x)$ and a target part $u_k(y)$, involves 'attended factors' that represent the content 'to be attended'. To investigate the contribution of different attending and attended factors, these factors are combined in different ways, leading to different M-NMT variants, as shown in 2. Note that *M-NMT($s; u^y$)* is the simplest configuration and the attention essentially learns a target-side language model. *M-NMT($s; u^{xy}$)* involves the source part of the memory, which implicitly learns a bilingual language model. Involving the decoding history y_{i-1} makes this learning more explicit.

Settings For a fair comparison, the models configurations in the NMT system and the M-NMT system were intentionally set to be identical. The number of hidden units, the word embedding dimensionality and the vocabulary size were empirically set to 500, 310 and 30000, respectively. In the training process, the batch size of the SGD algorithm was set to 80, and the parameters for AdaDelta were set to be $\rho = 0.95$ and $\epsilon = 10^{-6}$. The decoding is implemented as a beam search, where the beam size was set to be 5.

Evaluation metrics The translation performance was evaluated using the BLEU score with case-insensitive n $\leq$ 4-grams (Papineni et al., 2002).

System	IWSLT05	NIST03
Moses	52.5	30.6
NMT	43.9	31.3
NMT-L Arthur et al.	45.9	31.7
M-NMT(s, u^y)	49.8	32.3
M-NMT(sy, u^y)	50.7	32.5
M-NMT(s, u^{xy})	51.4	32.8
M-NMT(sy, u^{xy})	**52.9**	**34.0**

Table 3: BLEU scores with different translation systems on the two Chinese-English translation datasets.

5.3 SMT-NMT Integration Experiments

In the first experiment, the M-NMT architecture combined SMT and NMT by using SMT to construct the memory to assist with NMT. For comparison purposes, the lexical prediction approach proposed by (Arthur et al., 2016) was also implemented. This uses the phrase table produced by SMT to improve NMT. Our implementation is a linear combination, and for a fair comparison, the neural model part was kept unchanged. At each step i, the auxiliary probability provided by the lexical part is $P(y_i) = \sum_j \alpha_{ij} P(y_i|x_j)$, where α_{ij} is the attention weight from the neural model, and $P(y_i|x_j)$ is obtained from the phrase table. This can be regarded as a simple memory approach, with memory attention borrowed from the neural model, rather than being learned separately.

Table 3 shows the BLEU results with different systems. Firstly, it can be observed that with the small IWSLT05 dataset, the SMT outperforms the baseline NMT, but with the large NIST dataset, NMT outperforms SMT. This is unsurprising as neural models often need more training data. Secondly, the results show that with both datasets, the lexical approach (NMT-L) can improve NMT performance, showing that using SMT knowledge helps NMT. However, the improvement seems less significant than reported in (Arthur et al., 2016). This is likely to be because our implementation focuses on creating a simple, extensible, and generalizable system, and therefore does not allow re-training the neural model.

The M-NMT system provides significant performance improvement, even with the simplest setting (M-NMT(s, u^y)). More information factors tend to offer better performance, and the best M-NMT system, M-NMT(sy, u^{xy}), outperforms the baseline NMT by 9.0 and 2.7 BLEU points

	T-INV		T-OOV	
System	Recall	BLEU	Recall	BLEU
NMT	0.06	15.1	0	13.7
M-NMT	0.05	16.0	0	14.6
NMT-PL Luong et al.	0.09	15.4	0.08	14.3
M-NMT+OOV	**0.28**	**17.0**	**0.40**	**15.9**

Table 4: The OOV recall rates and BLEU scores on sentences with OOV words. 'T-INV' refers to the case where the target words of the OOV input are in-vocabulary, and 'T-OOV' means the case where the target words are also OOV.

on the two datasets respectively. Notably, the improvement with the IWSLT05 dataset is impressive, the best M-NMT system outperforms even the very strong SMT baseline, which strongly supports our conjecture that NMT must be equipped with a symbolic structure to deal with infrequent words. It also suggests that the M-NMT architecture is a promising way to apply neural methods to low-resource tasks.

5.4 OOV Treatment Experiments

Here the M-NMT architecture was used to handle OOV words. The experiments were conducted on the NIST dataset, for which we collected 312 test sentences containing OOV words. This test set was divided into two subsets: the T-INV set, containing sentences with source OOV words whose translations are NOT OOV in the target language; and the T-OOV set, containing sentences with OOV words that are OOV in both source and translation. There were 491 source-side OOV words in total, among which 276 words have in-vocabulary translations and 215 words only have OOV translation. We constructed a translation table with three items for each OOV word: (1) its translation; (2) its similar word; (3) the similar word of its translation, if the translation is also an OOV word. All the above was designed by hand, and for each OOV word, there was only a single translation. Although it is not difficult to collect most of this information automatically (e.g., by using an SMT phrase table), we are simulating the scenario where OOV words are newly coined, or where the system is migrated to a new domain, meaning that some words are totally new to the system. Handling OOV words of this type is certainly challenging, but it is also practically valuable.

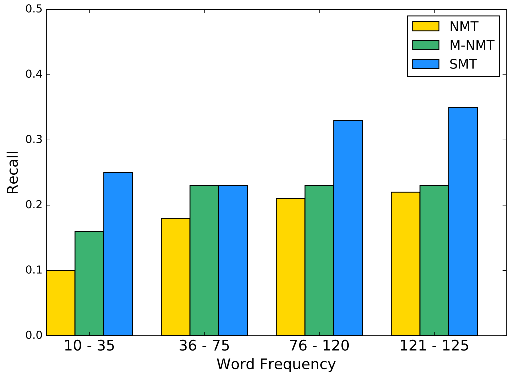

Figure 2: The recall rates of words in different frequency bins.

NMT	There are 23-year history of human history .
M-NMT	There have a total of 23 species of chromosomes .

Table 5: The translations from different systems for the Chinese-to-English 'meaning drift' example.

For comparison, the place-holder approach proposed by Luong et al. (2014) was also implemented. Here, OOV words in the target language are substituted by position-aware UNKs, and a post-processing step is used to replace UNKs with the correct translation. We denote this system as 'NMT-PL'. For M-NMT, only the best configuration M-NMT(sy, u^{xy}) was tested in this experiment. Two scenarios were considered: the original M-NMT system, and the M-NMT system with OOV words involved in the memory (denoted by M-NMT+OOV).

The results with the NIST dataset are shown in Table 4. In addition to the BLEU scores, we also report the OOV recall rates, defined as the proportion of OOV words that are correctly translated. It can be seen that both the basic NMT and M-NMT systems work badly with OOV words: they can only process OOV words whose translations are not OOV in the target language, and the recall rate is very low (0.05 approximately). The placeholder approach (NMT-PL) can address both types of OOV words, but the recall rate is still low. The M-NMT system with OOV memory, in contrast, is much more effective in OOV word translation, as shown in Table 4. We also implemented the replace-and-restore approach reported by Li et al. (2016), but found performance to be poor (the BLEU scores are 13.9 on T-INV and 13.3 on T-

OOV). This may be due to no re-training of the neural model (again, in order to keep the extensibility and generalizability of the M-NMT system).

5.5 Frequency Analysis

To form a better understanding of the memory mechanism, we distribute the test sentences into four bins according to the lowest word frequency among the sentence and compute the recall rates for words in these bins. Once a generated translation word is also in one of the references, we treat it as one hit. The experiment was conducted with the NIST dataset. The results in Figure 2 show that M-NMT offers more improvement with infrequent words, in accordance with our argument that the memory mechanism helps NMT in dealing with infrequent words.

Finally, we demonstrate the translation with M-NMT for the example in Table 1, as shown in Table 5. It can be clearly seen that the memory has remembered the infrequent word 'Chromosome', which resulted in an improved translation.

6 Conclusions

This paper presented a memory-augmented NMT approach, which introduces a memory mechanism for conventional NMT to assist with translating words not well learned by the neural model. Our experiments demonstrated that the new architecture is highly effective, providing performance improvement by 9.0 and 2.7 BLEU scores on two Chinese-English translation datasets, respectively. Additionally, it offers a very flexible and effective OOV treatment. In our experiments, The OOV recalls are 28% and 40% for the OOV words whose target words are INV and OOV, respectively, a significant improvement on competing methods. Future work will investigate better model-memory integration, e.g., by joint training.

Abstract

Intelligent selection of training data has proven a successful technique to simultaneously increase training efficiency and translation performance for phrase-based machine translation (PBMT). With the recent increase in popularity of neural machine translation (NMT), we explore in this paper *to what extent* and *how* NMT can also benefit from data selection. While state-of-the-art data selection (Axelrod et al., 2011) consistently performs well for PBMT, we show that gains are substantially lower for NMT. Next, we introduce *dynamic data selection* for NMT, a method in which we vary the selected subset of training data between different training epochs. Our experiments show that the best results are achieved when applying a technique we call *gradual fine-tuning*, with improvements up to +2.6 BLEU over the original data selection approach and up to +3.1 BLEU over a general baseline.

1 Introduction

Recent years have shown a rapid shift from phrase-based (PBMT) to neural machine translation (NMT) (Sutskever et al., 2014; Cho et al., 2014; Bahdanau et al., 2014) as the most common machine translation paradigm. With large quantities of parallel data, NMT outperforms PBMT for an increasing number of language pairs (Bojar et al., 2016). Unfortunately, training an NMT model is often a time-consuming task, with training times of several weeks not being unusual.

Despite its training inefficiency, most work in NMT greedily uses all available training data for a given language pair. However, it is unlikely that all data is equally helpful to create the best-performing system. In PBMT, this issue has been addressed by applying intelligent data selection, and it has consistently been shown that using more data does not always improve translation quality (Moore and Lewis, 2010; Axelrod et al., 2011; Gascó et al., 2012). Instead, for a given translation task, the training bitext likely contains sentences that are irrelevant or even harmful, making it beneficial to keep only the most relevant subset of the data while discarding the rest, with the additional benefit of smaller models and faster training.

Motivated by the success of data selection in PBMT, we investigate in this paper *to what extent* and *how* NMT can benefit from data selection as well. While data selection has been applied to NMT to reduce the size of the data (Cho et al., 2014; Luong et al., 2015b), the effects on translation quality have not been investigated. Intuitively, and confirmed by our exploratory experiments in Section 5.1, this is a challenging task; NMT systems are known to under-perform when trained on limited parallel data (Zoph et al., 2016; Fadaee et al., 2017), and do not have a separate large-scale target-side language model to compensate for smaller parallel training data.

To alleviate the negative effect of small training data on NMT, we introduce *dynamic data selection*. Following conventional data selection, we still dramatically reduce the training data size, favoring parts of the data which are most relevant to the translation task at hand. However, we exploit the fact that the NMT training process iterates over the training corpus in multiple epochs, and we alter the quantity or the composition of the training data *between epochs*. The proposed method requires no modifications to the NMT architecture or parameters, and substantially speeds up training times while simultaneously improving translation quality with respect to a complete-bitext baseline.

In summary, our contributions are as follows:

(i) We compare the effects of a commonly used data selection approach (Axelrod et al., 2011) on PBMT and NMT using four different test sets. We find that this method is much less effective for NMT than for PBMT, while using the exact same training data subsets.

(ii) We introduce dynamic data selection as a way to make data selection profitable for NMT. We explore two techniques to alter the selected data subsets, and find that our method called *gradual fine-tuning* improves over conventional static data selection (up to +2.6 BLEU) and over a high-resource general baseline (up to +3.1 BLEU). Moreover, gradual fine-tuning approximates in-domain fine-tuning in ~20% of the training time, even when no parallel in-domain data is available.

2 Static data selection

As a first step towards dynamic data selection for NMT, we compare the effects of a commonly used, state-of-the-art data selection method (Axelrod et al., 2011) on both neural and phrase-based MT. Briefly, this approach ranks sentence pairs in a large training bitext according to their difference in cross-entropy with respect to an in-domain corpus (i.e., a corpus representing the test data) and a general corpus. Next, the top n sentence pairs with the highest rank—thus lowest cross-entropy—are selected and used for training an MT system.

Formally, given an in-domain corpus I, we first create language models from the source side f of I ($LM_{I,f}$) and the target side e of I ($LM_{I,e}$). We then draw a random sample (similar in size to I) of the large general corpus G and create language models from the source and target sides of G: $LM_{G,f}$ and $LM_{G,e}$, respectively. Note that the data for creating these LMs need not be parallel but can be independent corpora in both languages.

Next, we compute for each sentence pair s in G four cross-entropy scores, defined as:

$$H_{C,s_b} = -\sum p\left(s_b\right) \log\left(LM_{C,b}\left(s_b\right)\right), \qquad (1)$$

where $C \in \{I, G\}$ is the corpus, $b \in \{f, e\}$ refers to the bitext side, and s_b is the bitext side b of sentence pair s in the parallel training corpus.

To find sentences that are similar to the in-domain corpus, i.e., have low H_I, and at the same time dissimilar to the general corpus, i.e., have high H_G, we compute for each sentence pair s the bilingual cross-entropy difference CED_s following Axelrod et al. (2011):

$$CED_s = (H_{I,s_f} - H_{G,s_f}) + (H_{I,s_e} - H_{G,s_e}). \qquad (2)$$

Finally, we rank all sentence pairs $s \in G$ according to their CED_s, and then select only the top n sentence pairs with the lowest CED_s.

Following related work by Moore and Lewis (2010), we restrict the vocabulary of the LMs to the words occurring at least twice in the in-domain corpus. To analyze the quality of the selected data subsets, we also run experiments on random selections, all performed in threefold. Finally, we always use the exact same selection of sentence pairs in equivalent PBMT and NMT experiments.

LSTM versus n-gram The described data selection method uses n-gram LMs to determine the domain-relevance of sentence pairs. We adhere to this setting for our comparative experiments on PBMT and NMT (Section 5.1). However, when applying data selection to NMT, we examine the potential benefit of replacing the conventional n-gram LMs with LSTMs[1]. These have the advantage to remember longer histories, and do not have to back off to shorter histories when encountering out-of-vocabulary words. In this neural variant to rank sentences, the score for each sentence pair in G is still computed as the bilingual cross-entropy difference in Equation (2). In addition, we use the same in-domain and general corpora as with the n-gram method, and we again restrict the vocabulary to the most frequent words.

3 Dynamic data selection

While data selection aims to discard irrelevant data, it can also exacerbate the problem of low vocabulary coverage and unreliable statistics for rarer words in the 'long tail', which are major issues in NMT (Luong et al., 2015b; Sennrich et al., 2016b). In addition, it has been shown that NMT performance drops tremendously in low-resource scenarios (Zoph et al., 2016; Fadaee et al., 2017; Koehn and Knowles, 2017).

To overcome this problem, we introduce *dynamic data selection*, in which we vary the selected data subsets *during* training. Unlike other MT paradigms, which require training data to be fixed during the entire training process, NMT iterates over the training corpus in several epochs,

[1] We use four-layer LSTMs with embedding and hidden sizes of 1,024, which we train for 30 epochs.

Training data epoch 5&6: Top 36%
Training data epoch 7&8: Top 21.6%
x 0.6
x 0.6
x 0.6
Most relevant data
Least relevant data

Figure 1: Illustration of two dynamic bitext selection techniques for NMT: *sampling* (left) and *gradual fine-tuning* (right). Measured over 16 training epochs (which is used in this work), the total training time of both examples would be ∼30% of the training time needed when using the complete bitext.

allowing to use a different subset of the training data in every epoch.

Dynamic data selection starts from a relevance-ranked bitext, which we create using CED scores as computed in Equation (2). Given this ranking, we investigate two dynamic data selection techniques[2] that vary per epoch the composition or the size of the selected training data. Both techniques aim to favor highly relevant sentences over less relevant sentences while not completely discarding the latter. In all experiments, we use a fixed vocabulary created from the complete bitext.

While we use in this work a domain-relevance ranking of the bitext following Axelrod et al. (2011), dynamic data selection can also be applied using other ranking criteria, for example limiting redundancy in the training data (Lewis and Eetemadi, 2013) or complementing similarity with diversity (Ruder and Plank, 2017).

Sampling sentence pairs In the first technique, illustrated in Figure 1a, we sample for every epoch n sentence pairs from G, using a distribution computed from the domain-specific CED_s scores. Concretely, this is done as follows:

First, since higher ranked sentence pairs have lower CED_s scores, and they can be either negative or positive, we scale and invert CED_s scores such that $0 \leq CED'_s \leq 1$ for each sentence pair $s \in G$:

$$CED'_s = 1 - \frac{CED_s - \min(CED_G)}{\max(CED_G) - \min(CED_G)}, \qquad (3)$$

where CED_G refers to the set of CED_s scores for bitext G.

Next, we convert CED'_s scores to relative weights, such that $\sum_{s \in G} w(s) = 1$:

$$w(s) = \frac{CED'_s}{\sum_{s_i \in G} CED'_{s_i}}. \qquad (4)$$

We then use $\{w(s) : s \in G\}$ to perform weighted sampling, drawing for each epoch n sentence pairs without replacement. While all selection weights are very close to zero, higher ranked sentences have a noticeably higher probability of being selected than lower-ranked sentences; in practice we find that top-ranked sentences get selected in nearly each epoch, while bottom-ranked sentence pairs get selected at most once. Note that the sampled selection for any epoch is independent of selections for all other epochs.

Gradual fine-tuning The second dynamic data selection technique, see Figure 1b, is inspired by the success of domain-specific fine-tuning (Luong and Manning, 2015; Zoph et al., 2016; Sennrich et al., 2016a; Freitag and Al-Onaizan, 2016), in which a model trained on a large general-domain bitext is trained for a few additional epochs only on small in-domain data. However, rather than training a full model on the complete bitext G, we gradually decrease the training data size, starting from G and keeping only the top n sentence pairs for the duration of η epochs, where the top n pairs are defined by their CED_s scores. Given its resemblance to fine-tuning, we refer to this variant as *gradual fine-tuning*.

[2] Code for bitext ranking and both selection techniques: github.com/marliesvanderwees/dds-nmt.

During gradual fine-tuning, the selection size n is a function of epoch i:

$$n(i) = \alpha \cdot |G| \cdot \beta^{\lfloor (i-1)/\eta \rfloor}. \qquad (5)$$

Here $0 \leq \alpha \leq 1$ is the *relative start size*, i.e., the fraction of general bitext G used for the first selection, $0 \leq \beta \leq 1$ is the *retention rate*, i.e., the fraction of data to be kept in each new selection, and $\eta \geq 1$ is the number of consecutive epochs each selected subset is used. Note that $\lfloor i/\eta + 1 \rfloor$ indicates rounding down $i/\eta + 1$ to the nearest integer. For example, if we start with the complete bitext ($\alpha = 1$), select the top 60% ($\beta = 0.6$) every second epoch ($\eta = 2$), then we run epochs 1 and 2 with a subset of size $|G|$, epochs 3 and 4 with a subset of size $0.6 \cdot |G|$, epochs 5 and 6 with a subset of size $0.36 \cdot |G|$, and so on. For every size n, the actual selection contains the top n sentences pairs of G.

4 Experimental settings

We evaluate static and dynamic data selection on a German→English translation task comprising four test sets. Below we describe the MT systems and data specifications.

4.1 Machine translation systems

While the main aim of this paper is to improve data selection for NMT, we also perform comparative experiments using PBMT. Our PBMT system is an in-house system similar to Moses (Koehn et al., 2007). To create optimal PBMT systems given the available resources, we apply test-set-specific parameter tuning using PRO (Hopkins and May, 2011). In addition, we use a linearly interpolated target-side language model trained with Kneser-Ney smoothing on 480M tokens of data in various domains. LM interpolation weights are also optimized per test set. Consistent with Axelrod et al. (2011), we do not vary the target-side LM between different experiments on the same test set. All n-gram models in our work are 5-gram.

For our NMT experiments we use an in-house encoder-decoder[3] model with global attention as described in Luong et al. (2015a). This choice comes at the cost of optimal translation quality but allows for a relatively fast realization of large-scale experiments given our available resources. Both the encoder and decoder are four-layer unidirectional LSTMs, with embedding and layer sizes of 1,000. We uniformly initialize all parameters, and use SGD with a mini-batch size of 64 and an initial learning rate of 1, which is decayed by a factor two every epoch after the fifth epoch. We use dropout with probability 0.3, and a beam size of 12. We train for 16 epochs and test on the model from the last epoch. All NMT experiments are run on a single NVIDIA Titan X GPU.

	Train		Dev/valid		Test	
Corpus	Lines	Tokens	Lines	Tokens	Lines	Tokens
EMEA	206K	3.3M	3.9K	59K	5.8K	93K
Movies	101K	1.2M	4.5K	54K	7.1K	87K
TED	189K	3.3M	2.5K	50K	5.4K	99K
WMT	3.8M	84M	3.0K	64K	3.0K	65K
Mix	4.3M	92M	3.5K	61K	–	–

Table 1: Data specifications with tokens counted on the German side. The WMT training corpus contains Commoncrawl, Europarl, and News Commentary but no in-domain news data.

4.2 Training and evaluation data

We evaluate all experiments on four domains: (i) EMEA medical guidelines (Tiedemann, 2009), (ii) movie dialogues (van der Wees et al., 2016) constructed from OpenSubtitles (Lison and Tiedemann, 2016), (iii) TED talks (Cettolo et al., 2012), and (iv) WMT news. For TED, we use IWSLT2010 as development set and IWSLT2011-2014 as test set, and for WMT we use newstest2013 as development set and newstest2016 as test set. We train our systems on a mixture of domains, comprising Commoncrawl, Europarl, News Commentary, EMEA, Movies, and TED. Corpus specifications are listed in Table 1.

The in-domain LMs used to rank training sentences for data selection are trained on small portions of in-domain parallel data whenever available (3.3M, 1.2M and 3.3M German tokens for EMEA, Movies and TED, respectively). Since no sizeable in-domain parallel text is available for WMT, we independently sample 200K sentences from the WMT monolingual News Crawl corpora (3.3M German tokens or 3.5M English tokens). This demonstrates the applicability of data selection techniques even in cases where one lacks parallel in-domain data.

Before running data selection, we preprocess our data by tokenizing, lowercasing and remov-

[3] github.com/ketranm/tardis

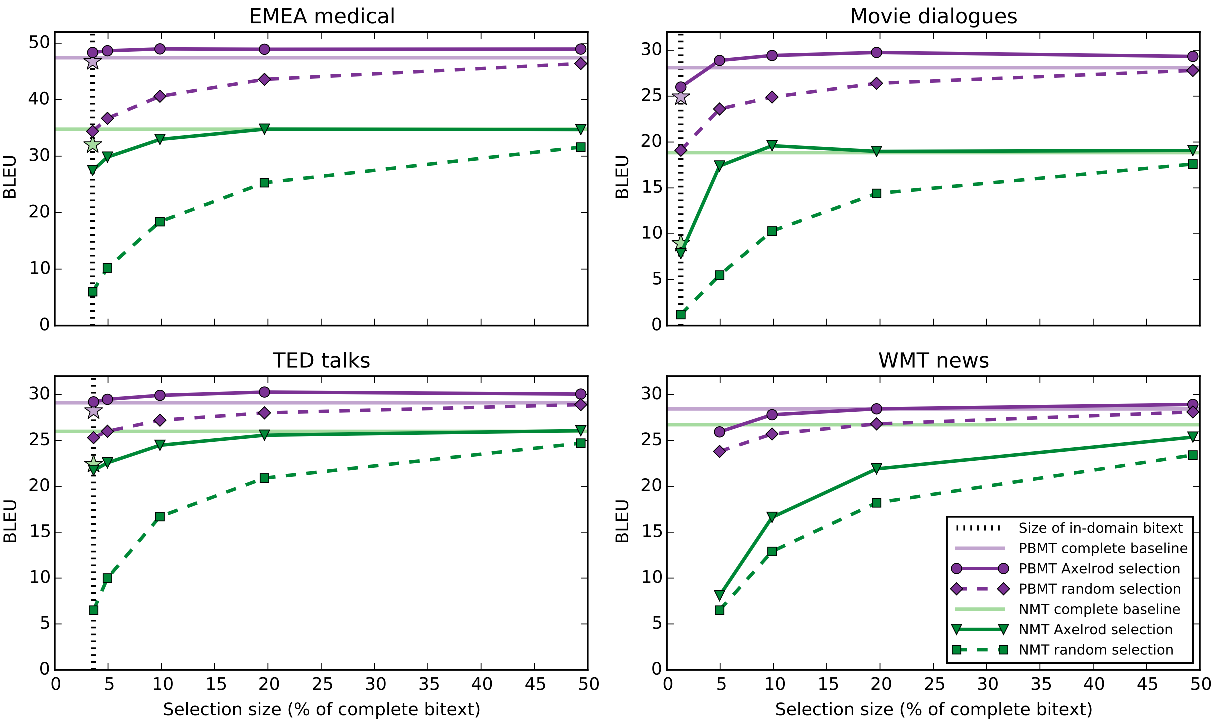

Figure 2: PBMT (purple) and NMT (green) German→English results of Axelrod data selection and random data selection (average of three runs) for four domains. Purple and green stars indicate BLEU scores when only the available in-domain data is used. We use selections of the in-domain size $|I|$, and 5%, 10%, 20%, and 50% of the complete bitext, which are exactly the same for PBMT and NMT.

ing sentences that are longer than 50 tokens or that are identified as a different language. After selection, we apply Byte-pair encoding (BPE, Sennrich et al. (2016b)) with 40K merge operations on either side of the complete mix-of-domains training bitext. For our NMT experiments we use BPE-processed corpora on both bitext sides, while for PBMT we only apply BPE to the German side. Our NMT systems use a vocabulary size of 40K on both the source and target side.

5 Results

Below we discuss the results of our translation experiments using static and dynamic data selection, measuring translation quality with case-insensitive untokenized BLEU (Papineni et al., 2002).

5.1 Static data selection for PBMT and NMT

We first compare the effects of static data selection with n-gram LMs on both NMT and PBMT using various selection sizes. Concretely, we select the top n sentence pairs such that the number of selected tokens $t \in \{5\%, 10\%, 20\%, 50\%\}$ of G, or $t = |I|$ (the in-domain corpus size). Figure 2 shows German→English translation performance in BLEU for our four test sets. The benefits of n-gram-based data selection for PBMT (purple circles) are confirmed: In all test sets, the selection of size $|I|$ (dotted vertical line) yields better performance than using only the in-domain data of the exact same size (purple star), and at least one of the selected subsets—often using only 5% of the complete bitext—outperforms using the complete bitext (light purple line). We also show that the informed selections are superior to random selections of the same size (purple diamonds).

In NMT, results of n-gram-based data selection (green triangles) vary: While for Movies a selection of only 10% outperforms the complete bitext (light green line), none of the selected subsets for other test sets is noticeably better than the full bitext.[4] Interestingly, the same selections of size $|I|$ that proved useful in PBMT, never beat the system that uses exactly the available in-domain data (green star), indicating that the current selections can be further improved for NMT. In all scenarios we see that NMT suffers much more from small-data settings than PBMT. Finally, the random se-

[4] Validation cross-entropy converges after 10–12 epochs, never reaching the scores of the complete bitext.

lections (green squares) show that NMT not only needs large quantities of data, but it is also affected when the selected data is of low quality. In PBMT, both low-quantity and low-quality scenarios appear to be compensated for by the large monolingual LM on the target side.

When comparing the different test sets, we observe that the impact of domain mismatch in NMT with respect to PBMT is largest for the two domains that are most distinct from the general bitext, EMEA and Movies. For WMT, both MT systems achieve very similar baseline results, but translation quality deteriorates considerably in data selection experiments, which is likely caused by the lack of in-domain data in the general bitext.

LSTM versus n-gram Before proceeding with dynamic data selection for NMT, we test whether bitext ranking for NMT can be improved using LSTMs rather than conventional n-gram LMs. Table 2 shows NMT BLEU scores of a few different sizes of selected subsets created using n-gram LMs or LSTMs. While results vary among test sets and selection sizes, we observe an average improvement of 0.4 BLEU when using LSTMs instead of n-gram LMs. For PBMT, similar results have been reported when replacing n-gram LMs with recurrent neural LMs (Duh et al., 2013). In all subsequent experiments we use relevance rankings computed with LSTMs instead of n-gram LMs.

Selection	LM type	EMEA	Movies	TED	WMT
5%	n-gram	29.8	17.4	22.6	8.1
	LSTM	**30.0**	**17.8**	22.6	**9.6**
10%	n-gram	33.0	19.6	24.5	16.6
	LSTM	33.0	**19.7**	**24.7**	**17.4**
20%	n-gram	**34.8**	19.0	25.6	21.9
	LSTM	34.5	**19.6**	**26.6**	21.9

Table 2: NMT BLEU comparison between using n-gram LMs and LSTMs for bitext ranking. Selection sizes concern the selected bitext subsets; LMs are created from the exact same in-domain data.

5.2 Dynamic data selection for NMT

Equipped with a relevance ranking of sentence pairs in bitext G, we now examine two variants of dynamic data selection as described in Section 3.

We are interested in reducing training time while limiting the negative effect on BLEU for various domains. Therefore we report BLEU as well as the *relative training time* of each experiment. Since wall-clock times depend on other factors such as the NMT architecture and memory speed, we define training time as the total number of tokens observed while training the NMT system, i.e., the sum of tokens in the selected subsets of all epochs. We report all training times relative to the training time of our complete-bitext baseline (i.e., 4.3M tokens × 16 epochs). Note that this measure of training time corresponds closely but not exactly to the number of model updates, as the latter relies on the number of sentences, which vary in length, rather than the number of tokens in the training data. For completeness: Training the 100% baseline takes 106 hours, while our fastest dynamic selection variant takes 19–21 hours. Computing CED scores takes ∼15 minutes when using n-gram LMs and 5–6 hours when using LSTMs.

Figure 3 shows BLEU scores of some selected experiments as a function of relative training time. Compared to static data selection (blue lines), our weighted sampling technique (orange triangles) yields variable results. When sampling a subset of 20% of $|G|$ from the top 50% of the ranked bitext, we obtain small improvements for TED and WMT, but small drops for EMEA and Movies. Other selection sizes (30% and 40%, not shown) give similar results lacking a consistent pattern.

By contrast, our gradual fine-tuning method performs consistently better than static selection, and even beats the general baseline in three out of four test sets. The displayed version uses settings ($\alpha = 0.5, \beta = 0.7, \eta = 2$) and is at least as fast as static selection using 20% of the bitext, yielding up to +2.6 BLEU improvement (for WMT news) over this static version. Compared to the complete baseline, this gradual fine-tuning method improves up to +3.1 BLEU (for TED talks).

Table 3 provides detailed information on additional experiments using other settings. For all three test domains which are covered in the parallel data—EMEA, Movies and TED—improvements are highest when starting gradual fine-tuning with only the top 50% of the ranked bitext, which are also the fastest approaches. For WMT, which is not covered in the general bitext, adding more data clearly benefits translation quality. These findings are consistent with the static data selection patterns; Using low-ranked sentences on top of the most relevant selection

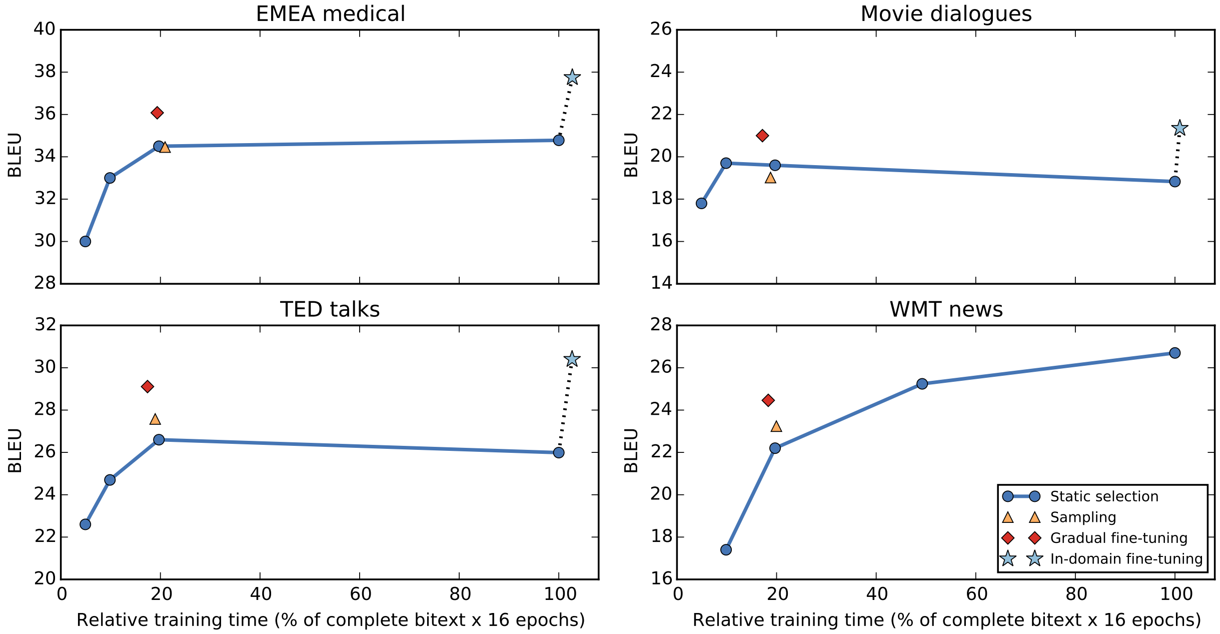

Figure 3: Selected German→English translation results of dynamic data selection methods (orange and red markers) compared to conventional static data selection (blue circles). *Relative training time* equals the total number of training tokens relative to the complete baseline, which takes 106 hours to train and is represented by the rightmost blue circle. Note that no parallel in-domain data is available for WMT news. All y-axes are scaled equally for easy comparison of BLEU differences across domains.

Experiment			Relative training time	BLEU			
Start size	Retention rate β	Decrease every		EMEA	Movies	TED	WMT
Static selection top 20%			20%	34.5	19.6	26.6	21.9
50% ($\alpha = 0.5$)	0.7	$\eta = 2$ epochs	18–20%	**36.1 (+1.6)**	21.0 (+1.4)	**29.1 (+2.5)**	24.5 (+2.6)
50% ($\alpha = 0.5$)	0.5	$\eta = 4$ epochs	21–23%	36.0 (+1.5)	**21.2 (+1.6)**	29.0 (+2.4)	25.0 (+3.1)

Gold: fine-tuning on in-domain data			101–103%	37.7	21.3	30.4	–

Table 3: German→English BLEU results of various gradual fine-tuning experiments sorted by relative training time. Indicated improvements are with respect to static selection using 20% of the bitext, and highest scores per test set are bold-faced. Results from the first experiment are also shown in Figure 3.

does not improve translation performance for any domain except WMT news.

Finally, we compare our data selection experiments to domain-specific fine-tuning (light blue stars in Figure 3), which is the current state-of-the-art for domain adaptation in NMT. To this end, we first train a model on the complete bitext, and then train for twelve additional epochs on available in-domain data, using an initial learning rate of 1 which halves every epoch. Depending on the test set, this approach yields +2.5–4.4 BLEU improvements over our baselines, however it does not speed up training and requires a parallel in-domain text which may not be available (e.g., for WMT). While none of our data selection experiments outperforms domain-specific fine-tuning, we obtain competitive translation quality in only 20% of the training time. In additional experiments we found that in-domain fine-tuning on top of our selection approaches does not yield improvements.

6 Further analysis

In this section we conduct a few additional experiments and analyses. We restrict to one parameter setting per selection approach: Static selection and sampling with 20% of the data, and gradual fine-tuning using ($\alpha = 0.5, \beta = 0.7, \eta = 2$). All have very similar training times.

First, we hypothesize that dynamic data selection works well because more different sentence pairs are observed during training, and it therefore increases coverage with respect to static data selection. To verify this, we measure for each test set the number of unseen source word types in the training data of different selection methods. Figure 4 shows indeed that the average number of unseen word types is reduced noticeably in both of our dynamic selection techniques, being much closer to the complete bitext baseline than to static selection. Note that all methods use the same vocabulary during training.

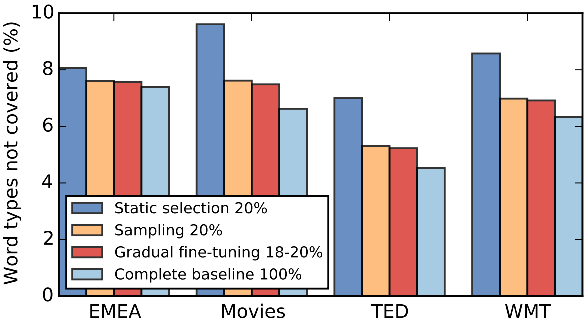

Figure 4: Test set source words not covered in the training data of different data selection methods.

Next, following the static data selection experiments in Section 5.1, we examine how well dynamic data selection performs using random selections. To this end, we repeat all techniques using a bitext which is ranked randomly rather than by its relevance to the test sets. The results in Table 4 show that the bitext ranking plays a crucial role in the success of data selection. However, the results also show that *even* in the absence of an appropriate bitext ranking, dynamic data selection—and in particular gradual fine-tuning—is still superior to static data selection. We explain this result as follows: Compared to static selection, both sampling and gradual fine-tuning have better coverage due to their improved exploration of the data. However, sampling also suffers from a surprise effect of observing new data in every epoch. Gradual fine-tuning on the other hand gradually improves learning on a subset of the selected data, suggesting that repetition across epochs has a positive effect on translation quality.

Ranking	Method	EMEA	Movies	TED	WMT
Relevance	Gradual FT	**36.1**	**21.0**	**29.1**	**24.5**
	Sampling 20%	34.5	19.0	27.6	23.2
	Static 20%	34.5	19.6	26.6	21.9
Random	Gradual FT	**29.2**	**16.1**	**23.2**	**21.3**
	Sampling 20%	26.7	14.4	22.0	19.8
	Static 20%	25.3	14.4	20.9	18.2

Table 4: BLEU scores of data selection using relevance versus random ranking of the bitext. Gradual fine-tuning uses ($\alpha = 0.5, \beta = 0.7, \eta = 2$), with relative training times of 18–20%.

One could expect that changing the data during training results in volatile training behavior. To test this, we inspect cross-entropy of our development sets after every training epoch. Figure 5 shows these results for TED. Clearly, static data selection converges most steadily. However, both dynamic selection techniques eventually converge to a lower cross-entropy value which is reflected by higher translation quality of the test set. We observe very similar behavior for the other test sets.

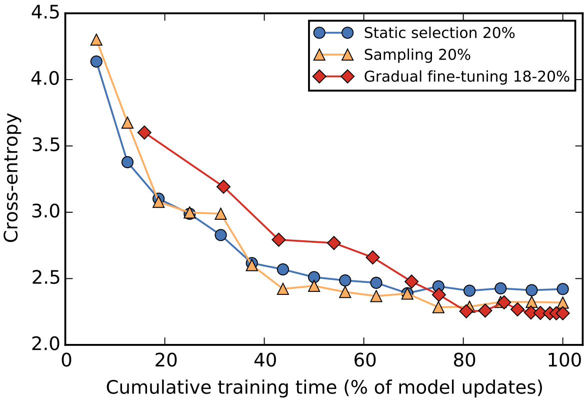

Figure 5: German→English cross-entropy of the TED dev set as a function of training time. Each data point represents a completed training epoch.

By its nature, our gradual fine-tuning technique uses training epochs of different sizes, and therefore also implicitly differs from other methods in its parameter optimization behavior. Since we decrease both the training data size and the SGD learning rate after finishing complete training epochs, we automatically decay the learning rate at decreasing time intervals. We therefore study how this approach is affected when we (i) decay the learning rate after a fixed number of updates (i.e., the same as in static data selection) rather than per epoch, or (ii) keep the learning rate fixed. In the first scenario, we observe that translation performance drops with –1.1–2.0 BLEU. When keeping a fixed learning rate, BLEU scores hardly change or even improve, indicating that the implicit change in search behavior may contribute to the success of gradual fine-tuning.

7 Related work

A few research topics are related to our work. Regarding data selection for SMT, previous work has targeted two goals; to reduce model sizes and training times, or to adapt to new domains. Data selection methods for domain adaptation mostly employ information theory metrics to rank training sentences by their relevance to the domain at hand. This has been applied monolingually (Gao et al., 2002) as well as bilingually (Yasuda et al., 2008). In more recent work, training sentences are typically ranked according to their cross-entropy *difference* between in-domain and general-domain data (Moore and Lewis, 2010; Axelrod et al., 2011, 2015), favoring sentences that are similar to the test domain and at the same time dissimilar from the general domain. Duh et al. (2013) and Chen and Huang (2016) present similar methods in which n-gram LMs are replaced by neural LMs or neural classifiers, respectively.

Data selection with the aim of model size and training time reduction has the objective to use the minimum amount of data while still maintaining high vocabulary coverage (Eck et al., 2005; Gascó et al., 2012; Lewis and Eetemadi, 2013). In a comparative study, Mirkin and Besacier (2014) find that similarity-objected methods perform best if the test domain and general corpus are very different, while a coverage-objected method is superior if test and general corpus are relatively similar. A comprehensive survey on data selection for SMT is provided by Eetemadi et al. (2015). While in this work we have used a similarity objective to rank our bitext, one could also apply dynamic data selection using a coverage objective.

In NMT, data selection can serve similar goals as in PBMT; increasing training efficiency or domain adaptation. Domain adaptation in NMT typically involves training a model on the complete bitext, followed by fine-tuning the parameters on a smaller in-domain corpus (Luong and Manning, 2015; Zoph et al., 2016). Other work combines fine-tuning with model ensembles (Freitag and Al-Onaizan, 2016) or with domain-specific tags in the training corpus (Chu et al., 2017). Finally, Sennrich et al. (2016a) adapt their systems by back-translating in-domain data, which is then added to the training data and used for fine-tuning.

Some other previous work has addressed training efficiency for NMT, for example by parallelizing models or data (Wu et al., 2016), modifying the NMT network structure (Kalchbrenner et al., 2016), decreasing the number of parameters through knowledge distillation (Crego et al., 2016; Kim and Rush, 2016), or by boosting parts of the data that are 'challenging' to the NMT system (Zhang et al., 2016). The latter is most related to our work since training data is also adjusted during training, however we reduce the training data size much more aggressively and study different techniques of data selection.

Finally, recent work comparing various aspects for PBMT and NMT includes (Bentivogli et al., 2016; Farajian et al., 2017; Toral and Sánchez-Cartagena, 2017; Koehn and Knowles, 2017).

8 Conclusions

With the recent increase in popularity of neural machine translation (NMT), we explored in this paper *to what extent* and *how* NMT can benefit from data selection. We first showed that a state-of-the-art data selection method yields unreliable results for NMT while consistently performing well for PBMT. Next, we have introduced *dynamic data selection* for NMT, which entails varying the selected subset of training data between different training epochs. We explored two techniques of dynamic data selection and found that our *gradual fine-tuning* technique, in which we gradually reduce training size, improves consistently over conventional static data selection (up to +2.6 BLEU) and over a high-resource general baseline (up to +3.1 BLEU). Moreover, gradual fine-tuning approximates in-domain fine-tuning using only $\sim$20% of the training time, even when no parallel in-domain data is available.

Neural Machine Translation
Leveraging Phrase-based Models in a Hybrid Search

Abstract

In this paper, we introduce a hybrid search for attention-based neural machine translation (NMT). A target phrase learned with statistical MT models extends a hypothesis in the NMT beam search when the attention of the NMT model focuses on the source words translated by this phrase. Phrases added in this way are scored with the NMT model, but also with SMT features including phrase-level translation probabilities and a target language model. Experimental results on German→English news domain and English→Russian e-commerce domain translation tasks show that using phrase-based models in NMT search improves MT quality by up to 2.3% BLEU absolute as compared to a strong NMT baseline.

1 Introduction

Neural machine translation has become state-of-the-art in recent years, reaching higher translation quality than statistical phrase-based machine translation (PBMT) on many tasks. Human analysis (Bentivogli et al., 2016) showed that NMT makes significantly fewer reordering errors, and also is able to select correct word forms more often than PBMT in the case of morphologically rich target languages. Overall, the fluency of the MT output improves when NMT is used, and the number of lexical choice errors is also reduced. However, state-of-the-art NMT approaches based on an encoder-decoder architecture with an attention mechanism as introduced by (Bahdanau et al., 2014) exhibit weaknesses that sometimes lead to MT errors which a phrase-based MT system does not make. In particular, PBMT usually can better translate rare words (e.g. singletons), as well as memorize and use phrasal translations. NMT has problems translating rare words because of limitations on the vocabulary size, as well as the fact that word embeddings are used to represent both source and target words. A rare word's embedding can not be trained reliably.

Another handicap of NMT is a general difficulty of fixing errors made by a neural MT system. Since NMT does not explicitly use or save word-to-word or phrase-to-phrase mappings, and its search is a target word beam search with almost no constraints, it is difficult to fix errors by an NMT system. It is important to quickly fix certain errors in real-life applications of MT systems to avoid negative user feedback or other (e.g. legal) consequences. An error identified in the output of a PBMT system can be fixed by tracing which phrase pair was used that resulted in the error, and down-weighting or even removing the phrase pair. Also, in PBMT it is easy to add an "override" translation.

In this work, we combine the strengths of NMT and PBMT approaches by introducing a novel hybrid search algorithm. In this algorithm, the standard NMT beam search is extended with phrase translation hypotheses from a statistical phrase table. The decision on when to use what phrasal translations is taken based on the attention mechanism of the NMT model, which provides a soft coverage of the source sentence words. All partial phrasal translations are scored with the NMT decoder and can be continued with a word-based NMT translation candidate or another phrasal translation candidate.

The proposed search algorithm uses a log-linear model in which the NMT translation score is combined with standard phrase translation scores, including a target n-gram language model (LM) score. Thus, a LM trained on additional monolingual data can be used. The decisions on the word

Proceedings of the 2017 Conference on Empirical Methods in Natural Language Processing, pages 1411–1420
Copenhagen, Denmark, September 7–11, 2017. ©2017 Association for Computational Linguistics

order in the produced target translation are taken based only on the states of the NMT decoder.

This paper is structured as follows. We review related work in Section 1.1. The baseline NMT model we use is described in Section 2, where we also recap the log-linear model combination used in PBMT. Section 3 presents the details of the proposed hybrid search. Experimental results are presented in Section 4, followed by conclusions and outlook in Section 5.

1.1 Related Work

In the line of research closely related to our approach, neural models are used as additional features in vanilla phrase-based systems. Examples include the work of (Devlin et al., 2014), (Junczys-Dowmunt et al., 2016), etc. Such approaches have certain limitations: first, the search space of the model is still restricted by what can be produced using a phrase table extracted from parallel data based on word alignments. Second, the organization of the search, in which only a limited target word history (e.g. 4 last target words) is available for each partial hypothesis, makes it difficult to integrate recurrent neural network LMs and translation models which take all previously generated target words into account. That is why, for instance, the attention-based NMT models were usually applied only in rescoring (Peter et al., 2016).

In (Stahlberg et al., 2017), a two-step translation process is used, where in the first step a SMT translation lattice is generated, and in the second step the NMT decoder combines NMT scores with the Bayes-risk of the translations according to the lattice. In contrast, we explicitly use phrasal translations and language model scores in an integrated search.

In (Arthur et al., 2016), a statistical word lexicon is used to influence NMT hypotheses, also based on the attention mechanism. (Gülçehre et al., 2015) combine target n-gram LM scores with NMT scores to find the best translation. (He et al., 2016) also use a target LM, but add further SMT features such as word penalty and word lexica to the NMT beam search. To the best of our knowledge, no previous work extends the beam search with phrasal translation hypotheses of PBMT, like we propose in this paper.

In (Tang et al., 2016), the NMT decoder is modified to switch between using externally defined phrases and standard NMT word hypotheses. However, only one target phrase per source phrase is considered, and the reported improvements are significant only when manually selected phrase pairs (mostly for rare named entities) are used.

Somewhat related to our work is the concept of coverage-based NMT (Tu et al., 2016), where the model architecture is changed to explicitly account for source coverage. In our work, we use a standard NMT architecture, but track coverage with accumulated attention weights.

2 Background

2.1 Neural MT

Neural MT proposed by (Bahdanau et al., 2014) maximizes the conditional log-likelihood of the target sentence $E : e_1, \ldots, e_I$ given the source sentence $F : f_1, \ldots, f_J$:

$$H_D = -\frac{1}{N}\sum_{n=1}^{N} \log p_\theta(E_n|F_n)$$

where (E_n, F_n) refers to the n-th training sentence pair in a dataset D, and N denotes the total number of sentence pairs in the training corpus. When using the encoder-decoder architecture by (Cho et al., 2014), the conditional probability can be written as:

$$p(e_1 \cdots e_I|f_1 \cdots f_J) = \prod_{i=1}^{I} p(e_i|e_{i-1} \cdots e_1, c)$$

with $p(e_i|e_{i-1} \cdots e_1, c) = g(s_i, e_{i-1}, c)$, where I is the length of the target sentence and J is the length of source sentence, c is a fixed-length vector to encode the source sentence, s_i is a hidden state of RNN at time step i, and $g(\cdot)$ is a non-linear function to approximate the word probability. When the attention mechanism is used, the vector c in each sentence is replaced by a time-variant representation c_i that is a weighted summary over a sequence of annotations $(h_1, \ldots, h_J)$, and h_j contains information about the whole input sentence, but with a strong focus on the parts surrounding the j-th word (Bahdanau et al., 2014). Then, the context vector can be defined as:

$$c_i = \sum_{j}^{J} \alpha_{ij} h_j \quad \text{where} \quad \alpha_{ij} = \frac{exp(r_{ij})}{\sum_{j=1}^{J} exp(r_{ij})}.$$

Therefore, α_{ij} is normalized over all source positions j. Also, $r_{ij} = a(s_{i-1}, h_j)$ is the attention model used to calculate the log-likelihood of aligning the i-th target word to the j-th source word.

2.2 Phrase-based MT

The log-linear model, as introduced in (Och and Ney, 2002), allows decomposing the translation probability $Pr(e_1^I|f_1^J)$ by using an arbitrary number of features $h_m(f_1^J, e_1^I)$. Each feature is multiplied by a corresponding scaling factor λ_m:

$$Pr(e_1^I|f_1^J) = \frac{\exp\left(\sum_{m=1}^M \lambda_m h_m(f_1^J, e_1^I)\right)}{\sum_{\tilde{e}_1^{\tilde{I}}} \exp\left(\sum_{m=1}^M \lambda_m h_m(f_1^J, \tilde{e}_1^{\tilde{I}})\right)}.$$

The standard PBMT approach uses a log-linear model in which bidirectional phrasal and lexical scores, language model scores, distortion scores, word penalties and phrase penalties are combined as features.

3 Hybrid Approach

In this section we describe our proposed hybrid NMT approach. The algorithm allows translations to be generated partially by phrases[1] and partially by words. Section 3.1 describes the models we use to score hypotheses. The search algorithm is presented in Section 3.2.

3.1 Log-linear Combination

We use a log-linear model combination to introduce SMT models into the NMT search. Since translations can be partially generated by phrases, we introduce the phrase segmentation s_1^K as a hidden variable into the models similarly to (Zens and Ney, 2008), where K is the number of phrases used in the translation. Note that, unlike standard PBMT, s_1^K does not need to cover the whole source sentence, as parts of the translation can be generated by words. Using the maximum approximation, the search criterion then is

$$\hat{e}_1^{\hat{I}} = \arg\max_{I, e_1^I} \left\{ \max_{s_1^K} \sum_{m=1}^M \lambda_m h_m(f_1^J, e_1^I, s_1^K) \right\}. \quad (1)$$

Let $\tilde{f}_k, \tilde{e}_k$ be the chosen phrase pairs in the segmentation s_1^K for $k = 1, \ldots, K$. In our experiments with the proposed hybrid search, we use the following features:

1. The NMT feature h_{NMT}.
2. The word penalty feature h_{WP} counts the number of target words. This feature can help control the length of translations.
3. The source word coverage feature h_{SWC} counts the number of source words translated by phrases:
$$h_{\text{SWC}}(f_1^J, e_1^I, s_1^K) = \sum_{k=1}^K |\tilde{f}_k|.$$
The purpose of this feature is to control the usage of phrases.
4. The phrase penalty feature h_{PP} counts the number of phrases used. Together with the word penalty and the source word coverage feature, the phrase penalty can control the length of chosen phrases.
5. The n-gram language model feature h_{LM}.
6. The bidirectional phrase features h_{Phr} and h_{iPhr}. Note that these features are only applied for those parts of the translation that are generated by phrases. The other parts get a phrase score of zero.

The scaling factors λ_m are tuned with minimum error rate training (MERT) (Och, 2003) on n-best lists of the development set.

3.2 Search

The algorithm is based on the beam search for NMT, which generates translations one word per time step in a left-to-right fashion. We modify this search to allow hypothesizing phrases in addition to normal word hypotheses. The phrases are suggested based on the neural attention, starting from the source position with the maximal current attention. We only suggest phrases if a source position is focused. We check that suggested phrases do not overlap with already translated source words by keeping track of the sum of attention in previous time steps for each source position. Thus, the problem of global reordering is left entirely to the NMT model and we follow the attention when hypothesizing phrases.

Hypotheses are scored by NMT and SMT models. The beam is divided into two parts of fixed size: the word beam and the phrase beam. The phrase beam is used to score target phrases which were hypothesized from an entry in a previous word beam. In order to score a target phrase consisting of k words with the NMT model, we use k time steps, allowing us to keep the efficiency of batched NMT scoring. Once a target phrase has been fully scored (and if the hypothesis has

[1] As in SMT, phrases can consist of only a single token.

not been pruned), the hypothesis is returned to the word beam. Both beams are generated and pruned independently in each time step.

The algorithm has some hyper-parameters that need to be set manually. First, we have the beam size N_p for phrase hypotheses and the beam size N_w for word hypotheses. Second, τ_{focus} is the minimum attention that needs to be on a source position to consider it for extending with a phrase translation candidate whose source phrase starts on that position. Third, τ_{cov} is the minimum sum of attention of a source position over previous time steps at which it is considered to be covered. We do not hypothesize phrases that overlap with covered positions.

In the following, we describe the search in detail. Let f_1^J be the source sentence. Before search, we run the standard phrase matching algorithm on the source sentence to retrieve the translation options $E(j, j')$ for source positions $1 \leq j < j' \leq J$ from a given SMT phrase table. With each hypothesis h, we associate the following items:

- $C(h, j)$ is the sum of the NMT attention to source position j involved in generating the target words of h. This can be considered as a soft coverage vector for h.
- $Q(h)$ is the partial log-linear score of h according to Equation 1.
- $E(h)$ is the n-gram target word history of h.
- If h is a phrase hypothesis with target phrase $\tilde{e}$, of which k words already have been scored by NMT, then $P(h) := (\tilde{e}, k)$ is the phrase state.

Also, each hypothesis is associated with its corresponding NMT hidden state. We initialize the beam to consist of an empty word hypothesis. Each step of the beam search proceeds as follows:

1. Let $B = [B_w, B_p]$ be the previous beam with word/phrase hypotheses, respectively. First, we generate the attention vector $\alpha_{h,j}$ and the distribution over target words $\hat{p}_h(e)$ for each hypothesis $h \in B$ and word e in the NMT target vocabulary V_T using the NMT model in batched scoring [2].
2. Initialize new beam $[B'_w, B'_p] = [\emptyset, \emptyset]$.
3. Generate new word hypotheses: find the maximal N_w pairs (h, e) with $h \in B_w$ and $e \in V_T$ according to the score $Q(h) + \lambda_{\text{NMT}} \cdot \log \hat{p}_h(e)$. For the top pairs $h' = (h, e)$, set
$$Q(h') = Q(h) + \lambda_{NMT} \cdot \log \hat{p}_h(e) \\ + \lambda_{LM} \cdot \log p_{\text{LM}}(e|E(h)) + \lambda_{WP}$$
and insert h' into B'_w. Update the soft coverage $C(h', j) = C(h, j) + \alpha_{h,j}$ for $1 \leq j \leq J$.
4. Generate new phrase hypotheses: for each previous word hypothesis $h \in B_w$, convert the soft attention $C(h, \cdot)$ into a binary coverage set C, such that $j \in C$ iff. $C(h, j) > \tau_{\text{cov}}$. Identify the current NMT focus as
$$\hat{j} = \underset{1 \leq j \leq J,\ \alpha_{h,j} > \tau_{\text{focus}}}{\arg\max} \alpha_{h,j}.$$
If there is no such j with $\alpha_{h,j} > \tau_{\text{focus}}$, no phrase hypotheses are generated from h in this step. Otherwise, for each source phrase length l with $C \cap \{\hat{j}, \hat{j}+1, \ldots, \hat{j}+l-1\} = \emptyset$ and each target phrase $\tilde{e} \in E(\hat{j}, \hat{j}+l)$, create a new hypothesis $h' = (h, \tilde{e}_1)$ with the score
$$\begin{aligned} Q(h') = {} & Q(h) + \lambda_{\text{NMT}} \cdot \log \hat{p}_h(e_1) \\ & + \lambda_{\text{LM}} \cdot \log p_{\text{LM}}(\tilde{e}|E(h)) + |\tilde{e}| \cdot \lambda_{\text{WP}} \\ & + \lambda_{\text{PP}} + l \cdot \lambda_{\text{SWC}}. \end{aligned} \tag{2}$$
Note that, in this step, the full target phrase is scored using the language model, while only the first target word is scored using NMT. Initialize the phrase state of h': $P(h') = (\tilde{e}, 1)$. As in step 3, update the soft coverage. If $|\tilde{e}| = 1$, insert h' into B'_w, otherwise insert into B'_p.
5. Advance previous phrase hypotheses: for each $h \in B_p$, with phrase state $P(h) = (\tilde{e}, k)$, score the $(k+1)$-th target word of $\tilde{e}$ using NMT, setting $h' = (h, \tilde{e}_{k+1})$ and
$$Q(h') = Q(h) + \lambda_{\text{NMT}} \cdot \log \hat{p}_h(\tilde{e}_{k+1}).$$
As in step 3, update the soft coverage. Set the new phrase state as $P(h') = (\tilde{e}, k+1)$. If $k + 1 = |\tilde{e}|$, we are finished scoring the phrase and h' is inserted into B'_w. Otherwise, h' is inserted in B'_p.
6. Prune B'_w to N_w entries and B'_p to N_p entries according to $Q(\cdot)$.
7. Insert all hypotheses from the pruned B'_w and B'_p where the last word is the sentence end token into the set of finished hypotheses B_f.
8. $B := [B'_w, B'_p]$.

[2] If a target word e is not in V_T, set $\hat{p}_h(e) = \hat{p}_h(\text{UNK})$ where UNK is a special token denoting unknowns. Note that this almost never happens when using a word segmentation like BPE (Sennrich et al., 2016b).

Data set		WMT		E-commerce	
Language		German	English	English	Russian
Training	Sentences	5,597,491		2,919,406	
	Running words	129,083,315	134,469,297	46,715,319	45,305,268
	Full vocabulary	1,961,186	884,075	326,015	774,435

	Running words	56,593	51,324	24,487	24,087
Test	Sentences	6002 (WMT 14 + 16)		1051 (item/product descriptions)	
	Running words	160,469	144,387	29,165	26,476

Table 1: Corpus statistics for the WMT German→English and e-commerce English→Russian MT tasks.

If phrase scores from a phrase table are to be included in the search, Equation 2 needs to be modified by adding $\lambda_{\text{Phr}} \log p(\tilde{f}|\tilde{e})$ and $\lambda_{\text{iPhr}} \log p(\tilde{e}|\tilde{f})$.

As in the pure NMT beam search, this procedure is repeated until either the last word of all hypotheses in a step is the sentence end token, or $2 \cdot J$ many beam steps have been performed. Finally, the best translation is chosen as the one in B_f with the highest score.

Note that the same target sequence can be generated with different phrasal segmentations. During search, if two hypotheses have the same full target history in a beam, we recombine them and discard the hypothesis with the lower score.

4 Experiments

We perform experiments comparing the translation quality of our hybrid approach to phrase-based and pure end-to-end NMT baselines. We present results on two tasks: an in-house English→Russian e-commerce task (translation of real product/item descriptions from an e-commerce site), and the WMT 2016 German→English task (news domain). The corpus statistics are shown in Table 1.

For the English→Russian task, the parallel training data consists of an in-domain part (ca. 5.5M running words) of product/item titles and descriptions and other e-commerce content. The rest is out-of-domain data (UN, subtitles, TAUS data collections, etc.) sampled to have significant n-gram overlap with the in-domain description data. Item descriptions are provided by private sellers and, like any user-generated content, may contain ungrammatical sentences, spelling errors, and other noise. Product descriptions usually originate from product catalogs and are more "clean", but on the other hand, are difficult to translate because of rare domain-specific terminology. Both types of text contain itemizations, measurement units, and other structures which are usually not found in normal sentences. We tune the system on a development set that is a mix of product and item descriptions, and evaluate on separate product/item description test sets. For development and test sets, two reference translations are used.

The German→English system is trained on parallel corpora provided for the constrained WMT 2017 evaluation (Europarl, Common Crawl, and others). We use the WMT 2015 evaluation data as development set, and the evaluation is performed on two sets from the WMT evaluations in 2014 and 2016. Only a single human reference translation is provided.

For the phrase-based baselines, we use an in-house phrase-decoder (Matusov and Köprü, 2010) which is similar to the Moses decoder (Koehn et al., 2007). We use standard SMT features, including word-level and phrase-level translation probabilities, the distortion model, 5-gram LMs, and a 7-gram joint translation and reordering model reimplemented based on the work of (Guta et al., 2015). The language model for the e-commerce task is trained on additional monolingual Russian item description data containing 28.2M words. For the WMT task, we use the English News Crawl data containing 3.8B words for additional language model data. The tuning is performed using MERT (Och, 2003) to increase the BLEU score on the development set. To stabilize the optimization on the English→Russian task, we detach Russian morphological suffixes from the word stems both in hypotheses and references using a context-independent "poor man's" morphological analysis. We prefix each suffix with a special symbol and treat them as separate tokens.

We have implemented our NMT model in

		Item descriptions		Product descriptions	
System description	Beam size	BLEU [%]	TER [%]	BLEU [%]	TER [%]
Phrase-based	-	21.3	61.6	22.7	56.6

Table 2: Overview of translation results on the e-commerce English→Russian task.

Python using the TensorFlow[3] deep learning library. We use the embedding size of 620, RNN size of 1000 and GRU cells. The model is trained with maximum likelihood loss for 15 epochs using Adam optimizer (Kingma and Ba, 2014) on complete data in batches of 100 sentences. The learning rate is initialized to 0.0002, decaying by 0.9 each epoch. For regularization we use L2 loss with weight 10^{-7} and dropout following Gal and Ghahramani (2016). We set the dropout probability for input and recurrent connections of the RNN to 0.2 and word embedding dropout probability to 0.1. On the English→Russian task, the model is then fine-tuned on in-domain data for 10 epochs. The vocabulary is limited using byte pair encoding (BPE) (Sennrich et al., 2016b) with 40K splits separately for each language. To speed up training we use approximate loss as described in (Jean et al., 2015). For pure NMT experiments, we employ length normalization (Wu et al., 2016), as otherwise short translations would be favored.

For the hybrid approach, we use the same trained end-to-end model as in the NMT baseline. We use all the phrase-based model features plus the NMT score and run MERT as described in Section 3.1. Language models are trained on the level of BPE tokens. We consider at most 100 translation options for each source phrase. If not specified otherwise, we use a beam size of 96 for phrase hypotheses and a beam size of 32 for word hypotheses, resulting in a combined beam size of 128. Furthermore, we set the focus threshold $\tau_{\text{focus}} = 0.3$ and the coverage threshold $\tau_{\text{cov}} = 0.7$ by default. We also perform experiments where these hyper-parameters are varied.

4.1 E-commerce English→Russian

The results on the e-commerce English→Russian task are summarized in Table 2.

NMT vs. phrase-based SMT

The pure NMT system exhibits large improvements over the phrase-based baseline[4]. These improvements are also significantly larger than when we use the NMT model to rescore PBMT 1000-best lists. NMT results are not improved when the beam size is increased from 12 to 128.

Hybrid search vs. pure NMT search

For the hybrid approach, we train a phrase-table on the in-domain data and split the source and target phrases with BPE afterwards for compatibility with the NMT vocabulary. With the hybrid approach, when using a LM trained only on the target side of bilingual data, we get an improvement of 0.3% BLEU on item descriptions and 1.4% BLEU on product descriptions over the pure NMT system. When we use the LM trained on extra monolingual data, we get total improvements of 1.0% BLEU and 2.3% BLEU with the hybrid approach. In contrast, when we add this language model and a word penalty on top of the pure NMT system and tune scaling factors with MERT, we get small improvements (last row of Table 2) only on product descriptions. This shows that the hybrid approach can exploit the LM better than a purely word-based NMT approach. We have also performed experiments utilizing the additional monolingual data for synthetic training data for NMT as in (Sennrich et al., 2016a), but did not get improvements.

To analyze the improvements of the hybrid system, we perform experiments in which we either

[3] `http://tensorflow.org`

[4] The significance of these improvements was also confirmed by an in-house human evaluation with 3 judges.

	Item descriptions		Product descriptions	
System description	BLEU [%]	TER [%]	BLEU [%]	TER [%]
Full hybrid approach	27.4	55.4	30.8	50.5
Without LM	26.5	55.9	29.2	51.0
Without source word coverage feature	26.7	56.1	29.4	51.2
Without phrase scores	27.2	55.9	30.6	50.6
Maximal source phrase length 1	26.7	56.4	29.1	51.6
Minimal source phrase length 2	27.0	55.9	30.0	51.1

Table 3: Translation results of the hybrid approach on the e-commerce English→Russian task with different SMT model combinations. The first row shows results with all models enabled. In the following rows, we either remove or limit exactly one model compared to the full system.

disable or limit some of the SMT models. The results are shown in Table 3. Without the language model, the hybrid approach has almost no improvements over the NMT baseline. This indicates that the language model is crucial in selecting appropriate phrase candidates. Similarly, when we disable the source word coverage feature, the translation quality is degraded, suggesting that this feature helps choose between phrase hypotheses and word hypotheses during the search. Next, we do not use phrase-level scores. Here, we observe only a small degradation of translation quality. Finally, we limit the source length of phrases used in the search, allowing only one-word source phrases in one experiment and only source phrases with two or more words in another experiment. In both cases, the translation quality decreases. Thus, both one-word phrases and longer phrases are necessary to obtain the best results.

Tuning the beam size

Next, we study the effect of different beam sizes on translation quality. The results are shown in Table 4. Note that we retune the system for each choice. With a total beam size of 128, we get the best results by using a phrase beam size of 96 and a word beam size of 32. When we use a phrase beam size of 116 or 64 instead, the translation quality worsens. In another experiment, we decrease the total beam size to 64. The translation quality degrades only slightly, which means that we can still expect MT quality improvements with hybrid search even if we optimize the system for speed. To further test this, we reduce the beam sizes to $N_w = 12$ and $N_p = 4$ after tuning with $N_w = 32$ and $N_p = 96$. We get BLEU scores of 27.1% on item descriptions and 30.1% on product descriptions, losing 0.3% and 0.7% BLEU respectively compared to the full beam size.

Beam size		Item descr.		Product descr.	
N_p	N_w	BLEU [%]	TER [%]	BLEU [%]	TER [%]
116	12	26.7	55.9	29.8	51.1
96	32	27.4	55.4	30.8	50.5
64	64	26.8	55.6	30.1	50.7
32	32	27.1	55.8	30.7	50.5

Table 4: Effect of the beam size (word beam size N_w + phrase beam size N_p) for the hybrid approach on the e-commerce English→Russian task.

Tuning the attention focus/coverage thresholds

Table 5 shows results with different values for the coverage threshold τ_{cov}. Again, we retune the system for each choice. Setting the coverage threshold to 1.0 or even disabling the coverage check (by setting $\tau_{\text{cov}} = \infty$) has little effect on the translation scores on this task. This can be explained by the fact that translation from English to Russian is mostly monotonic. We also tried varying the focus threshold τ_{focus} between 0.0 and 0.3 but did not notice any significant effect on this task.

		Item descr.		Product descr.	
τ_{focus}	τ_{cov}	BLEU [%]	TER [%]	BLEU [%]	TER [%]
0.3	0.7	27.4	55.4	30.8	50.5
0.3	1.0	27.2	55.4	30.3	50.3
0.3	∞	27.5	55.4	30.4	50.9

Table 5: Effect of the threshold parameters on the hybrid approach on the e-commerce English→Russian task.

Analysis

To understand the behavior of the hybrid search, we count the number of source words that are

		newstest2014		newstest2016	
System description	Beam size	BLEU [%]	TER [%]	BLEU [%]	TER [%]
Phrase-based	-	22.9	59.4	26.9	54.1
+ News Crawl LM data	-	25.4	59.0	29.2	53.8
NMT	12	26.9	53.0	32.3	47.6
NMT	64	27.0	53.0	32.2	47.6

+ tuning τ_{focus}, τ_{cov}	64	28.0	53.0	33.3	47.4
+ News Crawl LM data	64	29.7	52.2	35.3	46.7

Table 6: Overview of translation results on the WMT German→English task.

translated by phrases in the product descriptions test set. Of the 9320 source words, 7109 (76.3%) are covered by phrase hypotheses. 78.3% of the source phrases are unigrams, 19.5% are bigrams and 2.2% are trigrams or longer. Among the many one-word phrases used, almost all (99.2%) are also within the top 3 predictions of word-based NMT, and 90.3% are equal to the top NMT prediction.

Further human analysis by a native Russian speaker of the pure NMT vs. hybrid search translations shows that hybrid search is often able to correct the following known NMT handicaps:

- incorrect translation of rare words (among other reasons, due to incorrect sub-word unit translation in which rare words are aggressively segmented).
- repetition of same or similar words as a result of multiple attention to the same source word, as well as untranslated words that received no attention.
- incorrect or partially correct word-by-word translation when a phrasal (non-literal) translation should be used instead.

In all of these cases, the usage of phrasal translations is able to better enforce the coverage, and this, in turn, leads to improved lexical choice. The fact that not many long phrase pairs are selected indicates, in our opinion, that the search and modeling problem in NMT is far from being solved: with the right, diverse model scores, the proposed hybrid search is able to select and extend better hypotheses with words, most of which already had a high NMT probability. Yet they are not always selected in the pure NMT beam search, among other reasons, due to competition from words erroneously placed near them in the embedding space.

4.2 WMT 2016 German→English

The results on the WMT German→English task are shown in Table 6. The initial phrase-based baseline uses the 5-gram language model estimated on the target side of bilingual data. By adding the News Crawl LM data, we gain 2.5% and 2.3% BLEU on the test sets, but PBMT still is behind NMT.

For the hybrid approach, we use a beam size of 64 and a maximal number of beam steps of $1.5 \cdot J$ (instead of $2 \cdot J$) to speed up experiments. We use separate word penalty features, one for word-based hypotheses and one for phrase-based hypotheses to allow for more control of translation lengths. With the hybrid approach, using the 5-gram language model estimated on the target side of bilingual data, and phrase scores, we get small improvements in BLEU over the NMT baseline. However, the TER increases. We experiment with different thresholds, setting $\tau_{\text{focus}} = 0.1$ and $\tau_{\text{cov}} = 1.0$. With this hybrid system, we get improvements of 1.0% and 1.1% BLEU over pure NMT. Finally, we add the News Crawl LM data on top. This significantly improves the results by 1.7% and 2.0% BLEU. In total, we gain 2.7% and 3.1% BLEU over pure NMT. These results reinforce the fact that, similar to PBMT, language model quality is important for the proposed hybrid search. In contrast, we have also tried applying only the LM (including News Crawl data) with a word penalty on top of NMT, but did not get consistent improvements.

Figure 1 shows an example for the phrase pairs chosen by the hybrid system on top of the NMT attention. The hybrid approach correctly translates the German idiom “nach und nach” as “gradually”, while the pure NMT system incorrectly translates it word-by-word as “after and after”.

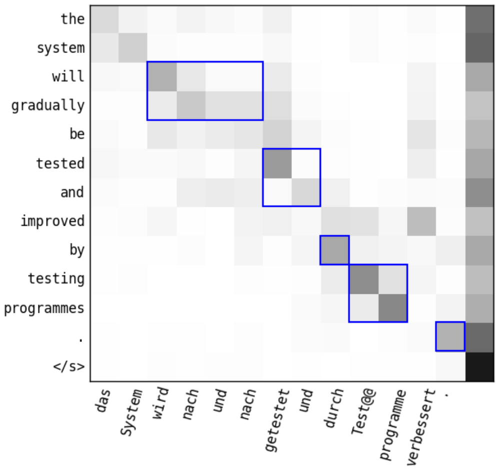

Figure 1: Example alignment from the hybrid search, with the source sentence on the bottom and the translation on the left. The blue rectangles signify phrase pairs on top of the NMT attention. The pure NMT translation is "the system is tested after and after testing and improved by testing programs."

5 Conclusion

In this work, we proposed a novel hybrid search that extends NMT with phrase-based models. The NMT beam search was modified to insert phrasal translations based on the current and accumulated attention weights of the NMT decoder RNN. The NMT model score was used in a log-linear model with standard phrase-based scores as well as an n-gram language model. We described the algorithm in detail, in which we keep separate beams for NMT word hypotheses and hypotheses with an incomplete phrasal translation, as well as introduce parameters which control the source sentence coverage. Numerous experiments on two large vocabulary translation tasks showed that the hybrid search improves BLEU scores significantly as compared to a strong NMT baseline that already outperforms phrase-based SMT by a large margin.

In the future, we plan to focus on integration of phrasal components into NMT training, including better coverage constraints, as well as methods for context-dependent translation override within our hybrid search algorithm.

Acknowledgments
